compound benzylidenetriphenylphosphorane. In other words: carbonyl-olefination with metalated isocyanides *(2)* might occasionally be of use when the Wittig reaction is impeded by enhanced stability of the phosphonium ylide.

Thanks are due to F. Gerhart, D. Hoppe, R. Schröder, I. Hoppe, R. Harms, R. Meyer, D. Stafforst, R. Jentsch, K. Madawinata, H.-H. Hausberg, K.-W. Henneke, K.-H. Scheunemann, E. Eilers, K. Hantke, E. Blume, P.-H. Porsch, and P. Böhme for their dedicated assistance. Support of this work by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen, is gratefully acknowledged.

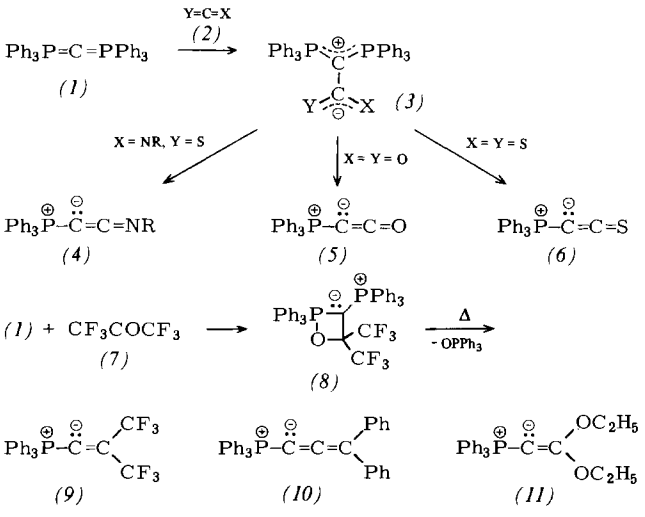
Phosphacumulene Ylides and Phosphaallene Ylides[**]

By Hans Jürgen Bestmann[*]



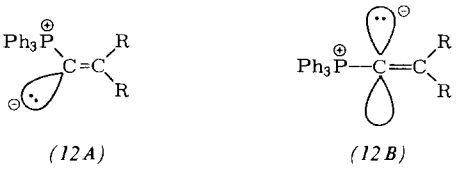
Dedicated to Professor Georg Wittig on the occasion of his 80th birthday

Phosphacumulene ylides and phosphaallene ylides are nucleophilic compounds which can add reactants in a variety of ways. Cycloadditions can occur both at the polar C—P ylide bond and at the C=C double bond.

1. Introduction

In three reviews we reported[1-3] that the nucleophilic phosphorus ylides are comparable in their scope and versatility to Grignard reagents[4]. These investigations were initiated by the discovery of carbonyl olefination by *Wittig* and coworkers. The 80th birthday of the discoverer of this reaction, of such great importance in preparative chemistry, is a fitting occasion to report a further chapter of phosphorus ylide chemistry which has been studied in recent years by our research team, and is still advancing on a broad front.

In 1961, *Ramirez et al.* described the synthesis of hexaphenylcarbodiphosphorane *(1)*[5]. This compound was later reacted with *(2)*, by *Birum* and *Matthews*, to give the betaines *(3)*, whose thermolysis afforded ketenylidenetriphenylphosphorane *(5)*[6], the analogous thio compound *(6)*[6], and the imino derivatives *(4)*[7].



From *(1)* and hexafluoroacetone *(7)* the same authors obtained the 1,2-oxaphosphetane derivative *(8)* which decomposes on heating into triphenylphosphane oxide and *(9)*[8].

A comprehensive report of reactions employing the phosphaallene ylides *(1)* and *(9)* and the phosphacumulene ylides *(4)* to *(6)* was published in 1969[9]. Syntheses and some reactions of the subsequently prepared compounds *(10)*[10] and *(11)*[11] were considered in an earlier review[2]. Surprisingly, these compounds have since found little preparative use[12]. Having developed productive syntheses of *(4)*, *(5)*, *(6)*, and *(11)* and of other phosphacumulene and phosphaallene ylides, we have now studied the chemistry of these interesting molecules in detail.

2. Structure of Phosphacumulene Ylides and Phosphaallene Ylides

Two structures with different degrees of hybridization at the ylidic C atom are conceivable for phosphaallene ylides of the general type *(12)*. If this C atom is sp^2 hybridized, then structure *(12A)* having a P—C_α—C_β angle of *ca.* 120° is expected, whereas sp hybridization should lead to a linear molecule *(12B)*: Interaction of the lone pair on C with the d orbitals of phosphorus is expected in either case, although the exact nature of the interaction has yet to be established[13,14].

X-Ray structure analysis of diethoxyvinylidenetriphenylphosphorane *(11)* [= *(12)*, R = OC_2H_5][15] gave a nonlinear structure with a P—C_α—C_β angle of 125.6°. The C_α—C_β bond length of 1.314 Å is the same as an allenic double bond. An electron density maximum was observed at the position expected for the lone pair in the occupied sp^2 hybrid orbital; its intensity approaches that of the electrons belonging to a hydrogen atom attached to a benzene ring.

In the ^{1}H-NMR of *(11)* the two alkyl groups give rise to only one sharp triplet at $\tau = 8.96$ and a quartet at $\tau = 5.63$. No line broadening occurs on cooling to −70 °C. Hence we conclude that the triphenylphosphonio group of *(11)* is subject to fast inversion in solution, as is known for substituents at the N atom of C=N double bonds. Inversion barriers of 9.2 and 12.2 kcal/mol were measured for two ketenimines which are isoelectronic with the phosphaallene ylides *(12)*[16].

Phosphacumulene ylides of type *(13)* with X = NR, O, and S [= *(4)*, *(5)*, and *(6)*, respectively] can be described by the principal resonance structures *(13A)* and *(13B)* which differ in their geometry and electron distribution.

[*] Prof. Dr. H. J. Bestmann
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (Germany)

[**] In line with IUPAC nomenclature, it is proposed that ylides of type $R_3P{=}C{=}C{=}X$ be designated as phosphacumulene ylides and those of type $R_3P{=}C{=}CR'_2$ as phosphaallene ylides.

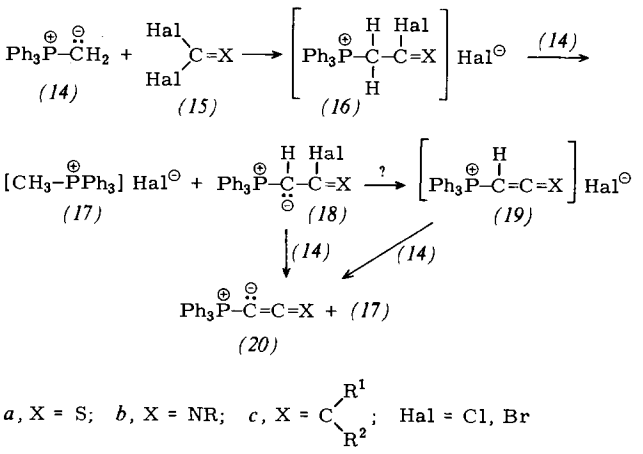
(13A) (13B)

X = O, S, NR

Table 1. P—C_α—C_β angles and C_α—C_β bond lengths in phosphaallene ylides of type (12) and phosphacumulene ylides of type (13).

Type	Cpd.	Angle P—C_α—C_β [°]	Distance C_α—C_β [Å]
(12)	(11)	125.6	1.314
(13)	(4), X = NC_6H_5	134.0	1.248
(13)	(5), X = O	145.5	1.210
(13)	(6), X = S	168.0	1.204

As the electron acceptor character of X increases and its tendency to participate in double bonding decreases, the weight of structure (13B) in the resonance hybrid will increase. Thus the P—C_α—C_β angle should increase and the C_α—C_β bond length decrease in the order (4), (5), (6). These expectations are confirmed by the results of X-ray structure analysis of compounds (4), R = C_6H_5[17], (5)[18], and (6)[19], which are listed in Table 1 together with the corresponding data for (11).



Along the series (11), (4), (5), (6), the PCCX grouping becomes progressively more linear, and the C_α—C_β distance shorter. Owing to the increasing contribution of structure (13B) to the resonance hybrid, and the greater delocalization of the carbanion lone pair the nucleophilic reactivity of the phosphacumulene ylides should decrease along the same series. Our studies, described below, confirm this.

3. Synthesis of Phosphacumulene Ylides and Phosphaallene Ylides

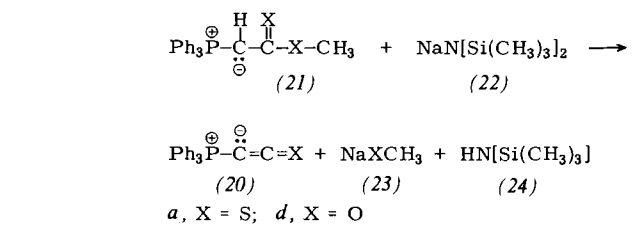
3.1. Phosphacumulene Ylides from Methylenetriphenylphosphorane and Geminal Dihalo Compounds

We have developed a synthesis for phosphacumulene ylides of the general type (20) from methylenetriphenylphosphorane (14) and geminal dihalo compounds (15)[20, 21]. Reaction of (14) with a geminal dihalo compound (15) in a molar ratio of 3 : 1 initially affords a phosphonium salt (16), primarily *via* nucleophilic substitution, which can be trans-ylidated with a further molecule of (14) to the phosphonium salt (17) and to the ylide (18). The third molecule of (14) removes hydrogen halide from (18). Additional salt (17) and the phosphacumulene ylide (20) are the final products. It has not yet been established whether (18) is initially transformed into the salt (19).

The overall reaction is: 3 (14) + 1 (15) → 1 (20) + 2 (17). The phosphonium salt precipitates during the reaction. After its separation, (20) is isolated by distillative removal of the solvent and recrystallization. Compound (14) and isocyanide dichlorides (15b), Hal = Cl, R = alkyl or aryl, give iminoketenylidenetriphenylphosphoranes (4), while the thioketenylidenetriphenylphosphorane (6) is obtained starting with thiophosgene (15a), Hal = Cl. Reaction is possible with

a, X = S; b, X = NR; c, X = $C(R^1)(R^2)$; Hal = Cl, Br

Table 2. Phosphacumulene ylides (20) from (14) and (15) (molar ratio 3 : 1).



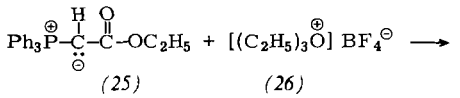
X	Hal in (15)	Yield [%]	M.p. [°C]	IR $\nu_{C=C=X}$ [cm^{-1}]
NC_6H_5	Cl	85	151—152	2000
NCH_3	Cl	70	157—158	1980
N-c-C_6H_{11}	Cl	68	137—139	2000
S	Cl	60	218—220	1950, 2110
$C_{13}H_8$ [a]	Br	80	188—189	1960
$C(CO_2CH_3)_2$	Cl	19	205	2100
$C(CN)CO_2CH_3$	Cl	51	220	2060

[a] $C_{13}H_8$ = 9-fluorenylidene.

compounds of type (15c) if R^1 and R^2 are substituents having electron-acceptor properties (Table 2).

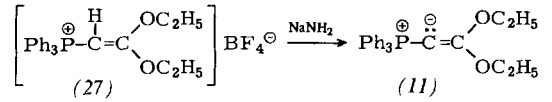
3.2. Phosphacumulene Ylides by β-Elimination from Methoxycarbonylmethylenetriphenylphosphorane and Its Dithio Analog

Attempts to prepare ketenylidenetriphenylphosphorane (5) from (14) and phosgene (15), X = O, Hal = Cl, as described in the previous paragraph led only to impure products. A facile new synthesis of (5) and its thio analog (6) was discovered in the β-elimination of methanol and methanethiol, respectively, from methoxycarbonylmethylenetriphenylphosphorane (21d) and the corresponding dithio compound (21a)[22].



a, X = S; d, X = O

On reaction of (21d) with sodium bis(trimethylsilyl)-amide[23, 24] in benzene, the base eliminates methanol from (21d). The cumulene ylide (5) [= (20d)], hexamethyldisilazane (24), and sodium methoxide (23d) are formed. After (23d) has been filtered off, compound (5) is isolated by concentration of the solution and precipitation with ether (yield 80 %). In an analogous manner, reaction of (21a)[25] and (22) furnishes the phosphacumulene ylide (6) [= (20a)] (yield 76 %) alongside (24) and sodium methyl sulfide (23a).

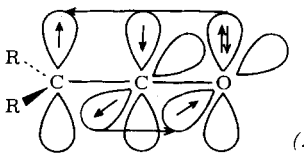


The mechanism of the elimination reaction has not yet been studied in detail[26].

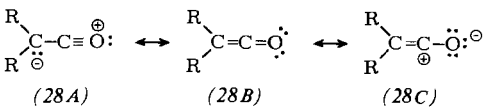
3.3. Synthesis of Diethoxyvinylidenetriphenylphosphorane (11)

Synthesis of the acetal (11) from (5) starts from ethoxycarbonylmethylenetriphenylphosphorane (25), which is O-alkylated by triethyloxonium tetrafluoroborate (26) to give the vinylphosphonium salt (27). Deprotonation of (27) with sodium amide yields the corresponding ylide (11)[12].

(25) (26)



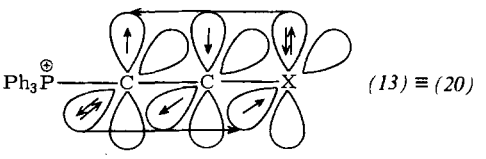
(27) (11)



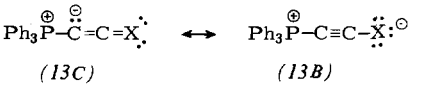
4. Nucleophilic Substitution of Phosphacumulene Ylides and Phosphaallene Ylides

4.1. General Reaction Scheme

In contrast to ketenes, the phosphacumulene ylides (4), (5), and (6) display no tendency to dimerize. Ketenes possess two orthogonal π-electron systems, one of which, being isoelectronic with that of the allyl anion, is occupied by four electrons, while the other is occupied by two electrons. The electron donor character of oxygen renders the π^4-electron system



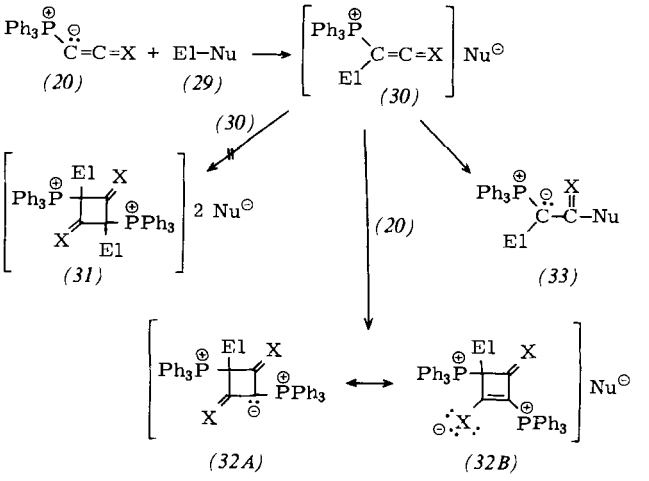
(28)



(28A) (28B) (28C)

nucleophilic with a partial negative charge on C_β. At the same time, the acceptor property of the oxygen atom in the π^2-system induces a partial positive dipolar character, being nucleophilic at C_β and electrophilic at C_α [(28A)↔(28B)↔(28C)]. This dipolarity is, no doubt, the driving force for dimerization and for numerous cycloaddition reactions of ketenes[27].

In the phosphacumulene ylides of type (13) [=(20)] both orthogonal π-electron systems are occupied by four electrons[28]. These compounds are isoelectronic with carbon dioxide, isocyanates, and carbodiimides. Unlike the ketenes (28) having a nucleophilic π^4 and an electrophilic π^2 system, both the π^4 systems of phosphacumulene ylides (13) are nucleophilic, *i.e.* these compounds have lost their electrophilic and thus their dipolar character compared to the ketenes (28). The notation (13C) ↔ (13B), which does not depict the true geometry of (13), expresses this situation. The driving force



(13) ≡ (20)

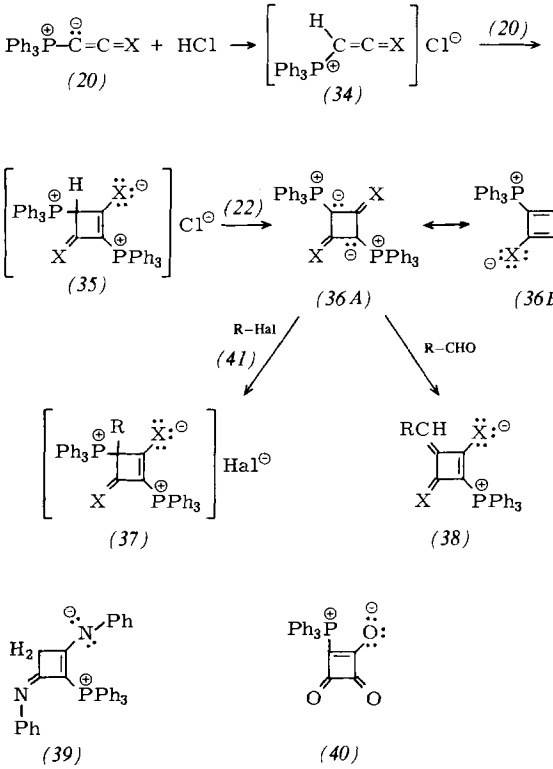
(13C) (13B)

for dimerization is absent. Compounds (13) [=(20)] are monomeric.

If a nucleophilic substitution is performed with the phosphacumulene ylides (20) on a compound El-Nu (29), then the primary product is a phosphonium salt (30). Addition of the electrophile El to the lone pair of (20) transforms the nucleophilic $\pi^4 \perp \pi^4$ system into the dipolar $\pi^4 \perp \pi^2$ system of the ketenes (28), *i.e.* the phosphonium ion in (30) becomes a "true" dipolar ketene which, as such, reacts in known manner.

(20) (29) (30) (31) (33) (32A) (32B)

We have not yet detected dimerization of (30) to the bisphosphonium salt (31). Whenever (20) is a stronger nucleophile than $Nu^\ominus$, compound (30) always reacts with a second molecule of unreacted (20) in a [2+2]-cycloaddition to give the 1,3-cyclobutanedione derivatives (32) which, like all α-keto ylides, can be described by the resonance structures (32A) ↔ (32B)[29].



If the anion $Nu^\ominus$ is a stronger nucleophile than (20), then the ylide (33) will be formed.

Transformation of the $\pi^4 \perp \pi^4$ system of (20) into the dipolar $\pi^4 \perp \pi^2$ system of the ketenes (28) on nucleophilic reaction is the cause of the variety of reactions to be treated in this article. Particular preparative interest attaches to the cyclobutanedione derivatives (32), whose rings can readily be opened by nucleophilic reagents to form open-chain β-dicarbonyl compounds.

4.2. Dimers of Phosphacumulene Ylides

The dimers (36) of phosphacumulene ylides (20) are of particular interest because their resonance form (36B) represents a new kind of "push-pull" cyclobutadiene[30]. Synthesis of this dimer is accomplished by reaction of (20) with HCl in the molar ratio 2:1[31]. The initial step is addition of

a proton to the ylidic C atom to form *(34)*, which as a "true" ketene can undergo a [2+2]-cycloaddition with *(20)* to give the phosphonium salt *(35)* as described in the foregoing section. The salt *(35)* yields the stable dimer *(36)* on treatment with bases, especially *(22)*.

b, X = NPh ; *d*, X = O; Hal = Halogen

Evidence for participation of the cyclobutadiene structure *(36B)* is provided by the frequencies of the C=O bands in the IR spectrum of *(36d)* at 1650 and 1610 cm^{-1}, and of the C=N bands of *(36b)* at 1563 and 1527 cm^{-1}. Reaction of *(36)* with halogen compounds gives the phosphonium salts *(37)*[31,32] and treatment with aldehydes gives the monophosphoranes *(38)* (see Section 5.2.1).

Hydrolysis of *(36b)* gives compound *(39)*[33]. Oxidation of *(36d)* with the adduct of ozone to triphenyl phosphite[34] leads to the cyclobutanetrione derivative *(40)* whose structural relationship with squaric acid is clearly evident [IR: 1769, 1651, 1629 cm^{-1} (CO)].

4.3. Reaction with Halogen Compounds

4.3.1. General Reaction Course

Reaction of phosphacumulene ylides *(20)* with the halogen compounds *(41)* proceeds *via* nucleophilic substitution, giving initially the phosphonium salts *(42)*. Once more the nucleophilic $\pi^4 \perp \pi^4$ system has been transformed into a dipolar $\pi^4 \perp \pi^2$ system. Substitution is then followed immediately by a [2+2]-cycloaddition of *(27)* to *(42)*, yielding the four-membered ylide phosphonium salts *(37)*[35,36] which are also obtained from *(36)* and *(41)*.

The overall reaction is thus: 2 *(20)* + *(41)* → *(37)*. In all cases studied so far the second step was faster than the first one. Examples are presented in Table 3.

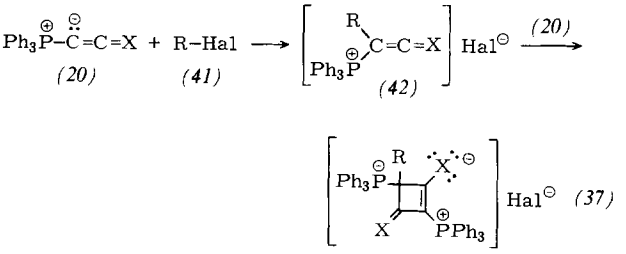


Table 3. Phosphonium salts *(37)* from phosphacumulene ylides *(20)* and halogen compounds *(41)* [35].

X	R	Hal	M.p. [°C] [a]	Yield [%]
O	CH_3	I	238—240	96
O	C_2H_5	I	226—227	85
O	C_3H_7	I	216—218	85
O	C_5H_{11}	I	212—214	87
O	C_6H_5—CH_2	Br	218—219	98
O	α-$C_{10}H_7$—CH_2	Br	213—215	95
O	Br	Br	204—206	96
NC_6H_5	CH_3	I	202—203	88

[a] All compounds listed decompose on melting.

In the ^{31}P-NMR spectrum of compounds *(37)*, the phosphonium P atom gives rise to a signal between −22 and −29 ppm and the ylidic P atom to one at −3 to +4 ppm (H_3PO_4 as external standard). Transannular coupling takes place between the two P atoms (J_{PP} = 5—7 Hz).

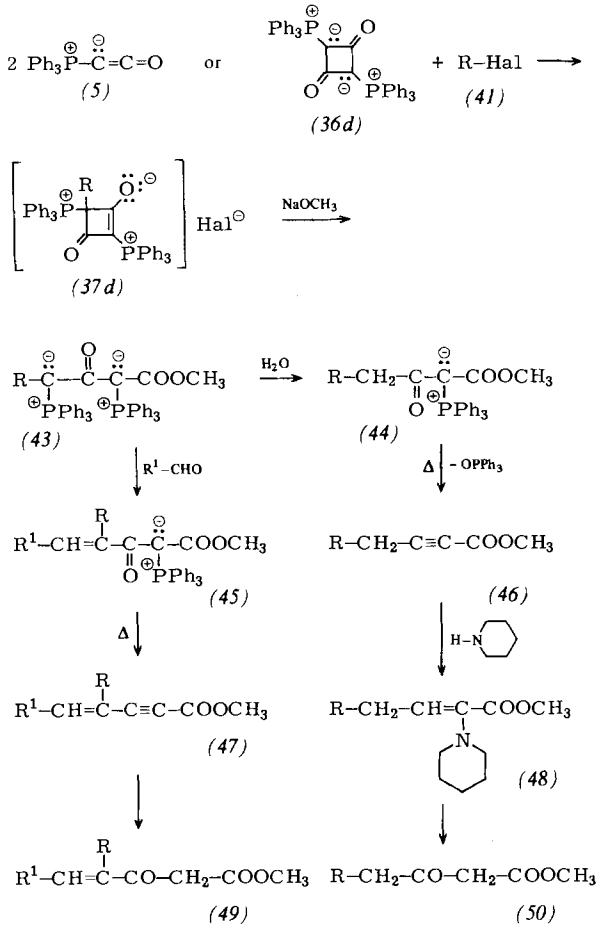
4.3.2. Possible Syntheses of β-Oxo Carboxylic Esters and Acetylenecarboxylic Esters

The 1,3-cyclobutanedione derivatives *(37)*, easily accessible from *(20)* and *(36)* by means of halogen compounds *(41)*, undergo ready ring opening. Treatment of compounds *(37)*, obtainable from *(5)* [= *(20)*, X = O] or *(36)* and *(41)*, with sodium methoxide gives the bis-ylides *(43)*[35]. Reaction of *(36d)* with methanol leads, *via* addition of a proton to the ylidic C atom and subsequent ring opening by the methoxide ion, directly to *(43)*, R = H[31].

The ylide function flanked by two carbonyl groups in the bisphosphoranes *(43)* is much more inert than that adjacent to only one CO group. Compounds *(43)* are hydrolyzed by water to the mono-ylides *(44)* and the Wittig reaction with aldehydes gives the phosphoranes *(45)*[35]. Examples of *(43)* and *(44)* are presented in Table 4.

Thermolysis of (1-acyl)methoxycarbonylmethylenetriphenylphosphoranes *(44)* affords acetylenecarboxylic esters *(46)*[37,38]. Compounds *(45)* likewise yield the alkenynecarboxylic esters *(47)*. Addition of piperidine to the triple bond of *(46)* leads to the enamines *(48)*, which can be hydrolyzed to the β-oxo carboxylic esters *(50)* with oxalic acid[38]. In the same reaction sequence, γ,δ-unsaturated β-oxo esters *(49)* are obtained from esters *(47)*.

Since *(5)*, and thus also *(37d)*, can easily be prepared starting from acetic esters (bromination, formation of phos-



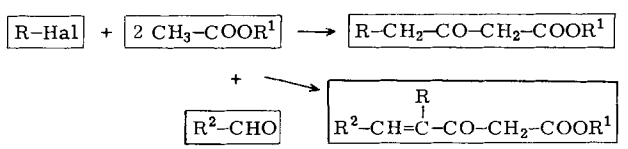


Table 4. Bis-ylides *(43)* from phosphonium salts *(37d)* and sodium methoxide; mono-ylides *(44)* by hydrolysis of *(43)*.

phonium salt and ylide) by the methods described, a highly versatile scheme is available for synthesis of β-oxo esters *(49)* and *(50)*:

4.4. Addition of Acidic Compounds

4.4.1. General Reaction Scheme

Matthews and *Birum*[39] reported that ketenylidenetriphenylphosphorane *(5)* adds ethanol, and mentioned that such additions also occur with imidazole, methanethiol, and malononitrile. However, no information was available about the nature of these addition products.

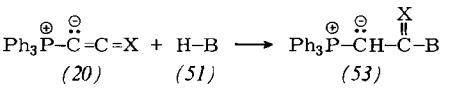
B = OR, SR, NR_2, CR_3

We have found that the phosphoranes *(20)* generally react with acidic compounds H—B *(51)*. In the initially formed ion pairs *(52)* the anion $B^{\ominus}$ is so nucleophilic that addition to give *(53)* is faster than cycloaddition of *(52)* to *(20)*.

The difference in the nucleophilic character of compounds *(20)* with X=NR [=*(4)*], X=O [=*(5)*], and X=S [=*(6)*] [*(4)* > *(5)* > *(6)*] is particularly evident in the reaction *(20)* + *(51)* → *(53)*. While *(4)* and *(5)* smoothly add alcohols, thiols, and acidic NH compounds, the thio compounds *(6)* react readily with thiols and phenols, less rapidly with aliphatic alcohols, and not with NH acids. Strongly activated CH_2 groups add readily to *(4)*, less rapidly to *(5)*, and not at all to *(6)*.

4.4.2. Possible Synthesis of Carboxylic Acid Derivatives

The addition of alcohols, thiols, and acidic amines to phosphacumulene ylides *(20)* is of particular preparative interest. Table 5 lists our studies.



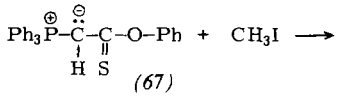


Table 5. Addition of alcohols, thiols, and NH acids H—B *(51)* to phosphacumulene ylides *(20)* to give products of type *(53)*.

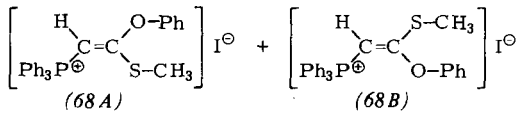


Product	X	B	M.p. [°C]	Yield [%]
(55)	NC_6H_5	OCH_3	179	72
(56)	NC_6H_5	OC_6H_4—OCH_3-*p*	159	68
(57)	NC_6H_5	SC_6H_5	151	59
(58)	NC_6H_5	SCH_2—C_6H_5	173	53
(59)	NC_6H_5		161	62
(60)	NC_6H_5		184	75
(61) [a]	NC_6H_5	H—B=*p*-CH_3—C_6H_4—SO_2NH_2	215	57
(62)	O	SCH_3	208	68
(63)	O	SC_6H_5	186	72
(64)	O		185	71
(65)	O		197	75
(66)	O	NH—SO_2—C_6H_5	195	83
(67)	S	OC_6H_5	109	69

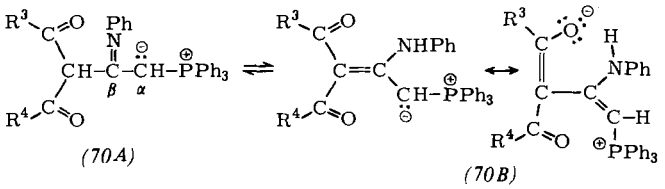
[a] Product: $(C_6H_5)_3\overset{\oplus}{P}$—$\overset{\ominus}{C}$H—C(=N—$SO_2$—$C_6H_4$—$CH_3$-*p*)—NH—$C_6H_5$.

A wide variety of carboxylic acid derivatives, particularly those of α,β-unsaturated acids, can be prepared by Wittig reaction of the ylides *(55)*—*(67)*, listed in Table 5, according to the general scheme *(53)* + R^1—CHO → *(54)*. These products are often difficult to prepare by other methods. Thus *(55)* and *(56)* give imino ethers[40], *(57)* and *(58)* imino thioethers[41], and *(59)*—*(61)* amidines[41,42]. *(62)* and *(63)*

(67)

(68A) (68B)

yield *S*-methyl and *S*-phenyl esters, respectively, of thiocarboxylic acids[42,43], while *(64)* and *(65)* give acylimidazoles[44] and pyrazoles[41], respectively, and *(66)* affords acylsulfonamides[41].



On reaction of *(67)* with methyl iodide, *S*-methylation takes place to give the two geometric isomers of the vinylphosphonium salt *(68)*[25,42,45].

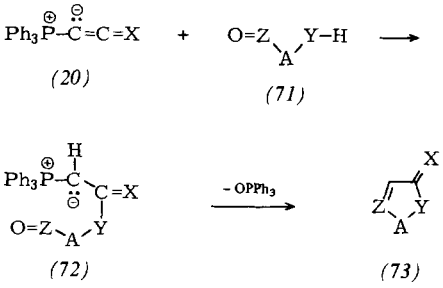
4.4.3. Addition of CH Acids to *(20)*

Addition of CH acids of type $CH_2R^1R^2$ to *(4)* [=*(20)*, X=NR] and *(5)* [=*(20)*, X=O] requires compounds having two electron-attracting groups R^1 and R^2, *e.g.* 1,3-dicarbonyl compounds *(69)*, cyanoacetic esters, and malononitriles[46].

(69) (4)

(70A) (70B)

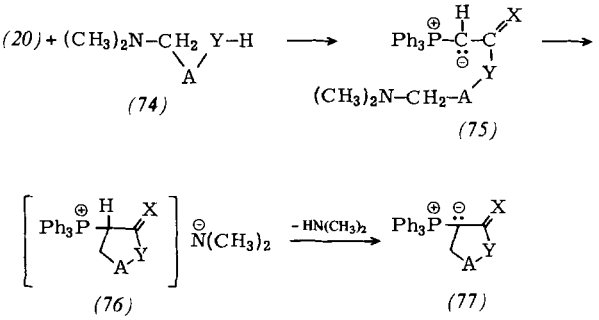
Table 6. Phosphoranes *(70)* from compounds of type *(20)*, X=NC_6H_5 [=*(4)*], or *(20)*, X=O [=*(5)*], and 1,3-dicarbonyl compounds *(69)*.



X in *(20)*	R^3	R^4	M.p. [°C]	Yield [%]
NC_6H_5	CH_3	CH_3	85	166
NC_6H_5	C_6H_5	CH_3	73	181
NC_6H_5	CH_3	NH—C_6H_5	75	188
O	C_6H_5	C_6H_5	78	147
O	C_6H_5	CH_3	71	151
O	CH_3	OCH_3	61	152

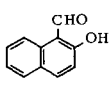
The adducts formed by *(69)* and *(4)*, R=NC_6H_5, can exist in the tautomeric forms *(70A)* and *(70B)*. The enol form is shown to predominate by the ^{1}H-NMR spectrum, which suggests partial double-bond character of the C_α—C_β bond in *(70)*[46,47].

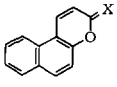
Similar properties are observed for the adducts obtained from *(5)* and *(69)*, the enol form corresponding to *(70B)* being present. Owing to extensive delocalization of the lone pair in *(70)* and in analogous compounds obtained from *(5)*, these phosphoranes can no longer be subjected to Wittig reaction. Several adducts are shown in Table 6.

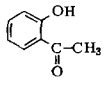


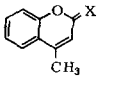
4.4.4. Addition of Acidic Compounds with Subsequent Cyclization

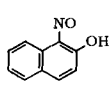
Phosphacumulene ylides *(20)* are interesting building blocks for the synthesis of heterocycles since they can react with molecules having an acid Y—H bond and a group capable of cyclization with the ylide function after addition[48]. Thus

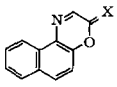


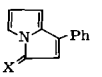




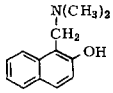


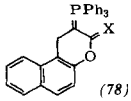






(20) (71) (72) (73)





compounds of the general type *(71)* add to *(20)* to give first the ylides *(72)* which cyclize by intramolecular Wittig reaction with formation of a C=C double bond (Z=CH) or a C=N double bond (Z=N) (Table 7).

(74) (75) (76) (77)

		S	172 [b]	93

(78)

[a] $C_{13}H_8$=9-fluorenylidene.
[b] Softening without definite melting point.

Molecules of type *(74)* bearing a Mannich base group react with *(20)* initially giving ylides *(75)*, which are transformed into *(76)* by nucleophilic substitution of the dimethylamine anion. Elimination of dimethylamine from *(76)* affords the cyclic ylides *(77)* which can undergo most ylide reactions[1-3].

Table 7 lists heterocycles prepared by this general, highly versatile synthetic principle[48,49]. *(78)*, X=O, reacts with aldehydes to give the compounds *(79)*; and *(78)*, X=S, gives the phosphonium salt *(80)* with methyl iodide[41].

(78) *(79)* *(80)*

4.4.5. Addition of CH Acids to 2,2-Diethoxyvinylidenetriphenylphosphorane *(11)*

The enhanced reactivity of 2,2-diethoxyvinylidenetriphenylphosphorane *(11)* relative to phosphacumulene ylides *(20)* can be seen in the ability of *(11)* to add CH acids which do not react with *(20)*. Reactions of *(11)* with carbonyl compounds *(81)* bearing a CO—CH_2 group are of particular interest because of the opportunity to construct γ,δ-unsaturated β-dicarbonyl compounds and their enol ethers, as well as 2,3-dihydro-4-pyranones[50].

The reagent *(11)* and the carbonyl compounds *(81)* initially form the ion pair *(82)*, which is in equilibrium with the Michael adduct *(83)*. Irreversible loss of ethanol from *(83)* gives the phosphoranes *(84)* which are vinylogs of α-keto ylides; they are stable toward oxygen and are hydrolyzed only slowly by cold water. They can be described by the resonance structures *(84A)* and *(84B)*. Participation of *(84B)* is indicated by the appearance of the carbonyl band in the IR spectrum at 1587—1595 cm^{-1}. In the ^{1}H-NMR spectrum of *(84)*, $R^1=R^2=H$, the signal of this proton is split into a doublet by long-range coupling.

The phosphoranes *(84)* undergo Wittig reactions with aldehydes *(85)*. One obtains the enol ethers *(86)* of γ,δ-unsaturated β-dicarbonyl compounds. They can be cleaved by acids to the unsaturated β-dicarbonyl compounds *(87)* which exist almost entirely in one of their enolic forms *(87B)* or *(87C)* (Table 8). If R^1 in *(87)* is hydrogen, R^2 aliphatic, and R^3 aromatic then the compounds cyclize to give 2-alkyl-6-aryl-2,3-dihydro-4-pyrones *(88)*, which regenerate *(87)* on treatment with alcoholic potassium hydroxide solution.

Since *(11)* can easily be prepared starting from ethyl acetate, a versatile synthetic scheme can be drawn for γ,δ-unsaturated β-dicarbonyl compounds *(87)* and their enol ethers *(86)*.

Like the ketones *(81)*, many CH acids *(89)* which are not activated by CO groups also undergo Michael addition to *(11)*[51]. The phosphoranes *(90)* are obtained, some of which are listed in Table 9. While compounds *(90a)*—*(90d)* fail to react with carbonyl compounds, *(90e)*—*(90h)* and aromatic aldehydes, give the dienes *(91)*. The resulting fulvenes

5. [2+2]-Cycloaddition of Phosphacumulene Ylides and Phosphaallene Ylides

5.1. General Reaction Scheme

Phosphaallene ylides of the general formula *(12)* [example: *(11)*] can undergo [2+2]-cycloaddition at both the C=C and the ylidic C—P bond. Reaction of phosphaallene ylides with π^2 double bond systems *(92)* is expected to yield the cycloadducts *(94)*, *(95)*, and/or *(96)*[52].

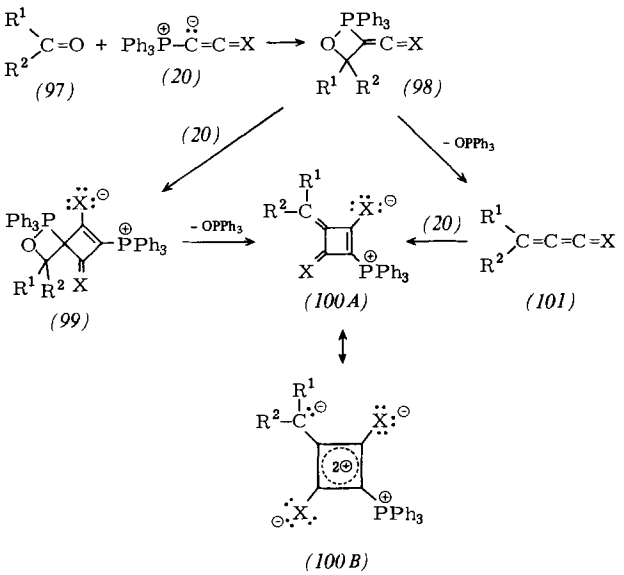
Compounds *(12)* and *(92)* can give the dipolar intermediates *(93)*. 1,4-Cyclization to the phosphorus leads to the four-membered rings *(94)* with pentavalent phosphorus, which in most cases undergo secondary reactions. On 1,4-cyclization to the C_β atom, *(93)* can yield the four-membered ring *(95)* with an ylidic function at C_α. Formation of *(94)* and *(95)* is also possible by a concerted reaction without going through the dipolar bond *(93)*.

If the lifetime of *(93)* is sufficiently long, as a result of charge delocalization, then [4+2]-cycloaddition with a second molecule of *(92)*, giving the ylide *(95)* with a six-membered ring, may be expected to occur. Mechanistic studies on these cycloadditions have not yet been completed.

5.2. Reactions with Aldehydes and Ketones

5.2.1. Synthesis of 1,3-Cyclobutanedione Derivatives

Reaction of the phosphacumulene ylides *(20)* with aldehydes or ketones *(97)* gives the 1,3-cyclobutanedione derivatives *(100)* in the case of *(4)* [=*(20)*, X=NR][53] and *(5)* [=*(20)*, X=O][36]; the same products [*(100)*=*(38)*, R^1=H] are also obtained from the dimers *(36)* and aldehydes. Which of the two reaction routes shown actually leads to *(100)* cannot yet be decided.



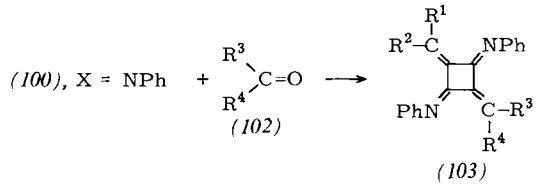


Table 10. Phosphoranes *(100)* from phosphacumulene ylides *(20)* and carbonyl compounds *(97)*.

	X	R^1	R^2	M.p. [°C]	Yield [%]
a	O	*p*-NC—C_6H_4	H	249	78
b	O	C_6H_5	CN	228	27
c	O	CF_3	*p*-Cl—C_6H_4	246	26
d	NC_6H_5	*p*-O_2N—C_6H_4	H	245	64
e	NC_6H_5	C_6H_5—CO	C_6H_5	232	58
f	NC_6H_5	$C_{13}H_8$ [a]		247	75

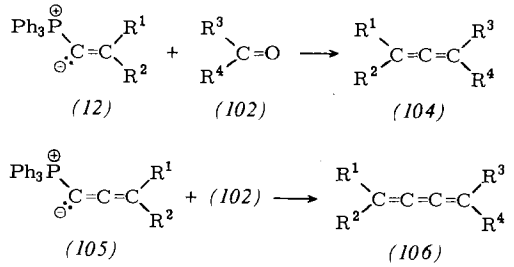
[a] $C_{13}H_8$ = 9-fluorenylidene.

A [2+2]-cycloaddition of the C=O bond of *(97)* to the ylidic C—P bond of *(20)* furnishes oxaphosphetane *(98)*[54], a dipolar ketene. It can react *via* [2+2]-cycloaddition to the C=C bond of *(20)*, giving spiro compounds *(99)* from which *(100)* arises on elimination of triphenylphosphane

(100), X = NPh + (102) → (103)

Table 11. Compounds (103) from phosphoranes (100), X = NC_6H_5. The relative orientation of R^1 and R^2 could not yet be determined. The geometrical isomerism indicated is arbitrary.

R^1	R^2	R^3	R^4	M.p. [°C]	Color	Yield [%]
p-NO_2—C_6H_4	H	p-NO_2—C_6H_4	H	245	black-red	65
p-CH_3—C_6H_4	H	p-CH_3—C_6H_4	H	239	red	36
p-CH_3—C_6H_4	H	p-NO_2—C_6H_4	H	221	red-violet	40
α-$C_{10}H_7$	H	α-$C_{10}H_7$	H	248	red	54
α-$C_{10}H_7$	H	p-NO_2—C_6H_4	H	218	red-violet	35



oxide. The second possible reaction route to (100) consists in elimination of triphenylphosphane oxide from (98) to form the alkylideneketene or -ketimine (101)[55], which in turn undergoes cycloaddition to (20) giving the four-membered ring (100). Some ylides of type (100) are shown in Table 10.

The cyclic ylides (100) with X = O cannot undergo further Wittig reaction. However, the *N*-phenylimino derivatives (100), X = NC_6H_5, react with carbonyl compounds (102) to form the deeply colored 1,3-bis(arylmethylene)-2,4-bis-(phenylimino)cyclobutanes (103) (Table 11), which also arise on reaction of (97) and (5) in the molar ratio 1:1[53]. The intermediate (100) then reacts with the second molecule of (97) to give (103), $R^1/R^2 = R^3/R^4$.

The reactivity of the ylides (100), X = NC_6H_5, crucially depends upon R^1 and R^2. Thus compounds (100e) and (100f) no longer react with carbonyl components. The diminished reactivity suggests increased delocalization of the negative charge, which can be explained in part by the contribution of a resonance structure (100B) with a cyclobutene dication. The negative charge on the exocyclic C atom of (100B) is further delocalized by ligands R^1 and R^2, *e.g.* by the benzoyl group in (100e) and by the fluorenylidene group in (100d).

5.2.2. Synthesis of Allenes and Butatrienes

Phosphaallene ylides of the general structure (22) undergo Wittig reaction ([2+2]-cycloaddition between carbonyl group and the ylide bond) with carbonyl compounds (102) to give allenes (104)[12,56]. With (11) [= (12), $R^1 = R^2 = OC_2H_5$], this reaction is possible only if there is no CH_2 group α to the carbonyl, since the Michael addition discussed in Section 4.4.5 will occur otherwise[50]. The allenes (104) obtained from (11) are particularly reactive. They dimerize in a known manner[12] or engage in secondary reactions[57]. Phosphacumulene ylides (105) and carbonyl compounds (102) react analogously to give butatrienes (106) (Table 12)[11,21].

(12) + (102) → (104)

(105) + (102) → (106)

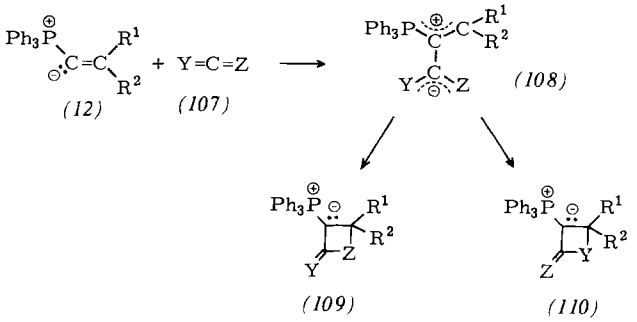


Table 12. Butatrienes (106) from phosphacumulene ylides (105) and carbonyl compounds (102).

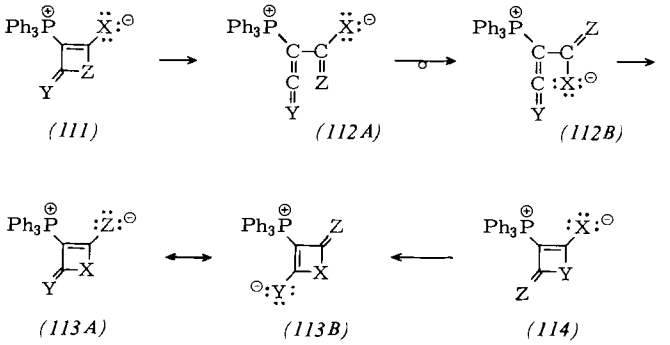
R^1	R^2	R^3	R^4	M.p. [°C]	Yield [%]
C_6H_5	C_6H_5	p-NO_2—C_6H_4	H	136	69
C_6H_5	C_6H_5	3,4-$Cl_2C_6H_3$	H	113	80
$C_{12}H_8$ [a]		p-NO_2—C_6H_4	H	288	68
$C_{12}H_8$ [a]		$C_{12}H_8$ [a]		323	71

[a] $C_{12}H_8$ = biphenylylene.



5.3. Reactions with Heteroallenes

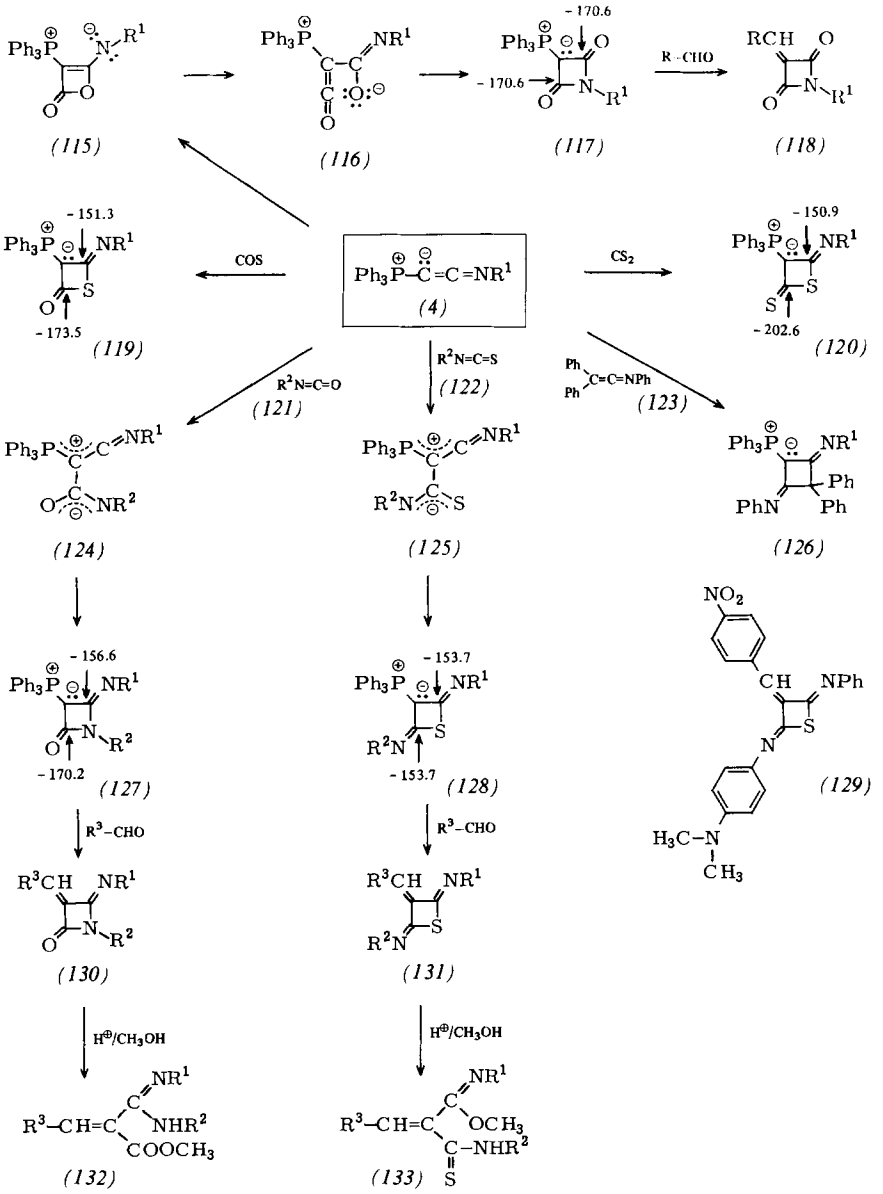
Reaction of heteroallenes (107) and phosphaallene ylides (12) can form the polar intermediates (108) which are able to undergo 1,4 cycloaddition to give both (109) and (110). The direction of ring closure depends decisively upon the nucleophilic character of Z compared with that of Y. 1,4-Cyclizations involving phosphorus have not been observed in these reactions.

(12) + Y=C=Z (107) → (108) → (109), (110)

If the ylides (20) are reacted with (107), then formation of the four-membered rings (111) and (114) becomes possible (not all the resonance forms are shown).

(111) → (112A) → (112B)

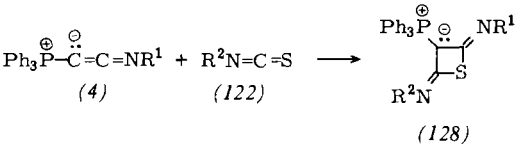
(113A) ↔ (113B) ← (114)



Compounds of type *(111)* can engage in electrocyclic ring cleavage to give *(112A)*. Ring closure, yielding the four-membered ring *(113)*, becomes feasible after prior rotation about the C—C bond, which gives the conformation *(112B)*. The overall reaction sequence amounts to exchange of the exocyclic substituent X with the ring member Z. *(114)* can rearrange analogously to *(113)*. Structural assignment of compounds *(111)*, *(113)*, and *(114)* is best accomplished by ^{13}C-NMR since the C atoms of the C=O, C=N—R, and C=S groups give rise to characteristic signals[58, 59] (see Scheme 1 for examples).

5.3.1. Cycloaddition of *N*-Substituted Keteniminylidenetriphenylphosphoranes

Reaction of *N*-phenylketeniminylidenetriphenylphosphorane *(4)*, $R^1 = C_6H_5$, with CO_2 affords the malonimidylide *(117)*[40] (see Scheme 1). We postulate initial formation of the cycloadduct *(115)* which rearranges to *(117)* according to the electrocyclic reaction sequence discussed in the preceding Section involving the open-chain intermediate *(116)*. Wittig reaction of *(117)* with aldehydes leads to the alkylidene- or arylmethylenemalonimides *(118)*. COS combines with *(4)* to give *(119)*, and CS_2 to form *(120)*[40].



After reaction between *(4)* and isocyanates *(121)* the cycloadducts *(127)* can be isolated. Their ^{13}C-NMR spectra show that ring closure has taken place at the nitrogen. The mass spectrum of the crude product demonstrates formation of small amounts of a six-membered ring analogous to compound *(139)* discussed in Section 5.3.2. We therefore presume that *(127)* is formed in a multistep reaction *via* the polar intermediate *(124)*[40]. Wittig reaction of *(127)* with aldehydes furnishes the novel *N*-substituted arylmethylene- and alkylideneazetidinone derivatives *(130)*, whose acid methanolysis gives the amidines *(132)*.

On reaction of *(4)* with isothiocyanates *(122)*, 1,4-cyclization in the polar intermediate *(125)* occurs *via* the sulfur, which is more nucleophilic than the nitrogen. Thus are obtained the phosphoranes *(128)*[40], which are the first thietane-2,4-diimines (Table 13). Their structures follow from the

Scheme 1. Chemical shifts *vs.* TMS are given for the C atoms (arrow) of selected compounds ($R^1 = R^2 = C_6H_5$).

^{13}C-NMR spectra. Once again, the appearance of a peak due to a compound formed from *(122)* and *(4)* in the molar ratio of 2:1 in the mass spectrum of the crude product is indicative of a polar mechanism. Wittig reaction of *(128)* with aldehydes affords the thietane derivatives *(131)*; their acid methanolysis provides an entry to the amino ethers of arylmethylene- and alkylidene-monothioamides *(133)* of malonic acid which, like *(132)*, should be of interest as starting materials for syntheses of heterocycles.

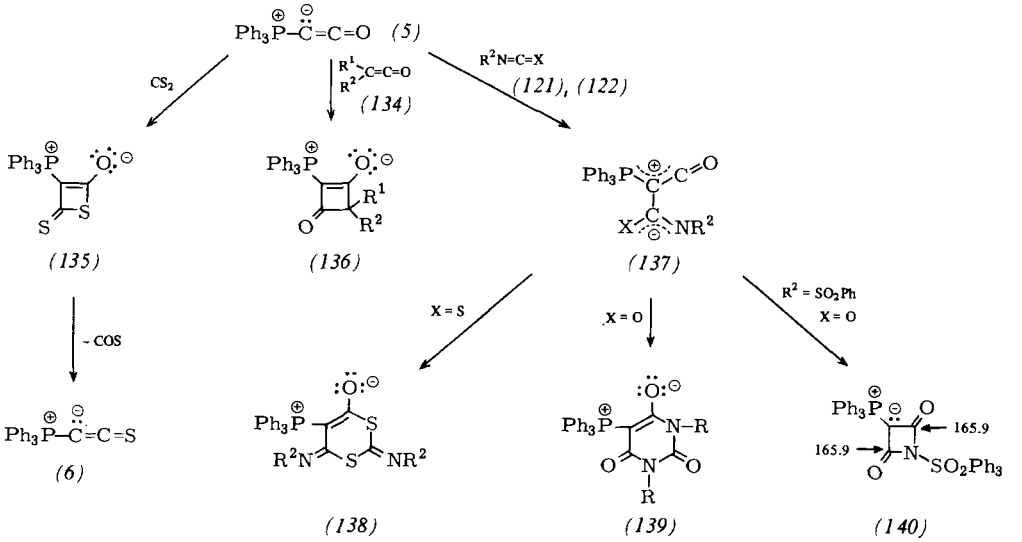
(4) *(122)* *(128)*

Table 13. Thietane derivatives *(128)* from *(4)* and isothiocyanates *(122)*.

R^1	R^2	M.p. [°C]	Yield [%]
C_6H_5	C_6H_5	191	73
C_6H_5	CH_3	156	71
CH_3	CH_3	127	53
C_6H_5	*p*-$(CH_3)_2N-C_6H_4$	200	68

The thietane *(128)* obtained from *(4)*, $R^1=C_6H_5$, and *p*-dimethylaminophenyl isothiocyanate *(122)*, $R^2=(CH_3)_2N-C_6H_4$, can be transformed into *(129)* by treatment with *p*-nitrobenzaldehyde. Owing to the conjugation between donor and acceptor substituents on the phenyl groups, this compound is blackish-red in crystalline form and gives dark red solutions[40]. Further dyes of this kind can be prepared easily.

N-Phenyldiphenylketenimine *(123)* combines with *(4)* to give four-membered carbocyclic phosphoranes *(126)*[40].



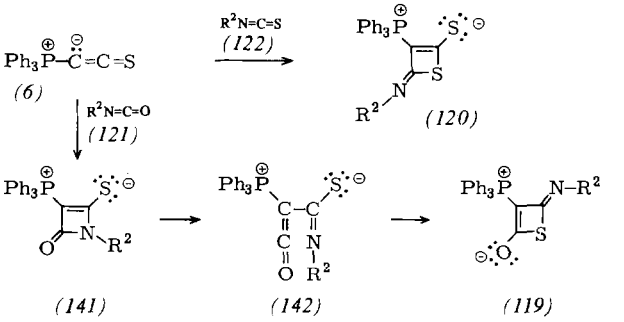
5.3.2. Cycloadditions of Ketenylidenetriphenylphosphorane *(5)*

Ketenes *(134)* undergo [2+2]-cycloaddition with ketenylidenetriphenylphosphorane *(5)* to give the 1,3-cyclobutadienones *(136)*[36]. *(5)* and CS_2 give thioketenylidenetriphenylphosphorane *(6)*. The four-membered ring *(135)* assumed as initial product decomposes by cycloreversion to COS and *(6)*[36].

Isocyanates *(121)* combine with *(5)* in the molar ratio 2:1 to form the pyrimidine derivatives *(139)*[36, 60]. If the reaction is performed with benzenesulfonyl isocyanate *(121)*, $R^2=SO_2C_6H_5$, then 1,4-cyclization proceeds faster than [4+2]-cycloaddition with a second molecule of isocyanate *(121)* in the dipolar intermediate *(137)*. The malonimide derivative *(140)*[41] is obtained.

Isothiocyanates *(122)* react with *(5)* once more in the molar ratio 2:1; however, the sulfur atom which is more nucleophilic than the nitrogen serves to close the ring. The products are the dithiane derivatives *(138)*, whose structure follows from the ^{13}C-NMR and mass spectra[60].

It remains to determine why iminoketenylidenetriphenylphosphorane *(4)* reacts with the heteroallenes *(121)* and *(122)* in the molar ratio 1:1 whereas ketenylidenetriphenylphosphorane reacts in the molar ratio 2:1. The assumption that stabilization of the positive charge in the polar intermediate *(137)* by the oxygen atom is greater than stabilization by the NR group in *(124)* and *(125)* would explain the difference in reaction stoichiometries. Such assumptions are in accord with calculations showing the $H-\overset{\oplus}{C}=O$ ion to be more stable than $H-\overset{\oplus}{C}=NH$[61], and the donor strength



(135) *(136)* *(137)* *(6)* *(138)* *(139)* *(140)*

of an O atom in ketenes to be greater than that of the NR group in ketenimines[62]. The reason for benzenesulfonyl isocyanate *(121)*, $R^2=SO_2C_6H_5$, reacting with *(5)* in the molar ratio 1:1 is still unknown.

5.3.3. Cycloadditions of Thioketenylidenetriphenylphosphorane *(6)*

While compounds *(4)* and *(5)* react both with aromatic and with aliphatic compounds *(121)* and *(122)*, the more

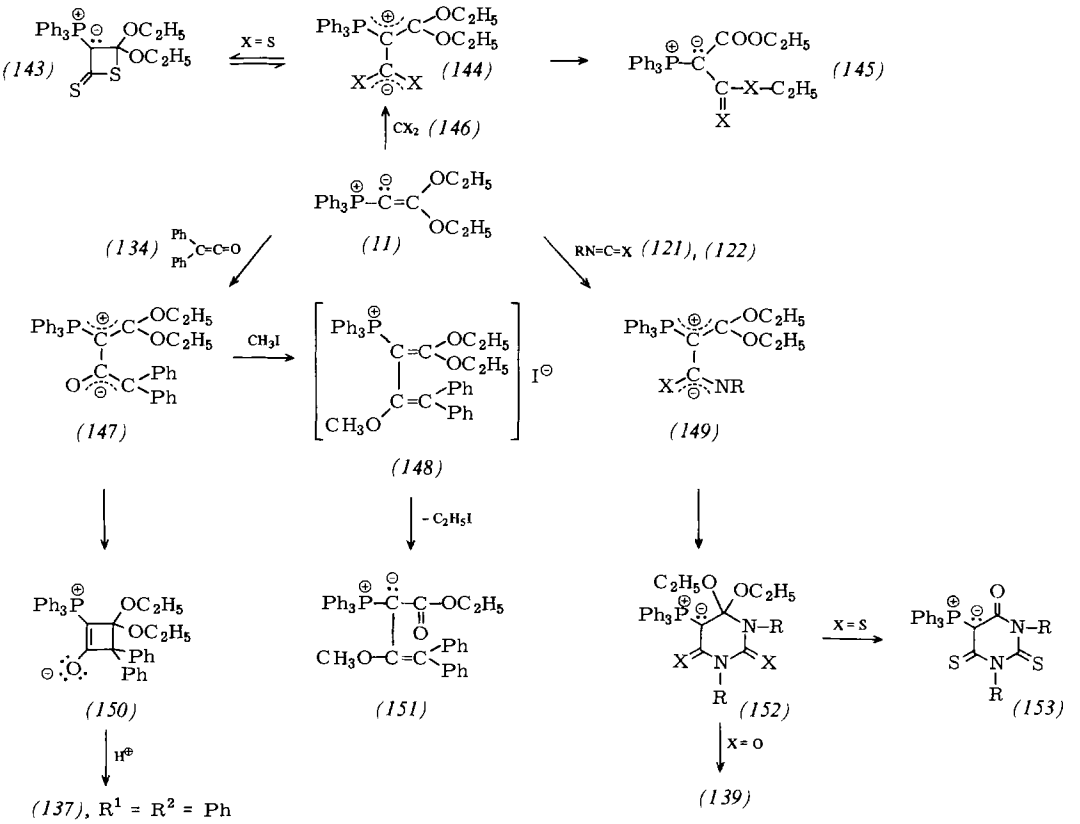
(6) *(120)* *(141)* *(142)* *(119)*

inert thioketenylidenetriphenylphosphorane *(6)* reacts only with aromatic compounds and benzenesulfonylheteroallenes *(121)* and *(122)*.

Reaction of *(6)* and isocyanates *(121)* gives the same ylides *(119)* as are obtained from *(4)* and COS[41]. We assume electrocyclic ring opening of the primary cycloadduct *(141)* to give *(142)*, which undergoes retrocyclization at the sulfur to form *(119)*. Decomposition of *(141)* to *(5)* and an isothiocyanate *(122)* is also conceivable, *(122)* then undergoing [2+2]-cycloaddition to form *(119)*. However, since our studies show that *(5)* and *(122)* always combine in a [2+2+2]-cycloaddition to give a six-membered ring, we rule out the second route.

On reaction of *(6)* with isothiocyanates *(122)*, cycloaddition again takes place at the C=S bond; the resulting phosphorane *(120)* is also formed from *(4)* and CS_2[41].

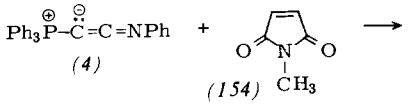
The slight donor action of sulfur in the C=S bond as a contribution to stabilization of the positive charge in a polar intermediate analogous to *(138)* could swing the balance in favor of a 1:1 molar ratio in the reaction of *(6)* with *(121)* and with *(122)*.



5.3.4. Cycloadditions of Diethoxyvinylidenetriphenylphosphorane *(11)*

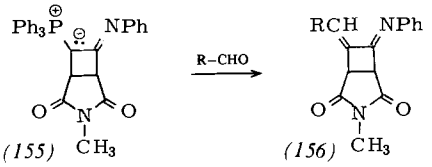
In cycloaddition reactions of *(11)* with heteroallenes *(107)* the positive charge is particularly well delocalized in the polar intermediates of the general form *(108)* by the two ethoxy groups. Reaction of *(11)* and CO_2 *(146)*, X=O, gives the polar compound *(144)*, X=O, whose ^{1}H-NMR spectrum shows two triplets and two quartets with widely different chemical shifts for the two OC_2H_5 groups. On heating, *(144)*, X=O, rearranges by intramolecular nucleophilic substitution at one of the two polar CH_2—O bonds to give *(145)*, X=O[63].

On treatment of *(11)* with CS_2 *(146)*, X=S, the primary product *(144)*, X=S, undergoes 1,4-cyclization to *(143)*, owing to the pronounced nucleophilic character of the sulfur; the ^{1}H-NMR spectrum of *(143)* displays a triplet for the two C_2H_5 groups and two very close quartets owing to the diastereomerism of the H atoms belonging to the CH_2 groups. On heating, *(143)* is converted into the open-chain, polar species *(144)*, X=S, which then rearranges to *(145)*, X=S[63].



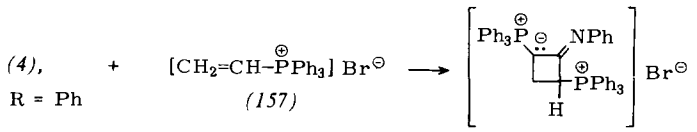
Compound *(11)* and diphenylketene *(134)*, $R^1=R^2=C_6H_5$, in the cold gives the dipole *(147)*, which is also recognized by two triplets and two quartets having very different chemical shifts in the ^{1}H-NMR spectrum. Methyl iodide attacks *(147)* at the oxygen to form the phosphonium iodide *(148)* which becomes *(151)* with loss of ethyl iodide on nucleophilic substitution. On warming to 30—40 °C, *(147)* undergoes irreversible 1,4-cyclization to *(150)*, which on acid treatment gives the cyclobutanedione derivative *(137)*, $R^1=R^2=C_6H_5$, also obtained from *(5)* and *(134)*, $R^1=R^2=C_6H_5$[63].

The lifetime of the polar compound *(149)* formed from *(11)* and isocyanates *(122)* is so long, owing to stabilization of the positive charge by the two ethoxy groups, that [4+2]-cycloaddition can compete with 1,4-cyclization: the six-membered rings *(152)* can be isolated. Acid cleavage of compounds *(152)*, X=O, gives the pyrimidinetrione derivatives *(139)*, which are also formed from *(5)* and *(121)*[63]. Analogous hydrolysis of the thio compounds *(152)*, X=S, gives the dithioxopyrimidinones *(153)* which are not otherwise accessible[60].

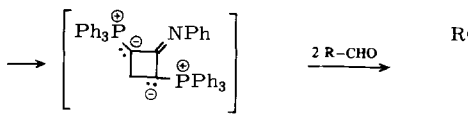


5.4. Cycloaddition to C=C Double Bonds

While ketenes add preferentially to electron-rich C=C double bonds[64], the nucleophilic compounds *(20)* will be expected to react with electron-poor double bonds. On reaction of *(4)*, R = C_6H_5, and *N*-methylmaleimide *(154)*, we obtained the *N*-phenyliminocyclobutane derivative *(155)*,



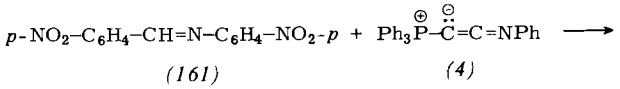
(4) *(154)*



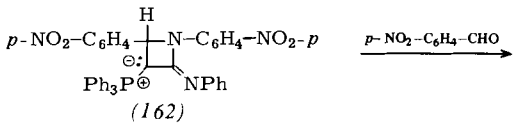
(155) *(156)*

which undergoes Wittig reactions giving *(156)*[65]. Compound *(4)*, R = C_6H_5, gives the same products in the molar ratio 2:1 with dimethyl maleate and dimethyl fumarate. Their structure has not yet been established unequivocally[40].

(4), R = C_6H_5, and triphenyl(vinyl)phosphonium bromide *(157)* add together to give the four-membered ring *(158)*. We have not yet succeeded in preparing the bis-ylide *(159)* in isolable form from *(158)*. However, it can be trapped with aldehydes to give the deeply colored cyclobutane derivatives *(160)*[65].

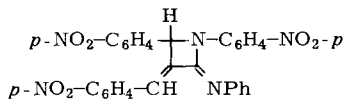


(4), R = Ph *(157)* *(158)*



(159) *(160)*

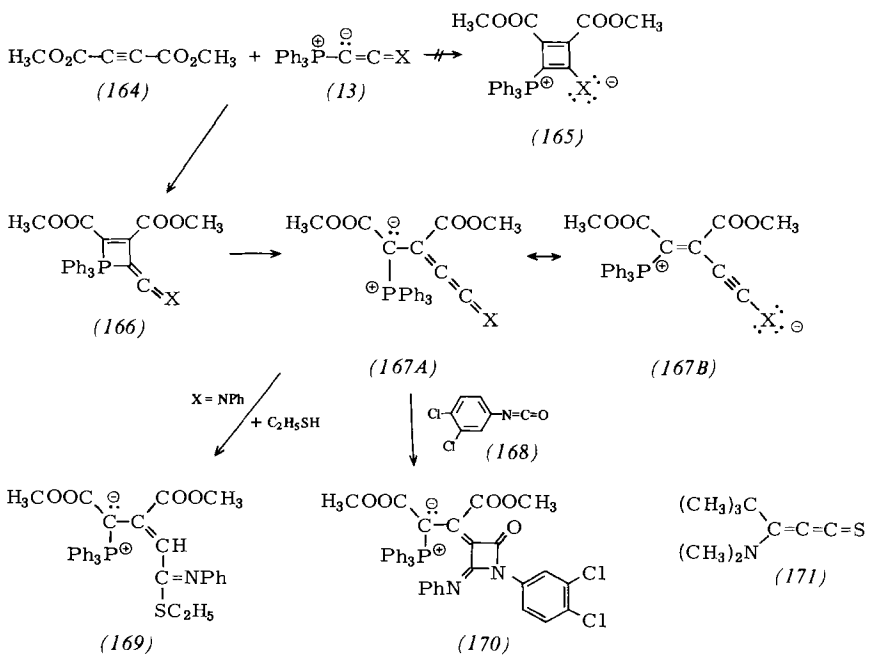
5.5. Cycloaddition to C=N Double Bonds



Schiff bases do not generally react with phosphacumulene ylides *(20)*. However, we were able to accomplish reaction of the activated species *N*-(*p*-nitrobenzylidene)-*p*-nitroaniline *(161)* with *(4)*, R = C_6H_5. The cycloadduct has the structure *(162)*. It reacts with *p*-nitrobenzaldehyde to give the 2-(phenylimino)azetidine derivative *(163)*.

(161) *(4)*

(162)



(163)

5.6. Cycloaddition to C≡C Triple Bonds

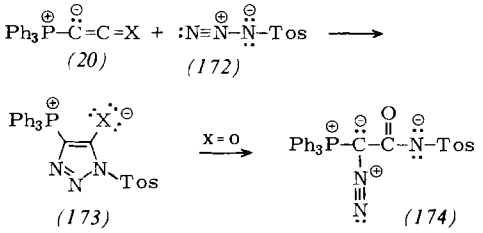
As may be seen from the results described so far, [2+2]-cycloadditions of *(20)* take place preferentially at the C=C double bond. The only exception is found in the C=O double bond of aldehydes and ketones, which adds to the ylidic bond.

Addition of dimethyl acetylenedicarboxylate *(164)* to the C=C double bond of *(20)* would, however, lead to a compound *(165)* shown in the cyclobutadiene-type resonance form. The reactants *(20)* and *(164)* combine to form the energetically more favorable phosphacyclobutene *(166)*[66] which undergoes electrocyclic ring opening to form *(167)*[67]. Together with compound *(171)*[68] discovered simultaneously,

(164) *(13)* *(165)* *(166)* *(167A)* *(167B)* *(168)* *(169)* *(170)* *(171)*

the ylides *(167)* are the first stable alkylidenethioketenes and alkylideneketenimines, respectively[55].

Owing to the reluctance of sulfur to form double bonds, we can expect a greater contribution of resonance structure *(167B)* to *(167)*, X=S. Accordingly, *(167)*, $X=NC_6H_5$, is more reactive than *(167)*, X=S. The analogy between the reactivity of *(20)* and *(167)* is self-evident.



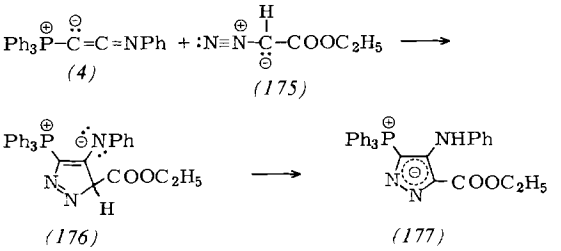
(167), $X=NC_6H_5$, adds ethanethiol to give *(169)*, and undergoes cycloaddition with 3,4-dichlorophenyl isocyanate to yield *(170)*.

6. 1,3-Dipolar Cycloaddition

The study of phosphacumulene ylides and phosphaallene ylides as 1,3-dipolarophiles is still in its infancy. The results we have obtained so far are surveyed in the following three sections.

6.1. Reaction of Phosphacumulene Ylides *(20)* with Toluenesulfonyl Azide

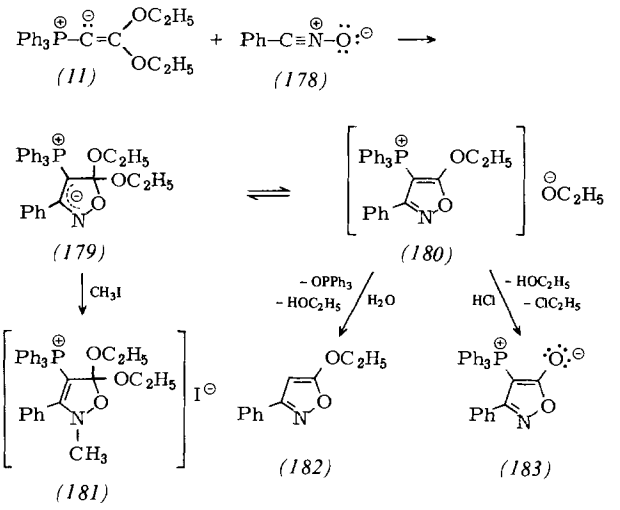
Compounds *(20)* add toluenesulfonyl azide *(172)* to give the triazole derivatives *(173)*[40,41].



Tos = *p*-CH_3–C_6H_4–SO_2

When X=O, cycloaddition is followed by ring opening to give the final product *(174)*, whose aliphatic diazo character is seen from the band at 2150 cm^{-1} in the IR spectrum.

6.2. Reaction of *(4)* with Ethyl Diazoacetate

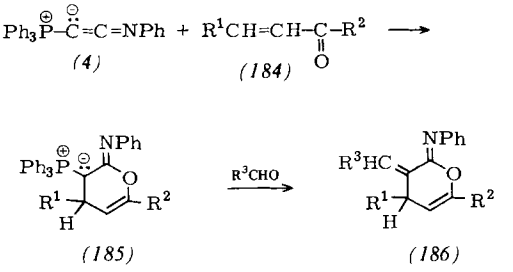


Ethyl diazoacetate reacts with *(4)*, $R=C_6H_5$, to give *(176)*. As shown by the ^{1}H-NMR and IR spectra, this compound rearranges to the tautomeric pyrazole derivative *(177)*[40].

On account of the delocalization of the ylidic electron pair in the aromatic heterocycle, compounds *(173)* and *(177)* are incapable of undergoing ylide reactions.

6.3. Reaction of *(11)* with Phenyl Nitrone

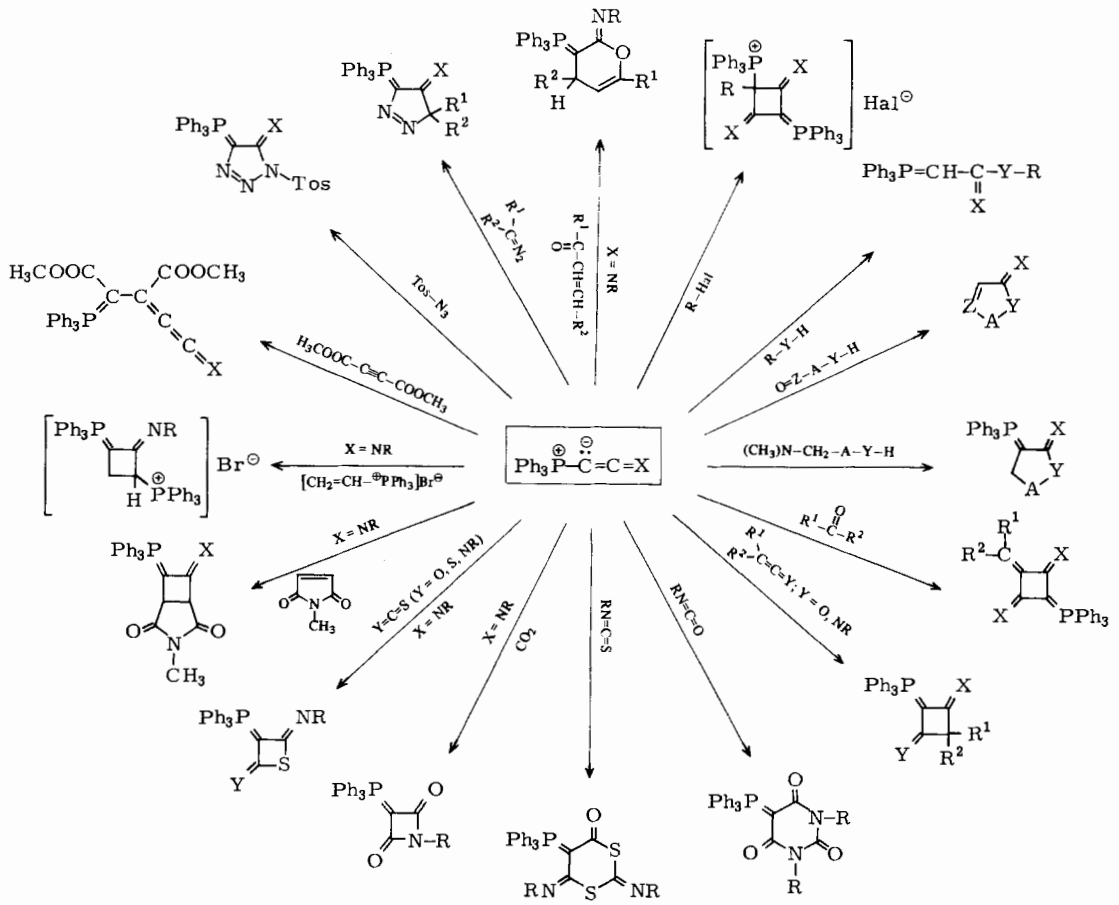
The acetal ylide *(11)* and phenyl nitrone afford the isoxazole derivative *(179)*, shown by its reactions and its ^{1}H-NMR spectrum to be in equilibrium with the phosphonium alkoxide *(180)*. On reaction of *(179)* ⇌ *(180)* with methyl iodide, *(179)* is removed from the equilibrium mixture by *N*-methylation. The phosphonium salt *(181)* is obtained.



If the reaction product of *(11)* and *(178)* is treated with water, the corresponding phosphonium hydroxide is formed from *(180)*. It is hydrolyzed in known manner[1] to triphenylphosphane oxide and 5-ethoxy-3-phenylisoxazole *(182)*. Aqueous hydrochloric acid transforms *(180)* into the corresponding phosphonium chloride, which very readily loses ethyl chloride to give the phosphorane *(183)*[63].

7. [4+2]-Cycloaddition. Synthesis of Unsaturated Cyclic Imino Ethers

α,β-Unsaturated ketones *(184)*, such as vinyl methyl ketone *(184a)* and benzylideneacetophenone *(184b)* react with *(4)*, $R=C_6H_5$, by [4+2]-cycloaddition[69] to give the cyclic imino ether ylides *(185)*[65]. Their structure follows, *inter alia*, from the ^{13}C-NMR spectra which exhibit a signal at −155 to −157 ppm for the C atom of the C=N double bond, but no signal for a C atom in the carbonyl region, as would be expected for a [2+2]-cycloadduct.



The phosphoranes *(185)* undergo Wittig reaction with aldehydes to form the α-arylmethylenimino or alkylidenimino lactones *(186)*[70].

a, R^1 = H, R^2 = CH_3; *b*, R^1 = R^2 = Ph

8. Conclusion

The orthogonal, strongly nucleophilic $\pi^4 \perp \pi^4$ electron system of the phosphacumulene ylides *(20)* [=*(13)*] and the ability to be transformed into the dipolar $\pi^4 \perp \pi^2$ system of ketenes by addition of an electrophile gives rise to a variety of addition reactions; those considered in the present article are summarized in Scheme 2.

Scheme 2. Addition reactions of phosphacumulene ylides. Most of the adducts are shown in the "phosphorane form" with a C=P double bond (cf. ref. [14]).

The adducts are ylides which can be used for numerous reactions[1-3]. [2+2]-Cycloadditions frequently lead to four-membered carbocyclic or heterocyclic carbonyl or imino compounds which can undergo ring cleavage, and are thus in turn also of interest as synthetic building blocks. Much scope for new experiments is available to the preparative chemist. The bonding in phosphacumulene ylides and their cycloadducts should be of particular interest to the theoretician[14].

This report was only made possible by the dedicated experimental work of Dr. G. Schmid, Dr. D. Sandmeier, Dr. R. W. Saalfrank, Dr. M. Ettlinger, Dipl.-Chem. Ch. Geismann, and Dipl.-Chem. L. Kisielowski, and by X-ray structure analyses performed by Prof. Dr. H. Burzlaff, Dr. U. Voll, and Dr. E. Wilhelm. I am grateful to all of them and my colleagues, especially Dr. P. Hofmann, for numerous stimulating discussions. We are all convinced that the above results represent but the beginning of an interesting new chapter of ylide chemistry.

[28] The fact that the molecule has a $P—C_\alpha—C_\beta$ angle differing from 180° according to X-ray analysis can be neglected in these considerations. There is no interaction between the carbanion lone pair and the π-electrons of the C=O group in the same plane even when $P—C_\alpha—C_\beta$ is linear.

[29] Since IR spectroscopic data show the betaine form to make the greatest contribution, we generally employ the betaine form for the α-carbonylphosphoranes.

Flash Thermolysis of Organic Compounds

By Günther Seybold[*]

Flash thermolysis is a special form of gas-phase thermolysis that is particularly suitable for the production and isolation of thermolabile reaction products. The theoretical basis and the instrumental requirements of the method are first given, and the preparative importance of flash thermolysis for the synthesis of thioketenes, allenes, arynes, highly strained ring systems, quinodimethanes, and other reactive compounds is then demonstrated with the aid of examples.

1. Introduction

Thermolysis has long been of great preparative utility in organic chemistry. A special form of thermolysis, *i.e.* flash thermolysis, has recently found wide application in the synthesis of thermolabile compounds, in spectroscopic characterization of short-lived intermediates, and in the investigation of thermolytic reactions[1-4]. The principle of this technique has long been applied in isolated cases, but it is only recently that the great potential of the method has been recognized and utilized in systematic fashion.

Since the generation of radicals has been described in detail in earlier reviews[1,4], the present article will deal mainly with the application of flash thermolysis to the production of nonradical compounds.

2. The Principles of Flash Thermolysis

Flash thermolysis is a special form of gas-phase thermolysis characterized by three important features:

1) The substance to be pyrolyzed remains in the hot zone for only a very short time. The mean residence or contact times are between 1×10^{-3} and 1 s.

2) Flash thermolyses are carried out in such a way that the steady-state concentration of the substance to be pyrolyzed, and thus also the concentration of the products in the hot zone, is very low.

3) Immediately after passage through the hot zone the thermolyzate is cooled to very low temperatures (−196 °C) and thus protected from modification by subsequent reactions.

The short contact times and the low steady-state concentrations are achieved by arranging that the substance to be pyrolyzed flows through a heated tube (the reactor) and is condensed in a cold trap as soon as it leaves the hot zone.

The necessary flow can be produced in two ways.

a) A high vacuum is used, the substance being brought into the reactor by molecular distillation. In this case molecular beams are produced[5]. According to *Knudsen*'s work[5,6], when the pressure is $\leq 10^{-3}$ torr the contact time τ depends only on the molecular velocity V and the reactor geometry, but it is independent of the pressure and of the rate of addition of the substance. τ can be readily calculated. Thus, for a cylindrical tube of length L and diameter D:

$$\tau = 4 \cdot L/(V \cdot k) \text{ [s]}$$

where k is a correction factor taking account of the ratio L/D[6]. Thermal excitation of the molecules occurs mainly by molecule-wall collisions. This form of flash thermolysis is also called flash vacuum thermolysis (often abbreviated to FVT) or very low pressure pyrolysis (VLPP).

b) The compound to be pyrolyzed is carried into the reactor in a stream of inert gas, pressures of 10^{-1} to 10 torr generally being used. The contact times can be calculated from *Poiseuille*'s flow equation when the flow is nonturbulent[6]. For a cylindrical tube of length L and diameter D, with pressures P_1 and P_2 at the tube ends, we have

$$\tau = \frac{8 \eta L^2}{(D/2)^2 (P_1 - P_2)} \text{ [s]}$$

where η is the coefficient of friction of the inert gas. Thus, in this form of flash thermolysis τ depends on the geometry of the reactor, the pressure drop in the reactor, and the viscosity of the carrier gas. In contrast to the situation in vacuum flash thermolysis, thermal excitation occurs here mainly by molecule-molecule collisions.

If the pressures and the rate of substance injection E (mol/s) are constant, a steady state is established within the reactor. The steady-state concentration c depends on the contact time τ, the reactor volume R, and the injection rate E:

$$c = E\tau/R \text{ [mol/l]}$$

In very fast thermolytic reactions ($t_{1/2} \ll \tau$), c defines the product concentration in the reactor. The steady-state concentration in the reactor increases if the rate of injection E is increased (high throughput); this has the consequence that the occurrence of undesirable reactions is greatly enhanced, such as dimerization, polymerization, chain reactions, and generally speaking subsequent reactions with a bimolecular initiation step.

We shall now show, by an example, how the still just tolerable steady-state concentration and thus the optimal injection rate E can be calculated.

Let A be a reactive thermolysis product that can dimerize in the reactor in an undesirable side reaction:

$$2\,A \xrightarrow{k_2} A_2$$

[*] Dr. G. Seybold
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)
Present address: BASF AG, Farbenforschung, D-6700 Ludwigshafen (Germany)

(k_2 = rate constant). We then have:

$$-\frac{d[A]}{dt} = k_2 \cdot [A]^2$$

or, for small time intervals:

$$-\frac{\Delta[A]}{[A]} = \Delta t \cdot k_2 \cdot [A] = \tau \cdot k_2 \cdot [A]$$

where $\Delta t = \tau$, because the reaction takes place only in the reactor.

If the proportion of A that undergoes the undesirable side reaction is less than 1 %, we have

$$\Delta[A]/[A] \leq 0.01$$

The steady-state concentration of A can then have, at the most, the value:

$$[A] \leq 0.01/(k_2 \cdot \tau)$$

For $\tau = 10^{-3}$ s and $k_2 = 10^4$ to 10^8 l mol^{-1} s^{-1} (order of magnitude for fast molecule-molecule reactions), a steady-state concentration of 10^{-3} to 10^{-7} mol/l may not be exceeded. If A has radical character, then k_2 lies in the region 10^{10} to 10^{11} l mol^{-1} s^{-1} and the steady-state concentration must be kept extremely low, which in turn requires a very slow rate of injection and hence means low throughputs. Conversely, with stable products (stable with respect to bimolecular subsequent reactions) correspondingly high rates of injection can be used and high throughputs are achieved.

While subsequent reactions with a bimolecular primary step can in all cases be excluded by an appropriate choice of the experimental conditions, it is in principle impossible to avoid fast monomolecular subsequent reactions.

3. Apparatus for Flash Thermolysis

In correspondence with the three basic steps in the thermolysis method, namely injection of the substance, thermolysis in the hot zone, and quenching or condensation of the pyrolyzate, a flash pyrolysis apparatus must in principle consist of three components: an injection unit for the sample, pyrolysis tube, and lastly a cooling or condensation region. The apparatus requirements depend on the problem in question. If the end products are all relatively stable, it is usually sufficient to use one of the types of apparatus in which the heating jacket is outside the vacuum system (external heating). This type of flash thermolysis apparatus is derived from the apparatus often used for conventional gas-phase thermolysis, *e.g.* for the pyrolysis of esters[7], and is characterized by simple construction and easy cleaning; a simple type is illustrated in Figure 1. Many variants of this type are described in the literature[8–12, 102]. The contact times can be extended as desired by the introduction of quartz wool or other filling material into the pyrolysis tube.

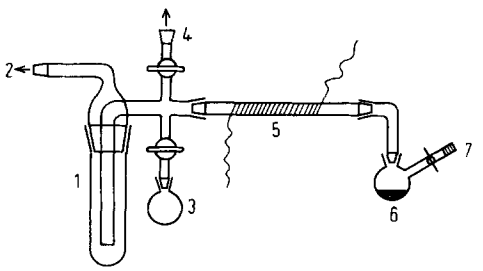

Fig. 1. Flash thermolysis apparatus with external heating. 1, cooling trap; 2, to pump; 3, solvent supply vessel; 4, to manometer; 5, electrically heated quartz tube; 6, substance supply vessel; 7, inert-gas inlet.

The disadvantage of this type of apparatus is the large distance between the hot zone and the cooling traps, and it is therefore unsuitable for the isolation of thermally very unstable products. For the latter purpose those types of apparatus are preferable in which the pyrolysis tube is heated inside the vacuum system[13–15]. This has the advantage that the distance between the surface of the cold traps and the hot zone can be kept very small, whereby even very short-lived molecules such as radicals can be investigated. The disadvantage here is the high cost of construction and operation of this type of apparatus, although this has been largely overcome in the apparatus developed by us[15] (Fig. 2). Our version is characterized especially by the facts that the contact times can be altered in a defined manner by changing the pyrolysis tube and that the capacity of the cold traps has been much increased by use of a rotatable cold finger. This apparatus has recently become commercially available[16]; it is suitable for preparative flash pyrolysis of amounts of up to 10 g. A modified injection system has been developed for substances of very low volatility[17].

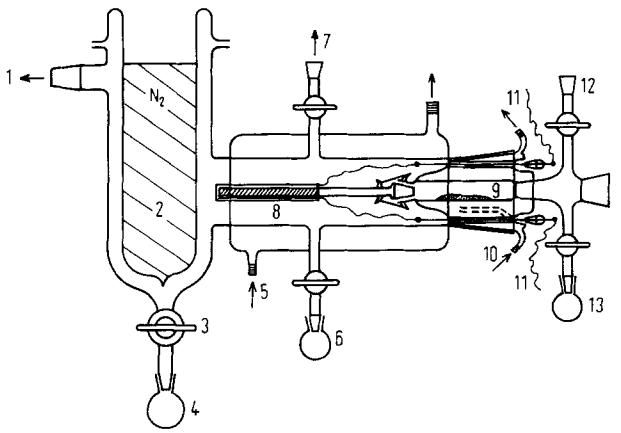

Fig. 2. Flash thermolysis apparatus with internal heating. 1, to pump; 2, rotatable cold finger; 3, coolable tap; 4, receiver; 5, cooling water inlet; 6, solvent supply vessel; 7, to manometer; 8, electrically heated quartz tube; 9, sublimation tube; 10, connection for thermostat; 11, electric leads; 12, inert-gas inlet; 13, storage vessel for volatile substances. The compounds to be pyrolyzed can optionally be introduced at 9 or 13.

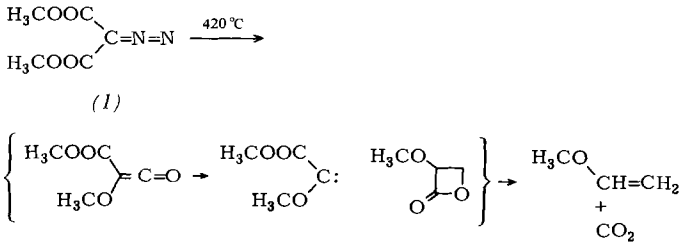
The type of cold trap shown in Figure 2 has proved particularly valuable in flash thermolysis, since the labile pyrolyzate can be collected under very mild conditions as the trap thaws. In flash pyrolyses an inert low-boiling solvent is usually added, so that a solvent matrix is formed on the cold trap surface, in which the pyrolyzate exists in finely divided form. When the cold trap thaws out one then obtains a dilute solution of the pyrolyzate[15]. Moreover, a trapping agent may be used in place of the solvent.

One prerequisite for successful flash thermolysis in a molecular beam or in a stream of inert gas is an efficient pumping

system. High-vacuum pumps fitted with ionization gauges are generally used for this purpose[15].

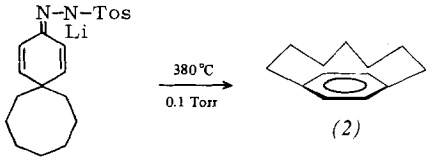
If the cold trap is fitted with quartz or NaCl windows, the thermolyzate can be investigated directly by spectroscopic methods[1,2,18–20]. If the cold trap is replaced by the ion source of a mass spectrometer, the pyrolysis products can be investigated by mass spectroscopy[1,4,21,22]. The combination of pyrolysis with mass spectroscopy not only provides valuable information about short-lived molecules, *e.g.* the ionization potentials of radicals in the gas phase, but also permits the optimal thermolysis temperatures for preparative flash thermolysis to be determined.

4. Applications of Flash Thermolysis



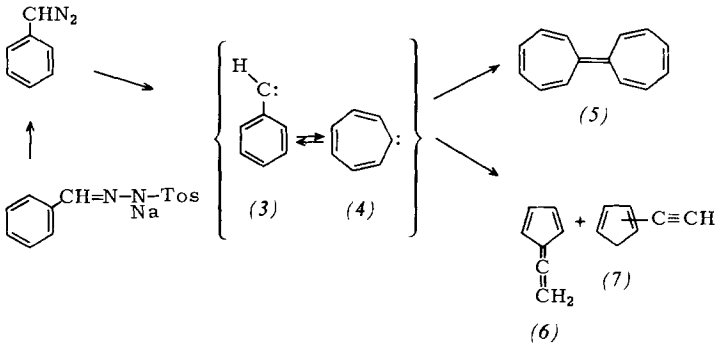
In the following sections the preparative uses of flash thermolysis will be demonstrated by selected examples, though the list of flash thermolyses given here is not claimed to be comprehensive.

Because of the short contact times, appreciably higher temperature are required in flash thermolyses than in thermolyses effected in solution or in the stationary gas phase. For example, whereas 1,2,3-benzothiadiazole in solution is completely cleaved at 200°C with evolution of N_2[23], in the gas phase with a contact time of 10^{-3} s a temperature of 850°C is required for quantitative fission[17]. Bond fissions leading to the formation of nonstabilized radicals generally require temperatures in excess of 1000°C. In the fission of methyl iodide into methyl and iodide radicals a conversion of 20% is achieved only above 1100°C[24]. The temperatures are lower when molecules with an even number of electrons are formed by the thermolysis, as is the case in retro-Diels-Alder reactions or when small stable molecules such as N_2, CO, CO_2, SO_2, or HX are expelled.

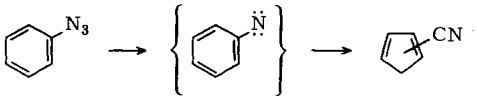


4.1. Flash Thermolysis with the Removal of Nitrogen

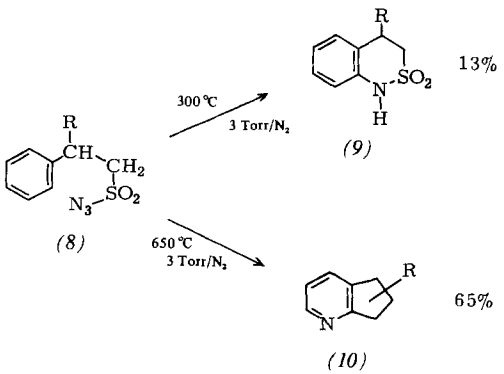
4.1.1. Flash Thermolysis of Diazoalkanes and Azides



Because of their relatively long lives in the gas phase, the carbenes formed as the primary products in the flash thermolysis of diazoalkanes stabilize themselves by rearrangement[100]. For example, whereas the Wolff rearrangement does not occur on thermolysis of diazomalonic ester *(1)* in solution, it is observed on flash thermolysis[25].

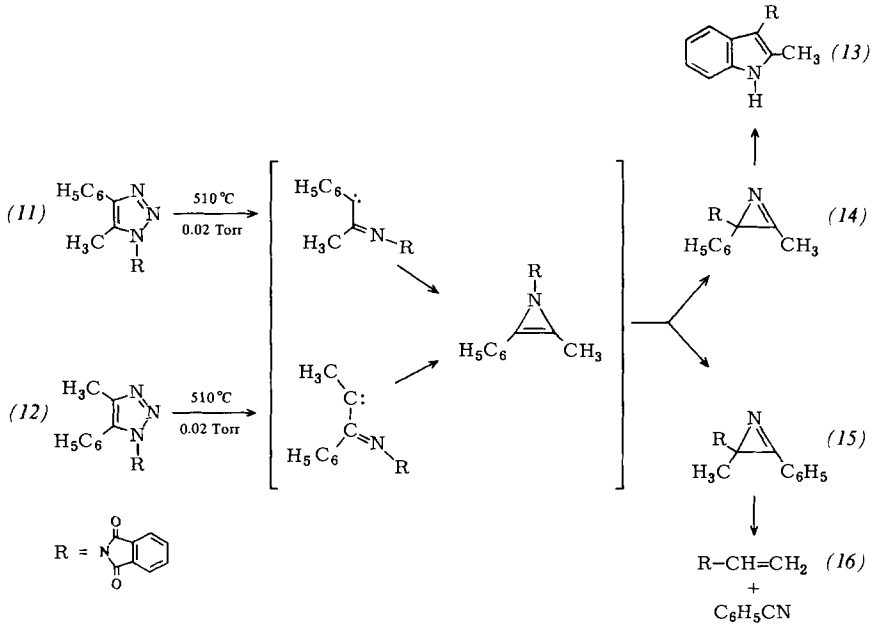


These considerations have found application in the preparation of [7]paracyclophane *(2)*[26]: the salt of the toluenesulfonylhydrazone affords first the diazo compound[27], which then decomposes in the gas phase with loss of nitrogen.



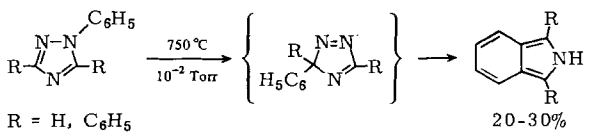
Flash thermolysis of phenyldiazomethane has been studied very thoroughly[28–32]. The phenylcarbene *(3)* first formed exists in equilibrium with cycloheptatrienylidene *(4)*, which at high steady-state concentrations dimerizes to heptafulvene *(5)*[28]; at low steady-state concentrations *(4)* stabilizes itself by ring contraction to give the products *(6)* and *(7)*[29]. If *p*-, *m*-, or *o*-tolyldiazomethane is used, dihydrocyclobutabenzene and styrene are formed as the end products in all cases[30,31]. The mechanism of these reactions has been elucidated by investigations with isotopically labeled compounds[32].

Phenylnitrene, formed as the primary product in the flash thermolysis of phenyl azide, stabilizes itself in a manner analogous to that observed with phenylcarbene: a cyclopentadienecarbonitrile is found as the main product[33–36,44]. *Wentrup et al.* also investigated the hetarylnitrenes formed in the flash thermolysis of annelated tetrazole derivatives[37,100].



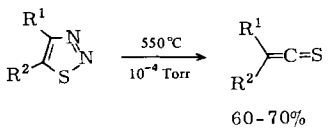
Flash thermolysis of the sulfonyl azide *(8)* gave surprising results: whereas at 300°C, as in thermolysis in solution, the formation of the thiazine derivative *(9)* predominated, at 650°C a 65% yield of the cyclopentapyridine derivative *(10)* was obtained[38]. Compound *(9)* is formed by an insertion

reaction of the nitrene formed as an intermediate. For the formation of *(10)* the authors assumed addition of the nitrene to the benzene ring with subsequent release of SO_2 and rearrangement.



4.1.2. Flash Thermolysis of Triazoles and Thiadiazoles

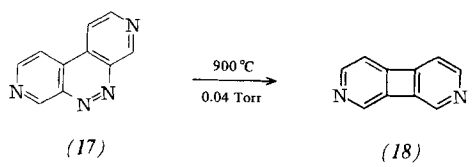
Flash thermolysis of 1*H*-1,2,3-triazole derivatives has been thoroughly investigated by *Rees et al.*[39–41]. 2*H*-Azirines, indole derivatives, ketene imines, and nitriles could be isolated, depending on the nature of the substituent and the pyrolysis conditions. According to the experimental data available, flash thermolysis of 1,2,3-triazole very probably involves the antiaromatic 1*H*-azirine as an intermediate. Thus, flash pyrolysis of the isomeric triazoles *(11)* and *(12)* gives in each case the same mixture of products *(13)* to *(16)* together with benzonitrile[39].



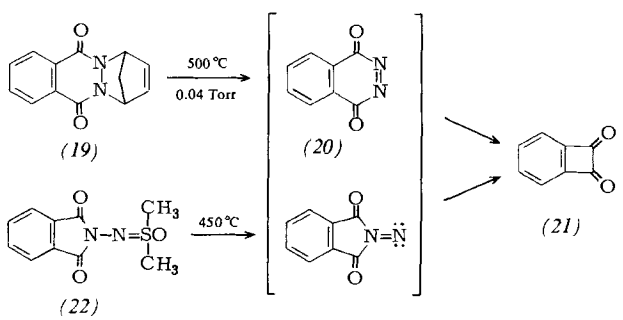
Similar results are obtained on using isotopically labeled compounds[41].

On flash thermolysis phenyl-substituted 1,2,4-triazoles yield, surprisingly, isoindoles, but the reaction becomes understandable if a primary 1,3-shift of the phenyl group is assumed[42].

Flash thermolysis of 1,2,3-thiadiazoles leads to good yields of thioketenes, a class of compounds that with a few exceptions was previously unknown[17,43]. Here the preparative advantage of flash thermolysis is particularly evident, since if the thermolysis of the thiadiazoles is carried out in a high-boiling solvent then only the secondary products derived from the thioketenes can be isolated[52].

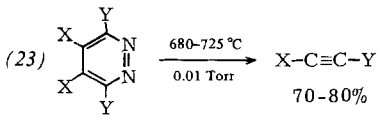


Flash thermolyses of benzotriazole[111] and benzothiadiazole[17] have also been investigated. In agreement with expectation, the ring-contraction products cyclopentadienecarbonitrile and fulvene-6-thione, respectively, are produced.



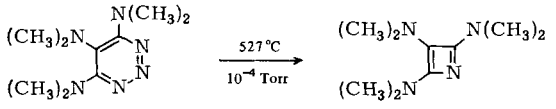
4.1.3. Flash Thermolysis of Pyridazine and Triazine Derivatives

The pyridazine derivative *(17)* loses nitrogen at 900 °C and the diazabiphenylene *(18)* is formed by ring contraction[45].



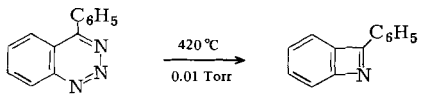
The diazanaphthoquinone *(20)* formed as an intermediate in the flash thermolysis of *(19)* behaves in the same way[46], the cyclobutabenzenedione *(21)* being isolated as the product

in 88 % yield. Compound *(21)* can also be prepared, but in a lower yield, by flash thermolysis of the sulfoximide *(22)*[8]. Nonannelated pyridazines such as *(23)* fragment into acetylene derivatives on flash thermolysis[107]; since no symmetri-



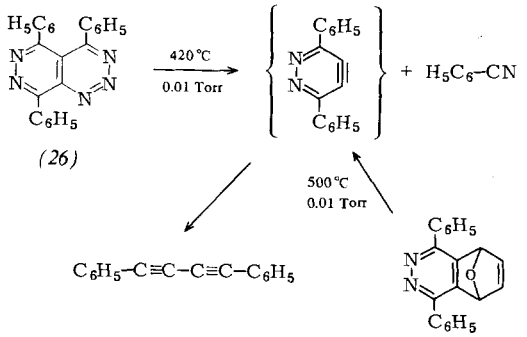
cally substituted acetylene is formed, it is impossible that the reaction should proceed through an intermediate cyclobutadiene or tetrahedrane[107].

(23)



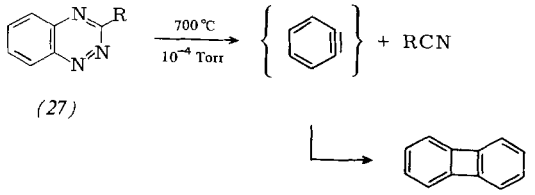
X = C_6F_5, C_2F_5, C_3F_7; Y = C_6F_5, 4-C_5F_4N

In contrast, on flash thermolysis of the triazine (24) an azacyclobutadiene could be isolated for the first time, namely tris(dimethylamino)azete (25)[47], in which the amino groups contribute in a special way to stabilization of the molecule[48].



(24) (25)

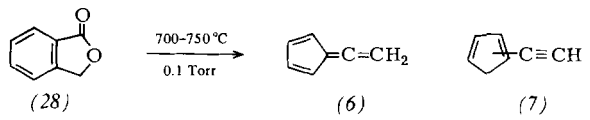
Similarly, benzotriazines afford benzazete, which can also be isolated in substance[49] and whose structure had been proved by a series of interesting trapping reactions[50].



However, unlike benzotriazine, the pyridazinotriazine (26) on flash thermolysis affords benzonitrile and a diacetylene derivative. The authors postulate the formation of dehydropyridazine as an intermediate in this reaction[53].

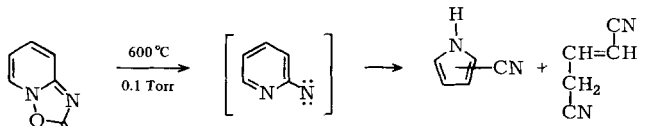
(26)

The readily accessible 1,2,4-triazines (27) also decompose on flash thermolysis; they yield dehydrobenzene, nitrile, and nitrogen[51].



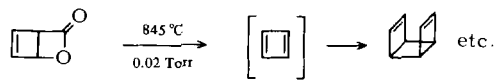
(27)

4.2. Flash Thermolysis with Removal of CO_2, CO, SO_2, or HX



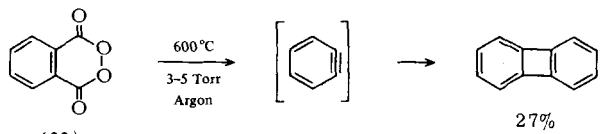
4.2.1. Flash Thermolysis of Lactones

The lactone (28) decomposes on flash thermolysis into carbon dioxide and the allenic derivative (6); a certain amount of the cyclopentadienylacetylene (7) is also produced as a secondary product from (6)[10, 54]. The reaction can be controlled in such a way that it serves as a preparative method for the allene (6)[10].



(28) (6) (7)

The pyridine nitrene (30) is similarly formed from the oxadiazolone derivative (29) and, as expected, stabilizes itself by the formation of mixed pyrrolecarbonitriles and by ring opening[55, 112].

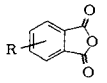


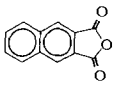
(29) (30)

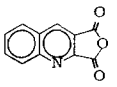
Hedaya et al. studied the flash thermolysis of the lactone (31)[56]. At 845 °C this smoothly extrudes CO_2 with the formation of cyclobutadiene which on working-up dimerizes into *syn*-tricyclooctadiene (32).

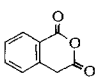
(31) (32)

Attempts to prepare cyclobutadiene by flash thermolysis of the cyclobutadiene(tricarbonyl)iron complex have so far been unsuccessful[57, 58]. Ready and smooth loss of carbon dioxide was observed on flash thermolysis of the peroxide (33)[59].





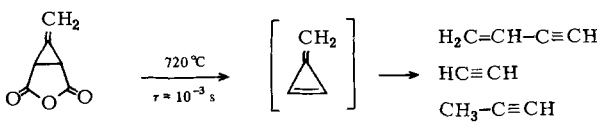




(33)

4.2.2. Flash Thermolysis of Acid Anhydrides

Cyclic acid anhydrides, *e.g.* succinic or maleic anhydride, split off carbon dioxide and carbon monoxide on flash thermolysis with the formation of olefins or acetylenes, respectively[101]. This reaction has been used especially for the preparation of arynes and hetarynes (Table 1), which are either trapped or are isolated as their dimers[60, 117]. Dehydropyridine stabilizes itself by ring opening to an acetylene derivative[62].



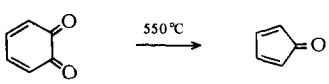
The reaction does not, however, always proceed so smoothly. In some cases only removal of carbon dioxide can be achieved[67, 68].

Table 1. Flash thermolysis of acid anhydrides.

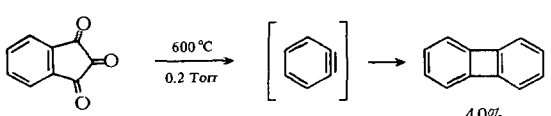
Starting material	Intermediate	Ref.
		[60, 61, 63, 106]
		[103]
		[62]
		[103]
		[64]
		[65]
		[66]

[a] Products isolated.

Hedaya tried to prepare triafulvene *(34)* (unknown until recently) by this reaction, but was able to isolate only a mixture of acetylenes, whose composition could not be used



(34)

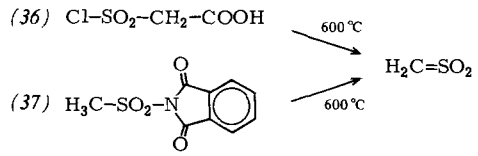


to establish with certainty the intermediate occurrence of *(34)*[69].

4.2.3. Flash Thermolysis of Quinones

On flash thermolysis, quinones lose one or two molecules of carbon monoxide[116]. The cyclopentadienone arising from the *o*-quinone at 550°C has been identified by *Chapman* by means of IR spectroscopy[19].

At higher temperatures two molecules of CO were removed, and it was concluded from the products that cyclobutadiene

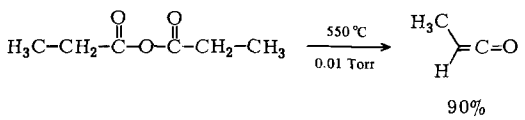


(35)

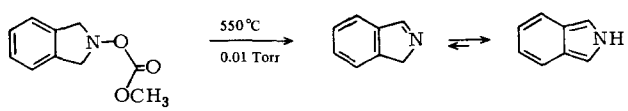
occurs as an intermediate[70–72]. However, direct proof is still lacking. Indantrione *(35)* splits off CO in a smooth reaction and gives biphenylene in a yield that amounts to 40% after working up[73, 117].

4.2.4. Flash Thermolysis of Carboxylic and Sulfonic Acid Derivatives

On flash thermolysis the methanesulfonic acid derivatives *(36)* and *(37)* give a highly reactive compound to which the structure of a sulfene could be assigned on the basis of trapping reactions and the IR spectrum[74, 75]. Sulfenes



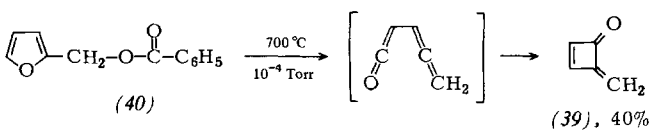
have in fact been postulated as intermediates in previous reactions, but so far their existence has not been demonstrated directly.



Sulfine could be obtained in the same way from methanesulfinyl chloride and other precursors[76].

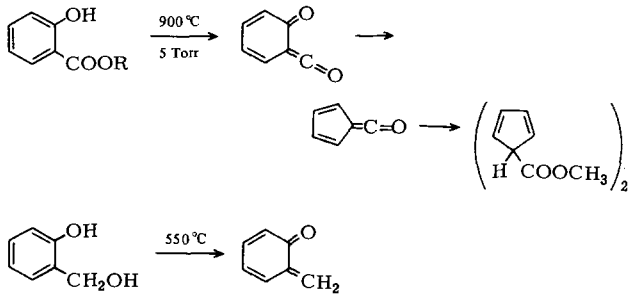
A method similar in principle to the above has long served for making reactive ketenes on a preparative scale[77].

The fission of the ester *(38)* into isoindole, methanol, and carbon dioxide[78] is a related reaction. A further interesting



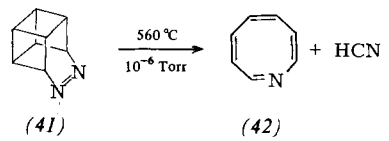
(38)

reaction of a carboxylic acid derivative is the formation of aromatic nitriles by flash thermolysis of thioformanilides[79].



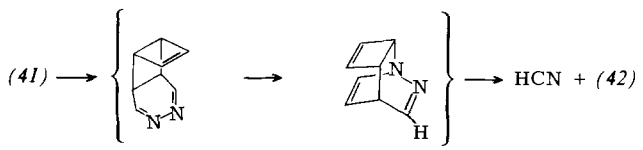
Trahanovsky obtained the very unstable methylenecyclobutenone *(39)* by flash thermolysis of the furan derivative *(40)*; he assumed that propadienylketene occurred as an intermediate[80].

(40) *(39)*, 40%



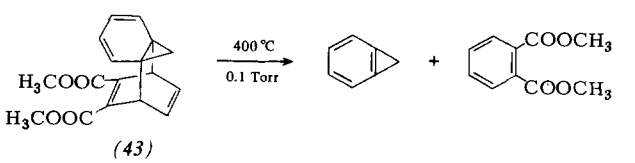
Fulven-6-one was demonstrated as an intermediate in the flash thermolysis of a salicylic ester[81, 82].

Quinone methides could be prepared in a related reaction and were then examined by IR spectroscopy[83].



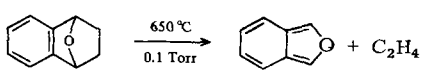
4.2.5. Flash Thermolysis of Diazabasketene

On conventional thermolysis in solution or in the gas phase, diazabasketene *(41)*, prepared as precursor of cubane in a multistep reaction, gave only an indefinite product mixture and not the expected cubane. Flash thermolysis of this compound *(41)* was investigated by *Hedaya*[84]. At 560°C the compound fragmented to hydrogen cyanide and a very labile compound to which the structure of azocine *(42)* could be assigned on the basis of spectroscopic findings and chemical reactions; this product *(42)* is stable only below −50°C.



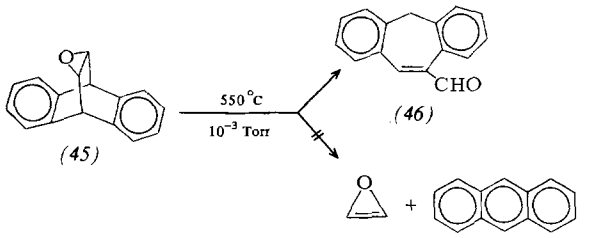
(41) *(42)*

For the interesting reaction *(41)* → *(42)* the course illustrated has been proposed[84]. Attempts to make *(42)* more easily accessible by flash thermolysis of tropyl azide were unsuccessful; the azide decomposes under these conditions into hydrogen cyanide, benzene, and nitrogen[51].



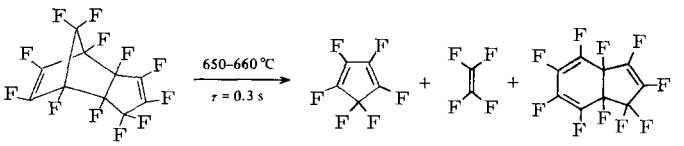
4.3. Retro-diene and -ene Reactions

The retro-Diels-Alder reaction is of preparative importance in organic chemistry[105]. If the conditions of flash thermolysis are chosen for this reaction, then thermally very sensitive products can be isolated. Thus, *Vogel* prepared cyclopropabenzene by flash thermolysis of the Diels-Alder adduct *(43)*[85].



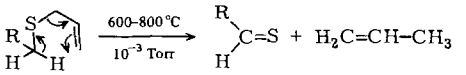
(43)

Another preparatively interesting reaction of this type is the fission of the epoxide *(44)* into isobenzofuran and ethylene[86].



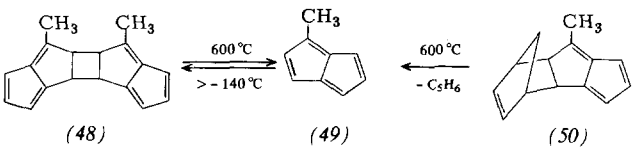
(44) 100%

Attempts to obtain oxirene by flash thermolysis of dibenzobarrelene oxide *(45)* ended in failure; the aldehyde *(46)* was the main product formed at 550°C[104]. However, pentatetraene and other sensitive olefins could be prepared smoothly by this reaction[115].



(45) *(46)*

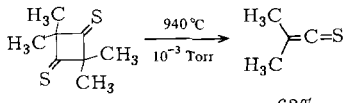
Unusual products are often obtained in the pyrolysis of fluorinated organic compounds[109, 114]. For example, in flash thermolysis of the dimeric perfluorocyclopentadiene *(47)* the retro-Diels-Alder reaction competes with cycloelimination of difluorocarbene[110, 113].



(47)

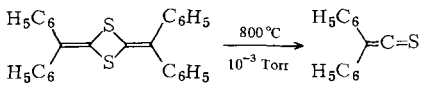
Flash thermolysis of allyl sulfides gives thiocarbonyl compounds in a reaction that is formally a retro-ene reaction[87, 88]. In this way thiocarbonyl compounds that were previously unobtainable, or obtainable only with difficulty, can be prepared by a relatively simple route: examples are thioacrolein, monothiobiacetyl, and thiobenzaldehyde.

4.4. Cleavage of "Dimeric" Molecules



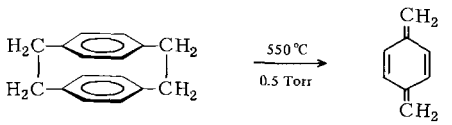
An interesting example of this type of reaction is the synthesis of the highly reactive methylpentalene *(49)* by flash thermolysis of the dimer *(48)*, which in turn is obtainable by a retro-Diels-Alder reaction of *(50)*. The latter reaction proceeds by way of methylpentalene *(49)*. This pentalene derivative *(49)* is stable essentially only below −140°C and at higher temperature dimerizes instantaneously into *(48)*. In spite of its instability, it was found possible to measure the IR and UV spectra of this compound, which is also of great theoretical interest[89].

(48) *(49)* *(50)*



The cleavage of diketenes into the monomers, which must happen to thermally sensitive ketenes under the conditions of flash thermolysis, is a further example of this type of reaction[90]. The thermally very unstable dimethylthioketene was

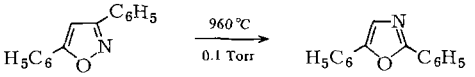
first obtained by flash thermolysis of the cyclobutanethione *(51)* in 62% yield[91].



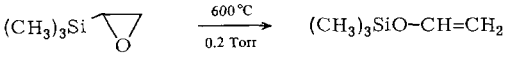
(51)

Bismethylene-1,3-dithietanes, *e.g.* the bisbenzhydrylidene compound, which are also formally thioketene dimers, can similarly be cleaved to monomers by flash thermolysis[17, 108].

A reaction that is of interest both industrially and theoretically is the fission of [2.2]paracyclophane into *p*-quinodimethane *(52)* whose IR and UV spectra were measured[18, 92]. The monomer *(52)* polymerizes at room temperature to a polymer which has found industrial use.



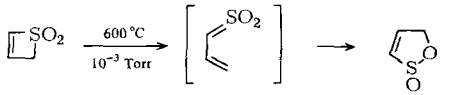
(52)



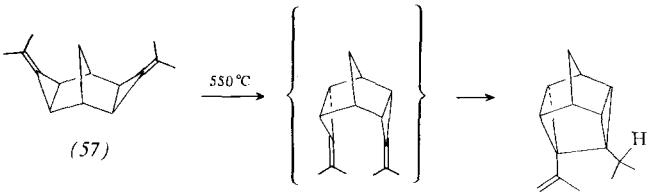
By suitable experimental arrangements it proved possible to deposit *(52)* on the surface of an article, so that the latter became covered by a film[93].

4.5. Rearrangements

Rearrangements have also been studied under the conditions of flash thermolysis, although in this type of reaction conventional thermolytic techniques are sufficient in many cases. Isoxazoles *(53)* rearrange at 960°C to oxazoles[94] and α,β-epoxy-silanes *(54)* are converted into enol ethers[95].

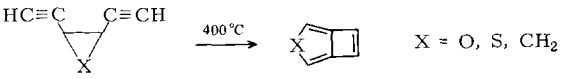


(53)



(54)

The sulfone *(55)* reacts on flash thermolysis by ring expansion, yielding *(56)*[96, 14].



(55) *(56)*

By flash thermolysis at 550°C the cyclization product *(58)* is obtained from the tetracyclic starting material *(57)*[97].

(57) *(58)*

In an interesting reaction, bicyclic trienes *(60)*, *e.g.* cyclobutafuran, could be prepared from the three-membered ring compounds *(59)*[98, 99].

(59) *(60)*

5. Final Remarks

Thermolabile thermolysis products cannot in principle be isolated by conventional pyrolysis techniques, but they can be obtained, even on a preparative scale, with the aid of flash thermolysis. This has led to the first isolation of many compounds, some of which were also of theoretical interest.

Use of this technique is still relatively complicated, and the amount of reacting substance is generally limited. Each case should therefore be examined carefully to determine the reaction conditions and the requirements essential for the solution of the problem.

Apparatus for flash thermolysis is now available commercially, removing an important obstacle to the use of this method, and it can thus be expected that chemists will in future make increasing use of this technique for the preparation and study of reactive compounds.

Electrophotography

By John W. Weigl[*]

Electrophotographic images are formed by the displacement of matter in electric fields: the deposition of charged particles or the deformation of a plastic surface is controlled by a geometric field pattern, configured by the photo-response of a photoconductive insulating material. Image amplification up to 10^5 may be achieved by the application of external potentials and the judicious selection of imaging particles having a high ratio of absorbance per unit charge. These particles may be ions, colloids, photoresponsive pigments, or (most commonly) colored plastic "toner" composites. Of the many processes which have been invented to date, transfer xerography remains the most useful. This paper presents a concise review of electrophotographic imaging processes and materials, as well as of some of their applications.

1. Introduction

Photography requires a photoreceptor of sufficient sensitivity to capture the fleeting imprint of light arriving through a lens. Optical systems are inefficient, exposure times must be short, light sources are limited in intensity. The photon flux available at the image plane is far less than what would be required for each quantum to print out one molecule of photoproduct. Therefore, an amplification step must be provided: the primary ("latent") image must be intensified. This process step, called "development", may be chemical or electrical in nature. Free energy must be supplied during development to convert the latent image into a high-contrast visible record. It is highly desirable to introduce a threshold, below which exposure is ineffective. This minimizes the effects of inadvertent low-level photo or thermal pre-exposure and improves the shelf life of the materials.

Let us consider how much amplification is required. With practical light sources, projection optics can furnish at most about 10^{12} photons/cm^2 to the photoreceptor in exposure times of one second or less. About 10^{17} light absorbing molecules/cm^2 are required to form a dense black image[**]. Since primary photochemical or photophysical events can yield, at most, one molecule of photoproduct per absorbed photon, photography requires a 10^5-fold image intensification.

Many imaging processes are available which lack amplification: namely, those in which diazo compounds, photochromics, dye bleach materials, most photopolymers and photoresists, and certain high resolution "printout" emulsions based on inorganic salts are employed. These processes are useful for the photofabrication of integrated circuits and for contact duplication of transparencies, but they lack sufficient photographic sensitivity for employment in projection set-ups at reasonable exposures. Systems of this type have been amply discussed in the literature and fall outside the scope of this review[1].

In silver halide photography, the image is developed by the reductive precipitation of black silver filaments in those microcrystals of the salt which have received threshold exposure. Typically, absorption of a few dozen photons can nucleate the complete conversion of a 1 μm crystallite to a tangled mass of black atomic silver. The effective intensification is measured by the ratio of metal formed per grain to the minimum number of photons required to render the latter developable. Since each microcrystal is either fully developed or not at all, the emulsion chemist may trade off resolution *vs* developed image density (and hence photographic sensitivity) by adjusting mean grain size. The materials thus formed cover the gamut from colloidal ("Lippmann") emulsions, having gains of *ca.* 1000, to relatively coarse-grained layers offering 10^8 to 10^9-fold amplification, with corresponding reduction in image resolution[2].

Alternatively, the primary product of photolysis may be used to nucleate the reductive precipitation of silver or other metal ions from a developer solution. This process—called "physical development"—allows the external developer to supply the material which forms the final image. Silver halides, as well as PbI_2, TiO_2, and certain diazonium salts, may be exposed to furnish the development nuclei[3]. In all these systems, the free energy required for amplification derives from the chemical potential of the developer system. The literature on "chemical" photography is enormous; we refer to it only to provide a reference base for the subject of this review.

In electrophotography the primary quantum yield is generally much higher than the 1 % value reported for silver halides[2]. Under favorable conditions, absorption of a photon of actinic radiation has a 50—90 % chance of forming a mobile electronic charge carrier—the primary unit of image information in all electrophotographic processes. Displacement of such carriers in an electric field forms a "latent" image, which must be developed (at once, or subsequently) to become visible. The intensification required for projection speed is produced by some form of "physical" development; for example, by the motion of large colored particles in response to relatively few surface charges, by a change in electrostatic adhesion, by the electrostatic wrinkling of a smooth thermoplastic layer, or by the electroplating of metal ions. The free energy required for image gain is supplied in the form of an electrostatic potential, typically applied to a dielectric layer prior to exposure or to a bias electrode during development. For example, on typical xerographic photoreceptors a charge density of *ca.* 10^{12} electrons/cm^2 suffices to attract a dense black layer

Webster, New York 14580 (USA)

[**] For purposes of illustration, assume a black image consisting of a mixture of three dyes with peak (log 10) extinction coefficients of 3×10^4 l/mol·cm, having their absorption bands evenly spaced across the visible spectrum, and a molecular volume of (3.35 Å)^3. Such a layer would have an average linear (log 10) extinction coefficient of *ca.* 3×10^4 cm^{-1}. For an absorbance of 2.0 (99 % light absorption) the image must be 0.67 μm thick; therefore, 1.2×10^{17} dye molecules/cm^2 must be exposed. Hence, a dye-based "molecular" photochemical imaging system of quantum yield Φ would require at least $1.2 \times 10^{17}/\Phi$ photons/cm^2 (see Ref. [56]).

of 10 μm toner particles (absorbance ≥1.5). At a primary quantum yield of 0.5, full exposure requires *ca.* 2×10^{12} photons/cm^2—an effective gain of about 10^5 over the "molecular" system cited above[*].

Electrophotography is still a relatively young science. Although the first efforts to use photoconductography were made during the 1920's, the field became active only after 1950 when a growing need for inexpensive photocopies stimulated the development of a new technology based on electrostatic imaging[13]. This application did not require portability—a seemingly unattainable goal for electrophotographic cameras which generally require external electric connections as well as special illumination. Instead of competing with silver photography in compactness, photosensitivity, or pictorial rendition, electrophotography offered complementary advantages: instant delivery of inexpensive copies of text and graphics, high-contrast prints on plain (or nearly plain) paper, and a liberation from the need for dark storage of photosensitive materials prior to use.

The principles and applications of electrophotography have been described in several monographs[5–12] as well as in numerous journal articles (*e.g.*, [13–18])[**]. In the limited space allotted to the present review, we shall try only to provide an overview of the main electrophotographic imaging processes known to date, with emphasis on certain materials-related topics which may be of special interest to chemists and occasional digressions to describe interesting inventions.

Lack of space prohibits our discussion of the active new field of photoelectronic image processing and transmission, the capture, manipulation, and transmission of graphic information by electronic, rather than optical means[19].

1.1. Overview of Electrophotographic Processes

The photosensitive material is invariably a photoconductive insulator. Exposure is used to generate, in image configuration, a concentration of mobile electronic charge carriers, far in excess of their thermal population. Externally applied electrical free energy is used to convert the latent photoconductivity pattern into a visible image. Although processes and configurations vary widely, they may be conveniently classified, as follows:

Electrostatic Imaging Processes using External Development

Exposure of a charged photoconductive dielectric layer produces an electric field pattern which may be made visible by the motion and selective capture of small colored particles. Familiar examples include direct and transfer xerography, imaging by transfer of electrostatic charges, and "persistent internal polarization" processes. A related phenomenon is the formation of electrostatic images by the modulation of ion flow through photoconductor-coated screens.

Photoplastic Imaging

Exposure of an electric field-stressed thermoplastic produces a charge pattern which is developed by electrostatic surface deformation to produce a light-scattering image. Variants of this process include "Frost" and xerographic thermoplastic holography.

Photo-Active Pigment Electrography (PAPE)

Exposure of "electrically photosensitive" particles under high-field conditions alters their charge/mass ratio—and in many cases, their polarity—sufficiently to cause imagewise migration of exposed particles through a dielectric liquid or through a softened thermoplastic matrix. Examples include photoelectrophoresis and imagewise particle migration; photoelectrically controlled adhesion imaging ("Manifold") is closely related.

Photoconductography

Exposure of a coating exhibiting persistent photoconductivity generates an image pattern of conductive areas which can be used to direct the electrodeposition of ions, colloids, or conductive "toner" particles to form visible images.

2. Transfer Xerography

In 1938, *Carlson* demonstrated the basic principles of a new imaging process, designed to produce inexpensive copies of office documents[13, 20]. His basic concept was to use image illumination to form a charge pattern on a large-area photoconductor, to develop this by means of oppositely charged "toner" powder and to transfer, then fix the powder image onto a receiving sheet such as paper. This process and its variants were eventually named "xerography"[*]. In the nearly 40 years since *Carlson*'s first successful experiments, xerography has become a mature technology. Selenium alloys, inorganic photoconductors, and organic polymer coatings have replaced *Carlson*'s sulfur and anthracene layers, providing much higher photosensitivity, stability and spectral response range. Carbon-pigmented thermoplastic "toners" and sophisti-

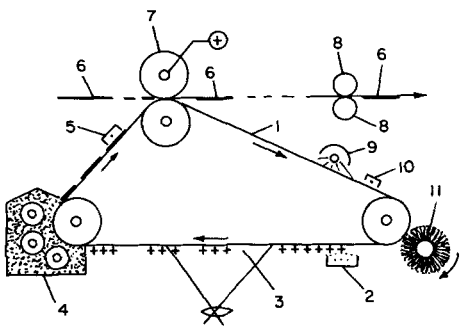

Fig. 1. Xerographic process steps—illustrated by a duplicator, based on a photoconductor-coated belt (1). Uniform charge, applied by scorotron (2) is converted into a latent image by flash exposure (3). Charged "toner" powder, applied by a brush mechanism (4), develops the image, is discharged by a corotron (5), then transferred to sheets of paper (6) by a pair of electrically biased rolls (7) and fused to the paper by heated pressure rollers (8). Charge remaining on the photoconductor is removed by uniform illumination (9) and AC corona (10); the remaining toner is brushed off (11). Within 3–5 seconds the same section of photoreceptor is ready to begin the cycle again. Duplicators such as this can turn out 1–2 copies per second.

[*] For independent estimates of electrophotographic gain and discussions of the implications of fluctuations in sensitivity, granularity, and other sources of "noise" upon image quality, see references [4, 179].

[**] The author has despaired of an attempt to provide adequate references to original work. In the limited space available it is quite impossible to cite any but the most pertinent publications: *Schaffert*'s monumental book [6] cites over 4000 patents and 1000 journal articles, and even it is far from complete! For a comprehensive background the reader is referred to the monographs cited and to recent publications—particularly in Photogr. Sci. Eng. and Japn. J. Electrophotogr.

[*] Greek: "dry writing" [20].

cated developer mixtures are used instead of lycopodium pollen. Several liquid development processes have been introduced. Elaborate automatic copiers, duplicators, and printers have been developed; yet, the basic process principles have endured with remarkably little change[5, 6].

The steps used in conventional ("transfer") xerography are outlined in Figure 1. A light image-modulated charge pattern on the surface of a photoconductive insulating layer is developed by the attraction or repulsion of charged thermoplastic "toner" powder; thus, positive or negative images may be produced. The toner image is transferred and fixed to paper or film; the photoreceptor is illuminated and reverse charged to remove residual charge, then cleaned and recycled.

2.1. Formation of Electrostatic Latent Image

Corona discharge devices—high-voltage "corotron" wires with stabilizing shields, optionally with "scorotron" control grids—have proven to be the most reliable means of applying a stable, uniform layer of charge to large-area photoconductors (Fig. 2)[21]. Gaseous ions, such as hydrated protons and CO_3^-, are transported to the surface of the dielectric[22] where they form a relatively stable blocking contact; *i.e.*, they are not readily injected into the bulk and thus discharged[23]. In the case of ZnO-binder layers, the charge layer is believed to comprise adsorbed O_2^- ions[24]; in other cases, the nature of the charge layer is less well identified.

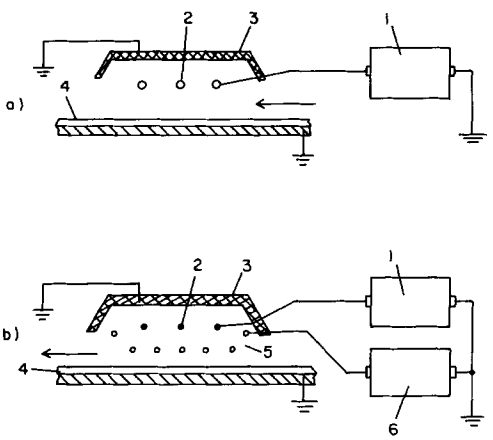

Fig. 2. Two common corona charging devices.—a) Three-wire corotron connected to high voltage power supply—typically 6–7 kV (1), and consisting of three 75 µm diameter tungsten wires (2) and a grounded shield (3). The photoconductor (4) passes under the corotron.—b) Scorotron, using three emitting wires set at 6–7 kV (2) and a seven-wire control grid (5) connected to a lower-voltage power supply (6), set at the potential to be applied to the photoconductor surface (4). After Ref. [6], p. 234.

Contact electrification of large areas has proven difficult to carry out reliably—partly because of asperities and chemical irregularities in the surface layers and partly because this process involves air breakdown and is therefore quite sensitive to fluctuations in ambient humidity. A somewhat more successful alternative is induction charging; this involves field-induced injection of carriers from the conductive base through the photoconductor, followed by surface trapping (Fig. 3)[25].

A dielectric overcoating may be used to protect the photoconductor surface and to act as a separate charge storage layer. Figure 4 shows one of several closely related photodielectric processes, whereby imagewise photodischarge of the photoconductor may be caused to impress a developable latent image across an overcoating of this type. The sequence of charging and illumination steps is readily altered to produce either positive or negative images of the original. Transfer, fixing, and cleaning steps are similar to those for other forms of xerography[26–31].

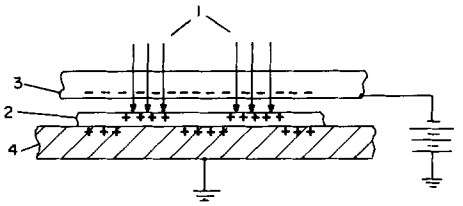

Fig. 3. Imagewise induction charging. Image illumination (1) of a photoconductor (2) in an external field applied by a closely spaced transparent electrode (3) may be used to form a latent image in a single step. Mobile charge is injected from the base electrode (4). Rear illumination may be used instead. After Ref. [21c].

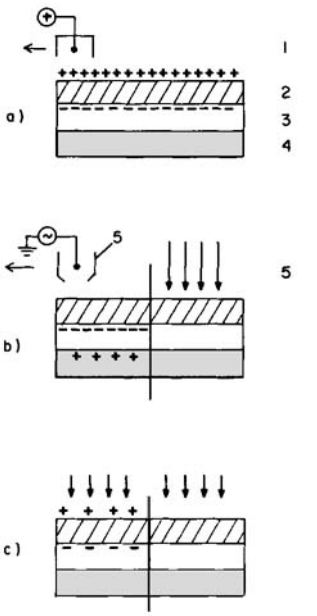

Fig. 4. A typical "photodielectric" process.—a) Charge is deposited by a conventional corotron (1) on dielectric (2), while countercharge is injected into the photoconductor (3) from base (4).—b) Image illumination (arrows) is applied through a transparent grounded AC corotron (5), to produce an equipotential surface whose charge density varies imagewise.—c) Uniform illumination produces a stable developable variable-potential image. After Ref. [29] (cf. also Ref. [27]).

In both plain and overcoated photoconductors, exposure produces a latent image consisting of a surface charge pattern. Field lines run from this surface to the counter-charge, induced in the base electrode or, in overcoated photoconductors, trapped at the interface between the dielectric and photoconductive layers. As Figure 5a shows, in charged areas the field lines run exclusively through the bulk of the dielectric. External fields appear only in the form of fringes around the charged areas; as *Schaffert*[32] and *Neugebauer*[33] observed, such fringes extend outward for a distance comparable to the thickness of the uppermost dielectric layer, be it the photoconductor itself or its overcoating. Close approach of a grounded counter-electrode draws the field lines outward in proportion to the ratio of capacitances of the dielectric and air gap (Fig. 5b). Charged particles introduced into this

space can now be drawn toward the interior, as well as toward the edges of the image, thus providing "solid area" development.

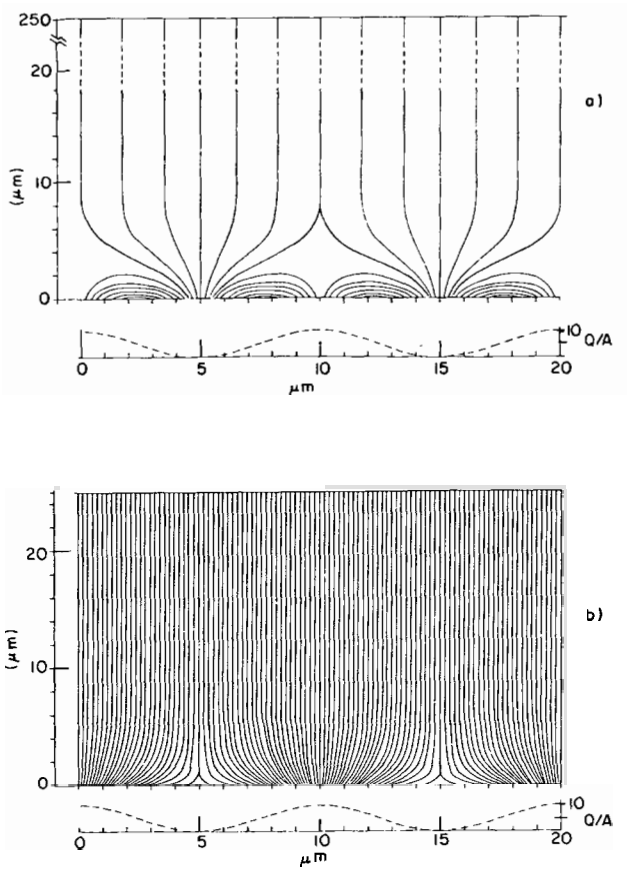

Fig. 5. Effect of electrode spacing on the electric field above a 25 μm selenium plate with sinusoidal charge pattern (Q/A in units of 10^{-4} C/m^2, $V_{max} = 500$ V). With the electrode relatively remote, at 250 μm (a), fringing fields predominate; as the electrode approaches close to 25 μm (b), the field lines are virtually straight and uniformly spaced. Adapted from Ref. [32].

2.2. Xerographic Development

In xerography the latent image is developed by the attraction of oppositely charged toner particles along electric field lines. A development system must provide:

Means for handling and introducing particles into the development space.

Reproducible means for charging the toner particles.

Control of the development field configuration[34, 35].

Contact electrification is generally used to apply the desired charge to dielectric toner powder. One way to do this is to pass the particles through a set of high-voltage-biased metal nozzles to form a charged aerosol. Ample space is required to insert the powder cloud between photoconductor and development electrode. Since individual toner particles approaching the latent image do not have sufficient capacitance to distort the field, they simply follow the existing field lines, depositing at the inner or outer edges of charged areas, according to their polarity. Central portions of the image lack external field and remain undeveloped (Fig. 6). The resultant edge enhancement is particularly useful for sharpening the perception of minor density differentials in soft-tissue xeroradiography[36, 37].

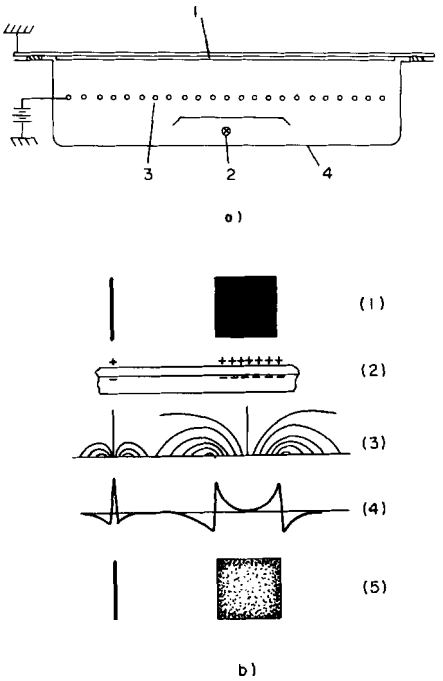

Fig. 6. "Edge development" of solid areas.—a) Schematic of powder cloud development with xeroradiographic plate in place: (1) selenium plate, face down; (2) powder cloud generator; (3) open wire control grid set at 1500 V; (4) container, typically 10 cm deep. After Ref. [37].—b) (1) Original to be reproduced, including black line and solid black square; (2) charge pattern on photoconductor resulting from exposure; (3) electrostatic field configuration—note strong lateral fringes; (4) normal field strength—note edge components; (5) developed image—note edge enhancement. After Ref. [35].

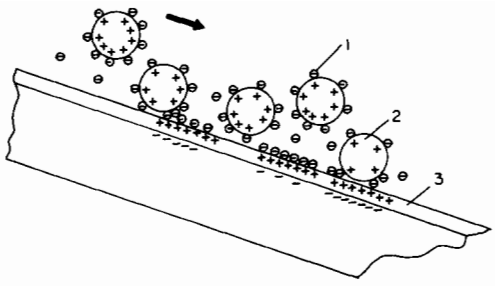

Fig. 7. Schematic of cascade development process: (1) 10 μm toner particles; (2) 500 μm carrier beads; (3) 50 μm thick photoconductor on conductive base. After Ref. [35].

Powder clouds proved unwieldy for use in photocopying applications. About 1945, *Wise*[38] devised "cascade development"—a method of delivering triboelectrically charged toner close to the photoreceptor surface (Fig. 7). The toner powder is mixed with 50—100 times its weight of relatively massive "carrier" particles having the desired triboelectric properties and the mixture is poured over the latent image. As such a developer mass slides and bounces over the photoreceptor, toner is knocked loose and redistributes itself between carrier beads and charged areas of the photoreceptor. In the usual case of insulating carriers, edge development is prominent and solid areas are largely suppressed. This is satisfactory for copying text and line drawings, but distorts the tone rendition of pictorial input. The size of carrier beads, typically 100–500 μm, makes it impractical to bring development electrodes close enough to straighten the field lines (cf. Fig. 5). Cascade development of solid areas may be improved somewhat by screening the latent image, albeit at the cost of maximum density[35, 39, 40].

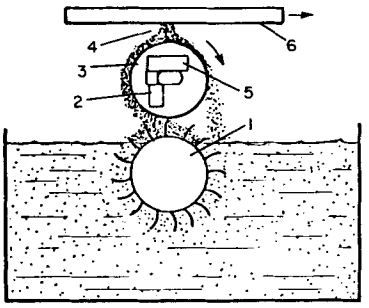

Fig. 8. Schematic of magnetic brush development: Feed roll (1) carries developer to pickup magnet (2). Development roll (3) forwards blanket of developer mixture into development zone (4), where development magnet (5) forms a raised "brush" structure, touching the photoconductor surface (6). After Ref. [42a].

A more rigorous solution is to raise the effective dielectric constant of the developer mixture sufficiently for it to act as its own "development electrode"; this may be accomplished by the use of conductive carrier beads. An elegant solution to the problem of handling such a developer mass was *Young* and *Giaimo*'s[41] invention of the "magnetic brush"—basically a magnet carrying a mixture of fine toner with coarse magnetized carrier beads in the form of a soft brush-like structure (Fig. 8). The latter are generally overcoated with a thin polymer layer which serves to provide the desired frictional charge on the toner as well as to prevent direct short circuits between developer mass and photoreceptor surface. The brush electrode may be biased to compensate for incomplete photoreceptor discharge or to alter contrast. When the proper choice of triboelectric properties is met and the mixture is well agitated, such a "brush" is capable of releasing toner in proportion to surface potential when drawn over an electrostatic latent image. By proper adjustment of the conductivity of the developer mixture, it can be made to favor either edge-contrast or solid-area development[41, 42].

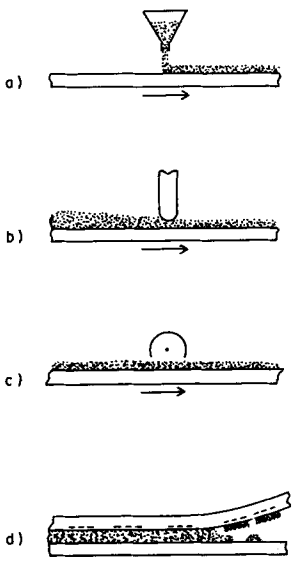

Fig. 9. Impression development.—a) Toner is applied to donor surface, b) leveled by means of a doctor blade, c) charged, and d) gently pressed against a photoconductor without shearing motion. Toner is deposited on the electrostatic image. After Ref. [43].

"Touchdown" (or "impression") development differs from the methods cited above in that the toner layer on a soft donor surface is gently pressed against the charge-bearing photoreceptor surface without shearing motion[34a, 43]. The "donor" may be a conductive brush fabric or an elastomer layer; the toner layer is generally precharged so as to keep the powder in place until it reaches the development zone (Fig. 9c). Close spacing between donor and photoreceptor may be used to provide solid-area coverage for pictorial xerography. Contrast can be controlled by biasing the development electrode. Since the toner now responds to absolute surface potentials—rather than to potential differences between adjacent areas, as with powder cloud and cascade—this method requires exceptionally close control of photoreceptor charging level and photodischarge, and special care must be taken to avoid background development. In an interesting variant of "touchdown" (originally proposed by *Wilson*) conductive toner is charged by induction from the development electrode and requires only a single-component magnetic brush[44, 45].

2.3. Other Process Steps in Transfer Xerography

The toner pattern is transferred to paper—generally with the assistance of an externally applied bias field (Fig. 10)[55]. Background in the final image may be reduced significantly by "selective transfer"—the use of corona charge to suppress transfer of the last layer of toner on the photoreceptor. An undesirable side effect of electrostatically assisted transfer is a slight lateral displacement of the pigment in the fringing fields as the paper is separated from the receptor; this effect has been shown[55, 107] to limit resolution in the final image to about 40—100 lp/mm, depending on toner particle size. Adhesive transfer, initially used by *Carlson*, is inherently capable of much higher resolution, but has the disadvantage of requiring specially coated sheets.

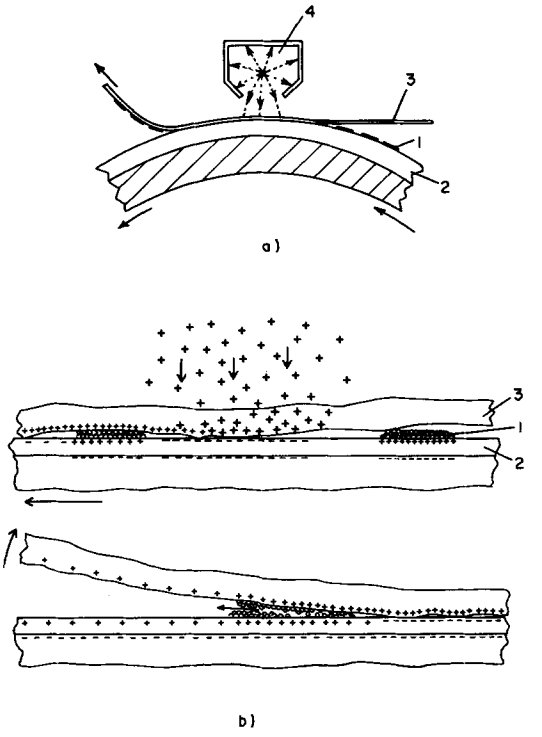

Fig. 10. a) Electrostatic transfer of negatively charged toner (1) from photoconductor (2) to paper (3), using a corotron (4) to apply reverse charge.—b) Detailed view at 50× magnification. After Ref. [55].

The thermoplastic toner may be fixed to the paper by radiant heat, or by contact with a heated roll having a fluorocarbon or silicone elastomer release surface[57]. Solvent vapor fixing is an alternative which has been used for special low-volume applications, particularly xeroradiography and color reproduction[58]. Residual charge on the photoreceptor is removed by uniform illumination; the last residues of toner are neutralized by AC corona and removed by mechanical means such as brushes, webs, wiper blades or vacuum nozzles[59].

2.4. Liquid Development

Three liquid development processes are known. The most important of these is an electrophoretic particle migration process which was invented independently by *Metcalfe* and *Wright* in Australia and by *Mayer* in the U.S. Micron-sized pigment particles are dispersed in a dielectric liquid, such as purified kerosene, and charged by selective adsorption of ionic species and polymers which are added as "charge control agents"; tacky fixatives may be included, as well. The dispersion is applied to the exposed photoreceptor, and pigment particles are electrophoretically deposited on the latent image (Fig. 11). Development rollers and other electrodes—or conductive additives—may be used to provide solid-area coverage. Because this method uses very fine particles which can approach the latent image very closely, electrophoretic development offers extraordinarily high image resolution; 800 lp/mm has been reported. Relatively simple apparatus may be used, and heat fixing may be avoided. Disadvantages include limited developer stability and objectionable carryout of suspending liquid on photoreceptor and copy sheets[46–48].

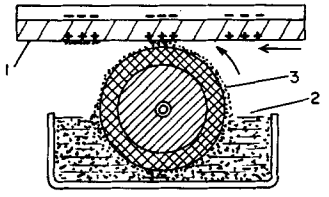

Fig. 11. Development of a latent image on a photoconductor (1) by means of electrophoretic liquid developer (2) and an applicator roll (3). After Ref. [6], p. 134.

A liquid version of induction-touchdown development, which avoids the liquid carryout problem, has been described by *Gundlach*[49]. Conductive ink is drawn out of the recesses of a finely patterned conductive applicator (*e.g.*, a gravure roll) onto the photoreceptor in response to the external field of the latent image pattern. Resolution is limited by the applicator pattern. In a third approach, *Gesierich*, *Cassiers*, and *Marx et al.* have described "selective wetting" development: aqueous developer is applied uniformly to a low-surface-energy photoreceptor, but retained selectivity only in charged areas. The effect may be understood in terms of an electrostatic enhancement of effective photoreceptor surface energy[50–53]. In this process, as in other liquid development schemes, incomplete transfer and cleaning are serious problems. For these reasons liquid development has, with rare exceptions[54], found its prime use in direct electrophotography.

2.5. Photoreceptors for Transfer Xerography

A typical photoreceptor comprises three layers (Fig. 12): a base electrode, a thin dielectric barrier layer, and the photoconductor itself.

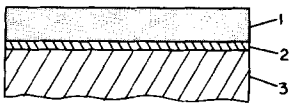

Fig. 12. Cross-section through typical xerographic photoreceptor: (1) photoconductive layer, (2) injection barrier, (3) base electrode.

The dark relaxation time of the photoreceptor must be long compared to the time between charging and development—usually 0.3 to 10 s, depending on the application. Mobile carriers must be absent initially, or swept out during the charging step. A thin barrier layer is used to minimize injection from the base electrode; metal oxides, sulfides, and organic polymers are commonly used[60]. The surface charge—believed to be generally in the form of adsorbed corona ions—may be stabilized by a surface layer of electron donors or acceptors for positive and negative charge, respectively, which appear to act as deep traps[*]. A series of investigations of ZnO surfaces has provided considerable insight into the energy levels involved[24, 63]; additional research in this area would be most desirable.

The optimal thickness of the photoconductor layer is determined by the potential required for development—typically, 300 to 800 volts. Since xerographic photoconductors are basically capacitive devices, and since each absorbed photon can generate, at most, one conduction electron, the voltage contrast produced by illumination is, in principle, proportional to the dielectric thickness. However, the transport of carriers becomes inefficient as the thickness increases past the mean trapping range of the carriers. In practice, the best compromise appears to be between 15 and 25 μm for organic and binder layers (dielectric constant 3 to 5) and between 30 and 100 μm for selenium and its alloys (dielectric constant from 6 to 9.5)[61].

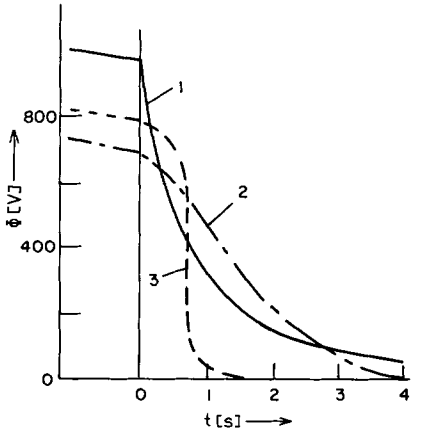

Fig. 13. Photoinduced discharge characteristics of typical photoconductors (steady illumination begins at time $t = 0$). (1) Typical homogeneous photoconductors such as selenium [62a] or PVK : THF charge transfer complex [73c]; (2) negatively charged ZnO-binder Electrofax layer [62b]; (3) phthalocyanine-binder plate exhibiting induction period followed by sharp discharge [66a].

[*] One of *Carlson*'s key contributions was his discovery that corona charge is not readily injected into xerographic photoconductors; hence they are stable against premature dark discharge [21a].

Dark and photo-induced discharge characteristics ("PIDC's") of typical xerographic photoconductors are shown in Figure 13. For high photosensitivity, the photoconductor must provide for effective light absorption in the desired spectral region, efficient separation of photoexcited electron/hole pairs in the applied field, and complete transport of the mobile charge carriers across the layer. Most photoconductor materials exhibit efficient transport either for electrons *or* for holes; it follows that the radiation should be absorbed strongly (extinction coefficient 10^4 to 10^5/cm), and for front illumination, electron-transport photoconductors should be charged negatively and hole transport layers positively. Since the required response times are of the order of 0.1 to 10 s, xerographic photoconductors are essentially "DC" devices, and drift mobilities of the order of 10^{-6} to 10^{-2} $cm^2/V \cdot s$ suffice[*].

Cycling stability requires that the photoreceptor be completely restored to its original state shortly after use; this is generally accomplished by optical untrapping and AC-corona neutralization of trapped carriers. In addition, the surface must be cleaned free of electrically active impurities, and surface abrasion, filming and mechanical failure must be minimized. Since transfer-xerographic photoreceptors must be reused, typically, between 10^4 and 10^6 times, this requirement places considerable stress on the reproducibility of materials and on the various erasure and cleaning steps.

Vitreous selenium, an amorphous mixture of eight-membered rings and linear Se-polymers produced by vacuum evaporation, has long been the basis of the most commonly used photoreceptors. Tellurium may be added to extend red response, and arsenic alloys have been found to enhance photosensitivity as well as stability against crystallization[64].

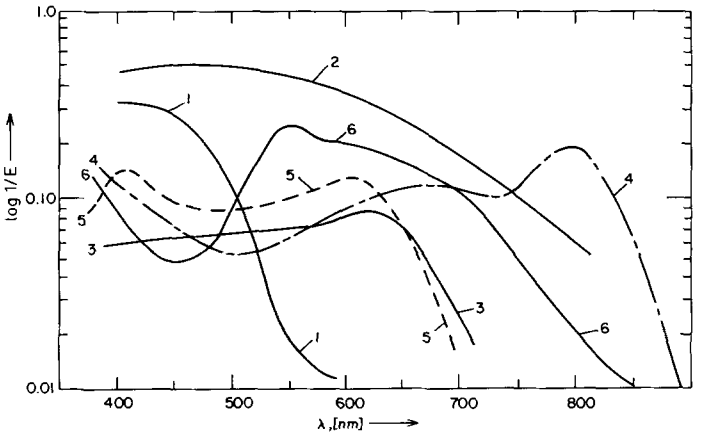

Fig. 14. Relative spectral response curves of typical xerographic photoreceptors. Data adapted from several sources. Photosensitivity ($1/E$) is measured, approximately, in cm^2/erg. (1) Selenium (after Ref. [64e]); (2) As_2Se_3 (after Ref. [62c]); (3) PVK:TNF, 1:1 molar complex of polyvinyl carbazole and trinitrofluorenone (after Ref. [73c]); (4) Phthalocyanine-binder photoreceptor (after Ref. [66a]); (5) ZnO-binder coating, dye-sensitized with Bromphenol Blue (after Ref. [62d]); (6) CdS-binder coating (after Ref. [65a]).

Dispersions of photoconductive pigments such as cadmium sulfide, zinc oxide and phthalocyanine in dielectric binders may be used, provided that the volume loading of pigment is sufficient to assure charge transport across the thin dielectric barrier to layers between adjacent particles[65, 66]. The particle-binder interface may be "doped" with sensitizing dyes, electron acceptors, or "supersensitizers" to enhance photoresponse, charge acceptance, and other desirable characteristics[67, 68].

Organic photoconductors are of special interest to chemists because their behavior bridges the gap between photochemistry and solid state physics. *Carlson*[69] used anthracene for some of his earliest experiments. Since then, many types of polynuclear aromatic and heterocyclic compounds have been shown to be useful, both in binder dispersion and as homogeneous polymers like polyvinylcarbazole[70, 71]. Although the inherent sensitivity of most of these materials lies in the ultraviolet, their response range may be extended into the visible by the addition of sensitizing dyes[67d, 72] and pigments[66c], or by the formation of donor-acceptor complexes having photoactive charge-transfer absorption bands in the visible range[71, 73]. Carrier generation in these materials is strongly field dependent: typically, the quantum yield is proportional to the square of the field intensity[74, 75]. Photogeneration of carriers appears to be analogous to the oxidation/reduction chemistry of photoexcited states of the same organic molecules in other media: singlet-singlet excitation is followed by electron transfer to a nearby site in the matrix—*i.e.*, a "redox" reaction takes place between neighboring molecules. Charge transfer complexing has been shown to enhance the quantum yield, as well as to extend spectral range—presumably by facilitating the initial separation of photogenerated electron-hole pairs, so that prompt ("geminate") recombination is suppressed by localization of carriers at adjacent D^+ and A^- sites[73]. Here, the slightly separated carriers may reside as an excited state, somewhat analogous to Pope's trapped "charge transfer exciton", until thermally activated diffusion, assisted by the strong externally applied field used in xerography, can remove the more mobile carrier from the generation site[76].

The slow, field-assisted drift of electronic charge carriers which follows their separation[82] may be represented, in molecular terms, as the migration of ion radical *states* through the matrix[*]. Only local orbital overlap between near neighbors is required for such a process; long range crystalline order is not necessary. Carrier transport may thus be considered analogous to the concentration-dependent spin migration between, *e.g.*, anthracenide ions through neutral anthracene in benzene solution[77]. From this perspective, charge transport is a purely molecular process—one which requires neither long-range structure nor cooperative effects, such as are invoked for band-model photoconductors. The effects of crystallinity and polymer tacticity are limited to the improvement of orbital overlap. Several investigators have found that electron donors such as aromatic amines, carbazoles and hydrocarbons transport holes but not (generally) electrons; conversely, efficient electron transport is observed in strong electron acceptors such as trinitrofluorenone[78–83].

Since the mechanism of dye sensitization, particularly in silver halides, has for decades been a controversial problem[2, 84], this subject has also been investigated in the context of electrophotography. The key question is whether the photoexcited dye sensitizes the UV-sensitive photoconductor by the transfer of neutral excitation energy or of charge carriers. Here electrophotography offers a convenient methodology:

[*] Most xerographic photoconductors exhibit transport characteristics with nonlinear field dependence; therefore, the term "mobility" must be used cautiously, with reference to the prevailing field intensity [61, 74, 75, 83].

[*] *Mulder et al.* were able to correlate the appearance of radical cations with photoconductivity in anthracene [82d].

one may construct a double layer photoreceptor, comprising a thin "sensitizing" layer in which visible light is strongly absorbed, coated over a relatively thick layer of UV-sensitive photoconductor (Fig. 15a). Since both layers may be made insulating, one may study the effects of both polarity and intensity of externally applied fields upon the photoresponse of the composite. Typical materials have included amorphous selenium and various organic pigments as "sensitizers", and layers of polyvinyl carbazole or trinitrofluorenone as photoconductors. The results have shown that—at least under high field conditions—the mechanism involves the photogeneration of charge carriers in the sensitizing layer and their injection and transport across the underlying photoconductor. Similar results have been obtained for the sensitization of amorphous selenium transport layers by the red-sensitive pigment, phthalocyanine. Spectroscopic measurements of the energy levels of the materials involved can be used to predict their ability to interact in this manner[74, 78, 80, 85]. Experiments of this type have led to a new family of double layer photoreceptors (Fig. 15a and b) in which a relatively thin "carrier generator" film sensitive to visible light is laminated to a much thicker, transparent, polymeric "active transport" layer. The former supplies photosensitivity, the latter dielectric strength and voltage contrast. Photoreceptors having desirable mechanical properties as well as high photosensitivity can be fabricated in this manner[79, 86].

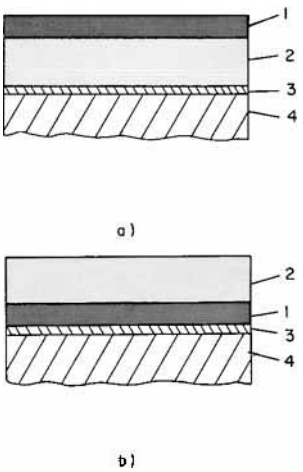

Fig. 15. Double layer photoreceptor with generator layer (a) at top, (b) at interface. (1) Generator (sensitizing) layer; (2) transport layer; (3) blocking interface; (4) base electrode.

Finally, the reader is reminded of the photoreceptor structure already shown in Figure 4, in which an *inert*, protective dielectric overlies a photoconductor layer. In some of the modes of use (*e.g.*[29]), the electrostatic latent image is formed exclusively across the dielectric layer so that the photoconductor is not subjected to prolonged high field stress. This allows the use of some highly sensitive photoconductor materials, such as sintered cadmium sulfide, whose excessive dark carrier concentration would prohibit their use in conventional single-layer photoreceptors. Since the imaging step requires simultaneous exposure and recharging, this process is most suitable for use with "slit scanning" optics. As mentioned previously, these photoreceptors have the advantage that the photoactive material is protected against corona ions, abrasion and other deleterious interactions with developer materials, paper, and cleaning devices used in the xerographic process.

2.6. Developer Materials

The "toner" particles used for developing xerographic images generally consist of 8—15 μm spheres of thermoplastic, colored by a dispersion of 5—10 % of submicron-sized carbon particles. Cyan, magenta, or yellow colorants may be substituted for use in color xerography[87, 88]. Pigment concentration and dispersion must be adjusted to impart a conductivity to the toner mass which is appropriate to the development process. For efficient *induction* development[44, 89], a conductivity greater than $10^{-4}\,\Omega^{-1}\,cm^{-1}$ is found to be desirable[90], whereas most other development processes require the toner to retain charge applied by contact electrification. The toner plastic is generally selected on the basis of its fusing characteristics: it must melt sharply at the lowest temperature consistent with stability in storage and under the vigorous agitation conditions which exist in xerographic development chambers[91, 92].

For cascade or magnetic brush development, typically, a 1—2 weight percent concentration of toner is dispersed in a freely mobile mass of glass, steel, or ferrite beads, each 100 to 500 μm in diameter[34, 42]. The beads are generally overcoated with an impact-resistant polymer, designed to transfer a controlled amount of positive or negative charge to the toner by contact electrification. The physicochemical effects responsible for charge transfer between insulators are as yet poorly understood[93]. The literature suggests that the process involves, in part, electron exchange, determined by the relative electrochemical potentials of the materials. However, charge exchange in dielectrics is a slow process, not likely to reach equilibrium[94]. In a churning developer mass, the situation is greatly complicated by abrasion and impact transfer of ions, polymer and adsorbates, and by the oxidation of polymer, as well as by localized electrical breakdown across the gaps between moving toner and carrier particles[95]. Humidity generally has profound effects on triboelectric behavior[39, 96]. In addition, the dielectric relaxation time of the developer mass must be kept below the development time if effective solid-area coverage is to be achieved; therefore, careful control of conductivity and dielectric constant are essential.

In a cycling process, additional long-term interactions of the developer with other system components must be taken into account. The toner particles must be readily transferable and fusible to the receiving sheet, but without being so soft as to coat the carrier beads. The developer mass must not abrade, poison or smudge the photoconductor surface; it must be readily removable by a simple cleaning system; it should not be excessively degraded by impaction, heat or corona oxidation. Finally, some blade cleaning systems require the addition of lubricants to minimize van der Waals forces between the photoconductor surface and toner residues[97]. Considering these complications, it will not surprise the reader that "practical" developer materials still tend to be selected by empirical choice, and that the patent literature abounds in mysterious recipes[98].

3. Direct Electrophotography: "Electrofax" and Related Processes

A chance observation is reported[99] to have led to the invention of "coated-paper xerography." It appears that *C. J. Young*[100] was experimenting with transfer xerography, using simple laboratory equipment: selenium "flat plates," a corona wand, a projector, and a rather dusty development box. To his astonishment, he discovered that a faint toner image had settled on a piece of "plain" paper, which had itself been accidentally charged, exposed, and sprinkled with toner residue—but never contacted to a selenium plate. Evidently, the paper itself was photosensitive! The experiment was quickly repeated with every type of paper available around the laboratory. The best results were obtained with a blank portion of glossy "LIFE" magazine cover stock. In due course, it turned out that those papers which were photosensitive had a surface sizing of zinc oxide. There followed the thought that xerographic images could be formed directly on white zinc oxide binder-coated paper and fused permanently to its surface—a process which became known under the trade name "Electrofax"[100]. Image transfer, and photoreceptor cleaning and recycling were avoided, albeit at the cost of requiring the use of a paper coating.

The commercial Electrofax base is generally treated with polymeric antistatics[101] to render it reliably conductive, and the zinc oxide is dye-sensitized[67] to extend its photosensitivity across the visible region. A uniform mixture of blue-, green-, and red-sensitive dyes may be used to keep the coating color a neutral light gray[102] while conferring panchromatic sensitivity. They key innovation in Electrofax was to produce images directly on the final sheet. (*Schaffert* has pointed out[103] that binder layers of zinc oxide, cadmium sulfide and other inorganic "phosphor" pigments had previously been shown to be useful for transfer xerography and persistent internal polarization[104, 105].)

Multiple filter exposures, alternating with dry[88a] or liquid[46c] development with "process" color toners may be used to produce full color prints. Electrofax has found wide use for low-volume black-and-white copying; in addition, at least one color copier has been marketed.

Metcalfe and *Wright* have described[108] an interesting form of "chargeless electrophotography", which owes its discovery to an amusing accident[109]. For some time after his invention of electrophoretic development, *Metcalfe* used to startle visitors to his laboratory by casually pulling a sheet of zinc oxide-coated paper out of his darkroom cabinet drawer, exposing it, and dipping it into a pan of his fine-particle liquid developer. As though by magic, a beautiful image appeared on the apparently *uncharged* sheet. This legerdemain was accomplished by means of a corotron, hidden within the drawer by the playful inventor[110]. But once the corotron accidentally failed to operate—and *Metcalfe* himself was astonished to find a negative image on his zinc oxide paper! Upon careful investigation, the latent image turned out to be an imagewise distribution of a 0.3 to 0.4 V positive Dember potential, created in the zinc oxide by the selective inward diffusion of photoelectrons, holes remaining trapped at the generation site close to the exposed surface[111]. The ultrafine liquid dispersion was able to develop these small potentials, offering extraordinarily high resolution, unaffected by the mottling due to corotron discharge streamers. Unfortunately, development times of the order of 30 seconds are required and the effect is strongly temperature-sensitive; therefore, the process has not been adaptable to automatic photocopiers.

Direct electrophotography on transparent organic photoconductor films has found use for the production of transparencies. Since the transfer step is omitted, images resolving 200 lp/mm and better can readily be produced, particularly with electrophoretic liquid developers[106]. "Strip-out" of additional pigment from a secondary donor film to a tackified primary image pattern provides a useful way to enhance image density[107].

4. Persistent Internal Polarization and Photoelectrets

We now turn to electrophotographic processes which are related to xerography, but differ in some essential respects. The first of these is "persistent internal polarization" ("PIP"), invented by *Kallmann et al.* in the USA[112] and, independently,—as "photoelectret imaging"—by *Fridkin et al.* in the USSR[113]. This process differs from xerography in the method used for establishing the electrostatic latent image. For xerography, as we have seen (Figs. 2 and 3), the *external* charge is applied to the photoconductor in the *dark*. In PIP, a polarizing field is applied to the photoconductor while the latter is *illuminated* to generate mobile charge carriers, which are separated and trapped within the layer. Blocking contacts serve to prevent degradation of contrast by corona deposition or electrode injection.

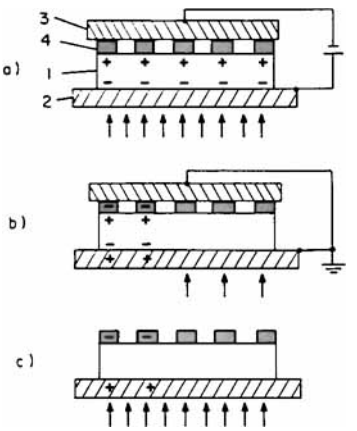

Fig. 16. Persistent Internal Polarization. In this form of PIP the polarizing field is applied to the photoconductor (1) on its base (2) by contact between an external electrode (3) and conductive dots (4) coated on the photoconductor surface. Illumination is shown by arrows.—(a) Plate is uniformly polarized, charge is trapped in the photoconductor layer.—(b) External electrode is grounded during image exposure.—(c) Electrode is lifted off, leaving developable latent image. After Ref. [112a].

The optical image may be projected onto the photoreceptor either *during* induction charging or *subsequently*; a developable surface pattern appears in illuminating areas in the first case, in dark areas in the second. In its polarized state, the photoconductor layer resembles an "electret"[114]. Special photoconductors having deep trapping levels—such as sulfur and ZnS : CdS phosphors—must be used if the photoinduced polarization state is to persist long enough to allow development of the field pattern. The presence of such traps in the bulk inherently

limits carrier transport; hence, the photosensitivity of PIP is very much lower than that of conventional xerography[115]. Although several uses for this process have been proposed, including portable cameras and displays, PIP appears to have found no commercial application.

5. Persistent Photoconductivity Imaging[*]

A number of attempts have been made to reverse the usual xerographic sequence: *i.e.*, to expose the photoconductor in a neutral state and then to charge it to form a latent image. This requires a photoconductor in which the photoexcited charge carriers retain their mobility sufficiently long to form a developable latent image. Materials suggested for this purpose include doped zinc oxide, acid-treated organic charge-transfer complexes, and photolyzable organic compounds[116-121]. None of these systems appear to have found practical use—at least in part because the photosensitivity of most photoconductive dielectrics is low in the absence of an external field capable of separating the newly formed carriers at the generation site.

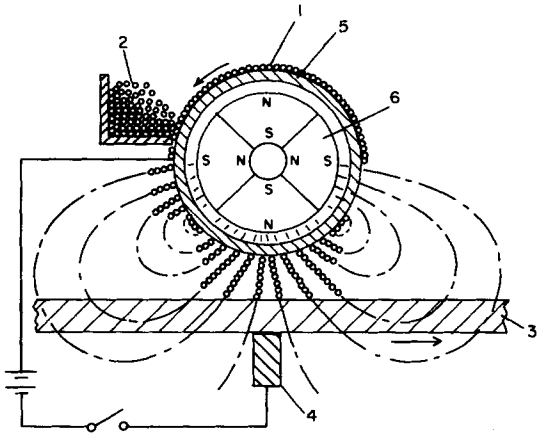

Fig. 17. Single-component magnetic brush. Magnetic toner (1) moves from a supply bin (2) to the imaging zone, where soft "bristles" make contact with the photoconductor (3), which is backed by a bias electrode (4). Either conductive shell (5) or sectored magnet (6) or both may be rotated to transport the toner. After Ref. [45a].

Shely's "Magnedynamic" process is a more sophisticated approach to "chargeless" electrophotography. An uncharged TiO_2-binder layer, coated on a metal-backed *dielectric* base, is exposed to an image pattern, then quickly developed with a positively biased "brush" of conductive magnetic toner loosely attached to a magnetized roller (Fig. 17). Illumination not only renders the photoconductor temporarily conductive, but also converts the contact between its surface and the subsequently applied toner mass from a blocking to an injecting state. In illuminated areas, positive charge is injected and toner is repelled, while in dark areas, toner is deposited by electrostatic attraction to the base. The positive toner image is thus developed; this may be transferred to paper, as in xerography, and the latent image redeveloped and reused a number of times without additional exposure. The photoreceptor may then be erased by ultraviolet exposure, cleaned, then rolled up, "rested" for several hours and reused at a later time[45, 89, 122].

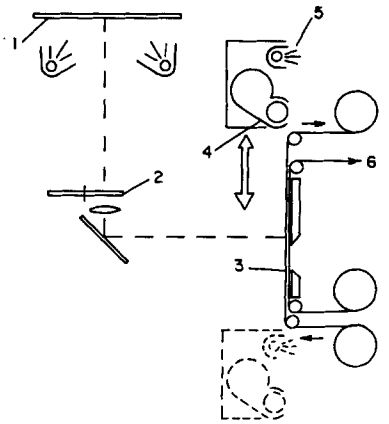

Fig. 18. Schematic of the Color-in-Color process. Original (1) is exposed through color filters (2) onto photoconductor (3). Magnetic toner development roll (4) and heat lamp (5) move up and down, parallel to face of fixed photoconductor sheet (3). Behind heat-absorbent toner pattern, dye is thermographically transferred to receiving paper (6). After Ref. [123a].

An ingenious extension of this process has been used for "Color-in-Color" imaging (Fig. 18). A special photoreceptor having a back coating of thermally vaporizable dye is prepared. After exposure through an appropriately matched color filter, a toner image is developed directly on the TiO_2 surface. The back of the photoreceptor is now pressed against the receiving sheet, while the front is uniformly irradiated. Toned areas absorb this radiation selectively and allow heat to be conducted to the back of the sheet, from which a corresponding dye pattern transfers to the receiving paper. The photoreceptor web is advanced to an adjacent section whose back side has been coated with a vaporizable dye of another color, and the process is repeated. Three photoreceptor sections having cyan, magenta and yellow back coatings, respectively, may thus be exposed through appropriate color filters to a stationary color original to cause a multicolor dye image to be deposited in registration on the receiving sheet[123].

6. Transfer of Electrostatic Images ("TESI")

In conventional xerography, as we have seen, the *developed (toner) image is transferred* to the receiving sheet, after which the photoreceptor must be erased and cleaned prior to reuse. An alternative, which obviates the toner transfer and cleaning steps, is to *transfer the electrostatic latent image itself* to a suitable receiving sheet prior to development. Transfer of an electrostatic charge pattern may be accomplished either *during* photoreceptor exposure (*i.e.*, while the latent image is being formed) (Fig. 19) or *after* a stable charge pattern is formed on the photoreceptor by conventional charging and exposure (Fig. 20). The names applied to these two process variants are "simultaneous TESI" and "sequential TESI," respectively[124, 125]. In either case, a dielectric-coated paper or film is pressed in intimate contact to the photoreceptor, generally in a suitable bias field. *Schaffert* and *Brodie et al.* have defined the conditions required for efficient charge transfer across the small air gap between dielectric surfaces[126, 127]. A third alternative, sequential TESI from a "persistently con-

[*] See also: Section 10, "Photoconductography".

ductive" latent image, has been described by *Sporer*[120] and by *Melz* and *Vahtra*[120, 172b].

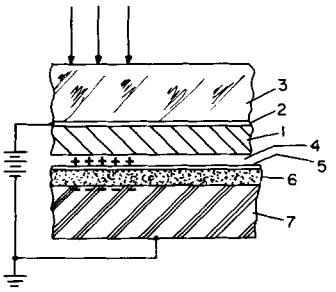

Fig. 19. Simultaneous TESI. Image radiation (arrows) enters the photoconductor (1) through a conductive-coated (2) glass backing (3). Positive charge is transferred across air gap (4) to a dielectric receiving layer (5) on a resilient conductive backing pad (6) and support (7). Threshold field across air gap is not exceeded in dark areas, therefore no charge is transferred there. After Ref. [128b].

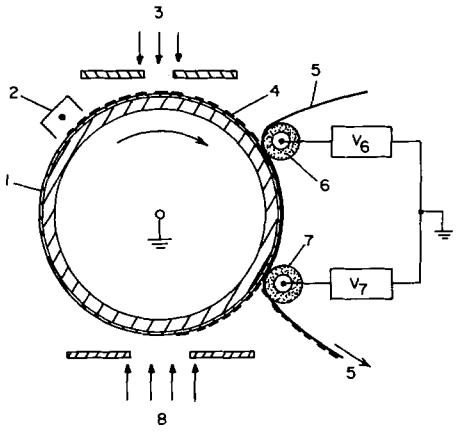

Fig. 20. Sequential TESI. Photoconductor drum (1) is charged (2) and slit-exposed (3). Latent image (4) is transferred to dielectric receiving sheet (5) with separately biased rolls (6, 7) at entrance and exist of transfer region. Sheet (5) is developed, photoconductor (1) is erased (8) and re-used. After Ref. [128b].

Although these processes were invented more than two decades ago, their commercial use has been delayed, in part by the need for specially coated paper and in part by the relatively severe effects of contact geometry and ambient humidity upon the efficiency of charge transfer. "Simultaneous TESI" has recently been applied to a CRT display terminal printer[128], and a compact copier has been introduced which uses the sequential process[129].

7. Photoplastic Imaging

In all the processes described so far, an electrostatic latent image is developed by the attraction of externally supplied charged particles. We now consider some alternatives in which the image-forming material is part of the photoreceptor.

The first of these is photoplastic imaging. The concept derives from the observation of *Thiemann*[130a] that the surface of a dielectric oil film could be deformed by writing on it by means of an electron beam; the surface deformations may be read out by means of schlieren optics[*]. This principle was later applied by *Glenn et al.*[131] for electron beam recording on softened thermoplastics, and eventually by *Mehl, Greig* and *Wolff, Gaynor et al.*, and others to direct optical relief recording on thermoplastic organic photoconductor layers (Fig. 21)[132, 133, 134].

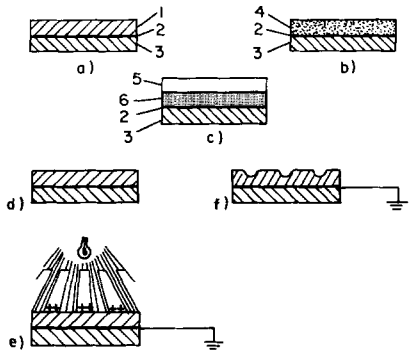

Fig. 21. Photoplastic imaging members (a—c) and process (d—f).—a) Transparent photoconductive thermoplastic film (1) on transparently metallized (2) film base (3). b) Photoconductive pigment dispersion in thermoplastic (4) replaces transparent layer (1). c) Frost configuration, in which transparent thermoplastic layer (5) overlies transparent photoconductive control layer (6).—d) Film (a) prior to imaging. e) Film has been charged and exposed, and... f) Heated to produce surface deformation.—After Ref. [133d].

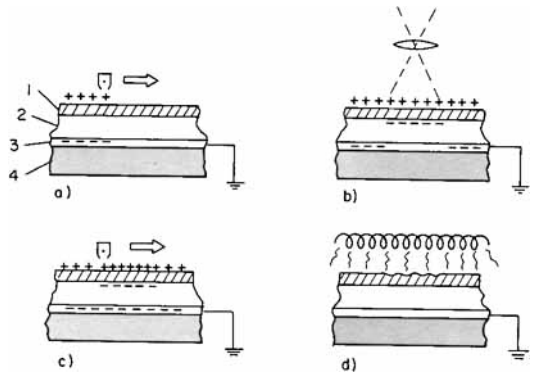

Fig. 22. Frost imaging process. Thermoplastic layer (1) on transparent photoconductor (2) over transparent metallized (3) film base (4) is a) charged, b) exposed, c) re-charged to constant surface potential, and d) heated to produce a light-scattering surface deformation in illuminated areas. After Ref. [139].

Meanwhile, *Gundlach* and *Claus*[135] devised an interesting two-layer variant of this process, called "Frost" imaging, which permits direct viewing of the deformation pattern without a schlieren screen (Fig. 22). The basic observation was that if a critical electrical stress is applied imagewise to a thin thermoplastic coating backed by a photoconductor layer, and the thermoplastic is then softened, the surface of the film will be deformed into a random wrinkle pattern. Since such a pattern scatters transmitted light, it may be used to display a latent electrostatic image. As *Cressman*[136] has shown, Frost deformation is due to a combination of two factors:

Mutual repulsion of trapped surface charges; this tends to increase the total surface area and produce a wrinkle pattern over the entire charged area.

Mutual attraction of trapped surface charge and counter charge induced in the photoconductor backing; this produces line deformation and enhances edge contrast.

The characteristic spatial frequency has been related to hydrodynamic instabilities[137]. The scattering image consists of random deformations having a preferred "cell spacing"

[*] This process is the basis of the "Eidophor" projection television system [130b].

of about twice the coating thickness. *Urbach et al.*[138] improved high frequency contrast by introducing a screen having the optimal spacing as "carrier" for the optical signals. High-resolution-screen thermoplastic holograms could be developed at the exposure site by means of a warm air stream so that the resultant holographic image could be viewed immediately. Resolution was sufficiently high that screen frequencies of 200 to 1000 cycles/mm could be used. *Sullivan et al.*[139] have described the effects of optical systems on the tone reproduction of Frost images.

Various photoconductors have been used for photoplastic recording, including selenium, dye- or charge transfer-sensitized organics, and phthalocyanine dispersions[133c, 135, 138]. Images may be erased by softening the film and discharging the field across it; the photoreceptor may then be used to form a new image. Since the photosensitivity depends upon light absorption in the layer, response has to be traded off against transparency, scattering efficiency against resolution, and image stability against ease of recycling. Although optical contact copying (*e.g.*, to diazo film) is not practical, photoplastic images may be replicated by surface casting[140]. Despite optimistic proposals to use photoplastic recording films for cyclic displays, "add-on-image" microfiche, and "instant" microfilm cameras, no commercial application has emerged[*].

8. Photoactive Pigment Electrography ("PAPE")

The first practical process which used the movement of electrically photosensitive particles to form images was invented by *R. W. Gundlach*[143]. He deposited a uniform layer of loose photoconductive toner on a flat electrode, charged the deposit, exposed it to a projected image and removed the loosely adherent powder from illuminated areas. The remaining toner pattern could be fused onto the plate. This imaging method has found extensive application in lofting—*e.g.*, the marking of ships' plates (particularly in Japan[144], Fig. 23). Attempts to adapt this process to photocopying did not meet with success[145]. However, more recently, photoconductive pigments have been used to form images in thermoplastic and liquid dispersions, which are easier to control than loose dry toner. These will be discussed in the next three sections.

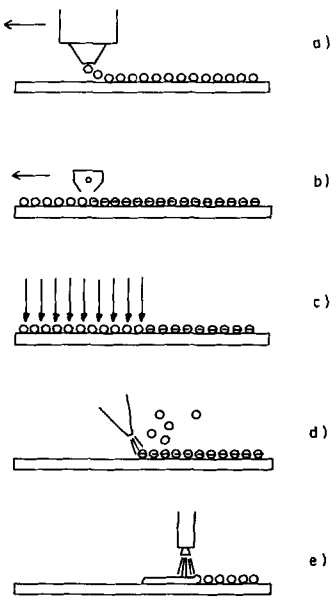

Fig. 23. Photoconductive toner imaging. Toner is a) deposited on base plate, b) charged, and c) exposed. The photodischarged powder is blown away (d), leaving toner electrostatically adhered in dark areas, to which it may be fused (e). After Ref. [144].

[*] Two related photoconductor-controlled elastomeric projection display devices, called "Elmikon" [141] and "Ruticon" [142], have been described in the literature.

8.1. Particle Migration Imaging

In the course of experiments on the photosensitization of charged Frost photoplastic layers by means of a thin overcoating of evaporated selenium, *W. L. Goffe* had occasion to use solvent vapor to soften the underlying thermoplastic layer. He made the startling observation that charged and exposed regions of the selenium layer did not merely deform, as expected, but literally tore themselves loose from the surface and raced through the thermoplastic layer to the transparent base electrode to which they then adhered tenaciously (Fig. 24). Detailed investigation of this phenomenon led him to the invention of a totally new form of electrophotography based upon the imagewise migration of charged photosensitive particles through a thin, temporarily softened thermoplastic[146]. Films capable of being imaged in this fashion are deliberately coated to produce a densely packed layer of microscopic selenium balls[148]. When these are charged, then illuminated, net negative charge is found to be firmly trapped on the illuminated selenium particles, forming a highly stable latent image[147]. The matrix is now softened by heat or solvent vapor, freeing the negatively charged selenium microspheres in illuminated areas to be attracted to the base by their counter-charge. This movement forms a "primary" image: in *exposed* regions, fully migrated particles pack closely at the base electrode, forming a dark red *negative* image, while unexposed particles spread out through the layer, allowing light

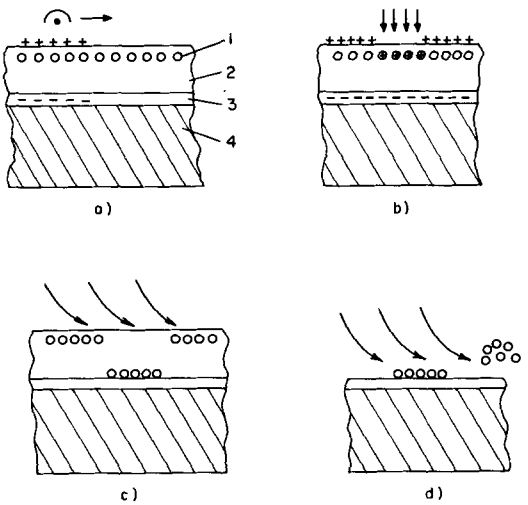

Fig. 24. Particle migrating imaging. Selenium particles (1) are imbedded just below the surface of 10 μm thermoplastic film on transparent metallized (3) film base (4). The film is a) charged, b) exposed, c) washed with hexane to leave (d) a dark, firmly adhered image of Se particles in illuminated areas of the film. After Ref. [148].

to be scattered forward and causing background areas to appear light blue. Full contrast may be developed in seconds by a quick solvent wash, which removes the thermoplastic and its residue of incompletely migrated pigment, leaving a fully developed deep red image on a clear background (Fig. 24).

The process is suitable for "instant" (and optionally "dry") high-resolution microimaging; negative images are formed (*i.e.*, dark selenium deposits correspond to illuminated areas). The sensitometric properties are well accounted for by particle size, extinction coefficients, and spectral response[148]. The process is strongly materials and configuration dependent: when dispersions of other photoconductive pigments, such as ZnO or phthalocyanine, are used, the image sense becomes positive, *i.e.*, particles migrate preferentially in dark areas[149]. The mechanism for this variant has not been explored in detail; a plausible hypothesis suggests that simultaneous ejection of electrons and holes from illuminated pigment particles into the surrounding thermoplastic discharges exposed areas, leaving the particles without external field to drive them to the base. Evidently, in these materials not much charge can be stably trapped on the particles themselves.

8.2. Photoelectrophoresis ("PEP")

In 1963, *V. Tulagin* invented an elegant solution to the intellectual challenge posed by single-step full-color electrophotography[150]. It was already known that the charge/mass ratio—and hence electrophoretic motion—of charged particles through a dielectric field could be influenced by their absorption of light. What *Tulagin* recognized was the power of using spectrally selective pigments: cyan pigment would respond only to red radiation, magenta particles to green, and yellow ones to blue light. The selective spectral response of individual electrically photosensitive particles in a mixture could therefore be used to devise an "instant" full-color reproduction process.

The inventor relates[151] that four quite separate concepts converged in his mind to enable this invention. Three were available to him when he started:

1. *Kaprelian*[152] had already shown that the electromigration of zinc oxide particles suspended in dielectric fluids could be influenced by illumination and had proposed that this effect could be used in an imaging system. *Yeh*[153] had extended this work to the cyan pigment, phthalocyanine, and experiments on the mechanism of charge exchange were already underway when *Tulagin* took over the project.
2. An experimental roller imaging device having just the right configuration was available in his laboratory. Originally designed for xerographic liquid development[154], its photoconductive plate was readily replaced by a transparent tin oxide-coated glass electrode through which a colored image could be projected into the imaging zone.
3. Brightly colored organic photoconductor pigments were under active investigation in an adjacent laboratory[106b]: in the eyes of the color photographer, the cyan phthalocyanines, the magenta quinacridones, and the yellow azo pigments were promptly perceived as potential red-, green-, and blue-selective sensors for a polychrome imaging system—and much simpler than the multi-layers prepared previously[152].
4. To these resources the inventor added an essentially aesthetic concept which he had harbored for years: "to pull a color image out of a black coating, instead of painting color on a white base."

Once outlined on paper, the new idea was swiftly demonstrated to be feasible. Within a year suitable materials were selected. *Tulagin* and his co-workers formulated an oil suspension of roughly equal parts of electrically photosensitive cyan, magenta, and yellow particles and pushed the brownish-black "ink" through a small gap between a transparent electrode and an electrically biased backing roller covered with a thin dielectric coating[150]. A full-color positive copy of an original image projected into the imaging zone through the transparent electrode was instantly reproduced on the latter as it emerged; a negative image comprising exposed pigment appeared on the dielectric coating of the roller (Fig. 25). To those who saw it at its inception, the speed, simplicity, and color rendition of the process were truly impressive.

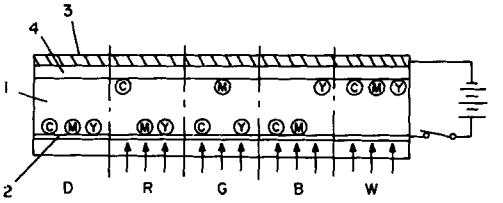

Fig. 25. Polychrome PEP. A dispersion of cyan Ⓒ, magenta Ⓜ, and yellow Ⓨ pigment particles in dielectric oil (1) is contained between a transparent "injecting electrode" (2) and a counterelectrode (3) coated with a blocking layer (4) to prevent particle oscillation. Exposure to light absorbed by each type of particle causes it to be detached and move to the marking electrode, leaving a subtractive color behind on electrode (2). Exposure to white light removes all particles, while in dark areas a black mixture remains. The positive color image formed on the lower electrode may be transferred and fixed to paper, whereupon this electrode is re-inked for the next use. Color of light (*R*ed, *G*reen, *B*lue, *W*hite) corresponds to color of particle mixtures left on electrode (2). In *D*ark area, the black particle mixture remains. After Refs. [6, 150].

Further study of PEP has revealed that complicated things happen in the narrow imaging zone between transparent electrode and imaging roller. The very compactness of polychrome PEP places a heavy burden upon the stability of process and materials. *Tulagin*'s original paper[150a] and subsequent publications and patents[155, 156] point out some significant problems:

Adventitious charge exchange between neighboring illuminated and dark particles must be minimized.

Maximum density is a sensitive function of ink film thickness and of the electric field within the imaging zone.

Unless special measures are taken, some particles tend to remain on the transparent electrode, forming background.

Most available pigments—particularly magenta—tend to have excessively broad absorption bands. Selectively filtered light sources can be used effectively to sharpen color response[156]. However, their properties as colorants remain imperfect. The color reproduction of the final prints is comparable to that obtainable by other non-masked color reproduction systems.

As expected, these problems have proven formidable and their solution has taken considerable time. No commercial use for the process has as yet been announced.

Snelling et al.[157] have demonstrated that monochrome PEP can be used to print very clean positive output from negative input directly on paper interposed between the imaging electrodes. Background may be suppressed by electrophoretic pre-deposition of the pigment on the imaging electrode. While working on this process, *Wells*[158] made the astonishing discovery that photosensitive pigments mixed in an ink with inert particles can be used to drive the two colorants in opposite directions to form complementary positive and negative images of *contrasting* colors! The process is called PEP-Stimulated Imaging ("PEPSI"); the phenomenon responsible is a photosensitized charge exchange between illuminated and inert particles. It permits the use of particularly sensitive pigments, such as phthalocyanine, to produce images of arbitrary color (Fig. 26). A photoconductor *layer* may be used instead of suspended phthalocyanine pigment to image inert colorant particles[159] (Fig. 27). Superposition of three filter-separated process color images on the same sheet of paper has been used experimentally to produce full-color positive prints[160].

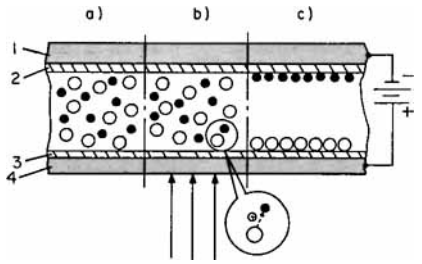

Fig. 26. PEP stimulated imaging (PEPSI). a) Mixture of photosensitive (○) and inert (●) pigments in a dielectric liquid is suspended in an electric field between electrodes (1, 4) with blocking layers (2, 3). b) In illuminated areas the pigments exchange charge and migrate c) to opposite sides of the liquid spacer. After Ref. [158].

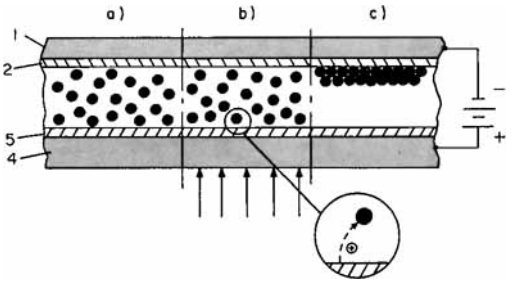

Fig. 27. "Layer PEPSI". a) Inert imaging particles (●) suspended in dielectric fluid are placed between photoconductor layer (5) on transparent base electrode (4) and a dielectric-coated (2) counter-electrode (1). b) Upon illumination in an external field, the photoconductor injects charge into nearby particles, causing them to move away. c) A high-contrast negative image is formed on electrode (1). After Ref. [159].

8.3. Manifold Imaging

The PAPE processes described so far share the concept that each pigment particle moves on its own. What happens if one sinters the particles together in 5–10 μm chunks of thermoplastic binder to force them to image as aggregates? As might be expected, the effective photographic speed rises—albeit at a sacrifice of resolution—and contrast is sharply enhanced.

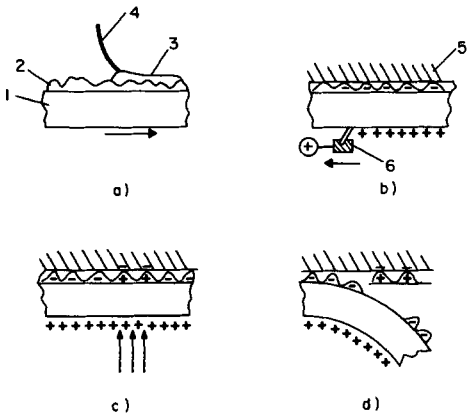

Fig. 28. Manifold imaging process. a) A sheet of plastic film (1), coated with a thermoplastic/wax dispersion of photoconductive pigment (2) is "activated" with hydrocarbon liquid (3), applied by a coating blade (4), and b) sandwiched to a metal foil (5) while another blade (6) applies contact charge. c) The softened manifold is exposed and d) separated into complementary images. After Ref. [161a].

VanDorn, Luebbe, et al. have described such a process (Fig. 28)[161a]. It is based on a coating of electrically photosensitive particles (such as the versatile phthalocyanine) in a wax-bonded thermoplastic binder. Prior to use, the dry layer is "activated" by a hydrocarbon liquid to loosen the weak adhesion between individual aggregates. The layer is then sandwiched between its metal foil backing and a plastic film backed by a transparent electrode to form an imaging "manifold". An image is projected through the film while a strong electric field is applied. When the layers are separated, exposed portions of the coating are completely transferred to the receiving sheet, while unexposed parts of the image remain completely on the donor. A pair of complementary high contrast images is thus formed. Either image may be electrostatically transferred to other receiving sheets, such as paper or cloth. Image-sense reversal may be accomplished by appropriate manipulation of the applied field. Various organic photoconductive pigments have been included in manifold coatings to produce black or single-color images. The size of the aggregates limits resolution to about 15 lp/mm. The authors have suggested a plausible mechanism based on electrostatic adhesion between the imagewise polarized thermoplastic layer and the counter-charge induced in the metal foil. Details of the separation and transfer process have recently been discussed by *Yang et al.*[161].

9. Photocontrolled Ion Flow Electrophotography ("PHIFE")

In conventional xerography, the dielectric imaging member is charged uniformly, then exposed to form an electrostatic latent image. Why not apply the charge imagewise to begin with? Several suggestions along these lines were made about 1960. For example, *Macgriff* and *McNaney* proposed switching individual members of a row of photoconductor-tipped corona electrodes by means of projected illumination. Unfortunately, the inventors did not succeed in fabricating arrays of photoconductive styli with sufficiently fast cycling response to enable a practical printer to be constructed[162, 163].

The first practical solution to the problem was devised by *Snelling*[164], who projected an image onto a Se-coated

metal screen interposed between an active corona source and a dielectric-coated paper. Illuminated areas of the screen freely passed corona ions to the dielectric, while the rims of the holes in dark areas quickly became charged and blocked additional corona ions from reaching the dielectric sheet. Development of the paper revealed a well defined negative image of the input. This was a "simultaneous PHIFE" process (analogous, in a sense, to *Walkup*'s "simultaneous TESI"[124]).

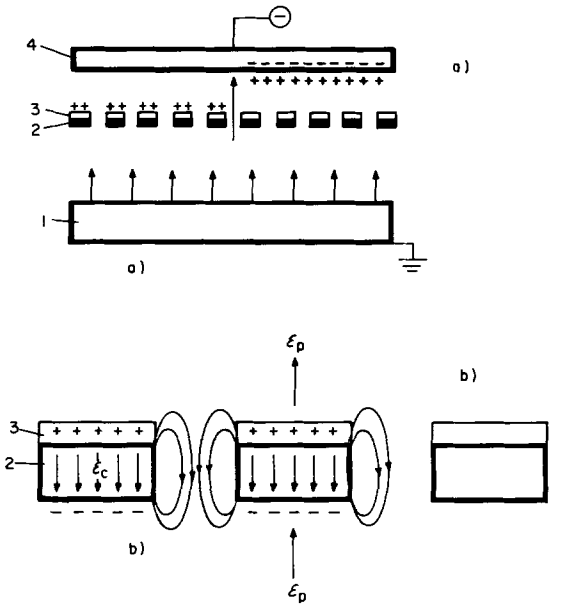

Fig. 29. Sequential PHIFE process. a) Corona ions are emitted from source (1) through a control screen (2) coated with photoconductor (3) towards dielectric-coated record sheet (4). Charged areas of the previously imaged screen block the passage of positive ions.—b) Enlarged section through screen shows full blockage of aperture at left, partial blockage of the one at right.

"Sequential PHIFE" processes were subsequently investigated in other laboratories[165] (Fig. 29). A latent electrostatic image is first produced on the screen by conventional charging and exposure, and the screen is then interposed between a corona source and a dielectric. Excellent positive images can be produced from both positive and negative input. *Pressman* has calculated the electrostatic fringing field patterns around small photoconductor-coated apertures and studied their use to control the passage of corona ions. His results show that excellent halftone reproduction is possible with 8 dot/mm screens. Multiple images can be printed from a single latent-image exposure[165a].

This process shares the important advantage of TESI that the photoconductor is never contaminated by developer or abraded by paper and feeding devices. Therefore, it appears peculiarly suitable for low-volume copying applications where more conventional apparatus is too complex. On the other hand, the screens may be a little fragile for use in fast duplicators. Rather than competing for the same applications, PHIFE and xerography promise to become nicely complementary[*].

[*] Another option—to use photoconductor-coated screens to control the flow of charged *toner* particles [166] (a photocontrolled version of electrostatic screen printing [167])—seems to have been abandoned as impractical. The toner evidently clogged the holes, and the cleaning brushes quickly abraded the photoconductor coating.

10. Photoconductography

Electrolytic imaging is the only form of electrophotography in which chemical change plays a significant role. A latent conductivity pattern is formed in a photoconductive insulator, then developed by electrochemical deposition. Photographic gain is achieved by drawing multiple charges through the photoconductor-electrolyte series circuit, by secondary chemical amplification, or both.

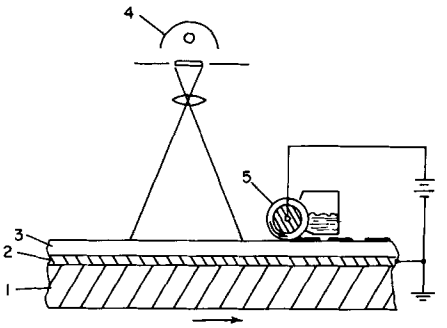

Fig. 30. Photo-electrolytic imaging process. The imaging sheet, consisting of a paper base (1), laminated to aluminum foil (2) and coated with a zinc oxide-binder mixture (3), is exposed from a microfilm projector (4), then developed by a biased sponge roll (5) wetted with silver salt solution.

Beginning about 1920, *Wilcke, Berchtold* and others[168] attempted to use image-illumination of various photoconductors to control the electrolytic coloration of contiguous layers such as paper and gelatin. Their work foundered for lack of photoconductor materials capable of adequate gain. A practical system[169] (Fig. 30) became possible when *Johnson* and *Neher*[119] found a way to dope zinc oxide in highly pigmented binder systems so as to enable the injection of multiple electrons per absorbed photon across the photoconductor layer[*]. In use, the dye-sensitized light-gray ZnO binder coating is imaged, then developed by passing it under a sponge wetted by an aqueous electrolyte containing reducible silver ions and biased about +100 V relative to the aluminum coating base. A dark-gray silver image forms where the photoconductor has been illuminated. Exposures of about 8×10^{16} photons/cm^2 are required, implying a system gain of only 2.0[**]. The intense exposure required limits this process to the projection printing of transparencies; it is not useful for "true" photography, such as the reproduction of opaque documents.

Generally, only a single image is formed on such a photoconductor, and the "fatigue" introduced by the long trapping life of the minority carriers has no adverse consequences. However, prompt re-exposure *is* needed for color printing. In the "Electro-color" version of this process, *Tulagin et al.*[173] substituted electrolytically reducible ionic dye precursors for the previously used metallic cations. Cyan, magenta, and yellow dye images were electroplated imagewise, in succession,

[*] The general conditions for such photoconductor gain have been defined by *Rose, Redington*, and others [170—172]. Injection contacts must be provided at both sides of the layer, and the minority carriers—holes, in the case of ZnO and CdS—must be trapped sufficiently long to permit passage of n majority carriers across the layer, n being a measure of the photoconductor gain. In a photoelectrolytic system, therefore, n ions may be deposited or removed for each photon absorbed, with corresponding photographic gain.

[**] *Johnson* and *Neher* [169b] cite an exposure of 25 mW s of visible radiation. Assuming an effective atomic volume of (4.1 Å)^3 for Ag, and an extinction coefficient of 10^5/cm, about 2×10^{17} silver atoms/cm^2 must be deposited to deposit an image of density *ca.* 1.0, the best available from the system.

each following an appropriately filtered exposure from a masked color negative which served as input. The fatigue problem alluded to above was solved by an engineering trick: a hot water wash between dye development and re-exposure, which served to free trapped holes while washing residues of the preceding developer from the surface[173b]. Although beautiful color prints were produced in experimental equipment, the process proved to be too slow, too difficult to automate, and ultimately too expensive to find significant commercial application[173b, 174].

An alternative approach to providing photoconductor gain was suggested by *Nail et al.*[175]: to use imagewise electrolysis to deposit a colloid whose ink receptivity differs from that of the surrounding photoconductor. The extra density of adhered ink provides, in effect, a 10—20-fold image intensification over the absorption of a monolayer of dye. Finally, it has been shown that one may achieve substantial chemical gain by using photoelectrolysis merely to deposit a pattern of development *nuclei*, which then serve as latent image for subsequent amplification, either by physical development[176] or by the local catalysis of photopolymerization[177]. ASA speeds of 100—150, comparable to those of fast silver halide emulsions, have been claimed in the literature. Despite the early apparent promise of such systems, they appear to have been abandoned. We conjecture that they failed because they required wet processing with unstable reagents.

11. Conclusion

What of the future? Pictorial electrophotography remains a tempting challenge. Figure 31 summarizes typical sensitometric properties of a few of the systems we have discussed. All of them (except for photoconductography) have image gain of about 10^4 to $10^5\times$, hence a photographic speed roughly equivalent to ASA 0.1 to 3. It is obvious that image reproduction may be altered by changes in materials and processing conditions. Nonetheless, a few interesting generalizations emerge.

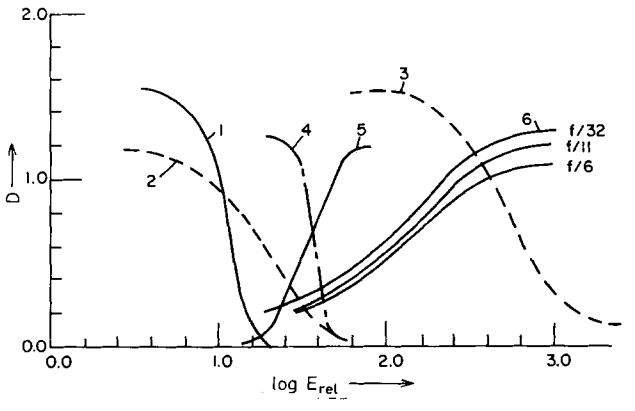

Fig. 31. Representative tone reproduction curves for electrophotographic processes. Horizontal coordinate: arbitrary ($\log_{10}$) exposure. Vertical coordinate: reflection density. (1) Xerography with magnetic brush development [180]; (2) xerography with optimal document screen [180]; (3) polychrome PEP [150a]; (4) manifold imaging [161]; (5) particle migration imaging [148]; (6) Frost: scattering image contrast depends on aperture of projection lens [139].

Photoelectrophoresis, particle migration imaging, and Frost are well suited to pictorial reproduction; they have the requisite fine grain, the "soft" tone-reproduction curves, and adequate exposure latitude. While fine-grain liquid development offers some promise for continuous-tone reproduction, dry xerography and manifold have problems: contrast is high, edges are sharp. These are accentuated in color xerography, where multiple images must be carefully registered with minimum moiré patterns. *Goren* and *Bestenreiner et al.* have given careful consideration to the improvements which might be achievable by optical screening and by modern electronic scanning methods—both familiar from other high-contrast processes used in the graphic arts[4b, 178, 180]. PHIFE, as *Pressman* has pointed out, is inherently screened and provides good tonal rendition[165a]. Optical buffering has been proposed as a means of controlling contrast as well as for color correction[4, 142]. Rapid advances in electronic image processing are likely to be of special benefit to electrophotography, where the pictorial elements are already represented in electronic form.

Schmidlin and *Shaw* have explored the limits of electrophotographic sensitivity in terms of the "detectivity" criterion, which quantifies the effect of the imaging system upon the signal/noise ratio of the incoming image. In xerography, it turns out that photoreceptor noise contributes relatively little to image noise, compared to fluctuations in developer spacing, toner particle size, and erratic adhesion in transfer. In PEP, on the other hand, *Schmidlin* suggests that fluctuations in particle size and adhesion could (in principle) be reduced sufficiently to improve the effective sensitivity by a factor of 100. Other systems have not yet been analyzed from this viewpoint[4a, 179].

What are some of the most interesting problems for the future—particularly for the chemist? A few have already been identified:

the nature of frictional electrification—a puzzle first encountered by the ancient Greeks—and more generally, the details of charge transfer across dielectric interfaces;

the roles of electrostatic and van der Waals forces in the adhesion and release of small particles;

the nature of ion adsorption and desorption on dielectrics, both in air and in dielectric liquid suspension;

an understanding of charge carrier generation and transport on a molecular level, particularly in disordered organic solids—a problem with spectroscopic, photochemical, as well as structural implications;

the rheology of thermoplastic composites;

the effects of materials composition and structure upon the ultimate limits of electrophotographic detectivity.

The field of electrophotography is still young, varied, and vital enough to admit significant advance by invention, as well as by scientific analysis. It cuts across many disciplines—from optics and photographic science to electronics and information theory; from mechanical engineering to the chemistry and physics of complex materials. The author hopes that this admittedly incomplete review will serve to stimulate new interest, and to keep the subject alive and open—rather than to close it by means of a deceptively tidy summary.

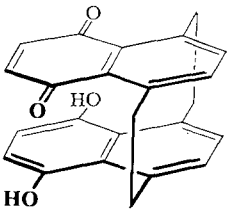
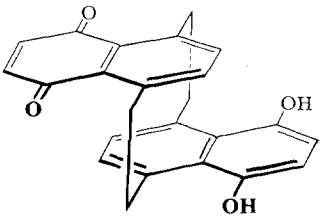
COMMUNICATIONS



Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

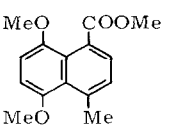
Stereoisomeric Quinhydrones of the [2.2](1,4)Naphthalenophane Series[1]



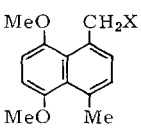
By *Heinz A. Staab* and *Claus P. Herz*[*]

Dedicated to Professor Georg Wittig on the occasion of his 80th birthday

Strong orientation dependence of charge-transfer interactions was experimentally proved by the investigation of the diastereomeric quinhydrones of the [2.2]paracyclophane series[2] and similar donor-acceptor paracyclophanes[3]. In this connection the two intramolecular quinhydrones *(1)* and *(2)* of the [2.2](1,4)naphthalenophane series were of interest: donor and acceptor regions of the molecule are closely superposed in the *syn* isomer *(1)* whereas in the *anti* isomer *(2)* they are separated so far that direct through-space interaction between them is impossible.



(1)



(2)

The synthesis of *(1)* and *(2)* started from methyl 1,4,4a,5,8,8a-hexahydro-4-methyl-5,8-dioxo-1-naphthoate[4] which, in the presence of tin(II) chloride, in acetic acid/hydrochloric acid (15 min, 80 °C, according to [5]) yielded methyl 1,4-dihydro-5,8-dihydroxy-4-methyl-1-naphthoate (m.p. 174—176 °C, dec.; yield 87 %). After etherification with dimethyl sulfate/sodium hydroxide to methyl 1,4-dihydro-5,8-dimethoxy-4-methyl-1-naphthoate (m.p. 85—86 °C; yield 76 %) aromatization with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ; 2 h, boiling benzene) led to methyl 5,8-dimethoxy-4-methyl-1-naphthoate *(3)* (m.p. 99—100 °C; yield 95 %). *(3)* was reduced by lithium tetrahydridoaluminate (2 h, boiling tetrahydrofuran) to the hydroxymethyl compound *(4)* (m.p. 78—79 °C; yield 94 %) which, *via* the bromomethyl derivative *(5)* (with phosphorus tribromide/benzene, 30 min, 5 °C) with dry trimethylamine, yielded the ammonium bromide *(6)*[6]. After conversion into the hydroxide *(7)* (silver oxide/

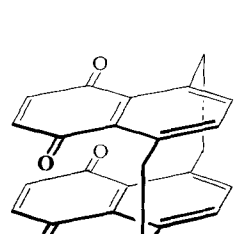
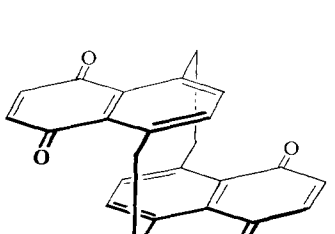
Max-Planck-Institut für medizinische Forschung, Abteilung Organische Chemie
Jahnstrasse 29, D-6900 Heidelberg (Germany)

water, 20 h), refluxing in xylene with a water separator gave a mixture of *syn*- and *anti*-4,7,14,17-tetramethoxy[2.2]naphthalenophanes *(8)* and *(9)* which were separated by chromatography (silica gel/benzene). The assignment of *(8)*[6] (smaller R_F; m.p. 250—251 °C; yield 3 %) and *(9)*[6] (m.p. 280—281 °C; yield 23 %) was based on ^{1}H-NMR: in the *anti* isomer *(9)* protons on C-9,10,19,20 are more strongly shielded by the neighboring naphthalene unit than in the *syn* isomer *(8)* where all aromatic protons are on the periphery of the naphthalenophane system [*(8)*: δ = 2.9—3.3 (A part of AA'BB', 4H, methylene-H), 3.82 (s, 12H, CH_3O—), 4.1—4.5 (B part of AA'BB', 4H, methylene-H), 6.26 (s, 4H, aromatic H), 6.75 (s, 4H, aromatic H); *(9)*: δ = 2.5—3.1 (A part of AA'BB', 4H, methylene-H), 3.93 (s, 12H, CH_3O—), 3.8—5.4 (B part of AA'BB', 4H, methylene-H), 5.95 (s, 4H, aromatic H), 6.77 (s, 4H, aromatic H), in $CDCl_3$].



(8)



(9)

Demethylation of *(8)* with methylmagnesium iodide (60 min, 200 °C, under argon)[2] and subsequent oxidation with silver oxide (acetone, 60 min, 20 °C) of the intermediate tetrahydroxy[2.2](1,4)naphthalenophane resulted in the formation of *syn*-[2.2](1,4)-5,8-naphthoquinonophane *(10)*[6] (gold-yellow plates, dec. > 250 °C; yield 58 %). In the same way, the *anti* isomer *(11)*[6] (yellow crystals, dec. > 250 °C; yield 70 %) was obtained from *(9)*. Compounds *(10)* and *(11)*, the mass spectrometric fragmentations of which are practically the same and in agreement with the proposed structure, differ significantly in their ^{1}H-NMR spectra for the reasons mentioned for the pair of stereoisomers *(8)*/*(9)* [*(10)*: δ = 3.0—3.4 (A part of AA'BB', 4H, methylene-H), 4.0—4.4 (B part of AA'BB', 4H, methylene-H), 6.70 (s, 4H, quinonoid H), 7.13 (s, 4H, aromatic H); *(11)*: δ = 2.6—3.2 (A part of AA'BB', 4H, methylene-H), 3.8—4.4 (B part of AA'BB', 4H, methylene-H), 6.70 (s, 4H, quinonoid H), 6.92 (s, 4H, aromatic H), in [D_6]-dimethyl sulfoxide]. Under conditions comparable with those of the demethylation reaction (1 h, 200 °C, under argon) no *syn-anti* isomerization was observed whereas after 1 h at 230 °C *(10)* was converted into a *(10)*/*(11)* mixture (about 1 : 1 according to preliminary results).

(10)

(11)

On partial hydrogenation of *(10)* (1 equiv. H_2, palladium/charcoal, dioxane, 20 °C) the quinhydrone *(1)*[6] was formed as an almost black substance (dec. > 250 °C; yield 72 %). Correspondingly, the *anti*-isomer *(2)*[6] was obtained (dark brown microcrystals, dec. > 250 °C; yield 65 %) from *(11)*. ^{1}H-NMR absorptions are in agreement with the assignments to the *syn*- and *anti*-constitution [*(1)*: δ = 2.7—3.2 (m, 4H), 4.0—4.5 (m, 4H), 6.40 (s, 2H), 6.45 (s, 2H), 6.80 (br. s, 4H), 9.08 (s, 2H); *(2)*: δ = 2.3—3.1 (m, 4H), 3.7—4.5 (m, 4H), 6.11 (s, 2H), 6.27 (s, 2H), 6.73 (s, 2H), 6.90 (s, 2H), 9.12 (s, 2H), in [D_6]-dimethyl sulfoxide]. Mass spectra of *(1)* and *(2)* are, in analogy to the pairs of diastereoisomers *(8)*/*(9)* and *(10)*/*(11)*, almost undistinguishable; they agree with the structures suggested.

For further characterization the naphthoquinhydrones were reacted with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (tetrahydrofuran, 20 °C; yield 75—85 %): the bis(trimethylsilyl) ether of *(1)* forms garnet-red needles of m.p. 299—300 °C[6], that of *(2)* brick-red crystals of m.p. 211—212 °C[6].

The electronic spectra of the *syn*- and *anti*-quinhydrones *(1)* and *(2)* are surprisingly similar in their absorption curves. Whereas the bis-quinones *(10)* and *(11)* [λ_{max} = 390 nm (ε = 5305) and 390 (4260), resp.] do not show absorptions above 500 nm, *(1)* as well as *(2)* exhibit broad charge-transfer (CT) bands between 500 and 700 nm [*(1)*: λ_{max} = 540 nm (ε = 1233); *(2)*: 550 (731), in methanol]; they are not concentration-dependent and, thus, must be due to an intramolecular charge-transfer even in the case of the *anti*-quinhydrone. The bis(trimethylsilyl) derivatives of *(1)* and *(2)* have similar absorption spectra, too, the broad CT bands of the *anti* isomer [λ (sh) = 525 nm (ε = 900)] and the *syn* isomer [λ(sh) = 510 nm (ε = 1500), in chloroform] showing only relatively small differences considering the very different donor-acceptor orientation.

In view of our earlier results on the orientation dependence of CT absorptions[2, 3], the similarity of CT absorptions of *syn*- and *anti*-quinhydrones of the [2.2](1,4)naphthalenophane type is rather unexpected. The only explanation we can offer at present is the assumption that the direct donor-acceptor interaction through space in these systems is less important than the interaction transmitted through the annelated [2.2]paracyclophane system the strong transanular interaction of which is well-known.

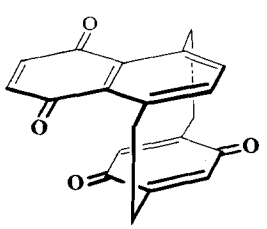
An Intramolecular Quinhydrone of the [2](1,4)Naphthaleno[2]paracyclophane Series[1]

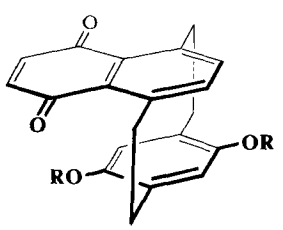
By *Claus P. Herz* and *Heinz A. Staab*[*]

In connection with the problem of the transmission of donor-acceptor interactions in the stereoisomeric [2.2](1,4)naphthalenophane quinhydrones[1] we were interested in the quinhydrone *(1)* where 1,4-naphthoquinone as acceptor and hydroquinone as donor are linked together in a [2](1,4)naphthaleno[2]paracyclophane system.

(1)



(2)



Joint 1,6-Hofmann elimination of (2,5-dimethoxy-4-methylbenzyl)trimethylammonium hydroxide[2] and (5,8-dimethoxy-4-methyl-1-naphthylmethyl)trimethylammonium hydroxide[1] in boiling toluene (12 h, water separator) yielded, in addition to the stereoisomer pairs of 4,7,12,15-tetramethoxy[2.2]paracyclophane[2] and of 4,7,14,17-tetramethoxy[2.2](1,4)naphthalenophane[1], the crossed product 4,7,12,15-tetramethoxy-[2](1,4)naphthaleno[2]paracyclophane *(2)*[3] [colorless cubes, m.p. 183.5—184 °C; yield 5—10 %; ^{1}H-NMR ($CDCl_3$): δ = 2.2—4.6 (m, 8H), 3.03 (s, 3H), 3.72 (s, 3H), 3.89 (s, 3H), 3.90 (s, 3H), 5.18 (s, 1H), 5.80 (s, 1H), 6.70 (s, 2H), 6.62 and 6.88 (AB, 2H, J_{AB} = 7 Hz)].

By demethylation with methylmagnesium iodide (30 min, 170 °C, under argon) and oxidation of the intermediate tetrahydroxy compound with silver oxide (1 h, 20 °C, acetone) [2]-(1,4)-*p*-benzoquinono[2](1,4)-5,8-naphthoquinonophane *(3)*[3] was obtained after chromatography (silica gel/chloroform) in 35 % yield [yellow needles, m.p. 190—191 °C; ^{1}H-NMR ($CDCl_3$): δ = 2.1—3.6 (m, 6H), 4.2—4.9 (m, 2H), 5.70 (s, 1H), 5.91 (s, 1H), 6.87 (s, 2H), 6.99 and 7.19 (AB, 2H, J_{AB} = 8 Hz)]. Due to incomplete demethylation, the dimethyl ether *(4)* of the quinhydrone *(1)* was formed as a by-product in this reaction sequence [red needles, m.p. 134—135 °C; yield 1—2 %; ^{1}H-NMR ($CDCl_3$): δ = 2.4—4.8 (m, 8H), 3.47 (s, 3H), 3.73 (s, 3H), 5.75 (s, 1H), 5.79 (s, 1H), 6.79 (s, 2H), 6.72 and 7.09 (AB, 2H, J_{AB} = 8 Hz)].

Partial hydrogenation of *(3)* (1 equiv. H_2, palladium/charcoal, dioxane, 20 °C) led to the quinhydrone *(1)*[3] [m.p. 193—195 °C (dec.); yield 74 %; M^+ (high-resolution) calc. 320.1046, obs. 320.1032; ^{1}H-NMR ([D_6]-dimethyl sulfoxide): δ = 2.2—3.4 (m, 6H), 3.8—4.6 (m, 2H), 5.45 (s, 1H), 5.65 (s, 1H), 6.84 (s, 2H), 6.83 and 7.26 (AB, 2H, J_{AB} = 8 Hz)].—With *N*-methyl-*N*-trimethylsilylacetamide (tetrahydrofuran, 20 °C) *(1)* was converted into the bis(trimethylsilyl) ether *(5)*[3] [brick-red crystals, m.p. 97—98 °C; yield 85 %; ^{1}H-NMR ($CDCl_3$): δ = 0.09 (s, 9H), 0.22 (s, 9H), 2.1—3.5 (m, 6H), 4.0—4.8 (m, 2H), 5.54 (s, 1H), 5.68 (s, 1H), 6.74 (s, 2H), 6.67 and 7.16 (AB, 2H, J_{AB} = 8 Hz)].

(3)

(4), R = Me; *(5)*, R = $SiMe_3$

The electronic spectra of the donor-acceptor [2.2]phanes *(1)*, *(4)*, and *(5)* are dominated by a broad structureless absorption around 400 nm [*(1)*: λ_{max} = 400 nm (ε = 1897), in dioxane; *(4)*: 402 (1870); *(5)*: 408 (1895), in chloroform]. This band is obviously due to the 1,4-naphthoquinone chromophore of the [2](1,4)-naphthalenophane system: this absorption is found with almost double the intensity for the bis-naphthoquinones of the [2.2](1,4)naphthalenophane series[1], and also *(3)* shows a similar broad absorption [λ_{max} = 375 nm (ε = 2050), in chloroform]. Whereas, however, for *(3)* this absorption ends at about 500 nm, for the donor-acceptor phanes *(1)*, *(4)*, and *(5)* absorption shoulders extend up to 570—600 nm. Thus, these compounds do not display such distinct charge-transfer absorptions as the quinhydrones of the [2.2](1,4)naphthalenophane[1] series. This result is especially surprising in comparison to the *anti*-[2.2](1,4)naphthalenophane quinhydrone showing that the discussion of indirect transmission of donor-acceptor interactions *via* the [2.2]paracyclophane system[1] calls for more experimental investigations.

C—C Linkage of Carboxylic Acids with Allyl Alcohols Using 2-Phenylglycine as Vehicle[**]

By *Norbert Engel, Börries Kübel*, and *Wolfgang Steglich*[*]

Dedicated to Professor Burckhardt Helferich on the occasion of his 90th birthday

Claisen and Cope rearrangements are steadily gaining in importance for synthetic purposes[1]. We now wish to report an application to chain elongation of carboxylic acids which is based on dehydration of the esters *(5)* to form oxazolinones *(7)*[2].

The carboxylic acid *(2)* is coupled with 2-phenylglycine methyl ester *(1)* to yield the *N*-acyl-2-phenylglycine methyl ester *(3)*, which then undergoes base-catalyzed trans-esterification with the allyl alcohol in the presence of a 4-Å molecular sieve[3] to form *N*-acyl-2-phenylglycine allyl ester *(5)* (Table 1). Treatment of *(5)* with phosgene[4a] or

[a] The crystalline compounds gave correct elemental analyses and the oils are spectroscopically pure. [b] For methods A, B, C, see procedure. [c] Prepared from the dicyclohexylammonium salt of *N*-acyl-2-phenylglycine instead of *(3)* and 3,3-dimethylallyl bromide instead of *(4)* in THF (6 h reflux). [d] Bisoxazolinone. [e] Prepared from the acyl chloride instead of *(2)* and 2-phenylglycine dimethylallyl ester instead of *(3)* and *(4)*. [f] Mixture with the (*Z*)-alcohol. [g] Crude product subjected directly to further reaction. [h] Contains *ca.* 50% of the (*Z*)-compound according to the ^{1}H-NMR spectrum. [i] (*Z*)-compound. [j] After 7 hours' refluxing in CCl_4 or several days' standing there is a mixture containing *ca.* 50% of *(6r)*; m.p. 107 °C (from methanol). [k] T/P = toluene/petroleum ether.

triphenylphosphane/CCl_4[4b] in triethylamine/acetonitrile affords 2-allyl-3-oxazolin-5-one *(7)*[2] in yields of up to 95%. Mild alkaline hydrolysis with aqueous barium or calcium hydroxide gives β,γ-unsaturated ketones *(8)* without shifting the isolated double bond (Table 1). If $NaBH_4$ is added during the cleavage of *(7b)* then the alcohol *(9)* is obtained directly (yield 81%, b.p. 120 °C/0.05 torr). Phenylglyoxylic acid or mandelic acid remains in the aqueous phase after hydrolysis. Examples of the new reaction sequence are given in Table 1.

Aromatic and heteroaromatic carboxylic acids can be transformed in a single move into *(7)* by treatment with 2-phenylglycine dimethylallyl or geranyl ester[5] and $PPh_3/CCl_4/NEt_3$[6].

With esters of allyl alcohols rearrangement stops at the stage of 4-allyl-2-oxazolin-5-one *(6)*[2,7], and with 2-butenyl

esters equilibration between *(6)* and *(7)* occurs on warming or prolonged standing.

Formation of the 3-oxazolin-5-ones *(7)* can be recognized from the C=O and C=N bands at *ca.* 1770 and 1610 cm^{-1}, resp., in the IR spectrum ($CHCl_3$). The 2-oxazolin-5-ones display these bands at 1810 and 1650 cm^{-1}, respectively. Characteristic differences also occur in the ^1H-NMR spectrum. Thus the signal of the phenyl protons appears at $\delta = 7.8$ in the case of *(6)*, and in a 3:2 distribution at $\delta = 7.5$ and 8.4 ppm in the case of *(7)*.

The novel method for chain elongation proceeds under very mild reaction conditions and affords high yields. Since organometallic intermediates are avoided, even sensitive functional groups remain intact. The amino acid serves merely as a vehicle and does not appear in the final product[8].

Procedure

Synthesis of *(5)*: Compound *(3)* (30 mmol), a molecular sieve (60 g; Merck, 4 Å, bead form, 2 mm), and compound *(4)* (45 mmol) in THF or toluene (80 ml) are shaken with an 80% NaH suspension in paraffin oil (50 mg) for 1—3 days. After filtration and washing, the Celite-clarified filtrate is evaporated down in a rotary evaporator. The residue is recrystallized.

Synthesis of *(7)*: Method A: An ice-cooled mixture of compound *(5)* (20 mmol), triethylamine (60 ml), and acetonitrile is treated within 30 to 45 min with phosgene (40 to 45 mmol, as a 5% solution in acetonitrile). When addition is complete the solution is stirred for 30 min and evaporated down in a rotary evaporator. The residue is partitioned between CH_2Cl_2 (150 ml) and water (100 ml). The organic phase is washed with 2% hydrochloric acid (100 ml) and vigorously stirred overnight with saturated $NaHCO_3$ solution (200 ml). Evaporation of the dried organic phase yields the NMR-pure product.

Method B: Triethylamine (27 mmol; 2.5 M in CH_3CN), CCl_4 or C_2Cl_6[9] (22.5 mmol; 2.5 M in CH_3CN), and triphenylphosphane (20 mmol) are added successively to compound *(5)* (10 mmol) and the mixture stirred overnight at room temperature. After evaporation in a rotary evaporator the triphenylphosphane oxide is removed by passage through a silica gel column with CCl_4/ethyl acetate.

Method C: Triethylamine (55 mmol), CCl_4 or C_2Cl_6[9] (45 mmol), and triphenylphosphane (40 mmol) are added successively, as described in method B, to *(2)* (10 mmol) and 2-phenylglycine dimethylallyl ester hydrochloride, the reaction mixture stirred overnight and then worked up.

Synthesis of *(8b)*: Compound *(7b)* (1 g) is stirred overnight in a suspension of calcium hydroxide (2 g) in water (40 ml) and THF (20 ml) under N_2 at room temperature. After removal of the THF in a rotary evaporator, the mixture is extracted with ether, the dried solution evaporated, and the residue distilled in a bulb tube; semicarbazone: m.p. 135 °C.

"Noncyclic Crown Ethers": The Terminal Group Concept[1]

By *Fritz Vögtle* and *Heinz Sieger*[*]

Dedicated to Professor Burckhardt Helferich on the occasion of his 90th birthday

The unusual complexing properties of the heptadentate species 1,11-bis(8-quinolyloxy)-3,6,9-trioxaundecane *(3)*[2] and the helical conformation of this open-chain neutral ligand in the crystalline RbI complex[3] raise a number of questions: is the arrangement of seven donor atoms particularly favorable, or are shorter chains having fewer donor atoms, as in *(1)* and *(2)*, also suitable as ligands? Are all the donor sites used for complexing in longer-chain "noncyclic crown ethers" such as *(4)*, as they are in *(3)*, leading to helices with more than one turn? What other "end groups" apart from quinolyl stabilize alkali metal ion complexes?

(1) – *(4)* *(5)* – *(13)*

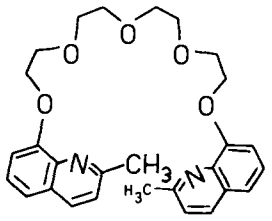
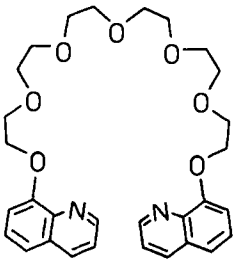
In order to answer important questions relating to our understanding of noncyclic ionophores[4] we have synthesized the open-chain crown ethers *(1)*, *(2)*, and *(4)*, as well as *(5)* to *(13)* (Table 1). Alkali metal ion complexes could be obtained with almost all the ligands having polar end groups (Table 2). X-Ray structure analysis of its RbI complex[5] shows *(1)* to be a pentadentate neutral ligand; all the donor atoms are arranged at distances between 2.98 (N) and 3.07 or 3.18 Å (O) in almost planar fashion around the central ion; however, the Rb—O distance of 2.87 Å in the RbSCN complex of dibenzo[18]crown-6 is much shorter.



Thus it has been shown for the first time that hetero atoms located in terminally fixed groups can serve as donors in neutral ligands.

Table 2. Alkali and alkaline earth metal ion complexes of the new crown ethers. The crystals are colorless or yellow.



Reactants			Products		
Ligand	Salt	Stoichiometry	Yield [%]	M.p. [°C]	
(1)	KSCN	1:1	68	195—196	(needles)

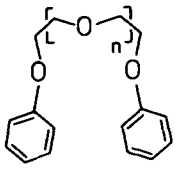
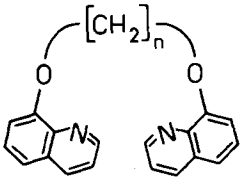
(21)	NaSCN	1:1	36	140	(needles)

[a] Yellow crystals.

No steric hindrance of complexation by methyl groups was observed in the quinaldine compound *(14)*: it forms crystalline complexes with KSCN and RbI (Table 2), whose ^{1}H-NMR spectra—and especially the large upfield shift of the pyridine and methyl protons—reveal the presence of a helical structure even in solution.

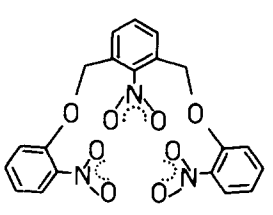


(14)

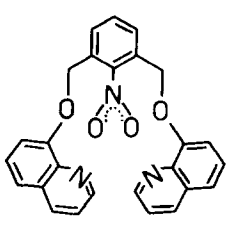


(4)

We were unable to obtain crystalline complexes of the reference compounds *(13)* and *(15)* having phenyl as a terminal group incapable of donating. Nor do two 8-quinolyloxy groups linked by an alkane chain as in *(16)* suffice for formation of crystalline complexes.



(15), n = 3
(13), n = 1

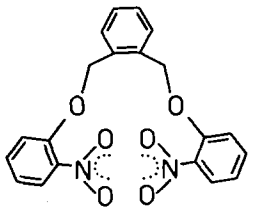


(16a), n = 8
(16b), n = 10

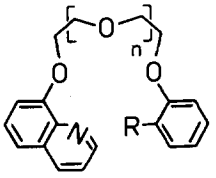
On the other hand, according to ^{1}H-NMR results (δCH_2O) only the seven ether oxygens appear to be involved in complexation of the formally nonadentate ligand *(4)*[6] with KSCN in $CDCl_3$; the upfield shift of the pyridine protons observed for *(3)* and *(14)* does not occur. Measurements of the complexation constant (K_S) and the kinetics of complexation and decomplexation of *(3)* show[4a] that the formation of crystalline alkali metal ion complexes does not parallel the stability of the complex or the selectivity[4c] of complexation in solution[7]. This can also be deduced from the finding that *(4)* does not form a crystalline RbI complex yet gives a KSCN complex, whereas *(1)* forms isolable complexes with RbI and KSCN.

It is highly remarkable that not only values for a 1:1 stoichiometry were found on determination of K_S by UV spectroscopy but also values for other ligand: cation ratios: *e.g.*, *(3)* forms 1:2 complexes with K^+ ions. This can be interpreted by assuming several metal cations to be accommodated at hitherto undefined sites. Formation of such loose addition complexes which, for *(3)* and Mg^{2+}, can even exist with the ratios 1:1, 1:2, 1:3, 1:4, and thus contrasts with the concept of complete enclosure of the cation as in the case of the cyclic crown ethers, hinders measurement of the complex constants by potential measurements with the usual ion-sensitive electrodes.

(17)



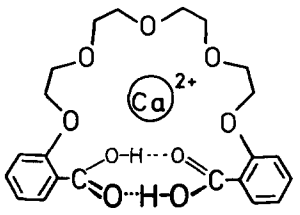
(18)



Apart from the end group donor effect geometrical factors also play a role: compounds *(17)* and *(18)* furnished with an adequate number of proven donor atoms neither form

crystalline complexes with alkali metal salts nor transfer alkali metal permanganates into organic phases.

The inferiority of the 2-nitrophenyl end group as against the 8-quinolyl group with regard to complexation follows qualitatively from the somewhat more pronounced phase transfer $NaMnO_4/CHCl_3$ on going from *(6)* to *(3)* as well as from *(19)* to the corresponding 8-quinolyl compound; in contrast to *(19)* the latter forms a crystalline KSCN complex.



(19)

(20), R = OCH_3, n = 2
(21), R = C≡N, n = 1

Crystalline alkali metal ion complexes were also obtained with the asymmetrical open-chain ligands *(20)* and *(21)* which we synthesized for the first time (Table 2)[6].

(22)

The dicarboxylic acid *(11)* differs from the neutral ligands in several of its properties: in spite of the relatively high acidity ($pK_1 \approx 3.8$, $pK_2 \approx 4.75$; cf. benzoic acid: $pK = 4.4$; 2-methoxybenzoic acid: $pK = 4.1$) the carboxyl protons are not dissociated in the crystalline KSCN and $Ca(SCN)_2$ complexes (Table 2), as is also substantiated by IR spectroscopy; we interpret this phenomenon in terms of an attractive intramolecular terminal group interaction as shown in *(22)*. In this respect *(11)* represents a model for biotic noncyclic carboxylic ionophores[8]. In contrast to *(11)*, the diester *(10)* complexes $Ca(SCN)_2$, but not KSCN and RbI.

Isolation of Isomeric Iodohydroborates of Type $[B_{10}H_{10-n}I_n]^{2-}$

By *Klaus-Georg Bührens* and *Wilhelm Preetz*[*]

A sharp increase in the number of geometrical isomers with increasing value of n (up to 5) might be expected[2] for the halohydroborate ions $B_{10}H_{10-n}X_n^{2-}$ (X = Cl, Br, I; $n = 1-10$)[1], which we recently isolated by high voltage electrophoresis. The question arising is whether electrophilic substitution gives all isomers in the expected statistical distribution or whether some are formed preferentially, as suggested by LCAO/MO calculations[3].

In the case of the lower iodohydroborates electrophoretic separation over a prolonged period (3 h) leads to separate zones (Fig. 1a). Subsidiary zones are also observed to a lesser extent with the brominated species but are not isolable. No separation at all is seen with the chlorinated species.

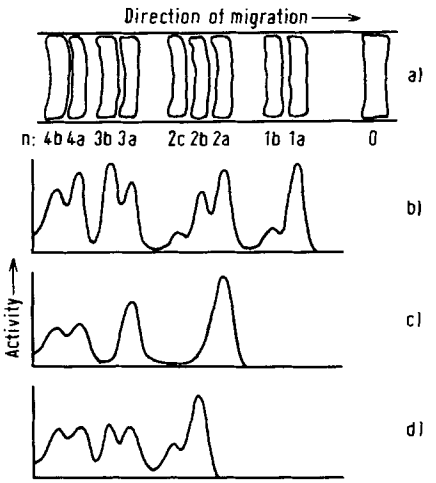

Fig. 1. a) Pherogram. b) Activity profile of the compounds $B_{10}H_{10-n}I_n^{2-}$ ($n = 1$—4) labeled with ^{131}I; c) secondary products of 2-$B_{10}H_9I^{2-}$ *(1a)* with $^{131}I_2$; d) secondary products of 1-$B_{10}H_9I^{2-}$ *(1b)* with $^{131}I_2$.

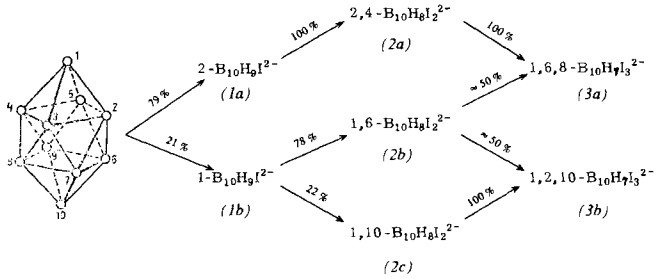
Analysis of the substances isolated from the various subzones shows them to be isomeric iodohydroborates. The reaction scheme for the formation of the species detected by electrophoresis could be established; the isolated compounds and their characteristic IR frequencies are listed in Table 1.



Separation of the isomers is feasible because of differences in molecular shape, since the ion mobility depends upon the shape of the ion[4]. Spherical particles are subject to less drag and will therefore migrate faster than extended ellipsoidal particles. In *(1b)* the molecular axis is lengthened by *ca.* 20% relative to that of $B_{10}H_{10}^{2-}$. In contrast, *(1a)* is more compact and migrates somewhat faster. The assignment could be confirmed because this isomer pair is accessible by an

alternative route[5]. Although the influence of substituents on the molecular geometry becomes slighter with increasing degree of iodination, the experimentally observed separation effects can likewise be interpreted in terms of ionic shape.

The reaction course for the initial substitution steps follows from a study of the individual steps of the reaction chains with the aid of radioactive iodine (Fig. 1). Since *(1a)* gives a homogeneous compound *(2a)*, the secondary product of which *(3b)* is also formed from *(1b)* *via* *(2b)*, the two I atoms must be in the 2,4 position in *(2a)*. Assignment of the isomers *(2b)* and *(2c)* resulting from *(1b)* is based upon the shape of the molecule. Only *(2b)* gives two secondary products, of which *(3a)* is also formed from *(2a)*, and *(3b)* also from *(2c)*. Further iodination leads to a complicated situation since six of the twenty possible isomers of $B_{10}H_6I_4^{2-}$ can be derived from *(3a)* and *(3b)*. In fact only two zones are observed which could represent mixtures.

Initial attack of I_2 on $B_{10}H_{10}^{2-}$ gives an almost statistical distribution, *i.e.* corresponding to the ratio of equatorial and axial positions (4 : 1). Formation of *(1b)* is only slightly favored (21 %). Further substitution proceeds under the directing influence of the iodine atoms already present, avoiding substitution at adjacent sites. It has also been observed in intramolecular rearrangements of $B_{10}H_8[N(CH_3)_3]_2$ that isomers with neighboring groups are less stable[6].

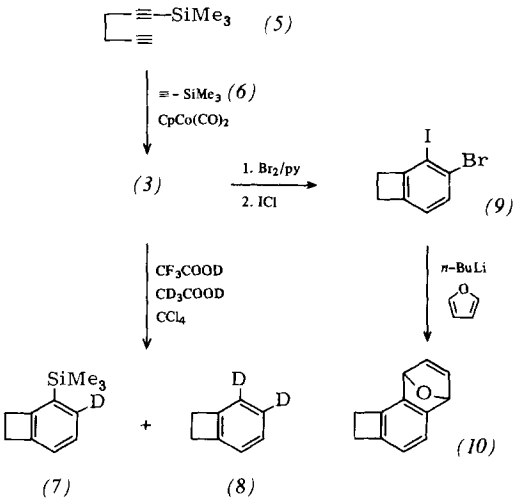
3,4-Bis(trimethylsilyl)benzocyclobutene—Synthesis by Acetylene Cotrimerization and Conversion into 1,2-Dihydrocyclobuta[*c*]benzyne[**]



By *Russel L. Hillard III* and *K. Peter C. Vollhardt*[*]

We recently reported the synthesis of 4,5-bis(trimethylsilyl)-benzocyclobutene *(1)*, a versatile synthetic intermediate *en route* to a variety of substituted benzocyclobutenes[1] and strained ring systems derived from 1,2-dihydrocyclobuta[*d*]-benzyne *(2)*[2]. We have now accomplished the synthesis of the isomeric 3,4-bis(trimethylsilyl)benzocyclobutene *(3)* and its conversion into 1,2-dihydrocyclobuta[*c*]benzyne *(4)*.

(1) *(2)* *(3)* *(4)*

Addition of a solution of 1-trimethylsilyl-1,5-hexadiyne *(5)*[3] (5 mmol), trimethylsilylacetylene *(6)*[4] (15 mmol), and dicarbonyl(cyclopentadienyl)cobalt [$CpCo(CO)_2$] (5 mol-%) in *n*-octane (10 ml) to refluxing *n*-octane (20 ml) under N_2 over a period of 5 d, followed by column chromatography with pentane on silica gave as a cocyclized product *exclusively* isomer *(3)* as a colorless oil[5] in 22 % yield [MS: *m/e* 248.1409 (calc. 248.1416, M^+, 21 %), 233 (79 %), 73 (100 %); ^{1}H-NMR (CCl_4): τ 2.60 (d, J = 8 Hz, 1 H), 3.11 (d, J = 8 Hz, 1 H), 6.87 (m, 4 H), 9.67 (s, 18 H); ^{13}C-NMR ($CDCl_3$): δ = 153.5 ppm (C-2a), 146.0 (C-6a), 134.1 (C-5), 122.1 (C-6), 34.1 (C-1 or C-2), 28.7 (C-1 or C-2), 2.6 ($Si(CH_3)_3$); UV (95 % ethanol): λ_{max} = 276 ($\lg\varepsilon$ = 3.52), 285 sh (3.46)].

Treatment with trifluoroacetic acid gave benzocyclobutene[1]. Deuteriodesilylation of *(3)* to *(7)* and *(8)* in $CD_3COOD/CF_3COOD/CCl_4$ (*ca.* 1 : 1 : 5 g/g) follows pseudo-first order kinetics and indicates that the $Si(CH_3)_3$ group at the 4-position is 500 times more susceptible to hydrolysis than that at the 3-position. This value appears to be a composite of a steric (and possibly electronic) factor of the *ortho*-

$Si(CH_3)_3$ substituent (*ca.* 40)[1] and a strain factor due to the four membered ring (*ca.* 10)[6].

The high selectivity observed in electrophilic substitutions lends itself to synthetic exploitation. Thus bromination of *(3)* with bromine/pyridine (mol. ratio 2:1) leads quantitatively to 4-bromo-3-(trimethylsilyl)benzocyclobutene[5], which on reaction with iodine monochloride affords the compound *(9)*[5]. Cyclobuta[1,2-*c*]benzyne *(4)* can be generated from *(9)* with *n*-butyl lithium and trapped with furan in 59% yield as the colorless adduct *(10)*[5] (m.p. 80—81 °C). So far we have not been able to detect dimers derived from *(4)*.

Interaction between the Nonbonding Orbitals of α-Dicarbonyl Systems and π or Walsh Orbitals[**]

By *Rolf Gleiter, Richard Bartetzko, Peter Hofmann*, and *Hans-Dieter Scharf*[*]

The interaction between the nonbonding orbitals n_1 and n_2 in 1,2-dicarbonyl systems is explained by a through-bond mechanism[1]. On the basis of the photoelectron spectra (PE) of glyoxal, biacetyl, and camphor quinone it could be shown that the energy difference $\Delta(n)=|\varepsilon(n_+)-\varepsilon(n_-)|$ between the linear combinations $n_+=(n_1+n_2)/\sqrt{2}$ and $n_-=(n_1-n_2)/\sqrt{2}$ is almost independent of the alkyl substituents and of the dihedral angle between the carbonyl groups; values of Δ(n) are found between 1.6 and 2.0 eV.

[**] This work was supported by the Fonds der Chemischen Industrie.

It is surprising, however, that the energy difference Δ(n) is strongly influenced by double bonds or three-membered rings separated by two σ bonds from the C_2O_2 fragment. This is shown by the PE spectra of the bicyclic α-diketones *(1)*—*(8)*[3].

The experimental first PE bands of the compounds *(1)*—*(8)* are compiled in Table 1. A common feature is the almost constant first ionization potential (8.7—9.2 eV) and a large energy difference between the first and the second band. The assignment is based on the validity of Koopmans' theorem ($-\varepsilon_J=I_{v,J}$)[4]. Both methods of calculation used predict the same orbital sequence (MINDO/3[5] and EH[6]).

Table 1. Comparison of measured vertical ionization potentials ($I_{v,J}$) and orbital energies (ε_J) of *(1)* to *(8)*; all values in eV.

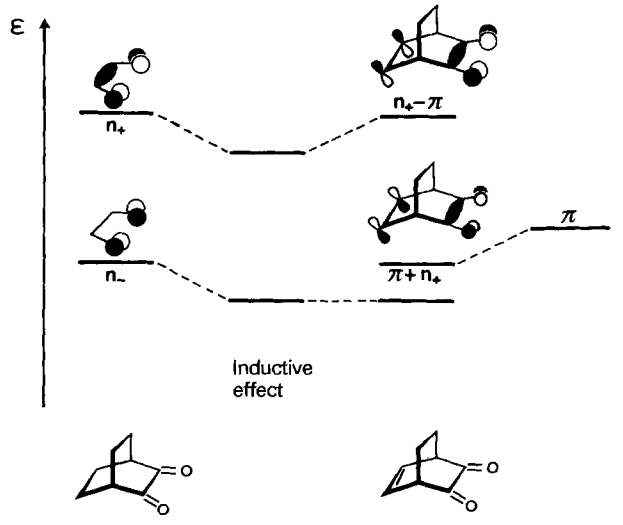

Fig. 1. Qualitative interaction diagram for the n_+ and n_- orbitals of the C_2O_2 group and the π orbital in *(2)*.

These results can readily be interpreted by assuming n_+ to be above n_- for the orbital sequence in the C_2O_2 moiety and a strong interaction between π- or Walsh orbitals and n_+ and/or n_-. In Figure 1 the orbital sequence in *(2)* is explained as the result of an inductive effect of the double bond on n_+ and n_- and a homoconjugative interaction between the π and the C_2O_2 part.

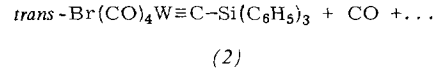
Triphenylsilylcarbyne Complexes of Tungsten[1]



By *Ernst Otto Fischer, Helmut Hollfelder, Peter Friedrich, Fritz Roland Kreissl*, and *Gottfried Huttner*[*]

Having already prepared *trans*-bromotetracarbonyldiethylaminocarbynetungsten[2] with an electron-repelling substituent on the carbyne C atom, we now describe the synthesis of *trans*-bromotetracarbonyltriphenylsilylcarbynetungsten *(2)* and dicarbonylcyclopentadienyltriphenylsilylcarbynetungsten *(3)* as the first carbyne complexes containing an electron-withdrawing hetero atom[3].

Reaction of pentacarbonylmethoxy(triphenylsilyl)carbenetungsten *(1)*[4] with aluminum bromide under mild conditions affords *(2)* as ivory-colored diamagnetic crystals which dissolve readily in dichloromethane but only moderately well in *n*-pentane.

(1)

(2)

The complex *(2)* reacts with sodium cyclopentadienide in tetrahydrofuran (evolution of CO, deepening of color) to give *(3)* as orange diamagnetic crystals which are readily soluble in ether and dichloromethane.

(3)

The IR spectra of *(2)* and *(3)* (CH_2Cl_2; cm^{-1}) show the expected vibrations in the νCO region (2132 w, 2052 vs and 2003 s, 1926 vs, respectively).—The ^{1}H-NMR spectrum ([D_6]-acetone, −30 °C) diplays a multiplet for *(2)* at δ = 7.55 ppm which is assigned to the triphenylsilyl group; the corresponding signal of *(3)* appears at δ = 7.53 ppm and is accompanied by a singlet due to the cyclopentadienyl protons at δ = 5.89 ppm (intensity ratio 15:5).—The ^{13}C-NMR spectrum of the two complexes (Table 1) evidences the relatively strong deshielding of the carbyne carbon atom, whose signal exhibits a considerable paramagnetic shift relative to arylcarbyne and alkylcarbyne complexes of tungsten[5].

Table 1. $^{13}C\{^1H\}$-NMR spectra of the carbyne complexes *(2)* and *(3)* in CD_2Cl_2; δ values in ppm, *vs.* CD_2Cl_2 = 54.16 ppm.

	W≡C	CO	C_6H_5		C_5H_5	Measuring temp. [°C]
(2)	337.14	192.57	135.72	131.73		−40
	(146.5) [a]	(131.8) [a]	130.75	128.60		
(3)	354.29	222.24	135.93	134.32	92.56	−20
	(178.2) [a]	(202.6) [a]	130.00	128.27		

[a] $^1J(^{183}W-^{13}C)$ in Hz for satellites.

Although the spectroscopic data prove that *(3)* has basically the same structure as already confirmed by X-ray studies for other cyclopentadienyldicarbonyltungsten-carbyne complexes[6], X-ray analysis[7] of *(3)* was undertaken in order to establish whether the triphenylsilyl substituent has a recognizable influence on the W—$C_{carbyne}$ bond length (Fig. 1).

The pseudooctahedral structure expected for *(3)* was confirmed. The W—$C_{carbyne}$ distance of 181(2) pm is just as long as that in $C_5H_5(CO)_2WC-C_6H_4CH_3$ *(4)* (182(2) pm[6a]); exchange of the *p*-tolyl group in *(4)* for the triphenylsilyl group in *(3)* apparently causes no change in the W—$C_{carbyne}$ bond length. As in *(4)*, the central group W≡C—R is almost linear (176(1)°). Within the limits of experimental accuracy all the SiC bonds in *(3)* are of equal length. Compared with a C_{sp}—Si single bond (181 pm[8]) the $C_{carbyne}$—Si bond length of 187(2) pm appears somewhat elongated; however, the effect is by no means so pronounced as in $(CO)_5Cr-[C(OEt)(SiPh_3)]$[4], for which a C_{sp^2}—Si distance of 200(2) pm was found.

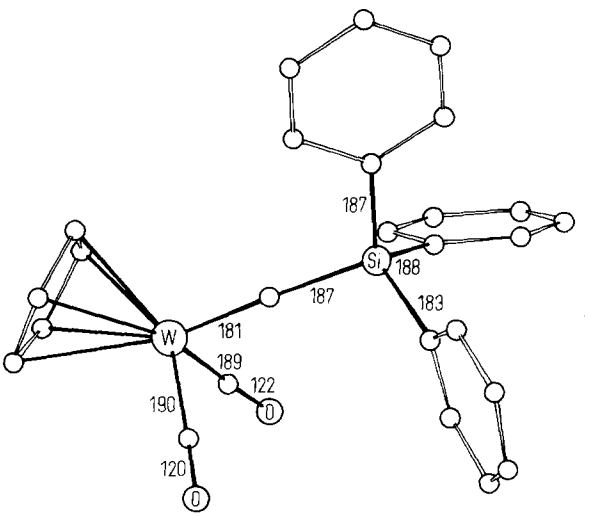


Fig. 1. Molecular structure of π-$C_5H_5(CO)_2W\equiv C-Si(C_6H_5)_3$ *(3)*.

Procedure

All operations should be performed under N_2 and with dried (Na, P_4O_{10}) and N_2-saturated solvents.

(2): An excess of Al_2Br_6 is added to a stirred solution of *(1)* (1.57 g, 2.5 mmol) in toluene (30 ml) at −78 °C. On

[*] Prof. Dr. E. O. Fischer, Dipl.-Chem. H. Hollfelder, Dipl.-Chem. P. Friedrich, Dr. F. R. Kreissl, Doz. Dr. G. Huttner

warming to −15 °C the reaction mixture evolves CO and slowly changes color from dark red to yellow. After 30 min methanol is added (5 ml) at −100 °C. The orange reaction mixture is then evaporated to dryness at −30 °C; the residue is taken up in the minimum amount of CH_2Cl_2 necessary (−50 °C) and chromatographed on silica gel (column: $l=15$, $d=2.5$ cm). After concentration of the yellow zone to 2 ml, addition of pentane (50 ml) at −78 °C leads to deposition of a finely crystalline precipitate. The mother liquor is decanted off and the precipitate recrystallized five times at −78 °C from CH_2Cl_2/pentane (1:40) and dried for 2 d at −30 °C *in vacuo*. Ivory crystals, dec. >*ca.* 65 °C; yield 1.5 g (93 %).

(3): An excess of NaC_5H_5[9] is added to a stirred solution of *(2)* (2.25 g, 3.5 mmol) in tetrahydrofuran (30 ml) at −78 °C, the reaction mixture evolving CO and turning orange-brown. Removal of solvent and chromatography of the residue at −30 °C on silica gel (column: $l=25$, $d=2.5$ cm) in pentane/CH_2Cl_2 (1:1) gives an orange zone which is evaporated to 2 ml at −30 °C. After addition of pentane (50 ml) at −78 °C fine crystals of *(3)* precipitate. They are recrystallized three times at −78 °C from ether/pentane and dried for 2 d at −20 °C *in vacuo*. Orange crystals, m.p. 103—104 °C; yield 1.1 g (55 %).

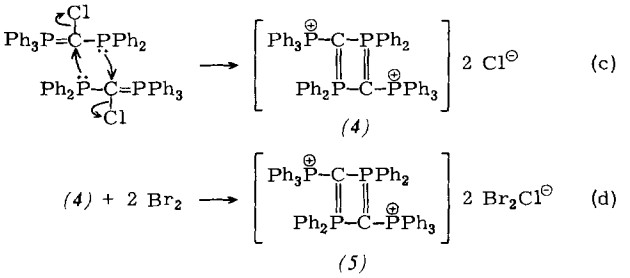
Synthesis of a Stabilized $1\lambda^5,3\lambda^5$-Diphosphacyclobutadiene[1]

By *Rolf Appel, Fritz Knoll*, and *Horst-Dieter Wihler*[*]

Dedicated to Professor Georg Wittig on the occasion of his 80th birthday

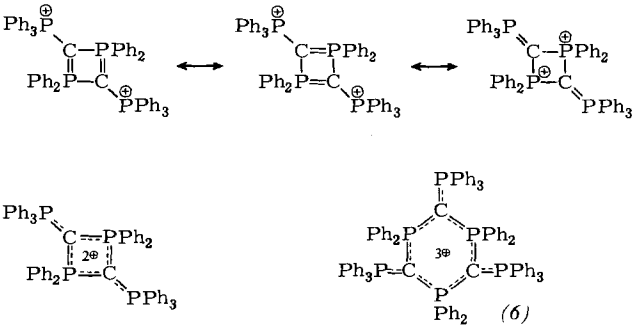
(Trichloromethyl)triphenylphosphonium chloride *(1)* is not only the first isolable intermediate in the reaction of triphenylphosphane with tetrachloromethane[2], but also a now readily accessible starting compound for the synthesis of phosphorus carbon ylides whose existence was hitherto only suspected or whose preparation is difficult[3]. From *(1)* and chlorodiphenylphosphane we have now obtained chloro(triphenylphosphoranediyl)methylchlorodiphenylphosphonium chloride *(2)*, which can be dechlorinated to the yellow ylide *(3)* by trimorpholinophosphane or tris(dimethylamino)-phosphane.



[*] Prof. Dr. R. Appel, Dr. F. Knoll, Dipl.-Chem. H.-D. Wihler
Anorganisch-chemisches Institut der Universität
Max-Planck-Strasse 1, D-5300 Bonn (Germany)

(a)

(b)



The ylide *(3)* is thermally unstable. On heating, or even on conducting reaction (b) without cooling, 1,3-cyclosubstitution occurs with dimerization to give 1,1,3,3-tetraphenyl-2,4-bis(triphenylphosphonio)-$1\lambda^5,3\lambda^5$-diphosphacyclobutadiene dichloride *(4)*, which melts at 385 °C, dissolves without decomposition in water, and does not display any ylide reaction. Compound *(4)* reacts with bromine to give a bright yellow solid, m.p. 365 °C, identified as the polyhalide *(5)* by the ^{31}P-NMR spectrum of the cation and its reaction with cyclohexene to regenerate *(4)*.

(c)

(d)

The unusual stability of the cation and its almost undetectable polarizing effect upon the counterion Br_2Cl^-[4] in spite of the double charge suggest extensive delocalization of the positive charge with participation of the exocyclic P atoms.

To our knowledge *(4)* and *(5)* contain the first four-membered PC ring system having partly endocyclic double bonds. In the uncharged ring systems of the cyclophosphazenes the four-membered ring is still unknown. We assume a stabilizing contribution of the positive charge in the case of *(4)* by partial withdrawal of π-electron density from the ring into the external P—C bonds.

Two triplets are observed in the ^{31}P-NMR spectrum of *(4)* at $\delta=14.4$ and 33.64 ppm [$J(P_aP_b)=7.35$ Hz], indicating a symmetrical structure in which each P atom must be surrounded by two identical P atoms having a different environment from the first one. However, a decision between the proposed structure *(4)* and the six-membered ring structure *(6)*, which could not be ruled out *a priori*, only became possible on considering the ^{13}C-NMR and the field desorption mass spectrum. In the ^{13}C-NMR spectrum (CD_3OD, TMS internal) the signal of the ring C atom ($\delta=18.29$ ppm) is split into 12 lines ($^1J_{CP}=111.69$, $^1J_{CP_2}=76.17$, $^3J_{CP}=15.4$ Hz), which is compatible with a four-membered ring but not with

a six-membered ring; a 36-line spectrum would be expected for *(6)*. The FD mass spectrum[5] also provides important evidence in favor of the four-membered ring. The peak at $m/e=459$ corresponds to the dication of *(4)*, but could also be assigned to the trebly charged cation *(6)*. The latter possibility is discounted by the appearance of the highest mass peak at $m/e=917$, *i. e.* for $[K^{2+}-H^+]^+$ and by the absence of ions in the range $m/e=1000$—1500. Another line at $m/e=841$ arises from a cation containing one less phenyl group $[K^{2+}-Ph^+]^+$.

Procedure

(2): To an ice-cooled, stirred solution of *(1)*[2] (17.4 g, 41.8 mmol) in a minimal amount of CH_2Cl_2 is slowly added dropwise Ph_2PCl (18.4 g, 83.6 mmol) diluted with the same amount of CH_2Cl_2. After 2 h the precipitated trichlorodiphenylphosphorane is filtered off (10 g = 34 mmol = 82 %) and that remaining in solution decomposed with 1,2-epoxybutane. The solvent is distilled off *in vacuo* and the dry residue dissolved in CH_3CN. Ether is added to the gently stirred solution until it becomes slightly turbid; precipitation is complete within 30 min. The product is filtered off, washed with ether, and dried *in vacuo* at 40 °C. Yield: 16.8 g (71 %) of *(2)*, m.p. 192 °C (dec.). ^{1}H-NMR: multiplet at $\delta=7.4$ to 8.0 ppm. ^{31}P-NMR: two doublets at $\delta=-23.63$ and $+62.63$ ppm; $J(P,P)=42.5$ Hz.

(4): To a solution of *(2)* (8.5 g, 15 mmol) in CH_2Cl_2 is added solid trimorpholinophosphane (4.3 g, 15 mmol) in a single batch and the mixture is stirred at room temperature for 10 to 20 min. After evaporation to dryness at 40 °C the residue is taken up in benzene and the mixture filtered. The filter cake is stirred with CH_2Cl_2, whereupon $(OC_4H_8N)_3PCl_2$ dissolves. The white residual solid is recrystallized from methanol. After washing with CH_2Cl_2 it is dried at 80 °C. Yield: 5.8 g (79 %) of *(4)*, m.p. 385 °C.—The action of bromine on the solution of *(4)* in CH_2Cl_2 gives *(5)*, dec. 365 °C, in quantitative yield. ^{31}P-NMR: two triplets at $\delta=14.44$ and 33.64 ppm; $J(P,P)=7.35$ Hz.

Preparation of Cyclohexasilane, Si_6H_{12}

By *Edwin Hengge* and *Dieter Kovar*[*]

Following the discovery of the first cyclic hydrosilicon Si_5H_{10}[1], we have now succeeded in preparing and characterizing the next homolog Si_6H_{12}. Starting from dodecaphenylcyclohexasilane, first obtained by *Kipping et al.*[2] from Ph_2SiCl_2 by reaction with alkali metal, we were able to remove all the phenyl groups with the aid of $AlCl_3$/HCl and to isolate Si_6Cl_{12}[3]. $AlCl_3$ had already been used on former occasions for cleaving Si-phenyl bonds in simple silanes[4]. The cleavage reaction, shown by our investigations to be electrophilic, also proceeds without ring cleavage with phenylcyclosilanes, whereas hydrogen chloride under pressure in the absence of $AlCl_3$ effects only partial removal of the phenyl groups[5]. Use of $AlCl_3$ has the considerable practical advantage that the reaction occurs with gaseous HCl and use of liquified HCl (bomb tube) can be avoided.

Si_6Cl_{12} can be smoothly hydrogenated to unsubstituted cyclohexasilane with pure $LiAlH_4$ in benzene/ether. Si_6H_{12} is a colorless liquid which ignites spontaneously on exposure to air. Owing to its low vapor pressure the new compound is easier to handle than Si_5H_{10}. Its ^{1}H-NMR, IR, Raman, and mass spectra were recorded for purposes of characterization.

^{1}H-NMR (60 MHz; in benzene TMS int.): singlet at $\tau=6.50$, $J_{SiH}=195$ Hz
IR [cm^{-1}]: 330 w, 384 m (br), 519 w, 625 vs, 720 vs (br), 865 m, 892 vs, 904 vs, 2120 vs
Raman [cm^{-1}]: 114 s (p), 350 vs (p), 379 w (p), 455 m, 476 vs (sh), 517 vw (p), 625 w, 655 m, 736 vw (?), 893 m, 2128 vs (br, p)
MS: Molecular ion at m/e 180, usual isotopic distribution due to ^{29}Si; fragmentation pattern results from successive loss of H and SiH_4

Assuming a chair conformation similar to that of cyclohexane, the Raman spectrum should display 14 lines ($6A_{1g}+8E_g$), which are indeed observed (νSiH must be counted fourfold). In the IR spectrum 13 vibrations are expected ($5A_{2u}+8E_u$) of which 9 are observable, the SiH stretching vibration being multiply degenerate; the ring deformation vibrations lie outside the range of measurement. These results and the polarization measurements strongly suggest the assumed conformation of cyclohexasilane.

Procedure

Benzene (200 ml) and $AlCl_3$ (1 g, 7.5 mmol) are added to Si_6Ph_{12} (4 g, 3.6 mmol). HCl is passed into this stirred suspension until a clear solution is obtained. $AlCl_3$ is filtered off, and a freshly prepared 0.5 M ethereal solution of $LiAlH_4$ (100 ml) is added to the vigorously stirred filtrate with ice-cooling (1 h). Stirring is continued at room temperature, the ether removed, and the precipitate filtered off; residual benzene is drawn off at 1 torr. At 0.01 torr and 80 °C Si_6H_{12} condenses over as a colorless liquid, yield 0.39 g (60 %).

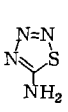
New Synthetic Methods for 6aλ^4-Thiapentalenes

By *Gerrit L'abbé, Gabriël Verhelst*, and *Guido Vermeulen*[*]

1,6,6aλ^4-Thiapentalenes and analogous compounds have recently acquired considerable interest owing to their ability

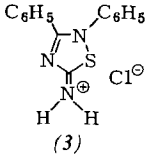
[*] Prof. Dr. G. L'abbé, G. Verhelst, G. Vermeulen
Department of Chemistry, University of Leuven
Celestijnenlaan 200 F, B-3030 Heverlee (Belgium)

to engage in no-bond resonance[1]. We have now found that a series of 6aλ⁴-thia-1,6-heteropentalenes of general structure *(1)* can be prepared from the readily available 5-amino-1,2,3,4-thiatriazole *(2)*[2]. Thus, when *(2)* is reacted with two equivalents of benzoyl chloride and triethylamine, a thermostable compound *(1a)* is obtained which exhibits spectral data (strong $M^{\bullet+}$, no ν(C=O) above 1600 cm^{-1}, symmetrical according to ^{13}C-NMR) consistent with its formulation as 2,5-diphenyl-3,4-dioxa-3aλ⁴-thia-1,6-diazapentalene (compounds *(1)* have to be designated as 3aλ⁴-thia-1,6-diaza-3,4-diheteropentalenes owing to the two nitrogen atoms). Furthermore, compound *(1a)* was converted by P_4S_{10} into a mixture of oxadithiadiazapentalene *(1e)* and the known[3] orange trithiadiazapentalene *(1f)*. Substituted benzoyl chlorides furnished compounds *(1b)* to *(1d)*.



(1)

Table 1. Compounds of type *(1)* prepared.



Cpd.	X	Y	R^1	R^2	M.p. [°C]	Yield [%] [a]
(1a)	O	O	Ph	H	195—197	36

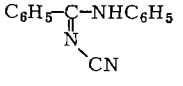
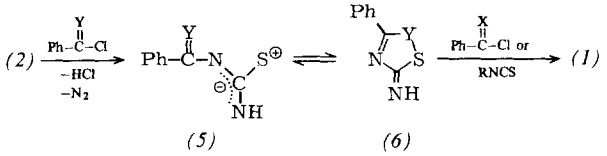
[a] Yield based on *(2)*.
[b] Yield based on *(1a)*; mixture of *(1e)* and *(1f)*.



Compound *(2)* was similarly treated with two equivalents of *N*-phenylbenzimidoyl chloride in the presence of triethylamine, but the unknown salt *(3)* (m.p. 227—227.5 °C) and *(4)* (m.p. 231—233 °C) were obtained instead of the anticipated

(2)



(3)

(4)

(1g). Compound *(3)* was the sole product formed when equimolar quantities of *(2)* and the imidoyl chloride were reacted in the absence of base. The salt *(3)* decomposes quantitatively to *(4)* and sulfur in the presence of bases. In order to avoid this base-induced decomposition in our attempted synthesis of thiatetraazapentalenes, pyridine was added to a mixture of *(3)* and *N*-phenylbenzimidoyl chloride: *(1g)* was obtained in 86 % yield. Similar treatment of *(3)* with benzoyl chloride furnished *(1h)* (84 %), and methyl and phenyl isothiocyanate yielded *(1i)* and *(1j)*, respectively, in addition to *(4)*.

(5) *(6)*

We believe, the inner salts of type *(5)* to be the key intermediates in our reactions.

Procedures

Synthesis of *(1a)*: To an ice-cooled solution of benzoyl chloride (0.02 mol) and triethylamine (0.02 mol) in dry tetrahydrofuran (10 ml) is added dropwise with stirring a tetrahydrofuran solution of *(2)* (0.01 mol in 15 ml). The reaction mixture is allowed to warm to room temperature and stirred for another two hours until nitrogen evolution has ceased. The solvent is removed and the residue is washed with water, dried, and crystallized from chloroform.

Synthesis of *(1g)*: Equimolar amounts (0.01 mol) of *(2)* and *N*-phenylbenzimidoyl chloride are allowed to react in dry acetonitrile (20 ml) until nitrogen evolution has ceased (2 hours). The precipitate *(3)* is collected, dried, and crystallized from methanol (yield 87 %).—To an ice-cooled mixture of *(3)* and *N*-phenylbenzimidoyl chloride (2.5 mmol of each) is added dropwise with stirring pyridine (10 ml). The reaction mixture is stirred for one hour at 0 °C, and then heated at reflux temperature for another hour. The mixture is poured onto ice and *(1g)* is filtered off, dried, and crystallized from CCl_4/hexane. Compounds *(1h)* to *(1j)* are prepared in a similar manner.

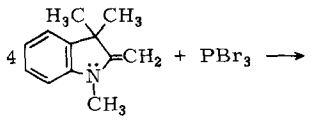
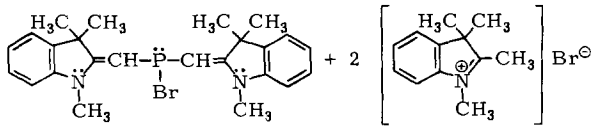
Preparation of a β-Phosphatrimethinecyanine Dye[**]



By *Norbert Gamon* and *Christian Reichardt*[*]

We wish to report the first synthesis of a β-phosphatrimethinecyanine dye. Hitherto, only phosphamonomethinecyanines[1,3] but no phosphapolymethinecyanines containing the structural unit —P= were known (cf. [1-4]).



Reaction of the enamine *(1)* with phosphorus tribromide in boiling dichloromethane affords bromobis(1,3,3-trimethylindolin-2-ylidenemethyl)phosphane *(2)* as a yellow powder, which is extremely sensitive to hydrolysis[5,6]. The preparation of *(4)* from *(2)*, whose UV/Vis spectrum in chloroform shows it to be slightly dissociated, can be accomplished by alkylation of the bromide ion with trimethyloxonium tetrafluoroborate. β-Phosphabis(1,3,3-trimethylindolin-2-yl)trimethinium tetrafluoroborate *(4)* forms dark blue, very fine crystals with a

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The results are taken from the Diplomarbeit of *N. Gamon*, Universität Marburg 1977.—Presented at the 6th International Color Symposium in Freudenstadt on September 30, 1976.

(1)

(2) (3)

(4)

metallic sheen, which dissolve in chloroform to give a dark blue solution ($\lambda_{max}=586$ nm)[5, 6].

The ^{1}H-NMR spectrum of *(4)* ($CDCl_3$) contains, *inter alia*, a doublet at 8.01 ppm ($J_{^{31}P,^1H}=15$ Hz) for the two α-methine protons, and the ^{31}P-NMR spectrum ($CDCl_3$) consists of just one downfield signal with a suggestion of triplet structure at +355.8 ppm (H_3PO_4 as external standard)[7]. The ^{13}C-NMR signal ($CDCl_3$) of the α-methine C atoms at +122.0 ppm is split into a doublet by the neighboring P atom ($J_{^{13}C,^{31}P}=39.7$ Hz).

Table 1. Longest wavelength UV/Vis absorption maxima of *(4)* and the analogous CH and N compounds in chloroform.

	$\tilde{\nu}_{max}$ [cm^{-1}]	$\varepsilon\times10^{-5}$ [1/mol·cm]	$\lvert\Delta\tilde{\nu}\rvert$ [cm^{-1}]
β-CH-cyanine	18080	1.39	0
β-P-cyanine *(4)*	17060	≥0.64	1020
β-N-cyanine	16610	1.14	1470

Table 1 compares the UV/Vis absorption maximum of *(4)* with the maxima of two analogous trimethinecyanines. The bathochromic shift of 1020 cm^{-1} (33 nm) relative to β-CH-cyanine can be understood as the resultant of two opposing effects: replacement of the β-CH group by the more electropositive P atom should lead to a hypsochromic shift[8], which, however, is overcompensated by elongation of the polymethine chromophore owing to the greater covalent radius of phosphorus and the consequent bathochromic shift. The absorption maximum of $\lambda_{max}=17210$ cm^{-1} (581 nm) calculated for *(4)*, paying due attention to *both* chromophore length *and* electronegativity, agrees well with the experimental value of 17060 cm^{-1}.

Procedure[6]

(2): *(1)* (13.9 g, 80 mmol) in CH_2Cl_2 (90 ml) is added dropwise at 25 °C to a vigorously stirred solution of PBr_3 (5.4 g, 20 mmol) in CH_2Cl_2 (100 ml) and the mixture is heated under reflux for 2 h. After cooling, precipitated *(3)* is filtered off, the filtrate evaporated to dryness, and the residue extracted on a glass frit with hot diethyl ether (3 × 50 ml). Product *(2)* crystallizing from the extract is dried at 90 °C/10^{-4} torr for 3 h; yield 6.6 g (72%); m.p. 163–166 °C (dec.).

(4): Compound *(2)* (0.84 g, 1.8 mmol) and trimethyloxonium tetrafluoroborate (0.27 g, 1.8 mmol) are stirred vigorously in chloroform (25 ml) at 25 °C for 1 h. The filtered dark blue solution is covered with a layer of petroleum ether (80 ml). After two days precipitated *(4)* is filtered off and dried at 70 °C/10^{-4} torr for 30 min; yield 98%; m.p. 220 °C (decomposition with evolution of gas).

Column Chromatography on Triacetylcellulose. Preparative Separation of Enantiomeric Diaziridines[**]

By *Harri Häkli* and *Albrecht Mannschreck*[*]

According to *Hesse* and *Hagel*[2] microcrystalline, swollen triacetylcellulose represents a versatile sorbent for the separation of enantiomers by column chromatography. We have tested triacetylcellulose as a stationary phase for low-pressure chromatography of enantiomeric diaziridines. The separation of invertomers within this class of compounds had been predicted[3a] and was accomplished for diastereoisomers, *e.g.* (1*R*, 2*R*, 3*S*)- and (1*S*, 2*S*, 3*S*)-*(1)*[3b]. However, the enrichment of enantiomers *via* diastereomeric salts with optically active acids has failed as yet[4]. In two cases[5] a slight kinetic enrichment was achieved; in a further case[5b] a purity of 63.5% was attained (after additional separation *via* a derivative of chloral). This procedure presumes a non-substituted nitrogen atom and in principle can only yield one of the enantiomers. Enantiomers like (1*R*,2*R*)- and (1*S*,2*S*)-*(2)* are of interest

(1*R*,2*R*,3*S*)-*(1)* R = C_6H_5 (1*S*,2*S*,3*S*)-*(1)*
(1*R*,2*R*)-*(2)* R = H (1*S*,2*S*)-*(2)*

[**] Protonenresonanz-Untersuchungen zur Inversion am dreibindigen Stickstoffatom, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. Professor Dr. *G. Hesse*, Erlangen, Germany, informed us about the details of his method of separation. We are grateful to Dr. *G. Becher*, Dipl.-Chem. *T. Burgemeister*, and Dr. *R. Rauchschwalbe*, Regensburg, Germany, for helpful suggestions.—Part 4: [1].

because of their chiroptical properties and since their racemization by consecutive nitrogen inversions[1] must proceed *via* two enantiomeric transition states, whereas the equilibration kinetics[1] for the diastereoisomers of *(1)* are more complicated.

3-Benzyl-1,2,3-trimethyldiaziridine[3b], (±)-*(2)*, in ethanol/H_2O (96:4) was passed through a column of triacetylcellulose[2] (85 g, particle size 0.056 to 0.071 mm, column length 30 cm, internal diameter 2.5 cm, 22 °C). A membrane pump generated a flow of ≈135 ml/h. Figure 1 shows an analytical chromatogram. Preparative separations were performed with 100 mg of (±)-*(2)* which were conducted through two columns in such a way that a total of seven passages took place ("recycling"). This was achieved with a manual gauge[6] which, in addition, separated the first 10% of eluate containing predominantly (+)-*(2)*. Thus, the remaining eluate resulted in practically pure (−)-*(2)* when divided by a fraction collector: 26 mg, $[\alpha]_{436}^{22} = -141 \pm 4°$ (0.05 g/100 ml CCl_4), enantiomeric purity[7] $P = 97 \pm 3$ %. Together the seperated frontier eluates contained 46 mg of (+)-*(2)*, $[\alpha]_{436}^{22} = +85 \pm 5°$ (0.35 g/100 ml CCl_4), $P = 59 \pm 3$ %. The ^{1}H-NMR spectra were in agreement with those of (±)-*(2)*[1,3b] although they showed ≈2% (by weight) of *n*-hexane originating from the eluent. The intensities of ^{1}H-NMR signals in the presence of an optically active auxiliary compound served for the measurement of P[1,4,8]. (±)-*(2)* in [D_8]-toluene at 34 °C exhibits *two* C—CH_3 singlets at δ = 2.87 and 2.93 (line widths 1.5 Hz) in the presence of 0.27 equivalents of (+)-tris[3-heptafluorobutyryl)-D-camphorato]europium(III). In the samples with enriched (+)-*(2)* the signal intensity at 2.87 prevailed; the (−)-*(2)* fractions showed practically only the signal at 2.93. The P values were determined by repeated cutting out of diagrams, dividing into the components, and weighing of the pieces. The CD spectrum of (−)-*(2)* in *n*-hexane at 25 °C, calculated for $P = 100$ %, exhibited maxima at 268 nm ($\Delta\varepsilon = -0.12$ l cm^{-1} mol^{-1}), 262 (−0.12), 256 (−0.08), 219 (≈ +1.6), and 214 (≈ +1.7).

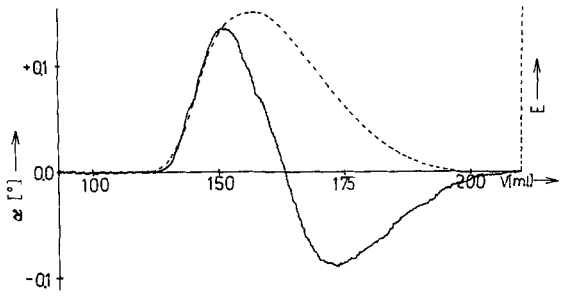

Fig. 1. Analytical chromatogram of 50 mg of (±)-*(2)* in ethanol/H_2O (96:4) after passage through a triacetylcellulose column (cf. text): α: Rotation angle (——) at 365 nm, measured by flow through a polarimeter. *E*: Extinction (– – – – –) at 254 nm, measured by flow through a photometer. *V*: Volume of the eluate (injection at $V = 0$).

The thermal racemization of (+)-*(2)*, obtained by chromatography, in toluene at 89.9 °C was monitored by polarimetry at 436 nm. This process was of first order with a half-life of 56.9 min and $\Delta G^{\neq} = 27.57 \pm 0.02$ kcal/mol for a *trans*→*cis* nitrogen inversion[1,3b]. This is in satisfactory agreement with the value 27.2 ± 0.1 kcal/mol[1] (C_2Cl_4, 89.9 °C) for an inversion in the diastereoisomers of *(1)* mentioned above.

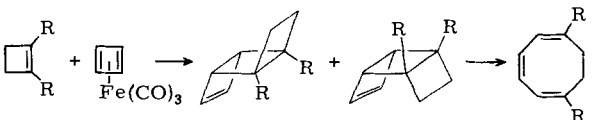
cis,trans-1,5-Cyclooctadienes[**]

By *Hans-Dieter Martin, Mirko Hekman, Günther Rist, Hans-peter Sauter*, and *Daniel Bellus*[*]



In some cases, eight-membered rings having *trans*-configurated double bonds differ considerably in their ground state energy[1], their reactivity[2], and their spectroscopic properties[3] from the *cis*-configurated stereoisomers. This confers interest upon methods for the preparation of such strained cycloolefins[4]. We here report thermal valence isomerizations permitting productive syntheses of *cis,trans*-1,5-cyclooctadienes *(2)*, which are either isolated or, if isolation is precluded by excessive reactivity, can be trapped by dienes.

(1) *(2)* *(3)*

(a), R = $COOCH_3$, R' = H;
(b), R = CN, R' = H;
(c), R = R' = $COOCH_3$

The inversion of a C atom known to occur on thermal cleavage of bicyclo[2.2.0]hexanes to form 1,5-hexadienes is also applicable to tricyclo[4.2.0.0^{2,5}]octanes[5,6]. The valence isomerization *(1)* → *(2)* can therefore be regarded as providing a synthetic entry to strained *trans*-cycloalkanes.

(4) *(5)* *(6)* *(7)* *(8)*

(a), R = $COOCH_3$
(b), R = CN

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.—Part 23 of the series "Small Rings".—Part 22: *H.-D. Martin, H.-J. Schiwek, J. Spanget-Larsen, R. Gleiter*, Tetrahedron Lett., in press.—Also Part 7 of the series "Synthesis and Reactivity of Four-Membered Ring Compounds".—Part 6: *D. Bellus*, Helv. Chim. Acta *58*, 2509 (1975).

Reaction of dimethyl cyclobutenedicarboxylate *(4a)* with the cyclobutadienecarbonyliron complex *(5)* at 0°C furnishes the two stereoisomers *(6a)* (m.p. 47—48°C) and *(7a)* in the ratio of 10:1.

Both isomers undergo thermal cleavage to give the cyclooctatriene derivative *(8)*[7] (m.p. 68—69°C), *(7a)* somewhat faster than *(6a)*. Hydrogenation of *(6a)* (Pd/C, CH_3OH) affords *(1a)* (m.p. 42—44°C). Heating of *(1a)* to 75°C in inert solvents gives *(3a)* as the only isolable monomer (m.p. 77—78°C). However, if a mixture of $CHCl_3$ and furan is used as reaction medium, not only *(3a)* but also an adduct *(9a)* or *(10a)* (m.p. 78—80°C) of *(2a)* to furan is obtained on chromatographic separation. Compound *(3a)* does not undergo cycloaddition under these conditions.

The dinitrile *(4b)* likewise adds to the cyclobutadiene complex *(5)* to form the relatively labile tricyclics *(6b)* and *(7b)* in the ratio of 4:1. Detectable isomerization to *(8b)* (m.p. 140—142°C) occurs already at 25°C. Hydrogenation of *(6b)* (Pd/C, CH_3OH, 0°C) leads to *(1b)*, which on account of the high reactivity and lability of *(2b)* is reacted directly with furan (50°C, 1 h). Unlike *(1a)*, *(1b)* yields *(3b)* (m.p. 125—126°C) and, *via* the intermediate *(2b)*, a pair of stereoisomers *(9b)* and *(10b)* (m.p. 166—168°C and 154—156°C, respectively).

(a), R = $COOCH_3$, R' = H; *(9)* *(10)*
(b), R = CN, R' = H

The instability of the disubstituted *cis,trans*-cyclooctadienes *(2a)* and *(2b)* results from the joint action of ring or torsional strain and the electron-withdrawing substituents, both of which increase the molecules' reactivity. However, it may be expected that, as the number and size of the substituents increase, the reactivity in cycloadditions will decrease and the configurative stability increase. This is indeed observed in the comparatively stable tetracarboxylic ester *(2c)*.

At 105°C *(1c)*[7] isomerizes to a 2:1 mixture of *(2c)* and *(3c)* which can be separated by chromatography over silica gel. The ^{13}C-NMR spectrum of *(2c)* recorded between −20°C and +90°C displays a clear temperature dependence owing to conformational mobility, which however is frozen at −20°C [^{13}C-NMR of *(2c)* (TMS, CD_3NO_2): (+90°C) 31.2, 36.1 (CH_2), 52.5, 52.6 (OCH_3), 140.4, 149.5 (C=C), 169.7, 170.2 (C=O); (−20°C) 25.3, 35.8, 35.9, 36.9 (CH_2), 52.9, 53.0, 53.1, 53.3 (OCH_3), 134.5, 145.5, 149.1, 150.8 (C=C), 168.0, 169.7, 170.1, 172.7 (C=O)].

Compound *(2c)* fails to give a Diels-Alder adduct on heating to 105°C in furan, presumably because of excessive steric hindrance. As in tetracyclo[4.4.0.0^{2,5}.0^{7,10}]decanes[8], the rate-determining step in the thermolysis of *(1)* and *(6)* is probably cleavage of the internal substituted bond of the four-membered ring. This is evidenced by the kinetic parameters compared with those of the reference compound dimethyl bicyclo[2.2.0]-hexane-1,4-dicarboxylate *(11)* [E_a (kcal/mol), log A, solvent: *(1a)* 25.5, 12.6, $CDCl_3$; *(1c)*, 26.5, 12.2, C_6D_5Cl; *(6a)*, 24.1, 11.5, CCl_4; *(11)*, 25.5, 12.1, C_4Cl_6; 24.6, 11.7, $C_6D_5CD_3$; 24.6, 11.7, $C_6D_5NO_2$].

$(RPNCH_3)_4$, Cyclotetra(λ^3-phosphazanes) Synthesis and Crystal Structure Analysis

By *Werner Zeiss, Wolfgang Schwarz*, and *Heinz Hess*[*]

While attempting to prepare the hitherto unknown permethylated 1,3,2λ^3,4λ^3-diazadiphosphetidine *(1a)* from methyldichlorophosphane and heptamethyldisilazane we obtained a compound which had the correct composition but twice the desired molecular mass *(2a)* in good yield:

(a): R = CH_3
(b): R = C_2H_5

The reaction with ethyldichlorophosphane took place in precisely the same way to give *(2b)*.

In the $^{31}P\{^1H\}$-NMR spectrum, *(2a)* shows a signal at −91.7 ppm, and *(2b)* one at −100 ppm[1], which both lie in the usual range for alkyldiaminophosphanes[2]. In contrast, 1,3,2λ^3,4λ^3-diazadiphosphetidines having methyl groups attached to the phosphorus and *tert*-butyl groups attached to the nitrogen, or *vice versa*, give ^{31}P shifts of −171.4 ppm or −201.7 and −281.7 ppm[3], respectively.—The ^1H-NMR spectra[1] of compounds *(2)* are complex owing to virtual H—P coupling. Compound *(2a)* exhibits approximately two quintets in the ratio 1:1; while deviation from the signal shape and intensity distribution of a quintet is only slight for the NCH_3 protons (δ = 2.95), *i.e. ca.* 1:3:4:3:1, it leads to a broad accumulation of signals in the case of the PCH_3 protons (δ = 1.41). The spectrum of *(2b)* also shows a "quintet"

($\delta = 2.87$) for the NCH_3 protons and two complex groups of signals for the PC_2H_5 protons in the ratio 3:3:2. $\{^{31}P\}$-decoupling[4] gives two singlets for *(2a)*, and one singlet for the the NCH_3 protons, a quartet for the PCH_2 protons ($\delta = 1.78$), and a triplet for the CH_3 protons ($\delta = 0.97$) in the case of *(2b)*. No change is observed in the ^1H-NMR spectrum of *(2a)* in 1,2-dichlorobenzene up to 170°C.

In the mass spectra (70 eV, 25°C) a molecular peak is observed only for *(2a)*, but an intense $(M-R)^+$ peak is seen in both cases. Further degradation leads *via* loss of $(RPNCH_3)$ units to the $(PNCH_3)^+$ ion (base peak).

On the basis of these findings the eight-membered ring structure which is unusual in cyclo(λ^3-phosphazanes) appears likely for *(2a)* and *(2b)*. It was proved by X-ray structure analysis of *(2a)*. The compound crystallizes in the tetragonal space group P4nc with $a = b = 8.775(2)$, $c = 9.920(2)$ Å; $Z = 2$. The structure was solved from 598 independent diffractometer data (512 observed) by Patterson and Fourier syntheses and refined to $R = 0.026$ (for observed reflections).

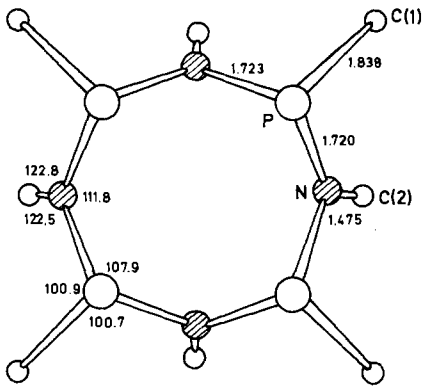

Fig. 1. Molecular structure of octamethylcyclotetra(λ^3-phosphazane) *(2a)*; bond lengths [Å] and bond angles [°].

The molecule has 4 mm (C_{4v}) symmetry to within the standard deviation; the eight-membered ring thus has the ideal crown configuration. The *P*-methyl group occupies the equatorial position, and the phosphorus lone pair the axial position. In contrast, the nitrogen lone pair is stereochemically almost inactive; the nitrogen has almost planar coordination. The structure is analogous to that of $(SNCH_3)_4$[5] except for the missing *S*-methyl groups. The P—N bond length is in good agreement with values determined for other cyclo(λ^3-phosphazanes)[6].

The eight-membered ring structure has therefore been confirmed for the first time in the cyclophosphazane *(2a)*, and it is the first P—N eight-membered ring to have the ideal crown shape. Only a strongly distorted crown has hitherto been found in *cis*-$[Cl(C_6H_5)PN]_4$[7]. All the other cyclotetra(phosphazenes) assume the boat, chair, or saddle form.

Formation of *(2a)* was recently reported during the reaction of $CH_3N(PCH_3Cl)_2$ with $(CH_3NH)_2Si(CH_3)_2$[8]; the melting point (75°C) and extreme sensitivity to hydrolysis of this product, which was isolated in only 2% yield, differ from the properties we have observed for *(2a)*.

Procedure

$RPCl_2$ (0.06 mol) and anhydrous acetonitrile (10 ml) are added to heptamethyldisilazane (0.06 mol) with stirring, water-cooling, and passage of a countercurrent of N_2. After removal of the water-bath an exothermic reaction ensues; when it has subsided the reaction mixture is heated under reflux for 15 min. At room temperature or −30°C *(2a)* or *(2b)* slowly precipitates as analytically pure colorless shiny crystals which are dried at 0.1 torr and room temperature. Yield *ca.* 50%. Relative molecular mass (osmometrically in $CHCl_3$): *(2a)* 273, *(2b)* 342. Neither compound has a sharp melting point; they both soften at *ca.* 120°C and 115°C, respectively, and finally melt at 180—185°C *(2c)* and 150—155°C *(2b)*.

Synthesis of Dinuclear Complexes Containing PCl_2 and PF_2 Bridges[1]

By *Wolfgang Malisch* and *Peter Panster*[*]

We recently synthesized transition metal-dichlorophosphanes of *(1)* and deduced a high charge density at the trivalent phosphorus from the ready oxidation of the species[1]. A further consequence of this electronic situation (transition metal substituent as donor) has now been observed in the extreme ease of addition to 6A metal-pentacarbonyl units. Reaction with tetrahydrofuran-solvated species of this kind at room temperature yields what we believe to be the first homo- or hetero-dinuclear complexes containing chlorine-substituted phosphorus bridges.

The colored compounds *(2a—c)* can be stored indefinitely in solution under N_2, are stable for a brief period when exposed as solids to the air, and decompose with evolution of $M(CO)_6$ only upon being heated to their melting point. Thus on coordinative participation of their P lone pair, the functional metallophosphanes experience a considerable inductive, and possibly also mesomeric ($d_M \rightarrow d_P$)π strengthening of the central bond system[2], with the result that the elimination of metal halide characteristic for the compounds in the free state is completely suppressed[1]. A further effect, the enhanced electrophilic character of the 5B element atom, follows from the proclivity of the fixed phosphanes to replacement in nucleophilic substitution reactions. It satisfies the requirements for controlled chlorine/fluorine replacement which always succeeds with $AgBF_4$ irrespective of the nature of the metallic center[3].

(3a—c)

Thus a clear-cut and generalizable entry is now available to PF_2-bridged complexes formerly known only in isolated cases[4].

The readily crystallizing dinuclear compounds *(3a—c)* differ from their chlorine homologs in their lower solubility. Their $Cp(CO)_3M—PF_2$ ligand can be liberated neither by thermal treatment[5] nor by the action of strongly basic phosphanes, which attack the $Cp(CO)_3M$ unit with exclusive *trans* substitution.

(4)

The constitution of *(4)* and the other bridged complexes follows from spectroscopic data (cf. Table 1). In the case of *(3c)* in particular, ^{19}F- and ^{31}P-NMR analysis of the heterospin system $^{183}W^1—^{31}P^{19}F_2—^{183}W^2$ permits characterization of the entire central bond system, all the theoretically expected couplings being detected. Without exception, positive coordination shifts $\Delta(\delta P_{complex} - \delta P_{ligand}$[1]) are calculated for the novel η^5-$C_5H_5(CO)_3M—PCl_2$ ligand system from the ^{31}P signals, the values obtained being 33 ppm (Cr), and 75 and 163 ppm, respectively, (W); owing to the *abnormal* downfield shift of *(3a)* and *(4)*, negative values of Δδ will probably have to be assigned to the still unknown fluorine analogs in the free state[6]. Cl/F exchange has only a slight effect on the frequencies of the $M(CO)_5$ stretching vibrations, suggesting a practically identical σ-donor/π-acceptor behavior of the two metallodihalophosphanes[7]. Like the magnitude of $^1J[^{31}P^{183}W(CO)_5]$[8], the frequencies also indicate strongly electropositive character of the transition metal grouping, which can also be detected by chemical means.

Procedure

(2c): A solution of $C_5H_5(CO)_3WPCl_2$[1] (1.13 g, 2.60 mmol) in THF (20 ml) is added to the THF·$W(CO)_5$ complex generated photochemically from $W(CO)_6$ (0.93 g, 2.64 mmol) in THF (70 ml). After stirring for 2 d the filtrate of the reaction mixture is evaporated *in vacuo*, unreacted $W(CO)_6$ is sublimed off, and the dark residue extracted with hot cyclohexane. Compound *(2c)* (0.94 g, 48 %) crystallizes on cooling.

(3c): $AgBF_4$ (0.83 g, 4.26 mmol) is added portionwise to a stirred solution of *(2c)* (1.58 g, 2.08 mmol) in benzene (60 ml) over 1 h at 50 °C. After completion of BF_3 and AgCl formation the mixture is filtered hot, the solvent distilled off from the filtrate *in vacuo*, and the crude product recrystallized from cyclohexane. Yield 0.91 g (60.2 %) of *(3c)*.

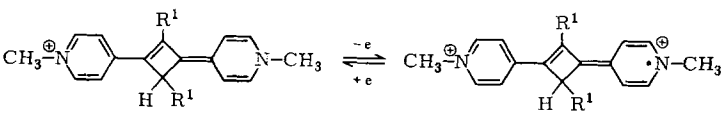
Reversible Transition between a [4]Radialene and a Cyclobutadiene by Electron Transfer[**]

By *Michael Horner* and *Siegfried Hünig*[*]

There are only few π-systems that can exist in five oxidation states which are connected by four reversible one-electron transfers[1]. In the present communication we describe the first example of such a system, in which a [4]radialene and a cyclobutadiene occur[2]. The reversible electron transfer is made possible by four *N*-substituted pyridyl moieties. The deep-red, sparingly soluble radialene *(1)* RED_c[3], which shows a typical radialene spectrum[4], serves as educt.

Voltammetric oxidation in methylene chloride/nitromethane[5] with DC, AC, and cyclic voltammetry affords similar potentials of which the CV data in particular fulfil the criteria for reversibility[6]. At +0.10 V (E_M^c) two electrons are transferred, as indicated by the doubly large current function $i_p^a/v^{1/2}$[7], compared to E_1^a and E_2^a. From the difference in the peak potentials $i_p^a - i_p^c = 30$ to 40 mV it follows that a two-stage redox system



$$(1)\,RED_c + (1)\,OX_c^{2+} \rightleftharpoons 2(1)\,SEM_c^+$$

is present with $K_{SEM}^c = 2.3 \times 10^{-1}$. Thus 19% of the radical cation *(1)* SEM_c^+ is present in the equilibrium. This small proportion of *(1)* SEM_c^+ is obviously determined by the greater thermodynamic stability of *(1)* OX_c^{2+}, which functions as *(1)* RED_a^{2+} for the following oxidation step. Despite the high sensitivity of the R = $CO_2C_2H_5$ groups on pyridinium nitrogen towards solvolysis, treatment of *(1)* RED_c in chloroform/acetonitrile with excess silver fluoroborate as oxidizing agent affords deep-blue solutions of *(1)* $OX_c^{2+} \equiv$ *(1)* RED_a^{2+}, which show a spectrum typical for cyanins with λ_{max} = 676 nm ($\log\varepsilon > 5.03$), and gradually decompose. The chromophore consists of two crossed pyridinetrimethinecyanins. In the equilibrium

$$(1)\,SEM_c^+ + (1)\,SEM_a^{3+} \rightleftharpoons 2(1)\,OX_c^{2+}/RED_a^{2+}$$

> 99.9% of the latter is present because $E_1^a - E_2^c = 0.80$ V.

The following oxidation steps are sharply separated from one another. The radical cation *(1)* SEM_a^{3+} is reached with $E_1^a = +0.88$ V. For *(1)* SEM_c^+, *(1)* OX_c^{2+}/RED_a^{2+}, and *(1)* SEM_a^{3+} the selected resonance formulae reveal that the four pyridine moieties are equivalent. A bond fixation in the sense of polyolefins and heteropolyolefins, which according to *Dewar*[8] contain practically no delocalization energy, occurs only in the case of the radialene *(1)* RED_c and the cyclobutadiene *(1)* OX_a^{4+}. For radialenes absence of delocalization has been demonstrated[9]; for cyclobutadiene a negative delocalization energy is expected because of its antiaromaticity[10]. This energy difference must be provided in the transition from *(1)* SEM_a^{3+} to *(1)* OX_a^{4+} (lifetime > 20 s). From this it follows that K_{SEM}^a is 4.5×10^9 [> 99.9% *(1)* SEM_a^{3+}]. Calculations using the potential difference $E_2^a - E_1^a = 0.51$ V and neglecting electrostatic effects yield an energy contribution of 11.8 kcal/mol as the highest value for the formation of the cyclobutadiene structure in *(1)* OX_a^{4+}. *Breslow*[11] obtained a value between 12 and 16 kcal/mol using, in part irreversible, potentials of asymmetrically substituted cyclobutadiene precursors.

(2a) RED^+ $E_a = 0.49$V R^1 =  *(2a)* SEM^{2+}

(2b) RED^{3+} $E_b = 0.69$V R^1 =  *(2b)* SEM^{4+}

That electrostatic effects play only a subordinate role is shown by a comparison of the potentials E_2^c and E_2^a of *(1)*

with the potentials E_a and E_b of equally charged cyanines *(2a)* and *(2b)*: the oxidation of the monocation *(1)*SEM_c^+ takes place at a potential about 0.41 V more negative than that of *(2a)*RED^+, that is "easier". In contrast the trication *(1)*SEM_a^{3+} is oxidized at a potential about 0.70 V more positive that *(2b)*RED^{3+}, that is essentially "more difficultly".

The precursor for the system *(1)* is *r*-1, *c*-2, *t*-3, *t*-4-tetra-4-pyridylcyclobutane *(3)*[12], which is formed in 70% yield by photodimerization of 4,4'-dipyridylethylene[13] in aqueous methanol, the solvent differing from that used in the literature procedure[14]. Quaternization of *(3)* with ethyl chloroformate and simultaneous deprotonation furnishes *(1)*RED_c in 55% yield[3].

Symmetry and Vibrational Frequencies of Dodecahedrane[**]

By *Otto Ermer*[*]

The as yet unknown dodecahedrane molecule *(1)*[11] with I_h symmetry (icosahedral group) is characterized by a very high torsional strain and a very small angle strain.

(1)

The partial conformations around all 30 symmetry-equivalent C—C bonds are exactly eclipsed, while the equivalent C—C—C and H—C—C angles (60 each) are close to the tetrahedral value. In the case of I_h symmetry all bond angles and torsion angles in the dodecahedrane molecule are fixed; they are: C—C—C 108°, H—C—C 110.9052°, C—C—C—C 0° and ±116.5651°[2], H—C—C—C ±121.7175°, H—C—C—H 0°.

The question arises, whether the minimum energy structure of dodecahedrane does in fact have I_h symmetry, or whether a deformation to lower symmetry exists leading to energetically more favorable torsion angles. Such a distortion would inevitably result in increased angle strain, since five-membered rings become non-planar, so that the average C—C—C angle is smaller than 108° and the average H—C—C angle larger than 110.9052°. Non-bonded repulsions between H atoms do not play an important role in this context at a calculated shortest H...H distance of 2.328 Å. (The calculated C—C and C—H bond lengths are 1.538 and 1.107 Å, respectively.)

We report here on force field calculations which show that the minimum energy structure of dodecahedrane indeed most likely has I_h symmetry. The decrease in torsional energy when distorting dodecahedrane away from I_h symmetry cannot compensate for the simultaneous increase in angle strain.

The problem under discussion is equivalent to the question of whether the optimum dodecahedrane geometry with I_h symmetry corresponds to a true minimum or to a partial maximum of the potential energy[2]. This may be analyzed in a straightforward manner if one applies symmetry-conserving energy optimization methods, and if one calculates the matrix **F** of the second derivatives of the potential energy with respect to the Cartesian atomic coordinates at the minimum and partial maximum, respectively. Both requirements are satisfied by the Newton-Raphson procedure. Diagonalization of the mass-weighted **F** matrix affords the vibrational frequencies and normal coordinates. If one or more imaginary frequencies result—corresponding to one or more negative eigenvalues of **F**—we are dealing with a partial maximum, otherwise with a true energy minimum.

The vibrational frequencies of dodecahedrane of I_h symmetry calculate with the aid of our previously described force field[4] are listed in Table 1. As angle deformation constants and reference angles for the methine group the values for the methylene group were used. All frequencies are real, and the dodecahedrane geometry of highest symmetry accordingly corresponds, within our force field, to a true energy minimum. Moreover, the I_h structure is fairly rigid, as expressed

by the relatively high value (395 cm^{-1}) for the lowest vibration frequency.

To establish what changes in the force field would be necessary for I_h symmetrical dodecahedrane to correspond to a partial energy maximum, *i.e.* to make less symmetrical structures energetically more favorable, we have performed a number of calculations with modified potential constants. A decrease in the C—C—C reference angle and an increase in the H—C—C reference angle has little influence, since not all angles become smaller and larger, respectively, on distortion but only the respective average values. A decrease in the angle deformation constants or an increase in the torsional constant effects the transition from the minimum to a maximum. As the relatively high value for the lowest vibrational frequency suggests, the changes in these constants necessary for the transition are absurdly large: For example, when reducing the deformation constant of the C—C—C and H—C—C angles by the same factor a decrease to about one fifth of the original values is required, when raising the torsional barrier around the C—C bonds an increase by a factor of about eight; when simultaneously reducing the angle deformation constants and raising the torsional barrier (equal changing factors) a change by a factor of about three effects the conversion from minimum to maximum. Hence we conclude that the dodecahedrane molecule has I_h symmetry.

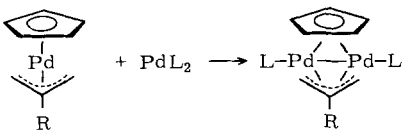
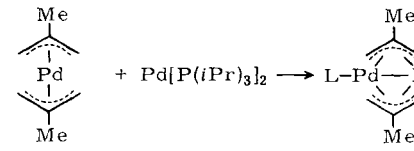
A General Method for the Synthesis of Sandwich-Type Complexes with a Pd—Pd or Pt—Pt Bond[1]

By *Helmut Werner* and *Alfred Kühn*[*]

Methods for the synthesis of metal complexes containing metal-metal bonds are still being sought after. We recently found[2] that reaction of the η^3-allyl-η^5-cyclopentadienylpalladium complexes *(1a—c)* with tertiary phosphanes or phosphites in the molar ratio 1:1 leads to dinuclear complexes having the composition $(\mu\text{-}C_5H_5)(\mu\text{-}C_3H_4R)Pd_2L_2$ *(2)*. Crystal structure analyses prove both the sandwich-like structure as well as the presence of a direct Pd—Pd single bond[2,3].

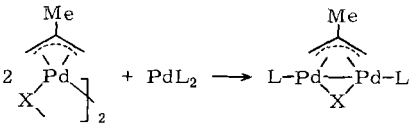


On the basis of NMR studies we had discussed the following suggested mechanism for the formation of *(2)*[4]:



The decisive step should be a nucleophilic attack of the very short-lived species PdL_2 (with $L=PPh_3$, $P(OMe)_3$ or $P(OPh)_3$) on *(1)*, leading, after reorientation of the ligand sphere, to formation of the characteristic structural element L—Pd—Pd—L.

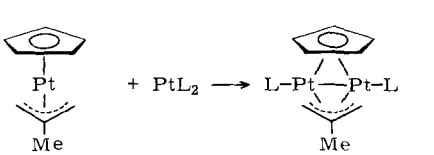
[*] Prof. Dr. H. Werner, Dipl.-Chem. A. Kühn
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)



We have now confirmed this assumption [see eq. (A)] and shown, moreover, [eqs. (B) and (C)] that dinuclear complexes with two η^3-bonded, bridge-forming allyl ligands and with one allyl ligand and one halide ion are also accessible *via* an analogous route. As reaction partner PdL_2, we used the compounds with $L=P(iPr)_3$[5], $P(tBu)_3$, and $P(C_6H_{11})_3$[6].

(1a), R = H — *(2a)*, R = H, L = $P(iPr)_3$
(1b), R = Me — *(2b)*, R = Me, L = $P(iPr)_3$
(1c), R = tBu — *(2c)*, R = tBu, L = $P(iPr)_3$
(1d), R = Cl — *(2d)*, R = Cl, L = $P(iPr)_3$
(2e), R = Me, L = $P(C_6H_{11})_3$

(3) — *(4)*, L = $P(iPr)_3$



(5a), X = Cl — *(6a)*, X = Cl, L = $P(iPr)_3$
(5b), X = I — *(6b)*, X = I, L = $P(iPr)_3$
(6c), X = Cl, L = $P(tBu)_3$

It must be mentioned that reaction of *(1d)* with PR_3 or $P(OR)_3$ in the molar ratio 1:1 does not lead to the corresponding dinuclear complexes *(2)* but to the η^1-allyl compounds $C_5H_5Pd(C_3H_4Cl)L$, which in some cases are isolable and eliminate allene with formation of $C_5H_5Pd(L)Cl$ on warming[7]. Such a C_3H_4-elimination is probably also the reason for the formation of $(\mu\text{-}C_5H_5)(\mu\text{-}Cl)Pd_2[P(iPr)_3]_2$—previously prepared by *Felkin et al.*[8] by reaction of $C_5H_5Pd[P(iPr)_3]Cl$ with Mg in THF—as a side-product in the reaction of *(1d)* with $Pd[P(iPr)_3]_2$.

Attempts to synthesize a compound of type *(2)* with $L=P(tBu)_3$ have so far proved unsuccessful. Reaction of *(1b)* or *(1c)* with $P(tBu)_3$ in the molar ratio 1:1 affords $Pd[P(tBu)_3]_2$ in 50% yield[6], which is inert toward *(1b)* or *(1c)* even at elevated temperatures.

(4) is the first example of an allyl complex in which not just a single metal atom M but an M_2 fragment is coordinated sandwich-like by two symmetrically π-bonded allyl groups. A compound of type *(6)*, $(\mu\text{-}C_3H_5)(\mu\text{-}I)Pd_2(PPh_3)_2$, has been described by *Kobayashi et al.*[9]; it was prepared from $(C_3H_5PdI)_2$ and PPh_3.

Systematic application of our knowledge about the mechanism of formation of *(2)* has also enabled the first synthesis of an analogous dinuclear complex containing a Pt—Pt bond.

(7) — *(8)*, L = $P(iPr)_3$

The rate of the reaction of *(7)* with $Pt[P(iPr)_3]_2$[6] is markedly lower than that of the reaction of *(1b)* with

$Pd[P(iPr)_3]_2$—probably because *(7)* is considerably less reactive than *(1b)*, and because the palladium complexes PdL_2 have a stronger nucleophilic character than their PtL_2 analogs.

Procedure

(2a): A solution of $Pd[P(iPr)_3]_2$ (114.4 mg, 0.77 mmol) in toluene (2.5 ml) is added dropwise with stirring to a solution of *(1a)* (56.9 mg, 0.77 mmol). The reaction mixture changes color from deep-red to orange. On cooling the solution to −30 °C orange-yellow crystals are formed. These are recovered by filtration on a G3 frit, washed with pentane, and dried in a high vacuum. M.p. 64 °C, yield 116.5 mg (68 %).—Preparation of *(2b—e)* and *(4)* analogous to that of *(2a)*; for better crystallization, however, it is recommended that some pentane be added to the toluene solution.

(6a—c): Starting materials analogous to those for *(2a)*. For isolation of the product the solvent is removed, the residue treated with pentane, and the resulting solution filtered. On cooling to −30 °C yellow crystals are obtained; these are washed with pentane and dried in a high vacuum. Yield 70—90 %.

Imidazolidin-2-ones by Anodic Oxidation of Conjugated Dienes in the Presence of Dimethylurea[1][**]

By *Herbert Baltes, Ludwig Stork*, and *Hans J. Schäfer*[*]

Conjugated dienes *(1)* can be anodically dimerized and dimethoxylated in methanol[2]. On electrolysis in acetonitrile/water, 1-acetylpyrrolines and oxazolines are formed[3]. In less nucleophilic electrolytes, dienes ought to react oxidatively with urea derivatives to give heterocyclic compounds containing two heteroatoms.

We have now found that the preparative electrolysis of *(1)* at a graphite anode in acetonitrile/sodium perchlorate in the presence of 1,3-dimethylurea *(3)* affords the 4,5-disubstituted 1,3-dimethylimidazolidin-2-ones *(4)* and *(5)* (see Table 1), presumably *via* the intermediate radical cation *(2)*.

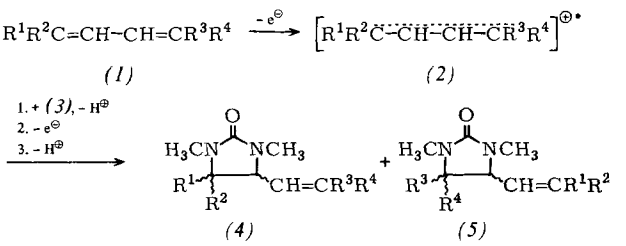

Table 1. Yields and oxidation potentials in the anodic preparation of imidazolidin-2-ones *(4)* and *(5)*.

	(1)				Anode potential E_p [a] [V]	*(4)* + *(5)* Yield [%] [b]
	R^1	R^2	R^3	R^4		
(a)	CH_3	CH_3	CH_3	CH_3	0.8—0.9	44 (50)
(b)	CH_3	CH_3	CH_3	H	1.0	39 (40 [c, d])

(e)	H	H	H	H	1.5	— [e]

[a] Against Ag/0.1 M $AgNO_3$ in acetonitrile.
[b] Isolated yields referred to current consumption; values quoted in brackets are chromatographic yields (3 % OV 225 on Chromosorb W).
[c] 15 % *(4b)* and 25 % *(5b)*, gas-chromatographically separated (15 % SE 30 on Chromosorb W).
[d] *Cis/trans* mixture (1 : 1).
[e] *(3)* (E_p = 1.68 V [a]) is oxidized more readily than *(1e)* (E_p = 2.0 V).

Procedure

(1) (0.1 mol) in an electrolyte consisting of acetonitrile (100 ml), sodium perchlorate (6.1 g) and *(3)* (0.1 mol) is electrolyzed at a graphite anode (P 127, Sigri, Meitingen) at 0 °C, a current density of 30 mA/cm², and at controlled potential until consumption of 0.1 F. Acetonitrile and unreacted *(1)* and *(3)* are distilled off. After hydrolysis with saturated sodium chloride solution the reaction mixture is extracted with ether and distilled over a short Vigreux column.

natural products. α,β-Unsaturated cyclohexenones chirally substituted at C-6 have hitherto not been synthesized. We have now found simple access to compounds *(4)*, which can be obtained in good yields under mild conditions and with only little loss of optical purity.

Achiral or chiral ketones *(1)*[1] react regioselectively with lithium diisopropylamide (LDA)[2] to give lithium enolates[3], which on reaction with trimethylchlorosilane afford the silyl enol ethers *(2)*. Sensitized photooxidation[4] of *(2)* followed by reduction of the hydroperoxides *(3)* with triphenylphosphane and subsequent methanolysis leads to formation of the ketones *(4)* (see experimental procedure and Table 1).

Formation of products *(3)* in a prototropic ene-reaction competes with two other ene-reactions, which lead to *(5)* (likewise prototropically) and *(6)* (silatropically). In the reduction step these side products are transformed into α-hydroxyketones that can readily be separated by distillation or by chromatography on silica gel (see Table 1).

Procedure:

(*R*)-6-Methyl-2-cyclohexen-1-one *(4a)* from (*R*)-2-methylcyclohexanone *(1a)*[1]: Reaction of (*R*)-2-methylcyclohexanone (3.26 g, 29.1 mmol), LDA, and trimethylchlorosilane according to Ref.[3] affords 3.58 g (19.4 mmol = 66.7%) silylenol ether [b.p. 64 to 66 °C/12 torr, $\alpha_D^{20} = +9.2°$ (1 dm, neat)]. This is dissolved in anhydrous tetrahydrofuran (140 ml) (10 mg Rose Bengal as sensitizer) in a glass Dewar flask and irradiated externally at −78 °C with two 450-W Hanovia medium pressure lamps using a 2% solution of $K_2Cr_2O_7$ as filter. Dry oxygen is passed through the enol ether solution during the reaction. On completion of reaction (established by thin-layer chromatography) triphenylphosphane (20 mmol) is added to the solution, the mixture stirred for 2 h at room temperature, and then treated with 50 ml anhydrous methanol (reaction time 14 h at room temperature). After concentration by evaporation the residue is digested with pentane, the resulting solution dried over $MgSO_4$, filtered, and the solvent removed. Distillation over quartz wool affords 6-methyl-2-cyclohexen-1-one[5] (1.49 g = 69.7%), b.p. 58 to 62 °C/12 torr.

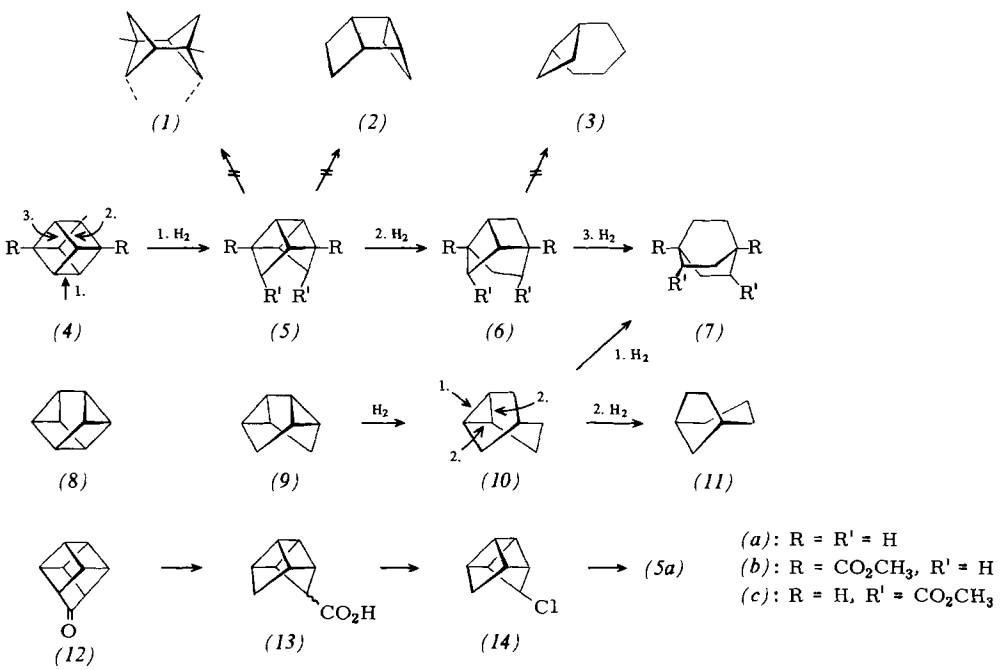
Hydrogenation of Cubane[1][**]

By *Reinhard Stober* and *Hans Musso*[*]

The high strain energy in the cubane skeleton *(4)*[2] would suggest that three C—C bonds could be hydrogenolytically cleaved under relatively mild conditions.



It has now been found that on hydrogenation of cubane *(4a)* in methanol over palladium/carbon at 20 °C and normal pressure, one mol of hydrogen is taken up in *ca.* 2 h with formation of secocubane *(5a)*, which on further uptake of hydrogen is slowly converted *via* tricyclo[4.2.0.0^{4,7}]octane *(6a)* into bicyclo[2.2.2]octane *(7a)*. Besides *(7a)* *ca.* 12% bicyclo[3.2.1]octane *(11)* is obtained, whose formation can be explained in terms of a rearrangement of *(4a)* to the cuneane *(8)* and of *(5a)* to the secocuneane *(9)* and their hydrogenation[3]. The separate hydrogenation of *(5a)* leads, *via* at least three gas-chromatographically recognizable intermediates, likewise to *(7a)* and *(11)* in the ratio 4:3. Dimethyl cubane-1,4-dicarboxylate yields, *via* only one dihydro- and one tetrahydro intermediate [*(5b)* and *(6b)*, respectively] pure bicyclo[2.2.2]octane-1,4-dicarboxylic ester *(7b)*[4], while the *endo,endo,endo*-secocubane ester *(5c)* affords the 2,5-dicarboxylic ester *(7c)* *via* *(6c)*. With Pd/C, *(4b)* does not yield *(7c)*, whereas with Pt in glacial acetic acid *(7b)* together with small amounts of *(7c)* are observed. Tricyclo[3.1.1.1^{2,4}]octane *(1)*, tricyclo[4.2.0.0^{2,5}]octane *(2)*, and bicyclo[4.2.0]octane *(3)* and corresponding dicarboxylic esters could not be detected in any of the reactions.

From these findings it can be concluded that the diester *(4b)* is attacked by hydrogen specifically at a non-substituted C—C bond on Pd/C, and that in the secocubane derivatives *(5a)* to *(5c)* the C—C bonds 2 and 3 inclined opposite to the already open bond 1 and common to two four-membered tings are cleaved. Thus the cubane skeleton also follows the empirical rules found for the hydrogenolysis of other cage compounds with small rings[5] and based on calculated enthalpies of formation ΔH_f^0 and strain energies SE (in kcal/mol)[6]:

	ΔH_f^0	SE
(1)	64.5	93.7
(2)	50.3	79.5
(3)	−4.4	30.7
(4)	148.6	165.9
(5)	88.9	112.0
(6)	32.9	62.1
(7)	−22.2	13.0
(11)	−23.0	12.1

Specifically those bonds are opened which afford the greatest relief of strain.

Secocubane *(2a)* was prepared by cleavage of homocubanone *(12)* with potassium *tert*-butoxide in THF/H_2O to the *exo-endo*-mixture of the carboxylic acids *(13)*[7], Grob degradation[8] to the *exo*-chloride *(14)* and dehalogenation[9]; m.p. 101—103 °C; ^{1}H-NMR ($CDCl_3$): qi 3.29 (2H, J = 3 Hz), m 3.04 (4H), d 2.43 (*endo* 4-H, 7-H, J = 10 Hz), m 2.15 (*exo* 4-H, 7-H); ^{13}C-NMR ($CDCl_3$): 25.9, 40.1 and 47.2 ppm. The hydrogenation products were identified by gas-chromatographic and spectroscopic comparison with authentic samples: *(6a)*[10], *(6c)*[11], *(7b)*[12], *(7c)*[13].

Crystallographic Analysis of a Topochemical Polymerization

By *V. Enkelmann* and *G. Wegner*[*]

Macroscopic single crystals[1] of polymer are formed from suitably substituted diacetylenes by topochemical polymerization. The polymerization is initiated thermally or by irradiation. Since polymerizable diacetylenes polymerize extremely rapidly on irradiation with X-rays, only structural data for the polymers[2] or for the inactive monomers[3] have thus far been available.

(1) *(2)*

We have now succeeded in elucidating the structure of a polymerizable diacetylene, hexa-2,4-diyne-1,6-diyl-bis-*p*-toluenesulfonate *(1)*, by recording X-ray data at 120 K. Since the structure of the corresponding polymer *(2)* at 120 K was also solved recently, the coordinates of each of the individual atoms before and after the reaction are now known.

For the three-dimensional X-ray structure analysis we used crystals of *(1)* which had been crystallized from acetone. The intensity data were collected by equi-inclination Weissenberg photographs (multifilm technique) at 120 K and the intensities determined by visual estimation. During the time necessary for recording a photograph the conversion never exceeded 5 %. A new monomer crystal was employed for each photograph. 1450 independent reflections were evaluated. Crystallographic data of the monomer at 120 K: $a = 1490(1)$, $b = 511.0(5)$, $c = 2602(4)$ pm, $\beta = 92(1)°$; space group $P2_1/c$. As in the case of the low-temperature form of the polymer *(2)*[4] the asymmetric unit consists of two independent molecules. The structure was solved by direct methods[5] and refined by the method of least squares (full matrix). The isotropic refinement was terminated at an R factor of 10 %.

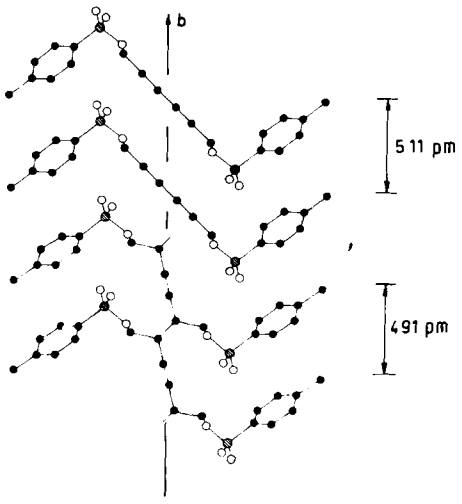

Fig. 1. Projection of neighboring molecules of *(1)* (above) and *(2)* (below) onto the plane of the main chain.

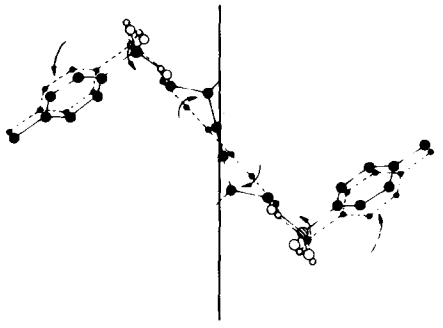

Fig. 2. Change of position of atoms on polymerization (projection of the monomer structure—dotted—onto that of the polymer).

Figure 1 shows a projection of neighboring molecules of the monomer and of the polymer in the low-temperature form on the plane of the main chain. During polymerization the length of the stacking axis b falls from 511 to 491 pm. The difference of 20 pm per addition must be accommodated by the monomer lattice, since no phase separation is observed. Projection of the monomer structure onto that of the polymer is illustrated in Figure 2. Besides the expected shifts of the coordinates of the atoms forming the main chain, shifts and rotations of the side groups are also observed whose contribution to the total mechanism of the polymerization was previously not taken into consideration[6].

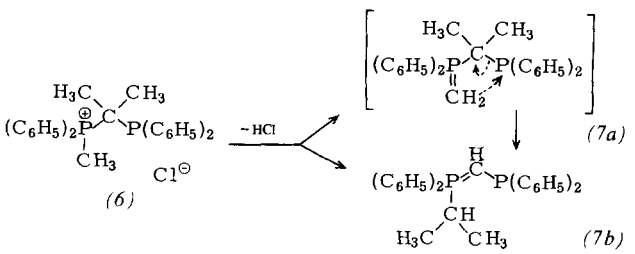
"Carbodiphosphoranes" by a New Rearrangement of Phosphorus Ylides



By *Anette Wohlleben* and *Hubert Schmidbaur*[*]

On account of their synthetic potential in organic chemistry[1], their particular ligand properties in metal complexes[2], and their unusual physicochemical properties (triboluminescence, crystal structure)[3], "carbodiphosphoranes" $R_3P{=}C{=}PR_3$ attract current interest[4].

The aryl-substituted compounds, which are usually bright yellow (*e.g. (2a)*), are formed with surprising ease on deprotonation of the conjugated phosphonium salts *(1)*; thus it is impossible to obtain the isomeric methylenebisphosphoranes (*e.g. (2b)*) in this way. In order to force deprotonation in the peripheral alkyl groups we have prepared a phosphonium salt *(3)* which is completely alkylated at the central $^{\oplus}P{-}C{-}P^{\oplus}$ bridge; this would be expected to rule out formation of a carbodiphosphorane.

However, in this case too we did not obtain the bisphosphorane *(4)* which appeared promising as a double ylide ligand; instead the carbodiphosphorane *(5)* was unexpectedly formed. In order to gain a clearer view of the reaction course, which seems to be complicated by extensive rearrangement, the monophosphonium salt *(6)* was also synthesized and subjected to the action of strong bases. A deep yellow ylide is formed which again does not have the structure *(7a)* but *(7b)* instead:

The structures of *(5)* and *(7b)* have been confirmed by elemental analysis and ^1H-, ^{13}C-, and ^{31}P-NMR spectra. As suggested in the formula [*(7a)*→*(7b)*], the mechanism of the hitherto unobserved rearrangement is to be interpreted in terms of nucleophilic attack by the ylidic carbanion in *(7a)* on the second P atom, whereupon the PCP bridge weakened by steric interaction opens at this P atom. A proton shift from the new PCH_2P bridge to the α-C atom of the concomitantly formed isopropylidene group completes the process, which can be formulated appropriately for the formation of *(5)* from *(3)*. Such prototropic processes in ylides are known and have already been carefully studied[5]; not so the ready P—C—P cleavage. The results imply that rearrangements can also be expected in the case of analogously configurated phosphorus compounds in other systems[6].

Procedure:

(3)→*(5)*: Reaction of methylenebis(diphenylphosphane) (1.75 g, 4.25 mmol) and methyl iodide (excess, 5 ml) in a sealed tube (2 d at 40 °C) affords compound *(3)*, yield 2.0 g (68 %), m.p. 283 °C.—^1H-NMR (CD_3OD; δ [ppm], J [Hz]): δCH_3P 2.8, d, 6H, *J*(HCP) 12.5; δCH_3C 2.0, t, 6H, *J*(HCCP) 16.0; δC_6H_5 7.9, m, 20H.

Methylenetrimethylphosphorane (1.44 g, 1.60 mmol) is added to *(3)* (0.56 g, 0.80 mmol) in ether (10 ml) and the yellow mixture stirred for two hours. After tetramethylphosphonium salt has been filtered off, the solution is concentrated, extracted with *n*-hexane, and crystallized. Yield 0.23 g (65 %) of *(5)*, m.p. 103 °C.—^1H-NMR (C_6D_6): δCH_3P 1.0, d, 3H, *J*(HCP) 12.0; δCH_3C 0.6, dd, 6H, *J*(HCCH) 7.0, *J*(HCCP) 16.0; δCH 2.0, m, 1H; δC_6H_5 8.0, m, 20H. ^{13}C-NMR (C_6D_6): δCH_3P 20.85, d, *J*(PC) 57.4; δCH_3C 17.9, s; δCH 28.45, d, *J*(PC) 66.2; δC 1.04, dd, *J*(PC) 122 and 128. ^{31}P-NMR (C_6D_6): δP 5.03 and −17.8, AB, *J*(PCP) 88.

(6)→*(7b)*: CH_3Cl (10 ml) is condensed onto $[(C_6H_5)_2P]_2CH_2$ (4.1 g, 10 mmol) dissolved in THF (20 ml) in a sealed tube. Heating (50 °C, 2 d) gives rise to *(6)* (3.8 g, 82 %), m.p. 185 °C.—^1H-NMR ($CDCl_3$): δCH_3P 2.8, d, 3H, *J*(HCP) 12.5; δCH_3C 1.70, dd, 6H, *J*(HCCP) 18.5 and 7.5; δC_6H_5 8.1, m, 20H. ^{31}P-NMR (CD_3OD): δP 3.7 and 31.8, AB, *J*(PCP) 73.

Finely powdered NaH (0.24 g) is added portionwise to a suspension of *(6)* (1.93 g, 4.2 mmol) in THF (30 ml). After 4 d at 20 °C the mixture is filtered, concentrated, extracted with *n*-hexane, and crystallized. Yield 0.93 g (52 %) of *(7b)*, m.p. 83 °C.—^1H-NMR (C_6D_6): δCH_3 1.10, dd, 6H, *J*(HCCH) 7.0, *J*(HCCP) 16.3; δCHC_2 2.60, m, 1H; δCH=P 1.60, dd, *J*(HCP) 1.5 and 10.4; δC_6H_5 7.9, m, 20H. ^{13}C-NMR (C_6D_6): δCH_3 16.7, s; δCHC_2 26.3, d, *J*(PC) 61.0; δCP_2 2.5, dd, *J*(PC) 9.8 and 114.7; δC_6H_5 131.7, m. ^{31}P-NMR (C_6D_6): δP 20.0 and 29.5, AB, *J*(PCP) 136.

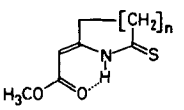
Reaction of Monothiodicarboximides with Phosphorous Ylides: A New Synthesis of ω-Alkylidenelactams[**]



By *Albert Gossauer, Ralf-Peter Hinze*, and *Harald Zilch*[*]

In the course of our work on the synthesis of bile pigments we found that the substituted monothiosuccinimide *(1)* reacts regioselectively with the phosphorane *(2)* in boiling toluene, yielding the 5-alkylidene-2-pyrrolidinone *(3)* in 79 % yield[1].

On the basis of this result, we have examined the reactivity of some cyclic monothiodicarboximides towards the phosphorous ylide *(5)* as a typical resonance-stabilized Wittig reagent. The five- to seven-membered monothiocarboximides *(4)*, $n = 1$—3, were found to give the corresponding alkylidenelactams *(6)*[2] (cf. Table 1)[3]. As their N—H stretching frequencies are independent of concentration, and hence characteristic for intramolecular bonding, the *Z*-configuration has been assigned to the products *(6)*.

In addition to *(6)* the corresponding alkylidenethiolactams *(7)*[2] are obtained as by-products in yields between 4 and 14 %, the reaction of monothioglutarimide being less regioselective than those of the corresponding five- and seven-membered homologs.

Most likely, formation of the alkylidenelactams *(6)* takes place by a reaction analogous to the Wittig olefin synthesis involving the C=S bond (cf. [4]).

Table 1. Alkylidenelactams *(6)* [2] from monothioimides *(4)*.

	Reactant *(4)*		Products *(6)* [a]		
n	M.p. [°C]	Yield [b] [%]	Yield [c] [%]	M.p. [°C]	$\tilde{\nu}_{N-H}$ [d] [cm^{-1}]
1	111—113 [e]	66	58	57—58	3355
2	118—119 [f]	45	43	48—49	3275
3	43—44	51	39	—	3230

[a] Purified by preparative TLC on silica gel with ether/*n*-hexane as eluent and subsequent crystallization from ether/*n*-hexane. [b] In boiling toluene for 20 h. [c] In boiling xylene for 4 h. [d] 6.0, 3.0, 1.2, and 0.6×10^{-2} M in CCl_4. [e] Lit. value [5]: 112—114 °C. [f] Lit. value [5]: 118—119 °C.

Preparation of the monothioimides (4):

The cyclic dicarboximide[6] (0.04 mol) is dissolved in ethanol (40 ml) and silver carbonate (prepared from 10 g $AgNO_3$ and 4 g anhydrous Na_2CO_3) is added. The mixture is heated under reflux until the formation of carbon dioxide is complete. The resulting silver salt of the imide is separated by filtration, dried, and suspended in ethyl iodide (30 ml). After the mixture has been heated for 2 h under reflux, the silver iodide which separates is filtered off, and the filtrate concentrated to dryness by evaporation of the solvent. The remaining readily hydrolyzable lactim ether is dissolved without purification in dry pyridine (20 ml), and hydrogen sulfide (dried over Al_2S_3) is introduced into the solution for 1 h. The product obtained after removal of the solvent is purified by chromatography on silica gel with CH_2Cl_2 as eluent.

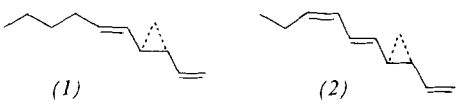
Reviews

Abstracts of selected progress reports and review articles

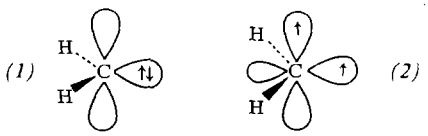


The uses of bicyclo[3.2.0]heptanones *(1)* **in organic syntheses** are surveyed by *S. M. Ali, T. V. Lee,* and *S. M. Roberts. cis*-Condensed bicyclics *(1)*, especially the readily accessible bicyclo[3.2.0]heptan-2-ones *(1a)* and -6-ones *(1b)* react differently, depending upon the nature and position of the substituents. The most appropriate synthesis of *(1a)* is by photoannelation of 2-cyclocyclopentenone and alkenes, *e.g. (2)*, and that of *(1b)* consists in the regiospecific cycloaddition of ketenes (subject to extensive variation) to cyclopentenes, *e.g.* cyclopentadienes. Fragmentation reactions of *(1)* and simple unsaturated derivatives in many cases require modifica-

tions of the molecule which can frequently be accomplished stereoselectively (*e.g.* reduction of bicyclo[3.2.0]hept-6-en-2-one *(3)* with $LiAlH_4$ to give the *endo* alcohol; bromination of *(3)* to give 2-*exo*,3-*endo*-dibromobicyclo[3.2.0]heptan-6-one). Cleavage of the C^1—C^5 bond of *(1)* by heating or by acid treatment leads to seven-membered ring systems (synthesis of tropolone and β-thujaplicin). Opening of the four-membered ring of *(1)* gives cyclopentane derivatives, including precursors of prostaglandins; opening of the five-membered ring gives cyclobutane derivatives. Other bicyclic ring systems are obtained by rearrangements. [The Use of Bicyclo[3.2.0]-heptanones as Versatile Synthons in Organic Chemistry. Synthesis *1977*, 155—166; 70 references]

[Rd 945 IE—M]

Volatile compounds from seaweeds are surveyed by *R. E. Moore.* The odor of brown seaweed *(Dictyopteris divaricata)* is due to non-isoprenoid C_{11} hydrocarbons; apart from the principal components *(1)* and *(2)*, undecatrienes and -tetraenes and



substituted cycloheptadienes also occur. The edible red seaweed *Asparagopsis taxiformis* contains chlorinated, brominated, and iodinated hydrocarbons, ketones, alcohols, and carboxylic acids, among other compounds. It may well be that the chloroform and carbon tetrachloride present in traces in the upper atmosphere and in drinking water arise from such algae. [Volatile Compounds from Marine Algae. Acc. Chem. Res. *10*, 40—47 (1977); 58 references]

[Rd 947 IE—L]

Analysis of the soil atmosphere by gas chromatography is considered by *K. A. Smith.* Apart from the usual components of air, various other compounds were detected, including NH_3, NO, NO_2, H_2S, CS_2, organosulfur compounds, H_2, hydrocarbons (C_2 to C_4), and other organic compounds such as volatile fatty acids, aldehydes, alcohols, and ketones. These substances are produced by roots or soil bacteria. Changes in the concentration of biologically active gases such as O_2 and CO_2 can affect plant growth and biological processes in the soil.—In addition the fate of gases such as brominated hydrocarbons in the soil is also examined. [Gas-Chromatographic Analysis of the Soil Atmosphere. Adv. Chromatogr. *15*, 197—231 (1977); 112 references]

[Rd 946 IE—F]

CIDNP studies on carbene reactions are reviewed by *H. D. Roth.* It could be shown by this method, for example, that singlet carbenes [type *(1)*], which only react *via* insertion with C—H bonds, can also undergo abstraction reactions, abstracting preferentially chlorine from chlorohydrocarbons, whereas triplet carbenes [type *(2)*] preferentially abstract

hydrogen. It was also established that the photosensitized decomposition of some diazo compounds which proceeds *via* carbenes is accompanied by energy transfer. [Chemically Induced Nuclear Spin Polarization in the Study of Carbene Reaction Mechanisms. Acc. Chem. Res. *10*, 85—91 (1977); 45 references]

[Rd 948 IE—L]

The proteinase inhibitors of plants and microorganisms is the title of a survey by *M. Richardson.* The article deals with the specificity, distribution, and occurrence of these proteins, and with modern procedures for their isolation. Homologies in the amino acid sequences and details of the reactive sites are compiled. There follow an account of experiments for intracellular localization of protein inhibitors and a description of the physiology and biological function of these substances. Their role in nutrition, in therapy, and in the laboratory are considered in conclusion. [The Proteinase Inhibitors of Plants and Microorganisms. Phytochemistry *16*, 159—169 (1977); 159 references]

[Rd 949 IE—R]

Phenomena of oscillation in biological systems are the subject of a symposium reported by *A. Boiteux, B. Hess, Th. Plesser,* and *J. D. Murray.* Although there are numerous periodic processes in living systems, only few of them can be attributed to the function of only one or just a few enzymes. Theoretical and experimental analysis show that a temporal and spatial organization rests on the following prerequisites: autocatalysis, network feedback of the enzymatic reactions, and a pronounced distance from equilibrium. [Oscillatory Phenomena in Biological Systems. A Meeting Report. FEBS Lett. *75*, 1—4 (1977)]

Propellanes. Structure and Reactions. By *D. Ginsburg*. Monographs in Modern Chemistry, Vol. 7. Edited by *H. F. Ebel*. Verlag Chemie, GmbH, Weinheim 1975. 1st Edit., viii, 272 pp., *ca.* 600 formulas, bound DM 138.—.

Ten years of propellane chemistry—is that a reason for writing a book about it? The author himself gives the best reply: the monograph is written so well that the question never even occurs to the reader.

A pioneer in this field of research, *Ginsburg* reports on the worthwhile results of 365 publications that appeared up to 1974. In this he covers a wide field and makes it convincingly clear why propellanes are the ideal molecules for studying many types of problems (bond fluctuation, aromaticity, homoconjugation, stereoelectronics, ring strain, dualism of photoinduction and thermal excitation, conservation of orbital symmetry, *etc.*). The reader finds all that is worth knowing about the synthesis, structure, and reactions of this fascinating class of substances. The book offers at the same time a glimpse into the preparative organic laboratory, for experimental details are discussed in detail when they are necessary for an understanding of the problem.

The particular attraction that endows this book with exceptional status is the courage repeatedly to leave pure chemistry aside. The marginal comments scattered here and there display a personal style and provide intellectual satisfaction.

The book contains an unusually large number of structural formulas; reading at a glance is thus made much easier. (That a few printing errors have crept in can be forgiven in a first printing.)

The book has given the reviewer valuable pointers for his own research. For those interested in alicyclic chemistry it is a true mine of information. Anyone new to the subject itself but finding pleasure in an elegantly formulated and highly stimulating text will also find his money well spent.

Günther Maier [NB 376 IE]

Isoelectric Focusing. Edited by *N. Catsimpoolas*. Academic Press, New York—London 1976. 1st Edit., xii, 265 pp., bound, $ 23.50.

The intention behind this work has been to validate the vigorous development of the isoelectric focusing(IF) method and to report new variants and the present state of knowledge. The book is aimed at users of the method who require an introduction and/or more information about it.

A defined individual theme is treated in each of the nine chapters. The authors are experts in their field who can provide valuable indications for the uses of IF from their own experience.

After a highly interesting review of the history and the future prospects of IF, with a brief description of the physical principles (*A. Kolin*), detailed theoretical-mathematical considerations of the method are given in Chapter 2 (37 pp., *H. Rilbe*). There follows a section on carrier ampholytes (*O. Vesterberg*), which outlines *inter alia* their synthesis and physicochemical properties and contains indications of the biological and biochemical aspects (*e.g.* interaction with proteins). In three further chapters the application of IF to gel-stabilized carrier systems is described. There is a general presentation of the technique (*A. Chrambach* and *G. Baumann*), and special mention must be made of the description of two-dimensional working (combination of gel electrophoresis with IF) in Chapter 5 (*C. W. Wrigley*) and of the comprehensive treatment of the preparative application of IF in granulated gels (Chapter 6, 48 pp., *B. J. Radola*). In these last two contributions precise experimental details are given together with numerous examples of separations. A section on its own (*J. Bours*) is devoted to IF in free solution, and there critical indications can be found about evaluating separation results (artefacts). Specialized applications are continuous working (Chapter 7, *J. S. Fawcett*) and "Trans-IF" (Chapter 9, *N. Catsimpoolas*); both these make great demands on apparatus.

The book makes no claim to comprehensive treatment of its theme and the numerous techniques, yet it provides much useful information.

Kurt Hannig [NB 374 IE]

Mikrobiologie (Microbiology). Vol. 13 of the further education series "Medizin und Werbung". By *H. Nolte*. Karl Demeter Verlag, Gräfeling 1976. 1st Edit., 78 pp., DM 11.80.

According to the publishers, this further education series is intended to provide essential basic information. This must be taken with a pinch of salt, for one cannot expect miracles in a booklet of 41 pages of text. On delving into the work, however, one cannot fail to wonder at the way in which the "basic information" has been presented. In the clumsily and unscientifically written and arbitrarily assembled sections on general and medical microbiology factual errors and unnecessary verbiage just about balance each other. A section "Metabolism of Bacteria" that is devoted exclusively to an extremely vague description of alcoholic fermentation in yeasts (!) and the statement that metabolites are the substances (enzymes, hormones, vitamins!) responsible for trouble-free occurrence and control of metabolism speak for themselves. Technical terms, if used at all, are not explained. In four pages of suspect hand-drawings the bacterial cell enjoys a representation in which an enzyme is sketched in (!)—it is presumably a mesosome, for the indicating arrow for "nuclear substance" points to an empty space. Five pages of terminology include, *inter alia*, DNA = complex, high-molecular protein, RNA = ribose = pentavalent sugar, cytoplasm = living substance of the cell = semifluid fine-grained mass. Finally in 26 pages of "programmed learning" one is invited to check what beauties one has retained from the text. For example, one must fill in that plants form carbohydrates from CO_2 by photosynthesis (= formation of chlorophyll with the aid of light energy).

The reviewer cannot recommend this pamphlet (indeed, must advise against reading it), and must contradict the author in at least the one point where he states that everything in nature has its sense.

Hans Bender [NB 373 IE]

Anorganisches Grundpraktikum (Basic Practical Course in Inorganic Chemistry). By *C. Mahr* and *E. Fluck*. Verlag Chemie, GmbH, weinheim 1976. 5th completely new, revised edition, XI, 460 pp., 84 figs., 6 tables, paperback, DM 39.80.

This book is divided into three parts. The first of these introduces experimental methods and apparatus by means of experiments and explanations, and the fundamental laws of chemistry in aqueous solutions are treated: 1. Conductivity of electrolyte solutions, indicators, neutralization, *etc.*; 2. Chemistry of complexes; 3. Solubility product; 4. Redox potentials, galvanic cells, electrolysis, *etc.*; 5. Reaction rate, catalysis.

In the second part the authors turn to the preparation, reactions, and detection of nonmetals and their compounds and ions, and then to the properties and reactions of the

most important oxidation states of metal cations. The nonmetals are arranged according to their position in the periodic system and the metals according to the methods of separation used in classical qualitative analysis. The separation of cationic groups is described in detail. In addition, this part of the book contains prescriptions for the preparation of nonmetals, their compounds, and complexes and further theoretical chapters (chemical bonding, paper chromatography, ion exchangers, adsorption, acid-base theory, spectroscopic analysis, and chemistry of complexes).

The third part covers the most important analytical reactions with organic reagents. Procedures differing from the classical methods for the separation of cations on semimicroscale are then proposed, in which reactions and crystallization are studied in drops under a microscope. In addition, a paper-chromatographic separation of the classical cationic groups is described. The anions are detected in mixtures by special reactions.

The Brønsted acid-base definition is used for reactions in aqueous systems and the Lewis acid-base system for reactions in molten salts. The many well-chosen experiments are described in detail and their theory is thoroughly explained; some of them are explained with the aid of illustrations, so that the student can carry out the work on his own. The general chapters with carefully selected experiments give a good review of the theoretical principles and the most important procedures. The well subdivided, clearly written book therefore can be recommended as an introductory practical chemistry text suitable for chemists and students of natural sciences.

Claus Hadenfeldt [NB 371 IE]

Applications of Mössbauer Spectroscopy. Vol. I. Edited by *R. L. Cohen*. Academic Press, Inc., New York 1976. 1st Edit., xi, 349 pp., illustrated, bound $ 2450.

Although it is only just over 15 years ago that *Rudolf Mössbauer* discovered the recoilless emission and absorption of gamma quanta by atomic nuclei, Mössbauer spectroscopy has become an important tool for investigations in a wide range of fields. The present first volume in a series devoted to its applications deals primarily with the results in metallurgy, solid-state chemistry, and the chemistry and biochemistry of colloids and surface boundaries. Following a brief introduction by the editor to the underlying physical principles, *L. H. Schwartz* looks critically at the extensive literature on Mössbauer-spectroscopic investigation of the phase changes in iron alloys. The method's application to the study of corrosion phenomena is dealt with by *G. W. Simmons* and *H. Leidheiser, Jr.* The special experimental technique required for biochemical research is given an illuminating description by *G. Lang* in a section leading into the chapter on biological studies. Two further sections provide information about experiments on the biological transport of iron, on structural questions concerning iron-containing storage compounds (*W. T. Oosterhuis* and *K. Spartalian*), and on measurements in enzyme systems (*P. G. Debrunner*). The final chapter is divided into four sections dealing with reactions in the solid state (*P. K. Gallagher*), analysis of archaeological artefacts (*A. Kostikas, A. Simopoulos*, and *N. H. Gangas*), examination of works of art (*B. Keisch*), and some applications in the field of polymer science (*V. I. Goldanskii* and *L. A. Korytko*). All the contributions are characterized by their critical treatment of the material. Admittedly much of the material has already been covered in earlier review articles, but with the ever-increasing difficulty in following the wealth of literature this volume will prove a valuable aid to all who wish to become familiar with Mössbauer spectroscopy.

The Wittig Reaction in Industrial Practice[**]

By Horst Pommer[*]

Dedicated to Professor Georg Wittig on the occasion of his 80th birthday

The effects of a scientific discovery on industrial practice are illustrated with reference to the Wittig reaction. The aim of utilizing the Wittig reaction for linking terpenoid building blocks to give vitamin A and carotenoids on an industrial scale prompted extensive research and development work of a synthetic and chemical engineering nature. The importance of the Wittig reaction and its variants in the synthesis of active compounds and fine chemicals in industrial research is demonstrated in the present article.

1. Discovery of the Wittig Reaction

Shortly after World War II, *Wittig* directed his attention to the question of the existence of pentavalent nitrogen compounds and discovered, in the course of these studies, the nitrogen ylides of type *(1)*[1].

Formation of the nitrogen ylides *(1)* was proved by addition to benzophenone *(2)* to give the (2-hydroxy-2,2-diphenylethyl)trimethylammonium salt *(3)*.

$$(CH_3)_4\overset{\oplus}{N}Hal^{\ominus} + C_6H_5Li \longrightarrow C_6H_6 + \underset{(1)}{(CH_3)_3\overset{\oplus}{N}-\overset{\ominus}{C}H_2} + LiHal$$

$$\underset{(1)}{} + \underset{(2)}{(C_6H_5)_2C{=}O} \xrightarrow{HX} \underset{(3)}{(C_6H_5)_2C(OH)-CH_2-\overset{\oplus}{N}(CH_3)_3X^{\ominus}}$$

Wittig's studies were always highly systematic, and it was therefore only a matter of course that the investigations carried out on nitrogen would be repeated with the next higher element of Group V, phosphorus. The declared aim of this work was stated, in a 1953 publication with *Geissler*[2], to be the preparation of stereoisomers of pentaphenylphosphorus as

48 *Wittig und Geissler*

Überraschend war das Verhalten von V gegenüber Benzophenon. Bei dieser Umsetzung wurden Triphenyl-phosphinoxyd (etwa 80%) und 1,1-Diphenyl-äthylen (84%) vom Schmp. 5—6° (Mischprobe) gewonnen. Danach hat sich die Methylengruppe gegen den Sauerstoff des Ketons vielleicht über den Vierring VI:

$$(C_6H_5)_3P{=}CH_2 + O{=}C(C_6H_5)_2 \longrightarrow \underset{VI}{(C_6H_5)_3P(-CH_2)-O-C(C_6H_5)_2} \longrightarrow (C_6H_5)_3\overset{(+)}{P}-\underset{(-)}{O} + CH_2{=}C(C_6H_5)_2$$

ausgetauscht;

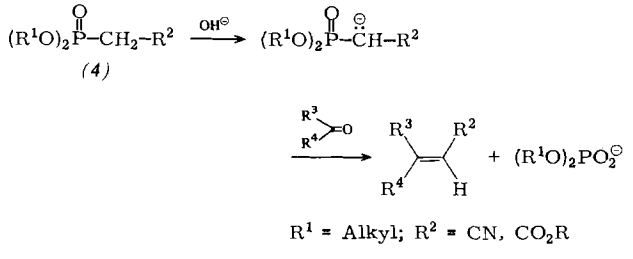
Fig. 1. The Wittig reaction; facsimile of the first publication [2].

[*] Prof. Dr. H. Pommer
BASF Aktiengesellschaft
D-6700 Ludwigshafen/Rh. (Germany)

[**] Based on an address delivered on the occasion of Prof. *Wittig*'s 80th birthday.

representatives of a new class of compounds. This work led to the first synthesis of crystalline methylenetriphenylphosphorane. When it was attempted to add this product to benzophenone (by analogy with *(1)*) a surprising new reaction was observed. In a total of six lines of text, *Wittig* and *Geissler* described the almost quantitative conversion of methylenetriphenylphosphorane with benzophenone to give triphenylphosphane oxide and 1,1-diphenylethylene (Fig. 1).

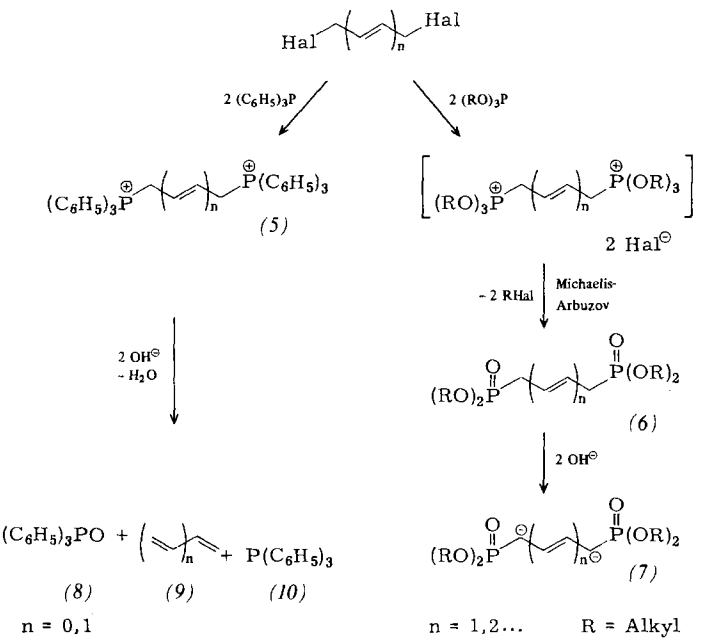
This reaction has since become general chemical knowledge as the Wittig reaction, or Wittig olefination, and it influenced the development of synthetic organic chemistry in the following years to an almost unparalleled degree. It initiated creative activity in laboratories throughout the world as the challenge was taken up to establish the preparative potential of the reaction, to study its mechanistic aspects, *e.g.* its stereochemistry, or to investigate its effects on neighboring disciplines.



2. The Wittig Reaction and Its Variants in Industrial Practice

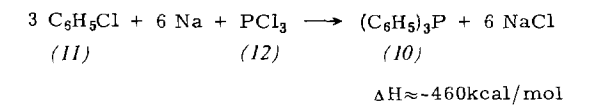
2.1. Process Simplification

The traditionally close contacts between the chemistry departments of German universities and the chemical industry led to the very early use of the Wittig reaction in industrial practice. At the beginning of the 1950's, when research at BASF was directed toward the development of syntheses for vitamin A and β-carotene, *Wittig* revealed the new reaction he had discovered in discussions with *Reppe* and *Pommer*. Its significance for the synthesis of compounds of the aforementioned kind was quickly recognized. Studies were immediately undertaken with the aim of utilizing the new reaction for an industrial-scale synthesis of unsaturated compounds, specifically vitamin A and carotenoids.



Simple though the reaction is in the laboratory, its translation to an industrial scale was fraught with difficulties, especially when the stringent criteria of safety and economics were taken into account. Other proton acceptors had to be found instead of the originally used organolithium compounds which are consumed in a molar ratio of 1:1; industrially acceptable solvents also had to be found. A further task was to develop an industrial synthesis of triphenylphosphane, which is also consumed in a molar ratio of 1:1 and leaves the reaction as triphenylphosphane oxide[4].

The question arose whether the Wittig reaction is limited to the use of triphenylphosphane. Other phosphorus derivatives were investigated at an early stage with the aim of simplifying the practical application of the Wittig reaction. *Wittig*'s co-workers[5] examined aryl phosphites, while at BASF *Pommer* and *Stilz* concentrated on alkyl phosphites, whose adducts with alkyl halides rearrange to phosphonates



in a Michaelis-Arbuzov reaction[6]. The latter authors found that phosphonates *(4)*, like alkylidenephosphoranes, can be subjected to olefination, and set down the results of this work in a number of patent applications[7].

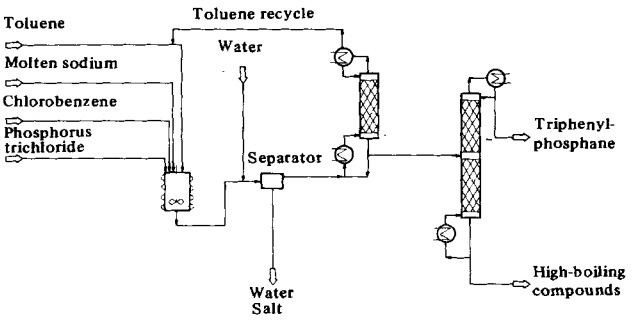
Working independently, *Horner et al.*[8] found this reaction to proceed with phosphane oxides and were the first to publish a report. Today this reaction is known as PO-activated olefination or the Wittig-Horner reaction. It is particularly useful as a variant of the Wittig reaction when the carbanion generated from the phosphonate *(4)* is resonance-stabilized by neighboring electron-withdrawing groups such as carbonyl, carboxylate, nitrile, or phenyl groups[9]. The activated phosphonic esters *(4)* can be deprotonated under mild conditions; thus aqueous alkali suffices to transform the alkoxycarbonyl or cyanomethylenephosphonates into the carbanions required for olefination[7]. Behavior deviating from that of triphenylphosphoranes is observed with the dianions *(7)* of vinylogous α,β-bisphosphonates, which can easily be prepared and subjected to double olefination; in contrast, the bis(triphenylphosphonium) salts *(5)* decompose to triphenylphosphane oxide *(8)*, olefin *(9)*, and triphenylphosphane *(10)* with alkali[10].

2.2. Production and Regeneration of Triphenylphosphane

The Wittig reaction of triphenylphosphorus ylides proves superior to PO-activated olefination when applied to compounds with alkyl groups or containing terpenoid hydrocarbon moieties. Hence the Wittig reaction became the preferred method for the production of vitamin A. For this reason,

the long-known synthesis of triphenylphosphane *(10)* from chlorobenzene *(11)*, sodium, and phosphorus trichloride *(12)* had to be developed into a safe industrial process. The problem

was eventually solved by a continuous process with a small controllable reaction volume (Fig. 2).



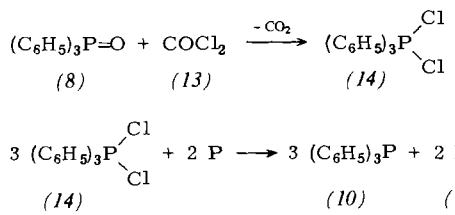


Fig. 2. Flowsheet of the industrial production of triphenylphosphane.

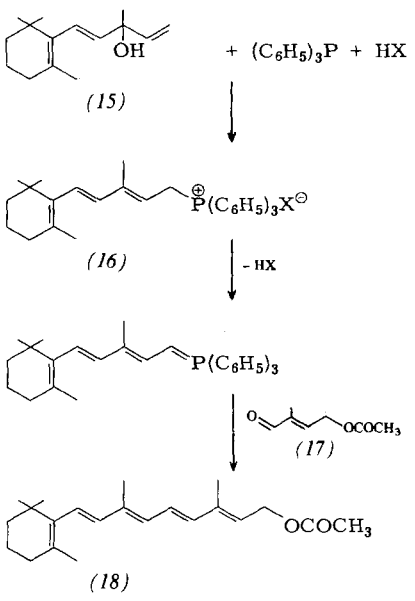
Since the expensive triphenylphosphane is irreversibly transformed into triphenylphosphane oxide during the Wittig reaction it was necessary either to utilize this unavoidable product in some other way or to find a way of re-using it. A new economical process was developed for recycling the triphenylphosphane oxide[11]. Triphenylphosphane oxide *(8)* is converted with phosgene into the dichloride *(14)* which gives triphenylphosphane *(10)* and phosphorus trichloride with elemental phosphorus.



It was possible to adapt the Wittig reaction to industrial practice in various other respects. Metal alkoxides were found to be inexpensive and easily handled proton acceptors as replacement for the originally employed organolithium compounds, and it was found that industrial solvents such as methanol and dimethylformamide could be used as reaction medium.

The decision to employ the Wittig reaction in an industrial synthesis thus prompted a series of studies which were essential for making it an economic proposition.

2.3. The BASF Vitamin A Process

A vitamin A production plant came on stream at BASF in 1971[25]. The key step of the BASF vitamin A synthesis employs Wittig olefination to link a C_{15} unit, *viz.* vinyl-β-ionol *(15)*, with a C_5 unit, *viz.* γ-formylcrotyl acetate *(17)*, as shown in the now well-known reaction scheme[4]. Vitamin A is obtained in the form of its acetate *(18)*.

Control of the exceptionally large amounts of heat involved, 60±2 kcal/mol in the reaction described above, proved fairly difficult. Even with sophisticated safety arrangements, execution of a Wittig reaction in a reaction vessel of several cubic meters in capacity still remained problematic. An industrial solution was found in the choice of a continuous adiabatic process with a small reaction volume.

A flowsheet of the industrial process used for the production of vitamin A and carotenoids is shown in Figure 3[25].

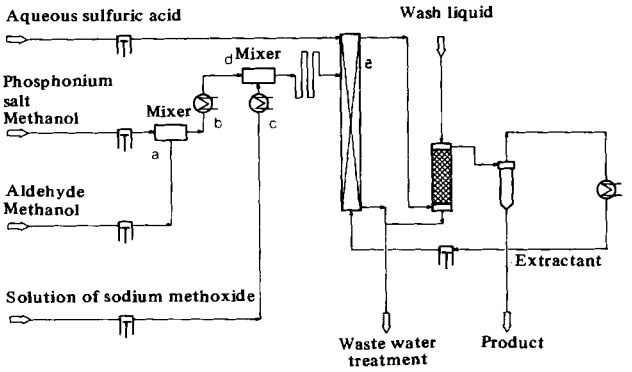


Fig. 3. Flowsheet of the continuous industrial Wittig synthesis. See text for details.

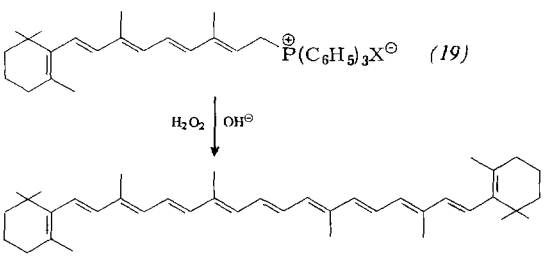
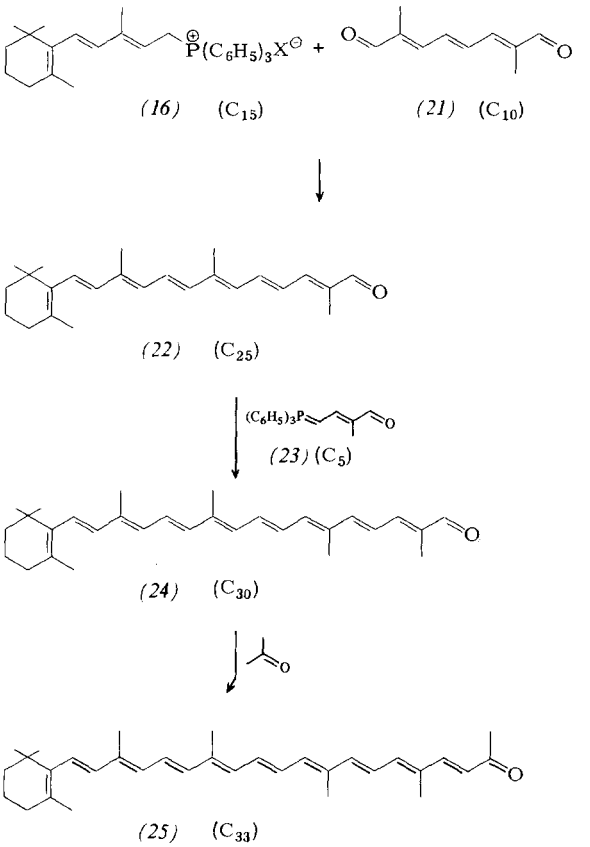


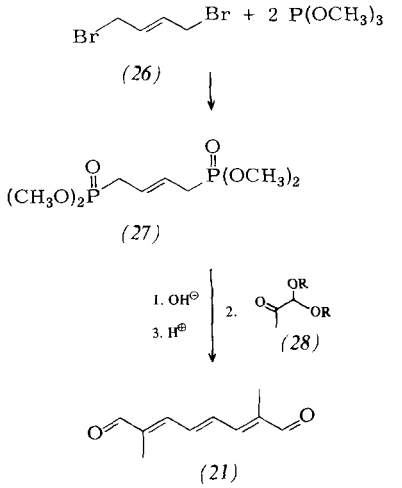
A solution of the triphenylphosphonium salt in methanol is mixed continuously with a methanolic solution of the carbonyl compound in a mixing reactor a) and cooled down to −30°C in a precooler b). A solution of sodium methoxide is simultaneously cooled to −25°C in another precooler c). Both solutions are then passed *via* cooled metering pumps into the mixing reactor d) and reacted therein. Reaction ensues immediately and is complete after a short residence time. The temperature rises and is maintained below the decomposition threshold of the phosphorane by running the reaction under adiabatic conditions. The mixture of reaction products and triphenylphosphane oxide, which is gelatinous owing to the formation of sodium chloride, is then passed to an extraction column in which the desired reaction product is extracted, after acidification with sulfuric acid, by a countercurrent of hydrocarbons. The hydrocarbon extract is washed, again continuously, with aqueous alcohol in a second column in order to remove final traces of triphenylphosphane oxide. The desired product is obtained by gentle evaporation of the extract in a thin-film evaporator. The distillate re-enters the extraction cycle. Figure 4 gives an impression of the dimensions of the plant.

Fig. 4. Part of the distillation equipment in the BASF vitamin A plant.

2.4. Production of β-Carotene and Citranaxanthin



While the production of vitamin A doubtless represents the most important industrial application of the Wittig reaction to date, the process of linking isoprenoid units by the Wittig reaction has provided convenient access to other products of economic significance. These include β-carotene *(20)* and citranaxanthin *(25)*, which occurs in citrus fruit. Both compounds are used as food dyes. β-Carotene and other symmetrical carotenoids can be obtained, *e.g.* by oxidative coupling of resonance-stabilized alkylidenetriphenylphosphoranes *(19)*, two alkylidene moieties combining with elimination of triphenylphosphane oxide to give the symmetrical olefin. This reaction was discovered in 1963 by *Bestmann*[12] in the autoxidation of alkylidenephosphoranes and studied in detail. The specific use of hydrogen peroxide brought about a substantial improvement in yield[13]. The preferred mode of operation consists in the reaction of aqueous solutions of the respective phosphonium salts with hydrogen peroxide in the presence of weak bases.

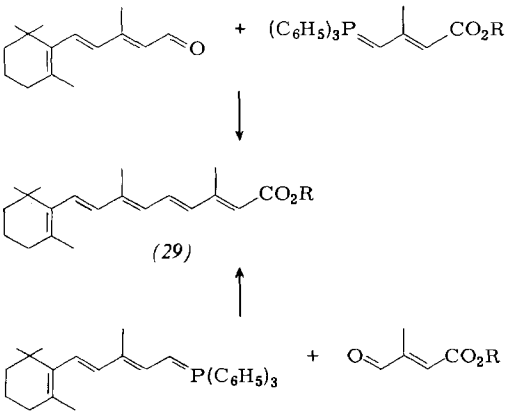


(20)

Production of citranaxanthin *(25)* can start from the same C_{15} unit *(16)* as in vitamin A synthesis, which is linked to one side of the C_{10}-dialdehyde *(21)* to form the aldehyde *(22)*. Subsequent Wittig reaction with the C_5-phosphorane *(23)* and aldol condensation with acetone[26] furnishes citranaxanthin *(25)*[4, 27].

The ability of the vinylogous bisphosphonates to undergo double olefination is exploited in the synthesis of the C_{10}-dialdehyde *(21)*[10], which is not possible, as already mentioned, with the corresponding bis-ylides. Reaction of 1,4-dibromo-2-butene *(26)* and trimethyl phosphite gives the 2-butene-1,4-bis(dimethyl phosphonate) *(27)*, which is converted with

alkoxide into the double anion and by addition of methylglyoxal diethyl acetal *(28)* into the bis(diethyl acetal) of the C_{10}-dialdehyde *(21)*.

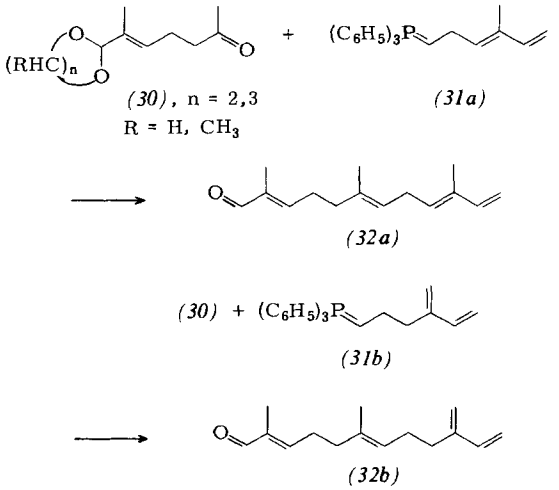


R = C_2H_5

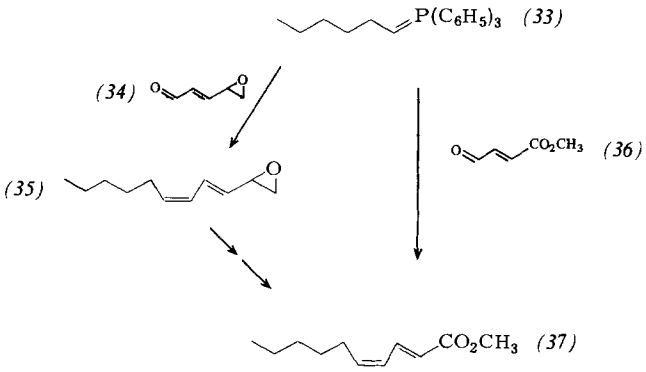
The phosphonate and triphenylphosphane methods are mutually complementary; this is particularly apparent in the synthesis of citranaxanthin *(25)*.

2.5. Production of Vitamin A Acid

One of the first compounds to be synthesized by the Wittig reaction in an industrial laboratory was vitamin A acid *(29)*. The synthetic building blocks just happened to be available in the main laboratory of BASF when the first details of the new reaction became known[4].



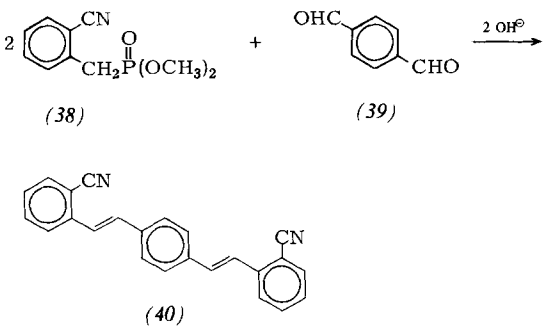
R = H, CH_3



Vitamin A acid was investigated in the 1950's by *Kimmig* in connection with its efficacy in the therapy of various skin diseases. It has been used for several years in medical practice for the treatment of acne[30].

2.6. Production of Aromas and Flavors

Since antiquity, terpenoid aromas and flavors have been among the most valuable objects of commerce. They are today being used in increasing amounts and the only way of satisfying demand would seem to be to synthesize them on an industrial scale. Introduction of the Wittig reaction into industrial practice opened a route to economic synthesis. The sesquiterpenes α- and β-sinensal [*(32)* and *(33)*, respectively], which determine the aroma of natural orange oils, may be cited as examples. They can be synthesized by linkage of a C_8- and a C_7 unit [*(30)* and *(31)*, respectively] with the aid of a Wittig reaction[14].

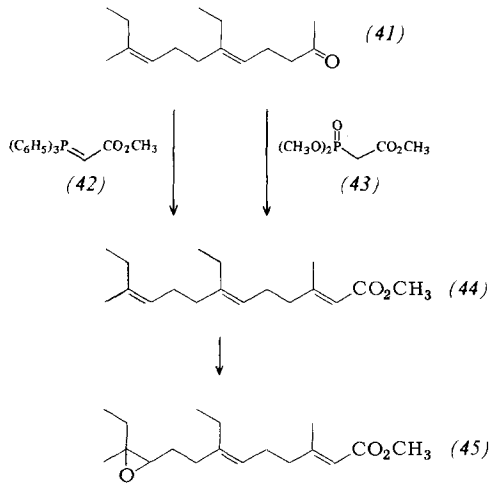


The quality of many perfumes and flavors depends very much upon their purity, and especially their stereochemical purity. The synthesis of "pear ester" *(37)* published by *Ohloff et al.*[15], in which hexylidenetriphenylphosphorane *(33)* reacts with 4,5-epoxy-2-*trans*-pentenal *(34)* under the usual conditions of the Wittig reaction, gives the desired *cis* double bond to the extent of 87%. Subsequent oxidative degradation of the epoxide *(35)* to "pear ester" reduces the *cis-trans* ratio to 75:25. Starting likewise from hexylidenetriphenylphosphorane *(33)*, the synthesis developed at BASF[16] employs fumaric ester hemialdehyde *(36)* and gives "pear ester" *(37)* directly. Linkage of *(33)* and *(36)* to give the *cis* double bond with

a selectivity of 85% is accomplished with the aid of the salt-free variant of the Wittig reaction originally introduced by *Schlosser*[17].

2.7. Production of the Optical Brightener ®PALANIL Brilliant White R

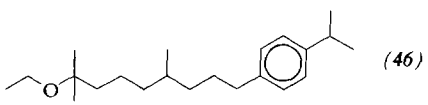
Industrial applications of the Wittig reaction or its variants are not limited to terpenoid compounds. Thus, BASF produces 2,2'-(*p*-phenylenedivinylene)dibenzonitrile *(40)* as an optical brightener for cotton and polyester fibers which is commercially available under the trade name ®PALANIL Brilliant



White R. Smooth double reaction affords the desired compound *(40)* from the *o*-cyanobenzylphosphonate *(38)* and terephthalyl aldehyde *(39)*[18].

3. The Wittig Reaction in Industrial Research and Development

3.1. Synthesis of Juvenile Hormone and Juvenile Hormone Mimics

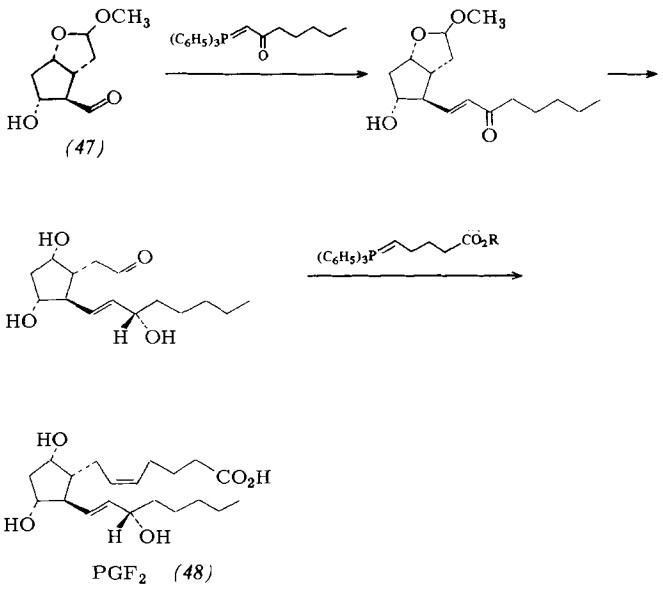


The Wittig reaction has proved particularly useful in the research and development of active compounds for the synthesis of compounds having specific effects in crop protection, animal nutrition, and medicine. It is one of the standard synthetic reactions suitable for preparing complex unsaturated compounds efficiently and in adequate amounts for detailed studies of the quality of active compounds. A few selected examples from the wealth of available material will now be presented.

A new era in the control of insect pests began with the structural elucidation of the C_{18}-Cecropia juvenile hormone *(45)*[18] by *Röller et al.* in 1967[19]. There are good reasons for hoping that selective destruction of pests can be achieved with juvenile hormones or structurally related compounds (juvenile hormone mimics) by using the species-specific hormonal activity to halt insect development in the larval stage. The very first juvenile hormone synthesis by *Röller et al.*[20] in 1967 made use of PO-activated olefination in two synthesis steps. In 1969 two published syntheses of the juvenile hormone *(45)* originating from industrial research laboratories also utilized the Wittig reaction and PO-activated olefination, respectively[28].

The two syntheses differ in the preparation of the unsaturated ketone *(41)*, which is also obtained *via* two Wittig olefinations in one case[21], and in the use of methoxycarbonylmethylenetriphenylphosphorane *(42)*[21] or dimethyl methoxycarbonylmethylphosphonate *(43)*[22] for synthesis of the unsaturated ester *(44)*.

The hopes pinned on juvenile hormones have not yet been fulfilled. Greater promise is now seen in juvenile hormone mimics, also synthesized with the aid of the Wittig reaction and its variants. Among the many compounds synthesized,



2-ethoxy-9-(*p*-isopropylphenyl)-2,6-dimethylnonane *(46)* is understood to have an extremely effective action on stable flies and houseflies[23].

3.2. Synthesis of Prostaglandins

In recent years the development of prostaglandins has played a prominent role in medical research. Chemists in industry and at universities have paved the way for detailed pharmacological studies on these compounds, occurring in only minute amounts in nature, by synthesizing prostaglandins and their derivatives.

A common feature of these compounds, which display such pronounced and varied activity and structural complexity, is a polysubstituted cyclopentane ring. In nearly all prostaglandin syntheses, the side chains on the cyclopentane ring *(47)* have been introduced by a Wittig reaction. The synthesis of prostaglandin PGF_2 *(48)* developed by *Woodward* and co-workers[24] at the Woodward Research Institute at Basel serves as an illustrative example.

(47)

PGF_2 *(48)*

4. Conclusion

The applications of the Wittig reaction presented above are but a small portion of the available material. New syntheses are currently being developed in numerous laboratories, and some of them will doubtless acquire industrial significance. Through his work, undertaken with the sole aim of expanding man's knowledge, *Wittig* has confirmed that pure science is also the motor of economic progress—a fact that is all too frequently overlooked in present-day discussions.

Steric Interactions in Organic Chemistry: Spatial Requirements of Substituents

By Hans Förster and Fritz Vögtle[*]

Dedicated to Professor Georg Wittig on the occasion of his 80th birthday

From the very extensive factual material available on steric interactions in organic chemistry, the present paper reviews the investigations that provide information about the "size" ("spatial requirement") of the substituents. After an introductory section on the results obtained with the aid of spectroscopic data and by analysis of chemical reactions, attention is turned to conformational processes, including hindered rotation in ethanes, in the biphenyl system, in butadienes, multiply substituted arenes, molecular propellers, and triptycenes. The main emphasis is placed on the explanation of sterically hindered ring inversions in bridged arenes, a class of compounds particularly suitable for the study of steric interactions. The results obtained by variation of the parameters in this system are also discussed with respect to the spatial requirements of organic substituents.

1. Introduction

While steric effects are encountered throughout organic chemistry and in many guises, they are difficult to quantify. As early as 1941[1] the situation was described in the following words: "Steric hindrance ... has become the last refuge of the puzzled organic chemist." Indeed, the influence of steric interactions on reaction rates and on the position of equilibrium in chemical reactions has long been called upon, with greater or lesser justification, to account for experimental findings.

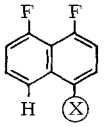
Kehrmann[2] was probably the first to recognize the influence of space filling by substituents on chemical reactions. *Viktor Meyer*[3], *Wegscheider*[4], and *Goldschmitt*[5] in particular studied sterically hindered reactions[6]. The steric origin of the observed effects was successfully demonstrated, but the first correlations with "radical weights" or atomic volumes of the substituents were unsatisfactory and contradictory. The amount of information on sterically influenced reactions subsequently increased very quickly[7]. The terminology[8] was modified in line with the various manifestations of the steric effects, but attempts at empirical quantitative description were seldom made. In the present review we shall try to present a critical collection of data on the quantification of steric effects insofar as they permit a differentiation beyond a general "large or small" classification.

2. The "Size" of Substituents

Since "size" is a geometric concept, the size of substituents should be expressed in geometric units. Van der Waals radii or volumes can be determined by several methods[9], whose results, however, differ considerably. In particular, in the case of atoms containing few electrons (elements of the second row) the values obtained will depend largely on the surroundings of the atom in question, *i.e.* on the type of the bonding, the state of aggregation, and the temperature[9, 10]. The measured size parameters are compromises between several effects and can thus have different values under different conditions. The problem becomes even greater in the case of polyatomic substituents, and it will come as

[*] Dr. H. Förster, Prof. Dr. F. Vögtle
Institut für Organische Chemie und Biochemie der Universität
Max-Planck-Strasse 1, D-5300 Bonn (Germany)

no surprise that compromise solutions had to be found for the construction of space-filling molecular models[11].



Geometric data do not provide the experimental chemist with an immediate insight into the energetic significance of steric interactions between the groups in a given molecular system, and it is therefore desirable to represent the size of a substituent by an energy contribution to the steric interaction in various systems. Empirical calculations can then be used to determine geometrical quantities; such procedures have recently been perfected[12]. If steric interaction contributes to ΔG or ΔG^{+} values ($\Delta\Delta G$ or $\Delta\Delta G^{+}$), then $\Delta\Delta H$ or $\Delta\Delta H^{+}$ should contain the component of the potential energy that arises from the deformation due to the steric interaction, while $\Delta\Delta S$ and $\Delta\Delta S^{+}$ are a measure of the decrease in translational, vibrational, and rotational motions due to the steric interaction; this interpretation is particularly valid when solvent influences are small[13]. Space filling by a substituent should thus be measurable as an enthalpy component of its steric influence in a suitable reaction. The advantage of this procedure is that the measurements are carried out under the "normal conditions" of chemical reactions and therefore isolate the steric components under these conditions. Nevertheless, the results obtained from a few experiments cannot be generalized: according to the geometry of the transition state (or the reactants) various steric restrictions arise in different systems, and the number of these restrictions increases as the symmetry of the energy-determining geometry decreases.

If it is to lead to reliable conclusions, the information must therefore be obtained by the analysis of model systems embodying as many different structures as possible. Analysis of thermodynamic data for their steric content is simple where the nonsteric effects can be readily calculated from other investigations and/or when steric factors predominate.

In what follows we review the work that enables the substituents to be arranged according to their size.

3. Determination of the Relative Spatial Requirements by Analysis of Spectroscopic Data

Distortion of a molecular skeleton due to steric causes can be detected by spectroscopic methods. Examples of this are the UV investigations into "steric hindrance of resonance"[14], in which for example the distortions of the resonating groups in *o*-halogenated acetanilides or nitrobenzenes are found to increase with increasing size of the halogen[15]. Remarkably, the "through space" F-F coupling in 4-substituted 1,8-difluoronaphthalenes *(1)* has been correlated with the size of the substituent in position 4[16].

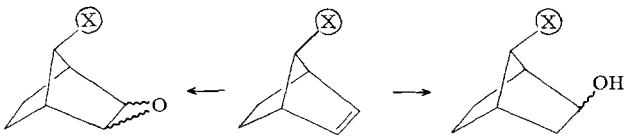
(1)

X = H, Br, CN, CH_3, NO_2, NH_2, NHAc, Cl

4. Determination of the Relative Spatial Requirements by Analysis of Chemical Reactions

Taft[17] investigated the rate of base and acid hydrolysis of substituted aliphatic carboxylic esters and *o*-substituted benzoic esters[18]. Because of the low sensitivity of the acid hydrolysis of esters to polar influences, it is possible to obtain steric substituent constants E_s[17] analogously to the substituent constants for the description of polar effects or resonance effects[19]:

$$E_s = \log(k/k_0)_A$$



Charton showed later in a statistical analysis[20a] that the E_s values from the aliphatic series can be correlated with van der Waals radii, but that this was not the case for the E_s values from the series of *o*-substituted benzoic acids (E_s^o). It was concluded that the E_s constants describe steric and the E_s^o constants electronic factors. From the rates of esterification and hydrolysis[20b, 20c] of acids XCO_2H and esters XCO_2R, by using the relationship:

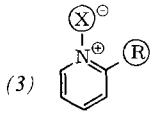
$$\log k = \psi v + h$$

Charton was also able to obtain new steric substituent constants for substituents for which, because of their unsymmetrical structure, v cannot be obtained directly from:

$$v_X = r_X - r_H,$$

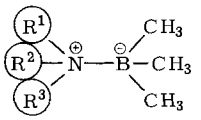
where r_X and r_H are the van der Waals radii of X and H. Since steric parameters of this type are energy parameters ($\Delta G^{+} = -2.303\,RT\,E_s$), a linear dependence on the van der Waals radii is not *a priori* comprehensible[20d], especially as the ΔH^{+} and ΔS^{+} values do not always vary in the same way as r_X.

(2c) *(2a)* *(2b)*



The *exo/endo* ratio in the hydroboration and epoxidation of *(2a)* to *(2b)* and *(2c)*, respectively, depends on the space filling by the substituent X[21]; conclusions about the size of X appear possible. Insertion of the $Sn(CH_3)_3$ group between Br and Cl:

$$C(CH_3)_3 > CH_3 > Br > Sn(CH_3)_3 > Cl > H$$



permits the conclusion that the increase in bond length on passing from C—C to C—Sn plays an important role. The order $CH_3 > Br$ is remarkable for the same reason, since it contradicts the results obtained by most other authors.

In a comparison of the base strength of substituted pyridines *(3)* towards Lewis acids of various sizes, *H. C. Brown*[22, 23b] found a strong dependence on space filling by the substituents;

the same was true for the rates of the reactions of these bases with methyl iodide.

(3)

(4)

X = $H^{\oplus}$, BH_3, BF_3, $B(CH_3)_3$

R = H, CH_3, C_2H_5, i-C_3H_7, t-C_4H_9

The dissociation energies of trialkylamine-trimethylborane adducts *(4)* similarly depend on steric factors[23]. However, only alkyl substituents can be compared in the investigation of such systems.

5. Determination of Relative Spatial Requirements by the Analysis of Conformational Processes

The requirement for a large contribution from the steric ("non-bonded" electronic) effect and a small one from other ("through-bond" electronic) influences is best met in conformational processes, since in these no bond is broken and none formed. Conformational processes are especially suitable when the following conditions are fulfilled:

a) If rotations around single bonds without a double bond component are being observed and/or the substituents are far away from the pivot bond, so that the transmission of electronic effects is prevented, the non-steric influences within the conformational process and within the substitulogous series[24] of compounds remain constant. Since no ionic species appear, solvent effects need be expected only when dipole forces make an appreciable contribution.

b) Since in conformational processes the "space filling" parameter is measured as the difference between the energy contents of different geometries of the same molecule, the requirements are that this difference should be as clearly expressed as possible and that the energy content of only *one* geometry should be determined by the substituent whose size is to be defined. This means that either the ground state *or* the transition state of a dynamic process or *one* ground state of an equilibrium is energetically determined by the size of the substituents, and not both to different extents. The requirement for a markedly different steric strain between structures favors measurements in dynamic processes over equilibrium determinations, since narrower limits are set on obtaining the populations of energy-richer equilibrium conformations.

c) The information value of stereochemical investigations increases if exact conclusions can be drawn about the structure with the greatest steric strain. This is most so when the number of possible molecular motions is smallest, *i.e.* when most rigid parts are contained in the molecular skeleton. At the same time, the entropy contribution in ΔG decreases with increasing rigidity. The assignment of relative substituent size and activation enthalpy thereby becomes more precise.

d) The conformational process or the equilibrium should be studied on compounds with the widest possible selection of substituents. However, this requirement is in contradiction to requirements b and c, since the range of processes that can be followed experimentally is strictly limited for rigid systems with strong steric interactions. Compromise solutions must therefore be found if, after variation of the parameters, it still proves impossible to use a sufficient variety of substituents.

e) Optional requirements are ease of synthesis of the variously substituted (substitulogous) compounds and ready monitoring of the stereochemical process [*e.g.* by dynamic NMR (DNMR) measurements[25]].

These requirements have been met in various ways by the conformationally mobile systems described below.

5.1. Hindered Rotation

5.1.1. Ethanes

Ever since *Pitzer*[26] postulated hindrance to free rotation around the C—C single bond in ethanes, the cause of the potential threshold has been the subject of many studies[27]. Steric factors alone cannot explain the findings[28], even in ethanes with large substituents. Since the substituents are oriented away from one another, bond lengths increasing with size can partially compensate the effect of steric interaction through space[29, 30]. The rotation threshold is more obviously connected with space filling by the substituents in the case of groups extending sideways, such as the methyl group[30]. Nevertheless, the lateral interaction remains slight, as is shown in *Anderson*'s P values $(\Delta G_X - \Delta G_H)$[30a] (Table 1). *Anderson* calls this the anisotropy of the van der Waals radius. The unfavorable orientation of the substituents and the effect of dipole forces (in the presence of strongly polar substituents) make ethane derivatives seem unfavorable for investigations of space requirements.

Similar reservations apply to the A values[31] as measures of size. The A values defined by *Winstein*[32] as the logarithm of the ax/eq equilibrium constant in the cyclohexane system[33] presumably contain other components besides the steric contribution of the *cis*-diaxial 1,3-interaction[34]. Furthermore, the steric component of the A values does not correspond to the expectations for larger atoms, since the longer bond lengths decrease the interaction with the small hydrogen atoms at C-3 and C-5[35]. This can be seen, for example, by comparing the A values for Cl, Br, and I (Table 1). If the two hydrogens on C-3 in cyclohexane derivatives are replaced by two methyl groups[36], the expected sequence of steric interactions is obtained. The values for Cl, Br, and I (Table 1) are calculated, since the axial isomers of these derivatives could no longer be detected[36]. Thus, the hindered rotation in ethanes and also the position of equilibrium in cyclohexanes are not very suitable for comparisons of spatial requirements:

a) The unfavorable orientation of the substituents leads on lateral contact only to relatively weak steric interactions, and therefore

b) it is impossible to exclude considerable participation of nonsteric interactions in the small effects that are measured.

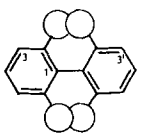


Table 1. Quantitative estimation of the spatial requirements of organic substituents (values in kcal/mol (kJ/mol)), arranged in order of increasing n values [see (34)]. The n values are taken as a measure of the substituent size; see Section 5.2, especially Fig. 1.

5.1.2. The Biphenyl System

In the biphenyl system (5)[37] the orientation of the colliding groups is more favorable than in the ethanes. By suitable

(5)

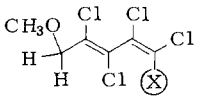
substitution of biphenyl various groups can thus for the first time be reliably arranged in the order of "size"[38]:

$$Br > CH_3 > Cl > NO_2 > COOH > OCH_3 > F > H$$

The "interference values" calculated from X-ray data show the same sequence[39]. The results are not quite conclusive, since the series was obtained by combining the findings for many derivatives carrying various substituents in the *ortho*-positions.

The position of several identical *o*-substituents relative to one another is not without influence on the sequence obtained[37]; this could be an expression of a slight through-bond or through-space electronic influence. The effects of substituents in positions 4 and 4′ are probably electronic in nature[37], showing that requirement a) (see Section 5) is not completely satisfied in the biphenyl system.

Comparison of the "sizes" of OCH_3, CH_3, and F makes it clear that the interaction of the methoxy group occurs *via* the oxygen. On the other hand, the size of group R in OR-substituted biphenyl derivatives cannot be neglected[40]. In this connection it is interesting to note the sequence of the "buttressing" effect[37a, 41] of substituents in position 3 and 3′:



$$NO_2 > Br > Cl > CH_3 > OCH_3$$

Here the methyl group appears to be smaller than Cl and the nitro group larger than Br. The lateral interaction of methyl groups due to their conical form[9a, 20a] is weaker than that of the more extensive spherical substituents such as Cl, which is in agreement with the P values in the ethane system[30]. The strong buttressing effect of aromatically bonded nitro groups indicates that the nitro-oxygen atoms extend in the plane of the benzene ring[42]; on the other hand, the steric interaction of the nitro group in *o*-nitrobiphenyl derivatives is weakened by the twisted orientation of the nitro groups. These examples show the importance of the *interaction geometry* with respect to the evasive behavior of substituents of lower symmetry (anisotropic space require-

ment). In spite of the relative rigidity of the biphenyl system, considerable differences are found between the activation entropies[43]; comparison of activation enthalpies would therefore be preferable.

5.1.3. Butadienes

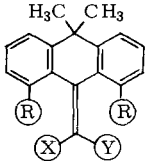
Numerical values of the steric buttressing effects in chiral penta- and hexasubstituted butadienes *(6)* were determined by *Mannschreck, Köbrich et al.*[44] for some substituents by means of DNMR spectroscopy (Table 1). The sequence of the $\Delta G_c^{\neq}$ values shows a slight buttressing effect for "flat" substituents such as methoxycarbonyl and dichlorovinyl;

(6)

X = H, CO_2CH_3,  , $Sn(CH_3)_3$, F, $Si(CH_3)_3$, Cl, CH_2OH, Br, I, CH_2OCH_3, $SiPh(CH_3)_2$, $C(CH_3)_2OH$

apparently these groups are twisted out of the plane of the double bond even in the ground state. Comparison of Cl, Br, and I with one another and of $C(CH_3)_2OH$ with $Si(CH_3)_3$ and $Sn(CH_3)_3$ shows again an inverse effect between size and increasing bond length:

$$Cl \approx Br \approx I \text{ and } C(CH_3)_2OH > Si(CH_3)_3 > Sn(CH_3)_3$$



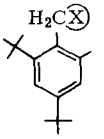
The strong effect of fluorine substituents [$\Delta\Delta G_c^{\neq} = 3.2$ kcal/mol (13.4 kJ/mol)] can, however, hardly be explained on steric grounds.

5.1.4. Methylenedihydroanthracenes

The rate of the ring inversion in substituted methylenedihydroanthracenes *(7)* is controlled to a considerable extent by steric interactions between the groups X, Y, and R[45]. The sequence

$$Br > Cl > CH_3 > C_6H_5 > CO_2CH_3 \gg H$$

again demonstrates the weak steric interaction of flat substit-

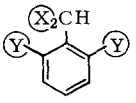


(7)

uents (C_6H_5, CO_2CH_3), while the position of CH_3 is explained by a "cogwheel effect".

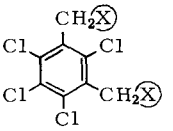
5.1.5. Multiply Substituted Arenes

Many authors chose arenes carrying several substituents as model systems for the study of steric interactions. For the series of compounds *(8)* *Cupas*[46] found the sequence



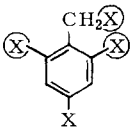
$$I > Br > Cl$$

(8)



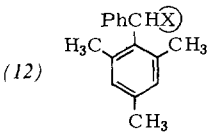
X = Cl, Br, I

with considerable differences between the rotation barriers (Table 1). *Schaefer*'s results for *(9)*, *(10)* (Table 1)[47a], and *(11)*[47b] confirm this sequence.



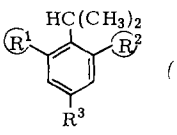
(9)

X = F, Cl, Br, I
Y = H, Cl, Br



(10)

X = Cl, Br, I



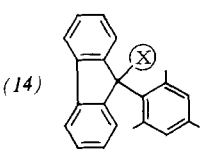
(11)

X = Cl, Br

(12)

(13)

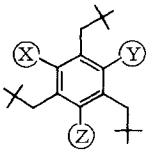
R^1, R^2 = CH_3, Cl, Br
R^3 = CH_3, NO_2



The magnitude of the $\Delta G^{\neq}$ values (Table 1) for the rotation barriers in *(12)* gives the sequence[48]:

$$Br > SH \approx Cl \approx CH_3 > CN > OH > OCH_3$$

while the equilibrium positions found for *(13)*[48,49] lead to:



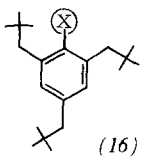
$$Br \approx CH_3 > Cl$$

In *(14)* an increasing rotation barrier of the mesityl group is observed as the size of the substituent X decreases—here the steric interaction influences preferentially the ground state[50].

(14)

X = H, OH, Cl

(15)



X, Y, Z = H, F, Cl, Br, I, CH_3, NO_2

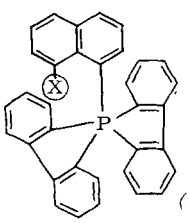
Rotational hindrance of the neopentyl groups in multiply ring-substituted 1,3,5-trineopentylbenzenes *(15)* was investigated by *Carter*[51] for several combinations of X, Y, and Z. Since the rotation barriers measured were determined

mainly by the smaller substituents (X, Y, or Z), it was possible to determine relative "sizes". This gives the sequence:

$$I > Br > CH_3 > Cl > F > H$$

The nitro group (in a twisted orientation) can be assigned the position $Cl > NO_2$[52], similar to its position in the biphenyl sequence. Linear free-energy relationships can be derived from data reported by *Anderson* (ethane derivatives)[30] and by *Cupas* (arenes)[46]; as expected, the arenes *(8)* more similar to *(15)* correlate with a gradient nearer to unity. The sp^2-sp^3 rotation barriers of many alkyl and acyl substituents X were also compared in the analogous system *(16)*[53].

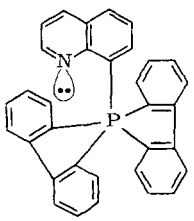
(16)



X = 

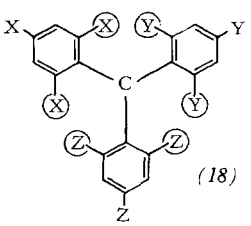
R = CH_3, C_2H_5, i-C_3H_7, t-C_4H_9, C_6H_5

Rotation barriers increase with increased branching. Acyl substituents hinder rotation more strongly than the corresponding alkyl substituents. This is to be expected from the larger spread of the acyl groups and the fact that the range of action of O is greater than that of H[54]. In *(15)*, X = Y = Z = Br, and *(15)*, X = Y = Br, Z = NO_2, large contributions from the "all-*cis*-conformers" could be demonstrated[55], in which all three neopentyl groups are directed to the same side of the benzene ring—an indication that steric effects cannot be regarded merely from the standpoint of destabilizing interactions but that attractive steric interactions must also be reckoned with[55, 56].



5.1.6. Molecular Propellers

Propeller molecules[57] offer a wide field for the study of steric phenomena. *Hellwinkel*[58] investigated the combined rotation/pseudorotation of the naphthyl and spiran units in



(17)

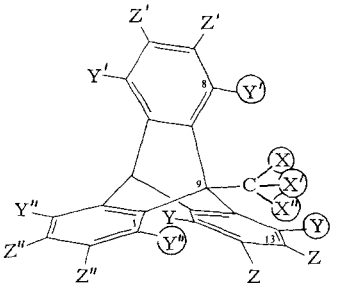
X = H, F, Cl, Br, CH_3, OCH_3, $N(CH_3)_2$

(17a)

(18)

X = Y = CH_3

Z = OCH_3



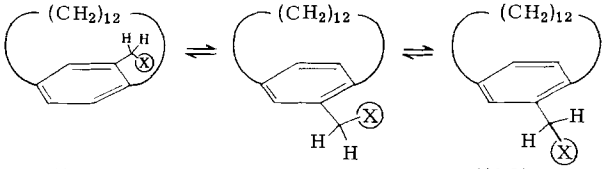
spirophosphoranes *(17)* and *(17a)*. A marked dependence on the space filling of the substituent on C-8 of the naphthyl group (Table 1) was observed. The sequence found in *(17)* was:

$$N(CH_3)_2 > OCH_3 > CH_3 \approx Br \approx Cl > F > H$$

and on the extreme right of this sequence should be placed the electron pair on the nitrogen atom in *(17a)*. Unlike what happens in most other systems, the methyl group of the OCH_3 substituent in *(17)* is brought into the steric interaction[59]. In the triphenylmethanes *(18)*, however, the CH_3 group hinders "ring rotation" more than does the OCH_3 group[60].

5.1.7. Triptycenes

Interesting conclusions about the effect of the relative orientation of colliding groups on rotation thresholds and equilibrium positions can be expected from 9- (bridgehead) and 1,8- or 1,8,13-(*peri*-)substituted triptycenes *(19)*[61]. In this system both "end-on" interactions (variation of the substituents X) and "side-on" interactions (variation of the substituents Y) can be investigated. However, the available results do not permit any clear conclusions. Unexpectedly, when X = X′ = X″ = Y′ = Y″ = Z = Z′ = Z″ = H, but Y = OCH_3 a larger

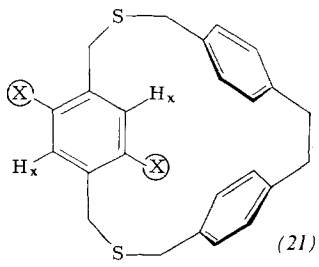


(19)

interaction is observed than for the analogous compound with Y = CH_3. The best explanation for this phenomenon seems to be cogwheel-like coupled rotation of the two methyl groups in positions 1 and 9[61] (the "gear-effect"[62]), these groups being arranged exactly like spur gears. The two spherical substituents Cl and Br, however, range themselves as expected in regard to size (Br > Cl). The position of the conformer equilibrium in 9-benzyl-substituted triptycenes indicates besides repulsive steric effects attractive interactions explicable by charge-transfer stabilization[63]. Non-steric effects here again appear important, particularly for equilibrium positions where the energy differences are relatively slight.

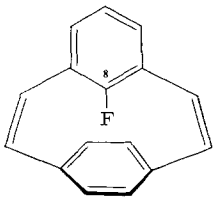
5.2. Steric Hindrance of Ring Inversion in Phanes

Investigations of bridged compounds[64] have recently contributed much to our understanding of steric (and electronic) effects[65], yielding a wealth of detailed information.



(20A) (20B) (20C)

In some cases comparative studies with varied substituents have been carried out:

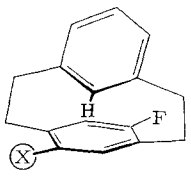


In the parabenzenophane system *(20)* the activation energies of the process (A)⇌(B)⇌(C) were found to be in the sequence[66]:

$$OH > Br > CO_2C_2H_5$$

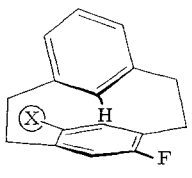
which was ascribed to the extent of the steric hindrance of benzyl rotation. This surprising sequence, however, indicates rather a steric ground-state effect.

(21)



(22)

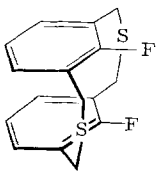
X = H, F, OCH_3, CH_3, Cl



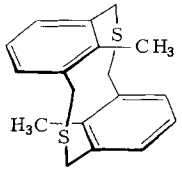
Tabushi et al.[67] compared the chemical shift of the H_X-proton in *(21)* with that of the H_X-proton in the dithiol starting material [the corresponding *p*-phenylenebis(methanethiol)]. As the steric repulsion between X and the unsubstituted benzene rings increases, the effect of the ring current on the H_X shrift decreases. The sequence:

$$Cl > CH_3 > OCH_3 > F > H$$

is the expected one except for $Cl > CH_3$; if the dithiol is a valid reference compound, this could be indicative of an



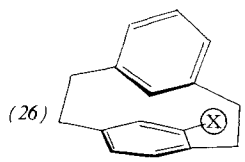
syn-(23)



anti-(23)

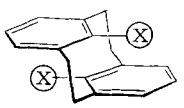
X = H, CH_3, Br

syn-(24)



anti-(25)

increased repulsion (or diminished attraction) between the aromatic π-cloud and the electronegative substituent Cl as compared with the CH_3 group. A surprisingly strong destabilizing interaction between the substituent F and an aromatic π-system was also found by *Boekelheide*[68] in 8-fluoro[2.2]metaparabenzenophanediene *(22)*. Replacement of the H by F in position 8 decreases the rate of flip of the *meta*-ring by a factor of at least 10^{11}. Since an increase of only 50 pm (0.5 Å) is obtained from the bond lengths and van der Waals radii of H and F, the question arises whether the potential energy function of the repulsion really rises so steeply in this region, or whether an especially strong destabilizing interaction exists between F and the π-cloud. From the position of the *syn/anti*-equilibrium in the metaparaphanes *(23)*, however, the expected sequence has been derived (Table 1):

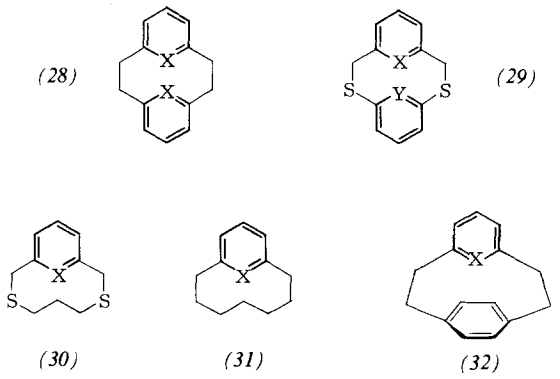


$$Br > CH_3 > F > H$$

Contrary to the situation with *(25)*, the *syn*-conformation of *(24)* predominates (*syn/anti* ratio 7:1), and that cannot be explained by an unusual repulsion between a π-cloud and a fluorine atom; accordingly, here attractive forces must be in operation[68]. The proportion of the *syn*-conformations in the metaparaphane system *(26)* decreases in the sequence

$$H > CHO > CH_2OH > CH_3 > COCH_3 > CO_2CH_3$$

(26)

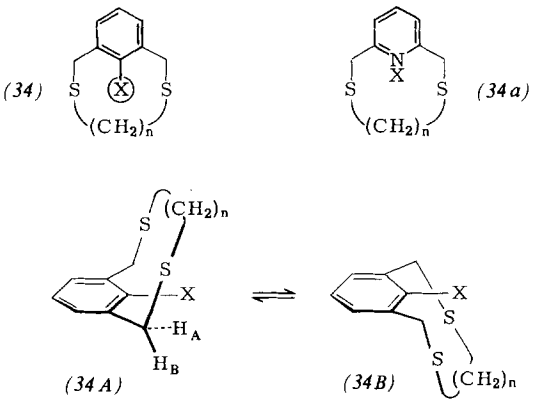


(27)

and this is attributed mainly to steric repulsion[69, 70]. The [2.2]metaphane system *(27)* might appear suitable for studying special interactions between substituents X and aromatic π-systems, for its conformation can be determined very exactly by means of the $^3J_{HH}$ coupling constants (H atoms of the ethylene bridges)[71].

Steric effects are especially marked when colliding parts of molecules are forced into close neighborhood by rigid groups and the possibilities of evasion are reduced to a minimum. This is largely the case with intra-annular interactions. Since extension or compression of bonds never contributes to any considerable extent to the total strain[12, 72], the often substantial van der Waals interaction energy is partly converted into angle deformation and torsion also affecting rigid groups[72]; in suitable structures one thus obtains a particularly large proportion of non-bonded interactions. Admittedly, the energetic results of such increased steric interactions can only be specified in the activation parameters of dynamic processes, and here too there are usually few possibilities of varying the colliding groups, unless it is possible to adjust the system to the steric requirements without a decisive change in the structure. Many of the conformational processes studied on phane systems with intra-annular steric interactions thus permit the size of substituents to be obtained only as a two-

sided comparison in the sense of a rigid/not rigid decision. Nevertheless, some important details could be studied on such systems, as for example the question of the "size" of the free electron pair on the nitrogen, which had arisen from conformational investigations of piperidines[73].



(28) (29) (30) (31) (32)

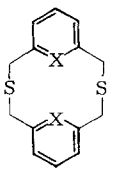
Phanes of the types (28)—(32), X=N, show in all cases lower flip thresholds than their carbocyclic analogs (X=C—H) (Table 2):

C—H > N⊖

(34A) ⇌ (34B) the intra-annular substituent X can still just pass through the interior of the ring[82]. The range of the

(34) (34a) (34A) (34B)

measurements can therefore be suited to the substituents. The following advantages are thus obtained:



a) Each substituent meets the same interaction partner; effects due to different polarizability can therefore be ascribed to the substituent alone.

b) Owing to the flexibility of the chain, no distinct steric destabilization of the ground state is present[83].

Table 2. Quantitative estimation of the "spatial requirements" of electron pairs. $G_c^{\ddagger}$ values in kcal/mol (kJ/mol).

X	Y	(28)	(29)	(30)	(31)	(32)
N	N	14.8 (62.0) [74]	<13.6 (<57.0)	<10.2 (<42.7) [76]	9.0 (37.7) [76]	10.7 (44.8) [79]
C—H	C—H	> 27 (>113) [75]	>23 (>96) [75]	10.2 (42.7) [77]	11.5 (48.2) [78]	20.6 (86.3) [65b, 68]
C—H	N		20.5 (85.9)			

If the size of the intra-annular substituent in such systems is increased, the barriers to the flip become much greater; in [3.3]dithiametabenzophane (33), X=C—H, and in the

(33)

X = N⊖, C-H, C-F, C-Cl, C-Br

pyridine analog (33), X=N, inversion of the mediocycle (*i. e.* the central large ring) is too fast for the DNMR method; when X=C—F it is observable, and if X=C—Cl or C—Br it lies above the accessible temperature range[80].

In the phane system (34), however, by choosing an aliphatic chain of suitable length, the diameter of the large ring can be adjusted so that in the topomerization process[81]

c) The chain contains only nonpolar bonds. Specific interactions between the substituent and the chain are thus unlikely.

d) The collision does not occur quasi-"one-dimensionally", but in a "two-dimensional" girdle, as the oligomethylene bridge "embraces" the intra-annular substituent in the transition state.

e) The benzyl protons absorbing as an AB system appear only slightly in long-range coupling. DNMR analysis is thereby simplified.

As a result of the synthetic variability it has already been possible to measure the free activation enthalpy of the diastereotopomerization for a large number of substituents X (Table 3); the series could be extended without difficulty to other substituents. The steric interaction of most of the substituents was measured for two or three bridge lengths $n+4$.

In Figure 1 the $\Delta G_c^{\ddagger}$ values for (34) and (34a) are plotted against n. It may be seen that $\Delta G_c^{\ddagger} = f(n)$ leads to similar slopes in all cases, even though a few lines do intersect. The lines for substituents whose DNMR investigation was possible at only one bridge length have been interpolated.

Table 3. Free activation enthalpies at the coalescence temperature ($\Delta G_c^{\ddagger}$) for the topomerization process *(34A)* ⇌ *(34B)* [82] of metaphanes *(34)*, arranged in order of increasing n values of the substituents (values in kcal/mol (kJ/mol)).

X \ n	3	4	5	6	7	8	9	10	12
(34a).	$T_c < -60°C$

—OCH_3						23.2 (97.3)	17.9 (75.0)	10.5 (44.0)	
—I								14.6 (61.2)	
—SCH_3								17.4 (72.9)	
—CO_2CH_3								23.6 (98.8)	
—SO_2CH_3									16.9 (70.8)

The value of n at $\Delta G_c^{\ddagger} = 15$ kcal/mol (62.8 kJ/mol) could be taken as a measure of the size of a substituent ("n values", Table 1).

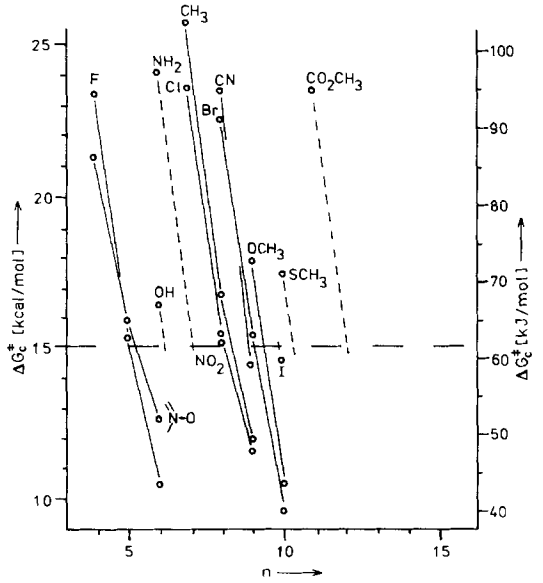

Fig. 1. Dependence of the free activation enthalpies $\Delta G_c^{\ddagger}$ for the topomerization process *(34A)* ⇌ *(34B)* on the bridge length $n+4$ in metaphanes *(34)*. n-Values: points of intersection of the straight lines with $\Delta G_c^{\ddagger} = 15$ kcal/mol (62.8 kJ/mol).

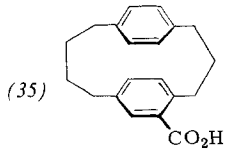
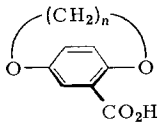
This $\Delta G_c^{\ddagger}$ value corresponds to coalescence at approximately 30 °C. It would, however, be desirable to have an exact $\Delta H^{\ddagger} = f(n)$ relationship. Different $\Delta H^{\ddagger}/n$ values could then be considered as related to different polarizability/bond-deformability of these substituents. $\Delta G^{\ddagger}$ values could replace the only imprecisely measurable $\Delta H^{\ddagger}$ values when $\Delta S^{\ddagger}$ is the same for one chain length (independently of the substituent).

Complete line-shape analyses[84] for some suitable cycles *(34)*, X = CH_3, $n = 7$ or 8, and *(34)*, X = OCH_3, $n = 9$, gave the following results: $\Delta S^{\ddagger}$ becomes more strongly negative with increasing activation enthalpy and increasing bridge length; substituents of lower symmetry also lead to a lowering of $\Delta S^{\ddagger}$. This agrees with the expectation that in the transition state of the process *(34A)* ⇌ *(34B)* the possibilities of rotation of chain members and substituents X are limited. Comparison of $\Delta G_c^{\ddagger}$ values is thus not without its problems[25, 81]. Differentiation between substituents with the same n value should, however, be reliable, even though the jump from one n value to another is difficult to quantify.



The method presented above arranges substituents according to their extension; the mobile $(CH_2)_n$ chains adapt themselves to substituents of different shape[83]; the results found for this system are thus not in any case applicable to other systems without any modifications. According to the method of measurement, the order of arrangement of in particular the unsymmetrical substituents often varies, showing how strongly a result may depend on special structural features. The aim of such conformational investigations must therefore be to isolate the individual effects involved in the broad concept of "steric interactions" by using many methods of measurement, and to characterize these effects. For this purpose not only is a large selection of systems necessary but also, within each system, there must be a graded variation of the structural characteristics. The effect of changing a single parameter within

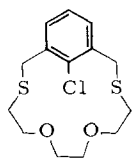
groups of similar compounds will now be illustrated by some examples.



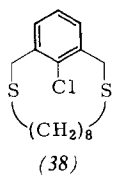
5.3. Variation of a Single Parameter

5.3.1. Size of the Mediocycle

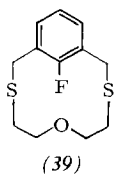
A change in the width of the mediocycle has a very strong effect on the inversion barriers: in the phanes *(34)* shortening of the bridge by one methylene group in the sterically critical region leads to an increase in $\Delta G_c^{\ddagger}$ of *ca.* 7 kcal/mol (29.3 kJ/mol). The [4.3]parabenzenophane *(35)*[85] racemizes at a measurable rate; the corresponding [4.4]phane is no longer separable into the enantiomers. The paraphane *(36)*, $n=9$, can be racemized above 70°C, but *(36)*, $n=8$, is stable, and *(36)*, $n=10$, is no longer separable into enantiomers[86, 87].



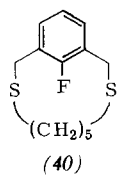
(35)



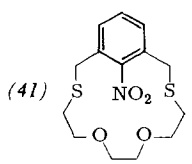
(36)



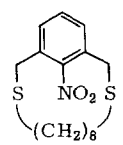
If methylene groups are replaced by heteroatoms the change in the bond lengths is generally as expected. Thus, replacement of $-CH_2-$ by —S— always facilitates inversion of the mediocycle, as is clearly shown by comparing phanes *(28)* with *(29)*, and *(31)* with *(30)*. If in the phanes *(33)* or *(34)* the —S— is replaced by —N(Tos)—[88], the inversion barriers increase by *ca.* 5 kcal/mol (20.9 kJ/mol). However, contrary to expectation, the topomerization threshold for the dioxaphane *(37)* is lower than that for *(38)* by *ca.* 1 kcal/mol (4.2 kJ/mol)[89], which is a sign that shortening the chain by four times 11 pm (0.11 Å) can be compensated by the greater flexibility of the C—O—C bonding and the suppression of



(37)



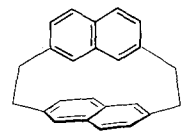
(38)



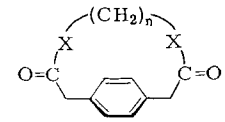
(39)

(40)

(41)



(42)

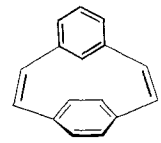


some *gauche*-H—H interactions. In *(39)* and *(41)* the $\Delta G_c^{\ddagger}$ values are again higher than those in the corresponding dithia compounds *(40)* and *(42)*. The nature of the atoms concerned in the steric interaction is thus also important[89, 90].

5.3.2. Flexibility

The change in molecular flexibility also has marked effects in other systems: Although there are two intra-annular H-π-interactions in the [2.2]naphthalenophane *(43)*, the ring-flip process is not more strongly hindered than in the [2.2]metaparaphane *(32)*, X=C—H[91]. This can be explained as a consequence of the greater flexibility of naphthalene compared with benzene[91–94]. If rigid ester or amide groups are introduced into the methylene bridge of [*n*]parabenzenophanes

(43)



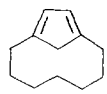
(44)

X = NH, O
R = H, CH_3

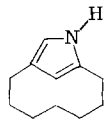
such as *(44)*, then the hindrance to *p*-phenylene ring-rotation is greater than would be expected from the bond lengths alone[95].

5.3.3. Changes in the Basic Skeleton

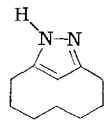
Even relatively slight changes in the basic molecular skeleton can have very drastic effects. Comparison of the coalescence temperatures of the flip processes in metaparabenzenophane *(32)*, X=C—H ($T_c=157$ °C) with that in the diene *(45)* ($T_c=-96$ °C)[65b, 68] shows clearly the decreased steric interaction



(45)

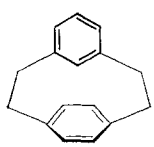


due to broadening of the angle in the bridge[96]. In the series *(46)*—*(49)* the free activation enthalpy for ring inversion increases rapidly with increasing angle α[97, 98]; $\Delta G_c^{\ddagger}$ amounts to 11.5 kcal/mol (48.2 kJ/mol) for *(46)*, to 18.2 (76.2) for *(47)*, and to >23 (>96) for *(48)* and *(49)*.

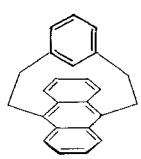


(46)

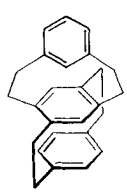
(47)



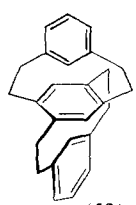
(48)



(49)



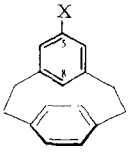
From a comparison of the coalescence temperatures[99] or the $\Delta G^{\ddagger}$ values for *(50)*[68], *(51)* and *(52)*[100] with those of the parent substance *(32)*, X=C—H, one may deduce the influences on the ground and the transition states. In *(50)* the ground state is destabilized by π-π interaction between the *m*-phenylene nucleus and the anthracene skeleton, but the transition state is stabilized relative to [2.2]metaparaphane



(32)

(50)

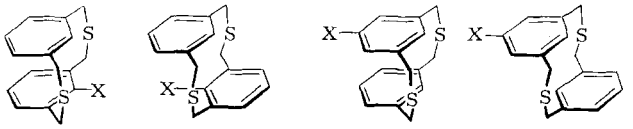
(51)



(52)

	(32)	*(50)*	*(51)*	*(52)*
$\Delta G_c^{\ddagger}$ [kcal/mol]	20.6	17.5	17.8	18.1
[kJ/mol]	86.3	73.3	74.6	75.8
T_c [°C]	156	82	100	116

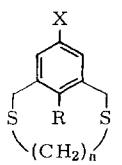
owing to the smaller loss of resonance energy. In *(51)* and *(52)* the flip is clearly facilitated by the prescribed boat-like deformation[101] of the central benzene ring.



5.3.4. Influence of Substituents

Strong steric compression of atoms and bonds must affect the electron distribution in the molecule. Since substituents also change the electron distribution, it should be possible to establish an influence of substituents on sterically hindered processes. *Boekelheide* found in the [2.2]metaparabenzenophane *(53)* a considerable influence of substituents at C-5 on the topomerization threshold[68, 102]. The relationship found between $\log(k_x/k_H)$ and Hammett's σ-parameters can be explained by assuming two opposing effects: stabilization of the ground state by electron-attracting substituents through the charge-transfer interaction of *m*- and *p*-rings, and destabilization of the transition state by electron-donor substituents, counteracting the charge displacement of H-8 and C-8 in the transition state.

(53)



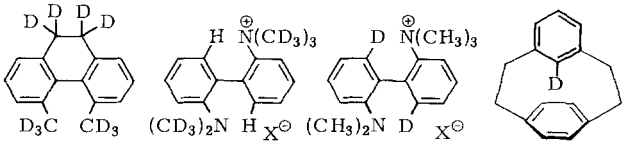
X = H, F, Br, NO_2, $COCH_3$, NH_2, OCH_3

syn-(54) *anti-(54)* *syn-(55)* *anti-(55)*

In compounds *(54)* and *(55)* the phanes with $X=NO_2$ exist preferentially in the *syn*-conformation, while those with $X=NH_2$ tend to adopt the *anti*-conformation[103]; this supports the assumption of charge-transfer interactions in *(53)*[104].

Such opposing effects are not to be expected in the metabenzenophane system *(56)*. However, here too the extra-annular substituents display a remarkable influence on the topomerization barriers[84]. A reasonably good correlation ($r=0.9$, 0.94, and 0.98) exists here with σ_R^0 parameters[105]; Hammett's parameters with an inductive component gave no correlation. The influence of substituents increases with increasing steric strain in the transition state and increasing polarizing effect of the substituent R. Hence it can be concluded that in the transition state of the topomerization *(34A)*⇌*(34B)* the intra-annular substituent is bent strongly out of plane and thus influences mainly the π-system[106].

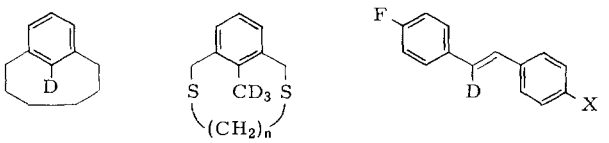
(56)



X = H, F, Cl, Br, I, NO_2, NH_2, NHAc, t-C_4H_9, CH_3, $CO_2C_2H_5$, CN

R = CH_3, OCH_3; n = 7, 8, 9

5.3.5. Deuterium Isotope Effects



Bartell[107] was the first to indicate that the smaller vibration amplitude of the C—D bond compared with the C—H bond was important for an explanation of the secondary deuterium isotope effect[108]. The fact that deuterium requires less space than hydrogen has been proved in numerous cases. The effect is so small that its detection can be taken as an indicator for the sensitivity of steric interactions in the process under study:

H. C. Brown[109] found the heat of reaction to be increased by up to 0.23 kcal/mol (0.96 kJ/mol) on the formation of the BF_3 adduct when 2,6-dimethylpyridine is replaced by 2,6-bis(trideuteriomethyl)pyridine. The influence of isotopes on the rate of racemization was investigated in the biphenyl system[110–112]; this again made clear the importance of the geometry of the energy-determining structure. In distinction from *(57)* ($k_D/k_H=1.18$)[110] and *(59)* ($k_D/k_H=1.18$)[111], no isotope effect was found for *(58)* in spite of the presence of 15 D atoms[112]. In *(58)* the D atoms clearly do not participate in an end-on interaction in the planar transition state, so that the shorter bond lengths do not come into play. Metaparabenzenophane *(60)*[68, 113] forces such interaction in an extreme measure, and accordingly, with $k_D/k_H=1.20$, exerts a very strong isotope effect on the flip rate.

(57) *(58)* *(59)* *(60)*

Similar relationships occur in the metaphane *(61)*[78]. The coalescence temperature of the deuterated derivative is *ca.* 3.5 °C lower than that of the deuterium-free compound ($k_D/k_H=1.07$). No isotope effect could, however, be established for the metaphanes *(62)* in spite of the three D atoms—here the orientation is clearly less favorable[84].

(61) *(62)*, n = 7,8 *(63)*

In *(63)* the substituent effect is clearly better transferred to the ^{19}F chemical shift than in the deuterium-free compound[114]—an example of a steric isotope effect in a compound that is itself only slightly sterically hindered.

Photodielectric Polymers for Holographic Use

By Shimon Reich[*]

The use of polymeric materials as "thick" recording media for holographic applications is discussed. These materials offer some interesting applications owing to their high diffraction efficiency, high storage density, excellent angular and spectral discrimination, as well as *in situ* real-time recording. The present state of art is outlined, as are prospects for the future.

1. Introduction

As often happens in science, *Gabor*'s idea[1, 2] of holography originated before the relevant technology for hologram recording was available. To appreciate this point we must briefly refresh our memory as to what holography really is; an interference method of recording light waves scattered by an object which is illuminated with coherent light. The scattered waves are caused to interfere with a phase-related reference wave, the reference beam, and thus produce an interference pattern. A record of this pattern contains all the information necessary to reconstruct the original wave scattered from the object. It accordingly contains the whole information about both the phase and the amplitude of this wave and is therefore called a hologram, being derived from the Greek "ὅλος", or whole. Recording and viewing configurations for a hologram are shown in Figure 1.

From the point of view of technology therefore we need a source of coherent light and a medium on which the interference pattern constituting the holographic information is efficiently recorded.

A practical coherent light source was realized only in 1960 with the advent of lasers, changing the fate of the idea of a holographic record from an interesting exercise in optics

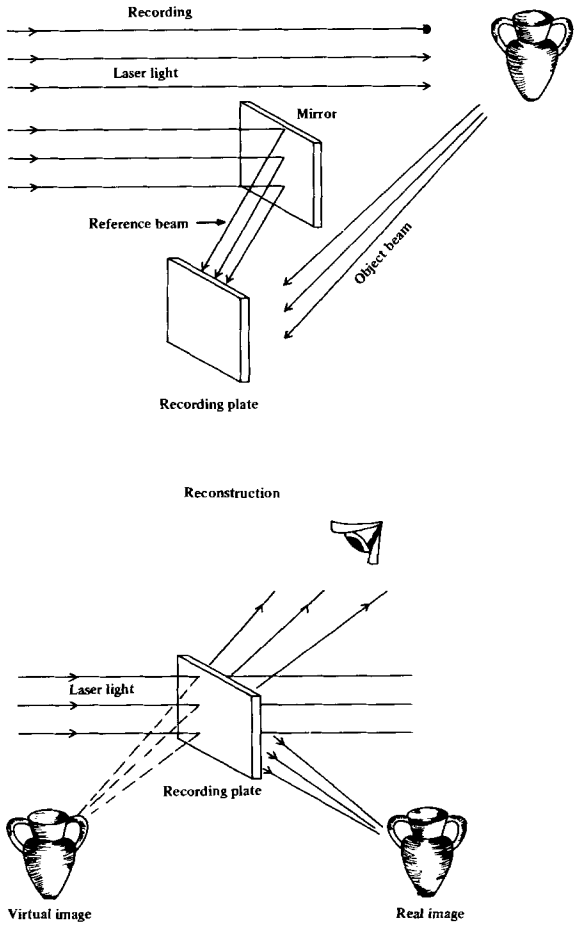

Fig. 1. Hologram recording and reconstruction configurations.

to a flourishing new branch of science and technology. As far as the recording medium was concerned the photographic plate was sufficiently advanced for holographic use. However, as we shall see it is not the ideal medium for many applications of the holographic method. To understand this we must look into the parameters that make the holographic record efficient. We know already that the hologram is just an interference pattern recorded on a piece of film; to see the object we must reconstruct the original wavefront diffracted by it. This is performed by illuminating the record with the readout beam.

The efficiency of this process is measured by so-called diffraction efficiency which is the ratio of the power in the diffracted image to the incident power of the reconstructing beam. This ratio does not exceed the theoretical value of 6.25 %[3] for an absorption light sensitive material—such as the photographic plate. However, the theory tells us that this limit is exceeded when instead of the "absorption material" we use a "phase material". The diffraction efficiency for a phase material may in some cases reach the ultimate limit of 100%.

In contrast to a photographic plate where the information is recorded by the magnitude of light absorption, in pure phase material this is done by photoinducing local changes in refractive index in the recording plate. By passing light through a "phase record" transparency we change the phase of the wavefront due to modulation of the refractive index; in conventional transparency we change the amplitude due to absorption. We see, therefore, that a good phase material would be a transparent photosensitive plate in which we can modulate the amplitude of the refractive index by light. To make this process efficient we wish to achieve the maximum amplitude of this modulation by investing minimum energy per unit area of the plate. It appears already at this stage of definition that polymers may indeed perform well as phase material. They are good film formers, they can be transparent and of good optical quality, they can serve as a solid solvent for various photosensitizers and also be photochemically activated by proper chemical substitution both in the UV or visible spectrum range. Polymers also exhibit a very wide rheological flexibility and can be formed as hard blocks or elastic sheets, viscoelastic films, adhesives between transparent glass plates, or coating on suitable substrates.

This physicochemical versatility together with the advanced technology of polymer chemistry, make them an attractive proposition as phase materials. For the last six years there have been serious attempts to produce polymeric phase material for holographic use. We shall try to follow one line in this attempt, namely the thick photodielectric polymers, and appreciate its achievements and prospects for the future.

2. Relevant Parameters in Thick Photodielectric Polymers

2.1. What are Photodielectric Materials?

We know already that, depending upon the type of recording materials, the storage mechanism for holographic information produces absorption or phase changes. These are best described in terms of a complex dielectric constant ε^*

$$\varepsilon^* \text{ (exposure)} = \varepsilon' + i\varepsilon'' \tag{1}$$

when $\varepsilon' = \text{const}$ and ε'' is the exposure dependent part of ε^*, then the recording material is an absorption medium, sometimes called an amplitude medium; when $\varepsilon'' = 0$ and ε' is primarily exposure dependent, this is a pure phase material which we shall call here a photodielectric.

2.2. What Are Thick Photodielectric Holograms?

Thick holograms have thicknesses hundreds of times greater than the wavelength of light[*]. To understand the basic difference between thick and thin holograms let us inspect Figure 2. We see recording and reconstruction geometries for thick and thin simple holographic gratings. When two monochromatic plane waves are overlapped on a thin photodielectric material, a record of sinusoidal variation in index of refraction (fringes of varying optical path) will result. The spacing d of these fringes is (Fig. 2a):

$$d = \lambda_0 / 2 \sin \theta_0 \tag{2}$$

where λ_0 = wavelength of recording laser; $2\theta_0$ = angle between object and reference beams.

[*] A more accurate definition [4] is: thick hologram $\equiv Q \geq 10$ where $Q = 2\pi\lambda D / n d^2$; D = hologram thickness; n = index of refraction; d see text.

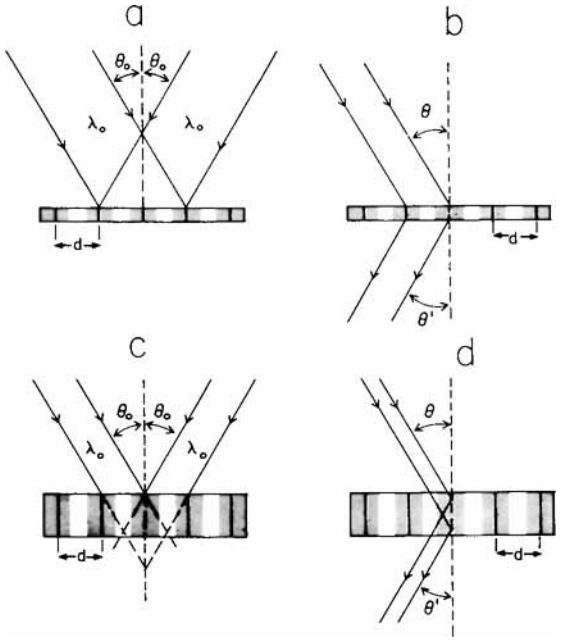

Fig. 2. Thin and thick photodielectrics, recording (left) and reconstruction (right) configurations: a, b, c, d—see text.

When reconstructing this hologram (Fig. 2b) with wavelength λ and incident angle θ the reconstruction will obey the thin gratings formula:

$$k\lambda = d(\sin\theta + \sin\theta') \qquad (3)$$
$$k = 0, 1, 2, 3, \ldots$$

where θ' is the angle for reconstruction. The angular discrimination for reconstruction is poor, since equation (3) is fulfilled for many θ' whatever the values of λ and θ in the incident wave may be. This is not the case in a thick photodielectric hologram. Upon recording, we produce in the plate a set of planes of varying index of refraction (Fig. 2c). Now the condition for reconstruction is obviously the Bragg condition (Fig. 2d).

$$2d\sin\theta = k\lambda \qquad (4)$$

The angular characteristics for reconstruction for such a grating will vary when we change λ, or both λ and θ. For large values of D the angular discrimination at fixed λ becomes critical—a small fraction of a degree. The diffraction efficiency (X) for such a thick hologram, which is sometimes also called a volume hologram, is given by the "coupled wave" theory[5–7] as

$$X \approx \sin^2(\pi D \Delta n/\lambda \cos\theta_B) \qquad (5)$$

where D = thickness of material; Δn = change in the refractive index; θ_B = Bragg angle (*i.e.* the half-angle between recording beams for the symmetrical case). Whenever the argument of the sine function approaches a multiple of $\pi/2$, the diffraction efficiency approaches 100%. In practice the limit of 100% can be reached to within a few percent only due to absorption and other unavoidable losses.

2.3. Some Other Important Parameters

Exposure sensitivity: The exposure required to produce a prescribed change in refractive index, and hence phase, for a given set of experimental conditions. Usually measured in joule/cm^2.

Spectral response: A measure of the exposure as a function of wavelength to produce a given phase change. Usually specified by means of a plot of sensitivity *vs.* λ.

Resolving power: A measure of the finest detail that a photodielectric can unambiguously record as a spatial variation of the refractive index.

Storage density: The maximum density of elementary units of information that the photodielectric can store; bits per unit volume.

Signal to noise ratio (SNR): SNR can be measured by recording Fresnel holograms[8] of a diffusely illuminated data mask consisting of a square with an opaque center. The recording geometry is arranged so as to have a known number of bits per unit area of the hologram. The average signal is determined from a scan across the bright area of the reconstructed image, and the average noise is determined from a scan across the dark area. The ratio of the average signal power to the average noise power is the SNR. Usually measured in dB.

In addition to the above well defined parameters, there is a class of experimental parameters which are much harder to standardize, but are of great practical importance. Those are temporal stability, temperature and humidity sensitivity and stability, mechanical integrity, and solvent stability.

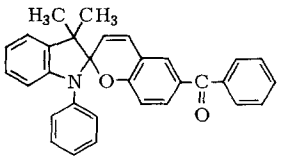
3. Photopolymers

In recent years a number of photopolymers have been proposed for recording phase holograms[9–16]. These are mixtures of one or more monomers with a dye-sensitized catalyst that initiates polymerization when activated by light. Typical formulations[9, 17] involve the photopolymerization of acrylates of barium, calcium, and lead, or acrylamide with methylenebis-(acrylamide) into polyamides. Table 1 shows an example[9].

Table 1. Starting material for a photopolymer [9]. The monomers were dissolved in water (pH = 6.3), and the photocatalysts in glycerol.

Monomers		Conc.
Barium acrylate	$(H_2C{=}CH{-}CO_2)_2Ba$	3.6 mol/l
Lead acrylate	$(H_2C{=}CH{-}CO_2)_2Pb$	0.9 mol/l
Acrylamide	$H_2C{=}CH{-}CONH_2$	30 g/100 ml solution
Photocatalysts		**Conc.**
Methylene blue		0.0022 mol/l
p-Toluenesulfinic acid		0.1 mol/l
4-Nitrophenylacetic acid		0.1 mol/l

Consider an example with methylene blue, which provides sensitization for He—Ne laser wavelength. In the excited state



it reacts with the *p*-toluenesulfinic acid to produce free radicals. Thus a free radical photopolymerization is initiated. A photopolymer of this kind is therefore a self-developing real time material. Fixing is achieved by uniform illumination so as to complete the polymerization process or by UV illumination that deactivates the methylene blue dye to a colorless product. The deactivation is effected by the UV photolysis products of the 4-nitrophenylacetic acid. The sensitivity of the material is about 0.5 mJ/cm^2 when presynthesized with 2 mJ/cm^2 of 632.8-nm light. This is considerably lower than that of a typical absorption material used in holography such as Agfa 8E75 Scientia ($\approx$0.0075 mJ/cm^2).

A system of acrylamide and methylenebis(acrylamide) is even less sensitive than the acrylate system ($\approx$5 mJ/cm^2 in the red spectral region[17]). The maximal amplitude of modulation of the refractive index (Δn) is high ($\approx$ 2.7%). The materials are capable of recording about 2000 lines per mm. This resolving power is apparently limited by formation of polymer clusters. Both volume and surface gratings are produced during the recording process. High diffraction efficiencies of approximately 50% are easily obtained. Plates of a few 100 µm in thickness can be prepared. Some of the photopolymer systems suffer a pronounced reciprocity failure *i.e.* they do not obey the Bunsen-Roscoe law which postulates that the sensitivity is independent of irradiation[17].

The time and light stability is not very good. The handling of the materials which have to be mixed just before use is inconvenient.

The mechanism of hologram formation in photopolymers was explained by *Colburn* and *Haines*[18]. A quite general characteristic of the polymerization process is that the resulting polymer exhibits higher density than the monomer. Thus, upon polymerization, an increase of index of refraction is observed. This is a pure density effect since the molecular polarizability per repeat unit of a polymer, for example, a vinyl polymer, is lower than the corresponding monomer[19]. According to *Colburn* and *Haines* when the photopolymer is illuminated by the interference pattern "fringes" of polymer exposed to higher light intensity will polymerize to a greater extent than other areas. This will create a gradient of monomer concentration driving a diffusion of the monomer from low irradiance areas (high concentration) to high irradiance areas (low concentration). This process will result in modulation of density and therefore index of refraction in the photopolymer plate that follows the interference pattern—*i.e.* the hologram.

An ingenious new photopolymer system was recently proposed by *Tomlinson*, *Chandross*, *Weber*, and *Aumiller*[19]. They call it a multicomponent photopolymer. They chose a liquid mixture of two monomers having very different rates of photopolymerization and molecular polarizabilities. During exposure, a preferential polymerization of the more sensitive monomer will result, creating gradients of this species. Diffusion depletes the areas of lower exposure. Thus the less exposed areas will be enriched in the second component which is chosen to produce a polymer of different index of refraction. Thus a selection process in chemical composition is established which will follow the intensity distribution in the holographic interference pattern. The refractive index modulation resulting from the above process is larger than the density effect described earlier.

(1)

Another ingenious photopolymer system was presented by *Jeudy* and *Robillard* in 1975[20]. They used a reversal photosensitization process in an *in situ* real time holographic recording. The reversed sensitization is accomplished by the use of a photochromic sensitizer, which reversibly changes color upon irradiation. They introduced indolinospiropyran *(1)* into acrylamide dissolved in poly(vinyl alcohol) with triethanolamine serving as promoter. When irradiated with UV light (λ = 300—400 nm) compound *(1)* goes into an excited state with an absorption band peaking near 600 nm. The colored excited species acts as a sensitizer for photopolymerization in the red region of the spectrum. The recording takes place only when the plate is subjected to UV irradiation. When the UV light is turned off, the sensitizer is deactivated from the colored excited state to a colorless ground state and the plate becomes transparent. This scheme possesses several advantages:

a) There is no need for fixation since the material is sensitive to red light only when irradiated with UV.

b) This scheme overcomes the classical dilemma in phase material; they should be as transparent as possible to exhibit high diffraction efficiency in the image reconstruction process; on the other hand, they must interact through absorption with the laser light in the recording stage. The reversal photosensitization solves this problem in an elegant way—the hologram is perfectly transparent on reconstruction.

4. Polymeric "Solid Network" Photodielectrics

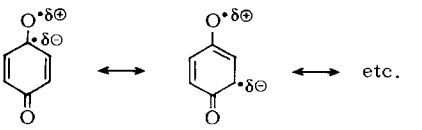
In 1970 *Tomlinson*, *Kaminow*, *Chandross*, *Fork*, and *Silvast* reported a new photodielectric medium sensitive in the UV range[21]. They found that suitably prepared poly(methyl methacrylate) (PMMA), when irradiated with actinic radiation (325 nm, He—Cd$^+$ laser), will change its refractive index by 8‰. This self-developing photodielectric is a pure phase material capable of very high resolution ($\approx$ 5000 lines/mm) and high diffraction efficiency ($\approx$ 70%). Though it is much less sensitive than dichromate-gelatin[21] it offered the great advantage of no wet processing. The authors realized the potential applications for this system for thick holograms[21, 22] as well as for induction of optical waveguides[23] into slabs of transparent PMMA.

The mechanism responsible for the observed modulation of the refractive index was attributed to photochemical cross-linking[21] or to photopolymerization of residual monomer[24]. The above system suffers mainly from two disadvantages; its exposure sensitivity is about 10^4 times lower than that of the photopolymer family, and its response is limited to the UV spectral range. To overcome these limitations *Laming*[25], *Zech*[26], and others[27, 28] introduced sensitizers active in the blue-green range of the spectrum into PMMA and other polymers. The materials obtained are pure phase materials a hundred times more sensitive than unsensitized PMMA and are capable of high resolution ($\approx$3000 lines/mm) with

diffraction efficiencies exceeding 90 %. Typical sensitizers are quinones such as *p*-benzoquinone, 2,5-dichloro-*p*-benzoquinone, 2,5-dimethyl-*p*-benzoquinone, chloranil, duroquinone[16], and α-diketones such as camphorquinone have also been used[27, 28].

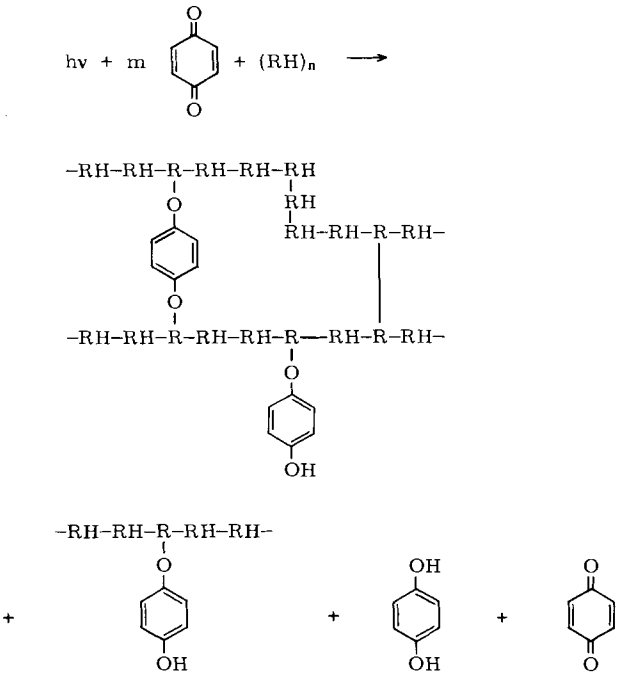
Apart from PMMA a broad family of polymers was tried as host materials, such as poly(vinyl acetate)[26], cellulose acetate butyrate, ethyl methacrylate[26], as well as acrylic polyesters and epoxies[27, 28].

In all these systems, the sensitizers are introduced into the polymer *via* a solvent, this procedure is dictated by the stabilizing nature of most of the sensitizers. For example, introduction of *p*-benzoquinone into methylmethacrylate monomer will hinder the radical polymerization process.



Recently[29] poly(α-cyanoacrylates) were tested as a polymeric host for sensitizers. Quinone sensitizers are introduced into the monomer. The methyl α-cyanoacrylate monomer for example, is highly reactive and it polymerizes both by free radical and by anionic initiation. When performed on a large scale bulk polymerization is inhibited by the introduction of quinone sensitizers. However, for large ratios of surface area to volume, anionic initiation is dominant and the polymerization occurs rapidly. When polymerization occurs, the excellent bonding and filling properties of the cyanoacrylates allow for the formation of an exact replica of a substrate of high optical quality to be achieved—such as optically polished glass—so that a recording plate of high optical quality is obtained. Furthermore, the volume of the polymer remains practically constant during the polymerization process[30], which is rather an exception. This allows the material to be used as a filling between glass optical elements and subsequently holographic optical elements (see Section 6) are recorded on it.

An important advantage in the preparation of these materials is that no solvent is needed to introduce the sensitizers into the polymer. Thus, the slow evaporation usually necessary in preparing other quinone-sensitized photodielectric media is avoided, resulting in excellent optical quality. The plasticizing action of the solvent on a polymer tends to degenerate its dimensional stability; also when it reacts with the sensitizer, the solvent degrades the sensitivity of the recording plate. Eliminating the solvent, thus makes it possible to obtain improved dimensional and chemical properties.



The fixation of the holographic record in solid network photodielectrics is generally performed by flooding the hologram with long-wave UV light. This procedure is believed to convert unreacted *p*-benzoquinone into quinhydrone complexes. The low sensitivity of this family of materials combined with a reciprocity failure effect observed in many of them permits hologram recording under conditions of high ambient illumination.

5. Recording Mechanism of Quinone-Sensitized Photodielectrics

It is known that a quinone sensitizer such as *p*-benzoquinone is a good hydrogen abstractor[31]. When irradiated with blue light, it is excited to the (n, π^*) triplet state which is responsible for the hydrogen abstraction.

Upon introducing this sensitizer into PMMA, for example the following photochemical reaction shown in Scheme 1 is expected[32].

Scheme 1. RH = methyl methacrylate unit with an abstractable hydrogen atom.

We see that *p*-benzoquinone may act as a hydrogen abstractor resulting in hydroquinone by a double abstraction and R—R crosslinkages.

Thus the *p*-benzoquinone effects photochemical branching and crosslinking in the PMMA. This scheme is well supported by a recent study[32]. When plotting the change in index of refraction Δn for various exposures *versus* the intrinsic viscosity of the post-exposure dissolved photodielectric, a monotonically increasing curve is obtained (see Fig. 3). This crosslinking mechanism is also supported by the observa-

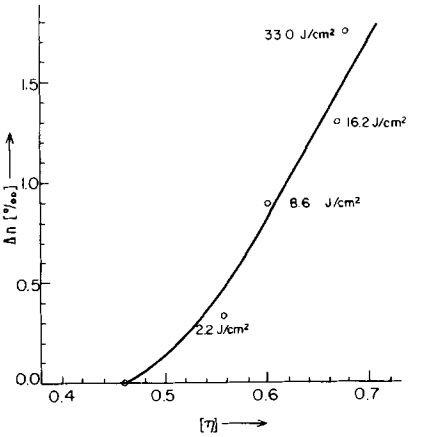


Fig. 3. Refractive index modulation Δn at various exposures for PMMA *versus* the intrinsic viscosity $[\eta]$ of the post-exposure dissolved photodielectric in chloroform. Dimensions of $[\eta]$: dl/g.

tion[29] that the main contribution to the index variation Δn is due to density increment.

Holograms are recorded, as we already know, by means of a small spatial modulation of the permittivity, $\Delta\varepsilon$, in the recording plate. This modulation is induced by variation of the molecular polarizability Δp or by a change in the number of molecules per unit volume ΔN which is a change in the density $\Delta\rho$. The Lorenz-Lorentz relation states that:

$$\varepsilon = \left(1 + \frac{2}{3\varepsilon_0} Np\right) \Big/ \left(1 - \frac{1}{3\varepsilon_0} Np\right) = \phi(p, N) \tag{6}$$

so that

$$\Delta\varepsilon = \frac{\partial\phi}{\partial p}\Delta p + \frac{\partial\phi}{\partial N}\Delta N \tag{7}$$

It was recently shown[29] that for certain families of quinone-sensitized polymers, the main photochemical effect is an increase in the density of the photodielectric material. The modulation of molecular polarizability is a secondary effect.

The above mechanism would suggest certain properties, some of them characteristic of macromolecular media. It would suggest that the holographic record in quinone-sensitized photodielectrics is a pure volume phenomenon and therefore obeys a master curve for different thicknesses of the recording plate. This is shown in Figure 4 where the refractive index modulation Δn is plotted *versus* exposure for various thicknesses of the recording plates.

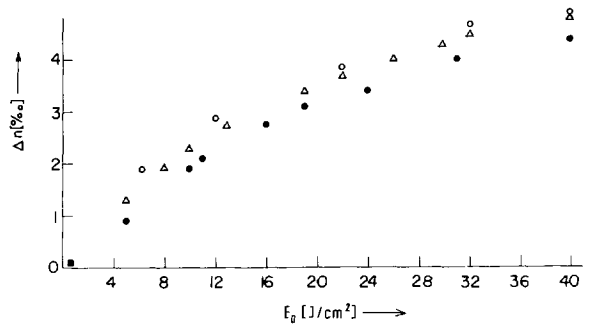

Fig. 4. Refractive index modulation Δn *versus* exposure (E_0) for PMCA plates of various thicknesses. △, 20 μm thick plate; ●, 30 μm; ○, 130 μm; ■, 1300 μm.

An extensive crosslinking of a solid polymer network also leads to a cooperative noise generation process. When the crosslinkage density is high enough, a local mechanical stress in the vicinity of one cluster of crosslinks will affect another adjacent cluster creating a small, relative displacement—this process will have a two-fold result. It interferes with the initial distribution of the crosslinks in the photodielectric—the record of the holographic signal—creating noise. A long term effect of creep of adjacent planes of high density towards each other will alter the spacing of the holographic volume grating in a thick record[33]. The last effect is particularly serious in reflection holograms in which the spacing of the adjacent grating planes is small $\lambda/2$ (the reflection holograms are recorded by impinging the signal and the reference beams one against the other in a frontal configuration with the recording plate in between, so that planes of high and low density are recorded parallel to the surface of the plate with a spacing of 244 nm for an argon blue laser (light). This effect is characteristic of viscoelastic polymeric medium[33].

6. Potential Uses of Polymeric Photodielectric Materials

Thick photodielectric polymers have not yet emerged from the laboratory to the market so that many of the applications are potential rather than actual. In 1963 *van Heerden*[34] already realized that thick holograms are capable of storing many holographic records at one time. This is due to their excellent angular and spectral discrimination, each hologram being recorded by using a different signal and reference beam direction. Thus in the volume of a small cube very many holograms are recorded.

In Figure 5 the excellent angular discrimination capabilities of a thick photodielectric are presented. The figure shows the reconstruction of 4 out of 20 superimposed but independent holograms that were recorded in a 1 mm thick plate. To separate the component holograms, the angular orientation between the reference beam and the sample was changed by 15 minutes of arc after each recording. Figure 5 depicts (a) the reconstructed image from the first recording, (b and c) those from the tenth and eleventh, and (d) that from the twentieth. The signal to noise ratio remains fairly constant for all reconstructed images, and there is little, if any, interaction between the reconstructed images.

In principle a 1 cm^3 cube of a high resolution material is capable of storing over 10^{12} bits of information. This figure, however, must be reduced by $\left(\frac{1}{\mathrm{SNR}}\right)^2$; taking SNR = 100:1 we obtain 10^8 bits[4]. Since an average book of 200 pages contains around 10^6 bits of information, one hundred such books may be stored in this cube. A large library of 100000 books may be therefore stored in a plate 1 cm thick, 25 cm wide and 40 cm high. This tremendous storage capacity may be used for archival purposes, for computer optical memories and even for storing cinematographic information. The stored information will be retrieved by slowly revolving the photodielectric in front of a powerful laser beam.

Another important use which is of immediate realizability is the production of holographic optical elements, such as lenses[35], spectral filters[4, 36], and diffraction gratings. Use of thick photodielectrics permits construction of holographic lenses with diffraction efficiencies of over 90 %[37]. It should be quite feasible to produce holographic gratings in thicknesses 10 mm or greater, with diffraction efficiencies of about 100 %, a spectral resolution of 0.1 nm, and an angular resolution of a few seconds of arc[4]. The use of such elements may be particularly desirable in very compact optical instruments and in integrated optics.

Another promising use is for display purposes, both for advertising use as well as for the display of rare artifacts. This may be particularly attractive when the three-dimensional holographic images are displayed in color[38]. By using thick,

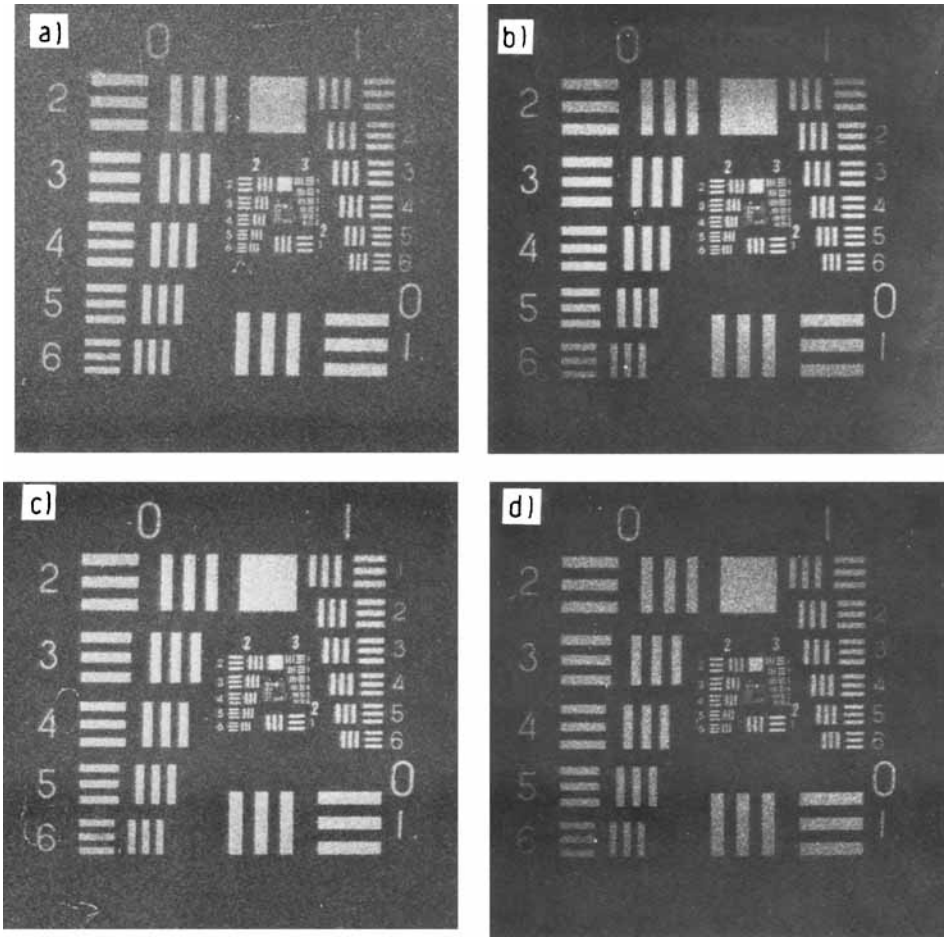

Fig. 5. Reconstructed images from multiple exposure hologram of twenty records; 1-mm thick PMCA plate. a) first recording; b) tenth recording; c) eleventh recording; d) twentieth recording.

reflection holograms, it is possible to record a scene illuminated with red, green and blue laser light. Read-out is performed by illuminating the holograms with a well collimated white light source. Such a technique may ultimately provide 3d pictures in color for illustration in books.

Finally, since many photodielectrics are *in situ* real time materials which do not require any wet process, they may be very successfully used for nondestructive testing applications[39]. This employs a holographic interferometric technique. The underlying principle is that the reconstructed image duplicates the original object in phase and amplitude. The reconstructed image may be substituted for the actual object in an interferometric application. This image may be used as a "standard" to test other similar objects. Likewise, the reconstructed image and the actual object can be compared by interferometry, which reveals the slightest differences in optical path. This technique may be used to measure vibrations, stress and strain patterns in three-dimensional objects. For instance, flaws may be easily detected by superimposing the hologram of an object before and after mechanical stressing. Figure 6 shows a real time differential hologram used to detect disbonds in a bonded honeycomb structure. A differential pressure of 20 torr was applied between two exposures, thus producing the interferometric effect. The holograms were recorded on a photoconductor-thermoplastic device[40]. This device records thin phase holograms by photoinducing a surface relief on a charged thermoplastic layer[41]. The use of thermoplastic polymers in these devices will not be reviewed in this article.

The main handicap of photodielectric materials is their low sensitivity and a narrow spectral response. The various materials are best compared with the aid of their "holographic sensitivity"[4, 42]. The so-called figure of merit S is given for thick holographic materials by

$$S=(X)^{1/2}/E_0 D \tag{8}$$

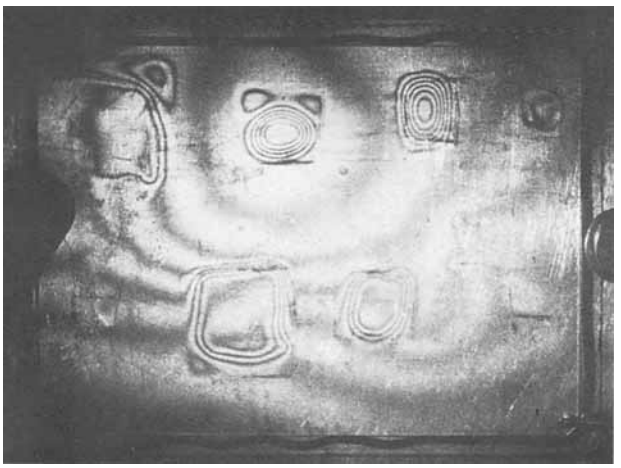

Fig. 6. Real time differential hologram of a stressed honeycomb structure recorded on photoconductor-thermoplastic device (recorded by Prof. *A. A. Friesem*).

where X = diffraction efficiency; E_0 = exposure; D = thickness of photodielectric. It is evident from Table 2, that the photodielectrics are many orders of magnitude behind the conventional photographic materials. Improving the sensitivity may bring the use of photodielectrics into the realms of both display and non-destructive testing. Another important development would be the introduction of panchromatic photodielectrics which will make color holography of high diffraction efficiency realistic. This would revive the old idea of *Lippman*[43, 44] of producing color photographs by an interference method and combine it with the 3d effect of holography.

Table 2. Figure of merit S for some recording materials used in holography [4]. PMMA, poly(methyl methacrylate); PBQ, *p*-benzoquinone; CAB, cellulose acetate butyrate; PMCA, poly(methyl α-cyanoacrylate).

Material	PMMA	PMMA +PBQ	CAB +PBQ	PMCA +PBQ	Dupont Photopolymer	
log$S$	−3	0	+1	+1	+2	
Material	NRC Photopolymer		Dichromate-gelatin		Kodak 649F bleached	Agfa 8E75
log$S$	+2		+4		+6	+8

An interesting and promising system could be created by using light-induced *cis-trans* transformations of small molecules embedded in a transparent polymeric host or bound chemically to the macromolecules. When accompanied by a change in the refractive index of the material, such *cis-trans* transformations may provide a thick photodielectric material with read/write/erase capability, that would be very attractive for optical computer memories.

Entropy, Binding Energy, and Enzymic Catalysis[**]

By M. I. Page[*]

Why are enzyme-catalyzed reactions so much faster than uncatalyzed reactions, and why are enzymes so specific? What is the effect of mere approximation of enzyme and substrate, and what is the influence of the strain energy? Attempts to answer these questions have led to comparisons between entropy changes in intermolecular and intramolecular reactions, and to determinations of the intrinsic energy of the bond arising by non-covalent interaction between enzyme and substrate.

1. Introduction

All of biology and chemistry is the result of intramolecular and intermolecular forces. The intermolecular non-covalent forces that hold two molecules together are responsible for such diverse phenomena as the existence of inert gas dimers to the formation of antibody-antigen complexes. The formation of enzyme-substrate complexes is also the result of these forces and the intrinsic binding energy resulting from the non-covalent interaction of a substrate with an enzyme appears to be responsible for a large fraction of the difference in the rates of enzyme and non-enzyme catalyzed reactions[1].

There appears to be nothing unusual in the pathways by which covalent bonds are formed and broken in enzyme-catalyzed reactions; the mechanisms used to account for ordinary chemical reactions are also applicable to nature's reactions. In fact, the rate enhancement of *some* enzyme-catalyzed reactions may be accounted for directly in terms of normal chemical mechanisms, such as covalent catalysis in which a covalent bond is formed between the enzyme and the substrate[2]. However, the actual mechanism does not always explain the enormous rate enhancements observed in enzyme-catalyzed reactions. This is especially true when the mechanism involves general acid or general base catalysis since these pathways are not particularly efficient as judged by the relatively small rate enhancements brought about by converting an intermolecular general acid- or general base-catalyzed reaction into an intramolecular one[3,4].

In the subsequent discussion we will address ourselves to the following questions:

1) Why are enzyme-catalyzed reactions so fast?

2) Why do some small non-specific substrates that bind to the active site of the enzyme react so slowly?

3) Why is the binding energy resulting from the non-covalent interaction of enzyme and substrate so large?

We believe that a large fraction of the rate enhancement brought about by enzymes is due to the high intrinsic binding energy between the substrate and the closely-packed covalently linked atoms in the protein. These substrate-enzyme interactions are greater than substrate-solvent or substrate-solid interactions because the number and, possibly, the magnitude of the dispersion forces are greater within the enzyme-substrate complex. However, we also believe that the separation of the substrate binding process from the chemical mechanisms of catalysis to explain specificity and the rate enhancement, respectively, does not give a comprehensive understanding of enzyme catalysis.

An upper limit to the rate enhancement that may be brought about by binding the reactants to the active site of an enzyme, or by covalently binding them together as in an intramolecular reaction, may be obtained, in the absence of strain effects, from the different entropy changes that occur in bimolecular and unimolecular reactions. It will be shown that theoretical and experimental studies of intramolecular reactions indicate that this maximum is about 10^8 mol l^{-1}.

It will also be shown that there is no justification for using the relative rates of a series of intramolecular reactions to substantiate novel theories of enzyme action. The variation may be adequately rationalized by the difference in entropy changes and strain-energy changes in the systems studied.

2. Some Selected Problems

2.1. Rate Enhancement

The rate of an enzyme-catalyzed reaction is very much higher than that of the uncatalyzed reaction. For example, liver esterase-catalyzed hydrolysis of esters proceeds very much faster than the non-enzyme catalyzed reaction[5]. However, several problems arise on putting even this simple statement on a more quantitative basis. Should one compare the rate of an enzyme-catalyzed hydrolysis reaction with the rate of the water-, the acid-, or the base-catalyzed hydrolysis of the same substrate? It appears that whatever the actual comparison made, the rate of the enzyme-catalyzed reaction is often about 10 orders of magnitude faster than that of the non-enzymic reaction. For example, the turnover number for the liver esterase-catalzyed hydrolysis of ethyl acetate is about 10^{13} times greater than the rate of the pH-independent water-catalyzed hydrolysis and about 10^{10} times greater than the hydroxide ion-catalyzed hydrolysis at $pH \approx 7$[5]. Another example is the increase of more than 10^9 brought about by triosephosphate isomerase in the rate of enolization of dihydroxyacetone phosphate compared with the uncatalyzed reaction[6]. This is a lower limit since for this reaction the rate-limiting step is diffusion apart of the enzyme and the product, D-glyceraldehyde 3-phosphate, rather than any bond making or breaking processes[6]. It is worth recalling that such large numbers as these mean that, for example, a rate enhancement of 10^{10}

would alter the half-life of a reaction from, say, 300 years to one second.

Another difficulty with evaluating the rate enhancement brought about by the enzyme is that it sometimes involves a comparison of the rates of reactions of different kinetic order which gives a number having the units of concentration (see Section 3).

2.2. Specificity

The situation where a large substrate binds poorly to an enzyme may be rationalized in terms of steric effects: the substrate is simply too large to fit into the active site. However, it is more difficult to explain why some small nonspecific substrates that can bind to the active site of enzyme react very slowly. For example, the rate of acylation of chymotrypsin by the specific substrate *N*-acetyl-L-tyrosine ethyl ester *(1)* is more than 4×10^7 times greater than that by the small nonspecific substrate ethyl acetate *(2)*[7, 8]. The reactivities of the ester group in these two molecules are probably similar and ethyl acetate should be able to fit into the active site and yet its free energy of activation is at least 43 kJ mol^{-1} higher than that of the larger substrate.

(1)

(2)

It is these two problems, the rate enhancement and the specificity of enzyme-catalyzed reactions, that we would like to understand.

3. Approximation and Intramolecular Reactions

The factors responsible for the efficiency of enzymic catalysis are usually interpreted in terms of the following contributions:

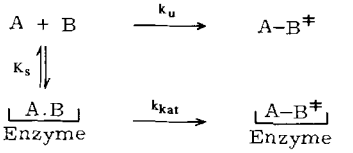
1) covalent catalysis;
2) general acid-base catalysis;
3) approximation;
4) strain or distortion.

Covalent catalysis occurs where an electrophilic or nucleophilic group on the peptide chain of the enzyme forms a bond with the substrate. Acidic and basic groups may act as general acids or general bases by, respectively, adding protons to or removing protons from the substrate. These mechanisms of catalysis have been well described[2] and we shall not consider them further. Enzymes are also thought to be effective by bringing the reactants together which is referred to as approximation or proximity, the effect of having the reactants near each other. Enzymes may also facilitate the reaction by inducing some sort of strain or distortion in the substrate. This may be manifested by geometric, desolvation, or electrostatic destabilization but this phenomenon is basically dependent upon the binding energy between the enzyme and the substrate since such destabilization induced in the substrate will only result in a rate enhancement if it is "paid for" by the binding energy[7, 9].

Attention here will be focused on approximation and the use of intramolecular reactions as models for enzyme-catalyzed reactions.

It has long been known that intramolecular reactions (a), in which the reactants are covalently bonded to one another, often proceed very much faster than the analogous intermolecular reaction (b). These intramolecular reactions are frequently taken as models for enzyme-catalyzed reactions where the reactants are held close together in the enzyme-substrate complex *(3)*. It is therefore suggested that the enzyme also facilitates the reaction by this approximation of reactants.

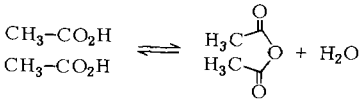
(a)



(b)

(3)

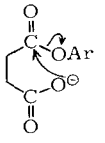
The problem, then, is to estimate the maximum rate difference between k_{cat} (for the enzyme-catalyzed reaction) and k_u (for the uncatalyzed reaction) [equation (c)] simply on the basis of approximation and in the absence of strain or solvation effects and without involving chemical catalysis by the enzyme.



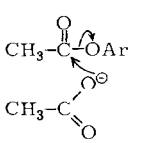
(c)

An understanding of intramolecular reactions is therefore of relevance to this problem of enzymic catalysis and we shall now attempt to rationalize the rate enhancements found in these systems.

Typical rate enhancements and favorable equilibria of intramolecular reactions are illustrated by some reactions of succinic acid and its derivatives. The equilibrium constant for



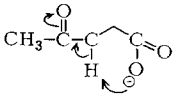
(d)



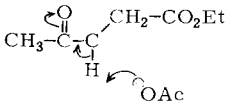
(e)

succinic anhydride formation from succinic acid [equation (d)] is 3×10^5 mol l^{-1} more favorable than that for acetic anhydride formation from acetic acid [equation (e)][10], an analogous intermolecular reaction. A similar situation exists

(4)

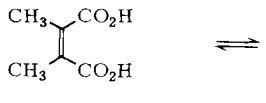


(5)

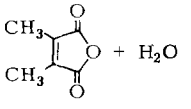


for the rates of reactions. For example, the rate of succinic anhydride formation from the succinate monoester, by intramolecular nucleophilic attack of the carboxylate group on the ester group *(4)*, is also about 10^5 mol l^{-1} greater than that of the analogous intermolecular formation of acetic anhydride *(5)*[11]. A special explanation for the rate differences which is peculiar to the activated complex is not required since the favorable reactions of intramolecular systems over their intermolecular counterparts are manifested in both rates and equilibria[4].

The rate enhancements and favorable equilibria have units of concentration because a unimolecular reaction is being compared with a bimolecular one. For this reason the rate enhancement is sometimes called the "effective concentration" or "effective molarity", which is the hypothetical concentration of one of the reactants in the intermolecular reaction required to make the intermolecular reaction proceed at the same rate as that of the intramolecular one.



In general, however, the effective concentrations or rate enhancements of intramolecular reactions do not show a constant value but cover a very wide range from about 1 to 10^{15} mol l^{-1}[4]. For example, the intramolecular general base catalyzed enolization reaction of 4-oxopentanoate *(6)*, in which the neighboring carboxylate group removes a proton in a five-membered ring transition state, shows an effective concentration of 0.5 mol l^{-1} compared with the analogous intermolecular reaction of *(7)*[12]. However, the equilibrium constant for the dehydration of dimethylmaleic acid *(8)* to give the five-membered ring acid anhydride *(9)* is about 10^{12} mol l^{-1} times more favorable than that for acetic anhydride formation from acetic acid[10, 13].



(6)

(7)

(8)

(9)

We believe that it is this wide variation in rate enhancements which has caused so much confusion in the literature and retarded a rational explanation of intramolecular catalysis.

Given this large range of rate enhancements one is again led to ask the question: "What is the maximum rate increase expected from approximation by simply bringing the reactants together without invoking strain or solvation effects"? Until recently[14], it had been generally accepted that the small rate enhancements are normal with the value 55 mol l^{-1} being commonly used. Thus the observation of a larger value was thought to require a special interpretation, such as rotamer distribution[15], orbital steering[16], stereopopulation control[17], vibrational activation[18], or freezing at the reactive centers of enzymes (FARCE)[19].

We believe that the large effective concentrations or rate enhancements are to be expected from known chemical principles[4, 14]. It is the observation of a low effective concentration, if anything, which requires a special explanation.

Actually it is quite easy to set an *upper* limit to the rate enhancement that may be brought about by covalently binding the reactants together, as in an intramolecular reaction, or by binding them to the active site of an enzyme. This may be done by considering the different entropy changes that occur in bimolecular and unimolecular reactions[4, 14].

There are different degrees of freedom lost in intramolecular and analogous intermolecular reactions which gives rise to large differences in the entropy change between the two systems. For a non-linear molecule containing n atoms there are three degrees of translational freedom, *i.e.* its freedom to move along the three axes in space; there are also three degrees of rotational freedom representing the freedom of the whole molecule to rotate about its center of gravity. This leaves $3n-6$ degrees of freedom associated with internal motions in the molecule, *i.e.* vibrations and internal rotations. On forming the product of a bimolecular association reaction [equation (f)] there is a loss of three degrees of translational

	A + B	⇌	A–B
Translation	3 + 3		3
Rotation	3 + 3		3
Vibration	3n − 6 + 3n′ − 6		3n + 3n′ − 6

(f)

freedom and a loss of three degrees of rotational freedom. There is a gain of six new vibrational modes in the product. However, in the uni- and intra-molecular reaction [equation (g)] there is *no* net change in the number of degrees of freedom

	A B	⇌	A–B
Translation	3		3
Rotation	3		3
Vibration	3n − 6		3n − 6

(g)

of translation, rotation, and vibration upon forming the product. The entropy associated with these motions may easily be calculated from the partition functions[4], which are simply an indication of the number of quantum states that the molecule may occupy for each type of movement.

The translational entropy of a molecule is proportional to its mass, the temperature, and the volume of space available to it. For a standard state of 1 mol l^{-1} and at 298 K physical constants make up the bulk of the contribution to translational entropy which for most molecules, therefore, has only a small dependence upon mass. A molecule rotates about its center of gravity and the rotational entropy of a molecule is proportional to the moment of inertia, the temperature, and the symmetry of the molecule. However, again physical constants make up the major contribution and so for average size molecules there is only a small dependence of rotational entropy upon the actual size and structure of the molecule. The entropy accociated with internal rotation, that is the rotation about a single bond of one group against another, depends upon the moment of inertia and the symmetry of the rotating group, the temperature, and the energy barrier to rotation. Finally, the vibrational entropy of a molecule depends upon the frequency of vibration and the temperature.

In Table 1 are shown some typical values of these entropy terms. For a standard state of 1 mol l^{-1} the translational entropy is normally about 120 to 150 J K^{-1} mol^{-1}, and, as previously mentioned, this value is not very dependent upon the molecular weight. For the majority of medium-sized molecules the entropy of rotation is about 85 to 115 JK^{-1} mol^{-1} and not normally very dependent upon the size and structure of the molecule. The exceptionally small value for water, 44 JK^{-1} mol^{-1}, results because in this molecule nearly all the mass is concentrated at the center of gravity and hence the moment of inertia, and thus the entropy, is small. The entropy of internal rotation makes a comparatively small contribution to the total entropy of the molecule and the vibrational contribution is even smaller except for the very low vibrational frequencies.

Table 1. Typical entropy contributions from translational, rotational, and vibrational motions at 298 K [14].

Motion	S^0 [JK^{-1} mol^{-1}]
Three degrees of translational freedom molecular weights 20 to 200 standard state 1 mol l^{-1}	120—148
Three degrees of rotational freedom	
water	44
n-propane	90
endo-dicyclopentadiene $C_{10}H_{12}$	114
Internal rotation	13—21
Vibrations $\omega = 1000$ [cm^{-1}]	0.4
800	0.8
400	4.2
200	9.2
100	14.2

These calculations apply to the gas phase and it is not possible, at present, to perform similar entropy calculations in the liquid phase. However, the entropy of a molecule in solution may be obtained from observed or empirically estimated entropies of vaporisation, the change in entropy for the transfer of a molecule from the liquid to the gas phase[4, 14]. The entropy change for a bimolecular reaction may thus be estimated in the gas phase and in solution (Table 2). In the gas phase, for a standard state of 1 mol l^{-1} and at 298 K the total loss of translational and rotational entropy for a bimolecular association reaction is about -220 JK^{-1} mol^{-1} and this value has only a small dependence upon the masses, sizes, and structures of the molecules involved. However, this loss is often compensated to varying extents by low frequency vibrations in the product or transition state. For several reactions having "tight" transition states or covalently bonded products the change in internal entropy is about $+50$ JK^{-1} mol^{-1}[4, 14] so the total entropy change is predicted to be about -170 JK^{-1} mol^{-1}, which is the value observed experimentally for many bimolecular gas phase reactions[4, 14]. In solution, the entropy change for a bimolecular reaction is estimated to be only about 20 JK^{-1} mol^{-1} less than that in the gas phase, at the same standard state of 1 mol l^{-1}. This is because the product or transition state usually has a higher boiling point than the reactants and consequently has a more negative entropy of transfer from the gas phase to solution (Table 2)[14].

Table 2. Entropy changes for a bimolecular reaction [4, 14] at a standard state of 1 mol l^{-1} and at 298 K in JK^{-1} mol^{-1}.

Gas	A	+	B	⇌	Product or transition state	ΔS
S_{trans}	135		135		140	−130
S_{rot}	100		100		110	− 90
S_{int}	12		12		74	+ 50
S_{tot}	247		247		324	−170
$-\Delta S_{vap}$	−40		−40		−60	
Solution	A	+	B	⇌	Product or transition state	−150

These suggestions are in accord with the well known experimental fact that equilibrium and activation entropies for Diels-Alder reactions of -125 to -170 JK^{-1} mol^{-1} are very similar in the gas and liquid phases. Many other bimolecular association reactions, which are apparently free of solvation effects, also have similarly large negative entropy changes in solution[4, 7, 14].

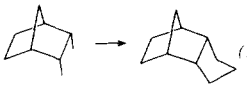
Since this large loss of entropy for a bimolecular reaction is avoided if the reactants are bound to an enzyme active site (equation (c)) or converted in an intramolecular reaction [equation (a)], the maximum entropic advantage from approximation may now be estimated [equation (h)].

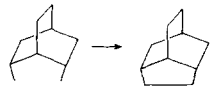
$$A + B \rightleftharpoons A\cdots\cdots B \rightleftharpoons A - B \qquad (h)$$

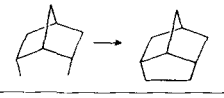
	"Loose" transition state or product	"Tight" transition state or product	Maximum
ΔS [JK^{-1} mol^{-1}]	−40	−150	−210
Effective concentration [mol l^{-1}]	10^2	10^8	10^{11}

The theoretical most negative entropy change for a bimolecular reaction is about -210 JK^{-1} mol^{-1} which is equivalent to 63 kJ mol^{-1} at 298 K and makes such a reaction unfavorable by a factor of 10^{11} mol l^{-1}. However, this is very rare and a more general situation is that this large loss of translational and rotational entropy is compensated for by an entropy change of about $+60$ JK^{-1} mol^{-1}, resulting from changes in internal motions on going from the reactants to the product or transition state and from differences in entropies of vaporization of reactants and products giving bimolecular reactions a total entropy change of about -150 JK^{-1} mol^{-1}. Since this loss of entropy does not take place for a reaction in which the reactants are bound to the active site of an enzyme [equation (c)] or for an intramolecular reaction [equation (a)] the approximate *maximum* effective concentration or rate enhancement for these reactions from entropic factors alone is about 10^8 mol l^{-1}. In the comparatively rare situation of a bimolecular reaction having a very "loose" transition-state or product then association will be even less entropically unfavorable since the entropy of the low frequency vibrations in the "loose" complex will counterbalance the large loss of translational and rotational entropy[4, 14]. The rate enhancement for the analogous intramolecular reaction will, therefore, be smaller, perhaps in the range of 100 mol l^{-1} or less.

It is important to emphasize that these entropy differences will not necessarily be reflected in the observed entropy changes of a reaction since these are dominated by solvent effects and are difficult to interpret[7].







In summary, rate enhancements of about 10^8 mol l^{-1} are expected for intramolecular and enzymic reactions simply on the basis of the difference in entropy changes between bimolecular and unimolecular reactions. Reactions which show rate enhancements greater than this are probably the result of additional contributions from potential energy differences. Smaller rate enhancements may result either from a "loose" transition state or product or from unfavorable entropy changes, such as the loss of internal rotations, and/or potential energy changes in the intramolecular reaction[4].

It is instructive to examine how these factors may account for the large variation in rate enhancements found in intramolecular reactions because these differences have often been used to justify new concepts and theories related to enzyme catalysis. We believe that the variation in the rates of reaction observed in the systems used by the proponents of these theories may be satisfactorily explained using the existing concepts of entropy and strain-energy effects[4].

4. Strain-Energy Effects

The intramolecular reaction, which invariably proceeds *via* a cyclization step, is often accompanied by the introduction and sometimes the relief of strain in the molecule; these changes may therefore either decrease or increase the effective concentration. As a model for the changes in strain energy that occur when a molecule undergoes cyclization one may examine an analogous hydrocarbon system[4]. The strain energy of a hydrocarbon may be evaluated either from a "molecular mechanics" procedure[20] or from a group additivity scheme[21]. Table 3 shows examples of the changes in strain energy that occur upon cyclization of some hydrocarbons[20–22]. Also shown are the estimated changes in entropy due to the loss of internal rotation upon cyclization[4].

Table 3. Estimated relative energy changes of ring closure reactions of hydrocarbons at 298 K in kJ mol^{-1} (see also Section 1).

System		ΔH Strain	$-T\Delta S$ Int. Rot.	$\log K_{rel}$ $\log k_{rel}$
	*(10)*	33.5	16.3	0.0
	*(11)*	26.8	10.9	2.1
	*(12)*	23.8	10.9	2.6
(13) 	*(14)*	14.0	10.9	4.3
	*(15)*	18.8	5.4	4.5
	*(16)*	−4.2	5.4	8.5

The combination of these data gives the predicted relative rates or equilibrium constants for a series of intramolecular reactions of similar structure to these hydrocarbons. For example, Fig. 1 shows a plot of the observed relative equilibrium constants for anhydride formation from a series of dicarboxylic acids[13] against the predicted values calculated as just described. This comparison means that, for example, the change in strain energy in the cyclization of 2,3-dimethyl-2-butene *(13)* to 1,2-dimethylcyclopentene *(14)* is used as a model for the cyclization of dimethylmaleic acid *(8)* to dimethylmaleic anhydride *(9)*. The justification for this procedure is that the strain energy is, to a crude approximation, characteristic of the ring size of a molecule and not of its constituent atoms[4]. In Figure 2 are shown the data for the hydrocarbons

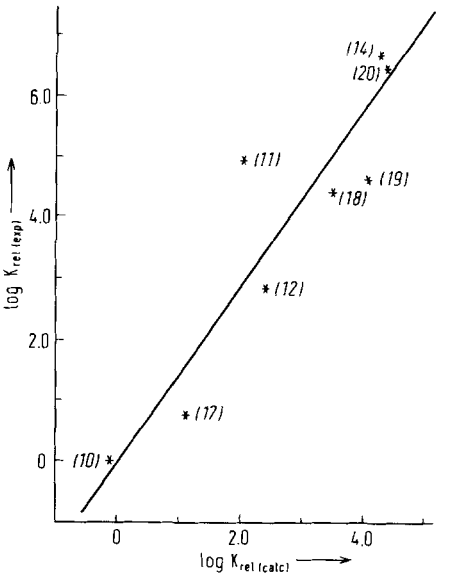


Fig. 1. Relative equilibrium constants $K_{rel(exp)}$ for anhydride formation from dicarboxylic acids plotted *vs.* $K_{rel(calc)}$ for cyclization of the corresponding hydrocarbons [products *(10)*, *(11)*, *(12)*, *(14)*, see Table 3; *(17)* to *(20)*, see below].

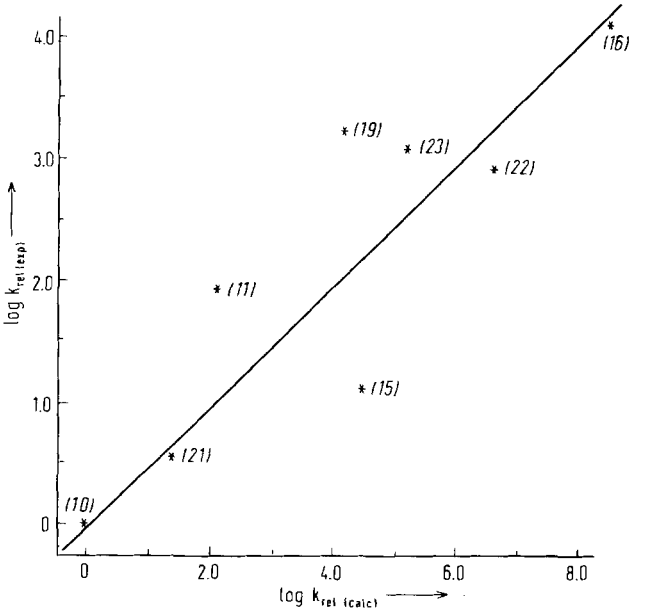

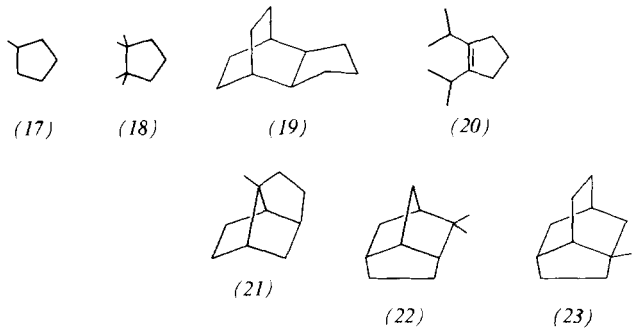

Fig. 2. Relative rate constants $k_{rel(exp)}$ for acid-catalyzed lactonization of hydroxy acids, plotted *vs.* $k_{rel(calc)}$ for cyclization of the corresponding hydrocarbons [products *(10)*, *(11)*, *(15)*, *(16)*, see Table 3; *(19)*, *(21)* to *(23)*, see above].

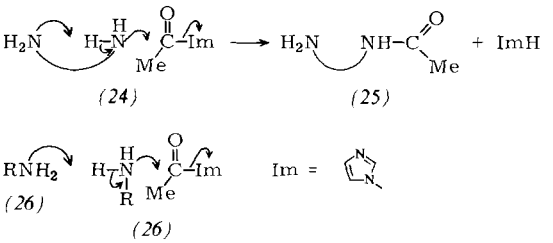
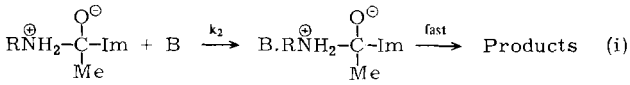


(17) (18) (19) (20) (21) (22) (23)

which correspond to the hydroxy acids and lactones used to justify the concept of "orbital steering"[16]. Despite the obvious limitations to the use of such models, the results do serve to show that the variation in the rates and equilibria of a series of intramolecular reactions may be accounted for simply by the differences in the strain energies of the reactants and products, or transition states, and by the differences in the entropy changes due to the loss of internal rotations[4]. Several other series of intramolecular reactions have been treated in this way and show similarly good correlations[23].

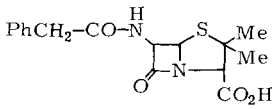
5. Reactions with "Loose" Transition States



Bimolecular reactions which proceed through "loose" transition states are entropically less unfavorable than those involving "tight" transition states[4, 14]. This is because the entropy of low frequency motions in the transition state compensates for the large loss of translational and rotational entropy. Consequently, an analogous intramolecular reaction should show a smaller rate enhancement or effective concentration. Such a situation exists in proton transfer reactions and, to date, all reactions involving intramolecular general acid or general base catalysis have low effective concentrations. This appears to be true for proton transfer to or from both electronegative atoms and carbon atoms[4]. Presumably this is because such reactions either have a transition state which is a very loose hydrogen-bonded complex or have a rate-limiting step which is diffusion controlled[24]. Thus there does not seem to be much of an advantage upon changing an intermolecular general acid or general base catalyzed reaction to an intramolecular one.

A system which exemplifies this situation is the intramolecular general base-catalyzed aminolysis of acetylimidazole by several diamines *(24)* to give the corresponding amides *(25)* and imidazole. The effective concentration of the catalyzing amino group compared with the analogous intermolecular

(24) (25) (26)



reaction of the amines *(26)* is only about 1 mol l^{-1}[3]. Potential energy effects are not predominant in this reaction since there is only a small sensitivity to the structure of the diamine[3]. General base catalysis in the intermolecular reaction of the amines *(26)* probably involves rate-limiting diffusion-controlled encounter of the tetrahedral intermediate with the base[25], k_2 in equation (i). The transition state is thus very

(i)

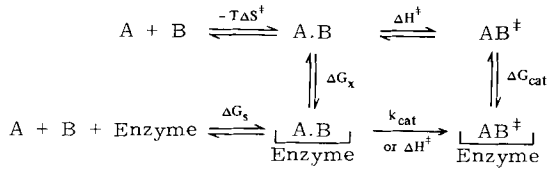
loose and the bimolecular step (k_2) will be associated with a small entropy change giving rise to the low effective concentration of the intramolecular reaction.

A similar situation exists for the aminolysis of benzylpenicillin *(27)*. The rate constant for the uncatalyzed reaction of ethylenediamine with benzylpenicillin is at least 25 times greater than that of a monoamine of the same basicity, which is indicative of intramolecular general base catalysis. However, the effect of intramolecularity itself is small and the effective concentration compared with the intermolecular general base-

(27)

catalyzed reaction is only about 1 mol l^{-1}, which is also suggestive of a "loose" transition state[26].

In summary, there is little or no advantage of having the catalyst covalently bonded to one of the reactants if the transition state is a very "loose" one.



6. Binding Energy and Enzymic Catalysis

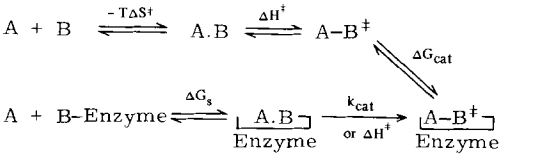
Bringing two molecules together is entropically unfavorable and although the situation for an enzyme-bound substrate [equation (c)] is similar to an intramolecular reaction [equation (a)] where this large loss of entropy is avoided, there will, of course, be an unfavorable entropy change for initially binding the substrate to the enzyme. If catalysis is to be efficient then this large loss of entropy must be compensated by the binding energy resulting from the favorable noncovalent interaction between the substrate and the enzyme.

The importance of binding is evident when the substrate concentration is below K_M, the Michaelis constant, and the rate of reaction is given by v_{max}/K_M so that an increase in binding, that is a smaller value of K_s, results in an increased rate of reaction. We will consider two examples where the binding energy compensates for the loss of entropy occurring in the uncatalyzed reaction; these are for the situation where there is no chemical catalysis by the enzyme and for the case of the substrate reacting with a catalytic group on the enzyme[1, 7].

6.1. Reaction without Chemical Catalysis by the Enzyme

Suppose two compounds A and B react to form a transition state AB^+ in an uncatalyzed reaction. The free energy of activation may be arbitrarily separated into the entropy and enthalpy of activation [equation (k)]. This *same* transition

(k)



state may be reached with the reactants bound to the active site of an enzyme, *i.e.* we are considering a process in which there is no chemical catalysis by the enzyme, the function of which is simply to bring the reactants together. Any increase in the rate of reaction brought about by the enzyme is given by the enthalpy of binding the enzyme and substrates minus the entropy of association of the transition state and the enzyme[1] [equation (l)]. The term $T\Delta S_x$ in equation (l)

$$\Delta G_{cat} = \Delta H_s - T\Delta S_x \quad (l)$$

represents the unfavorable loss of entropy in having the enzyme act as a catalyst. Any excess of the intrinsic binding energy between the enzyme and substrates over this entropy loss will thus appear as catalysis of the reaction. Pictorially, the entropy effect may be regarded as "entropic strain" that is compensated by the binding energy[1].

6.2. Reaction with a Group in the Enzyme[7]

Suppose, as previously, two molecules A and B react to form a transition state $AB^{\ddagger}$, but this is now compared with the situation where B is covalently bonded to the enzyme [equation (m)]. Any free-energy advantage of the enzymic

(m)

reaction is then given by equation (n) which may be simplified to equation (o), if it is assumed that the entropy of activation $T\Delta S^{\ddagger}$ is equal to the entropy change of binding the substrate A to the enzyme, $T\Delta S_s$, which will be, as we have already seen, approximately true.

$$\Delta G_{cat} = \Delta H_s + T\Delta S^{\ddagger} - T\Delta S_s \quad (n)$$
$$\Delta G_{cat} = \Delta H_s \quad (o)$$

In this case the amount of catalysis is given directly by the binding energy between the enzyme and substrate and shows the advantage of covalent catalysis in enzymic reactions.

It should be emphasized, again, that the quantities referred to here will not be reflected in measured enthalpies and entropies of reaction which are dominated by solvent effects.

Before going on to consider the magnitude of the enzyme-substrate binding energy it is worth pointing out that the classical separation of specificity and catalysis may not be valid[1]. Often the specificity of the substrate binding process, which may be described by some sort of "lock and key" model, is treated as a separate process from the catalytic rate acceleration which is explained in chemical terms. In fact, many enzymes exhibit their specificity in their maximal rates of catalysis rather than in substrate binding.

In the derivation of equation (o) it was assumed that $T\Delta S^{\ddagger} = T\Delta S_s$, which will be true for good substrates that bind tightly. However, poor substrates, which will often have a smaller enthalpy of binding, will bind more loosely and the loss of entropy will be smaller so that $T\Delta S_s$ may be less than $T\Delta S^{\ddagger}$. Since enough entropy will then not have been lost to reach the transition state k_{cat} would be smaller but the apparent free energy of binding would be unchanged for the poorer substrate, if changes in $T\Delta S_s$ are exactly compensated by changes in ΔH_s. Much or all of the more favorable intrinsic binding energy of good substrates may therefore appear as a rate acceleration rather than as an increase in the binding constant. Only when $T\Delta S_s = T\Delta S^{\ddagger}$ will the increased interaction energy of good substrates be reflected in better binding.

7. The Magnitude of the Binding Energy

Observed free energies of binding substrates to enzymes are often less than the enthalpic intrinsic binding energy because much of the binding energy is "used up" in bringing about the required loss of entropy and in inducing any destabilization of the reactants[1]. However, there are a few examples of free energies of binding that indicate that the interaction energy between proteins and other molecules is very much greater than is generally believed. For example, in Table 4 are given the binding constants of several associations showing large free energies of binding[7]. In addition to these examples there are other instances involving the favorable association

Table 4. Some examples of large binding energies [7].

System	Binding constant [mol l^{-1}]	$-\Delta G$ [kJ mol^{-1}]	Ref.
1) Camphor/Fe^{II} cytochrome P 450	2.2×10^8	46	[30]
2) Amethopterin/dihydrofolate reductase	10^{10}	57	[31]
3) Amethopterin/reductase-NADPH complex	10^{11}	63	[32]
4) Biotin/avidin	10^{15}	85	[33]
5) Glucose-1-phosphate/phosphoglucomutase	10^{15}	85	[34, 7]

of large molecules such as the inhibition of proteolytic enzymes by protein inhibitors to form complexes with dissociation constants as low as 10^{-13} mol l^{-1}[27], the high affinity of the *lac* repressor for its specific locus in *E. coli* DNA shown by half-maximal binding of repressor to operator occurring at a repressor concentration of 10^{-13} mol l^{-1}[28] and the low dissociation constants of antibody-antigen complexes like the value of 6×10^{-12} mol l^{-1} for the shark IgM antibody-dinitrophenylated ΦX-174 virus complex[29a]. The formation of stable complexes between the serine proteinases and protein inhibitors is not the result of covalent bond formation between the two proteins but is simply a consequence of the summation of a large number of non-covalent interactions[29b]. In all of these complexes there are, of course, a very large number of interactions and it is difficult to appreciate the magnitude

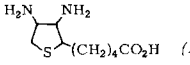
of the individual forces involved. A better estimate of the magnitude of the intrinsic binding energy between a molecule and a protein may be obtained from the increased binding energy that is observed when the "molecule" is added as a substituent to a larger molecule. This aspect of the binding energy has been given the trivial name of the anchor principle[11].

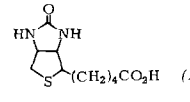
8. The Anchor Principle[11]

The intrinsic binding energy of a small group or "molecule" A may be obtained from a comparison of the free energies of binding the larger molecule B and the molecule A—B, where A is a covalently bonded substituent. The tight binding of the small molecule A to an enzyme requires the loss of its translational and rotational entropy which makes an unfavorable contribution to the overall free-energy change. However, when A is a substituent in the molecule A—B most of this entropy loss is accounted for in the binding of B since the loss of entropy upon binding A—B will be much the same as that upon binding B, $T\Delta S_{AB} \approx T\Delta S_B$. The difference in the free energies of binding A—B and B therefore approximates the true binding energy of A [equation (p)].

$$\Delta G_{AB} - \Delta G_B = \Delta H_{AB} - T\Delta S_{AB} - \Delta H_B + T\Delta S_B \approx \Delta H_{AB} - \Delta H_B \quad \text{(p)}$$
$$\Delta G_{AB} - \Delta G_B \approx \Delta H_A$$

Consequently, this difference, $\Delta G_{AB} - \Delta G_B$, is very much greater than the observed free energy of binding of A, ΔG_A, since it is free of the unfavorable entropy term.





Incidentally, a comparison of ΔG_A with $\Delta G_{AB} - \Delta G_B$, provides a lower limit to the intrinsic loss of entropy upon the binding of A [equation (q)].

$$\Delta G_{AB} - \Delta G_B - \Delta G_A = \Delta H_{AB} - \Delta H_B - \Delta H_A + T\Delta S_A \quad \text{(q)}$$
$$\Delta G_{AB} - \Delta G_B - \Delta G_A \approx T\Delta S_A$$

In Table 5 are shown some data for the binding of various molecules to the protein avidin[33]. Urea *(28)* binds weakly to avidin but the difference between the free-energies of binding

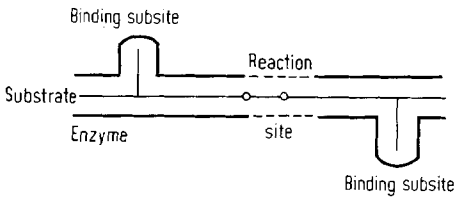
Table 5. Dissociation constants K for various avidin complexes at $T = 298$ K [33]. *(28)*: typical component A; *(29)*, *(30)*: typical component B; *(31)*: typical species A—B.

Avidin·S $\overset{K}{\rightleftharpoons}$ Avidin + S

S		K	$-\Delta G$ [kJ mol^{-1}]
H_2N–CO–NH_2	*(28)*	3.6×10^{-2}	8
	*(29)*	7×10^{-7}	≈35
	*(30)*	3×10^{-7}	≈37
	*(31)*	10^{-15}	≈85

biotin *(31)* and some analogous molecules lacking the ureido group [*(29)* and *(30)*] is very much greater than the free-energy of binding urea. Of course, the ureido group in biotin is not an ideal model for urea, but this example does serve to show that if the required loss of translational and rotational entropy is brought about by the binding of one molecule, the anchor molecule B which, in this case, is the biotin analog *(29)* or *(30)*, then a large favorable decrease in the free energy of binding is made possible by the addition of the ureido group. This change, about 50 kJ mol^{-1} (Table 5), is an indication of the intrinsic binding energy of urea to avidin.

This model for evaluating intrinsic binding energies depends on the assumption that the loss of entropy for binding A—B is similar to that for B [equation (p)]. If the anchor molecule B is only loosely bound then the intrinsic binding energy of A in A—B may cause a greater restriction of motion in A—B so that $T\Delta S_{AB} > T\Delta S_B$ and consequently there will be no change, or even a decrease, in the observed binding constant. Intrinsic binding energies estimated in this way are, therefore, likely to be lower limits.



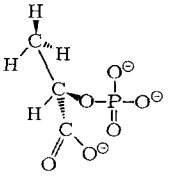


Fig. 3. Reaction site and binding subsites of an enzyme, schematic. o—o, substrate bond to be broken.

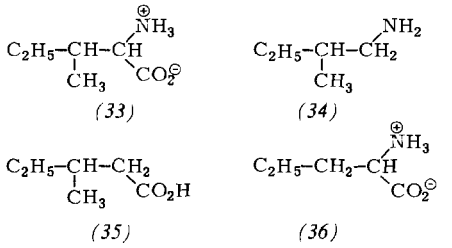
The importance of subsites for various parts of the substrate at some distance from the bond breaking site (Fig. 3) may be accounted for by the anchor principle. For example, the catalytic efficiency of pepsin in cleaving polypeptides is sensitive to changes in substrate structure some distance from the peptide bond which is cleaved[35a]. The binding of the peptide chain to the subsites provides the required binding energy to compensate for the loss of translational and rotational entropy and any destabilization of the substrate required to reach the transition state. If this anchoring is incomplete then the required loss of entropy to reach the transition state will not occur upon binding and a slower rate of catalysis will be observed [cf. equation (p)]. This provides one explanation for the variation in k_{cat} of up to 7×10^3 with K_M remaining approximately constant for substrates of pepsin with different amino acids that bind at subsites removed from the place of bond fission[35a].

Evidence for this restriction of motion of the molecule upon binding to the protein comes from NMR and ESR spectroscopy. For example, ESR spectra indicate that the nitroxide groups in some acyl chymotrypsins are not free to rotate with respect to the enzyme[35b]. NMR studies show that even the internal rotation of the methyl group of L-phospholactate *(32)*, an inhibitor of pyruvate kinase, is restricted upon binding to the enzyme[19].



(32)

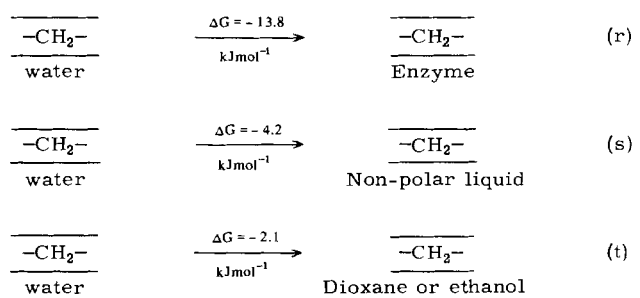
One of the most interesting problems concerned with enzyme-substrate interactions is the magnitude of the binding energy between small substituents and proteins. We believe that the usual method of evaluating these interactions from the energy of transfer of the substituent from one liquid to another underestimates the binding energy.

For example, the binding energies of isoleucine *(33)* and the related compounds *(34)* to *(36)* to isoleucyl-tRNA synthetase are given in Table 6[36]. Isoleucine has a free-energy of binding of -29.7 kJ mol^{-1} and replacing the carboxylate

Table 6. Contribution of small groups to the binding energy, illustrated for isoleucine *(33)* and the related compounds *(34)* to *(36)* in the system *(33)* to *(36)*/Ile-tRNA synthetase.

(33)

(34)



(35)

(36)

Cpd.	Group removed	$-\Delta G$ [kJ mol^{-1}]	$-\Delta\Delta G$ [kJ mol^{-1}]
(33)	—	29.7	—
(34)	CO_2^-	11.7	18.0
(35)	NH_3^+	<1.7	>28.0
(37)	β-CH_3	15.9	13.8

group of this molecule with hydrogen [giving *(34)*] lowers the binding energy to -11.7 kJ mol^{-1}, which indicates that the carboxylate group has an intrinsic binding energy of -18 kJ mol^{-1} with the enzyme. Similarly, the protonated amino group has an estimated binding energy of at least -28 kJ mol^{-1}. These are intrinsic binding energies and are presumably so favorable because the required loss of entropy upon binding is already compensated by the binding energy of the remainder, or the "anchor" part, of the amino acid molecule.

The intrinsic binding energy of a methylene group estimated in this way is -13.8 kJ mol^{-1} (Table 6) and a similar value is obtained from data for valyl-tRNA[37a]. The addition of a methylene group to substituted phenyl *N*-methylcarbamates increases the free energy of binding these compounds to acetylcholinesterase by as much as 12.1 kJ mol^{-1}[37b]. Why are these numbers so large? It is often assumed that the interior

of a protein is analogous to an organic liquid[38] and that the transfer of a group from water to a non-polar liquid may be taken as a model for the transfer of the same group from water to the enzyme [equations (r) to (t)]. However, the change in interaction energy estimated in this way for a methylene group, about -4.2 kJ mol^{-1} for transfer to a non-polar liquid[39] and about -2.1 kJ mol^{-1} for transfer to dioxane or ethanol[40], is at least three times *less* favorable than the change upon transfer to an enzyme. There are many other examples which show that these estimations of the interaction between a substituent and a non-polar liquid underestimate the forces between the same substituent and an enzyme[7].

The comparison between the two "enzymic" process [equation (r)] and the analogous "non-polar" process [equation (s)] involves an examination of the following changes in interaction energies[41]. Firstly, since the initial state is the same in the two systems, changes in energy when the solute is removed from water will be the same in each case. When a solute is transferred to a non-polar liquid [equation (s)] there is a gain of solute-solvent interactions and a loss of solvent-solvent interactions, which is equivalent to the free energy of formation of a cavity in the solvent of a suitable size to accommodate the solute molecule[42].

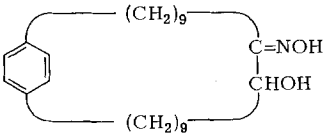
When a solute is transferred to an enzyme [equation (r)] there is a gain of solute-enzyme interactions if water is initially absent from the binding site. If water is initially bound to the site of binding and is then displaced by the substituent there is also a gain of water-water interactions and a loss of water-enzyme interactions. However, the sum of the free energy changes of these two interactions would be thermodynamically unfavorable, otherwise water would not initially be bound to the enzyme, and hence, in this situation, the observed free energy of transfer of a substituent from water to an enzyme provides a *lower* limit to the magnitude of enzyme-substrate interactions.

Approximately 16 localized water molecules have been detected within the chymotrypsin molecule[43] but much larger numbers in general for proteins are probably unlikely[44]. If water is *not* initially bound to the enzyme then the transfer in equation (r) could be thermodynamically more favorable than that in equation (s) because the latter process involves a loss of solvent-solvent interactions, *i.e.* the free energy of cavity formation, and thus the free-energy change for equation (s) provides an underestimation of solute-solvent interactions. According to the scaled particle theory[45], and other calculations[46], the free energy of cavity formation in non-polar liquids is of similar magnitude, but, of course, of opposite sign, to the free energy of interaction of the solute with the solvent. This, therefore, may explain, in some cases, part of the discrepancy between equations (r) and (s) since the enzyme may have a ready-made "cavity" and the binding of a substituent to this site would not result in the unfavorable changes which accompany cavity formation in liquids. However, it is difficult to see how water could be prevented from binding to a site that may be occupied by a methylene group, and another important factor is that the *number* of the favorable dispersion or van der Waals interactions of the substituent with the enzyme are probably greater than with a liquid solvent.

The atoms in an enzyme molecule are very closely packed since they are linked together by covalent bonds and, in

some cases, the polypeptide chains are cross-linked by covalent disulfide bonds. The fraction of space occupied by the atoms in a molecule of protein is 0.75[47] which may be compared with 0.74, the value for the most efficient known way of packing spheres, cubic close-packing or hexagonal close-packing. In a liquid the fraction of space occupied is very much less, for example upper limits for water, cyclohexane and carbon tetrachloride are 0.36, 0.44, and 0.44, respectively[47]. The inside of a protein thus contains little space and is more analogous to a solid than to a liquid. It may be more appropriate, therefore, to compare equation (r) with the free-energy of transfer of a substituent from water to a solid [equation (u)]. An indication of this energy change may be estimated from the fusion of hydrocarbons[41]. The enthalpy of melting

$$\underset{\text{water}}{\overline{\underline{-CH_2-}}} \longrightarrow \underset{\text{Pure liquid}}{\overline{\underline{-CH_2-}}} \longrightarrow \underset{\text{Solid}}{\overline{\underline{-CH_2-}}} \qquad \text{(u)}$$



per additional methylene group in *n*-alkanes, up to $C_{20}H_{42}$, containing an even number of carbon atoms is 4.1 ± 0.1 kJ mol^{-1}[48]. The heat capacity changes per additional methylene group are also approximately constant, about 26 and 15 JK^{-1} mol^{-1} for the liquid and solid respectively[48]. The hypothetical enthalpy of melting per additional methylene group at, say, 25 °C will therefore not deviate much from the above values. There will, of course, be an unfavorable entropy change on transfer from the liquid to the solid but it can now be estimated from equations (s) and (u) that the maximum favorable free-energy of transfer of a methylene group from water to a non-polar solid is about -8.3 kJ mol^{-1}[41].

The atoms in an enzyme surrounding the substrate are very compact and most are separated only by their covalent radii. In a liquid, a solute is surrounded by molecules separated by their van der Waals radii. Hence the effective coordination number is much greater in the enzyme than it is in a liquid. For example, the van der Waals radii for carbon, nitrogen, and oxygen are about 2.2 times greater than their respective covalent radii and a very simple treatment of the packing of spheres shows that the coordination number of a sphere is about 2.5 times greater when surrounded by other spheres separated by such covalent radii than when they are separated by van der Waals radii. In a liquid a large fraction of the surface of a solute molecule is surrounded by empty space between the solvent molecules[49]. Even in a non-polar solid the closest approach of neighboring molecules is governed by their van der Waals radii; therefore the energy of transfer of a group from water to a solid may underestimate the interaction energy between the same group and an enzyme. Such a comparison indicates that as far as interaction energy is concerned enzymes may be more solid-like than solids!

Not only will there be a greater surface area of contact between a bound molecule and a protein, compared with the situation in a liquid, giving rise to a greater number of interaction energies but also the dispersion forces themselves may be greater. It has been suggested that dispersion interactions between a molecule and surrounding atoms is greater if the atoms are covalently bonded to each other[49].

Physical adsorption of molecules on to solid surfaces possesses certain similarities to enzyme-substrate binding. The atoms in a solid present a closely-packed surface and in some cases, for example graphite, the interatomic distance is similar to that found in covalently bonded molecules. Instead of the normal r^{-6} dependence of the London attractive potential between a pair of molecules there is a r^{-3} dependence for the interaction between a molecule and a solid[50]. This longer range interaction is the basic reason why gases are adsorbed at pressures lower than those at which they condense to liquids or solids. The differential heat of adsorption is often of the order of twice the heat of condensation of the adsorbed vapour[51].

The formation of clathrates and cage-type compounds also shows similarities to the enzyme-substrate binding process. The acylation of the oxime *(37)* with 4-nitrophenylalkanecarboxylates shows saturation type kinetics consistent with the pre-equilibrium formation of an inclusion complex between

(37)

the oxime and the substrate[52]. The binding constants are about 10^5—10^6 mol l^{-1} which are larger than the values of 10^2—10^3 mol l^{-1} usually observed with cycloamyloses[53]. Interestingly, the oxime *(37)* is not acylated by smaller chain esters such as 4-nitrophenyl acetate[52]; this is presumably because there is not enough binding energy with this smaller molecule to compensate for the loss of entropy upon binding.

It has recently been concluded that the contribution of non-covalent interactions to the stability of the cofactor-protein complex formed from D-serinedehydratase and pyridoxamine phosphate is at least 20—30 times greater than the contribution of the covalent >C=N— bond[54].

A large fraction of the rate acceleration of chemical reactions brought about by enzymes thus appears to be due to the high intrinsic binding energy between the substrate and the closely-packed covalently linked atoms in the enzyme.

I thank Professor W. P. Jencks for many stimulating discussions and his continual encouragement. I thank Professor P. von R. Schleyer for some of the molecular-mechanics calculations.

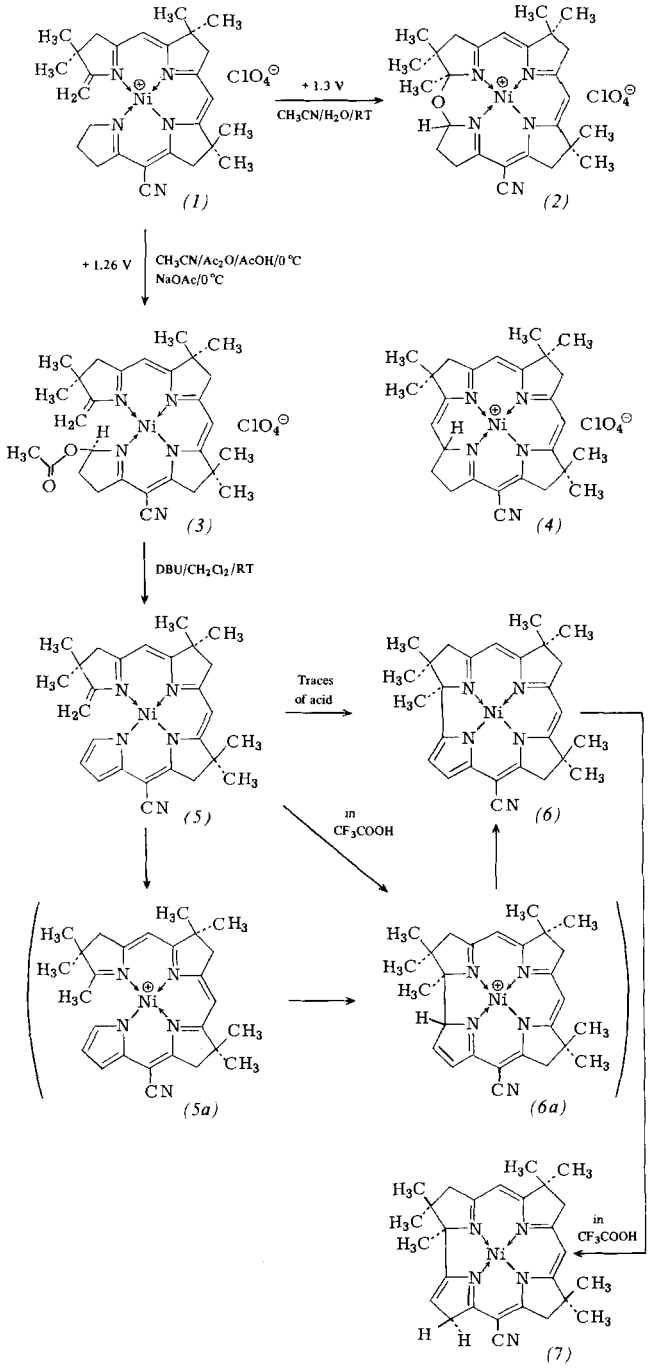
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

(A→D)-Cyclization of a Nickel(II) Δ^{18}-Dehydro-1-methylidene-1,19-secocorrinate[**]



By *Vittorio Rasetti, Bernhard Kräutler, Andreas Pfaltz*, and *Albert Eschenmoser*[*]

Direct coupling of rings A and D in the formation of the corrinoids has proved not to be the bottleneck that had been envisaged at the start of synthetic work on corrins[1]. On the contrary, the simplest synthetic routes presently available for corrinoids and corrins use (A→D)-cyclizations in chromophore construction[2]. Here we report, as a further example,

a facile (A→D)-closure in the Δ^{18}-dehydro-1-methylidene-1,19-secocorrin series, induced by traces of acid at room temperature [see *(5)*→*(6)* in the reaction scheme]. This is the type of ring closure considered by *A. I. Scott* in his discussions of the biosynthesis of vitamin B_{12}[3].

We have previously reported[4] the electrochemical oxidation of nickel(II) 1-methylidene-1,19-secocorrinate perchlorate *(1)* in moist acetonitrile to yield almost quantitatively the 1,19-oxido derivative *(2)* *via* a sigmatropic 1,16-hydrogen shift and incorporation of oxygen from water. If this electrochemical oxidation is conducted in anhydrous acetonitrile/acetic anhydride/acetic acid (30:3:1) at 0 °C[5] and the mixture is immediately quenched with 2 mol. equiv. of sodium acetate when the current falls (at *ca.* 1.2 F), then crystalline nickel(II) 19-acetoxy-1-methylidene-1,19-secocorrinate perchlorate *(3)* can be isolated in up to 40% yield, in addition to starting material (*ca.* 35%) and side-product *(4)*[6] (*ca.* 5%). Treatment of *(3)* with 8 mol. equiv. of DBU[7] in methylene chloride at room temperature, carefully excluding oxygen, at once gives the nickel(II) secocorrinate *(5)*. The cyclization of *(5)* to the nickel(II) dehydrocorrinate *(6)* occurs with such ease that it is difficult to prevent. Crystallization of spectroscopically and analytically pure samples of *(5)* can be achieved in up to 50 to 65% yield by working with alkali-washed glassware and by rapid chromatography of the crude product at 0 °C, with exclusion of oxygen, on kieselgel[8] that has been pretreated with triethylamine dissolved in the eluent mixture benzene/methyl acetate/methylene chloride (1:1:1). Normal chromatography leads to mixtures of *(5)* and *(6)*, as does use of solvents such as chloroform, methylene chloride, or carbon tetrachloride of usual reagent purity. A ^{1}H-NMR spectrum of pure *(5)* is obtained only in deuteriochloroform that has been treated with basic alumina immediately prior to use; even in this solvent the ^{13}C-NMR spectrum (recorded over a period of *ca.* 65 hours) was that of *(6)*. Preparatively the cyclization *(5)*→*(6)* is carried out at room temperature in methyl acetate/methylene chloride (1:1) on alumina[9] pre-

MS (130 °C): m/e = 483 (71 %/$M^+ - HClO_4 - CH_3COOH$), 481 (68 %/$M^+ - HClO_4 - CH_3COOH - H_2$), 468 (100 %/$M^+ - HClO_4 - CH_3COOH - CH_3$).

(5): Mp > 250 °C; λ_{max} (ethanol): 268 (shoulder/log ε = 4.19), 282 (4.23), 307 (flat/4.16), 320 (shoulder/4.15), 372 (4.17), 477 (3.68), 578 (3.74) nm; λ_{min} = 337 (4.06), 440 (3.62), 514 (3.62) nm. IR ($CHCl_3$): 2210 (CN), 1625, 1610, 1575, 1555 (strong), 1500 (strong) cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ = 1.10/1.15/1.19/1.33/1.35/1.42 (6s/6CH_3), 2.56/2.78 (AB-system/J = 18 Hz/CH_2), 2.80 (s/CH_2), 3.14 (s/CH_2), 4.40/4.95 (AX-system/J = 2 Hz/=CH_2), 5.56 (s/2 —CH=), 6.05/6.26/6.38 (3 m/pyrrole-CH) ppm. MS (< 160 °C): m/e = 483 (45 %/M^+ with ^{58}Ni), 468 (100 %/$M^+ - CH_3$ with ^{58}Ni).

UV/VIS of *(5)* [or *(6a)*] in CF_3COOH: λ_{max} = 315 (4.26), 330 (4.26), 408 (shoulder/3.89), 438 (shoulder/4.06), 452 (4.19) nm; λ_{min} = 284 (3.95), 324 (4.25), 360 (3.47) nm. ^{1}H-NMR (CF_3COOH): δ = 1.05 (s/CH_3), 1.39 (s/CH_3), 1.44 (s/CH_3), 1.49 (s/3CH_3), 1.57 (s/CH_3), 3.02/3.40 (AB-system/J = 18 Hz/CH_2), 3.32 (s/CH_2), 3.46 (s/CH_2), 4.91 (s broad/H on C-19), 6.16/6.46 (2s/2—CH=), 7.25/7.61 (AB-system/J = 6 Hz/—CH= on C-17 and C-18) ppm.

treated with methyl acetate/acetic acid (100:1)[10]. The crystalline product is isolated in over 90% yield, and is identical in its spectroscopic properties with *(6)* as previously obtained[4a,11] by pyrolysis of the chloride salt of *(2)*[12].

The reaction *(5)*→*(6)* is doubtless initiated by protonation of the exocyclic methylidene group on ring A, after which the closure step *(5a)*→*(6a)* can take place. The ^{1}H-NMR spectrum of *(5)* dissolved in trifluoroacetic acid is that to be expected from the intermediate *(6a)*, and is clearly different from the ^{1}H-NMR spectrum of *(6)* dissolved in trifluoroacetic acid, corresponding to the constitution *(7)*[4]. We have here a case where two distinct protonated forms of a single pyrrole derivative are separately observable; of the four possible *C*-protonations of the pyrrole nucleus in *(6)*, that giving *(7)* is likely to be both kinetically and thermodynamically favored.

Difluorooxobromine(v) Ion, $BrOF_2^+$ [**]

By *Manfred Adelhelm* and *Eberhard Jacob*[*]

Synthesis of the cation $ClO_2F_2^+$ containing chlorine(VII) was first achieved by *Christe*[1] by reaction of chloryl fluoride ClO_2F with platinum hexafluoride. As the existence of the oxidation state +VII of bromine was also demonstrated[2], and it was later shown by one of us *(E.J.)* that the less stable bromyl fluoride BrO_2F yielded, by cocondensation with SbF_5, a fluoroantimonate of BrO_2^+[3], we have attempted to oxidize BrO_2F with PtF_6 to the unknown $BrO_2F_2^+$.

Bromyl fluoride and platinum hexafluoride were cocondensed *in vacuo* at −196°C in a low-temperature infrared cuvette. Reaction took place on warming up to −120°C. The red-brown film was stable at room temperature and showed four additional bands besides the absorptions of PtF_6^- and PtF_5[4]: 1052 (1002) vs, 930 (890) m, 365 (355) vs, 315 (304) m. On cautious heating to 110°C the color changed to mustard-yellow and the absorption at 930 (890) cm^{-1} disappeared. This band must be assigned to the strongest band of BrO_2^+[3].

The reaction could be carried out on a preparative scale using a Teflon PFA or stainless steel reaction vessel[5]. We obtained a brown to yellow-brown product, which proved to be relatively stable at room temperature in the absence of moisture. Its IR spectrum was identical with that of the thin films. Reaction of the finely powdered product with excess nitryl fluoride at −78°C furnishes the oxide fluorides $BrOF_3$ and BrO_2F, which can be identified by IR spectroscopy[6].

On cocondensation of the oxide fluorides with arsenic pentafluoride the cations are regenerated in the form of hexafluoroarsenates. The BrF stretching vibrations could then also be measured, which are masked by PtF absorptions in the PtF_6^-/PtF_5-containing products.

The following reactions appear to take place:

$$BrO_2F + 2.5\,PtF_6 \rightarrow BrOF_2^+PtF_6^- + {}^1/_2O_2^+PtF_6^- + PtF_5$$
$$BrO_2F + \quad PtF_6 \rightarrow BrO_2^+PtF_6^- + {}^1/_2F_2$$

The side reaction yielding BrO_2^+ can largely be suppressed by using an excess of platinum hexafluoride.

$$BrOF_2^+PtF_6^- + NO_2F \rightarrow BrOF_3 + NO_2^+PtF_6^-$$
$$BrO_2^+PtF_6^- + NO_2F \rightarrow BrO_2F + NO_2^+PtF_6^-$$
$$BrOF_3 + AsF_5 \rightarrow BrOF_2^+AsF_6^-$$
$$BrO_2F + AsF_5 \rightarrow BrO_2^+AsF_6^-$$

The main product of the reaction of BrO_2F with PtF_6 is therefore the new cation $BrOF_2^+$[7].

Table 1 lists the results of the IR measurements. The assignments suggested correspond to the fundamental vibrations of the isoelectronic $SeOF_2$[8].

Table 1. Fundamental vibrations of $BrOF_2^+$ and gaseous $SeOF_2$ in cm^{-1}.

	$SeOF_2$ [8]	$BrOF_2^+$ [a]	$Br^{18}OF_2^+$ [b]	Intensity
$\nu_1(A')$	1049	1062	1002	vs
$\nu_2(A')$	667	655		s
$\nu_3(A')$	362	365	355	vs
$\nu_4(A')$	253	290		w
$\nu_5(A'')$	637	630		s
$\nu_6(A'')$	282	315	304	m

[a] $BrOF_2^+AsF_6^-$, thin film at −78°C.
[b] $Br^{18}OF_2^+PtF_6^-$, powder, AgBr-disk.

Thus, whereas ClO_2F can be oxidized by PtF_6 to $ClO_2F_2^+$[1], the analogous reaction with BrO_2F does not lead to $BrO_2F_2^+$ but to $BrOF_2^+$ and O_2^+. So far, this appears to be the only case in which the oxygen is partially eliminated from an oxide fluoride by PtF_6. Complete elimination of the oxygen by PtF_6 has been observed in the case of $XeOF_4$[9].

Homologization of Aldehydes and Ketones to Thiiranes or *S*-Vinyl Thiocarbamates *via* 2-Alkylimino-1,3-oxathiolanes[**]

By *Dieter Hoppe* and *Rainer Follmann*[*]

We have previously reported on the metalation of dialkyl *N*-alkyl- (or *N*-aryl)iminodithiocarboxylic esters of type *(1)* to give the lithium compounds and on their conversion with carbonyl compounds *(2)* to β-thioalkanols *(3)* or to 2-alkyl- (and 2-aryl)imino-1,3-oxathiolanes *(4)*[1]. In some cases we had observed formation of thiiranes *(8)*[1]. Since methods for the general syntheses of thiiranes[2] in which direct formation of the (C-2)—(C-3) bond occurs are rare[3], we have extended the scope of this secondary reaction.

To increase their reactivity the 2-methylimino-1,3-oxathiolanes *(4)* [obtained from *(1a)* or *(1b)* and the carbonyl compound *(2)*[1]] were alkylated with methyl iodide in nitromethane to the immonium iodides *(5)* and then cleaved with sodium ethoxide in ethanol to the thiiranes *(8)* (cf. Table 1) and ethyl *N*,*N*-dimethylcarbamate *(6)*.

Presumably the β-iodothiolate *(7)* is formed as intermediate. In favor of this (or a related) intermediate is the fact that the reaction of 5-(cyclo)alkyl-substituted imino-1,3-oxathiolanes[4] proceeds with extensive retention[5] of the configuration at C-2 and C-3 in *(8)*, relative to C-4 and C-5 in *(4)*. Thus *trans-(4i)* afforded the *trans*-thiirane *(8i)* (^{1}H-NMR, $CDCl_3$: τ = 6.37 and 7.08, ^2J = 5.2 Hz), while *cis-(4i)* yielded over 95 % *cis-(8i)* (τ = 5.89 and 7.04, ^2J = 7.0 Hz)[6]. In contrast *trans*-4,5-diphenyl-1,3-oxathiolane *(4k)* reacts less stereoselectively to give a 57:43 mixture of *cis*- and *trans*-stilbene sulfide *(8k)*.

In the reactions of the *cis*-immonium salts *(5h)* and *(5i)*, besides *(8)* we also isolated the 1,3-oxathiolane-2-ones *cis-(12h)* and *cis-(12i)*, formed by hydrolysis of *(5)*.

On heating, the salts *(5)* eliminate hydrogen iodide to give the *S*-vinyl *N*,*N*-dimethylthiocarbamates *(9)*, which as thioenol esters are hydrolyzable to the carbonyl compounds, *e.g.* with trifluoroacetic acid[7]. The reaction sequence thus permits homologization of aldehydes or ketones to the next-higher aldehyde *(10)* [with *(1a)*] or aryl ketone *(11)* [with *(1b)*].

Procedure

2-Methylimino-1,3-oxathiolanes *(4)*: 40 mmol of the *N*-alkyliminodithiocarboxylic ester *(1a)* or *(1b)* is added dropwise at −78 °C to a solution of lithium diisopropyl amide (44 mmol) in tetrahydrofuran/*n*-hexane (60 ml, *ca.* 2:1). After one hour's stirring compound *(2)* (40 mmol) is added and the reaction mixture is stirred for a further hour, then warmed to −30 °C and neutralized with 5.3 g acetic acid. The solvent is removed under a water-jet vacuum, the residue dissolved in ether (100 ml) and water (50 ml), and the organic phase washed with water and dried over sodium sulfate. The mixture of *(3)* and *(4)* remaining after removal of ether is heated for 2—6 h under reflux in benzene to ensure complete cyclization. Crystallization (ether/cyclohexane) and chromatography of the mother liquor over silica gel (neutral), *e.g.* with ether/*n*-pentane (2:1), R_F *ca.* 0.4, yielded *(4)* (IR: 1650—1670 cm^{-1}).

Thiiranes *(8)*: A mixture of *(4)* (10 mmol) and methyl iodide (20 mmol) in nitromethane is stirred in the dark for

Phenyl-[2,2-dimethyl-1-(trimethylsiloxy)propylidene]-arsane, an Arsane with an Isolated As=C Bond[**]

By *Gerd Becker* and *Gerhard Gutekunst*[*]

P-Alkyl- or -arylbis(trimethylsilyl)phosphanes *(1)* react with 2,2-dimethylpropionyl chloride (pivaloyl chloride) in cyclopentane with substitution of a trimethylsilyl group by the acyl moiety[1]. The products *(2)* are stable for some time only below 0 °C and rearrange, *via* a 1,3 shift of the trimethylsilyl group from the phosphorus to the oxygen atom, into the [2,2-dimethyl-1-(trimethylsiloxy)propylidene] phosphane *(3)*.

(1a), X = P, R = CH_3
(1b), X = P, R = C_6H_5
(4), X = As, R = C_6H_5

(2a), X = P, R = CH_3
(2b), X = P, R = C_6H_5
(5), X = As, R = C_6H_5

(3a), X = P, R = CH_3 (*Z* isomer)
(3b), X = P, R = C_6H_5 (*Z* isomer)
(6), X = As, R = C_6H_5

By application of these reactions to *As*-alkyl- or arylbis(trimethylsilyl)arsanes *(4)* we have been able to synthesize the first acyclic compounds containing an isolated As=C double bond[2]. The methyl, *tert*-butyl, and phenyl compounds were investigated, but only reaction of the phenyl compound was found to proceed without side-reactions. If substitution of both trimethylsilyl groups is avoided by suitable choice of conditions, almost pure phenyl-(2,2-dimethylpropionyl)trimethylsilylarsane *(5)* remains after condensing off all the volatile components. In contrast to the analogous phosphane this compound is stable at room temperature for a short time; we attribute this to less pronounced spatial interaction of the bulky substituents at the central atom, since the bonds from the arsenic atom are longer than those from phosphorus. Rearrangement to the phenyl-[2,2-dimethyl-1-(trimethylsiloxy)propylidene]arsane *(6)* can be followed ^{1}H- and ^{13}C-NMR spectroscopically. The resonances caused by the carbon atom of the C(O) group appear at very low field (Table 1). Noteworthy here is the small difference between *(5)* and *(6)*, even though the carbon atom is doubly linked to the oxygen atom in *(5)* and to the arsenic atom in *(6)*. Whether similar polarities of C=O and As=C double bonds are responsible for the almost equal chemical shifts cannot be decided on the grounds of NMR data alone. The analogous phosphanes absorb in the same region. Since phenyl-(2,2-dimethylpropionyl)-trimethylsilylphosphane *(2b)* could not be measured on account of thermal instability the values of the stable methyl compounds are listed in Table 1 for comparison[1].

Table 1. Characteristic ^{1}H- and ^{13}C-NMR data of *(5)* and *(6)* compared with the corresponding methyl- and phenylphosphanes. Chemical shifts in δ values [ppm] rel. TMS ext., downfield positive; limits of error: δ^1H: ±0.1 ppm, δ^{13}C: ±1.0 ppm (without solvent).

	C(O)	$C(CH_3)_3$	$C(CH_3)_3$		$Si(CH_3)_3$	
	^{13}C	^{13}C	^{13}C	^{1}H	^{13}C	^{1}H
(5)	228.5	51.0	26.5	1.12	1.5	0.18
(2a)	229.0	46.0	27.0		0.0	
(6)	239.0	47.0	30.0	1.26	2.0	−0.14

[**] Part 1 of The Formation and Properties of Acylarsanes. This work was supported by the Deutsche Forschungsgemeinschaft. The results were presented in a lecture delivered at the Chemiedozententagung in Marburg March 23, 1977.

by the molecular weight (determined cryoscopically in benzene) and the mass spectrum, *(6)* is monomeric.

The assignment of the substituents at the As=C double bond can be determined only by an X-ray structure analysis. Studies on models suggest the presence of *Z* isomers in which the aryl and the trimethylsiloxy group are situated at the same site.

Procedure

A solution of phenylbis(trimethylsilyl)arsane (22.4 g, 75.1 mmol) and 2,2-dimethylpropionyl chloride (9.1 g, 75.5 mmol) in cyclopentane (25 ml) is allowed to stand for 12 h at 4 °C. The reaction is followed ^{1}H-NMR spectroscopically. After condensing off all components that are volatile at −20 °C, there remains almost pure *(5)*. The rearrangement to *(6)* is complete after 12 h at 50 °C: reddish liquid, b.p. 82 to 86 °C/5×10^{-2} torr; quantitative yield.

$[C_5H_5(CO)_2Mn—N_2H_2—Cr(CO)_5]$, a Complex with a Diazene Bridge and Two Different Coordination Centers[1]

By *Dieter Sellmann* and *Klaus Jödden*[*]

Three kinds of diazene (diimine) transition metal complexes have been proposed as intermediates of N_2 reduction in enzymatic nitrogen fixation, *viz.* mononuclear complexes *(1)*, homodinuclear complexes *(2)*, and heterodinuclear complexes *(3)*[2].

M–HN=NH *(1)* M–HN=NH–M *(2)* M–HN=NH–M′ *(3)*

Hitherto, however, the diazene structure of the N_2H_2 ligand could be demonstrated unequivocally only in complexes of type *(2)*[1,3].

We have now been able to synthesize the first complex of type *(3)* in which the HN=NH molecule bridges two different metal centers.

Reaction according to

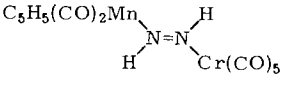
$$\eta\text{-}C_5H_5(CO)_2Mn(N_2H_4) + (OC)_5Cr(THF) \xrightarrow[20\,^\circ C]{THF} \eta\text{-}C_5H_5(CO)_2Mn\text{–}N_2H_4\text{–}Cr(CO)_5 + THF$$

(4)

affords the heteronuclear hydrazine complex *(4)* which precipitates as orange-yellow crystals analytically pure from tetrahydrofuran at −78 °C [IR (KBr) in cm^{-1}: 3332 s, 3310 m, 3283 s (ν_{NH}), 1570 m (δ_{NH}); ν_{CO} (THF) 2068 w, 1935 s, 1898 s, 1849 s.—^{1}H-NMR (90 MHz, [D_6]-acetone, −30 °C, rel. to TMS in ppm): 4.56 (s, $\delta C_5H_5(5)$), 4.80 (br, $\delta NH_2(2)$), 5.50 (br, $\delta NH_2(2)$).—UV (THF, 20 °C): λ_{max} 410, 240 nm; ε_{max} 3700, 31 100 l/mol·cm.—Dec. p. 88 °C].

The hydrazine complex *(4)* can be oxidized in THF solution to the heteronuclear diazene complex *(5)* by atmospheric oxygen or preferably (60 % yield) by hydrogen peroxide:

$$(4) + H_2O_2 \xrightarrow[-25\,^\circ C]{THF} \eta\text{-}C_5H_5(CO)_2Mn\text{–}HN{=}NH\text{–}Cr(CO)_5 + 2\,H_2O$$



(5)

Compound *(5)* crystallizes as analytically pure, deep-violet needles from THF at −78 °C. It is stable in the solid state, decomposing only above 104 °C. In CH_3OD rapid exchange of the N_2H_2 protons occurs at room temperature to form η-$C_5H_5(CO)_2Mn$—DN=ND—$Cr(CO)_5$ (νND in KBr: 2428 m, 2382 m cm^{-1}). Even traces of bases, *e.g.* NaOH, effect fast decomposition in solution, yielding the hydrazine complex *(4)*, and simultaneously probably also the labile dinitrogen complex η-$C_5H_5(CO)_2Mn$—N≡N—$Cr(CO)_5$. The structure and composition of *(5)* follow from the method of preparation, elemental analysis, chemical reactions, and spectroscopic data (Table 1).

Table 1. Spectroscopic data of *(5)*.

IR (KBr) in cm^{-1}: 3250 m, 3215 m (ν_{NH}); ν_{CO} (THF) 2064 m, 1960 s, 1942 vs, 1908 s.—^{1}H-NMR (90 MHz, [D_6]-acetone, −30 °C, rel. to TMS in ppm): 15.64 (d, δNH(1)), 14.74 (d, δNH(1), $^3J_{HH}$ = 23.5 Hz), 5.10 (s, $\delta C_5H_5(5)$).—MS (70 eV, T_S 76 °C): M^+ at m/e = 398.—UV (THF, 20 °C): λ_{max} 528, 245 (sh), 237 nm; ε_{max} 14 800, 31 200, 33 700 l/mol·cm.

Apart from the molecular ion, the mass spectrum[4] displays, *inter alia*, successive loss of the seven CO ligands of *(5)*; the presence of a M—HN=NH—M′ group in *(5)* is evidenced by the intense absorption in the visible region of the electronic spectrum and the large chemical shift of the NH protons in the ^{1}H-NMR spectrum, which is typical for protons bound to sp^2-hybridized N atoms[1]. Moreover, the ^{1}H-NMR spectrum permits the first determination of the proton coupling constant of the HN=NH molecule: coordination to different metal centers leads to magnetic non-equivalence of the two diazene protons, thus affording an AX system with $^3J_{HH}$ = 23.5 Hz. By analogy with ethylene, which exhibits a coupling constant of 19.1 Hz[5] for the *trans* protons, this value suggests a *trans* configuration of the diazene ligand and a *trans* structure of complex *(5)*[6].

Thus the isoelectronic character of the HN=NH and H_2C=CH_2 molecules is manifested, not in their—completely different—chemical behavior, but rather in their similar proton coupling constants.

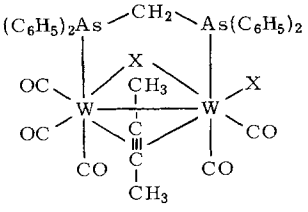
[6] While $^3J_{HH,trans}$ usually decreases for olefins on coordination to transition metals owing to the change in sp hybridization such an effect will only be slight for σ-bonded diazene since the sp^2 hybridization of the N atoms is retained on coordination.



Synthesis of Alkyne-Bridged Dinuclear Complexes by Reaction of *trans*-Halotetracarbonyl(methylcarbyne)-tungsten with Methylenebis(diphenylarsane)[1]

By *Ernst Otto Fischer, Alexander Ruhs, Peter Friedrich*, and *Gottfried Huttner*[*]

trans-Bromotetracarbonyl(phenylcarbyne) complexes of chromium and tungsten[2] react with donor molecules such as triphenylarsane with the substitution of one or two carbonyl ligands[3]. In contrast, the reaction of *trans*-halotetracarbonyl-(methylcarbyne)tungsten[2] *(1)* with methylenebis(diphenylarsane) in the ratio 2:1 leads surprisingly to the synthesis of dinuclear compounds of type *(2)* with the release of three equivalents of carbon monoxide. The bridging ligand dimethylacetylene is probably formed from the carbyne ligands in the coordination region of the metal atoms.

(1)

(2)

(a): X = Cl
(b): X = Br

The diamagnetic, red-brown complexes *(2a)* and *(2b)* are readily soluble in acetone or methylene chloride but then slowly begin to decompose on exposure to air and at room temperature. Both compounds are insoluble in nonpolar solvents.

Since no definite conclusions about the structure of the new compounds could be drawn from their spectra, we established the structure of *(2b)* by X-ray structure analysis[4] (cf. Fig. 1).

The asymmetrical unit of the triclinic cell[4] contains, in addition to a molecule of *(2b)*, a molecule of acetone which is only held by van der Waal's forces. Crystals of *(2b)* become amorphous at temperatures above 273 K with loss of the solvent component; measurement was therefore carried out at 206 K.

[*] Prof. Dr. E. O. Fischer, Dipl.-Chem. A. Ruhs, Dipl.-Chem. P. Friedrich, Doz. Dr. G. Huttner
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

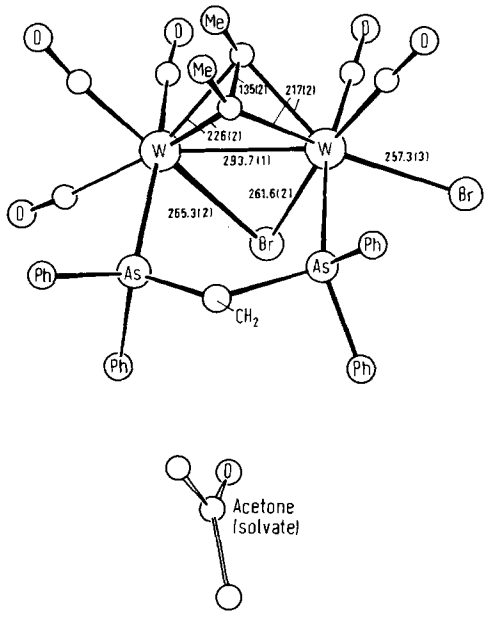


Fig. 1. Molecular structure of the dinuclear compound *(2b)* in crystalline form.

The basic structural units of *(2b)* are two pseudooctahedrally coordinated tungsten atoms which are linked by three different bridging ligands; according to the diamagnetism of the complex a metal-metal bond is also present (d_{W-W} 293.7 (1) pm; compare $[C_5H_5(CO)_3W]_2$: 322.2 (1) pm[5]). The substitution with different terminal ligands (three CO groups or two CO groups and one Br atom respectively) causes the bonding of the bridging ligands between the tungsten atoms to be unsymmetrical; this can be clearly recognized from the $W-C_{acetylene}$ distances (Fig. 1). As in other alkyne-bridged complexes[6], the triple bond is characteristically lengthened by the coordination to two metal centers; the acetylene ligand is also bent (Me—C—C 133 (2)°).

The following spectroscopic data of compound *(2b)* in solution are in agreement with the X-ray findings: The IR spectrum (CH_2Cl_2) shows five bands in the ν_{CO} region at 2023 s, 1978 vs, 1945 s, 1930 s and 1881 m cm^{-1}. In the ^1H-NMR spectrum (CD_2Cl_2, −20 °C, rel. to TMS int.) signals are found at δ = 7.40 (m, 20), 3.13 (s, 3), 2.60 (s, 3), and 2.13 (s, 2). The methylene protons appear at surprisingly high field when compared with other μ-methylenebis(diphenylarsane) complexes[7]; their differing magnetic environments result in a broadening of the signal. The CH_3 groups of the dimethylacetylene ligand are also not equivalent—their resonance lines appear at different field strengths.—In the ^{13}C-NMR spectrum (CD_2Cl_2, −20 °C, rel. to CD_2Cl_2 = 54.2 ppm) both the two carbon atoms of the acetylene (99.68 and 100.44) as well as those of the methyl groups (19.74 and 22.55) exhibit different chemical shifts. A signal at δ = 205.52 can be assigned to the carbonyl groups and that in the region from 128.71 to 135.18 to the phenyl groups. The signal of the methylene carbon atom is to be found at δ = 3.15.

Experimental

All work must be carried out under N_2 with anhydrous and oxygen-free solvents.

(1b)[2] (1.39 g, 3 mmol) and $[(C_6H_5)_2As]_2CH_2$ (0.76 g, 1.5 mmol) are dissolved in 40 ml CH_2Cl_2 at −20 °C. The solu-

tion is slowly warmed until it boils; the color changes from pale yellow to brown with evolution of gas. Reaction is complete after *ca.* 20 min. The product is cooled to −30 °C and purified by column chromatography on silica gel with CH_2Cl_2/pentane (2:1). When the red-brown band of the complex *(2b)* reaches the last third of the column, the uppermost layer of silica gel containing the decomposed products is removed. The column is then eluted with CH_2Cl_2/ether (1:1) and the solvent removed. The remaining residue is dissolved in acetone at −20 °C and after cooling slowly to −78 °C red-brown crystals of analytically pure *(2b)* are formed; yield 0.9 g (43 %).

The analogous reaction of *(1a)*[2] (1.26 g, 3 mmol) with $[(C_6H_5)_2As]_2CH_2$ (0.76 g) in CH_2Cl_2 (40 ml) affords 0.74 g (41 %) of *(2a)*.

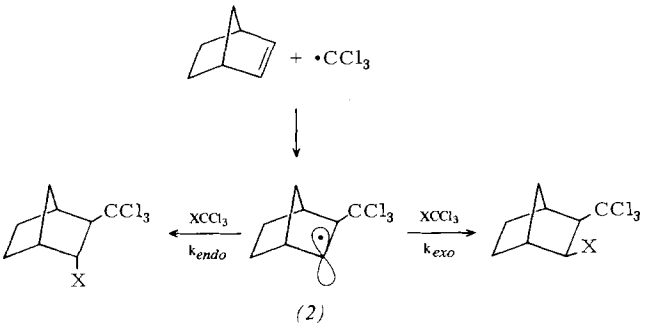
Temperature Dependence of the Selectivity of the Halogen Donors $XCCl_3$[**]

By *Bernd Giese* and *Klaus Jay*[*]

Reaction of alkyl radicals *(1)* with the halogen donors $BrCCl_3$ and CCl_4 leads to the formation of alkyl bromides and alkyl chlorides, respectively[1]. Since the abstraction of bromine from $BrCCl_3$ requires a lower activation energy than that of chlorine from CCl_4, the radical selectivities of the competition system $BrCCl_3/CCl_4$ ($\lg k_{Br}-\lg k_{Cl}$) are temperature dependent[2a].

$$RBr \xleftarrow[k_{Br}]{BrCCl_3} \underset{(1)}{R\cdot} \xrightarrow[k_{Cl}]{CCl_4} RCl$$



$$\lg\frac{k_{Br}}{k_{Cl}} = \frac{\Delta H^{\ddagger}_{Cl}-\Delta H^{\ddagger}_{Br}}{2.303RT} - \frac{\Delta S^{\ddagger}_{Cl}-\Delta S^{\ddagger}_{Br}}{2.303R}$$

Variation of the radical *(1)* is accompanied by such large changes in the activation entropy differences ($\Delta S^{\ddagger}_{Cl}-\Delta S^{\ddagger}_{Br}$) that the radical selectivities become equal within the temperature range 60±20 °C—the isoselective temperature T_{is}[2]. Below and above T_{is} the order of radical selectivity is exactly reversed.

[*] Priv.-Doz. Dr. B. Giese, Dipl.-Chem. K. Jay
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

On the basis of this observation it can be predicted that the selectivities of the halogen donors $XCCl_3$ (X = Br, Cl) in the radical competition systems also coincide at approximately 60±20 °C. This prediction can be tested by studying the radical addition of $XCCl_3$ to 2-norbornene in which the *exo*-trichloromethylnorbornyl radical *(2)* is formed during the primary attack[3].

(2)

The radical *(2)* is attacked from both the *endo* and the *exo* side. Halogen transfer from $XCCl_3$ (X = Br, Cl) is predominantly *endo* due to the shielding influence of the *exo*-trichloromethyl group. The temperature dependence of the stereoselectivity ($\lg k_{endo}-\lg k_{exo}$) of the abstraction of bromine from $BrCCl_3$[4] and of chlorine from CCl_4 was determined between 0 and 127 °C. The selectivity plots shown in Figure 1 demonstrate that below 90 °C the transfer of chlorine from the less reactive CCl_4[1, 2a] proceeds with greater selectivity than the transfer of bromine from the more reactive $BrCCl_3$. At 90 °C—the isoselective temperature T_{is}—the selectivities of the halogen donors $XCCl_3$ become equal; their order is reversed above 90 °C. Here, the more reactive $BrCCl_3$ is more selective than the less reactive CCl_4. The selectivity principle[5] is thus only valid below 90 °C. The isoselective temperature deviates but slightly from the expected value of 60±20 °C.

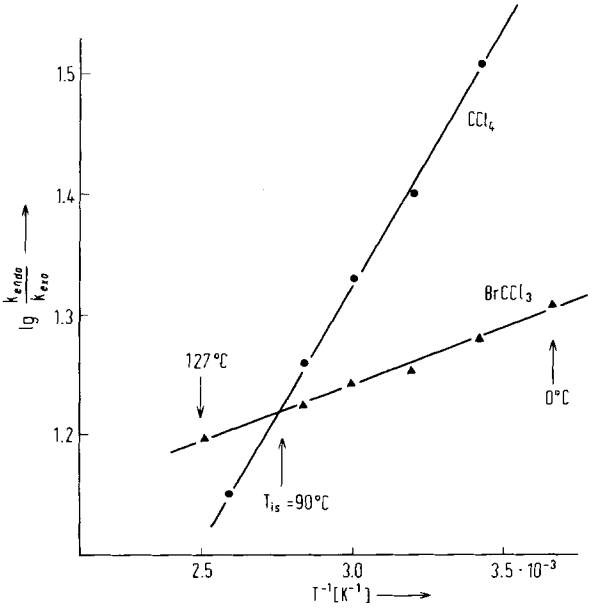


Fig. 1. Temperature dependence (0 to 127 °C) of the stereoselectivity ($\lg k_{endo}-\lg k_{exo}$) of halogen transfer from $XCCl_3$ (X = Br, Cl) to the norbornyl radical *(2)*.

The activation parameters can be calculated from the selectivity plots shown in Figure 1—correlation coefficient $r=0.993$

(X=Br); $r=0.999$ (X=Cl). The data in Table 1 show that the activation enthalpy of chlorine transfer from the Cl—CCl_3 bond, which is stronger by 18 kcal/mol[6], is influenced to a greater extent by the steric shielding of the radical than that of bromine transfer from Br—CCl_3. The activation entropy of chlorine abstraction, however, remains constant whereas that of bromine transfer to the *exo* position of the radical *(2)* is clearly not so favorable.

Table 1. Differences between the activation enthalpies [kcal mol^{-1}] (average error ±7%) and the activation entropies [cal K^{-1} mol^{-1}] (average error ±0.5 cal K^{-1} mol^{-1}) of halogen transfer from $XCCl_3$ to the norbornyl radical *(2)*.

$XCCl_3$	$\Delta H^{\neq}_{exo}-\Delta H^{\neq}_{endo}$	$\Delta S^{\neq}_{exo}-\Delta S^{\neq}_{endo}$
X=Br	0.5	−4.1
X=Cl	2.0	−0.1

Since perhalomethanes are used as halogenating agents in radical substitution reactions[1], the occurrence of the isoselective temperature at 90°C is also of preparative significance.

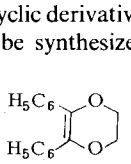
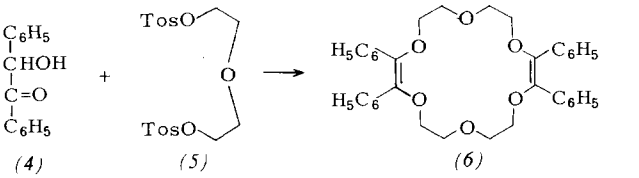
2,3,11,12-Tetraphenyl-1,4,7,10,13,16-hexaoxa-2,11-cyclooctadecadiene: A New Crown Ether from Benzoin[1][**]

By *Andreas Merz*[*]

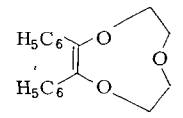


Recently, we found[2] that the stilbenediol dianion *(1)* is formed from benzoin *(4)* and aqueous sodium hydroxide under conditions of phase-transfer catalysis[3]. *(1)* is alkylated by dialkyl sulfates and alkyl tosylates to give predominantly the *E* isomers of the α,β-dialkoxystilbenes *(2)*[2,4]. However, when bifunctional alkylating agents are used, cyclic derivatives of *(2)* fixed in the *Z* configuration can also be synthesized,

(1)



(2)



(3)

e.g. with ethylene glycol ditosylate the 2,3-dihydro-5,6-diphenyl-1,4-dioxine *(3)* is obtained.

From the structure of *(3)* it is evident that the stilbenediol unit is a potential building block for crown ether systems. Thus, the title compound *(6)* is indeed obtained with a yield of 20% by reacting *(4)* with diethylene glycol ditosylate *(5)* in boiling benzene with 50% aqueous sodium hydroxide as base and tetra-*n*-butylammonium bromide as phase-transfer catalyst[5].

(4) *(5)* *(6)*

(7)

The smaller crown ether 2,3-diphenyl-1,3,7-trioxa-2-cyclononene *(7)* is also produced in 14% yield.

Apart from the related compound dibenzo-[18]crown-6[6], in which the double bounds are integrated into benzene rings, *(6)* is the only macrocyclic polyether to have double bonds within its ring and thus fills a gap in the series of known [18]crown-6 systems.

In addition to their use as complexing agents[7] and phase-transfer catalysts[8], crown ethers have recently become especially important as basic structural units of receptor molecules for "host-guest-molecule" relationships and for the separation of enantiomers by "chiral recognition"[9]. On account of its ready accessibility and the many conceivable reactions which could take place at its double bonds with their prochiral centers, the new crown ether *(6)* could prove very valuable.

Experimental

A mixture of *(4)* (4.24 g, 0.02 mol), *(5)* (8.33 g, 0.02 mol), tetra-*n*-butylammonium bromide (100 mg, *ca.* 0.3 mmol), 50% aqueous NaOH (20 ml), and benzene (100 ml) is stirred at 80°C for 14 h. The product is then poured into water and the organic phase used for further purification. The partially solid residue is suspended in ethyl acetate and filtered under suction: 1.1 g crude *(6)*, m.p. 165—175°C (19.5%); purified by recrystallization from chloroform/ethyl acetate. Physical data of *(6)*: colorless needles, m.p. 173—175°C (slow heating); mass spectrum (70 eV), *m/e*: 564 ($M^{\cdot+}$, 100%), 238 ($C_{16}H_{14}O_5^{+}$, 70%), 105 ($C_6H_5CO^{+}$, 96%); ^{1}H-NMR ($CDCl_3$): δ=4.00 and 7.26, slightly broadened singlets, intensity ratio 4:5; IR (KBr): $\tilde{\nu}_{C=C}=1620$, $\tilde{\nu}_{C-O}=1255$, 1135, 1120, 1060 cm^{-1}; UV (CH_2Cl_2): λ_{max} [nm] (ε) = 300 (17200), 245 (9800), 228 (14000).

After filtration with dichloromethane through a short silica gel column 800 mg (14%) of *(7)*, m.p. 78°C, are obtained from the mother liquor. Physical data of *(7)*: mass spectrum (70 eV), *m/e*: 282 ($M^{\cdot+}$, 98%), 177 ($M^{\cdot+}-C_6H_5CO^{\cdot}$, 100%), 149 (85%), 133 (16%), 105 ($C_6H_5CO^{+}$, 97%); ^{1}H-NMR: δ=3.7—4.1 (m, 4H), 4.1—4.4 (m, 4H), 7.14 (narrow m, 10H); IR (KBr): $\tilde{\nu}_{C=C}=1625$, $\tilde{\nu}_{C-O}=1250$, 1145, 1070 cm^{-1}; UV (*n*-hexane): λ_{max} [nm] (ε) = 306 (9700), 245 (6800), 222 (12900).

η-Cyclopentadienyl(η-diborolenyl)nickel—A Diamagnetic Nickelocene Analog[1]

By *Walter Siebert* and *Manfred Bochmann*[*]

1,2,5-Thiadiborolenes react as two-electron acceptors with metal carbonyls to form double-[2] and triple-decker[3] compounds. The structurally related 1,3-diborolenes[4] *(1)* should likewise form mono- and dinuclear complexes as three-electron acceptors after elimination of H. We now report the thermal reaction of *(1)* (R = C_2H_5) with nickelocene, which affords the diamagnetic species *(2)*.

(1) *(2)*

The spectroscopic and analytical data of the orange-red, in solution air-sensitive compound *(2)* are in accord with a sandwich structure. Apart from the molecular ion $C_5H_5NiL^+$ [L = {*(1)* – H}, R = C_2H_5] (I_{rel} = 100 % relative to $^{11}B_2{}^{58}Ni$), the mass spectrum (70 eV) displays *inter alia* the fragments $\{C_5H_5NiL-C_2H_5\}^+$ (14), $\{C_5H_5NiL-C_2H_5-C_2H_4\}^+$ (14), $\{LNi-H\}^+$ (25), $\{NiL-C_2H_5\}^+$ (16), and $C_5H_5Ni^+$ (13). In the ^{1}H-NMR spectrum [δ = 3.97 (S, 5), 1.3 (M, 4), 0.70 (S, 3), 0.66 (T, 6), 0.37 (T, 6); in C_6D_6 relative to external TMS] only one of the two ABX_3 multiplets for the magnetically nonequivalent methylene protons can be recognized since the CH_2 signals of the BC_2H_5 group are superposed by the two triplets and the singlet.—The ^{11}B-NMR signal exhibits a pronounced upfield shift (Δδ = 33.3) on going from free *(1)* [δ = 68.6; in hexane relative to external $BF_3 \cdot OEt_2$] to complex *(2)*, which can be explained only in terms of a *pentahapto* bonding of the C_3B_2 ring.

The electron balance in *(2)* can be described by assuming construction of the sandwich from two aromatic rings (C_5^-, $C_3B_2^{3-}$) and the Ni d^6 cation. On viewing *(2)* as nickelacarbaborane with a *nido*-C_3B_2Ni skeleton it follows that the bonding molecular orbitals are to be occupied by $2n+4 = 16$ skeletal electrons[5] [3 × 3 (C), 2 × 2 (B), 3 (Ni)]. Complex *(2)*, which is isoelectronic to the metallocenes $[Fe(C_5H_5)_2]$, $[Co(C_5H_5)_2]^{\oplus}$, and $[Ni(C_5H_5)_2]^{2\oplus}$[6], is derived from the paramagnetic, 20-electron sandwich compound nickelocene by replacement of two CH groups by BR groups and from the diamagnetic η-cyclopropenyl complex $[Ni(C_5H_5)(C_3Ph_3)]$[7] by insertion of two BR groups with ring expansion. The metal center in *(2)* is formally Ni^{IV} (for comparison, see $[Ni(\eta^5\text{-}C_2B_9H_{11})_2]$[6]).

Halogenonitrosylmolybdates—Isolation of the First Classical Mo^I Complex

By *Sabyasachi Sarkar* and *Achim Müller*[*]

Little is known about classical complexes of the lower oxidation states of molybdenum (Mo^0, Mo^I, Mo^{II})[1], and although the oxidation of $[Mo(NO)(CN)_5]^{4-}$ has repeatedly been investigated no corresponding Mo^I complex could be isolated. We recently reported salts with the anions $[Mo(NO)X_4]^-$ *(1)* and $[Mo(NO)X_5]^{2-}$ *(2)* (X = Cl, Br)[2] as mononuclear coordination compounds with simple ligands where Mo can be regarded as being in the formal oxidation state II (nitrosyl group as NO^+[1], $\{MNO\}^4$ configuration[3]). We have therefore attempted the synthesis of the missing species between $K_4[Mo(NO)(CN)_5]$ (formally $Mo^{0[1]}$) containing the $[MoNO]^+$ group and *(1)* as well as *(2)* with the group $[MoNO]^{3+}$ in the series[4]

$[MoNO]^+$	$[MoNO]^{2+}$	$[MoNO]^{3+}$
$\{MoNO\}^6(\equiv e^4b_2^2)$	$\{MoNO\}^5(\equiv e^4b_2^1)$	$\{MoNO\}^4(\equiv e^4)$

in order to systematically study the electron distribution over the three centers M—N—O.

The Mo^I-compound[5] $Cs_2[Mo(NO)Cl_4H_2O]$ *(3)* containing the $[MoNO]^{2+}$ group is isolated as stable green crystals by a new method for the *reduction* of nitrosyl complexes[6]:

[*] Prof. Dr. A. Müller, Dr. S. Sarkar [**]

381 vw	≈360 sh		A_1	ν(Mo—OH_2), ν(Mo—OD_2)
304 s, br	304 s, br	320 vs, br	E [b]	$\nu_{as}(MoCl_4)$

[a] Additional very weak bands appear at 3190 and 2364 cm^{-1}, respectively. [b] $\nu_s(MoCl_4)$ is overlapped by $\nu_{as}(MoCl_4)$. [c] In principle reverse assignments are possible.

spectral studies. The data presented in Tables 1 and 2 confirm that the new species has C_{4v} symmetry with the ground state configuration $e^4b_2^1$. The electron density in the group $[MoNO]^{n+}$ is expectedly larger in the reduced species *(3)* than in *(2)*. Comparison of the ESR data with those of the only known Mo^I-species in solution[7a] showed a greater difference $|g_\perp - g_\parallel|$ as well as a greater Δg_{av} value for *(3)* (see [7]).

A knowledge of the complexes of the series $[Mo(NO)]^{n+}$, $n = 1$—3 should improve our understanding of nitrosyl complexes and especially the coordination complexes of lower valent molybdenum. Redox and ligand exchange reactions permit development of a "classical" complex chemistry of Mo^0, Mo^I, and Mo^{II}, the various complexes being stabilized by the NO group.

Experimental

To a suspension of *(2)* (1 g) in dilute, oxygen-free hydrochloric acid (20 ml, 3 N) is added Mg powder (0.14 g) in the cold. On addition of methanol (10 ml) green crystals of *(3)* separate slowly. Yield *ca.* 50 %.

Formation of Benzocyclobutenone by Gas-Phase Pyrolysis[**]

By *Peter Schiess* and *Markus Heitzmann*[*]

We recently demonstrated the formation of alkenylketenes by elimination of hydrogen chloride from β,γ-unsaturated acyl chlorides at 400 to 600 °C in the gas phase. In turn, the alkenylketenes are transformed into α,β;γ,δ-unsaturated aldehydes by an intramolecular 1,5-hydrogen shift[1].

We have now found that thermal HCl elimination also occurs readily with *ortho*-alkyl-substituted aromatic acyl chlorides *(1)*[2]. The *ortho*-quinonoid ketene *(2)* formulated

St. Johanns-Ring 19, CH-4056 Basel (Switzerland)

[**] This work was supported by the Schweizerischer Nationalfonds (Project No. 2480075) and by CIBA-GEIGY AG.

as intermediate is stabilized by 1,5-hydrogen shift to give the aldehyde, provided that the alkyl side chain bears β-protons[3]. Thus gas-phase pyrolysis (600 °C/0.3 s) of 2-propylbenzoyl chloride *(1)*, R^1 to R^4 = H, $R^5 = C_2H_5$, gives a mixture of the isomeric aldehydes *(3)*[4]. If the side chain is a methyl group, however, then benzocyclobutenone *(4)* is obtained (see Table 1).

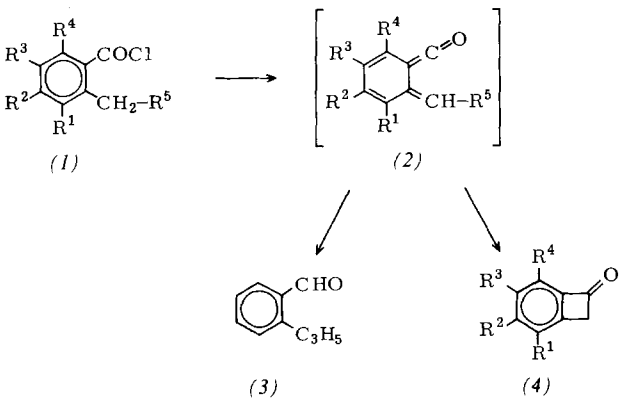

Table 1. Formation of benzocyclobutenones *(4)* by gas-phase pyrolysis [a] of *(1)*, $R^5 = H$.

	R^1	R^2	R^3	R^4	Pyrolysis temp. [°C]	Conversion [%]	Yield [b] [%]	M.p. [°C] b.p. [°C/torr]

(e)	H	CH_3O	H	H	590	59	43 (72)	49—50 95—105/1.5	[6c]
(f)	H	H	—CH=CH—CH=CH—		550	89	73 (82)	96—97	[7]

[a] 14 torr, contact time *ca.* 0.3 s.
[b] Based on amount of acyl chloride weighed in (reacted).

In the case of compounds *(1a)* and *(1b)* the conditions necessary for HCl elimination are so drastic that benzyl chloride and other volatile decomposition products derived from *(4)* arise on complete reaction of the acyl chloride[5]. With compounds *(1c)* to *(1f)*, 1,4-elimination of HCl is facilitated by steric or electronic substituent effects and/or bond delocalization in the aromatic ring, and the benzocyclobutenones *(4)* can be isolated in excellent yields. The above method of preparing benzocyclobutenones[6] should compete successfully with other procedures on account of the ready accessibility of the reactants and experimental simplicity.

Procedure

o-Toluoyl chloride (30.0 g, 0.194 mol) is distilled at 12 torr through a quartz tube (30 × 1 cm) packed with quartz chips heated to 620 °C over a period of 2.5 h. The pyrolyzate condensed onto a cold finger (−78 °C) located at the end of the tube is dissolved in tetrahydrofuran (300 ml) and stirred for 1 h at 25 °C with saturated sodium hydrogen carbonate solution (400 ml). Extraction with pentane and fractional distillation (Vigreux column, 10 × 1 cm) affords benzocyclobutenone *(4a)* (6.5 g; b.p. 89 to 90 °C/14 torr[6a]). *o*-Toluic acid (6.4 g) can be recovered by acidification of the aqueous phase.

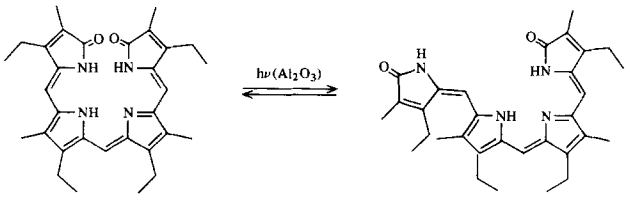
A Geometrically Isomeric Bilatriene-abc[**]

By *Heinz Falk* and *Karl Grubmayr*[*]

The synthesis and constitution of bile pigments have already been extensively investigated[1]. However, only very recently has any appreciable understanding of their structure (configuration, conformation, tautomerism) been achieved[2–4]. Geometrical isomers of a bile pigment were hitherto unknown; they are of interest, however, with regard to hypotheses on the function of the plant photoreceptor phytochrome[5].



We have now been able to demonstrate a $Z \rightleftharpoons E$ isomerization in a bilatriene-abc, *viz.* etiobiliverdin-IV-γ *(1)*, and to isolate the new isomer.

After irradiation of *(1)*, which had been adsorbed on aluminum oxide, chromatographic separation afforded besides the educt a slowly migrating product which was characterized as an isomer by its mass spectrum [MS (70 eV, 140 °C); *m/e* (%): 498 (100, M^+), 483 (15), 469 (16), 249 (13, M^{2+})]. The reaction is photoreversible, *i.e.* on renewed irradiation of the

[**] This work was supported by the Fonds zur Förderung der wissenschaftlichen Forschung (Project No. 2732).

product under the given conditions the mixture of both forms is regenerated, the more rapidly migrating component proving to be identical with the educt in all its properties[6]. The absorption spectrum of the isomer [UV-VIS ($CHCl_3$): 262 (18000), 323 (27000), 369 (41000), 598 (21000), nm (ε)] differs from that of the educt by a hypsochromic shift of the long-wave band of about 38 nm.

(Z,Z,Z)-(1) *(E,Z,Z)-(1)*

Owing to its structural analogy with the methyl ester of biliverdin[2] and in view of the characteristics of partial structures[4, 7], the educt is assigned the configuration *(Z,Z,Z)-(1)*. For the product, five geometric isomers are conceivable. Three of these, namely those having the configurations (*E,Z,E*), (*Z,E,Z*), and (*E,E,E*) are ruled out on the basis of the ^{1}H-NMR spectra, which should be analogous to that of the educt[6] (this is of course very much simplified by the formal C_{2v} symmetry). Only the configurations (*E,Z,Z*) and (*E,E,Z*) are consistent with the typical spectrum[8] for the isolated material, which shows four separate methyl signals, a methyl triplet of an ethyl group separated from the signal of the other three groups, and three methine signals. The positions of these methine signals compared with those in *(Z,Z,Z)-(1)*[6] and the finding that no isomerization is observed in the pyrromethene unit[9] afford evidence for the isomeric product having the configuration *(E,Z,Z)-(1)*.

Procedure

A solution of *(Z,Z,Z)-(1)*[6, 10] (249 mg, 0.5 mmol) in $CHCl_3$ (20 ml) is added to 5 g Al_2O_3 (after *Brockmann*, degassed, loaded with argon) and the solvent evaporated. After slurrying in *n*-hexane (200 ml) the vigorously stirred suspension is irradiated in an argon atmosphere for 2 h at 10 °C with a 200-W tungsten lamp. CH_3OH (25 ml) is then added to the suspension, the mixture filtered, and the residue washed with CH_3OH. After removal of solvent from the filtrate in a rotary evaporator the residue is chromatographed on 40 g Al_2O_3 (after *Brockmann*) with $CHCl_3$ in the absence of light. 180 mg *(Z,Z,Z)-(1)* is obtained as a rapidly migrating zone and (after addition of about 1 % CH_3OH) also 25 mg crude *(E,Z,Z)-(1)*. Re-chromatography of this fraction on silica gel thin-layer plates (0.5 mm, $CHCl_3/CH_3OH$ = 20/1) affords 20 mg (8 %) pure *(E,Z,Z)-(1)*, m.p. 260 °C.

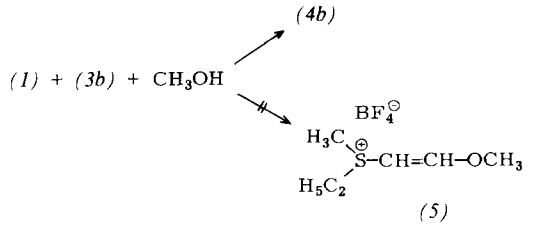
Vinylenedionium Salts Containing Different Onium Groups[**]

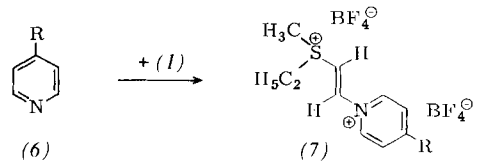


By *Heinz Braun, Anton Amann*, and *Manfred Richter*[*]

Vinylenediammonium[1], vinylenediphosphonium[2], and vinylenedisulfonium[3] salts are well known. In contrast, vinylenedionium salts containing dissimilar onium groups have to our knowledge so far not been described. We report here on the synthesis of S^+,N^+-substituted vinylenedionium salts.

On reaction with the *cis*-vinylenedisulfonium salt *(1)*[3a] in the molar ratio 1 : 1 the trialkylamines *(3a)* to *(3c)* afford the *trans*-salts *(4a)* to *(4c)*. Compound *(4a)* was also synthesized from the *trans*-salt *(2)*[3a] and *(3a)*. According to NMR spectral data the reaction of *(1)* with *(3b)* in acetone at room temperature is complete within a few minutes. To our knowledge the substitution of an sp^2-bonded sulfonium group by a tertiary amine has hitherto not been observed.

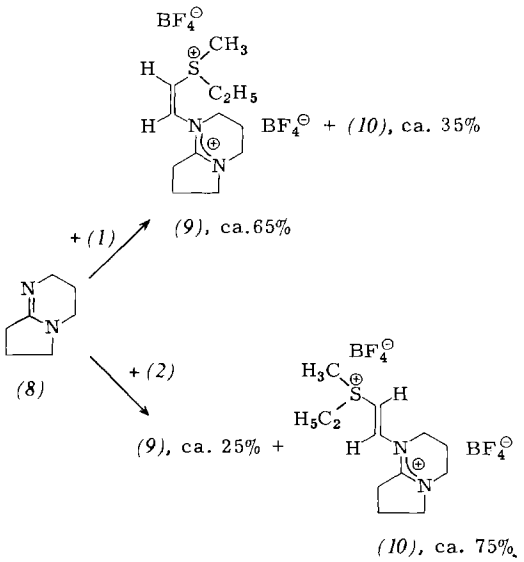
Compounds *(4)* are stable at room temperature, *(4a)* and *(4b)* are crystalline and water-soluble, *(4c)* (yield 80 %, picryl sulfonate dec. 124 to 127 °C) is obtained as a wax which is soluble in benzene.



[*] Dr. H. Braun, A. Amann, M. Richter
Organisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

Reaction of *(1)* with *(3b)* and methanol in the molar ratio 1:1:1 in acetone affords *(4b)*. The methoxyvinylsulfonium salt *(5)*[3b] was not detectable by NMR spectroscopy.



The hypernucleophilic pyridines *(6a)* and *(6b)*[4] react with *(1)* to give the crystalline salts *(7a)* and *(7b)*, respectively.

(6) *(7)*

(a), R = NH_2
(b), R = $N(CH_3)_2$

Reaction of *(1)* or *(2)* with the typical elimination reagent *(8)*[5] furnishes mixtures of the stereoisomeric amidinium salts *(9)* and *(10)*. The product patterns were determined NMR spectroscopically on the crude reaction mixtures. The reactions of *(8)* with *(1)* and *(2)* proceed stereoselectively with retention of configuration. This finding is not consistent with an initial elimination step *via* ethynylsulfonium salt[6].

(8)

(9) crystallizes in pure form from the reaction mixture formed on reaction of *(1)* with *(8)*. Compound *(10)* was isolated by fractional crystallization. *(9)* and *(10)* are the first *cis,trans*-isomer pair of a vinylenedionium salt containing dissimilar onium groups.

Supporting evidence for the constitutions of the compounds described here was provided by correct CHN analyses and by IR, ^{1}H-NMR, and ^{13}C-NMR data (Table 1). The configurations of *(4)* and *(7)* were determined by ^{1}H-NMR spectroscopy. Vinylammonium salts of known stereochemistry[7], and the compounds *(9)* and *(10)* in particular, were used for comparison.

Strong nucleophiles substitute the ammonium group in *(4)* chemospecifically[8]. The vinyl-group proton situated α to the sulfonium group can be replaced selectively by deuterium[8].

Procedure

Compound *(4b)*: A freshly prepared solution of *(3b)* (4.05 g, 0.04 mol) in anhydrous acetone (50 ml) is added dropwise within 5 min at room temperature to a stirred suspension of *(1)* (14.10 g, 0.04 mol) in acetone (250 ml). Solvent is removed from the resulting light-red solution by evaporation (bath-temperature 30 to 40 °C). The residue crystallizes on addition of a little ethanol. After washing with cold ethanol and drying (*ca.* 0.01 torr) there remains 13.10 g (87 %) of light-beige *(4b)*. Recrystallization from methanol/ethanol furnishes 12.05 g (80 %) colorless crystals.

Compound *(7b)*: A suspension of *(1)* (6.00 g, 17 mmol) and *(6b)* (2.08 g, 17 mmol) in anhydrous acetone (150 ml) is stirred for 30 min at room temperature. Work-up of reaction mixture as for *(4b)*. Recrystallization from methanol affords 6.49 g (95 %) *(7b)* as colorless crystals, m.p. 147 °C (dec).

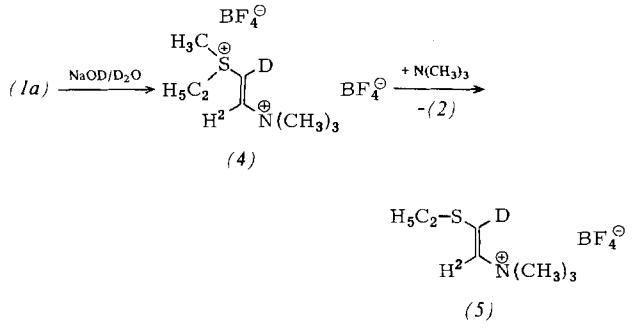
Reactions of (2-Dialkylsulfoniovinyl)trialkylammonium Salts[**]

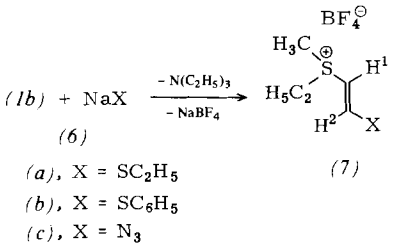
By *Heinz Braun* and *Anton Amann*[*]



Trialkylamines undergo reaction with vinylenedisulfonium salts with substitution of a sulfonium group to give the salts *(1)*[1]. We have examined whether further exchange of an onium group can be achieved by reaction of *(1)* with a tertiary amine. Reaction of *(1a)* or *(1b)* with trimethylamine affords, however, an almost quantitative (NMR spectra) 1:1 mixture of *(2)* and *(3a)* or *(3b)*, respectively. Compound *(3a)* is crystalline, *(3b)* was obtained as a colorless oil which was analyzed as crystalline hexafluorophosphate.

(1) *(2)* *(3)*

(a), R = CH_3
(b), R = C_2H_5



If the weakly acid solution of *(1a)* in deuterium oxide is adjusted to pH ≈ 7.5 with dilute sodium deuterium oxide solution H/D exchange of one of the two olefinic protons can be observed NMR spectroscopically.

(4)

(5)

The monodeuteriated compound *(4)* was isolated. It yields compound *(5)* on reaction with trimethylamine in dimethoxyethane. The structure of *(5)* was deduced NMR spectroscopically by comparison with *(3a)* and with β-substituted vinylammonium compounds[2] (Table 1). The structure of *(4)* was inferred from *(5)*. The reaction *(1a)* → *(4)* shows that sp^2 bonded protons are more strongly acidified by sulfonium groups in the α position than by ammonium groups. The selective deuteration of compounds having a structure analogous to *(1)*[1], moreover, enabled unequivocal assignment of the CH=CH signals in the ^1H- and ^{13}C-NMR spectra[3].

(6) *(7)*

(a), X = SC_2H_5
(b), X = SC_6H_5
(c), X = N_3

Strong nucleophiles substitute the ammonium group in *(1)* chemospecifically: reaction of *(1b)* with *(6a)* or *(6b)* in methanol at 0 °C yields the oily tetrafluoroborates *(7a)*[4] or *(7b)*, respectively. Reaction of *(6c)* with *(1b)* in water at room temperature yields *(7c)*. The crude solutions of compounds *(7)* still contain < 5 % of the corresponding *cis* isomer (NMR spectra). Compounds *(7b)* and *(7c)* were obtained in sterically pure form as the crystalline 2,4,6-trinitrobenzenesulfonate and hexafluorophosphate, respectively.

Vinylsulfonium salts are excellent Michael acceptors and productive building blocks in syntheses[5]. The reaction sequence *cis*-vinylenedisulfonium salt → *trans*-*(1)*[1] → *trans*-*(7)* constitutes a novel route to *trans*-substituted vinylsulfonium salts. The *cis* isomers of *(7)* are formed stereoselectively from *cis*-vinylenedisulfonium salts and *(6)*[3, 4b]. The method thus offers the possibility of synthesizing both isomeric vinylsulfonium salts from a readily accessible starting compound.

Compound *(7)* and its *cis* isomer[3] are to our knowledge the first azidovinylsulfonium salts reported in the literature. The compounds are interesting water-soluble "vinyl azides"[6].

Procedure

A solution of trimethylamine (126 mg, 2.13 mmol) in anhydrous acetone (1.3 ml) was added to a stirred solution of *(1b)* (400 mg, 1.06 mmol) in acetone at room temperature. After 1 h the reaction mixture was concentrated to 7 ml and filtered free from precipitated *(2)*. The filtrate after removal of solvent and drying (0.01 torr) afforded 285 mg (98 %) *(3b)* as a colorless oil.—Hexafluorophosphate: an aqueous solution of *(3b)* (285 mg) was treated with an excess of aqueous ammonium hexafluorophosphate solution. Recrystallization of the precipitate from ethanol yielded 230 mg (72 %) of colorless crystals, m.p. 78 to 79 °C.

Compound *(7c)*: A solution of *(1b)* (5.00 g, 0.13 mol) and *(6c)* (0.87 g, 0.13 mol) in water (50 ml) was stirred for 30 min at room temperature. After removal of water (rotary evaporator, bath temperature 40 °C) the residue was treated with 10 ml acetone and 15 ml dichloromethane and then filtered to remove sodium tetrafluoroborate. After removal of solvent and drying there remained 2.33 g (76 %) *(7c)* together with

Lithium 7b*H*-Indeno[1,2,3-*jk*]fluorenide, an Organolithium Compound Having a "Sandwich" Structure[**]

By *Dieter Bladauski, Hans Dietrich, Hans-Jürgen Hecht*, and *Dieter Rewicki*[*]

Crystal structure studies have shown that alkyllithium compounds[1] exist in systems associated *via* electron-deficient bonds and containing Li atoms of coordination number ≥ 4. Amine[2] or ether complexes[3] of organolithium derivatives with resonance-stabilized carbanions, on the other hand, are composed of typical intimate ion pairs with ionic and covalent bonding contributions, the lithium lying in a trigonal environment made up of the carbanion π-base and the N and O basic centers.

We have now accomplished the first isolation of the lithium salt of a hydrocarbon exhibiting extreme charge delocalization in crystalline form, without any need for hetero atom bases as crystallization-promoting or stabilizing ligands. The ruby-red compound lithium 7b*H*-indeno[1,2,3-*jk*]fluorenide *(1)* slowly crystallizes on interdiffusion of dilute benzene solutions of 7b*H*-indeno[1,2,3-*jk*]fluorene and butyllithium and contains one half molecule of benzene per formula unit. X-Ray structure analysis[4] performed at $-160\,^{\circ}C$ revealed the structure shown in Figure 1.

The crystal lattice consists of isolated units containing two carbanions and two lithium ions each. The essentially planar

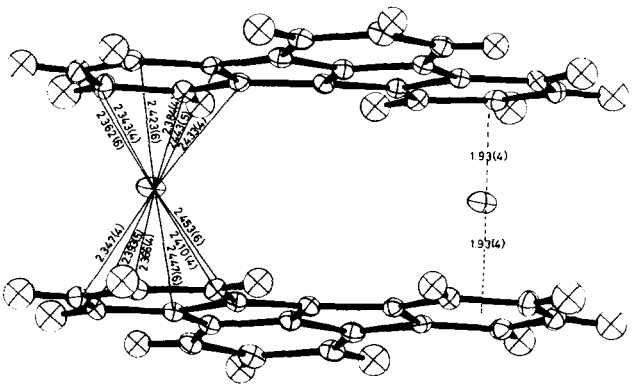

Fig. 1. Structure of the lithium salt *(1)*; *xy* projection of a section of the unit cell. The benzene molecules incorporated in the lattice are omitted for the sake of clarity.

carbanions[5] (mean deviation of the plane through the molecule: 0.04 Å) are mutually parallel and separated by 3.9 Å; the central six-membered rings are *anti* orientated. The lithium ions are coordinated in sandwich fashion with a pair of external six-membered rings. The distance between the lithium ion situated almost concentrically above the six-membered rings and the two rings is uniformly 1.93(4) Å, and the distance to the C atoms of the six-membered ring varies between 2.343(4) and 2.453(6) Å, having a mean value of 2.41(4) Å. The benzene incorporated into the lattice lies outside the coordination sphere of the lithium.

On comparison with the known structures of organolithium compounds, structure *(1)* is seen to have the following distinctive features: 1) This is the first case of lithium being present in *linear* coordination with two *hexahapto*-bonded six-membered ring ligands in the form of a bis(arene)metal type complex. The Li—C distances, which are only 0.25 Å longer on average than in alkyllithium compounds and correspond approximately to those in indenyllithium[2], as well as the short $Li^{\oplus}$—ring distance[6] show the "sandwich" structure to be a consequence of bonding interactions and not merely a packing phenomenon.—2) In contrast to the lithium compounds with resonance-stabilized carbanions examined so far[2] no preferred orientation of the lithium atoms on the C center of highest charge density can be detected in the case of *(1)*. On the basis of charge densities at the carbanion calculated by MO methods, the $Li^{\oplus}$ should be preferentially located over the five-membered rings. The observed position of the lithium can be interpreted by assuming that, given pronounced charge delocalization within the carbanions and in the absence of hetero atom bases, the structure of the lithium compound is largely determined by covalent interaction between the unoccupied atomic orbitals of lithium and the occupied molecular orbitals of the carbanion and to a lesser degree by electrostatic interactions.

5-Methoxysemibullvalene

By *Reinhard W. Hoffmann, Norbert Hauel*, and *Fritz Frickel*[*]

Dedicated to Professor Burckhardt Helferich on the occasion of his 90th birthday

The equilibrium between the valence isomers of semibullvalene is influenced by substituents in the 1,5-positions[1]. In all the derivatives (alkyl, aryl, cyano) so far obtained, the 1-isomer predominates. However, a π-donor substituent is predicted to favor the 5-position[2]. We describe the synthesis of 5-methoxysemibullvalene *(6)*, the first donor-substituted semibullvalene.

(a), X = I; *(b)*, X = Br; *(c)*, X = Cl

Reaction of *(1)*[3] with an equimolar amount of AlX_3 (ether, 0 °C) led to *(2)* in 70 to 78 % yield[4]. $(C_2H_5)_2AlCl$ in refluxing ether gave 90 % of *(2c)*. The *endo*-position of the halogen in *(2)* follows from the coupling pattern of the CHX proton in the ^{1}H-NMR spectra. The absence of hydrogen *anti*-peri-planar to the halogen thwarted attempted E_2-eliminations (KOtBu, DMSO, 80 °C). Reaction of *(2a)* with an excess of sodium methanethiolate (DMF, 24 h, 25 °C) gave 80 % of crude *(3)*, which has been alkylated by an excess of methyl iodide to *(4)* (neat, 24 h, 25 °C, 71 %) (cf. Table 1).

Elimination of the axially positioned sulfonium group in *(4)* (KOtBu/DMSO, 1 h, 25 °C) proceeded smoothly to give > 70 % of a methoxysemibullvalene[5] (b.p. 19 °C/0.01 torr)[6]. The structure *(6)* rather than *(5)* is deduced from the ^{1}H-NMR-spectrum (CCl_4): $\tau = 4.5$ (d, $J = 4.6$ Hz, 4-H, 6-H); 5.0 (dd, $J_1 = 4.6$ Hz, $J_2 = 1.5$ Hz, 3-H, 7-H); 6.7 (d, $J = 5$ Hz, 2-H, 8-H); 6.9 (s, OCH_3); 7.1 (t, $J = 5$ Hz, 1-H). ^{13}C-NMR ($CDCl_3$/TMS): δ = 51.43, d; 51.60, d; 52.41, q; 100.26, s; 120.26, d; 124.43, d. The ^{13}C-NMR spectrum (CF_2Cl_2) exhibited a broadening and a shift of the C-2, C-8 and the C-4, C-6 signals between −30 and −130 °C. This can be interpreted by assuming the presence of less than 10 % of *(5)* in the equilibrium. Hence the prediction[2] of *(6)* being favored in the equilibrium *(5)* ⇌ *(6)* is substantiated.

Table 1. Physical data of the new compounds.

Synthesis and Chemistry of Alkylidenediaziridines

By *Gerrit L'abbé, Chih-Chou Yu*, and *Suzanne Toppet*[*]

Aziridinimines have been reported by *Quast*[1], but their valence isomers, alkylidenediaziridines, were hitherto unknown. We report here on their synthesis, thermal isomerization and behavior in cycloaddition reactions.

When ketenimines *(1a)* to *(1c)* are treated with methanesulfonyl azide at room temperature, evolution of nitrogen occurs and, as indicated by the ^{1}H-NMR spectra ($CDCl_3$) of the crude reaction mixtures, almost single products are obtained. These were isolated by careful crystallization from appropriate solvents (see Table 1) and identified as alkylidenediaziridines *(2a)* to *(2c)*[2] on the basis of:
molecular weight determination (osmometric);
^{1}H-NMR (non-equivalence of the alkylidene methyl groups with signals at δ = 1.7 and 1.8);
^{13}C-NMR spectra [olefinic carbon absorptions at δ = 98 (C-β) and 162 (C-α), Δδ = 64, which is characteristic for enediamines[3]].

The IR spectra (KBr) manifested absorptions at 1630 to 1650 cm^{-1}, which are unusually low for stretching vibrations of C=C bonds attached to three-membered rings[4a]; however, this is not without precedence[4b].

Table 1. Compounds synthesized.

	Yield [%]	Recrystallization solvent	M.p. [°C]	$M^{+\cdot}$ [calc/found]
(2a)	42	Carbon tetrachloride	82—83	238.0775/238.0781
(2b)	56	Carbon tetrachloride	93—94	252.0931/252.0904
(2c)	74	*n*-Hexane/chloroform	119—120	317.9859/317.9850
(3a)	78	Ether/chloroform	105—106	238.0774/238.0763
(3b)	84	Ether/petroleum ether	93—94	252.0931/252.0941
(3c)	≈100	Ether/chloroform	121—122	317.9859/317.9868
(4a)	64	Methanol	165—166	357.1145/357.1128
(4b)	70	*n*-Hexane/chloroform	192—193	371.1302/371.1322
(4c)	73	*n*-Hexane/chloroform	203—204	437.0228/437.0207
(5)	82	Methanol	190—191	296.0829/296.0807
(6)	24	Carbon tetrachloride	138—139	237.0999/237.0992

Compounds *(2a)* to *(2c)* underwent quantitative isomerization into methacrylic amidines *(3)* upon heating in chloroform for 2 to 3 days (see Table 1).

Whereas phenyl isothiocyanate, *tert*-butyl isothiocyanate, dicyclohexylcarbodiimide, acetonitrile, and benzonitrile were unreactive towards *(2)*, phenyl isocyanate reacted readily at room temperature to give the oxazolidinimines *(4a)* to *(4c)* in good yields (Table 1).

The IR spectra (KBr) of *(4)* showed characteristic imine bands at 1700 to 1710[5] and 1600 cm^{-1}, while the NMR spectra indicated the presence of two equivalent methyl groups (at $\delta = 1.95$ in the ^{1}H-NMR and at $\delta = 25$ in the ^{13}C-NMR). The ring carbon absorptions were found at $\delta = 147$ (C-2), 168 (C-4) and 88 (C-5) in the ^{13}C-NMR spectra ($CDCl_3$). In particular, the $\delta = 88$ peak reveals the presence of a O—C—C grouping in the adducts, meaning that addition occurred to the C=O bond, instead of the C=N bond, of phenyl isocyanate. Indeed, a comparable absorption value was found for model compound *(7)*[6], whereas the corresponding C-atom in hydantoins absorb at about $\delta = 60$ ppm[7].

(7) [6]

In further accord with its structure, *(4b)* underwent acid hydrolysis in ethanol at room temperature to yield *(5)* in 82% yield. Its identification was based on IR (1795, 1625 cm^{-1})[5], ^{13}C-NMR [$\delta = 153$ (C-2), 86.4 (C-5); comparable with those in model *(7)*], and also on its expected[8] conversion into the urethane *(6)* upon basic hydrolysis in 20% methanolic potassium hydroxide.

Experimental

Synthesis of *(2a)* to *(2c)*: The ketenimine *(1)* was treated with a five-fold excess of methanesulfonyl azide at room temperature until gas evolution ceased (1 to 2 days). The excess of azide was then distilled off under reduced pressure at room temperature and the crude products were crystallized from CCl_4 [*(2a)* and *(2b)*] or *n*-hexane/ether *(2c)*.

Cycloadditions: A mixture of *(2)* and a ten-fold excess of phenyl isocyanate was stirred at room temperature for 2 to 3 days. Then the excess of isocyanate was removed *in vacuo* and the residue crystallized from the appropriate solvent (see Table 1).

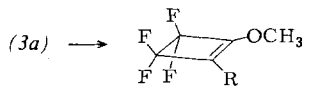
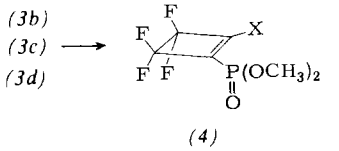
Phosphoranes as Intermediates in the Michaelis-Arbusov Reaction[**]

By *Gert Bauer* and *Gerhard Hägele*[*]



The Michaelis-Arbusov reaction is generally considered to proceed *via* an intermediary phosphonium ion[1]. There is only little evidence quoted in the literature which would indicate that phosphoranes are also possible intermediates[2]. We have now been able to prepare the first cyclobutenyl(fluoro)trimethoxyphosphoranes *(3)* in pure form and in almost quantitative yields from trimethyl phosphite and 1-halo(pentafluoro)-cyclobutenes.

(1) *(2)* *(3)*



(a): X = F; *(b)*: X = Cl; *(c)*: X = Br; *(d)*: X = I

While the pure phosphoranes *(3)* are relatively stable at temperatures around 0 °C, heating or, surprisingly, dissolution in methylene chloride induces autogenic decomposition reactions: *(3a)* does not furnish the expected Michaelis-Arbusov product *(4a)*, but the compounds *(5a)* to *(5g)*.

(5e): R = P(O)$(OCH_3)_2$
(5f): R = P(O)(OCH_3)F
(5g): R = P(O)F_2

Compounds *(3b)* to *(3d)*, on the other hand, afford the desired dimethyl phosphonates *(4)*.

(4)

Secondary reactions[3] of the phosphonic acid esters of type *(4)* prepared here for the first time, show that the P(O)$(OCH_3)_2$ group activates the vinylically bonded halogen.

The structures and purity of compounds *(3)* to *(5)* have been confirmed by elemental analyses and NMR spectra (Table 1), and in the case of *(4)* and *(5)* also by chromatography and mass spectra.

Procedures

(2-Chloro-3,3,4,4-tetrafluorocyclobuten-1-yl)(trimethoxy)-fluorophosphorane *(3b)*:*(2b)* (8.9 g, 0.05 mol) is dissolved in ether under anhydrous nitrogen and treated dropwise with 6.2 g (0.05 mol) *(1)*. After the exothermic reaction has subsided the solution is heated under reflux for 1 h. After removal of volatile components by distillation at 30 °C/0.05 torr there remains 15 g (almost quantitative yield) of *(3b)* as a pure, colorless liquid.

Dimethyl 2-chloro-3,3,4,4-tetrafluorocyclobuten-1-ylphosphonate *(4b)*: 12.1 g (0.04 mol) of *(3b)* is dissolved in 200 ml CH_2Cl_2. After evolution of gas has subsided the solution is allowed to stand for 30 min at room temperature and then heated under reflux for 10 min. Subsequent fractional distillation affords 6.45 g (60%) of *(4b)* as a colorless liquid, b.p. 48 °C/0.02 torr, $n_D^{25} = 1.4022$.

Table 1. NMR data of compounds *(3b)* and *(4b)* [a].

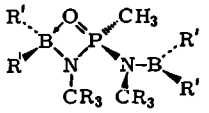
New Pathways to Four-Membered Boron-Nitrogen Heterocycles

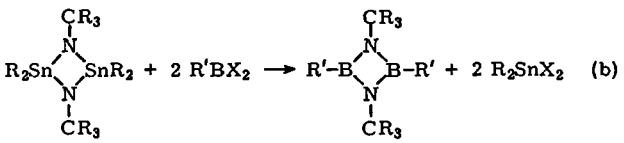
By *Wolfgang Storch, Wolfgang Jackstiess, Heinrich Nöth*, and *Gerhard Winter*[*]



Condensation of boron-nitrogen compounds preferentially affords the borazine ring system[1], ring closure being preceded by linkage of B—N chains[2]. Similar observations are made on formation of heteroborazines[3]. Thermolysis of borylaminoelement compounds of type *(1)*[4] $E[NCH_3—B(CH_3)_2]_2$ *(1)*, with $E=CH_3P, C_6H_5P, CH_3(S)P, (CH_3)_2Si, CH_3B, C_6H_5B$, yields trimethylborane, oligomeric and/or polymeric iminoelement compounds $(ENCH_3)_n$, as well as derivatives of borazine and heteroborazines. In contrast, only the hydrolysis- and oxidation sensitive diazaboretidines *(2)*[5] are obtained if intermolecular condensation is hindered by introduction of the bulky *tert*-butyl group in place of the CH_3 group on the N atoms of *(1)*. Yields and characteristic data of selected compounds are listed in Table 1.

(3) *(2)* (a)

R = CH_3



Starting compounds of type *(3)* are accessible by reaction of the corresponding *N*-lithio derivatives of the diamines $E(NHCR_3)_2$ with R'_2BX (X = Cl, Br, R' = CH_3, C_2H_5; X = R' = F). Their thermal stability is determined by the nature of the element E and the migrational tendency of the substituent R'. Thus compounds *(3)* having $E=(CH_3)_2Si$, CH_3P, or $CH_3(S)P$ and $R'=CH_3$ are unstable at room temperature. Accordingly, their attempted preparation merely affords *(2a)*, *(2b)*, or *(2c)*. When $R'=C_2H_5$, the threshold of BR'_3 elimination rises to 70 to 75 °C. Compound *(3)* with $E=CH_3(O)P$ and $R'=CH_3$ is particularly stable, owing to intramolecular B—O coordination as shown in *(4)*, which has been confirmed by NMR spectroscopy.

(4)

Unlike the reaction of $E[N(Li)C(CH_3)_3]_2$ with R_2BX, that with RBX_2 or BX_3 generally gives difficultly separable mixtures, even when performed at −70 °C. The reason lies in the cleavage of Si—N or P—N bonds by the boron halides, which competes with LiX formation.

Diazadiboretidines[6] cannot be obtained by reaction (a) since the corresponding bis(borylamino)boranes *(3)*, E = RB, have not yet been prepared. On the other hand, reaction of boron halides RBX_2 and BX_3 with the diazadistannetidines

(5) *(6)* (b)

R = CH_3

(5) according to (b) leads, even under mild conditions, to the diazadiboretidines *(6)*, which are extremely sensitive to hydrolysis and oxidation.

This reaction also permitted the first preparation of compounds functionalized at the boron atom (*e.g. (6b)* with R' = Cl). Difficulties encountered in the removal of tin halides also formed in the reaction preclude any increase in yield over 75 %, in spite of quantitative reaction. The reactant *(5)* is obtained by treatment of $(CH_3)_2SnBr_2$ with $LiHNC(CH_3)_3$ in the ratio of 1:2 and subsequent elimination of H_2NCR_3 from the resulting $R_2Sn(NHCR_3)_2$ at 100 °C[7].

Table 1. Physical properties of some compounds of types *(2)* and *(6)*.

	E	R'	Yield [%]	B.p. [°C/torr]	δ(¹¹B) [a]	δ(¹⁴N) [a]	δ(³¹P) [a]
(2a)	$(CH_3)_2Si$	CH_3	75	27/10^{-2}	36.4	−263	—
(2b)	CH_3P	CH_3	64	40–42/10^{-2}	33.7	−271	126.6

Experimental

1,3-Di-*tert*-butyl-2,4-dimethyl-1,3,2λ^5,4-diazaphosphaboretidine 4-oxide *(2f)*: *(3f)* (2.9 g, 10 mmol) is heated to 160 to 170 °C for 5 h in a slow current of N_2. $B(CH_3)_3$ (0.5 g, 90 %) ($\delta^{11}B$: −86.3; ref. [1]: −86.5) condenses in a cold trap at −78 °C. Only *(2f)* can be detected in the residue by NMR spectroscopy. Distillation at 65 °C/0.3 torr afforded *(2f)* (1.8 g, 78 %) as a colorless liquid which forms needle-like crystals (m.p. 53 to 55 °C).

1,3-Di-*tert*-butyl-2,4-dimethyl-1,3,2,4-diazadiboretidine *(6a)*: CH_3BBr_2 (4.1 ml, 43 mmol) in CH_2Cl_2 (10 ml) is slowly added dropwise to a stirred solution of *(5)* (9.5 g, 22 mmol) in CH_2Cl_2 (15 ml) at −65 °C. The reaction mixture is warmed up and heated under reflux for 2 h; all volatiles are then removed *in vacuo* and the residue fractionated by sublimation. $(CH_3)_2SnBr_2$ (12 g, 90 %) sublimed at 30 to 65 °C (oil-bath temperature)/10^{-2} torr, and *(6a)* (2.5 g, 67 %) between 80 and 100 °C/10^{-2} torr. The colorless crystals of *(6a)* are freed from traces of $(CH_3)_2SnBr_2$ by resubliming twice.

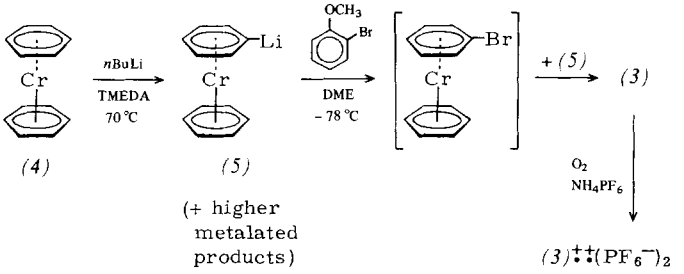
μ-(η-Biphenyl)-bis[(η-benzene)chromium(0)], the Arenechromium Analog of Biferrocene[**]



By *Christoph Elschenbroich* and *Jürgen Heck*[*]

Polynuclear sandwich complexes and their oxidation products are currently being intensively studied from the aspect of interactions in systems containing mixed oxidation states[1]. As opposed to such compounds in the bis(η-cyclopentadienyl)- and (η-cyclopentadienyl)(η-arene) series, *(1)*[2] and *(2)*[3], no corresponding representative of the bis(η-arene)metal type has so far been reported[4].

(3) *(2)* *(1)*

We have now synthesized μ-(η-biphenyl)-bis[(η-benzene)-chromium(0)] *(3)* by reaction of lithiated[5] bis(η-benzene)-chromium with *o*-bromoanisole.

Complex *(3)* [orange-brown, microcrystalline from toluene, m.p. 285—287 °C (dec.)], the composition of which was confirmed analytically as $C_{24}H_{22}Cr_2$, is moderately soluble in benzene and cyclohexane, sparingly soluble in ethers and is sublimable at 170 °C/10^{-4} torr.

Spectroscopic and physical data of *(3)* and *(3)*‡‡.
(3), MS (70 eV): m/e = 414 (4 %; M^+), 284 (21 %; $C_{12}H_{10}CrC_6H_6^+$), 206 (20 %; $C_{12}H_{10}Cr^+$), 154 (77 %; $C_{12}H_{10}^+$), 130 (3 %; $C_6H_5Cr^+$), 78 (100 %; $C_6H_6^+$), 52 (59 %; Cr^+).—Field ionization: 208 (14 %; $[M+2H]^{2+}$), 207 (100 %; M^{2+}), 205 (9 %; $[M-4H]^{2+}$).
(3), ^{1}H-NMR ([D$_8$]toluene): δ = 4.87, 4.32, 4.15 (η-$C_{12}H_{10}$); 4.10 (η-C_6H_6).
(3), Polarography (10^{-4} M in CH_3CN, 0.1 M Et_4NBF_4): $E_{1/2}$ = −0.82, −0.37 V (against Ag/AgCl electrode).
(3)‡‡, ESR (THF, +25 °C): $\langle g \rangle$ = 1.9872; a(11 ^{1}H) = 3.27 G.

Air oxidation of *(3)* leads to formation of the dication *(3)*‡‡, which can be isolated as the bis-hexafluorophosphate *(3)*‡‡$(PF_6^-)_2$. The ESR spectrum of *(3)*‡‡ in solution is characteristic for a diradical, since hyperfine splitting by eleven protons, equivalent within the resolution attained, is observed. An interaction between the two halves of the molecule, to which we assign a *trans* configuration in analogy to the structures of biferrocene[6] and μ-(η-biphenyl)-bis(tricarbonylchromium)[7], manifests itself in the polarogram:

$$(3) \xrightarrow[-e^-]{(E_{1/2})_1 = -0.82\ V} (3)^{\ddagger} \xrightarrow[-e^-]{(E_{1/2})_2 = -0.37\ V} (3)^{\ddagger\ddagger}$$

The separation $\Delta E_{1/2}$ = 0.45 V between the two oxidation waves is similar to that of the biferrocene system ($\Delta E_{1/2}$ = 0.33 V[8]). Consistent with the electron-donor character of the (η-C_6H_6)Cr(η-C_6H_5) moiety, mono-oxidation of *(3)* occurs at a potential more negative than that of (η-C_6H_6)$_2$Cr ($E_{1/2}$ = −0.76 V[9]). The second oxidation step, on the other hand, requires a substantially more positive potential, since the positive charge in *(3)*‡ renders the removal of a further electron more difficult.

Procedure

(4) (4.04 g, 19.4 mmol) is lithiated with *n*-butyllithium (40 mmol, 26.6 ml of a 1.55 M solution in hexane) in the presence of 6.15 ml (40 mmol) *N,N,N',N'*-tetramethylethylenediamine (TMEDA) over 24 h at 70 °C. The red solution of the metalation product obtained on addition of 250 ml dimethoxyethane (DME) is cooled to −78 °C and slowly (6h) treated with a solution of *o*-bromoanisole (2.2 ml, 17.5 mmol)

[**] Metal π-Complexes of Benzene Derivatives, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 6: *Ch. Elschenbroich, F. Gerson*, J. Am. Chem. Soc. 97, 3556 (1975).

in DME (140 ml). After warming to 0°C and hydrolysis with 2 ml H_2O the solution is evaporated to dryness. The residue is taken up in a toluene/methanol/water mixture (1:1:1) and oxidized by passage of a stream of air. The orange-red aqueous solution is covered with a layer of benzene, treated with 25 g each of $Na_2S_2O_4$ and KOH, and stirred for 2 h. For separation of higher substitution products the brown benzene phase is concentrated to 100 ml and chromatographed on Al_2O_3/10 % H_2O (2.5 × 25 cm column) with toluene/THF (9:1). The solvent of the eluate is removed and the residue fractionally sublimed in a temperature gradient (Cu mantle 2 × 45 cm, bath temperature 180°C, 10^{-4} torr). Compound *(3)* is obtained as the lowermost red-brown zone and can be recrystallized from toluene. Yield *ca.* 200 mg (5 %).

Synthesis and Properties of Tris(trimethylsilyl)aluminum[**]

By *Lutz Rösch*[*]

Attempts to synthesize tris(trimethylsilyl)aluminum have so far merely led to isolation of cleavage products (polysilanes and methylaluminum compounds) from whose occurrence the intermediary formation of silylaluminum compounds was postulated[1].

We have now been able to synthesize tris(trimethylsilyl)aluminum *(1)* in *ca.* 90 % yield.

The crystalline product ignites spontaneously in air. Its NMR spectrum shows in addition to the signal of the coordinated tetrahydrofuran (THF) only one sharp signal in the neighborhood of the tetramethylsilane signal. On decomposition with H_2O or D_2O trimethylsilane or trimethyldeuteriosilane, respectively, are formed. The given composition was confirmed by elemental analysis and by the mass spectrum. The latter shows the signal for the molecular ion along with the expected isotopic splitting as well signals for the expected fragmentation products.

$$3\ Hg[Si(CH_3)_3]_2 + 2\ Al \xrightarrow{\text{Pentane/THF}} 2\ Al[Si(CH_3)_3]_3 \cdot THF + 3\ Hg$$

(1)

Compound *(1)* is not very stable thermally; it already begins to decompose at *ca.* 50°C with formation of polysilanes and methylaluminum compounds. Those products would indicate that dimethylsilanediyl is formed in the decomposition.

The vibrational spectra show two bands (both in the IR as well as in the Raman spectrum) in the region where AlSi stretching vibrations are expected to appear. From their intensities these are assigned to the symmetrical and the asymmetrical vibrations [$\nu_{as}AlSi_3$: IR 416 cm^{-1} (m), R 418 cm^{-1} (0); ν_sAlSi_3: IR 360 cm^{-1} (w), R 362 cm^{-1} *(2)*]. It follows that the $AlSi_3$ group has a trigonal pyramidal structure, as would be expected in view of the coordination with THF.

Attempts to prepare base-free tris(trimethylsilyl)aluminum have so far failed. On the other hand, it is possible to replace THF by other donors, *e.g.* phosphanes. Thus, the adduct *(2)* with tris(trimethylsilyl)phosphane can be obtained by suitable modification of the experimental conditions.

$$[(CH_3)_3Si]_3Al \cdot P[Si(CH_3)_3]_3 \quad (2)$$

This compound is also colorless and crystalline, and is formed in *ca.* 90 % yield. It formally possesses three positively polarized trimethylsilyl groups on the phosphorus and three negatively polarized such groups on the aluminum. The difference in character of the silyl groups is confirmed by the vibrational spectrum, which displays two pairs of SiC stretching vibrations. The ^{1}H-NMR spectrum shows a doublet for the trimethylsilyl groups bound to phosphorus $^3J_{HCSiP}$ 5.2 Hz and a singlet for those bound to aluminum in the correct ratio. We conclude from the above findings that no exchange takes place between the silyl groups on the phosphorus and those on the aluminum. Consistent with this conclusion, both trimethylsilane as well as hexamethyldisiloxane are formed on hydrolysis with water.

Procedure

All operations should be carried out under oxygen in the absence of air and moisture.

(1): A solution of sublimed $(Me_3Si)_2Hg$ *(5 g)* in pentane (50 ml) and THF (2 ml) is stirred together with aluminum powder *(5 g)* until disappearance of the yellow-green color can be observed (*ca.* 24 h). The solution is filtered through a glass frit and the readily volatile components removed by evaporation in an oil-pump vacuum at room temperature. The residue is recrystallized twice from a small amount of pentane at −78°C. 2.7 g (90 %) $Al[Si(CH_3)_3]_3 \cdot THF$ is obtained as a white crystalline powder.

(2): A mixture of 2.5 g $(Me_3Si)_2Hg$, 3 g aluminum powder and 1.3 g $(Me_3Si)_3P$ in 50 ml pentane is treated in the same way as described for *(1)*. After *ca.* 3 d, 2.1 g of the phosphane adduct (88 %) *(2)* is obtained as a white crystalline powder, m.p. ≈60°C (dec).

Reaction of Dicyanocobyrinic Heptamethyl Ester with Ascorbic Acid[**]

By *Albert Gossauer, Burghard Grüning, Ludger Ernst, Wulf Becker*, and *William S. Sheldrick*[*]

Dedicated to Professor Robert B. Woodward on the occasion of his 60th birthday

Most reactions of cyanocobalamin (vitamin B_{12}) which proceed with alteration of the oxidation state of the complex-bonded cobalt ion are accompanied by the formation of by-products which are called stable yellow corrinoids[1]. Despite numerous attempts, it has not previously proved possible to elucidate the structure of these compounds. Owing to the biological (metabolism of the vitamin B_{12}-coenzyme in the living cell) and pharmacological interest (incompatibility of cyanocobalamin and vitamin C in mixtures of vitamins), we have investigated the formation of such pigments by treating dicyanocobyrinic heptamethyl ester *(1)*[2] with ascorbic acid. As the former is readily soluble in aprotic solvents, its use as substrate is more advantageous from the preparative and analytical point of view.

Thus, reaction of a solution of *(1)* in methanol-water with ascorbic acid in the presence of oxygen yields a yellow corrinoid *(4)*, whose physical data are summarized in Table 1, and whose structure was established by X-ray analysis[3] (Figure 1).

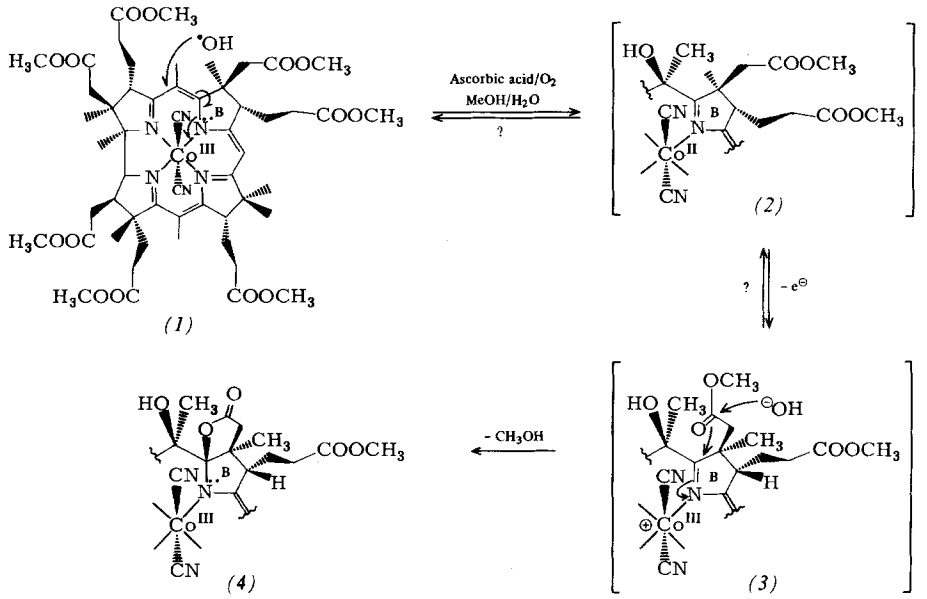

Table 1. Physical data of compound *(4)* [a].

[**] Part 1 in the series on the structure of the stable yellow corrinoids.—This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The hydroxy group at C-5 (O-5) is situated above the plane of the molecule. It may be inferred from the values of the bond lengths and angles in *(4)* that the atoms of the "inner" ring between N-22 and N-24 form a polyazamethine system with four conjugated double bonds. The (C-15)—(C-16) bond is, however, significantly longer than that in related corrins

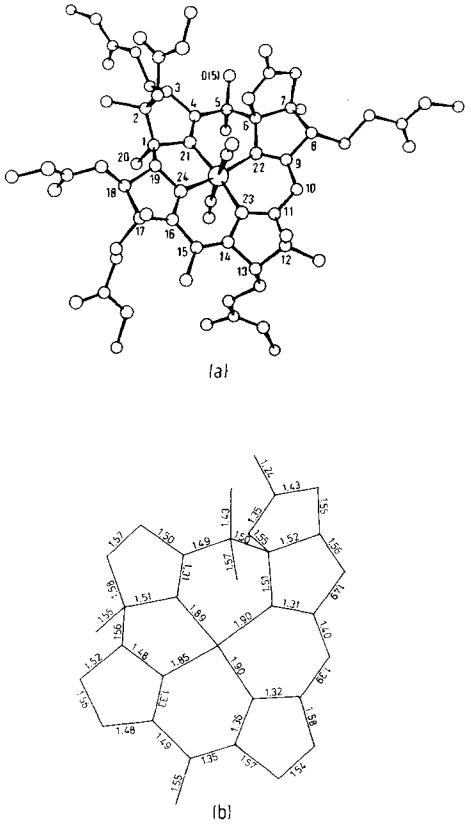

Fig. 1. a) Structure of *(4)* with numbering of the atoms; b) bond lengths (Å) in the chromophore of *(4)*. Standard deviations are: 0.01 Å for Co—N, and 0.02 Å for other bond lengths.

(*e.g.* 1.46 in cobyrinic acid[4]). On the other hand, the (N-21)—(C-4) bond remains as an isolated double bond. Compound *(4)* crystallizes together with one molecule of methanol, which is hydrogen-bonded to the CN ligand situated above the plane of the molecule (O—H···N = 2.67 Å) and with O-5 (O···H—O = 2.66 Å), as well as with one molecule of water which is linked by an O—H···N bridge of 2.82 Å to the CN ligand situated below the plane of the molecule.

In the ^{1}H-NMR spectrum, the transformation of *(1)* into *(4)* is demonstrated in particular by the shift of the (C-5)—CH_3 signal from $\delta = 2.13$ (or 2.08) to $\delta = 1.85$ and by the appearance of a singlet for the OH group. The ^{13}C-NMR spectra display the following characteristic differences[5]: (i) C-4 is deshielded both by interruption of the conjugation at C-5 and the presence of a OH group at this position. Thus, C-4 whose resonance frequency in *(1)* lies in the range $\delta = 171$—176, gives rise to an isolated peak at $\delta = 191.8$ in *(4)*; (ii) a diminution of the number of signals in the characteristic range for C-5 and C-15 ($\delta = 100$—105) from two to one; (iii) a displacement of the C-6 signal from $\delta = 164$ to $\delta = 112.2$ ppm. The lactone ring in *(4)* is readily recognizable in the ^{1}H- and ^{13}C-NMR spectra by the absence of one methoxy signal, as well as in the IR spectrum, by the presence of a characteristic absorption band at $\tilde{\nu}_{max} = 1785\ cm^{-1}$.

The transformation of *(1)* into *(4)* may be rationalized as follows: Addition of a hydroxy free radical at C-5 and concomitant reduction of the complex bonded cobalt ion lead to the formation of a cobalt(II) complex *(2)* which is readily re-oxidized to the corresponding cobalt(III) intermediate *(3)*. Stabilization of the latter takes place by intramolecular attack of the acetic ester residue at C-7 with closure of the lactone ring.

Hydroxylation reactions of organic substrates which are induced by ascorbic acid in aqueous media are well known. Most likely, they involve free radicals and formation of hydrogen peroxide as an intermediate[6]. In fact, *(1)* can be transformed into *(4)*, although in lower yield, by treatment with H_2O_2. The regioselective formation of *(4)* is interesting from a mechanistic point of view. Probably, the closure of a five-membered lactone ring from the acetic ester chain at C-7 is the rate-determining step of the reaction.

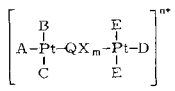
Novel Monobridged Dinuclear Platinum Species

By *E. A. V. Ebsworth, Hugh M. Ferrier, Bernard J. L. Henner, David W. H. Rankin, Francis J. S. Reed, Heather E. Robertson*, and *John D. Whitelock*[*]

In most of the dinuclear platinum complexes known the platinum atoms are linked by *two* bridging ligands. Two ligands capable of forming *singly* linked complexes are dimethyl sulfide and dimethyl telluride[1]. Recently *Manzer* and *Parshall*[2] described the cyanide-linked dinuclear cation

trans-$[PtH(PEt_3)_2]_2CN^+$



in which the lone pairs of electrons on carbon and nitrogen each act as nucleophiles. This is, however, an example of a different type of bridging in which three, rather than two, bonds separate the metal atoms. As far as we are aware no examples of monobridged bis-platinum(IV) species have been reported as yet.

We report here the formation of several monobridged bis-platinum(II) species and one monobridged bis-platinum(IV) cation; we have characterized them by NMR spectroscopy, and in one case, by IR spectroscopy and analysis (see Table 1).

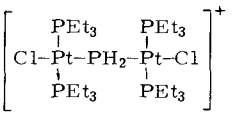
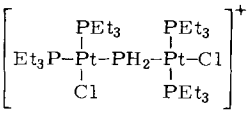
Treatment of two equivalents of *trans*-$[PtClH(PEt_3)_2]$ with one equivalent of trimethylsilylphosphane, Me_3SiPH_2, affords the compound (1)

trans-$[PtH(PEt_3)_2]_2PH_2^+Cl^-$ (1)

and Me_3SiCl. This follows the identification of the same cation as one of the products of the reaction between *trans*-$[PtClH(PEt_3)_2]$ and H_3SiPH_2[3]. Compound (1) has been isolated as yellow crystals which give a conducting solution in dichloromethane. Its NMR parameters, as well as its IR data and C,H elemental analyses, confirm its identity.

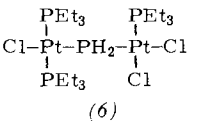


(2)



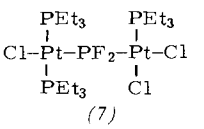
(3)

The PH_2 bridged cation (1) undergoes reactions typical of both a platinum(II) hydride and a phosphonium ion. Thus with HCl either the completely oxidized species (2) is obtained or the partially oxidized complex, containing one four-coordinate and one six-coordinate Pt atom (see (A) in Table 1), depending on the proportion of HCl used. Treatment with potassium *tert*-butoxide, on the other hand, brings about proton abstraction from the bridging group to give the neutral compound (3).



The reaction between $SiMe_3PH_2$ and $PtCl_2(PEt_3)_2$ also yields products containing PH_2 bridges. If *trans*-$[PtCl_2(PEt_3)_2]$ is used, cation (4) is identified as the initial product which then partly rearranges to give the *cis,trans* isomer (5). When *cis*-$[PtCl_2(PEt_3)_2]$ is used as the starting material again both isomers of the PH_2 bridged cation are observed. In addition, in each reaction mixture resonances are found which are assigned to the neutral complex (6).

(4)



(5)

(6)

Analogous products are obtained using *trans*-$[PtBr_2(PEt_3)_2]$ and *trans*-$[PtI_2(PEt_3)_2]$; the symmetrical PH_2 bridged diodide is the least stable with regard to isomerization.

(7)

The monobridged dinuclear complex (7) with a PF_2 bridge was found to be a product of the reaction between PF_2Cl and either *trans*-$[PtClH(PEt_3)_2]$ or a mixture of *trans*-$[PtCl(Me_3Si)(PEt_3)_2]$ and *trans*-$[PtCl_2(PEt_3)_2]$.

An attempt to prepare a dinuclear species with an SH bridge by the action of $SiMe_3SH$ on *trans*-$[PtClH(PEt_3)_2]$ was unsuccessful but this complex was obtained by the treatment of a mixture of *trans*-$[PtClH(PEt_3)_2]$ and $AgBF_4$ with *trans*-$[PtH(SH)(PEt_3)_2]$[4]. This reaction, similar to that used[2] to synthesise *trans*-$[PtH(PEt_3)_2]_2CN^+$, yielded the complex *(8)* and AgCl. The selenium analog was prepared similarly.

trans-$[PtH(PEt_3)_2]_2SH^+BF_4^-$ *(8)*

Coordination Number 3 in Oxozincates: $Rb_8[OZnO_2ZnO_2ZnO_2ZnO]$ and $K_2[Zn_6O_7]$[1]

By *Karl-Rainer Wambach* and *Rudolf Hoppe*[*]

Although the amphoteric nature of $Zn(OH)_2$ has long been known the only hydroxozincate to have been characterized in detail is $Na[Zn(OH)_3]$ having the coordinate number 5[2]. All the oxozincates studied so far exhibit the coordination number 4, whether they are *framework* ($BaZnO_2$[3], $Na_2Zn_2O_3$[4]), *layer* ($SrZnO_2$[5]), *chain* (K_2ZnO_2[6]), or "*soro*" zincates (Na_6ZnO_4[7]). We have now found a case of coordination number 3 while searching for anions of unusual structure[8].

Rb_2ZnO_2, obtained from intimate mixtures of $RbO_{0.48}$ and active ZnO [Rb:Zn = 2.3:1, closed Ni cylinders, 600 °C, 50d] as colorless, transparent, coarse single crystals of almost spherical habit, proves to be extremely sensitive to hydrolysis and, according to rotating crystal, Weissenberg, and precession photographs, is monoclinic with $a = 9.55_8$, $b = 6.33_5$, $c = 15.91$ Å, $\beta = 118.5_7$, $Z = 8$ in $P2_1/c$.

For purposes of structure elucidation 759 symmetry-independent reflections *h0l-h4l* were recorded [Mo-K_α, two-cycle diffractometer, Stoe Stadi 2]. The structure was solved by Patterson syntheses with least squares refinement (cf. Fig. 1); $R = 7.32\%$ for 759 of 759 possible reflections.

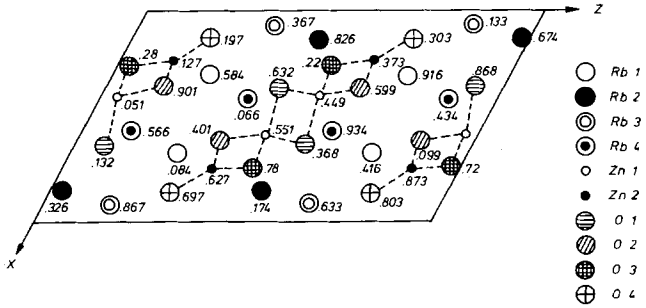

Fig. 1. Unit cell of Rb_2ZnO_2, projection along [010]; heights in fractions of *b*.

Primary structure: Half of the Zn atoms are in a tetrahedral environment of O and the other half in a trigonal-planar environment [interatomic distances: 2.01 Å (4×), and 1.84, 1.91, and 1.97 Å, respectively].

Secondary structure: Surprisingly, "isolated" tetranuclear chains are present $[OZnO_2ZnO_2ZnO_2ZnO]$ which are almost linear with respect to Zn. This is the first *oligooxozincate*.

Tertiary structure: The linear groups are oriented parallel to one another along (120), being slightly inclined (*ca.* 10°) towards (010).

Each $[Zn_4O_8]$ group is surrounded by a total of 14 Rb atoms which link them to 12 other such groups. The coordination number of Rb towards O^{2-} is 4 (Rb-1, Rb-2, Rb-3) or 4+1 (Rb-4).

$K_2Zn_6O_7$, which is likewise very sensitive to hydrolysis, was obtained in studies on the ZnO rich side of the K_2ZnO_2/ZnO phase diagram in the form of coarse, slightly yellow tinted single crystals [K:Zn = 2.2:3, closed Ni cylinders (under argon), 700 °C, 200d]; it forms tetragonal crystals with $a = 10.91_2$, $c = 3.32_5$ Å, $c/a = 0.305$, $Z = 2$ in $P4_2$ nm.

The I_0 data of 354 symmetry-independent reflections were recorded (four-cycle diffractometer, Philips PW 1100), and the structure solved by direct methods (cf. Fig. 2); at the present state of refinement $R = 8.52\%$ for 297 of 354 possible reflections.

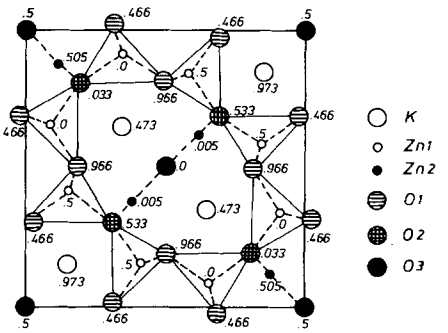

Fig. 2: Unit cell of $K_2Zn_6O_7$, projection along [001]; heights in fractions of *c*.

Primary structure: Two thirds of the Zn atoms are surrounded "tetrahedrally" by four O atoms, and the other third in "trigonal-planar" fashion by three O atoms [interatomic distances: 1.88, 1.96, 2.04, and 2.07 Å, and 1.85, 1.93, and 2.08 Å, respectively].

Secondary structure: The ZnO_4 tetrahedra (with Zn-1) form rings made up of tetrahedra parallel to (001) according to

$$[\{O_{1/2}(ZnO_{3/2})\}_2\{O_{2/2}(ZnO_{2/2})\}_2\{O_{1/2}(ZnO_{3/2})\}_2\{O_{2/2}(ZnO_{2/2})\}_2]$$

the atoms participating in ring formation being enclosed in parentheses when they belong to a tetrahedron; different tetrahedra are indicated by curly brackets. Each ring contains eight Zn atoms. Zn—O—Zn groups (with Zn-2) are incorporated between opposite $\{O_{1/2}(ZnO_{3/2})\}_2$ units of the rings in such a way that the rings are subdivided by two trigonal planar $ZnO_{3/2}$ units.

Tertiary structure: The O atoms not participating in ring formation are responsible for two-dimensional bridging parallel to (001), while along [001] the O atoms involved in ring formation supplement these linkages to form a three-dimensional skeleton.

[*] Prof. Dr. R. Hoppe, Dipl.-Chem. K.-R. Wambach
Institut für Anorganische und Analytische Chemie der Universität
Heinrich-Buff-Ring 58, D-6300 Lahn-Giessen (Germany)

The arrangement and mutual linkage of the rings is of such a kind that each K atom is surrounded by eight O atoms roughly occupying the corners of a cube around K [interatomic distances: 2.79, 2.82, 2.87 (2×), 2.90 (2×), 2.95, 3.05 Å].

If the usual interpretation of the structure of ZnO and the oxozincates mentioned above is adopted, *i.e.* assuming a covalent Zn—O bond (sp^3 hybrid orbitals), it remains inexplicable why Rb_2ZnO_2 should not be isotypic with K_2ZnO_2, both containing $ZnO_{4/2}$ tetrahedral chains analogous to SiS_2. It is even more difficult to understand that a trigonal planar configuration should occur in $K_2Zn_6O_7$ whose composition shows it to be so close to ZnO. However, a plausible interpretation can be formulated if the predominant role is assigned not to the hybridization of the orbitals but to the influence of the counterions (Rb^+ in place of K^+) and account is taken of the composition of the Zn/O part of the zincate.

Hexameric $KN_2Co[P(CH_3)_3]_3$—A Novel Potassium-Dinitrogen Cluster[**]

By *Reinhard Hammer, Hans-Friedrich Klein, Peter Friedrich*, and *Gottfried Huttner*[*]

In the few previously reported bimetal-dinitrogen complexes, in which the N_2-unit is bonded side-on or end-on to a transition metal and an electropositive main group element, ether- or alkoxide-donor ligands are essential components of the molecular structures[1]. We have now synthesized a potassium salt of the dinitrogentris(trimethylphosphane)cobalt anion[2], which crystallizes free of ether from ethereal solutions.

Surprisingly, the dark brown solutions of the olefintris(trimethylphosphane)cobaltates *(1)*[3] in tetrahydrofuran or diethyl ether react spontaneously under 1 bar N_2 in accordance with Eq. (a), whereupon the color changes to bright orange and the dinitrogencobaltate *(2)* is formed in almost quantitative yield.

$$K[(Me_3P)_3Co(olefin)] + N_2 \xrightarrow{20\,^\circ C} K[(Me_3P)_3CoN_2] + olefin \quad (a)$$

(1) *(2)*

olefin = propene, cyclopentene

(2) is also obtained from the magnesium complex *(3)*[1a] according to Eq. (b). On slow cooling of *(2)* in pentane/diethyl ether (4:1) orange-red crystals are formed which are

$$[(Me_3P)_3CoN_2]_2Mg(THF)_4 + 2\,K \xrightarrow{Et_2O} 2\,(2) + Mg + 4\,THF \quad (b)$$

(3)

stable up to 140 °C under 1 bar N_2 but immediately ignite on exposure to air. The structure of compound *(2)* was determined by X-ray crystallography. The monoclinic unit cell (space group C2/c)[4] contains four $[KN_2Co(PMe_3)_3]_6$ molecules. Their fundamental structural unit can be described in simple terms as a double cube made up of six K atoms and six N_2 groups (Fig. 1).

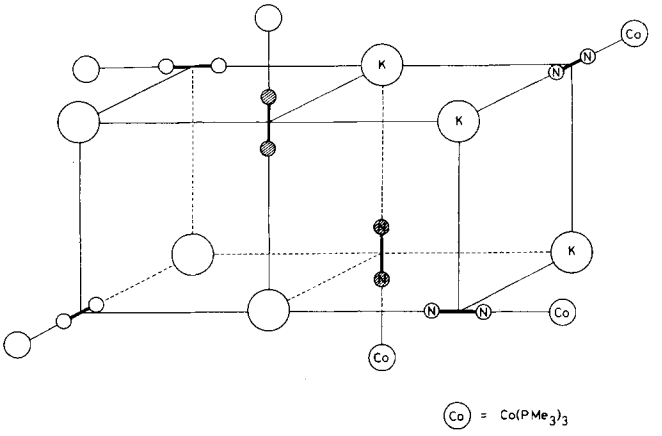

Fig. 1. Crystal structure of *(2)* [for bond lengths see text].

The N_2 dumbbells [*d*(NN): 116 to 118 pm] are orientated pairwise along the three axes of the inversion-symmetric skeleton. In the extension of these axes the N_2 units bear terminal $Co(PMe_3)_3$ groups, which shield the cluster externally [*d*(CoN): 170 to 171 pm]. Each dinitrogen unit is involved in bonding, both along the N—N axis as well as perpendicular to it: along the axis each unit is bonded to a cobalt atom outside the cluster, and to a potassium atom inside the cluster [*d*(KN): 276 to 293 pm]. Perpendicular to the N—N axis, two and three K—N_2 interactions, respectively, are observed: The N_2 groups bound to the corners of the double cube are thus each in contact with two K atoms; the two N_2 groups at the center of the edges (hatched groups in Fig. 1), on the other hand, have three nearest K neighbors in the plane perpendicular to the N—N axis.

It would appear that the observed structure of the complex cluster has no parallel in the structural chemistry of molecules; however, there are striking similarities when compared with solid-state structures (ThC_2, ...)[5]. Accordingly the usual electron counting rules of molecular chemistry cannot be applied in a simple manner. Since there are more bonds than electron pairs in the cluster, the bonding might be best described with models having multicenter electron-deficient bonds.

Procedure

A solution of chlorotris(trimethylphosphane)cobalt[6] (485 mg, 1.50 mmol) in tetrahydrofuran (50 ml) saturated with propene is stirred together with 500 mg clean pieces of potassium for 24 h at 20 °C under argon. The volatile components are removed *in vacuo*, and the ocher-colored residue taken

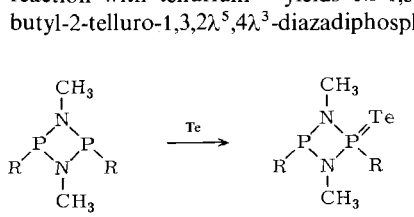
cis-2-Telluro-1,3,2λ⁵,4λ³-diazadiphosphetidine—A Fluxional Redox System

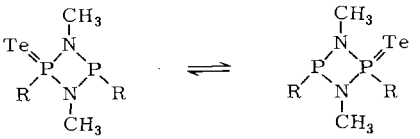


By *Otto J. Scherer* and *Günter Schnabl*[*]

Judicious choice of X and Y and of the other ligands attached to the two P atoms in the phosphorus-chalcogen compounds *(1)* [*e.g.* X=O, S; Y=O, S, $(CH_2)_n$, NR] known in such great variety should permit preparation of a fluxional redox system in which X undergoes reversible intramolecular shift.

(1)

Conditions for the study of such a process are ideally fulfilled by *cis*-1,3,2λ³,4λ³-diazadiphosphetidine *(2)*[1], whose 1:1 reaction with tellurium[2] yields *cis*-1,3-dimethyl-2,4-di-*tert*-butyl-2-telluro-1,3,2λ⁵,4λ³-diazadiphosphetidine *(3)*.



(2) R = $C(CH_3)_3$ *(3)*

Unlike the few known phosphorus-tellurium compounds of similar kind[3], compound *(3)* is exceptionally stable[4]. Temperature dependent ^{1}H- and ^{31}P-NMR studies[5] show *(3)* to have dynamic behavior.

[*] Prof. Dr. O. J. Scherer, Dr. G. Schnabl
Fachbereich Chemie der Universität
Pfaffenbergstrasse 95, D-6750 Kaiserslautern (Germany)

The site-exchange of the tellurium is fast on the NMR time scale[6] but can be perceptibly slowed down by lowering the temperature. Compound *(3)* forms pale yellow crystals (softening 77—83 °C, melting range 83—90 °C) which dissolve very well in ether and methylene chloride, readily in benzene

R = $C(CH_3)_3$

or toluene, and modestly in pentane. Elemental analysis, mass spectrum [16 eV: *m/e* = 362 (50 % M^+), 178 (100)], molecular weight determination (378, cryoscopic in benzene), and a crystal structure analysis[7] confirm the composition and structure of the molecule, which is monomeric both in solution and in the solid state.

Procedure

Tellurium (0.67 g, 5.25 mmol) is added to an ice-cooled (*ca.* 6 °C) stirred solution of *(2)*[1] (1.2 g, 5.12 mmol) in benzene (16 ml). After 3 h at room temperature, excess tellurium is filtered off (G4 frit), the solvent is drawn off and the product *(3)* dried under oil-pump vacuum; yield quantitative.

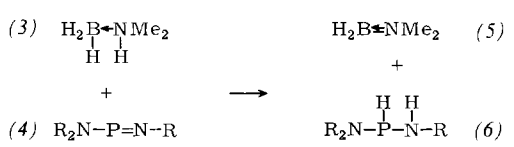
Synthesis of a Secondary Aminophosphane[1]

By *Edgar Niecke* and *Gerhard Ringel*[*]

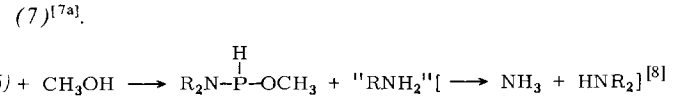


Aminoiminophosphanes, phosphorus-nitrogen compounds containing a strongly polar $3p_\pi(P)—2p_\pi(N)$ bond *(1)*, undergo addition with proton donors to give aminophosphanes *(2a)* and the tautomeric iminophosphoranes *(2b)*[2].

[*] Priv.-Doz. Dr. E. Niecke, Dipl.-Chem. G. Ringel
Anorganisch-chemisches Institut der Universität
Tammannstrasse 4, D-3400 Göttingen (Germany)

(1) *(2a)* *(2b)*

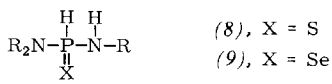
By using dimethylaminoborane *(3)*, which is also an efficient proton- and hydride-transfer agent, we have now been able to synthesize a secondary aminophosphane *(6)*. Compounds of this type were previously considered incapable of existing in the free state[3].



(3) *(4)* *(5)* *(6)*

R = $SiMe_3$

Even at 0°C the reaction of *(3)* with bis(trimethylsilyl)-amino(trimethylsilylimino)phosphane *(4)* leads quantitatively to (dimethylamino)borane *(5)* and *N,N,N'*-tris(trimethylsilyl)-diaminophosphane *(6)*, which can be separated by distillation.



Composition and constitution of *(6)* are confirmed by elemental analysis and by IR, NMR and mass[4] spectra. The IR spectrum (capillary film) shows characteristic absorptions at 3400 m, 3180 m, br[5] (νNH), and 2265 s (νPH) cm^{-1}. The ^{31}P-NMR spectrum (30% in CH_2Cl_2, 85% H_3PO_4 ext.) proves the presence of a secondary phosphane: δ = 33.8 (d), $^1J_{HP}$ = 220 Hz. Finally, the ^1H-NMR spectrum (30% in CH_2Cl_2, TMS int.) exhibits all the four groups of signals expected for *(6)*: 0.12 $^4J_{HP}$ = 0.75 Hz [$N(SiMe_3)_1$]; 0.21, $^4J_{HP}$ = 1.18 Hz [$N(SiMe_3)_2$]; 1.22 [NH]; 6.93 [PH] ($^1J_{HP}$ = 220.2 Hz, $^3J_{HH}$ = 6.65 Hz).

The colorless diaminophosphane is remarkably thermally stable towards α-elimination at the central atom. This surprising observation for secondary phosphanes containing the —PH—X (X = electronegative ligand) skeletal unit can possibly be explained by the steric and electronic stabilizing effect of the trimethylsilyl group in the molecule. *(6)* is practically inert towards hydrolysis[6]; however, in the presence of methanol the RHN—P bond is smoothly cleaved, resulting in formation of the bis(trimethylsilyl)aminomethoxyphosphane *(7)*[7a].

(6) *(7)*

The high reactivity of *(6)* on oxidative attack at the phosphorus atom [in the finely divided state *(6)* is pyrophoric] manifests itself *e.g.* by the addition of sulfur or selenium at room temperature to give the phosphoranes *(8)*[7b] and *(9)*[7c].

(8), X = S
(9), X = Se

The chemical behavior of the secondary aminophosphane is, in addition, determined by the presence of a labile P—H bond in the molecule[9].

Procedure

A solution of *(3)* (5.9 g, 0.1 mol) in ether (50 ml) is added dropwise to an ice-cold solution of *(4)* (30.6 g, 0.11 mol) in ether (100 ml). The stirred reaction mixture is warmed to room temperature and the solvent, together with most of the aminoborane *(5)* that is formed, is removed in an oil-pump vacuum at 30°C. Double fractional distillation of the residue at 60°C/0.5 torr yields 23 g (82%) pure aminophosphane *(6)*.

Reaction of Arsonium Ylides with Carbonyl Compounds—Effect of Substituents at Arsenic[1]

By *Ian Gosney, Terence J. Lillie*, and *Douglas Lloyd*[*]

While phosphonium ylides form alkenes and sulphonium ylides form epoxides as the products of Wittig reactions, arsonium ylides *(1)* can give rise to either alkene or epoxide, or a mixture of both[2] (see Scheme 1).

The product distribution depends upon the nature of R^1 in *(1)*: more stabilized arsonium ylides [R^1 = —C(O)R] always afford alkenes[3], whereas less stabilized ylides [R' = H, CH_3, C_6H_5] produce epoxides almost exclusively[4].

Scheme 1. Reaction of arsonium ylides with carbonyl compounds.

In this communication we show for the first time that the nature of the arsonium group also influences the course of the reaction, but not in a manner that can be correlated with the relative stabilities of the arsonium ylides.

[*] Dr. I. Gosney, Dr. T. J. Lillie

Dr. D. Lloyd
Department of Chemistry, University of St. Andrews
Purdie Building, St. Andrews, Fife KY16 9ST (Scotland)

We have studied the reaction between arsonium salts of type *(3)* and benzaldehyde in tetrahydrofuran solution, using *n*-butyllithium to generate the ylide. The results are summarized in Table 1 and clearly show that electron-donating substituents at the arsenic atom promote the formation of alkene [path (a) in Scheme 1]. At one extreme, reaction of *(3j)* gives a notable yield of stilbene almost to the exclusion of stilbene oxide; at the other, reaction of *(3a)* yields predominantly stilbene oxide.

Table 1. Reaction products of compounds *(3a)* to *(3j)* with benzaldehyde and *n*-butyllithium in tetrahydrofuran.

	$X_2YAs^{\oplus}-CH_2Ph\ \ Br^{\ominus}$ [a] *(3)*		Yields [b]	
	X	Y	*cis*+*trans*-Stilbene oxide [c] [%]	*cis*+*trans*-Stilbene [c] [%]
(a)	C_6H_5	C_6H_5	79	7
(b)	p-$CH_3OC_6H_4$	p-$CH_3OC_6H_4$	66	10
(c)	C_6H_5	p-$(CH_3)_2NC_6H_4$	65	11
(d)	p-$(CH_3)_2NC_6H_4$	C_6H_5	57	15
(e)	p-$(CH_3)_2NC_6H_4$	p-$CH_3OC_6H_4$	33	12
(f)	p-$(CH_3)_2NC_6H_4$	p-$(CH_3)_2NC_6H_4$	24	25
(g)	C_6H_5	C_2H_5	47	27
(h)	C_2H_5	C_6H_5	13	62
(i)	n-C_3H_7	C_6H_5	18	70
(j)	C_2H_5	C_2H_5	1	87

[a] All new compounds gave correct elemental analyses and spectral data.
[b] Determined by gas chromatography.
[c] Samples were almost entirely *trans*; only small amounts ($\approx 1\,\%$) of the *cis*-isomer were detected.

From these data it follows that the course of the reaction for arsonium ylides is related not solely to the nature of the carbanion moiety, as hitherto assumed, but also to the electronic character of the substituents at arsenic, although at present the relative importance of the two effects is not assessable.

We assume that heterolytic cleavage of the As—C bond in *(2)* occurs in an opposite sense depending upon whether an alkene or an epoxide is formed; in the former case the electrons are displaced towards carbon and in the latter case towards the arsenic atom. Thus electron-donating substituents at arsenic should increase the ratio of alkene to epoxide. The results compiled in Table 1 support this view.

General procedure

To a slurry of *(3)* (1.0 mmol) in anhydrous tetrahydrofuran (20 ml) is added 0.70 ml of a 1.6 M solution of *n*-butyllithium in *n*-hexane. The mixture is stirred at room temperature (N_2 atmosphere) and the resulting deeply colored solution is treated with benzaldehyde (1.0 mmol); a rapid decolorization takes place[5]. After 24 h the mixture is diluted to 50 ml with chloroform and the solution is analyzed by GC (2 % 20 M carbowax column; 180 °C) using α-methylstilbene as reference standard. The products are isolated by concentration *in vacuo* and chromatography over silica.

Regiospecific Synthesis of Mono- and Polyiodo Derivatives of Benzene

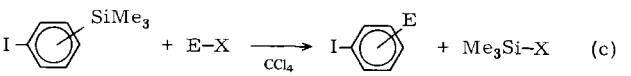
By *Guy Félix, Jacques Dunoguès, Françoise Pisciotti*, and *Raymond Calas*[*]

The method most commonly employed for the synthesis of aromatic iodo compounds consists in the substitution of a nitro group by an iodine atom *via* amino and diazo compounds as intermediates. This method is not always convenient, even for monoiodination; on polyiodination, problems arise because many steps are involved starting from materials which are often difficult to prepare. On the other hand, it is known that the Me_3Si group in aryl(trimethyl)silanes can be replaced by iodine on reaction with iodine[1] or iodine chloride[2], and we have recently reported on the synthesis of polysilylated aromatic compounds[3].

We describe here the regiospecific formation of mono- and polyiodo derivatives of benzene from the corresponding commercially available chloro compounds *via* the trimethylsilyl derivatives as intermediates. These syntheses proceed rapidly, afford high yields of desired product, and are easy to carry out.

Three reagents were employed:
I_2 (procedure A)
ICl (procedure B)
IBr (procedure C)

The reactions proceed according to equations (a) and (b). Results are summarized in Table 1.



(a)

$$C_6H_{6-n}(SiMe_3)_n + n\ I{-}X \longrightarrow C_6H_{6-n}I_n + n\ Me_3SiX \qquad (b)$$

The yields are 80 % or more, regardless of whether the trimethylsilyl groups are partially or totally replaced by iodine. Procedure B affords almost quantitative yields. The substituents have little if any effect on the orientation of the reaction. For example, *o*-, *m*-, and *p*-iodotoluene are obtained in comparable yields, and the yields of *o*- and *p*-iodobenzenesulfonic acids are only slightly lower than the yield of the *meta* derivative.

Mixed dihalobenzenes can also be easily synthesized, even if the halogen atom is in the *meta* position.

The last two examples in Table 1 show that the Me_3Si group in iodo(trimethylsilyl)benzenes can also be replaced by electrophiles in accordance with equation (c).

[a] Only the substituents for which the product differs from the starting material are given.

Experimental

Arylsilanes are obtained in high yields from chloroarenes by means of a Grignard reaction in tetrahydrofuran as solvent (all the monosilyl compounds were obtained in this way). Polysilyl derivatives are obtained from chloroarenes using $Me_3SiCl/Mg/HMPT$[3] as silylating agent. 1,4-Bis(trimethylsilyl)benzene can be prepared directly from benzene[4]. In reaction (c) we used $ClSO_3SiMe_3$[5] as sulfonating agent under the conditions previously described in the literature[3a, b]. For the bromination reaction according to equation (c) we also employed a procedure already described in the literature[6].

Synthesis of *m*-iodotoluene (Procedure A): A mixture of trimethyl-(*m*-tolyl)silane (16.4 g, 0.1 mol), iodine (25.4 g, 0.1 mol), and aluminum (100 mg) is heated under reflux for 4 hours. After cooling, the reaction mixture is taken up in 100 ml ether and washed, firstly with 50 ml of a 0.3 M aqueous solution of sodium thiosulfate and then with distilled water. After drying over Na_2SO_4 the *m*-iodotoluene is isolated by distillation. Yield: 19.6 g (90 %), b.p. 95 to 97 °C/25 torr.

Synthesis of 1,2,4,5-tetraiodobenzene (Procedure B): ICl (3.25 g, 2×10^{-2} mol) is added slowly to a solution of 1,2,4,5-tetrakis(trimethylsilyl)benzene[3b] (1.85 g, 0.5×10^{-2} mol) in CCl_4 (50 ml). The mixture is allowed to stand at room temperature for ½ h and then heated under reflux for 1 h. After cooling, 1,2,4,5-tetraiodobenzene is separated by filtration and recrystallized from benzene as white needles. Yield: 2.7 g (95 %), m.p. 253 °C.

Synthesis of *m*-iodophenyl(trimethyl)silane: A solution of IBr (11.4 g, 0.055 mol) in CCl_4 (30 ml) is added dropwise at 0 °C to a solution of *m*-bis(trimethylsilyl)benzene (11.1 g, 0.05 mol) in CCl_4 (80 ml) and the mixture allowed to stand for 1 to 2 h without cooling. After removal of $BrSiMe_3$ and CCl_4 by distillation the residue is taken up in ether and treated as in Procedure A. Yield: 11.5 g (85 %).

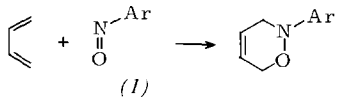
This column contains abstracts of selected progress reports and review articles. Orders for photocopies of publications reviewed should be directed to specialist libraries offering such services, *e.g.* British Library Lending Division, Boston Spa, Wetherby, Yorkshire LS23 7BQ, England. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

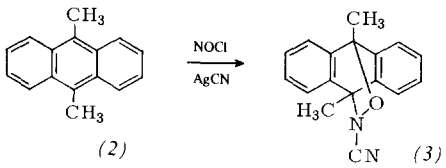
Phenethylamines and tryptamines as well as related compounds of plant origin are reviewed by *T. A. Smith*. These compounds can be used in chemotaxonomic studies, and also command practical interest since many of them exert far-reaching physiological effects on higher animals. [Phenethylamine and Related Compounds in Plants. Phytochemistry *16*, 9—18 (1977); 183 references. Tryptamine and Related Compounds in Plants. *Ibid. 16*, 171—175 (1977); 119 references]

[Rd 951 IE—R]



Phosphates in ceramics form the subject of a comprehensive survey by *A. E. R. Westman*. Following a general description of the structure of phosphates and phosphorus acids and oxides, the author discusses the four most important two-component and three-component systems, namely Na_2O—P_2O_5, CaO—P_2O_5, K_2O—Na_2O—P_2O_5, and CaO—Al_2O_3—P_2O_5, including notably the composition of the liquid phases. Technical glasses and their applications are discussed extensively. Further sections deal with refractories, porcelain, ceramic-metal systems, cements, and similar substances. [Phosphate Ceramics. Top. Phosphorus Chem. *9*, 231—405 (1977); 963 references]

[Rd 952—L IE]

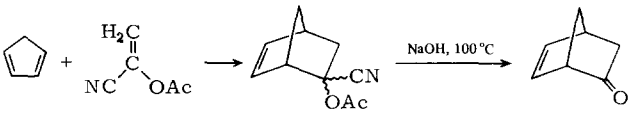


Micelles of ionic detergents in aqueous solutions are reviewed in a paper by *L. R. Fisher* and *D. G. Oakenfull*. In fairly concentrated solutions, 10—100 detergent molecules aggregate into micelles, shaped like oblate spheres, with the nonpolar hydrocarbon chains pointing inward and the polar groups outward. The "bound" gegenions also lie in this layer, while the "nonbound" ones are further off. The detergent molecules and their gegenions are in dynamic equilibrium with their environment; the mean residence time of a molecule in a micelle is 10^{-5} s. [Micelles in Aqueous Solution. Chem. Soc. Rev. *1*, 25—42 (1977); 89 references]

[Rd 954—F IE]

Electrophilic *C*-nitroso compounds *(1)* are the subject of a survey (Tilden lecture) by *G. W. Kirby*. NO compounds are more reactive than the corresponding NO_2 compounds. Their dimerization, rearrangement to oximes, and Diels-Alder reaction with dienes have long been known. Nitrosyl cyanide, a particularly strongly electrophilic compound, can be captured with *(2)* relatively safely and then liberated from the

(1)



(2) *(3)*

(3) ⇌ *(2)* + NC–N=O

adduct *(3)*. *C*-Nitrosocarbonyl compounds can be prepared from hydroxamic acids by oxidation, captured with *(2)*, and liberated from *(3)*, where —CN is replaced by —COR. [Electrophilic *C*-Nitroso-compounds. Chem. Soc. Rev. *6*, 1—24 (1977); 45 references]

[Rd 953—F IE]

Reactions with ketene synthons are surveyed by *S. Ranganathan*, *D. Ranganathan*, and *A. K. Mehrotra*. Ketene synthons permit reactions which are not feasible with ketene itself. For instance, while norbornenones are not accessible by [4+2]-addition of ketene to cyclopentadienes, use of the ketene synthons of type $H_2C{=}CX^1X^2$ permits the synthesis of intermediates $>CX^1X^2$, *e.g. (2)*, which can be transformed into carbonyl compounds such as *(3)*. Suitable compounds are the esters

(1) *(2)* *(3)*

(1) and α-chloroacrylonitrile whose [1+4]-adducts can be converted into ketones under mild conditions. α-Chloroacryloyl chloride likewise affords norbornenone-like ring systems (chloride → azide → isocyanate → amine → imine → ketone). This reaction sequence is particularly suitable for dealing with 5-substituted cyclopentadienes in prostaglandin syntheses. Nitroethane is an interesting ketene synthon which can be used above all for the reaction of highly sensitive cyclopentadienes to give norbornenones (reaction at −100°C; cleavage of the nitronate with $TiCl_3$ at pH 5—6 to form the ketones). Adducts of acrylic acid can also be transformed *via* several steps into the ketones. The ideal ketene synthon—very easy addition to dienes and extremely facile transformation of the adducts into the final products—has yet to be discovered. [Ketene Equivalents. Synthesis *1977*, 289—296; 28 references]

Methods of Seawater Analysis. By *K. Grasshoff*. With Contributions by *T. Almgreen, R. Dawson, M. Ehrhardt, S. H. Fonselius, B. Josefsson, F. Koroleff*, and *K. Kremling*. Verlag Chemie, Weinheim—New York 1976. 1st edit., xv, 324 pp., 58 figs., 29 tables, bound, DM 98.—.

Methods for the determination of elements and chemical compounds in seawater have developed very rapidly in recent years. Thus, routine procedures can now be used for quantitative analysis of trace metals and many organic compounds for which not a single reliable value was available ten years ago. The analytical methods for "classical" components of marine chemistry (*e.g.* for silicate, nitrate, and ammonia) have meanwhile also been improved. A powerful impetus toward this development came from the need to monitor changes in the environment—and thus also in the sea—including those due to human activity.

In view of this development, the books hitherto available on analysis of seawater are in part outdated. The best of them, "A Practical Handbook of Seawater Analysis" by *J. D. H. Strickland* and *T. R. Parsons*, is after all nearly ten years old. It is therefore very welcome that *Grasshoff* and his colleagues have taken the trouble to provide a largely new volume.

In this book methods are described for the determination of "dissolved" materials (particle size $<0.45\,\mu m$) as well as of particulate carbon and nitrogen. The authors do not restrict themselves to giving precise analytical directions, but also tell the reader about the occurrence and concentration range of the materials in seawater and about the physical and chemical background of the analytical process. After two general sections on the collection, filtration, and storage of seawater samples, methods are described for the determination of the following substances and parameters: the salinity, calcium, strontium, magnesium, chloride, sulfate, bromide, fluoride, boric acid, oxygen, hydrogen sulfide, thiosulfate, pH, alkalinity, total carbon dioxide, phosphate, ammonia, nitrite, urea, silicate, arsenate, and organically bound nitrogen. Only slight changes in these procedures are likely to be made in the near future, but the situation is different for the other materials and groups treated in the book, namely the trace metals zinc and cadmium, particulate organic carbon and nitrogen, polyphenolic compounds, aromatic and chlorinated hydrocarbons, and carbohydrates. In the case of these materials the development of analytical methods is at present so rapid that the procedures described do not all represent current practice. For example, there is no mention of atomic absorption spectrophotometry, by which many heavy metals can be very elegantly determined; similarly, the methods published recently for the analysis of chlorinated hydrocarbons in seawater are not yet taken into account.

The nutrient salts dissolved in seawater are now determined automatically in many seaborne and land laboratories, and in view of their importance these methods are described in a special section.

"Methods of Seawater Analysis" will be of great value to marine chemists, practising analysts, and many marine biologists. However, since it does not include all the substances and groups occurring in seawater, *Strickland* and *Parson*'s "Handbook" is still essential. To keep up to date with the analytical procedures the *Grasshoff* book should be revised and supplemented a few years hence.

Günter Weichart [NB 377 IE]

Principles of Pyrometallurgy. By *C. B. Alcock*. Academic Press, London—New York 1976. 1st edit., xiii, 348 pp., various figs. and tables, bound, 8.50.

This monograph is an excellent presentation of the physicochemical principles of high-temperature isolation of metals.

The book is divided into three chapters describing very clearly the experimental data, theoretical principles, and models, which can be read independently of one another.

The thermodynamics and kinetics of roasting and sintering reactions as preliminaries to isolation of the metals are treated in the first chapter. The second chapter contains the most important principles of extractive metallurgy and isolation of the metals from sulfides, oxides, and halides. Reduction of iron ores is briefly described, but not the direct reduction process. Refining processes are given in the third chapter, namely zone melting, high-temperature distillation, remelting of metals in slags (including the electro-slag-remelting process), vacuum degassing, chemical transport, and electrolytic methods.

Owing to the number and variety of the processes described it cannot be expected that the reader will receive a complete picture in the mere 340 pages of this book. An extensive bibliography (including monographs) is therefore given at the end of each section; the original literature cited extends up to 1972.

In many respects this book and *F. D. Richardson*'s two-volume "Physical Chemistry of Melts in Metallurgy", a work published in 1974 by Academic Press, complement each other. Unlike *Richardson*, however, *Alcock* cites also the most important German publications. The book is addressed to advanced students in the fields of inorganic (industrial) chemistry, applied physical chemistry, and metallurgy. In addition, it provides a good review for engineers and chemists working in industry. As there are few modern books dealing with the economically important field of raw-material treatment, *Alcock*'s work can be recommended.

Advances in Phase-Transfer Catalysis[1]

New synthetic methods (20)

By Eckehard V. Dehmlow[*]

Phase-transfer catalysis (PTC) has grown into a versatile preparative method in the last few years. The most notable new developments include the use of crown ethers as phase-transfer catalysts and the introduction of solid-liquid PTC. Some representative examples have been selected from the large number of new PTC reactions and some of them are summarized in tables.

1. Introduction

Three years ago we published in Angewandte Chemie an initial survey of a new method in preparative organic chemistry, in which substances located partly in an aqueous and partly in an organic medium are made to react in the presence of onium salt catalysts[2]. This phase-transfer catalysis (PTC) often has considerable advantages over conventional methods, namely:

saving on expensive anhydrous aprotic solvents,
shorter reaction time and/or lower reaction temperature,
use of aqueous sodium hydroxide instead of alkali metal alkoxides,
simpler workup.

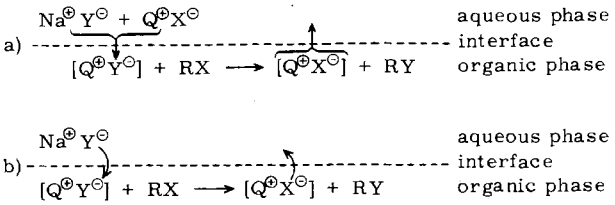
The PTC method sometimes offers further advantages, such as:

the discovery of reactions that do not proceed otherwise,
modification of the selectivity and the product ratio (*e.g.* *O*-/*C*-alkylation), *i.e.* increased yields by suppression of side reactions.

The field has been developing very fast, as can be seen from the fact that some 400 new publications have appeared since 1974, and this circumstance, combined with the good response to our previous review[2], motivated the publication of the present article. The aim has been not to give a complete literature survey, but to describe new research on the mechanisms and to discuss the practical applications of PTC, with special reference to:

assessment of the practicability of the reactions on the basis of tabulated literature data on the extraction of anions and cations,
use of crown ethers as catalysts instead of onium salts,
the extension of PTC to solid-liquid reactions,
reaction mechanism in the presence of concentrated sodium hydroxide solution,
development of PTC versions of new types of reactions.

The concept of phase-transfer catalysis has meanwhile gained ground in the literature: three PTC-based preparations have been included in "Organic Syntheses", namely the alkylation of phenylacetonitriles[3], a PTC version of the carbylamine reaction[4], and the addition of alkylphenylacetonitriles to alkynes[5], so that PTC can now be regarded as an established method. The various fields have been surveyed not only in ref. [2], but also by *Mąkosza*[6] and in a brochure by *Brändström*[7a], which gives a thorough physical and mathematical derivation of the theory of ion-pair extraction together with a description of some preparative applications.



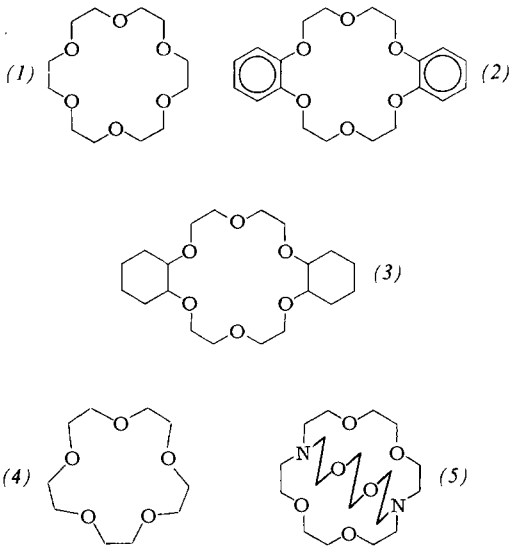
2. Fundamentals and Mechanisms

2.1. Mechanism of the Displacement Reactions

The assumed mechanism of PTC in the case of nucleophilic substitutions in particular[8] is shown in Scheme 1a, in which $Q^{\oplus}$ is an onium salt cation and $Y^{\ominus}$ is assumed to be more

[*] Prof. Dr. E. V. Dehmlow
Institut für Organische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

lipophilic than $X^{\ominus}$. The catalyst cation $Q^{\oplus}$ migrates with the anion $Y^{\ominus}$ from the aqueous phase into the organic phase, where the weakly solvated ion pair formed undergoes very fast further reaction, after which $Q^{\oplus}$ returns to the aqueous phase with the anion $X^{\ominus}$. (The ion pairs are shown in square brackets throughout.)



Scheme 1. PTC in nucleophilic substitutions (ion pairs in square brackets).

However, highly lipophilic catalyst cations are generally used, so that $Q^{\oplus}$ does not exist in the aqueous phase in any appreciable concentration. *Brändström*[7b] and more recently *Landini et al.*[174] have shown that $Q^{\oplus}$ stays in the organic phase and only the anions are exchanged across the interface, so that the simpler mechanism shown in Scheme 1 b applies. Apart from this slight variation, the mechanism of the displacement reactions discussed in ref. [2] is supported by subsequent investigations[9, 10]. In particular, there is a certain correlation between the rate constant of the PTC reaction and the ability of the catalyst to extract the anion into the organic phase[9]. However "correlation" here does not mean "proportionality", since other factors, such as anion solvation and anion-cation interactions in the ion pair dissolved in the organic phase, are also involved. Thus, it can be shown that a specific amount of water of solvation migrates into the organic medium with the anion and there influences the relative reaction rates (*e.g.* Cl:Br:I) and the absolute reaction rate[10]. For example, 3.4, 2.1, and 1.1 molecules of water are extracted per $Cl^{\ominus}$, $Br^{\ominus}$, and $I^{\ominus}$ ion respectively in the case of a water-chlorobenzene system with $Q^{\oplus} = C_{16}H_{33}P^{\oplus}(C_4H_9)_3$[10]. The question may arise whether the ion pair $[Q^{\oplus}Y^{\ominus}]$ or only the "free" anion $Y^{\ominus}$ is involved in the nucleophilic substitution (or both). The concentration of $Y^{\ominus}$ in the organic phase is determined by the dissociation equilibrium $[Q^{\oplus}Y^{\ominus}] \rightleftarrows Q^{\oplus} + Y^{\ominus}$. Kinetic measurements carried out by *Brändström* on several examples have shown that, in solvents of relatively low polarity (such as CH_2Cl_2, $CHCl_3$, and benzene), the ion pair is the dominant nucleophilic species[11, 12]. In solvents of higher dielectric constant, such as acetone, the dissociated anion presumably also plays a part.

2.2. Crown Ether PTC

Crown ethers can solubilize organic and inorganic alkali metal salts even in nonpolar organic solvents by providing the cation with an "organic mask" by complex-formation[13]. It follows logically from the mechanism of PTC shown above that $Q^{\oplus}$ need not necessarily be an onium salt but can also be an alkali metal ion complexed with a crown ether. Crown ethers were introduced into PTC by several teams in the years 1972—1974[14–19], and since then they have often been recommended, particularly for solid-liquid PTC reactions (see Section 2.3). However, their use outside the laboratory is not very attractive, since they are 50—100 times as expensive as the most inexpensive commercial quaternary ammonium salt Aliquat 336® = Adogen 464®.

So far nearly always only [18]crown-6 *(1)*, dibenzo[18]-crown-6 *(2)* and dicyclohexyl[18]crown-6 *(3)* have been used, irrespective of whether the other component is a potassium or a sodium salt. However, compounds *(1)*—*(3)* are known to bind potassium better than sodium, and stable sodium complexes are formed instead by the smaller crown ether [15]crown-5 *(4)*, which has so far been neglected. Detailed descriptions are now available for the laboratory preparation of these four crown ethers [cf. [20, 21] for *(1)*, [22] for *(2)* and *(3)*, and [20] for *(4)*], and an even simpler method has recently been reported for the direct preparation of *(1)* and *(4)* from ethylene oxide[68]. Other compounds sometimes suggested for use as ligands include differently substituted crown ethers[23], *Lehn*'s cryptates[24] [particularly [2.2.2], with the trade-name Kryptofix 222® (Merck) and with the formula *(5)*], and the so-called "polypodes"[25] and "octopus molecules"[26]. However, these have not gained wider application, since they are relatively difficult to prepare and are commercially unavailable or have only recently become available.

2.3. Solid-Liquid PTC

The high rate of PTC reactions in comparison with conventional reactions in hydroxylic solvents is due to the presence of weakly solvated and therefore highly reactive ion pairs in organic media. As mentioned in Section 2.1, a certain amount of water of hydration is co-extracted with the ion pair migrating from the aqueous to the organic phase. This can sometimes interfere, and sometimes it can fully suppress a reaction or direct it to a different path. It was therefore reasonable to suggest that the use of troublesome water should be abandoned, and that PTC should be carried out with solid salts. However, this raised new problems: dissolution on the crystal surface and deposition of a new salt, stirring speed, particle size of the salt, and possibly also deposition of the new salt on the salt to be dissolved acquire major importance. A further difficulty occurs when crown ether com-

plexes can be prepared only in homogeneous solutions in hydroxylic solvents, from which the undesirable solvent must then be displaced with the aid of a nonpolar one. This undoubtedly leaves a more or less substantial solvation envelope on the ion pair. In spite of these apprehensions, however, in many cases solid-liquid PTC is free from complications. Crown ethers are often used as catalysts, but quaternary ammonium salts generally also seem suitable. Recently it has been found that open-chain polyethers, diamines, and polyamines can also be used to catalyze the reaction of solid alkali metal salts with alkylating agents[32, 33].

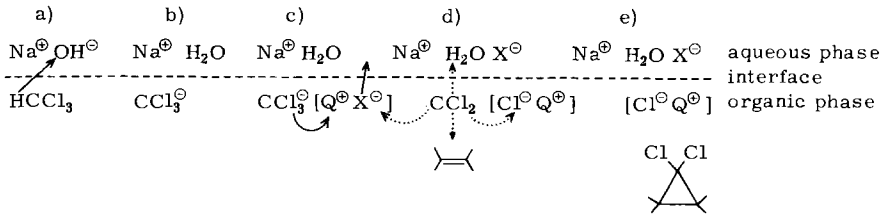
The changed character of some well-known anions under these conditions is particularly remarkable. Thus, fluoride[18] and acetate[27] ions become strong nucleophiles and bases, and a slow substitution sometimes occurs even at room temperature (for the experimental data see Table 6). We have investigated a case in which liquid-liquid PTC fails while solid-liquid PTC is successful[28, 29]: sodium trichloro- or tribromoacetate is quite stable when dissolved in water and boiled with the phase-transfer catalyst, chloroform, and an olefin although $Q^{\oplus}{}^{\ominus}O_2CCX_3$ is extracted into the chloroform. With finely powdered solid sodium trihaloacetate decomposition and dihalocarbene addition occur slowly at room temperature and fast at 50—80°C in the presence of a phase-transfer catalyst.

$$[Q^{\oplus}{}^{\ominus}O_2CCX_3]_{org} \rightarrow [Q^{\oplus}X^{\ominus}] + CO_2 + :CX_2 \rightarrow \text{addition products}$$

In the conventional version of this reaction expensive anhydrous dimethoxyethane is used as the solvent. The sodium trihaloacetate does not react in this medium at room temperature, only at about 80°C and above. Solid-liquid PTC thus enables us to achieve something here that otherwise could not be done so simply, namely to obtain dihalocarbenes in a neutral solution at relatively low temperatures.

The changed reactivity observed in solid-liquid PTC has made some authors call these processes "reactions of naked anions", a striking though inaccurate phrase. It is true that in polar solvents, such as acetonitrile and acetone, partial dissociations of ion pairs does occur, particularly when the cation is a crown ether complex. On the other hand, however, as was tested in the reaction between *e.g.* benzyl chloride and solid potassium acetate in acetonitrile, the "anion activation" (relative reaction rate) depends to a large extent on the nature of the complexing agent used. Furthermore, the anion activation is not connected in a simple way with the extent to which the crown ether solubilizes potassium acetate[32]. The conclusion is that anion-cation interactions must play a part. In substitution reactions of benzyl tosylate with [18]crown-6 complexes in homogeneous acetonitrile solution, *Liotta et al.* observed extensive leveling out of nucleophilicity: $I^{\ominus}$, $Br^{\ominus}$, $Cl^{\ominus}$, and $F^{\ominus}$ ions gave practically the same reaction rate, while acetate and azide ions remarkably gave a reaction 7—10 times as fast[34]. Whereas the sequence of nucleophilicities in acetonitrile was similar to that found in the gaseous phase, the absolute reaction rates in acetonitrile were about 10^{11} times lower[34]. It must therefore be assumed that solvation persists in non-polar solvent solution, but is less pronounced and is very similar for different anions or ion pairs (cf. [30, 31]).

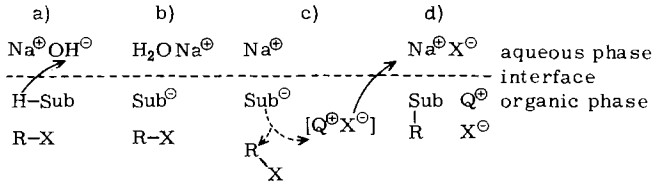
2.4. Mechanism of PTC in the Presence of Aqueous Alkali



Some of the PTC reactions of the greatest interest for preparative purposes are carried out in the presence of concentrated aqueous alkalis—reactions such as the alkylation of C—H acidic compounds with a pK_a value down to 22—24, carbene synthesis, hydrolysis, H/D exchange and isomerizations, eliminations, and Wittig and Horner reactions.

At first sight, the mechanisms of these reactions have little in common. The C—H acidic compounds exhibit a gradual transition: relatively strong acids of the type of acetylacetone dissolve in sodium hydroxide and can be extracted into the organic medium by the catalyst as ion pairs, while weaker C—H acids are present in the organic medium partly as ion pairs and partly as the unchanged neutral molecules, and very weak acids such as fluorene are presumably almost entirely un-ionized.

Yet all three types can be alkylated by PTC. In the first two cases the mechanism is as shown in Scheme 1b, with the rider that $Y^{\ominus}$ is the conjugated base of the substrate; in the case of the alkylation of very weak C—H acids (and in the other reactions mentioned above) it was assumed before that the quaternary ammonium hydroxide is extracted and then reacts further in the organic medium[2]. These quaternary ammonium hydroxides are known to be soluble to some extent in nonpolar media. For example, Triton B (benzyltrimethylammonium hydroxide) is marketed as a methanolic solution. Displacement by a solvent like toluene is in principle possible, but only a slight solubility remains after the thorough removal of methanol. The solubility can be increased by using more lipophilic cations (see Section 3.2). However, further investigations have now shown that the phase transfer of $OH^{\ominus}$ ions frequently does not explain the catalytic reaction, for as soon as a more lipophilic anion is present—and it is formed necessarily from the alkylating agent—it is extracted preferentially into the organic medium (cf. Table 5). In fact, when tetrabutylammonium chloride in benzene is shaken with concentrated caustic soda, titration shows that only 0.5—2% of it is in the OH form and about 50% of it remains in the chloride form in the organic phase; the rest is in the aqueous phase[*]. The situation is of course different when the organic medium is partially miscible with water or rather aqueous caustic soda (*e.g.* THF or higher alcohols), for then a large amount of the $OH^{\ominus}$ form is titratable in the organic layer.

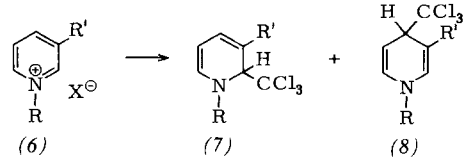


Catalysis by micellar[35] or reverse micellar systems[35, 36] similarly cannot be decisive for the course of the reaction in the presence of concentrated alkalis. Typical micelle-forming compounds (surfactants) have rod-shaped molecules with a polar head and a long lipophilic tail, whereas typical PTC compounds have a symmetrical structure. Besides, the fact that the ammonium salt is present in the organic phase and the latter contains practically no titratable alkalinity indicates that the onium salt does not bring about either partial dissolution of the organic substances in water (micellar phase) or partial dissolution of NaOH in the organic medium (reverse micelles).

[*] In the conc. $NaOH/CH_2Cl_2$ system, more than 97% of the ammonium salt is in the organic phase, while when dilute NaOH is used, this salt is distributed between the two phases according to the lipophilicity. CH_2Cl_2 reacts with $NR_4^{\oplus}OH^{\ominus}$ slowly forming $NR_4^{\oplus}Cl^{\ominus}$ [44].

Scheme 3. Stages in the preparation of dichlorocarbene by the PTC method.

After the exclusion of all other possibilities only the interfacial area remains as a site for the PTC reaction in the alkylation of very weak C—H acids (H-Sub) and the preparation of carbenes. According to the mechanism proposed by *Makosza*[6], a double layer of deprotonated substrate molecules and alkali metal gegenions is formed at the interface (Scheme 2). The cations and anions are present in different phases, neither can exist in the other phase, and both are extensively immobilized by Coulombic forces, so that only H/D exchange and isomerization are possible as fast reactions at this stage (a, b). The catalyst ion pair $[Q^{\oplus}X^{\ominus}]$ acts partly by facilitating the deprotonation but mainly by detaching the substrate anions anchored at the phase boundary, with the release of the original gegenion of the catalyst into the water and fast subsequent reaction with the alkylating agent (c, d). This assumption is supported by the finding that a number of PTC reactions proceed without a catalyst but are accelerated by one[6]. Furthermore, we have been able to show that the alkylation of benzyl cyanide[67] proceeds equally fast with the catalysts tetrabutylammonium chloride and tetrabutylammonium picrate. These two catalysts also have the same activities in the preparation of dichlorocarbene[37]. However, their extraction constants differ by a factor of no less than 10^6 (Table 5). If the small amount of extracted $OH^{\ominus}$ were significant, the competition with the picrate would show a very pronounced effect. Further indications of reactions at the interface have been published very recently[176].



Scheme 2. Stages in the PTC alkylation of very weak C—H acids (H-Sub).

The analogous sequence shown in Scheme 3 is followed in the preparation of dihalocarbenes: first an $Na^{\oplus}/CCl_3^{\ominus}$ double layer is formed (a, b) and then the "anchored" $CCl_3^{\ominus}$ at the interface is detached by the catalyst cation (c). However, it is very important to note that no *stable, long-lived* $[Q^{\oplus}CCl_3^{\ominus}]$ exists in the organic medium; instead, the free carbene (d) coming from (c) is in equilibrium with the "anchored" trichloromethylide (b) *via* (c), and thus remains reactive for days when the subsequent sequence of steps is slow. In contrast, conventional dihalocarbene reactions come to an end the moment contact is established with the base. For example, $LiCCl_3$ decomposes above $-73\,^{\circ}C$[175]. The following species compete for the free carbene (d): the leaving group $Cl^{\ominus}$ (reverse reaction), any free halide $X^{\ominus}$ that may be present (the mixed carbenes: CClX can be captured as adducts), water or $OH^{\ominus}$ (hydrolysis), and finally the olefin (e). Since H_2O is present in the other phase, CCl_2 hydrolyzes very slowly. The proportion of hydrolysis of the chloroform varies between 4 and 58 %, depending on the nucleophilicity of the olefin used. In addition, the reaction rate depends on the nucleophilicity of the olefin[38] (cf. Table 1).

Table 1. Reaction of 0.4 mol of chloroform with 0.2 mol of 50 % NaOH and 0.1 mol of olefin in the presence of 1 mmol of TEBA (triethylbenzylammonium chloride) for 4 h at 23 °C [38].

Olefin	Amount of $HCCl_3$ consumed [mmol]	of this, amount hydrolyzed [mmol]	[%]	As CCl_2 adduct [mmol]
Without TEBA (cyclohexene)	3.4	3.4	100	0.0
With TEBA, without olefin	20.8	20.8		—
3,3-Dimethylbut-1-ene	25.0	14.5	58	12.0
n-Hexene	53.6	8.4	15.7	45.2
Cyclohexene	67.3	11.85	17.6	55.45
2-Methylbut-2-ene	80.4	3.3	4.1	77.1

Another indication of the importance of the phase boundary is that, in the presence of concentrated caustic soda, the kinetics becomes independent of the stirring speed only at over 750 rpm, whereas in "normal" PTC reactions this already happens at speeds between 80[39] and 200[9a] rpm. On shaking pyridinium salts *(6)* in chloroform with aqueous alkali, only the adducts *(7)* and *(8)* are formed in a clean reaction, but not pyridylmethanols, which tend to undergo resinification[40,41,6]. This again indicates that $OH^{\ominus}$ is not extracted into organic media.

(6) *(7)* *(8)*

It still remains to be established whether the mechanism shown in Schemes 2 and 3 applies not only to the alkylation of weak C—H acids and the formation of carbenes but also to all other reactions with aqueous caustic soda. In the hydrolysis of esters with concentrated NaOH, we have found that besides tetrabutylammonium hydrogen sulfate (best catalyst) anionic and non-ionic micelle-forming agents were effective catalysts[42].

2.5. Polymer-Bound Catalysts

Several authors have recently used polymer-bound catalysts. This "three-phase catalysis" method[43] simplifies the removal

of the catalyst after the reaction, but presents problems connected with swelling, mixing, and diffusion during the reaction. These problems are often not easy to solve. The reaction of course again takes place at the interface. In the case of dichlorocarbene additions carried out in a system of aqueous NaOH, chloroform, and olefin at room temperature in the presence of weakly or strongly basic commercial ion exchangers, we obtained very low yields[44] in preliminary experiments, although examples from the literature indicate that these reactions are in principle possible. A survey is shown in Table 2.

Table 2. Reactions of polymer-bound catalysts.

Reaction	Catalyst	Max. yield [%]	Ref.
$CN^{\ominus}$ + R Br(Cl)	Crosslinked polystyrene with $-CH_2-N^{\oplus}(CH_3)_2(n\text{-}C_4H_9)Cl^{\ominus}$	92 (50)	[43]
Dichlorocarbene addition	Crosslinked polystyrene with $-CH_2-N^{\oplus}(CH_3)_2(n\text{-}C_4H_9)Cl^{\ominus}$	99	[43]
$CN^{\ominus}$ + R Br	Crosslinked polystyrene with $-CH_2-CO-(CH_2)_n-N^{\oplus}(CH_3)_3Cl^{\ominus}$	100	[45]
O/*C*-Alkylation of β-Naphthol	Crosslinked polystyrene with $-CH_2-CO(CH_2)_n-N^{\oplus}(CH_3)_3Cl^{\ominus}$	60—95 % (*O*-Alkylation)	[45]
Dichlorocarbene Addition	Amberlite IRA-400	66	[46]
$I^{\ominus}$, $CN^{\ominus}$ + R Br	Crosslinked polystyrene with onium salts, crown ethers, and other ligands	95	[47]

The kinetics of this three-phase catalysis have been settled recently. The activity of the resin is directly proportional to the number of $NR_4^{\oplus}$ groups, though only at a relatively low substitution density. Normal ion-exchange resins, in which a higher proportion of the phenyl rings carry $NR_3^{\oplus}$ groups, have been found to be much less suitable[173].

3. Choice of Solvent and Catalyst

3.1. Extraction Constants with Water/Organic Solvent Systems

The distribution of onium salts between water and an organic medium depends to a large extent on the latter's nature. Table 3 shows some of the values obtained by *Brändström* for tetrabutylammonium bromide[48].

Table 3. Apparent extraction constants calculated from the distribution of 0.1 M $N(C_4H_9)_4^{\oplus}Br^{\ominus}$ between water and the solvent (after *Brändström* [48]).

CH_2Cl_2	35	$ClCH_2-CH_2-CH_2Cl$	2.9	*n*-$C_3H_7-CO-CH_3$	1.7
$CHCl_3$	47	C_6H_5Cl	< 0.1	$C_2H_5-CO-CH_3$	14
$CDCl_3$	41	*o*-$Cl_2C_6H_4$	< 0.1	*n*-C_4H_9OH	69
CCl_4	< 0.1	$CH_2=CCl_2$	< 0.1	$C_2H_5-CHOH-CH_3$	23
CH_3-CHCl_2	0.5	*trans*-CHCl=CHCl	< 0.1	*n*-C_3H_7-CN	13.7
$ClCH_2-CH_2Cl$	6.1	*cis*-CHCl=CHCl	33	CH_3NO_2	168
$ClCH_2-CHCl_2$	8.6	$CHCl=CCl_2$	0.2	$ClCH_2-CN$	170000
$Cl_2CH-CHCl_2$	145	$CH_3COOC_2H_5$	0.2	Cl_3C-CN	2.3
$Cl_2CH-CCl_3$	< 0.1	$C_2H_5OC_2H_5$	< 0.1		
n-C_3H_7Cl	< 0.1	$C_2H_5-CO-C_2H_5$	1.1		

The solvents in the right-hand column can hardly be used, because of their partial solubility in water and the risk of side reactions. It can be seen from these data that, of the aprotic solvents that are virtually immiscible with water, chloroform and dichloromethane show by far the most favorable extraction behavior. They are therefore nearly always preferable to other solvents occasionally used in PTC reactions, such as benzene, ether, chlorobenzene, and *o*-dichlorobenzene, when the reaction cannot be carried out without any solvent at all. When good nucleophiles are reacted with unreactive alkylating agents in dichloromethane, the difficulty is that reaction with this solvent gives rise to compounds of the type of *(9)* as by-products[49, 50]. By changing the conditions one can prepare these compounds *(9)* in a satisfactory manner[51–53].

$$CH_2Cl_2 + 2\,[Q^{\oplus}X^{\ominus}] \longrightarrow CH_2(X)_2 + 2\,[Q^{\oplus}Cl^{\ominus}]$$

(9)

X = *O*-Aryl, *O*-Alkyl, S-R, OCR, $CH(Z)(Y)$ (O)

When chloroform is used in the presence of strong bases, the danger is that a possibly undesirable dichlorocarbene reaction occurs and that orthoformic esters may be formed[54].

3.2. Extraction Constants for Cations and Anions

The extraction behavior of the quaternary ammonium salts with a great variety of anions has been elucidated in a series of fundamental studies by *Schill*, *Modin*, *et al.* A detailed theoretical discussion of the distribution of a salt $Q^{\oplus}X^{\ominus}$ between water and an organic phase has been presented by *Brändström*[7a] on the basis of this series of studies. The distribution D_Q of Q between the two phases is given by:

$$D_Q = \frac{[QX]_{org}}{[Q^{\oplus}]_{water}} = E_{QX}[X^{\ominus}]_{water} \qquad (a)$$

where $[QX]_{org}$ is the concentration or the activity of the ion pair in the organic phase, $[Q^{\oplus}]_{water}$ and $[X^{\ominus}]_{water}$ are the concentrations (activities) in water, and E_{QX} is the extraction constant. It is important to bear in mind that the distribution D_Q is governed not only by the distribution coefficient but also by $[X^{\ominus}]_{water}$, which is in turn influenced by the pH of the aqueous layer and the association and dissociation of the ion pair in the organic phase.

In the case of competition between two anions $X^{\ominus}$ and $Y^{\ominus}$ for $Q^{\oplus}$, we have:

$$\frac{[QX]_{org}}{[QY]_{org}} = \frac{E_{QX}[X^{\ominus}]_{water}}{E_{QY}[Y^{\ominus}]_{water}} \quad (b)$$

The extraction constants of *e.g.* symmetrical quaternary ammonium picrates have been listed in the literature[55] (Table 4).

Table 4. Extraction constants E_{QX} of picrates between water and an organic medium [55, 7a].

Solvent	Cation $N(CH_3)_4$	$N(C_2H_5)_4$	$N(n\text{-}C_3H_7)_4$	$N(n\text{-}C_4H_9)_4$	$N(n\text{-}C_5H_{11})_4$
CH_2Cl_2	1.5	219	2.9×10^4	4.8×10^6	2.5×10^8
$CHCl_3$	0.22	21	4365	8.1×10^5	
Benzene		0.22	35	3890	7.9×10^5
CCl_4				87	2.9×10^4

Comparison of the logarithms of these values (*i.e.* $\log E_{QX}$) shows that they increase by about 0.54 per carbon atom in the cation. In a first but relatively good approximation, this also applies to the quaternary ammonium salts of other anions. Less symmetrical ammonium ions have deviating absolute values but show a similar increase in the E_{QX} values within the homologous series[56, 57].

What is important is that the lipophilicity of a benzyl group is comparable not to that of an *n*-heptyl residue but to that of an *n*-propyl or *n*-butyl group.

For normal anions less lipophilic than picrate, a useful PTC catalyst should contain 15 or more carbon atoms, for otherwise the extraction of the salt is insufficient. Thus, TEBA is in many cases too hydrophilic. On the other hand, the salts of even lower ammonium cations are only sparingly soluble in concentrated solutions of alkali metal hydroxides, and TEBA is suitable in these cases.

For multiply charged anions the extraction rule is that a singly charged anion (*e.g.* $H_2PO_4^{\ominus}$) is extracted more easily than a doubly charged one (*e.g.* $HPO_4^{2\ominus}$), which in turn is extracted more easily than a triply charged one (*e.g.* $PO_4^{3\ominus}$). Therefore, tetrabutylammonium hydrogen sulfate can be used with advantage for the preparation of tetrabutylammonium salts of variously lipophilic anions according to *Brändström*, since, unlike the $HSO_4^{\ominus}$ ion, the sulfate formed in the neutralization remains quantitatively in the water.

Table 5 shows the extraction constants of some simple anions. It can be seen that the lipophilic groups have a strong influence on these values. If we ignore the concentration-dependent complicating factors (like ion-pair association and dissociation and the influence of the pH), we can attempt to predict whether a certain PTC reaction will proceed or not. For example, consider the reaction:

RX (0.05 mol, without solvent, ≈10 ml) + KOAc (0.1 mol in 20 ml of water) $\xrightarrow[0.5\ \text{mmol}]{Bu_4NX}$ ROAc

The relative reaction rates for X = Cl, Br, I will be affected by: a) the reaction itself (for which, I > Br ≫ Cl) and b) the relative degree of the extraction of $OAc^{\ominus}$ in comparison with $X^{\ominus}$. We assume that practically all $Q^{\oplus}$ is present in the organic phase and that the ratio of the extraction constants is independent of the medium. We now calculate the fraction x of $Q^{\oplus}$ that is paired with $OAc^{\ominus}$; substitution into Eq. (b) gives for iodide:

$$\frac{x}{0.05-x} = \frac{7.6\times10^{-3}}{1023} \times \frac{10}{x}$$

Solution of the quadratic equation gives $x = 0.0019$. This means that 3.8% of the tetrabutylammonium ions exist in the form of Bu_4NOAc and the rest (96.2%) in the form of Bu_4NI, this portion thus being inactive for the reaction. A similar calculation shows that, after a 50% conversion, only 0.002% of the catalyst exists in the $OAc^{\ominus}$ form. For chloride and bromide we obtain the more favorable values of respectively 72.8 and 23.7% for the $Q^{\oplus}OAc^{\ominus}$ form at the beginning of the reaction. The favorable acetate/bromide extraction relationship combined with the still fast reaction seems the best combination for the planned experiment. In the case of the iodide, the question is whether enough acetate is extracted to maintain the reaction. These obviously rough calculations were confirmed in principle by experiments in which the reactants were heated for 2 h at 100°C, and where the conversion was 100% for the bromide, 22% for the chloride, and 37% for the iodide[71].

Table 5. Anion extraction constants E_{QX} of tetra-*n*-butylammonium ion pairs between water and chloroform and—in square brackets—between water and dichloromethane [7a].

Anion	E_{QX}		Ref.	Anion	E_{QX}	Ref.
$Cl^{\ominus}$	0.78	(0.35)	[58, 59]	$CH_3COO^{\ominus}$	7.6×10^{-3}	[60]
$Br^{\ominus}$	19.5	(17)	[58, 59]	$C_6H_5\text{—}CH_2\text{—}COO^{\ominus}$	1.86	[60]
$I^{\ominus}$	1023	(2188)	[58, 59]	$C_6H_5\text{—}COO^{\ominus}$	2.45	[60]
$ClO_4^{\ominus}$	3020	(4.37×10^4)	[58, 59]	Salicylate	263	[60]
$NO_3^{\ominus}$	24.5	(79)	[58, 59]	3-Hydroxybenzoate	0.03	[60]
				Phenoxide	0.93	[60]
				Picrate	8.1×10^5	[60]
				p-Toluenesulfonate	214	[61]
				Naphthalene-2-sulfonate	2818	[61]
				Anthracene-2-sulfonate	1.3×10^5	[62]
				Trinitrobenzenesulfonate	2.9×10^4	[61]

Similar but somewhat more complicated calculations can be used to predict the ease of alkylation of weak C—H acids[7a].

The literature values for the extraction constants of quaternary ammonium hydroxides show scatter and are conflicting, unreliable, and several orders of magnitude too high. Firstly, they have sometimes been determined in the presence of water and organic solvents partially miscible with water (THF, alcohols). Secondly, the co-titration of tertiary amines in the organic medium easily leads to anomalies, these amines being formed in the reaction $R_4N^{\oplus}OH^{\ominus} \rightarrow R_3N + ROH$ or introduced as $R_3NH^{\oplus}X^{\ominus}$ impurities in $R_4N^{\oplus}X^{\ominus}$. A rough estimate of the extraction constant of tetra-*n*-heptylammonium hydroxide between water and benzene is 1.2, from which extrapolation gives $E_{Bu_4NOH} \approx 10^{-6}$[44]. This means that the extraction constant of hydroxyl ion is about 10^4 times smaller than that of chloride. This result should be valid, to a first approximation, for all water-immiscible solvents[44].

3.3. Empirical Comparison of Catalysts

3.3.1. Reactions without Concentrated Alkalis

Herriott and *Picker* compared the activities of 23 catalysts in the reaction of alkyl bromide with the thiophenoxide ion in a water/benzene system[9a]. It has been pointed out in Section 3.1 that benzene is not an ideal organic medium for such reactions. Accordingly, these authors found that the catalysts differed less in more strongly polar organic solvents. As shown in Section 3.2, the very hydrophilic catalysts such as the lower alkyl compounds up to tetra-*n*-propylammonium halide and TEBA fail almost completely. The same applies to alkylpyridinium salts. Surfactants of the type $(n\text{-}C_{6-16}H_{13-33})N^{\oplus}(C_2H_5)_3X^{\ominus}$ show somewhat better but still low activity. It has been found that symmetrical ions are more active than ions with only one long chain. In the case of the same substituents, phosphonium ions are somewhat better than ammonium ions, and alkyl groups are more suitable than phenyl groups in the onium salt. The highest activity is shown by methyltrioctylammonium chloride (tradenames of technical-grade, not entirely uniform product Aliquat 336® and Adogen 464®; cf. [69]), tetra-*n*-butylphosphonium chloride, ethyltrioctylphosphonium bromide, and dicyclohexyl[18]-crown-6, together with tetra-*n*-butylammonium salts, but the activity of this last group is reduced in benzene. Numerous examples from the literature, where no rigorous comparison of several catalysts was made, confirm that these ammonium and phosphonium salts with 15—25 carbon atoms can be used with advantage. Mention should be made here again of the possible undesirable effect of the gegenion (see Section 3.2).

3.3.2. Reactions in the Presence of Concentrated Alkalis

The situation is different here, because the solubilities are different, and even lower alkyl groups can often be used in the onium salt. Numerous catalysts have been compared in the case of dihalocarbene reactions[37, 46, 63]. There are only small differences between most tetraalkylammonium and tetraalkylphosphonium catalysts, and it is interesting to note that these differences do not run parallel for dichlorocarbene and dibromocarbene[37, 63]. Phosphonium salts with three or four aryl groups are inactive, and so are tetramethylammonium iodide and alkylpyridinium salts. On the other hand, tertiary amines are active in this case[64], since under the reaction conditions they are converted into catalysts of the type $R_3N^{\oplus}—CX_2H\ X^{\ominus}$[65]. The anion introduced with the catalyst also affects the catalytic activity; hydrogen sulfate and chloride are the best in this respect. The following catalysts can be particularly recommended for CCl_2 reactions: tripropylamine, tetrabutylammonium hydrogen sulfate or chloride, TEBA, Aliquat 336, trialkylsulfonium salts, and tetraalkylphosphonium salts, while symmetrical tetraalkylammonium bromides, Aliquat 336, and TEBA can be recommended for CBr_2 reactions. [18]Crown-6 and tetraphenylarsonium chloride were also found to be highly suitable in both cases.

We have compared some catalysts for the alkylation of benzyl cyanide[67] (cf. also [66]), and found that tetrabutylammonium hydrogen sulfate and chloride, tetraethylammonium bromide, and [18]crown-6 are the best, while TEBA and Aliquat 336 are somewhat less good. As regards the effect of the anions, iodide interferes, and perchlorate does so even more. We have found that ammonium salts have a low thermal stability at elevated temperatures. Thus, TEBA is converted into benzyldiethylamine to an extent of 72% after 20 h at 110°C in conc. NaOH and to one of 11.5% after 20 h at 60°C in conc. NaOH/CH_2Cl_2; phosphonium salts are somewhat more stable.

3.4. Amount of Catalyst

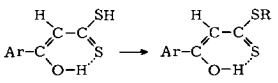
In substitution reactions the reaction rate is proportional to the amount of catalyst and can therefore vary within relatively wide limits. One generally uses between about 0.5 and 10 mol-% catalyst. When a lipophilic anion such as $I^{\ominus}$ threatens to bind the catalyst, or when a more selective reaction is attempted one can use molar quantities of the catalyst, which can often be easily recovered. Unlike most reaction products, many ammonium salts are insoluble in ether.

4. Preparative Applications

The most important recent preparative applications are listed in the following tables without any claim to comprehensiveness.

4.1. Simple Substitutions

Table 6 shows examples of simple substitutions and the preparation of esters, dithioesters, mixed phosphoric acid esters, aminophosphoric acid esters and phenyl aminosulfonates.



4.2. Alkylation of O—H, S—H, and N—H Bonds

While the preparation of ethers and thioethers is straightforward, *N*-alkylation generally requires an acidifying neighboring group (Table 7).

4.3. Alkylation of Activated C—H Bonds

The site of attack in the alkylation of ambidentate anions is influenced by the reactivity of the alkylating agent (dimethyl

Table 6. Recent examples of phase-transfer-catalyzed simple substitution reactions.

Reaction	Solvent	Catalyst	Yield [%]	Remarks	Ref.
$RBr \rightarrow ROAc$	CCl_4/H_2O	$(C_8H_{17})_3N^{\oplus}—C_3H_7Cl^{\ominus}$	68—75		[70]
$RBr \rightarrow ROAc$	Substrate/H_2O	NBu_4Br	100	2 h, 100 °C, 2 mol KOAc with RCl 22 %, with RI 37 %	[71]
$RX \rightarrow ROAc$ (X = Br, OTos, Cl)	CH_3CN or C_6H_6	[18]Crown-6	≈ 90	With sec. cpds, 10 % elimination	[27]
$RX \rightarrow RNO_2$ (much) + RONO (little)	CH_3CN	[18]Crown-6	32—70	With prim. alkyl	[72]
$ArCH_2X \rightarrow ArCH_2CN$	CH_3CN	[18]Crown-6	90—100		[72]
$ROMes \rightarrow RCN$	C_6H_6/H_2O	Aliquat 336	≈ 70		[73]
$RX \rightarrow RCN$ (X = Cl, Br)	C_6H_6 or CH_3CN	[18]Crown-6	≈ 100	With benzyl or prim. alkyl; with sec. cpds some elimination; with cyclohexyl only elimination	[74]
$RBr \rightarrow RCN$	Substrate/H_2O	Amines	Highly variable up to ≈ 100	Catalyst *in situ* from amines	[75]

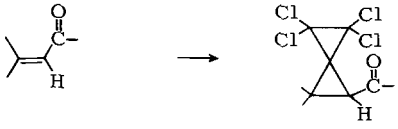
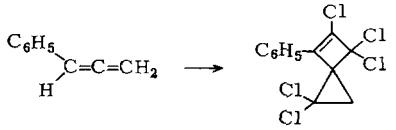
sulfate gives more *O*-alkylation than does methyl iodide[112, 113]). A number of studies have been published on the direction and stereochemistry of these reactions, both with intermediate isolation of the salts and also for the catalytic process[112–114] (see Table 8).



4.4. α-Elimination to Form Carbenes

Since the very large number of papers published on the PTC addition of dihalocarbenes to C=C bonds can hardly be surveyed here, only a few important results will be mentioned. Thus, α,β,γ,δ-unsaturated esters take up only one CX_2, and that across the γ,δ double bond[115, 116]. Reactions have also been carried out with imines[117] and enamines[87, 118]. In an NaOH/$CHCl_3$/TEBA system, naphthalene and anthracene give complex mixtures of ring-expansion products and their dimers[119]. The formation of the unusual reaction products *(10)*[120], *(11)*[115, 121], and *(12)*[122] has been elucidated.



On the basis of our extensive optimizing experiments, the procedures described below can be recommended for dihalocarbene reactions. Contrary to earlier hypotheses[2], these give the same or sometimes even better yields with dibromocarbene than with dichlorocarbene. Furthermore, the previously used very large excess of bromoform can be dispensed with by the selection of dichloromethane as co-solvent.

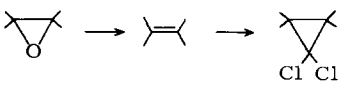
poured into a large volume of water. Without putting too much stress on complete phase separation, the bulk of the aqueous phase is discarded and the emulsion is broken by repeatedly pouring it into fresh water or possibly dilute hydrochloric acid. The liquid is dried and, if possible, processed further by distillation. Solid or high-boiling nonpolar products can be conveniently freed from dark by-products by eluting the solution in petroleum ether/ether or toluene down a short silica gel column.

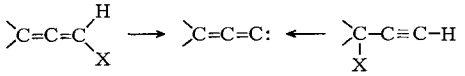


Dibromocarbene[63]: The substrate (0.1 mol) and Aliquat 336[*] (1 mmol) are dissolved in bromoform (0.2 mol), ethanol (1 ml), and dichloromethane (20 ml), and the solution is stirred vigorously with freshly prepared ice-cold 50 % NaOH (0.4 mol) for 1 h at room temperature and then for 3—6 h at 50 °C, using a magnetic stirrer. This is followed by processing as described above.

Other new preparative applications of CCl_2 obtained by PTC are shown in reactions (c)—(g):

$R_2NH \longrightarrow R_2N{-}CHO$ [123, 124] (c)

$N_2H_4 \longrightarrow CH_2N_2$ [19] (d)



$R{-}\overset{\overset{NH}{\|}}{C}{-}NH_2 \longrightarrow R{-}C{\equiv}N$ [125] (e)

[126] (f)

$Ar{-}CHO \longrightarrow Ar{-}\underset{\underset{OH}{|}}{CH}{-}COOH$ [127] (g)

Japanese authors recommend the use of β-hydroxyethyltrialkylammonium salts as less active, selective catalysts, which attack *e.g.* only one out of a number of double bonds in the molecule[128, 129] (cf. also Section 4.8).

In the preparation of CX_2 by PTC, exchange with external halogens is possible. Both $HCBrCl_2$ and $HCBr_2Cl$ give adducts of all the combinations: CBr_2, CClBr, and CCl_2[38]. The use of dichloromethane as co-solvent seems to accelerate CX_2

[*] The thin commercial liquid product must be freed from high-boiling hydrocarbons, first by the application of aspirator vacuum and then oil-pump vacuum at 125 °C, which leaves behind a product with honey-like consistency.

reactions quite generally. Like dihalocarbenes, dialkylvinylidenecarbenes can be synthesized from haloallenes[130] or 3-halopropynes[131, 132].

4.5. Wittig and Horner Reactions

Wittig and Horner reactions that proceed with phase-transfer catalysis are shown in Table 9. The *E/Z* ratios have been found to depend on the solvent[133] and on the catalyst (extreme values 43:57 and 83:17)[137].

4.6. PTC Reactions with Oxidizing Agents

Table 10 gives a survey of the oxidizing agents used, together with the types of compounds to which they are applied.

4.7. Miscellaneous PTC Reactions

A large number of other interesting reactions catalyzed in this way are shown in Table 11.

4.8. The Use of Optically Active Catalysts

Several teams have tried to accomplish kinetic racemate resolution and optical induction with optically active quaternary ammonium salts. The esterification of DL-acids in the presence of chiral catalysts derived from α-phenylethylamine led to products with disappointingly small or zero rotation[165]. Japanese authors have introduced catalysts derived from ephedrine, but, when reacted with strong bases under the conditions used, these are converted at least in part into the chiral epoxide *(13)*, which can simulate optical activity as an impurity in the reaction product. As a result, the previously asserted[166] formation of chiral epoxides, *e.g.* from benzaldehyde and trimethylsulfonium iodide in the presence of such catalysts has now been partially withdrawn[167]. We have, moreover, disproved[38] the formation of optically active dichlorocarbene adducts which had been asserted before[128], but which is *a priori* unlikely on the basis of the mechanism

(13)

(the intermediacy of free CCl_2 is well documented). Asymmetric inductions have been reported to occur in the phase-transfer-catalyzed reduction of ketones with hydridoborate in the presence of catalysts similarly derived from ephedrine. One team observed the formation of partially chiral products only from sterically rather hindered ketones[168], while another claimed an optical yield of up to 39 % even with acetophenone under similar conditions[169]. It is clearly necessary to check these results and also the reported maximum 6 % optical induction in an alkylation[170] with a catalyst of the same type.

The chiral catalysts discussed so far have their chirality center at a site removed from the positively charged nitrogen. However, a greater effect and a smaller tendency to disturbance by decomposition products can be expected when the nitrogen itself is chirally substituted, and we have tackled the preparation of such catalysts[165]. It is encouraging that *Wynberg et al.* have obtained optical inductions of up to 68 % in Michael additions in a homogeneous solution in the presence of quinine[171]. The same group has recently reported a true PTC reaction: the formation of optically active epoxides from chalcones with a benzylquinine salt and H_2O_2, with an optical yield of up to 25 %[172].

5. Future Prospects

Phase-transfer catalysis has reached a certain maturity in a few years, and we now know the important factors that govern the choice of the catalyst and the reaction conditions. It may be expected that remaining uncertainties about the course of the reactions in the presence of concentrated alkalis will soon be resolved. No doubt, PTC versions will in future be proposed for many more types of reactions. We can also expect innovations in the use of optically active catalysts with chirally substituted key atoms. In particular, however, preparative improvements should be possible in the field of reactions with bases stronger than aqueous sodium hydroxide. For reasons of stability, crown ethers and cryptates will be the main catalysts here.

The author wishes to thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Gesellschaft von Freunden der T.U. Berlin for supporting his work mentioned in this article. The author has also enjoyed the cooperation of colleagues named in the references, and would like to express his thanks to his wife, Dr. Sigrid Dehmlow, for critical discussions and her assistance with the preparation of the manuscript.

The Role of Birth Control in the Survival of the Human Race

By Rudolf Wiechert[*]

Analysis of the growth of the world's population shows that if no trenchant measures are taken, the number of the earth's inhabitants is likely to double to 8 billion people within as few as 35 years. Hormonal contraception is presently the best method available which would be capable of counteracting this trend. 6.5 tons of estrogen and 32 tons of progestogen would in theory be sufficient to protect the 500 million women of child-bearing age from unwanted pregnancies for one year.—In addition, the history, industrial methods of synthesis, mode of action and side effects of steroid contraceptives as well as the possible future developments are briefly mentioned.

1. Introduction

Politicians and scientists now agree that the survival of the human race is threatened by the consequences resulting from destruction of living space, the arms race, and the excessive growth of the world's population. In view of this, surprisingly few people are engaged in the task of dealing with the problems of environmental pollution and the population explosion.

In 1974 these two topics were the subject of a conference held in Bucharest that was attended by 5000 delegates from 138 countries. A world population plan of action aimed at reducing the birth rate was agreed upon. The efforts of the individual countries were to be coordinated and exchange of information was to take place.

The outcome of this conference and the hope that the governments concerned will put the recommendations into practice should enable one to view the future with a measure of optimism. However, if one considers the present rate of growth of the world population one cannot help seriously doubting whether we have the ability to master the problem.

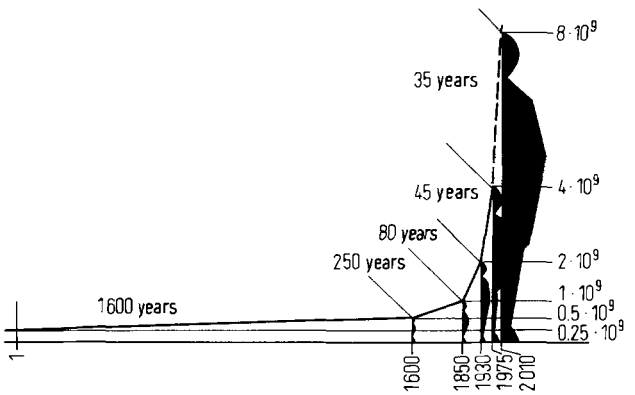

Fig. 1. World population and the times taken for it to double (based on data supplied by the United Nations).

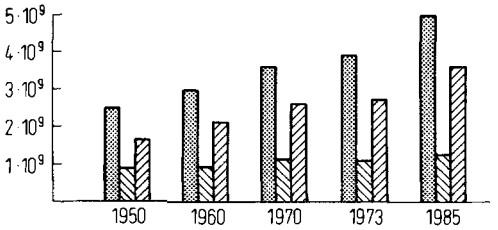
The world population at present numbers approximately 4 billion. Figure 1 shows the growth of the world population and the periods of time required for it to double: in year 1 there were some 250 million people and it took 1600 years for that figure to double to 500 million. The present figure of 4 billion will have doubled to 8 billion in the next 35 years[1]. 220000 babies are born every day, *i.e.* another 6900 children every 45 minutes. To put it yet another way, over a period of 250 days 55 million people are born into the world, that figure being the same as the total number killed in the second world war.



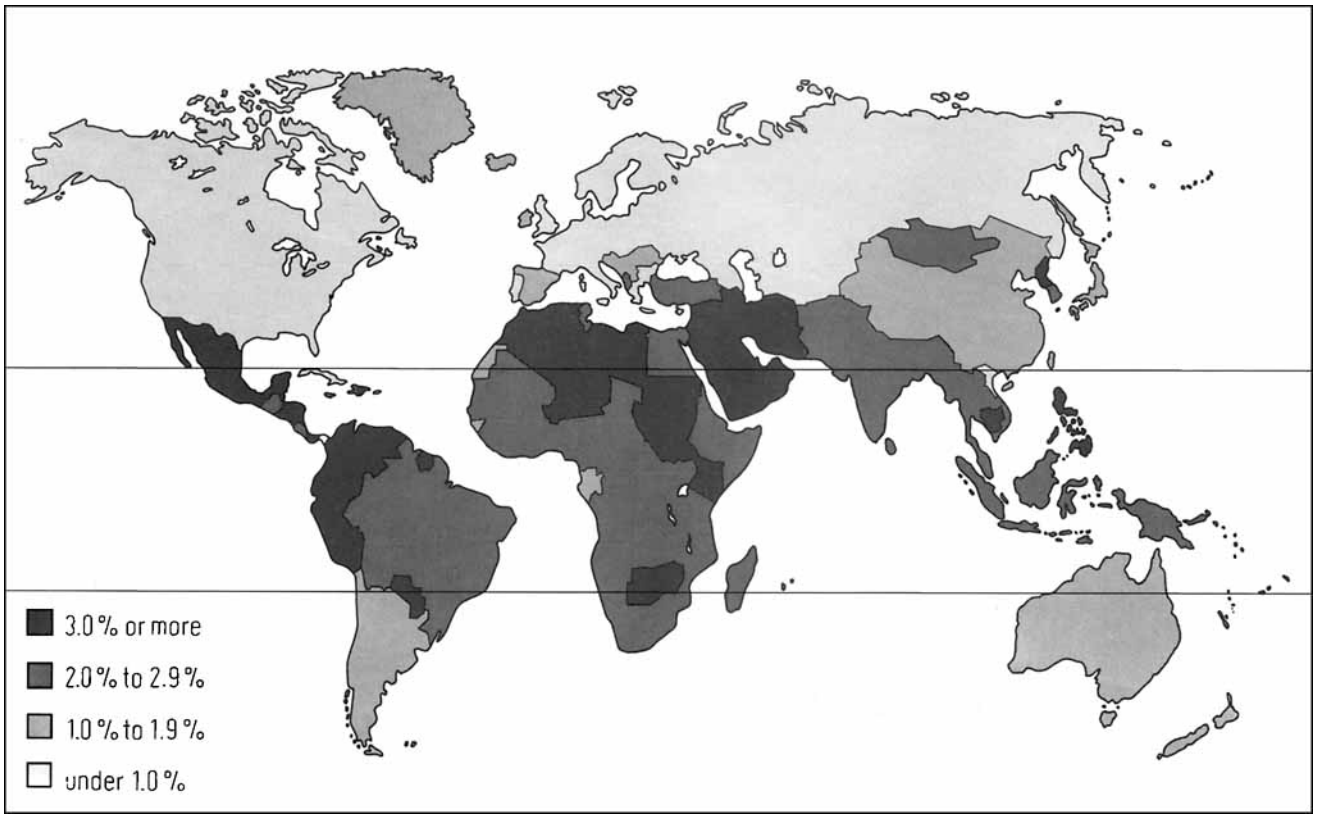


Fig. 2. Population growth in industrialized and developing countries: total population. population in the industrialized nations. population in the developing countries. Values for 1973 estimated, those for 1985 projected.

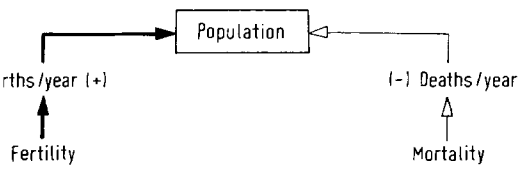
It is clear from the different population growth rates in the industrialized nations and the developing countries since 1950 that the general trend is determined almost exclusively by the latter (Fig. 2). It is striking to note that Pakistan's population is likely to double in only 21 years and that of India in 28. In contrast, the number of inhabitants of the German Federal Republic has in fact fallen slightly over the last decade. The world map (Fig. 3) shows the geographic distribution of population growth, the dark areas indicating the regions with the highest growth rates.



The population figures are determined by two regulating factors, which are represented in simplified form in Fig. 4. The first of these represents the growth rate and is dependent upon fertility and the number of years between generations. The second reflects the death rate in the population which is, to a great extent dependent upon the health of the people involved[2].

The population explosion that has taken place over the course of the last century has not been brought about by any rise in the birth rate but is due exclusively to a fall in the death rate. The industrialized nations have made considerable progress in medicine and have exported their knowledge to the developing countries, with the result that the death rates in those countries have fallen considerably.

g. 3. Geographic distribution of population growth in 1972 (after FSP Center U.S. April 1974).

g. 4. The change in population figures brought about by two regulating ;tors.

g. 5. Birth rates n and death rates m in a) industrialized nations and developing countries.

Fig. 5 shows the birth and death rates for the industrialized ıtions and the developing countries from 1850 to 1975. In e industrialized countries the fall in the death rate has ;en accompanied by a decline in the birth rate. However, the developing countries since approximately the beginning this century it has been possible to achieve only a decline the death rate.

Looking back at the figure showing the regulating factors ig. 4), it is clear that it is really only possible to reduce ›pulation growth *via* the left-hand factor, *i.e.* by reducing the birth rate, and the only way to do this is through birth control.

We saw on the world map (Fig. 3) the areas of our planet with the highest population growth rates and where birth control is most urgently required. Consequently, faced with the population explosion and all its inherent dangers, what can *Homo sapiens* do?

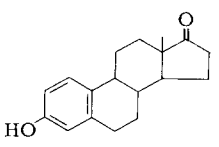
Table 1. Methods of birth control practised (estimates). There are approximately 500 million fertile and sexually active women of childbearing age (after [4, 11, 14]).

Pill	55×10^6
Condom	25×10^5
Intrauterine device	15×10^6
Spermicides	12×10^6
Sterilization (male and female)	10×10^6
Diaphragm	3×10^6
Injection	1×10^6
	121×10^6
Knaus-Ogino rhythm method Coitus interruptus Vaginal douches	40×10^6
Abortions (legal and illegal)	30×10^6
	70×10^6

There are now some 500 million women of child-bearing age[3]. The Medical Center of the George Washington University has published figures, based on estimates and sales figures, showing the methods of birth control practised (Table 1). It is interesting to note that almost 40 % of the women do not use any form of contraception. 55 million women use the ovulation-inhibiting steroid hormones known as "the pill"[4].

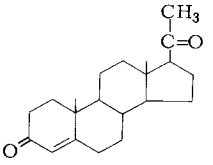
The development of hormonal contraceptives is one of the greatest scientific achievements of our century. It is a classic example of international cooperation between scientists of a wide variety of disciplines.

2. The Biology and Chemistry of Contraceptive Steroids



The possibility of hormonal contraception was first proposed by the Innsbruck physiologist *Haberlandt* in 1919[5]. Although a number of observations, papers, and hypotheses had already been published at that time concerning the corpus luteum and the ovarian tissue, none of the authors had seen any connection between his work and the possibility of hormonal contraception. Over the next few years *Haberlandt* was able to provide experimental evidence to support his hypothesis. He succeeded in making rabbits infertile by transplanting ovaries from other pregnant animals under their skin. He published his findings in the Münchner Medizinische Wochenschrift in 1921 under the title: "Hormonal sterilization of the female animal organism".

With considerable far-sightedness, *Haberlandt* writes in this very first paper of the possibility of clinical administration of extracts by injection or even by mouth. Over the course of the next ten years he carried out successful experiments with extracts of corpus luteum, ovary, and placenta. He explained the resulting sterility as brought about by inhibition of ovulation.

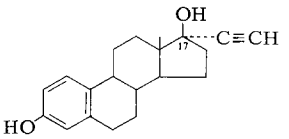


The space here is insufficient to mention every contribution that eventually led to the development of oral contraceptives, but the milestones along that road must be mentioned[6–8].

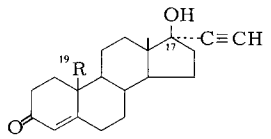
In 1923 *Aschheim* and *Zondeck* found a relatively abundant source of follicle hormone in the urine of pregnant women and pregnant mares. *Allan* and *Doisy* developed a test to determine its biological activity. The prerequisites for the isolation of the pure hormone were thus provided. In 1927, at *Schöller*'s suggestion, *Butenandt* began isolating the hormone from crude extracts. Two years later he, and also, independently, *Doisy* in the United States and *Laquer* in the Netherlands, succeeded in isolating estrone *(1)*. Clarification and confirmation of its structure followed shortly afterwards.

The second female sex hormone, namely the corpus luteum hormone progesterone *(2)*, was isolated from pig ovaries almost simultaneously by four research groups working independently. The test necessary for its isolation had already been developed in 1929 by *Allan*, *Corner* and *Hohlweg*.

(1)



(2)

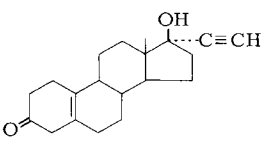


Soon after the two hormones, estrone and progesterone, had been isolated it was demonstrated in animal experiments that they inhibit ovulation and can be used to create a state of pseudo-pregnancy.

Since the pure hormones were available, it should have been possible to apply *Haberlandt*'s ideas about contraception. However, when orally administered, these two pure hormones were found to be rapidly metabolized and therefore exhibited a very weak effect. In 1938 *Inhoffen* and *Hohlweg* reported from Berlin the synthesis of 17α-ethynylestradiol *(3)*, an estrogen that is highly effective when administered by the oral route. Today, nearly 40 years later, this estrogen is still used in the majority of hormonal contraceptives.

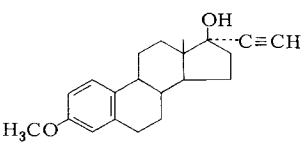
In the same year *Inhoffen* and *Hohlweg* were also responsible for producing the first orally-active synthetic progesterone, 17α-ethynyltestosterone *(4)*, although they were in fact looking for an orally-active androgen. *Schöller* recommended that they test the substance for progestational activity, after, he writes, "they (meaning *Hohlweg* and *Inhoffen*) had informed [him] with great disappointment that it did not have the masculinizing effect they had hoped for".

(3)



(4), R = CH_3
(5), R = H

In the United States *Djerassi* and *Colton* later synthesized 19-nor-compounds of 17α-ethynyltestosterone, *e.g. (5)*, the constituents of the first hormonal contraceptives used clinically.



In 1951 in the United States, *Gregory Pincus* together with *Chang*, *Rock*, *Garcia* and others began working on the development of an oral hormonal contraceptive. Two women who were active in the American Family Planning Association, namely *Margaret Sanger* and the wealthy *Katherine Dexter*, had offered *Pincus* financial backing. When, in 1963, the above-mentioned orally-active 17α-ethynyl-19-nor-compounds became available, *Pincus*' team concentrated their studies on these steroids. Two years later the first effective method of hormonal birth control was available in the form of a daily dose of 10 mg of norethynodrel (17α-ethynyl-17β-hydroxy-19-nor-5(10)-androsten-3-one) *(6)* for 20 days.

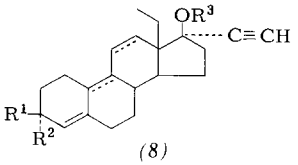
It was a chance observation that eventually led to a small amount of estrogen being added to the progestogen: it was found that groups of women who received different batches of the progestogen exhibited different cycle patterns. With some batches a certain percentage of the women experienced intermediate bleeding, whereas this did not occur with other batches.

Closer examination of the progestogen *(6)* revealed that, because of the method of synthesis used, it occasionally contained small quantities of etherified 17α-ethynylestradiol *(7)*. The cycles of the women who had received these batches were by far the better controlled. This was the manner whereby the first oral contraceptive was discovered that contained both a progestogen and an estrogen and acted by inhibiting ovulation but at the same time enabling monthly menstruation to take place. Combination pills of this type are the ones used most commonly nowadays.

(6)

(7)

The mode of action is simple to explain: roughly half-way through a normal menstrual cycle an ovum capable of being fertilized is released by the ovary and passes along the fallopian tube to the uterus. In the lower section of the fallopian tube, before it reaches the uterus, it may be fertilized. If this is the case, hormones send messages *via* the brain and the pituitary gland to ensure that for the time being no more ova mature in the ovary.



The pill supplies a woman with the hormones that bring about this state resembling pregnancy. The first combination method developed involved the administration of mixtures of a progestogen and an estrogen, *e.g. (6)* and *(7)*, from the 5th to the 24th day of each cycle.

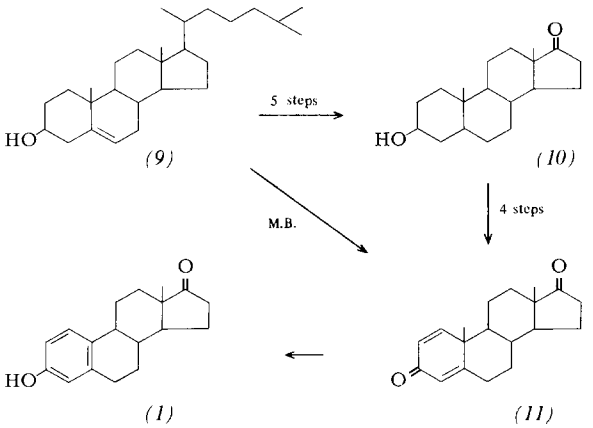
The sequential method that came later mimics the natural sequence of hormone production: only the estrogen is given from the 5th to the 19th day of the cycle and the combination of estrogen and progestogen is then given from the 19th to the 24th day[9, 10].

Longer-acting hormonal contraceptives in the form of injections, implants, or tablets have not yet been developed to the same stage as the two methods described above and still have major disadvantages.

For a long time it was believed that the contraceptive effect of the steroid hormones was due solely to the inhibition of ovulation outlined above. We now know that this effect is the sum of several partial effects; in addition to inhibition of ovulation, changes have been observed in the cervical mucus, the endometrium, and the motility of the fallopian tubes. This raised the question whether contraception can be achieved without inhibiting ovulation. The answer came with the development of the famous "minipill". This supplies continuous small doses of only the progestogen. However, the minipill has not fulfilled expectations, and is now used only on a limited basis as an alternative in special cases[11].

Today's contraceptives still contain the estrogen used by *Pincus*, ethynylestradiol *(3)*, or its 3-methyl ether *(7)*. However, several improved variants of 17α-ethynyl-19-nortestosterone (norethisterone) have since been synthesized, which have proved clinically reliable[12, 13]. Seven progestogens are in use at present in the Federal Republic of Germany. It has been possible to reduce the required daily dose to almost one-hundredth of that necessary in the case of the first preparations tested.

(8)



$R^1 = R^2 = H$
$R^1 = OAc$, $R^2 = H$
$R^3 = H$, OAc

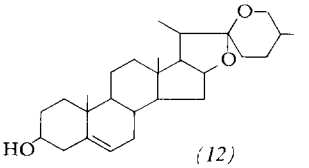
A number of these structural changes can be seen in formula *(8)*. For example, the 3-keto group is removed or reduced and acetylated, or additional double bonds are introduced in positions 9 and 11. A quantitative and qualitative improvement in effect that is particularly worth mentioning was achieved by introducing a methyl group in position 18.

One feature that has remained common to all the compounds is that they belong to the 19-nor series and carry the ethynyl group in the 17α-position.

3. Syntheses of Contraceptive Steroids

The development of the methods of synthesizing estrone and the 19-nor steroids constitutes one of the most interesting chapters in the history of chemistry, providing an excellent illustration of the major advances made in theoretical and synthetic organic chemistry over the last 40 years[8, 12]. Following the first isolation of estrone from pregnant mare urine it was immediately clear that this would not be an adequate source of raw material for the large quantities of the hormone that it would soon be necessary to produce.

(9) *(10)* *(1)* *(11)*



Cholesterol *(9)*, which is present in large quantities in such substances as wool fat, was the most obvious starting material. Two problems faced the chemists with regard to the synthesis of estrone from cholesterol: breakdown of the sterol side chain and elimination of the nonactivated 19-methyl group.

They succeeded in breaking down the side chain with chromic acid to give very moderate yields of the 17-ketone *(10)* after providing intermediate protection for the hydroxyl group and the double bond. In 1940, *Inhoffen* succeeded in aromatizing the diene-dione *(11)* to estrone *(1)* with elimination of the angular 19-methyl group. This reaction, which is carried out at approximately 600 °C in Tetralin, proceeds by a radical mechanism.

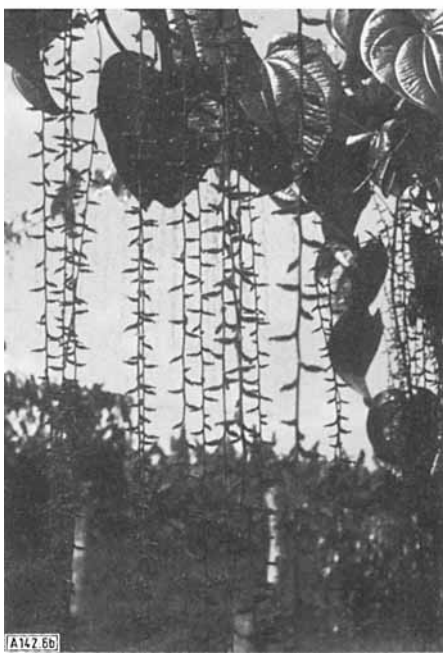
It was later found that ionic aromatization can be achieved by treating the dienone system with lithium and biphenyl, a reaction that can be carried out at the modest temperature of 66 °C.

17α-Ethynylestradiol *(3)* can be obtained from the estrone *(1)* with the aid of the appropriate Grignard reagent.

In the last few years, an interesting new development has taken place concerning the microbiological degradation of sterols. It is now possible to convert sterols, *e.g. (9)*, directly into the diene-dione *(11)*, with good yields by means of a microbiological process (M.B.). As a result of this process, sitosterol, which is present in large quantities in soya beans for example, has acquired major importance as a raw material.

(12)

For decades diosgenin *(12)* was undoubtedly the most widely used and most suitable raw material for the production of all steroids. Diosgenin is found in the roots of several varieties of *Dioscorea* which grow wild in such countries as Mexico, Guatemala, India, South Africa, and China (Fig. 6). This natural substance was discovered by *Russell E. Marker*.



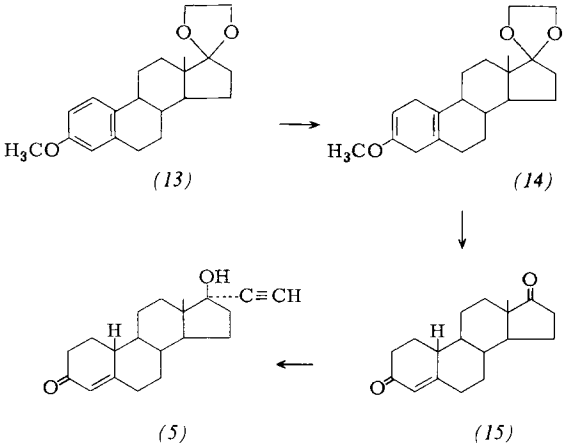


Fig. 6. a) The root and b) the foliage of *Dioscorea composita*.

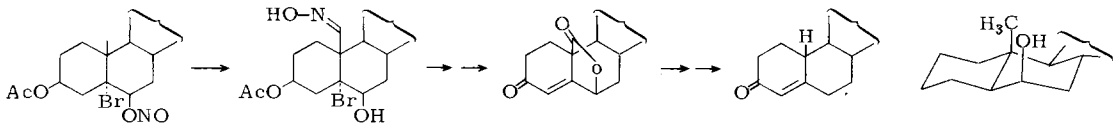
Diosgenin can be converted into an androstene derivative in a number of stages which give excellent yields. The main country producing diosgenin is Mexico. In 1974 the State of Mexico began itself to undertake and monopolize gathering of the roots. For this reason, the sterols which are available throughout the world will certainly gain importance as a raw material.

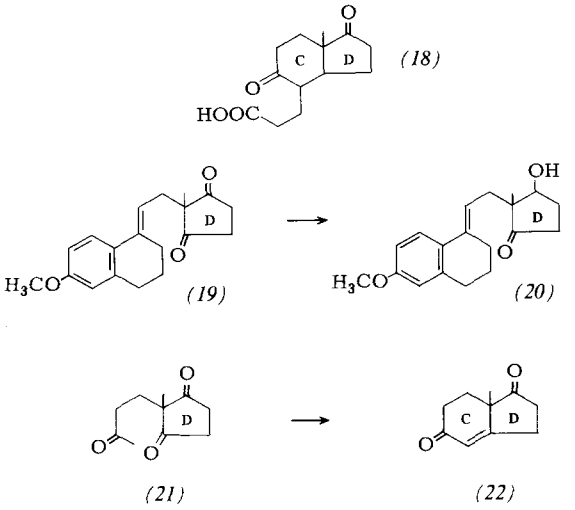
Technically perfected and economic methods of producing completely synthetic estrogens and nor-steroids, whose capacity can be extended at will, have now been available for a number of years. The problems of producing completely synthetic steroids on an industrial scale are dealt with briefly in a later section.

Estrone is a suitable starting material for the production of the progestogen component 19-nortestosterone.



The key reaction is the reduction of phenols with lithium in liquid ammonia, developed by *Birch*. This converts the 17-ketal of the estrone methyl ether *(13)* into the enol ether *(14)*, which on acid hydrolysis gives 19-nor-4-androsten-3,17-dione *(15)*. The compound *(15)* can be converted stereoselectively into 17α-ethynyl-19-nor-testosterone *(5)*.

In 1960 *Barton* discovered a new possibility of synthesizing 19-nor steroids by intramolecular functionalization of the nonactivated 19-methyl group.



The action of light results in the transfer of the nitrite ester in *(16)* to the δ-carbon in the 19-methyl group to give *(17)*. For this to occur the nitrite residue and the methyl group must be axial. This radical reaction can also be achieved under modified conditions with hypoiodites or lead acetate and alkoxides. Compound *(17)* is then converted into a structure from which the C-19 can easily be eliminated in a number of stages.

All the methods of synthesizing steroids discussed so far start from natural substances that already contain the natural tetracyclic structure.

Producing totally synthetic steroids meant finally finding a solution to the difficult problem of synthesizing a substance with several asymmetric centers. In addition, it had to be possible to carry out the process economically on an industrial scale. Although methods of producing completely synthetic steroids had been worked out as early as 1939, with various and, in some cases, highly elegant solutions being published,

only three recently developed methods, in which all the requirements cited above are satisfied, are available for this purpose[12].

Chirality is introduced in each case at different stages in the synthesis. For example, the racemic building block *(18)*, which contains rings C and D, can be resolved into the enantiomers by classical methods. In another synthesis, the prochiral diketone *(19)* is reduced asymmetrically to the alcohol *(20)*, in high yields, by a microbial process. This gives rise to two chirality centers on the later C-atoms 17 and 18.

Finally, the optically active building block CD can be produced at a very early stage in the synthesis by an asymmetric ring closure reaction of the triketone *(21)*. This cyclization is carried out with catalytic quantities of L-proline, obtaining virtually optically pure *S*-configuration indene derivative *(22)* in yields of over 90 %.

To conclude this section on syntheses, it can be said that with the partially and totally synthetic methods of producing steroids we now have at our disposal a wide range of processes that make use of various sources of raw material.

There is not likely to be any shortage of supply of contraceptive steroids in the future.

It is worth mentioning at this point that the country with the largest population in the world, the People's Republic of China, has now built up its own steroid production and makes enough for its own requirements. The production is based on diosgenin obtained from the varieties of *Dioscorea* that grow in China and on fully synthetic production methods.

4. Experience with Contraceptive Steroids

Hormone contraception has been practised throughout the world since 1959 and we can now look back on a period of almost twenty years of use. In 1974, in the Federal Republic of Germany alone, some 34 % of the women of childbearing age were on the pill. Never before in the history of mankind have highly active drugs been used to such an extent for a nontherapeutic purpose, *i.e.* to influence a physiological process in healthy people. Scientists and governments were virtually unprepared to deal with this situation and with the multitude of problems created by it. We are now in the possession of extensive data enabling us to assess the advantages and the possible dangers involved.

There is no doubt that hormonal contraception is more reliable than any of the previously known methods of birth control. The failure rate is 0.2—0.6 per 100 women-years, and these figures even take account of errors in taking the pill and absorption anomalies caused *e.g.* by diarrhea.

The suppression of pituitary hormone stimulation over a prolonged period by ovulation inhibitors is no more unnatural than the situation that prevails during pregnancy and lactation.

Experts consider that the side effects[14] of ovulation inhibitors must be viewed in relation to the side effects and dangers of pregnancy, birth, or even abortion. To consider it in the right context, the method must be viewed as preventive medicine.

The most extensive prospective study of the side effects was published in Britain in 1974 by the Royal College of General Practitioners under the title "Oral Contraceptives and Health". At that time data had been assessed on 46000 women who had been taking oral contraceptives for more than 4 years. The report comes to the conclusion that the advantages of oral contraception outweigh the disadvantages.

In his detailed critical review of the available literature, *Döring*[15] differentiates between harmless, serious, and useful side effects. Here we shall cover just a few of the important points. Given the present state of knowledge, there is no evidence that women who use ovulation inhibitors are more likely to suffer from cancer. Indeed, there are even indications that progestogens give some protection against breast cancer.

The possibility that oral contraceptives promote thromboembolic diseases in predisposed women cannot be excluded on the basis of the data available at present. The risk, however, is much smaller than that associated with pregnancy. In statistical terms, it is equivalent to the risk of dying as a result of smoking $^1/_3$ of a cigarette per day.

Many women make use of oral contraceptives explicitly because of the useful side effects brought about by their application. During the years that the pill has been in use, good results have been obtained in the treatment of such conditions as dysmenorrhea, premenstrual tension, endometriosis, acne vulgaris, and intermediate bleeding. It is an interesting fact that the incidence of endogenous depression is lower among women taking the pill.

5. Other Methods of Birth Control

In addition to the most important method of birth control, namely oral contraceptives, the use of various intrauterine devices[9] has become more and more widespread over the last few years. A figure of as many as 20 million users has been quoted for 1975.

The mode of the action of these devices has not yet been fully clarified. It is thought that they may cause increased peristalsis of the fallopian tubes, with the result that the ovum arrives in the endometrium too early, before nidation is possible.

Copper-coated devices have a greater contraceptive effect, probably because they release minute quantities of the metal

and so cause biochemical changes in the reproductive organs and the sperm. Devices of this type remain effective for about two years.

The discovery of new methods of birth control more effective than those already available depends primarily on a better understanding of the physiological, biochemical, and immunological processes involved in reproduction. However, consideration must also be given to whether new methods are likely to be accepted by the majority of cultures.

The development of a new contraceptive is an extremely risky undertaking and involves a tremendous expenditure of time and money[16, 17]. Thus, if these imponderables are to be realistically assessed, one must be skeptical of those who quickly overestimate the value of every new possible method of birth control with optimism and lack of criticism.

The starting points for new methods of female contraception are offered by intervention in the physiological process of egg-cell development before and after fertilization. Increasing or reducing the rate at which the ovum is transported causes a fertilized egg cell to die. Transportation of the ovum can be influenced with the aid of hormones.

The environment in the fallopian tubes and the uterus is of decisive importance to the ability of the ovum to survive. Changes in the hormonal estrogen-progestogen balance also produce a change in the composition of the tubal and uterine secretions. The hormone-dependent process of implantation of the ovum in the endometrium can only take place if the structure of the uterine mucosa is right. Effective antiestrogens prevent implantation, for example.

The corpus luteum and the hormone it produces are of major importance to the normal course of a number of processes after fertilization. If no progesterone is available, a pregnancy cannot become established and one that has become established will be aborted.

There are a number of possible ways of intervening actively in these processes:

1. Degeneration of the corpus luteum, in which the progesterone is produced, *i.e.* luteolysis. It had been hoped that certain prostaglandins[19] of the $F_{2\alpha}$ series would cause abortion through luteolysis. This has been demonstrated in a number of animal species, *e.g.* in cattle, sheep, and guinea pigs. However, in women, prostaglandins cause abortion only by inducing labor. Their use involves a large number of unpleasant side effects since the action is not selective on the uterus but involves all other smooth-muscle organs to varying degrees. There are indications that these side effects can be averted by local administration.

2. Prevention of the establishment of pregnancy or production of an abortive effect requires true progesterone antagonists, *i.e.* antiprogestogens. Such substances are not yet available.

3. Another promising research direction is looking into compounds that intervene in the enzymatically-controlled biosynthesis of progesterone.

The use of immunological methods of contraception seems highly promising[18]. Some time ago prolonged sterility had been produced in a number of animal species by active immunization with sperm, seminal plasma and testicular and fetal extracts.

One method that might be feasible is active immunization with human chorionic gonadotropin or with the β-unit, a fragment of this peptide hormone. Such immunization has the great advantage of preventing only pregnancy, since the hormone concerned is formed only in the placenta.

New prospects for birth control are offered by the highly successful work done in recent years in the field of releaser hormones. These substances are produced in the hypothalamus and are responsible, since they cause the release of pituitary hormones, for the production of the steroid hormones. The releaser hormone of luteinizing hormone was isolated and synthesized a few years ago. It is a polypeptide comprising ten amino acids. This discovery has opened up the way for intensive biological research.

Another starting point is offered by one of the side effects of the pill which contribute to its contraceptive effect, namely the change produced in the cervical secretions. This important barrier to sperm penetration can be altered with the aid of progestogens so that it becomes impenetrable to sperm. Furthermore, sperm only becomes capable of fertilizing the ovum after it has been in the female genital tract for a certain time. This process, which is also dependent on hormones, is known as capacitation.

It will be clear from this brief review of possible future methods of birth control that there are numerous starting points for female contraception. It would be pointless, however, to speculate which of them can be developed to the point of being put into practice.

It is also too early to say whether one day a method of chemical birth control for men will be found[20]. We are still a long way from being able to suppress male fertility while maintaining potency and libido.

One of the reasons for this lies undoubtedly in the fact that insufficient research has so far been done on the reproductive process in men. A comparable male preparation to the female ovulation inhibitors would be one that inhibited spermatogenesis. However, ovulation takes place only once every four weeks, whereas spermatogenesis is a continuous process, millions of spermatozoa maturing every hour. It is easy to see that intervention here is far more complicated.

Although reversible inhibition of spermatogenesis can be achieved by administering large doses of progestogens, endogenous production of testosterone is brought to a standstill, resulting in loss of libido. This makes it necessary to administer an androgen in addition, again in large doses.

Apart from being badly tolerated, such a combination does not take effect until some weeks after the administration has been commenced. When the treatment is withdrawn, it again takes weeks or months for the fertility to be restored.

The results obtained with nonhormonal chemicals are even less favorable. It is to be hoped that the intensive research going on throughout the world in this very important field of reversible control of male fertility will in the end prove successful.

Finally, we must mention the growing importance of surgical sterilization of men in the developing countries, and also in the industrialized nations.

Female hormonal contraception could undoubtedly provide a reliable method of solving the problem of excessive growth of population. It would certainly not be too difficult to produce the quantities of hormones required to cover world requirements. Only about 6.5 tons of estrogen and 32 tons of progestogen per year would be needed to produce a modern, low-dose

contraceptive in sufficient quantities for the 500 million fertile women in the world.

The American anthropologist *Cora Du Bois* has a terse answer to the question of why this simple sum has not made any impact: in her view, every method of contraception that can be understood only in technical terms and every demographic improvement plan will prove unsuccessful until individuals are convinced of the importance of the problem.

6. Future Outlook

Throughout the millenia over many generations, man has observed that only fertility prevented his race from becoming extinct. The danger of extinction of the human race was only averted three or four generations ago, but this inherited drive has not been forgotten.

The difficulty of explaining the danger of overpopulation is clear when one considers that 900 million people are still illiterate, and the figure is rising despite the UNESCO literacy program.

In the developing countries imported family planning products are often regarded suspiciously as a new variant of colonial imperialism.

This means that the national and private organizations in the industrialized countries must take account of the cultural and social situation in the developing countries when offering assistance with population policy. Even in the industrialized countries family planning is more and more a part of development planning.

Birth control could provide one way for the human race to survive. However, the most important prerequisite is that every person is made aware of the urgent need to stem population growth. Achieving this state of awareness is one of the major tasks of our age.

The Chlorofluorocarbon/Ozone Theory—A Scientific Status Report

By J. Peter Jesson[*]

In 1974 Professors *Rowland* and *Molina* of the University of California at Irvine developed a theory concerning the possible adverse impact of chlorofluorocarbons on the earth's ozone shield. These compounds are the working fluids responsible for the safety and efficiency of almost all air-conditioning and refrigeration equipment and are used as propellants in many types of aerosol products.—The present article is divided into five sections. The first is an historical perspective of the scientific situation up to the end of 1974. The second section examines the various findings and observations on which the theory is founded and outlines new knowledge gained in this sector since early 1975. The third section is devoted to the possible consequences of ozone depletion while the fourth and fifth sections consider the question of the risk taken in delaying a decision to stop production of certain halocarbons.

1. Introduction

1.1. State of Our Knowledge in June 1974

In their original paper[1] *Rowland* and *Molina* derived the ozone depletion theory from the following pieces of scientific information:

There are detectable concentrations of chlorofluorocarbons in the atmosphere [CCl_3F (FC-11) and CCl_2F_2 (FC-12)][2].

Gases rise in the atmosphere and, in the absence of rapid removal processes, are well mixed to altitudes above the ozone layer (most of the ozone is present at altitudes between 10 and 60 km)[3].

Ultraviolet light can break down chlorofluorocarbon molecules, releasing chlorine atoms[4].

[*] Dr. J. P. Jesson
Central Research and Development Department
E. I. du Pont de Nemours and Company
Wilmington, Delaware 19898 (USA)

Computer models, which simulate both the "vertical diffusion" of molecules in the atmosphere and the gas phase chemical reactions (including photochemical processes), had already been developed[5].

A variety of gas phase reactions involving chlorine atoms, ozone, and other known atmospheric constituents had been identified in laboratory experiments and their rates established with varying degrees of certainty[6]. Some of the relevant reactions are:

$$Cl + O_3 \rightarrow ClO + O_2 \quad (1)$$
$$ClO + O \rightarrow Cl + O_2 \quad (2)$$
$$HCl + OH \rightarrow Cl + H_2O \quad (3)$$
$$Cl + CH_4 \rightarrow HCl + CH_3 \quad (4)$$
$$ClO + NO \rightarrow Cl + NO_2 \quad (5)$$

Reactions (1) and (2) describe the catalytic cycle for conversion of O_3 into O_2.

1.2. The Statement of the Theory

On the basis of this information *Rowland* and *Molina* put forward the important theory which suggests a possible impact of chlorofluorocarbon release on the steady state ozone concentration in the atmosphere. They presented new experimental information on ultraviolet absorption characteristics of chlorofluorocarbons and estimated the rate of destruction of CCl_3F and CCl_2F_2 by ultraviolet light at different altitudes.

1.3. The Initial Assessment

To assess the risks involved in a continued experimental program and to provide a baseline to determine whether new experimental information revises predicted ozone depletions up or down, it is necessary to carry out time dependent

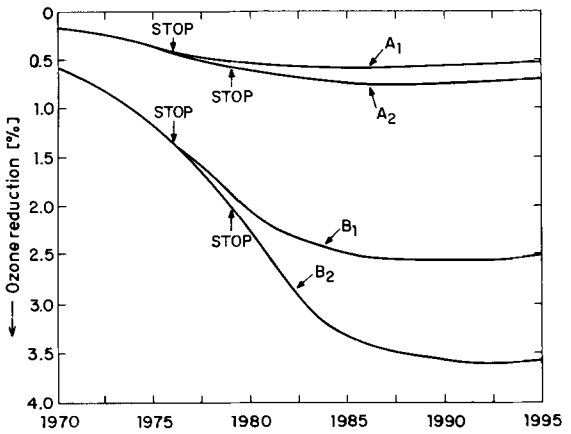

Fig. 1. A comparison of the effects on ozone depletion of stopping fluorocarbon production. Curves A_1B_1: production stop on January 1, 1976; curves A_2 and B_2: production stop on January 1, 1979. Calculations based on the original assumptions of *Wofsy et al.* [7] (B curves) and the best available data todate (A curves). In both cases ozone depletion would peak around 1990, but the estimates are now reduced by a factor of about 5 (the values in curves A are about a factor of 5 lower than the values in curves B).

ozone depletion calculations. This was first done by *Wofsy*, *McElroy*, and *Sze*[7]. The results of calculations based on their original assumptions are shown in Fig. 1 (B curves). These are compared with curves calculated using the same procedures but with the latest experimental input information (A curves). Two production scenarios were assumed in each case (curves A_1 and B_1 correspond to a production stop on January 1, 1976 curves A_2 and B_2 to a stop on January 1, 1979). It can be seen that the estimated short term risk (ozone depletion) is now about a factor of 5 less than the original estimate.

The second important step was to list critical experiments needed to validate or invalidate the theory. A broadly agreed upon experimental program[8] was rapidly set in motion and has now been in progress for about two years. Results have been obtained at an encouraging rate. The basic outline of the program remains the same although priorities change as new information is obtained. Thus it is now thought that chlorine nitrate ($ClONO_2$) is a molecule of considerable importance in the stratosphere, so that attempts to detect it would now rank high on most researchers' lists of experiments. As a secondary consequence simultaneous measurements of ClO and HCl as a function of altitude are urgently required in order to determine whether other molecules, analogous to $ClONO_2$, compete with HCl as a stratospheric chlorine reservoir.

2. The Elements of the Theory and New Experimental Results

We now examine the successive steps in the theory from production, and release of CCl_3F and CCl_2F_2 into the atmosphere, to the eventual removal of their decomposition products, and we consider the progress in defining each step experimentally.

2.1. Production and Release of Chlorofluorocarbons into the Atmosphere

Accurate data on the production and release of CCl_3F and CCl_2F_2 to the atmosphere have been obtained through a survey of the manufacturers carried out by independent examiners. The totals to the end of 1975 are now known. Release to the atmosphere is estimated as being close to 85 % of the amount produced at any given time; this value was obtained by breaking down sales in terms of end use (refrigeration, aerosols, closed cell foam *etc.*) and combining it with a release pattern for each application. For instance is takes roughly twenty years for all the CCl_3F in closed cell foam to be released, whereas aerosol propellants are released quickly.

Total world release to the atmosphere by the end of 1975 was 2.93×10^9 kilograms of CCl_3F and 4.4×10^9 kilograms of CCl_2F_2. Overall estimates of release to the atmosphere are probably accurate to $\pm 5\,\%$[9].

2.2. Tropospheric Lifetimes

It is still not known whether there are processes in the troposphere which destroy chlorofluorocarbons at a rate sufficiently fast to compete with photolysis in the stratosphere as a removal process. If there are such processes, they could lead to large downward revisions in ozone depletion calculations (it is presently assumed that chlorofluorocarbons have an infinite lifetime in the troposphere).

One way to check this point is to compare the amount of CCl_3F and CCl_2F_2 known to have been released to the atmosphere with the amount found to be present by atmospheric measurements. There have been extensive measurements of CCl_3F over a period of five years. Most of these measurements have been carried out at places with mid-latitudes in the Northern hemisphere. Whatever the latitude, any given set of measurements must be converted to a global average before it can be compared with calculated values. There is a higher concentration in the Northern hemisphere, where the halocarbons are released, than in the Southern hemisphere. Experimental latitude data were obtained by *Lovelock*[10] on a voyage of the Shackleton from the north to the south and back in 1971—2. We have used a least squares fit to these data to generate empirical latitude conversion factors[11].

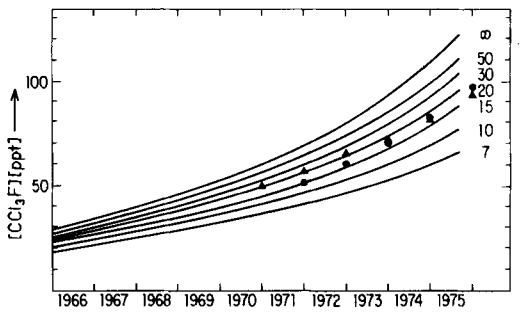

Fig. 2. A comparison of CCl_3F mixing ratios in the troposphere calculated for tropospheric lifetimes of ∞, 50, 30, 20, 15, 10, and 7 years (unbroken curves) with the measurements of *Lovelock*. ▲ Data from exponential least squares fit to all Bowerchalke (England) and Adrigole (Ireland) data (51 °N) adjusted for latitude. ● Southern Hemisphere data adjusted for latitude. ppt = parts per trillion.

A set of theoretical curves for CCl_3F concentrations, calculated as a function of tropospheric lifetime, is compared with the data of *Lovelock*[12] (corrected for latitude) in Figure 2. These data, which were collected in both the Northern and Southern hemispheres over a period of five years lie between the 15 and 20 year lifetime curves. The fact that the Northern and Southern data, after correction for latitude, lie close together is an indication of the internal consistency of the procedure. In all cases the relatively slow Hunten diffusion profile has been chosen. Faster diffusion will lead to longer estimated tropospheric lifetimes.

Recent data from *Rasmussen*[13] suggest a much smaller latitude gradient than found by *Lovelock*[10]. The data of *Rasmussen* could be interpreted in terms of less tropospheric removal than was previously assumed. Further work will be required to resolve this difference. The differences may be real and could be related to atmospheric circulation patterns giving bigger gradients over the Atlantic than over the Pacific. It should be noted, however, that the gradient measured by *Lovelock* has persisted almost unchanged to the present day (if this were not the case, the experimental lines in Fig. 2 would move apart as we approach the present day). A second important point is that if the Adrigole measurements of *Lovelock* are assumed to be high because of industrial release, the calculated global averages would be even lower than estimated in reference[11], indicating a still shorter lifetime. It would also mean a calibration discrepancy between the measurements of *Lovelock* and *Rasmussen*. (The data of *Lovelock* and *Rasmussen* should agree in the Southern hemisphere where there are no local sources of halocarbons, while *Lovelock*'s data in the Northern hemisphere should be higher then *Rasmussen*'s if there is an effect from proximity to centers of release. In fact the reverse is true, *Lovelock* and *Rasmussen* agree quite well in their Northern hemisphere measurements while *Lovelock*'s Southern hemisphere data are lower than those of *Rasmussen*.) Absolute calibrations and cross calibrations are urgently needed.

In recent months, the first direct evidence for possible tropospheric sinks has been obtained. Workers at the National Bureau of Standards have shown that chlorofluorocarbons can be broken down by ordinary sunlight in the presence of sand particles[14]. Large sections of the atmosphere contain sand or dust clouds. It has also been suggested[15] that the detection of $CHCl_2F$ in the troposphere is evidence of a sink for CCl_3F. However, in the meantime some of the measurements have been withdrawn, so that the situation with regard to $CHCl_2F$ is presently unclear. Tropospheric sinks are still an open question.

If the compounds have tropospheric lifetimes as short as ten years, up to 90% of the molecules could be destroyed in the troposphere, lowering depletion estimates by an order of magnitude.

2.3. Upward Mixing and Photolysis

After release halocarbons "diffuse" upwards in the atmosphere and a significant fraction of them reach the stratosphere.

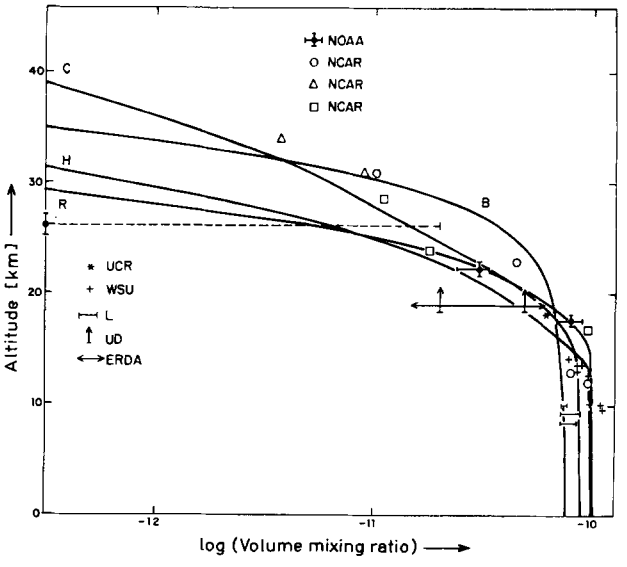

Fig. 3. Comparison of calculated and observed mixing ratios for CCl_3F in the stratosphere. Several eddy diffusion models were used in the calculation. The overall lifetime calculated for CCl_3F assuming an infinite tropospheric lifetime in *Crutzen*'s model II (C) is 34 years, in *Brasseur*'s "Maximum" model (B) 18 years, in *Hunten*'s model (H) 91 years, and in *Rowland*'s model A (R) 97 years. The measurements were carried out by the following groups: ERDA (Energy Research and Development Administration), October 25, 1974; L (*Lovelock*), June 1974; NCAR (National Center for Atmospheric Research), ○: September 9, 1973; △: May 7, 1974; □: June 2, 1975; all at 30° south; NOAA (National Oceanic and Atmospheric Administration), 41° north; UCR (University of California at Riverside), May 23, 1973; UD (University of Denver), August 12, 1968 and September 26, 1975; WSU (Washington State University), May 1975.—Concentrations (v/v).

Measurements have been made of CCl_3F concentrations from below the tropopause to high altitudes in the stratosphere. Figure 3 shows calculated and observed profiles of CCl_3F in the atmosphere for a variety of models. *Hunten*'s model is supported by ^{14}C measurements, but gives theoretical fluorocarbon concentrations (140 ppt at 16 km, 93 ppt at 21.5 km, and 40 ppt at 26 km) which are in poor agreement with the observed mixing ratios. The best fit to the observed data is obtained with the Crutzen II model (one of the faster diffusion schemes). The stratospheric chlorofluorocarbon profiles are largely indications of diffusion and photolysis. Since these steps in the theory have not been questioned, the measurements, although important, do not contribute greatly to the overall testing of the theory.

2.4. Chlorine Atoms by Photodissociation

At sufficiently high altitudes in the stratosphere, chlorofluorocarbon molecules are broken down by sunlight to release chlorine atoms.

2.5. Reactions of Chlorine in the Stratosphere

The fate of the liberated chlorine atoms in the stratosphere is by far the biggest gap in the theory. This concerns both the quantitative aspects of the known chemistry and, more importantly, the possibly existing but still unknown gas phase chemistry. The only way these questions can be answered is by direct measurement in the stratosphere.

The quantitative aspects of the known chemistry can be refined by laboratory measurements—primarily by measurement of reaction rate constants and photodissociation cross sections. This information is then used as input to computer models which attempt to simulate the atmosphere. The models predict concentrations of trace species (HCl, ClO, Cl, NO_2, NO, O_3 *etc.*) in the atmosphere as a function of altitude and these predictions are in turn tested by direct measurement, usually using balloons. Discrepancies are then discussed in terms of possible missing chemistry or inadequacies in the models or the available experimental data. It is believed that, over the next two years, this process will have progressed to the point where we have a good understanding of the effects of chlorine in the stratosphere.

We shall discuss the present situation using a unidimensional computer model of the atmosphere developed at Dupont, together with input information recommended to NASA for use in recent modelling comparisons. The test of the model is how well it can reproduce the concentrations of species already measured in the stratosphere. The modelling results described include multiple scattering of the sun's radiation but do not include diurnal effects.

The basic features of the model include a kinetic scheme covering in excess of 80 chemical and photolytic reactions for 30 atmospheric molecules, atoms, and radicals. Four of these species have fixed concentration profiles (O_2, N_2, H_2, and H_2O). The remaining 26 species (ranging from stable molecules like CH_4 and N_2O to highly reactive radicals and atoms such as HO_2 and $O(^1D)$) are floating, with concentration profiles determined by the kinetics and the boundary conditions. The atmosphere is divided vertically into a variable number of grid points (x) and the resulting array of $30 \times x$ coupled ordinary differential equations is solved using Gear integration techniques. Photodissociation rates are continuously updated. The model is fully time-dependent within the 24-hour average sun approximation and all depletion calculations are carried out using time-dependent fluorocarbon fluxes. Multiple scattering is incorporated using an isotropic scattering radiation model.

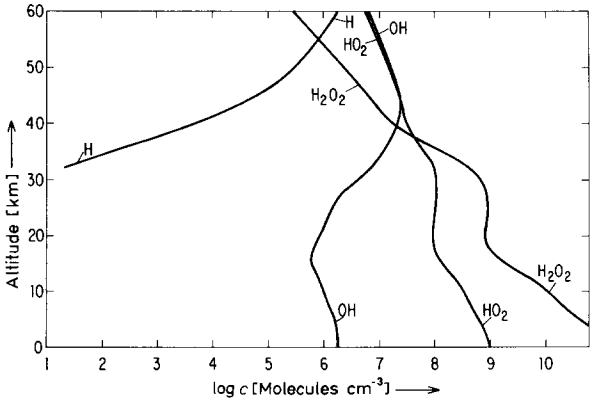

Fig. 4. Calculated concentration profiles for H, OH, HO_2, and H_2O_2 in the atmosphere under present day conditions.

Figure 4 shows calculated concentrations of hydrogen-containing species as a function of altitude. The content of OH radicals in the stratosphere has been measured by *Anderson*[16]. The calculated value of 2×10^7 radicals/cm^3 at 40 km is in good agreement with the measured value. Similar comparisons can be made with measurements on nitrogen-containing species such as NO, NO_2, and HNO_3. Again good agreement is obtained with experiment.

The molecules of greatest interest in the halocarbon problem are those containing chlorine. The detection of HCl in the stratosphere (the major postulated holding tank for chlorine) was recognized at an early date as the most important qualitative evidence supporting the Rowland-Molina theory. Most of the HCl arises from sources of atmospheric chlorine other than chlorofluorocarbons; CH_3Cl, CCl_4, and CH_3CCl_3 are major known contributors. The methyl chloride is of natural origin. The carbon tetrachloride could be either largely man-made or largely natural, depending on its somewhat uncertain atmospheric lifetime. The CH_3CCl_3 is probably man-made. In order to interpret the HCl measurements it is necessary to know the total amount of chlorine reaching the stratosphere—measurements of this type have not yet been made and we still do not know whether all sources of atmospheric chlorine have been identified.

The two other chlorine species, recognized as being important from the beginning, are Cl atoms and ClO radicals. These have recently been measured in spectacular experiments, once again carried out by *Anderson*[17]. The ratio of the concentrations [ClO]/[Cl] is in good agreement with theory but the absolute amounts are higher than predicted.

The chlorine problem has been complicated by the suggestion[18] that chlorine nitrate ($ClONO_2$), a molecule originally thought to be of no importance in stratospheric chemistry, may, in fact, play a major role. The calculated present day concentrations of the various chlorine species in the stratosphere arising from the known amounts of CH_3Cl, CCl_4,

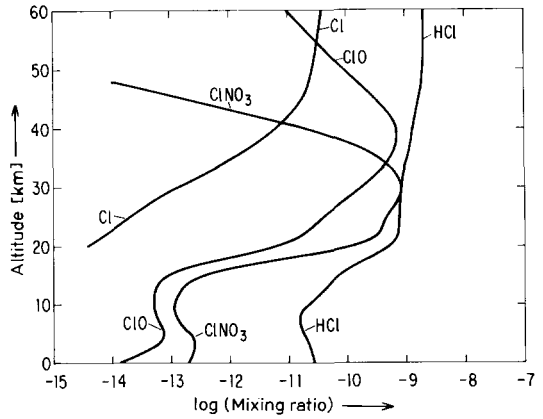

Fig. 5. Calculated concentration profiles for Cl, ClO, HCl and $ClNO_3$ in the stratosphere under present day conditions. Concentrations (v/v).

CH_3CCl_3, and fluorocarbons, are shown in Figure 5. As noted above, the calculations include multiple scattering, which reduces the calculated concentration of $ClONO_2$ (but does not materially effect ozone depletion estimates). The $ClONO_2$ concentrations calculated are, at all altitudes, below the upper experimental limit established by *Murcray*[19]. The inclusion of multiple scattering affects the concentration of all 26 floating species; sometimes, as in the case of $ClONO_2$, quite markedly. As an illustration of this type of effect, the percent change of concentration of $ClONO_2$ as a function of altitude, on including multiple scattering, is shown in Figure 6. Reductions in excess of 65% are calculated in the region just below 20 km.

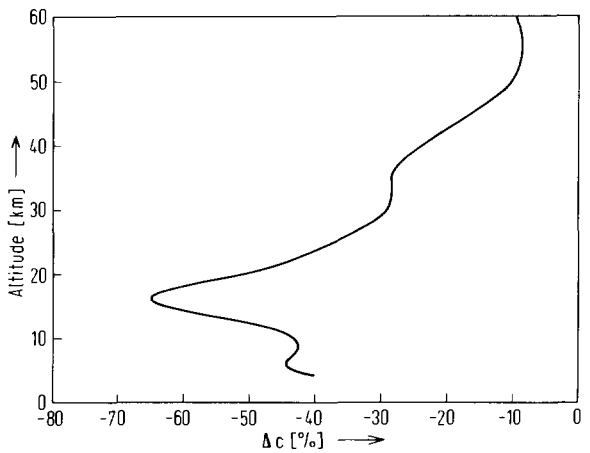

Fig. 6. Calculated effect of multiple scattering of sun's radiation on $ClONO_2$ concentration as a function of altitude. Change of concentration Δc is quoted. An albedo of 0.25 is assumed.

For meaningful comparison of theory and experiment in the case of chlorine species in the stratosphere most of the following steps are essential: a) construction of models which accurately account for diurnal variations, b) determination of the total amount of chlorine reaching the stratosphere, c) more extensive simultaneous measurements of Cl, ClO, and HCl, particularly determination of the [ClO]/[HCl] ratio, and d) measurement of $ClONO_2$ in the stratosphere. For the present, we briefly outline the current anomalies in the data on chlorine species in the stratosphere and indicate the types of explanations which may account for these anomalies.

HCl: hydrogen chloride has now been measured in the stratosphere at altitudes between 16 and 39 km using a balloon-borne, pressure-modulated radiometer[20]. A peak mixing ratio of about 2 ppb is observed at 32 km with a steady decrease above and below that altitude. From Figure 5 it can be seen that the calculated HCl mixing ratio at 32 km from the known sources of chlorine is *ca.* 0.8 ppb, a factor of about 2 too low. More importantly, the calculated HCl mixing ratio increases monotonically above 32 km, whereas the measured value goes through a maximum.

ClO and Cl: The measured ClO values peak between 30 and 35 km with peak values covering the range 2×10^8 to 8×10^8 radicals/cm^3. The calculated value in Figure 5 peaks at about 35 km with a value of 9×10^7 radicals/cm^3, *i.e.* between a factor of 2 and a factor of 9 less than the measured values.

As already mentioned above, the [Cl]/[ClO] ratio is in very good agreement with theory.

Variability of the overall data is expected (hence the importance of obtaining simultaneous measurements of ClO and HCl) so that from a theoretical point of view, the key feature to be explained is the decrease in HCl mixing ratio above 32 km. The following overall explanations are possible:

1. The ratio of ClO to HCl is higher than the models predict because of errors in the known chemical reaction rates. Under these circumstances more of the chlorine would be in the form of ClO and a decrease in concentration of HCl above 32 km would be calculated. This type of effect can be reproduced theoretically by arbitrarily adjusting reaction rates.

2. The ratio of ClO to HCl is similar to that calculated in the models. Under these circumstances the only likely explanation for the decrease in HCl mixing ratio would be the role of hitherto unknown chemical factors which have not been taken into consideration in the models (*e.g.*, another chlorine holding tank analogous to $ClONO_2$).

3. The decrease in HCl mixing ratio is an experimental artifact. This now seems unlikely since it has been observed on numerous occasions.

In all three cases it is possible that we are seriously underestimating the amount of chlorine reaching the stratosphere. It could be that the flux of CH_3Cl is much greater than currently assumed (the measured concentrations of CH_3Cl in the atmosphere are very variable, so that a serious underestimation of the flux is not unlikely) or there may be other unidentified sources of chlorine such as volcanic activity.

Alternatively, the current estimates of chlorine flux in the stratosphere may be quite accurate, in which case the high experimental values could arise from calibration errors.

2.6. Removal of Chlorine from the Stratosphere

This is the final step in the chain bringing the chlorine back to the earth's surface. At present this is assumed to occur by downward diffusion of HCl followed by rainout in the troposphere. If there are other stable chlorine compounds in the stratosphere, they could also contribute to this process.

From the above discussion it can be seen that the major uncertainties in the theory lie in the following areas:

The fate of the chlorine atoms in the stratosphere.
The tropospheric lifetimes.
The quantitative aspects of the known chemistry.
The problem of transport.

The uncertainties in these areas can be substantially narrowed within the two year period for research suggested by the National Academy of Sciences[21]; progress is already being made in that direction.

3. Current Estimates of the Effects of Fluorocarbons on Ozone

Although it is clear from Section 2 that much more research is required to settle the question whether chlorofluorocarbons have a significant effect on stratospheric ozone, it is important to make the best possible estimates of the effect on the basis of current knowledge, particularly to assess the potential risk of a continued experimental program.

Ozone depletion estimates can be made using the kind of computer models already described in Sections 1.3 and 2.3 of this article. The best starting point for the present discussion is an appraisal of the results published by the National Academy of Sciences (NAS) in September 1976[21]. The report concluded that continued release of fluorocarbons at 1973 levels would lead to an ultimate decrease in stratospheric ozone of about 7.5 % (a level which would be reached about 100 years from now). It was also concluded that the risks of delay are small (about 0.07 % incremental effect for each additional year of production).

Since the publication of the NAS report a number of rate constants have been refined (particularly those for the reactions HO_2+OH and $ClO+NO_2$). These result in a reduction of the 7.5 % figure to 3—5 % (5.1 % in the Dupont model, *ca.* 3 % in the NAS model), with a corresponding reduction in the incremental effect for continued production (*ca.* 0.05 % per year).

The NAS calculations did not include the effects of diurnal variations in the sun's radiation. Complete calculations of this type have not yet been carried out. Approximate treatments suggest that the effect will revise the depletion estimates upwards. Complete diurnal calculations should be available in the near future.

4. The Question of Delay

It is important to recognize that steady state depletion estimates, such as the 7.5 % NAS number, refer to conditions which would pertain about 100 years from now if chlorofluorocarbon production were maintained indefinitely at 1973 levels. These numbers are not directly relevant to the questions of immediate risk and of regulation. To address these questions we need estimates of the effects of allowing production to continue while research is being carried out, relative to stopping production immediately. The incremental effects for each additional year of production are *ca.* 1/100 of the steady state numbers (*i.e. ca.* 0.07 % for the NAS 7.5 % figure). In terms of the known latitudinal variation of ozone, a 0.07 % effect corresponds to the increased ultraviolet light experienced in moving 5 miles south of one's present location.

Considerations of this kind, combined with the uncertainties in the science, led the NAS to recommend that regulations restricting the production of chlorofluorocarbons not be enacted at this time and to allow up to two years delay for research to be carried out in order to establish the facts with regard to ozone depletion.

As an alternative approach to monitoring the risk of delay, it would be desirable, using measurements of trends in total ozone, to establish a sensitive early warning system for possible man-made effects on the ozone layer. An important first step has been taken in this direction by *Hill et al.* and by *Parzen* and *Pagano* using time-series analysis of ozone records from a number of specific ozone monitoring stations. *Hill et al.* reported at the Autumn 1976 meeting of the American Chemical Society that on the basis of a worldwide sample of nine stations, an abnormal global ozone change of 0.26 % per year persisting over 6 years would be judged statistically significant, if it were to occur and could not be explained by historical patterns. A resulting 1.56 % early warning can limit maximum reversible depletion to 2.3 % if the cause were due to the chlorofluoromethanes CCl_3F and CCl_2F_2. The analysis shows no abnormal global trend persisting in the 1970's. The potential exists for detecting even smaller changes by using data from all the current land based stations and satellites.

Thus, this approach already offers the possibility of an early warning system which could limit the maximum ozone depletion to a level close to that which many people would find acceptable, and that level would persist for a relatively short period of time.

This type of ozone-trend analysis should be given highest priority.

5. Tolerable Depletion

It is clear that many of man's activities such as the use of nitrogenous fertilizers, the flight of jet aircraft, and the production of halocarbons, will have some effect on the ozone layer. In each case an acceptable effect will have to be decided upon by governmental bodies. We do not live in a zero risk world. (*Conventional* subsonic aircraft are currently thought to have a 0.1—0.2 % impact on ozone.)

The NAS has suggested that a 2 % figure is one "which we think most informed people would judge to be tolerable". It is clear that new scientific knowledge could lead to ozone depletion estimates well below 2 %.

"Organic Metals"—The Intermolecular Migration of Aromaticity

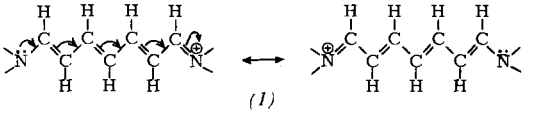
By Jerome H. Perlstein[*]

The electrical conductivity of a wide variety of organic materials is reviewed and a comparison made between those materials which transport charge efficiently and those that do not. This comparison reveals that the most efficient conductors contain molecules a) whose radical ions form a new aromatic sextet upon one-electron oxidation or reduction and b) whose aromaticity can migrate by mixed-valence interaction. The electrical data are presented in light of the chemistry of these materials and the importance of chemical bonding interactions in the electron transport process. Several new examples are discussed and directions for further research explored.

("... an experimental and very real result of ours, points towards the reason why high-transition-temperature superconductors are so difficult to make ... We have realized that most high-transition-temperature superconductors are not very stable, they are metastable at best. Therefore, any search for high-transition-temperatures must concentrate on metallic phases that should never have been formed in the first place.")

Bernd T. Matthias[1]

1. Introduction

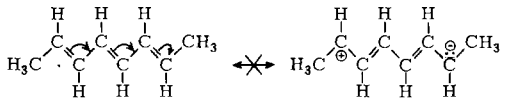


The concept that certain organic molecules in the solid state can have the electrical properties of a metal has received considerable attention among solid state chemists and physicists. No less than nine review articles[2–10] and the proceedings of three conferences[11–13] have been published on this subject in less than four years. One may well ask why write another review? A perusal of the literature on organic conductors indicates that the majority of papers have been directed toward solid state physics with little attention given to the needs of the synthetic organic and physical organic chemists who, after all is said and done, are the creators of those magnificent molecular structures which keep solid state research alive and well. This review then is written by a solid state chemist, for chemists and especially for those synthetic chemists I have had and still have the privilege to work with.

The majority of the theoretical models that have been developed to explain the creation and migration of electrons in organic conductors are highly physical in their origin as in fact they must be if the subject is to have a firm foundation. The chemist, however, in reading through the vast literature must be perplexed by an apparent lack of any chemical foundation for the subject; I say apparent, because either the foundation a) is obvious and therefore need not be stated or b) has been completely forgotten in what can only be described as a mad rush to synthesize and study anything that looks as if it might be potentially useful.

A close examination of what has been done chemically reveals that there are some unifying features of the chemistry which ought to have predictive consequences for what to look for in future materials; chemical features which the synthetic chemist can latch on to.

2. Some Solid State Fundamentals—Mixed Valence Interactions



The most general feature of efficient charge transport in organic systems is the existence of equally spaced atoms or molecules not all in the same oxidation states. The simplest example[14] is a cyanine *(1)*, in which the resonance structures

(1)

indicate the migration of positive charge from one end of the molecule to the other. There are ten electrons distributed over nine atoms, *i. e. ca.* 1.1 electrons/atom. This incommensurate ratio arises from the formally different oxidation states of the two nitrogen atoms. Such a molecule would be "metallic" if it were infinitely long and one could attach electrical leads to it. Compare, however, *(1)* with *(2)*: the resonance structure for *(2)* is energetically unfavorable. Charge migration will thus not occur here. There are no mixed-valence interactions; all the π-electrons are on atoms in the same oxidation state

[*] Dr. J. H. Perlstein
Research Laboratories, Eastman Kodak Company
1669 Lake Avenue, Rochester, New York 14650 (USA)

(2)

and there is exactly one electron/atom. The bond lengths will thus alternate between pure single and pure double bond character. In *(1)* the π-electrons can delocalize over all sites, but in *(2)* they cannot.

There is a molecular orbital approach equivalent to the above resonance description which is instructive and can be applied to some practical examples from donor-acceptor chemistry. A linear array of iodine atoms each with one unpaired electron in a valence p orbital is shown in Figure 1.

In Figure 1a, two iodine atoms are brought together to form an I_2 molecule with two electrons in a bonding orbital. The separation between the filled bonding orbital and the empty antibonding orbital is four times the one-electron exchange integral t (also called the transfer integral).

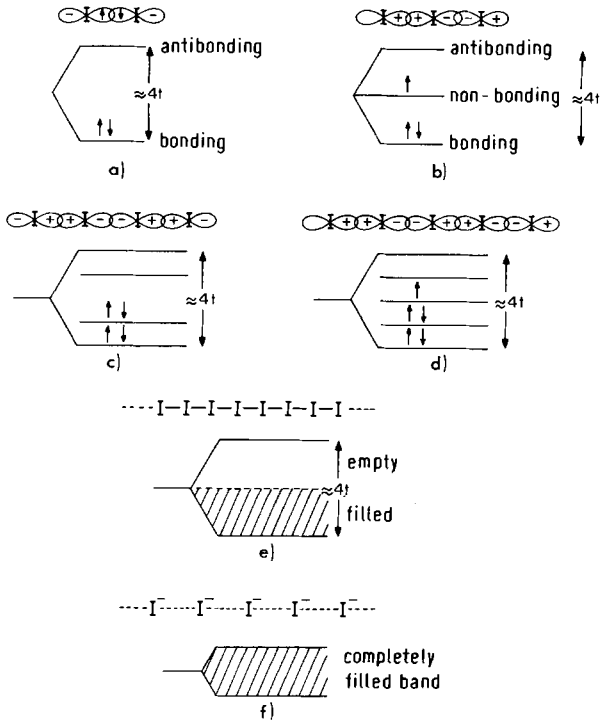


Fig. 1. LCAO-MO energy level scheme for: a) I_2 molecule; b) I_3; c) I_4; d) I_5; e) I_x; and f) $(I^-)_x$. Notice that separation between lowest filled and highest empty MO (*ca.* 4 *t*) is roughly independent of the number of atoms in the chain.

In Figure 1b, for a chain of three iodine atoms there are now three molecular orbitals and three valence electrons to fill them. The bonding-antibonding separation is still about 4 *t*. In Figures 1c and 1d, there are four and five iodine atoms bonded together with a concomitant increase in the number of energy levels. The total energy spanned by these states is still about 4 *t*. Finally in Figure 1e is shown a large number of iodine atoms bonded together. The number of energy levels has now increased enormously and the levels are still all crammed into a width of *ca.* 4 *t* wide. The resulting energy band (Fig. 1e) is only half-filled because in filling it we put *two* electrons into each state obeying the Pauli exclusion principle but there is only *one* valence p electron from each iodine atom. In this molecular orbital description, the electrons in Figure 1e can easily move into the nearby vacant adjacent levels and thus such a linear chain of iodine atoms would be metallic. It does not, however, exist. An iodine crystal is not metallic, it does not contain iodine atoms with equal bond lengths, and it is not mixed valence.

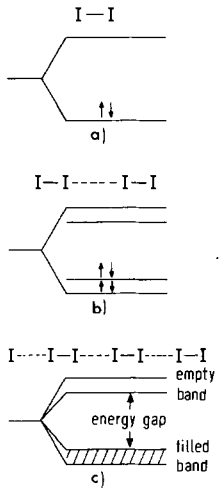

Fig. 2. LCAO-MO energy level scheme for a chain of I_2 molecules a) I_2; b) $(I_2)_2$; c) $(I_2)_x$. Dimerization produces an energy gap not present in Fig. 1e.

A chain of I_2 molecules is an insulator because it has a localized single bond between every two atoms. The equivalent MO picture is shown in Figure 2. In Figure 2a the I_2 energy level scheme is again shown; in Figure 2b two I_2 molecules are brought together. The bonding and antibonding orbitals of I_2 split into two states each, with the bonding orbitals filled. Finally in Figure 2c for the long linear array of I_2 molecules, the bonding orbitals of each I_2 molecule form a band which is completely filled and the antibonding orbitals also form a band which is completely empty. The linear I_2 chain is an insulator, the filled states are separated by a large energy gap from the empty states. Chemically this result comes as no surprise. Interestingly, however, Figure 2c is obtained from Figure 1e simply by moving every other

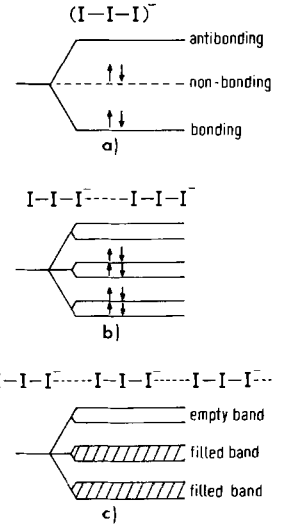

Fig. 3. LCAO-MO energy level scheme for a chain of I_3^- ions. a) I_3^-; b) $(I_3^-)_2$; and c) $(I_3^-)_x$.

iodine atom a little to the left. The one-dimensional iodine metal is thus transformed into the one-dimensional I_2 insulator by alternating the bond lengths (also called a Peierls' distortion or Peierls' instability in solid state physics). One can also see that a linear chain of I^- ions is an insulator as in Figure 1f, and that a linear chain of I_3^- ions is an insulator (Fig. 3a—c).

The instability of the metallic polyiodine chain with respect to a distortion into poly-I_2 insulator can be understood in still another way. The polyiodine chain has only one electron per bond or a bond order of $^1/_2$ while the poly I_2 chain has two electrons per bond or a bond order of unity. Thus as long as we insist on maintaining one electron per iodine atom, we cannot stabilize a metallic state.

3. Charge Transport in Donor-Acceptor Complexes: Aromatic Hydrocarbon-Halogen Interactions

Suppose we now do some chemistry. We take advantage of the known electron acceptor properties of iodine by placing it in the presence of a donor which transfers electrons to iodine. We thus start filling the empty antibonding band of Figure 2c. It is at this point where the chemist's perceptual knowledge of donor-acceptor interactions becomes crucial. If he uses a super-donor like an alkali atom, the empty antibonding band will be completely populated. As a consequence the I_2 bond order will drop precipitously towards zero causing the iodine atoms to separate into I^- ions and to become insulating (Fig. 1f). It would be preferable to transfer just a small electron density to I_2, and thus to maintain the bond order close to unity while at the same time putting electron density into the empty antibonding band (Fig. 2c). In effect the I_2 chain becomes mixed-valent by reducing some of the iodine molecules.

Table 1. Room temperature electrical conductivity of iodine complexes with aromatic hydrocarbons.

Uncomplexed aromatic hydrocarbons		$<10^{-14}$	
I_2		$\approx 10^{-11}$	[21, 24]

Table 1 presents a number of interesting complexes of iodine with aromatic hydrocarbons acting as weak donors. Structurally they are not well characterized but nevertheless represent the first examples of moderately high electrical conductivity in organic materials.

Electrical conductivity σ is experimentally determined from relation (a)

$$\sigma = \frac{L}{AR} \qquad \text{(a)}$$

where L and A are the specimen length and cross-sectional area in cm and cm^2, respectively, and R is the specimen resistance in ohms [Ω]. R is determined from Ohm's Law

$$R = \frac{V}{I} \qquad \text{(b)}$$

where V is the voltage measured along the length L when a current I in amperes is passed along L.

These iodine complexes have electrical conductivity 8—10 orders of magnitude larger than iodine itself and 12 orders of magnitude larger than the pure hydrocarbons. The unpaired spin concentration per iodine atom is small[22], about 0.016 electrons/I atom. The small free electron density is consistent with a weak donor-acceptor interaction

$$D + I_2 \rightleftarrows D^{\delta+}(I_2)^{\delta-} \qquad (5)$$

with $\delta \approx 0.032$ and with the fact that iodine readily sublimes out of the complexes in air.

The electrical conductivity measurements were unfortunately all performed on compressed powders. The polyiodine chain is broken up by such a procedure, lowering the σ values considerably. We can nevertheless get a good estimate of the true bulk values from the known spin density. σ depends on the product of two quantities[23], a) n the number of charge carriers/cm^3 in the band and b) μ, the velocity of charge carriers per unit of applied electric field (also called the mobility):

$$\sigma = ne\mu \qquad \text{(c)}$$

where e, the charge of an electron is in coulombs (1.6×10^{-19} C) and μ in cm^2/Vs. For I_2[24], μ is about 1[*]. For the perylene·I_3 complex of density[18] 2.94 g/cm^3:

$$n = \frac{(0.016/\text{I})(3 \times 6.02 \times 10^{23}\ \text{I/mol})(2.94\ \text{g/cm}^3)}{633\ \text{g/mol}} = 1.3 \times 10^{20}\ \text{electrons/cm}^3$$

$$\sigma = (1.3 \times 10^{20})(1.6 \times 10^{-19}\ \text{C})(1\ \text{cm}^2/\text{Vs}) = 20\ \Omega^{-1}\ \text{cm}^{-1}$$

This value for σ is about two orders of magnitude larger than the compressed powder measurements of Table 1 which

[*] This value is for holes. Electron mobility is probably somewhat larger.

is about right when a comparison between powder conductivities and single crystals is made on a large number of organic conductors.

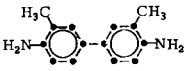
In Table 2 the electron concentration n, the mobility μ, and the electrical conductivity σ of the perylene·I_3 complex are compared with the corresponding values for a variety of other well-known materials in order to put the conductivity data in better perspective.

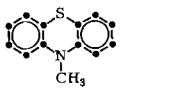
Table 2. Electrical properties for a variety of well known materials.

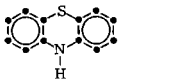
Material	σ [Ω^{-1} cm^{-1}]	n [cm^{-3}]	μ [cm^2/Vs]
Ag	6.6×10^5	5.8×10^{22}	70
Cu	6.4×10^5	8.5×10^{22}	47
Hg	4.4×10^4	4.2×10^{22}	6.6
InSb	3.5×10^2		6.5×10^4
n-Type Si	4×10^1	1×10^{18}	240
TCNQ salts	$1-10^3$	$\approx10^{21}$	4 [25]
Perylene·I_3	2×10^1	1.3×10^{20}	$\approx$ 1
Anthracene	$\ll10^{-14}$	$\ll10^{+5}$	$\approx$ 1
Teflon	$\ll10^{-14}$		

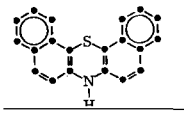
Two comparisons can be made immediately. Organic crystalline materials generally have charge carrier mobilities of order unity comparable with that of mercury but considerably lower than that of the best semiconductors such as silicon or the good metals copper and silver. Secondly, where organic crystalline materials have high conductivity it is generally due to the presence of a high density of unpaired *electrons which are free to migrate* from molecule to molecule. Where the conductivities are low, however, it is not necessarily due to the absence of unpaired electrons (as shown by anthracene). The mere presence of radical ions is no guarantee that the unpaired spins will migrate, as will be shown by examples presented in Section 4.

Thus for the aromatic hydrocarbon-iodine complexes, I have assumed that the unpaired electrons associated with the hydrocarbon do not contribute to σ. The reasons for this will be outlined in Section 5.









4. Aromatic Amine-Iodine Complexes

All else being equal, a decrease of the ionization potential of the donor will result in an increase in the amount of charge transferred from the donor to the I_2 antibonding band of Figure 2c. The bond order of I_2 will drop below unity and thus the iodine-iodine spacing will increase. Since the energy gap in Figure 2c is determined by the iodine-iodine spacing, this gap will also decrease. Will this gap go to zero? Probably not. At exactly $^1/_3$ electron/I atom transferred the polytriiodide state $(I_3^-)_x$ becomes stable (Fig. 3c). However, slightly more or slightly less than $^1/_3$ electron/I transferred should help to stabilize a metallic state.

Table 3 surveys some data on aromatic amines, oligoanilines, and phenothiazine complexes with iodine. Except for *N*-methylphenothiazine, all the data were determined by compressed powder measurements. The *N*-methylphenothiazine result is interesting. It shows the two order of magnitude increase in σ of single crystals over compressed powders.

The amine complexes as a group tend to be more air stable and somewhat more conductive than the aromatic hydrocarbon complexes.

Table 3. Room temperature electrical conductivity of iodine complexes of aromatic amines and phenothiazines.

	DI_3	0.05	[28]
	DI_3	0.05	[28]

[a] Single crystal data in parenthesis.

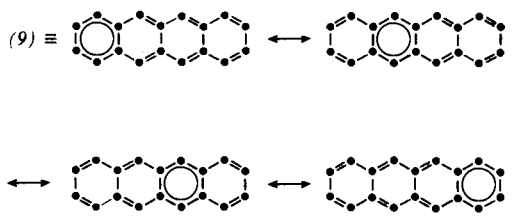
Two crystal structures are known, that of *(7)*[32,33] and that of *(8)*[34]. In *(7)* the iodine atoms are indeed arranged in I_3^- columns with two short bonds of 2.99 Å and one longer bond of 3.44 Å. The interlayer amine spacing is large, about 3.77 Å. Little charge transport along the organic ions is expected for this large separation and the entire conductivity can be attributed to charge migration along an I_3^--like chain. In comparison, the crystal structure of *(8)* shows I^- ions and no polyiodine chain; the interlayer amine ring contacts are 3.42—3.48 Å.

The structure of *(7)* and its five order of magnitude higher conductivity than *(8)* strongly suggests that where high conductivity occurs in aromatic amine-halogen complexes it is due to charge migration along a polyhalogen chain.

5. Mixed-Valence Interaction and the Intermolecular Migration of Aromaticity

The picture that emerges from an examination of the data on iodine complexes is one in which there are separate chains

of donor molecules D and acceptors A with only partial charge transfer from D to A. D and A are then formally present in more than one oxidation state. We indicated earlier that such mixed-valence interaction is one condition necessary for stabilizing a metallic state against a distortion into an insulating state (the Peierls distortion)[*].



There is one serious dilemma, however. If there is partial charge transfer in the iodine complexes, then the mixed-valence donor stack should transport charge as well as the iodine acceptor chain. Nevertheless, although they form radical cations, the donors listed in Tables 1 and 3 do not seem to effectively transport charge. This observation is generally true for the large number of radical cations and radical anions that are known in organic chemistry, with a few exceptions.

An examination of efficient charge-transporting organic donors and organic acceptors shows one common chemical feature not possessed by other donors or acceptors—the donors upon forming a radical cation by loss of one electron also form a new aromatic sextet not present in the neutral donor. Similarly the acceptors upon gaining an electron form a new aromatic sextet not present in the neutral acceptor.

(9)

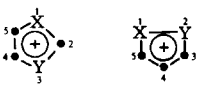
In a simple and convincing exposition, *Clar*[35] has shown that a molecule like naphthacene *(9)* has only one aromatic sextet. In *(9)* the Robinson-Clar[36] notation is used, where a circle symbolizes the aromatic sextet[36] and an arrow[35] indicates that the sextet can migrate intramolecularly from ring to ring as in *(10)*.

(10)

A structure such as *(11)* would be incorrect since it indicates that there are four aromatic sextets with a total of 24 π electrons.

(11)

Examination of the donors in Tables 1 and 3 shows that none of them forms a new aromatic sextet upon radical cation formation. Thus *(12)* has the same number of aromatic sextets as its radical cation *(13)*.



(12)

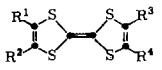
(13)

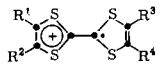
Examination of the donors and acceptors in Table 4 on the other hand indicates that at least one new aromatic sextet is formed upon radical ion formation. All of these donors form good electrical conductors when complexed with the acceptors 2,2′-(2,5-cyclohexadiene-1,4-diylidene)bispropanedinitrile (TCNQ) or 2,2′-(1,4,6,9-bicyclo[4.4.0]decatetraene-3,8-diylidene)bispropanedinitrile (TNAP), some of them having room temperature σ values within an order of magnitude of mercury metal. In those cases where crystal structures are known, there are separate stacks of donors and acceptors, so that charge migration can occur along each stack.

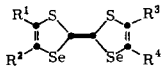
As a perusal of Table 4 indicates, the class of donor radical cations are all derivatives of either 1,3- or 1,2-dithiolium, -diselenolium, or -thiaselenolium cation *(30)*, the aromaticity of which has been reviewed in some detail in ref. [77].

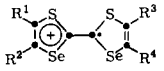
X, Y = S, Se

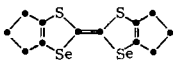
(30)

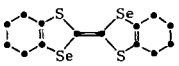


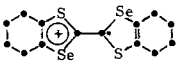


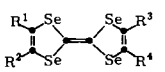


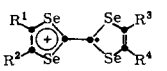


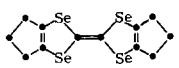


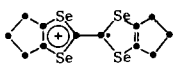


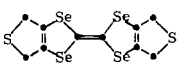


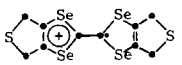


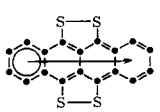


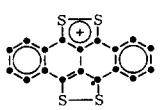




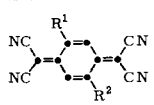


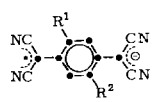


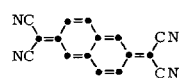




The aromaticity of the acceptor radical anions, particularly $TCNQ^{\cdot-}$, is consistent with a) the tendency toward ring bond length equalization in ring *(28)* on going from neutral TCNQ[78] to the anion radical[79], b) the small unpaired spin density per ring carbon atom (0.066) as determined by EPR[80,81], and c) *ab initio* calculations of the electron density[82] which indicate benzenoid character for the radical anion.







While the number of donors and acceptors which form a new aromatic sextet and have high electrical conductivity is presently limited in scope, there is considerable weight of other evidence which supports the conclusion that the presence of aromaticity plays an essential role in charge transport. Thus in Table 5 are listed a considerable number of donors and acceptors, none of which form a new aromatic sextet upon oxidation or reduction, respectively. Except for *(37)* and *(40)*, the σ values are considerably lower than those measurements in Table 4 which were done on compactions [*e.g.*, compare *(16)*, *(17)*, *(20)*, *(21)*, *(22)*, and *(27)*]. *(37)* is interesting in that the electrical conductivity of *ca.* $10^{-1}\,\Omega^{-1}\,cm^{-1}$ can only be due to the cation in the mixed-valence state. Compared to the fluoroborate of *(14)*[93] with $\sigma < 10^{-6}\,\Omega^{-1}\,cm^{-1}$, *(37)* is unusual and should be studied in more detail. *(40)* is also unusual. It is not formed cleanly by direct reaction of donor with acceptor in trichlorobenzene. An X-ray crystal structure would help to determine whether the donor contributes to the charge transport.

It would thus appear on the basis of what we have discussed so far that the ability for charge to efficiently migrate from one molecule to another is closely linked to the presence of an aromatic sextet which can also migrate from one molecule to another. Figure 4 qualitatively demonstrates for TCNQ how this charge migration might occur along with the aromaticity. A TCNQ stack will formally contain molecules with mixed valency; some neutral and some as radical anions but all equally spaced. In Figure 4a the radical anion is aromatic; the neutral molecule below it is not. Migration of the unpaired electron transfers the aromaticity to the neutral molecule as in Figure 4b and then again as in Figure 4c. The aromaticity in effect diffuses intermolecularly over the molecules in the chain. The idea here is similar to that expressed by *Clar*[35] for intramolecular migration of aromaticity as in *(10)*.

[*] There are other conditions necessary for stabilizing a "one-dimensional" metal. See Section 7.

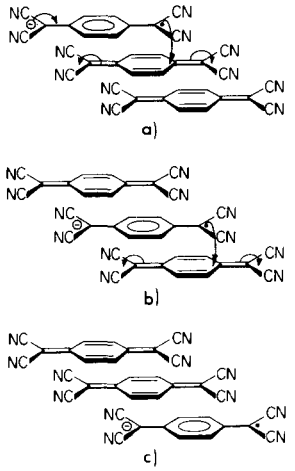

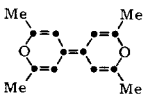

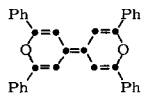

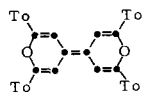

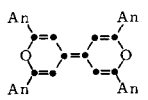

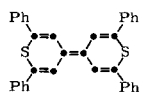

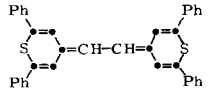

Fig. 4. Stacking arrangement for mixed-valence TCNQ ions: a) $TCNQ^{\bullet-}$ with aromatic sextet transfers charge to neutral TCNQ with no aromaticity resulting in b) and then again in c). Aromaticity migrates down the TCNQ stack along with the unpaired electron.

Perhaps the most important utility of the formation of a new aromatic sextet is its predictive capability. Thus *(45)*—*(47)* and the unannelated donors of *(31)* and *(35)*—*(38)* would be expected to form one aromatic sextet on one-electron oxidation. They belong to the more general class of Weitz radicals described by *Hünig*[95,96] in which there is an even number of carbon atoms between the heteroatoms. Any Weitz radical whose formation involves generation of a new aromatic sextet should transport charge more readily than any radical that does not have this capability. Table 6 lists some examples: if grown as single crystals the TCNQ salts *(52)* and *(53)* should be comparable to complexes listed in Table 4.

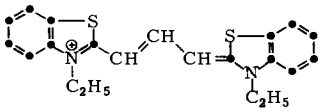
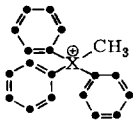
Table 6 also points out one of the dilemmas associated with choosing new donors. Substituting phenyl groups for methyl groups on the bispyranylidene rings enhances the conductivity by 10^6. Most of this difference is probably associated with the chemical reactivity of the methylated carbon in the cation radical state, but part of this difference is most likely related to the wrong stacking behavior of the radical ion, as in *(51)* where a bent CH_3—O bond sterically interferes with the overlap of neighboring donors and thereby severely reduces the transfer integral for charge migration.

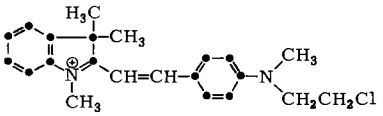


6. Tetracyanoquinodimethane Salts with Closed Shell Nonconducting Cations—General Structural Properties of $D_x^+\,TCNQ_y^-$



Tetracyanoquinodimethane *(28)* readily forms a radical anion reversibly, with a new aromatic sextet ($E_{PC}=+0.17$ V *vs.* SCE in CH_3CN[99]). Formation of the dianion is much more difficult ($E_{PC}=-0.36$ V *vs.* SCE in CH_3CN[99]) and only one isolable compound of the dianion has been reported[100]. The dianion has no additional aromatic stabilization.

Salts of the radical anion form a rich variety of stoichiometries[101] and crystal structures. In a number of instances a salt will form more than one phase depending on the rate and temperature of crystallization from solution (see Section 8).

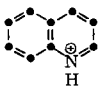


Crystal structures elucidated up to 1972 have been reviewed by *Shibaeva* and *Atovmyan*[102]. The general features of these structures indicate that the arrangement of the $TCNQ^-$ ions within a stack is a very strong function of the nature of the cation. Cations which are very much smaller than or very much larger than TCNQ do not form salts in which the TCNQ molecules are equally spaced and structurally equivalent. Thus the salts of small alkali metal cations[103], $Na^+TCNQ^{\bullet-}$ and $K^+TCNQ^{\bullet-}$, have $TCNQ^{\bullet-}$ dimer structures. $Rb^+(TCNQ)^{\bullet-}$ has two phases, one with dimers, the other with equally spaced but structurally non-equivalent ions[103]. Cs_2TCNQ_3 shows trimer formation[104]. Salts with large or bulky cations tend to show either TCNQ dimers

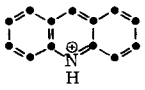
$(TCNQ)^{\bar{}}$ *(54)*

$(TCNQ)_2^{\bar{}}$ *(55)*

$(TCNQ)_2^{\bar{}}$ *(56)*



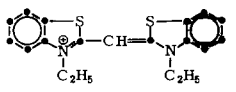
X = P, As

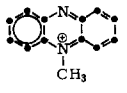


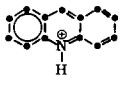
$(TCNQ)_2^{\bar{}}$ *(57)*

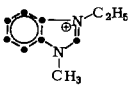
as in the examples *(54)*[102] and *(55)*[102], or tetramers as in *(56)*[102] and *(57)*[102].

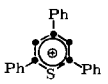
The electrical conductivity of these salts is low ($\sigma < 10^{-2}$ Ω^{-1} cm^{-1}).











The best conductors ($\sigma > 10^{+2}$ Ω^{-1} cm^{-1}) in this group, *i.e. (58)*[105–107] and *(59)*[108], contain cations which are planar and approximately the same size as TCNQ.

$(TCNQ)_2^{\bar{}}$ *(58)*

$(TCNQ)_2^{\bar{}}$ *(59)*

Crystal structures of *(58)*[102] and *(59)*[109] show equally spaced and equivalent TCNQ molecules with an interplanar spacing of *ca.* 3.2 Å. The interplanar spacing of the cation is of the order of van der Waals spacing 3.5 Å for *(58)* and 3.4 Å for *(59)*, respectively. The mixed-valence TCNQ stack has a very low bond order ($^1/_4$) which could be increased to $^1/_2$ if dimers formed or to $^1/_3$ if tetramers formed.

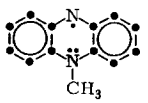


Table 7. Comparison [a] between electrical conductivity of closed shell cation TCNQ salts $D^+(TCNQ)^{\bar{}}$ and $D^+(TCNQ)_2^{\bar{}}$.

[c] Compressed powder measurements.

The TCNQ interplanar geometry, however, may be dominated by what appears to be a hydrogen bonded interaction[109] between the cyano group of TCNQ and the $HN^{\oplus}$ group of the cation in both *(58)* and *(59)* rather than the electron transfer energy between TCNQ sites. In addition the cations are also disordered (the $HN^{\oplus}$ group does not always point towards the same TCNQ stack) so that the transport properties may very well be dominated by this feature[110–111].

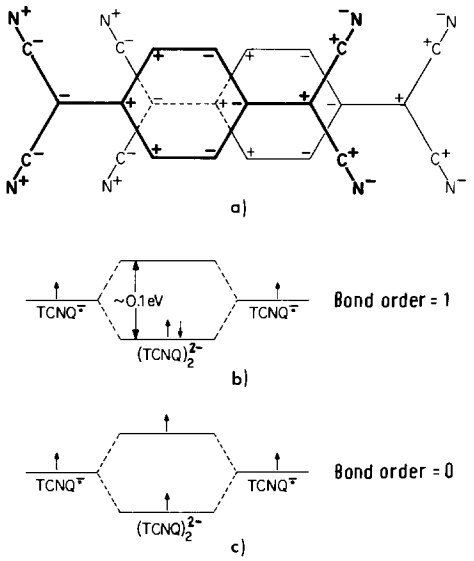
It is also generally found that regardless of cation size, the 1:2 salts $D^+(TCNQ)_2^{\bar{}}$ are orders of magnitude more conductive than their 1:1 counterparts $D^+TCNQ^{\bar{}}$. The 1:1 salts tend to form pairwise interacting $TCNQ^{\bar{}}$ ions either as isolated dimers such as in *(54)* with an interplanar separation of 3.2 Å or as stacked dimers as in the alkali TCNQ salts. In neither case does one have an infinite stack of equivalent equally spaced ions, which is one of the necessary conditions for high electrical conductivity. On the other hand, the 1:2 salts in almost all cases form a stacked arrangement of $(TCNQ)_2^{\bar{}}$ and even though in most cases the stack does not contain equivalent equally spaced molecules, the mixed-valence nature of the stack allows some charge migration to occur. Table 7 summarizes this result by comparing some 1:1 and 1:2 salts with different TCNQ stacking arrangements. Except for the *N*-methylphenazinium salt *(65)*, the best conductors are the 1:2 salts *(66)* and *(67)* with mixed-valence equally spaced TCNQ molecules. *(65)* is an unusual example. Available NMR evidence[126] indicates that there is incomplete charge transfer from the donor to the acceptor amounting to 6 mol %. Thus the TCNQ stack and the donor stack are formally mixed-valent with the presence of *N*-methylphenazinyl free-radical *(71)*.

(71)

Note too that *(71)* has a new aromatic sextet not present in *(65)*, so that charge transport along the donor stack may also occur. Further studies on molecules like *(71)*[127] would be highly desirable.

7. Does TCNQ· Form a Chemical Bond with Itself?

The separation between TCNQ molecular planes in the various structures in Tables 4 and 7 is large, about 3.2 Å. Nevertheless this is less than van der Waals spacing of 3.4—3.5 Å. Is there a chemical bond formed between these molecules? There is at present no satisfactory answer to this question. In discussing the properties of polyiodine chains, we assumed that one-electron molecular orbital theory would be adequate to understand the electrical properties where strong σ-bonded interactions occur. However, for aromatic hydrocarbons, this may not be a good starting point. The problem is illustrated in Figure 5. The lowest unoccupied orbital (LUMO) of TCNQ has b_{2g} symmetry in the D_{2h} point group[82, 128]. Reduction of TCNQ to $TCNQ^{\bar{}}$ places one unpaired electron in this orbital. If a bond is formed with another $TCNQ^{\bar{}}$, it is the b_{2g} orbitals which will overlap. The most favorable geometry is that which maximizes the overlap and minimizes the nuclear repulsion between the rings as shown in Figure 5a. This is the geometry which occurs in the highly conductive salts *(65)*, *(66)*, and *(67)* and is also the geometry which occurs in the nonconductive salt *(64)* which has isolated dimers.



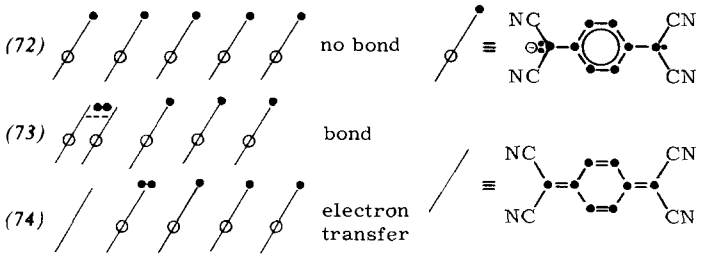


Fig. 5. a) Preferred stacking arrangement of TCNQ ions. Positive and negative signs of the b_{2g}-p_π orbitals above the plane of each molecule are indicated, b) LCAO-MO energy scheme for $(TCNQ^{\bar{}})_2$ assuming that Coulomb repulsion between electrons is small. c) Same as (b) but with large Coulomb repulsion.

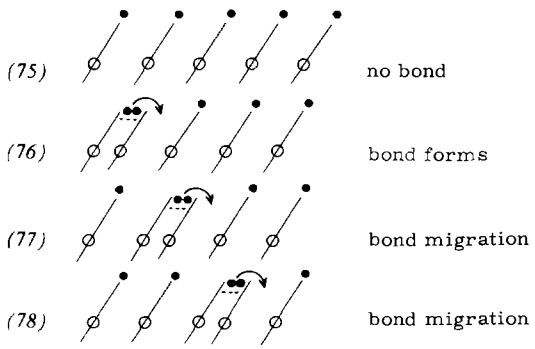
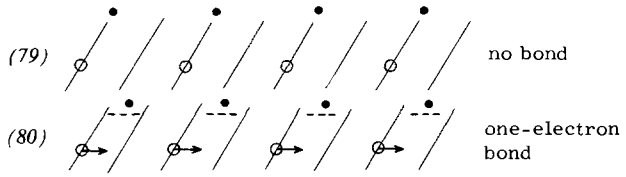
If overlap occurs, there will be a bonding MO and an antibonding MO. The energy separation of these states is between 0.1 and 0.2 eV (2.3 to 4.6 kcal). If a σ bond is formed, the two electrons will occupy the bonding MO with bond order 1 (Fig. 5b). This is a very weak bond at best. If the Coulomb repulsion between the two electrons is large enough, then it may be more favorable to put one electron in the bonding MO and one in the antibonding MO as in Figure 5c. The bond order here is 0. The electrons are in effect localized on each TCNQ site and kept in this configuration because of their mutual Coulomb repulsion. The situation here is analogous to the low spin-high spin electron configurations occurring in the crystal field theory of transition metal ion complexes. At first sight, it would seem that a clear answer to the question might be had by measuring the magnetic susceptibility of the isolated dimer. The low spin state is a singlet, whereas the high spin state is a triplet. However, the problem is complicated by the fact that the singlet-triplet splitting here is not much larger than thermal energies and thus a bond-no bond dynamic equilibrium can exist whose equilibrium constant is a strong function of temperature. The theoretical aspects of this question have been reviewed by *Soos*[129, 130] and the experimental situation for the alkali $TCNQ^{\bar{}}$ salts has been discussed from different viewpoints by *Kommandeur*[131] and *Heeger*[132].



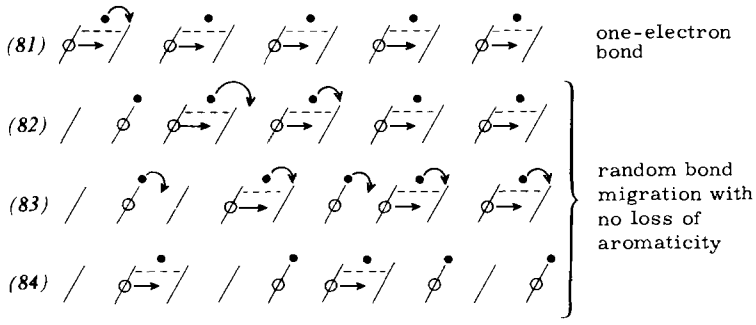
From a chemical point of view, the formation of a bond between two radical ions each with an aromatic sextet seems unlikely. The wave function for the bonding orbital with two electrons contains contributions in which both electrons reside on one TCNQ site. This contribution is in fact necessary if electron transport is to occur. But such a contribution destroys the aromatic sextet on one TCNQ without creating

a new aromatic sextet on the $TCNQ^{2-}$ dianion as in *(72)* to *(74)*:

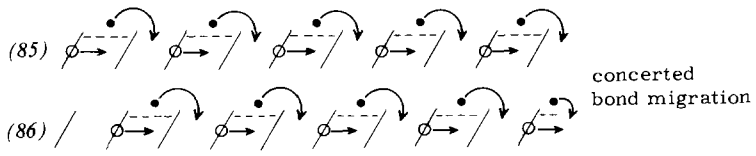


In *(72)* there are no bonds and no charge migration. In *(73)* two $TCNQ^{\cdot-}$ anions approach and form a bond. In *(74)* the bond breaks leaving two electrons on the second TCNQ site with aromaticity destroyed on the first site. Charge has migrated from the first site to the second but at the expense of destroying the aromaticity on the first site. *(74)* ought to be energetically unfavorable and lead to low conductivity with high activation energy.

What can occur instead of charge migration is bond energy migration as in *(75)*—*(78)*.



In *(75)* there is no bond. In *(76)* a bond forms between two ions. In *(77)* and *(78)* the bond migrates down the TCNQ chain. These bond migrations manifest themselves as excitons (singlet or triplet) or as charge density waves. As might be expected the charge density wave intensity is enhanced in the neighborhood of a phase transition. In the 1:1 salts, however, there is no charge migration associated with this charge density wave.



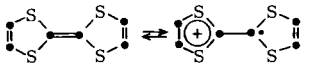
The mixed-valence 1:2 salts $D^{+}(TCNQ)_2^{-}$, on the other hand, formally have one neutral molecule and one radical anion between which a one-electron σ bond can form as in *(79)* and *(80)*.

In *(79)* there is no bond and the aromatic sextet is localized on every other site. In *(80)* a one-electron bond is formed and the aromatic sextet can migrate to the second site as indicated by the arrows. Considerable controversy surrounds the question whether the electron migration occurs more or less randomly as in *(81)*—*(84)*,

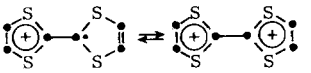
or concertedly as in *(85)*—*(86)*.

In *(81)*—*(84)* there will still be an activation energy for electrical conduction associated with the bond-breaking which occurs with increased temperature. The activation energy, however, will be much smaller than in *(72)*—*(74)* since the dianion contribution to the transport is virtually absent. In effect the mixed-valence state allows for the migration of charge without the formation of the highly energetic dianion.

The concerted migration of charge (the Peierls-Frölich superconductor)[133] in *(85)*—*(86)*, on the other hand, should occur with no activation energy since the σ bonds and the unpaired electrons migrate together. Further discussions of the experimental situation will be deferred to the next section.



8. Tetracyanoquinodimethane Salts with Open Shell Conducting Cations, $D^{\frac{1}{2}+}TCNQ^{\cdot-}$



More has been said and written about the properties of this class since our discovery of its first member *(14)*[41] than about all the other organic conductive salts put together. The properties of *(14)* in particular have been studied in great detail. There presently exists a wealth of data on its electrical conductivity[134] and its pressure depen-

dence[135, 136], magnetoresistance[137], specific heat[138–140], Seebeck coefficient[141–143], EPR and magnetic susceptibility[66, 144–146], photoconductivity[147], visible and IR optical properties[148–152], thermal expansion[153], photoelectron spectra[154–158], X-ray structure[159], diffuse X-ray scattering[160–162], neutron scattering[163, 164], and chemical doping and impurity effects[165–167].

As has been pointed out, the donors of this class are all typified by the formation of an aromatic sextet upon one-electron oxidation to the cation radical. The cation radicals in Table 5, which do not have this property do not efficiently transport charge.

For many of the donors in Tables 4 and 6, the dication is also an isolable species[37, 95], the second oxidation potentials (*vs.* SCE in CH_3CN)[99] being unusually low for dication formation; *(87)* and *(88)* are examples.

(87)  $E_{pa} = +0.34$ V

(88)  $E_{pa} = +0.68$ V

Unlike the dianion $TCNQ^{2-}$, the dication TTF^{2+} may thus make significant contributions to the transport process along the donor stack since the dication contains a second aromatic sextet not present in the monocation.

That $TTF^{+\cdot}$ radical cation itself will efficiently transport charge has been well substantiated by a study of the mixed-valence halides, $(TTF)Br_{0.71}$ and $(TTF)I_{0.71}$. The halogen is present in the crystal structures as well-separated ions[168, 169] (*e.g.* I^- spacing in $(TTF)I_{0.71} \approx 5$ Å; compare with *(7)*)[169] and thus does not contribute to the electrical conductivity. Room temperature σ values for both these salts as single crystals lie in the range of 100 to $550\,\Omega^{-1}\,cm^{-1}$[170–171]. As with the TCNQ salts, a variety of stoichiometries and crystal structures can occur in these cation radical salts[93].

The electrical conductivity of salts formed between open shell cations and the open shell anions $TCNQ^{-\cdot}$ *(28)* and $TNAP^{-\cdot}$ *(29)* has been presented in Tables 4 and 6. Separate conducting donor and acceptor stacks exist in these salts as shown by X-ray structure investigations[159]. What is not known is the amount of charge transferred from the donor to the acceptor and whether or not this quantity is temperature dependent. Also not understood is how interstack interactions affect the conductivity along the stacks and perpendicular to them.

The temperature dependence of σ normalized to room temperature for six samples of *(14)* measured along the stacking axis is shown in Figure 6[172]. There are two distinct features:

a) a metallic region for $T > 60$ K in which the electrical conductivity *increases* with decreasing T and

b) a semiconducting or insulating region for $T < 60$ K in which the electrical conductivity *decreases* with decreasing T and approaches zero as $T \rightarrow 0$ K. Not shown is another weak inflection near 38 K[173].

TTF-TCNQ thus goes through an insulator-metal transition around 60 K. This is not an uncommon feature in the highly conducting organic salts and occurs in *(65)*, *(66)*, and *(67)*. Considerable controversy has ensued over what is the ratio

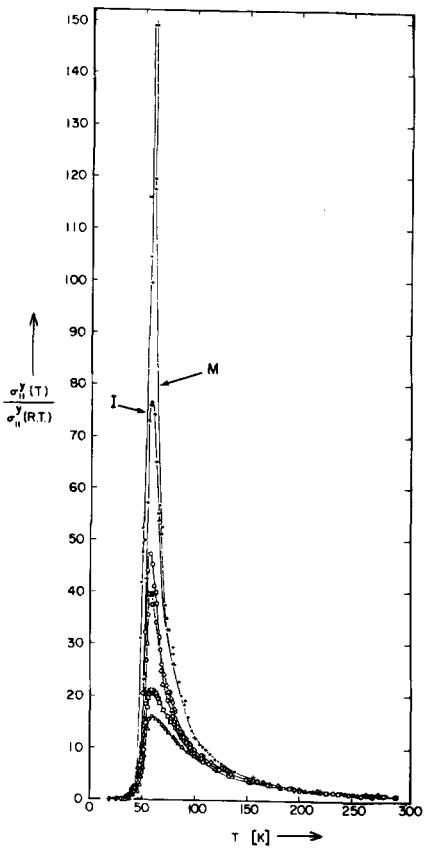


Fig. 6. Electrical conductivity along the stacking axis *vs.* temperature for six crystals of TTF-TCNQ *(14)*; data normalized to room temperature [172]. Notice that the peak conductivity varies from sample to sample. M: curve for metal; I: curve for insulator.

of the peak conductivity at $T = 60$ K to that at room temperature. For *(66)* the peak occurs at $T = 230$ K and the ratio to the room temperature value is only 1.10[106]. For TTF-TCNQ the ratio varies from 10 to 150 depending on the crystal sample as indicated in Figure 6. This is very much unlike the other high-conductivity salts *(66)* and *(67)* where the data appear more reproducible from sample to sample and the conductivity normalized to room temperature is sample independent.

If the true normalized conductivity of TTF-TCNQ is as high as 150, it could imply a mechanism such as in *(86)* in which there is concerted motion of the electrons with the chemical bonds. Such a mechanism is a superconducting-like state[*] in which the transporting charges are not scattered by the longitudinal vibrational motions of the molecules but travel with them.

On the other hand if the normalized conductivities are only 10 to 20 then a mechanism according to *(81)*—*(84)* is more reasonable, in which the transporting charges move randomly and are scattered randomly by the molecular vibrations.

No less than 17 laboratories have measured the normalized conductivity of TTF-TCNQ along the stacking axis[134]. Of these, 11 report normalized peak values of 26 or less, five report values ranging from 30 to 60, and one reports a value of 150.

[*] But not a true superconductor as in BCS theory.

The conduction mechanism is thus unresolved and will remain unresolved until more charge-transporting donors and acceptors unrelated to TTF or TCNQ are synthesized and examined. Compounds such as *(25)* which show no metal-insulator transition but remain metallic as T approaches 0 do not resolve the problem[62]. *(25)* is a two-dimensional conductor (there are "strong" exchange interactions both parallel and perpendicular to the stacking axis as shown by the structure in Figure 7).

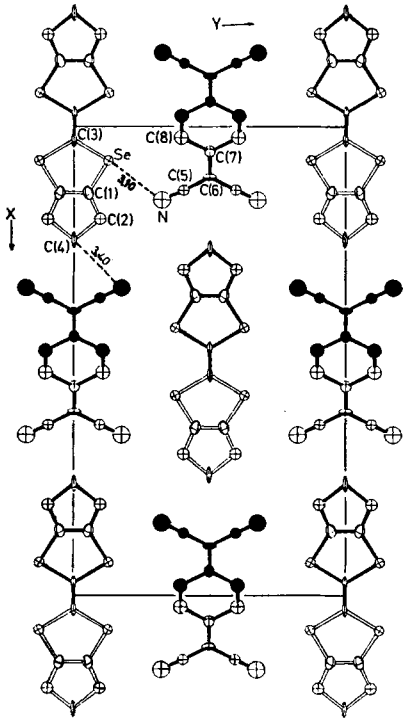

Fig. 7. Projection of crystal structure of HMTSeF-TCNQ *(25)* onto the stacking axis. Separate stacks of donor (D) and acceptor (A) occur along z with what appears to be a "strong" interaction between the Se atom of D and the nitrogen atom of A. [After *T. E. Phillips, T. J. Kistenmacher, A. N. Bloch, D. O. Cowan*, J. Chem. Soc. Chem. Commun. *1976*, 334.]

A concerted charge transport can only occur for a strictly one-dimensional stack. Any two- or three-dimensional coupling of the stacks destroys the one-dimensional concerted reaction. The transition to the insulating state in TTF-TCNQ at 60 K occurs either by (a) weak interstack interaction which destroys the concerted one-dimensional motion at 60 K, or (b) a simple metal-insulator transition due to a static lattice distortion at 60 K similar to that in Figure 2 which produces an insulating state.

The two transport mechanisms would seem to have vastly different consequences if an insulating layer could be placed between the chains and thus reduce two- or three-dimensional interactions. For the concerted charge-migration mechanism *(86)* the peak conductivities should get larger and shift to lower temperatures, whereas for a static Peierls' transition the peak should move out to higher temperature.

Neither of the above two mechanisms approaches the problem as to the nature of the charge transport perpendicular to the stacking axis. The structure of TTF-TCNQ shown in Figure 8[159] indicates that along the x-axis the molecular planes form a dihedral angle of 58.5° yet the electrical conductivity along x, although ≈ 100 times smaller than along y (the stacking axis), still has a metallic-like temperature dependence[66]. No concrete mechanism for the charge migration along the x-axis has been presented.

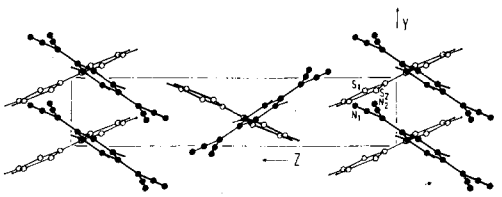

Fig. 8. Projection of crystal structure for TTF-TCNQ *(14)* along the x-axis [159]. Separate stacks of TTF and TCNQ occur along the y-axis but along x the donor and acceptor are at an angle of 58.5°.

Chemically, it seems reasonable to expect that as electrons migrate up and down the TCNQ stack and holes up and down the TTF stack, there will be many configurations in which a *neutral* TTF will be a neighbor to a *neutral* TCNQ. Interstack charge transfer might then occur at these points as shown in *(89)*. Interestingly enough, the equilibrium constant K_a for *(89)* will determine not only the conductivity

along the x-axis but also along the stacking axis, y. According to Reference [85], the conductivity along the stacking axis will depend on the product of neutral and ionic species concentrations and this will be determined by K_a which may be a strong function of temperature. Temperature-dependent X-ray data[174] from 45 K to room temperature show that below 60 K the bond lengths for TTF are like that of the neutral species but becoming more like the cation with increasing T suggesting that the equilibrium for *(89)* shifts from left to right with increasing T. Above the $T = 60$ K transition temperature experimental data from photoelectron spectroscopy, diffuse X-ray scattering and neutron scattering all indicate at least 0.5 electron transferred per TTF-TCNQ pair but definitely less than one electron transferred per pair.

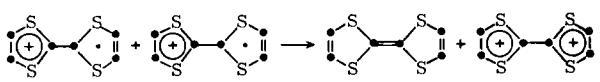
9. Are Organic Conductors Thermodynamically Stable?

The binding energy for a number of salts has been calculated taking into account the ionization energy of the donor, electron affinity of the acceptor, the amount of charge transferred, and the Madelung energy[175–177].

For low-conductivity TCNQ salts with strong donors like the alkali metals, binding energies are typically -3.0 eV (*ca.* -70 kcal/mol). On the other hand, the mixed-valence high-conductivity salts like NMP-TCNQ *(65)*, TTF-TCNQ *(14)*, and (TTF)$Br_{0.7}$ either have a small binding energy [-0.6 eV for (TTF)$Br_{0.7}$[177]] or a positive binding energy [$+3.7$ eV for *(65)*, $+0.6$ eV for *(14)* assuming 0.5 electron transferred]. While polarization energy may also be important and was neglected in the above calculations, inclusion of polarization energies by estimation does not substantially change the conclusion that the conductive salts like *(65)* and *(14)* may not be thermodynamically stable (by instability here I do not mean that the ions do not exist as chemically stable species but rather the crystal structures which produce the

high conductivity may not be the most favored structures). Some observations bear on this point. Attempts to grow conducting crystals by slow crystallization of a saturated solution containing the salt invariably fails; rather the best conductive materials are obtained by rapid crystallization either by rapid cooling of a saturated solution or by interdiffusing of two solutions at room temperature, one of which contains the donor, and the other the acceptor. Thus, depending on the rate of crystallization from CH_3CN, NMP-TCNQ *(65)* exists either as the high-conductivity phase[178] with separate donor and acceptor stacks[116] or the low-conductivity phase $NMPH^{+}TCNQ^{\cdot}$ ($\sigma = 8 \times 10^{-5}\,\Omega^{-1}\,cm^{-1}$)[179] with alternating donor and acceptor[180]. Similar observations have been made on the crystallization of *(24)*[61] and *(55)*[181].

10. Where Do We Go From Here?



The synthetic organic chemist confronted by the multitude of confusing ideas in this area must wonder about what new contributions he can possibly make. There are a number of common chemical features of organic conductors, the implication of which needs to be explored much more thoroughly. These are as follows:

1) The creation and destruction of aromaticity in the charge generation and transport scheme. The best organic conductors consist of donors which generate a new aromatic sextet upon oxidation and of acceptors which do the same upon one-electron reduction. Extension of this observation to other $4n+2$ Hückel aromatic systems needs to be studied.

2) The presence of mixed valence states. This also is a necessary condition for charge transport and appears to be related to 1) in that aromaticity cannot migrate from molecule to molecule unless there are some neutral molecules in the stack which have no aromaticity. Thus the reaction

$$TCNQ^{-} + TCNQ^{-} \longrightarrow TCNQ + TCNQ^{2-}$$

is not favorable; aromaticity is not conserved. In comparison the reaction

may be energetically feasible since aromaticity is conserved. A comparison of other donor-acceptor combinations with and without this property would be worthwhile.

3) Finally, as pointed out in the last section, neither the phase diagram nor any experimental information on the thermodynamic stability of segregated stack complexes is known. A study of the thermochemistry of these systems would greatly facilitate our understanding of why these organic conductors form in the first place.

The author would like to acknowledge the many helpful discussions on organic molecular structure he has had with James Van Allan, Fred Chen, Neil Haley, and George Reynolds.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Detection of an Orthonitrate by Vibrational Spectroscopy: Na_3NO_4[**]

By *Martin Jansen*[*]

It has recently been shown that Na_3NO_3 does not exist as orthonitrite (NO_3^{3-} anion) as formerly assumed, but instead has a structure derived from the perovskite type made up of $(NO_2^-)ONa_3$[1]. This suggests that Na_3NO_4[2] might also be an adduct, *viz.* $Na_2O \cdot NaNO_3$.

All attempts to prepare single crystals of Na_3NO_4 suitable for X-ray structure analysis have so far failed; however, vibrational spectroscopy should also provide unequivocal information as to whether nitrate ions are present in Na_3NO_4.

Na_3NO_4 was obtained as a microcrystalline colorless powder by heating of equimolar amounts of $NaNO_3$ (analytically pure, Merck) and Na_2O[3] in a sealed silver crucible (300 °C, 7 d). The product is extremely sensitive to moisture and CO_2, and decomposes within minutes to hydroxide and carbonate on exposure to air.

[*] Dr. M. Jansen
Institut für Anorganische und Analytische Chemie der Universität Heinrich-Buff-Ring 58, D-6300 Lahn-Giessen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The samples are sealed under argon in glass capillaries for recording the Raman spectrum (Coderg, LRDH 800, Ar laser, 514.5 nm)[4], which is reproduced in the form of a line diagram in Figure 1a.

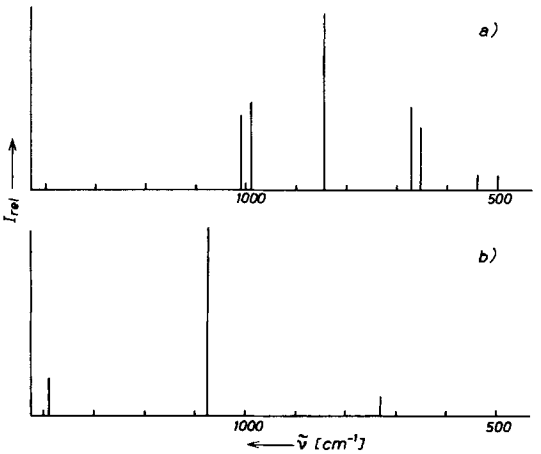

Fig. 1. Raman spectra of a) Na_3NO_4 and b) $NaNO_3$.

Comparison with the Raman spectrum of $NaNO_3$ (Fig. 1b) and other nitrates[5] shows that Na_3NO_4 does not contain NO_3^- ions; thermal degradation to nitrites can also be ruled out on the basis of the spectrum. Instead the Raman absorptions can be interpreted assuming an orthonitrate with tetrahedral NO_4^{3-} ions. A proposed assignment of the observed vibrational frequencies is shown in Table 1. The splitting of the vibrations ν_2, ν_3, ν_4, which should be degenerate in the case of strict T_d symmetry, is probably due to crystal field effects; it can be explained by assuming D_{2d} site symmetry. However, a final interpretation of the spectrum requires a knowledge of the space group of Na_3NO_4 and the site symmetry of NO_4^{3-}. The vibrational frequencies observed for NF_4^+[6] are given for comparison in Table 1; the similarity of the two spectra corresponds to expectations since NF_4^+ is isoelectronic with NO_4^{3-} and the atomic masses of O and F are comparable. The existence of NO_4^{3-} appears to apply only to the solid state: cold 1 N sodium hydroxide decomposes Na_3NO_4, regenerating NO_3^-.

Table 1. Raman spectrum of Na_3NO_4; comparison with NF_4^+ (in NF_4SbF_6).

N,N-Bis(trimethylsilyl)enamines—Stereoselective Synthesis from *N,N*-Bis(trimethylsilyl)thioformamide[**]

By *Wolfgang Walter* and *Hans-Wolfgang Lüke*[*]

Monosilylated enamines have only recently been described[1]. In the course of our studies on silylated thioamides[2] we have now prepared the hitherto unknown *N,N*-bis(trimethylsilyl)enamines *(9)* and *(13)*, which are of preparative interest as masked *N*-unsubstituted enamines.

The starting material *(1)* was obtained as the first bis-silylated thioamide by metalation and silylation of *N*-trimethylsilylthioformamide *(2)*[2a] [eq. (a)] or alternatively by reaction of *O*-ethyl thioformate *(3)*[3] with lithium bis(trimethylsilyl)-amide *(4)* [eq. (b)].

$$\underset{(2)}{H\text{–}CS\text{–}NHSiMe_3} \xrightarrow[-\ LiCl]{1)\ n\text{BuLi},\ 2)\ Me_3SiCl} \underset{(1)}{H\text{–}CS\text{–}N(SiMe_3)_2} \qquad (a)$$

$$\underset{(3)}{H\text{–}CS\text{–}OEt} + \underset{(4)}{LiN(SiMe_3)_2} \xrightarrow[-\ LiCl]{Me_3SiCl} (1) + Me_3SiOEt \qquad (b)$$

The structure of *(1)*, which crystallizes as colorless needles that are very sensitive to hydrolysis, is confirmed by its IR and ^{13}C-NMR spectrum (Table 1).

In contrast to the thiophilic addition generally observed on attack of organolithium compounds *(5)* on thiocarbonyl groups[4], these compounds react with *(1)* by carbophilic addition to form the salts *(6)*. Carbophilic addition was also detected in the reaction of phenyllithium with *N,N*-dimethylthiobenzamide or -thioformamide[5]. Reaction of *(6)* with trimethylchlorosilane gives the 1-(trimethylsilylthio)-*N,N*-bis(trimethylsilyl)alkylamines *(7)*, which decompose spontaneously by elimination of trimethylsilanethiol *(8)* into the *N,N*-bis(trimethylsilyl)enamines *(9)*. Compound *(8)* condenses immediately with elimination of H_2S to give hexamethyldisilathiane *(10)*[6].

$$(1) + \underset{(5)}{RCH_2Li} \longrightarrow \underset{(6)}{H\text{–}C(SLi)(CH_2R)\text{–}N(SiMe_3)_2} \xrightarrow[-\ LiCl]{Me_3SiCl} \underset{(7)}{H\text{–}C(S\text{–}SiMe_3)(CH_2R)\text{–}N(SiMe_3)_2}$$

$$(7) \longrightarrow \underset{(9)}{H(R)C^2{=}C^1(H)N(SiMe_3)_2} + \underset{(8)}{[Me_3SiSH]} \xrightarrow{-\frac{1}{2}H_2S} \underset{(10)}{1/2\ (Me_3Si)_2S}$$

(a): R = H

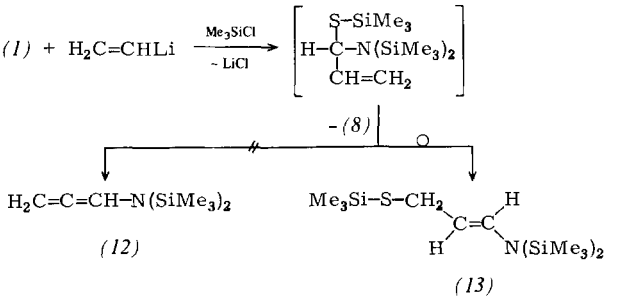
Institut für Organische Chemie und Biochemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The proposed mechanism for the formation of *(9)* is supported by the isolation of *(11)* on reaction of *(1)* with phenyllithium.

(11)

Reaction of *(1)* with vinyllithium failed to give propadienylamine *(12)*, but instead afforded the enamine *(13)* (see Table 1) by allyl rearrangement.

(12) *(13)*

Procedure[8]

N,N-Bis(trimethylsilyl)thioformamide (1) according to eq. (a): Compound *(2)* (50 mmol) is suspended in pentane (50 ml). After dropwise addition of an equivalent amount of *n*-butyllithium in hexane (31 ml) the reaction mixture is stirred for 1 h before addition of trimethylchlorosilane (50 mmol). Stirring is continued for *ca.* 10 h, lithium chloride is filtered off, and the residue obtained on vacuum evaporation is recrystallized from pentane.—Synthesis of *(1)* according to eq. (b): A solution of *(4)* (0.1 mol) in hexane (120 ml) is added dropwise to compound *(3)* (0.1 mol). After three hours' stirring trimethylchlorosilane (0.1 mol) is added and the reaction mixture worked-up as described above.

Synthesis of *N,N-bis(trimethylsilyl)enamines (9)* and *(13)* and of the *silylthio compound (11)*: A solution of the organolithium compound (25 mmol) in a suitable solvent is added dropwise to a solution of *(1)* (25 mmol) in pentane (20 ml) at −45 °C. After brief stirring at room temperature, trimethylchlorosilane (25 mmol) is added. The resulting precipitate is filtered off and the product mixture is distilled[9].

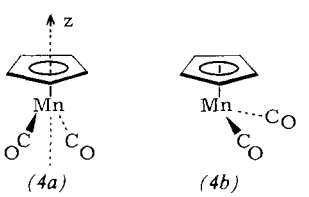
Unsaturated Organometallic Intermediates: Electronic Structure and Structural Dynamics of $(\eta^5\text{-}C_5H_5)Mn(CO)_2$[**]

By *Peter Hofmann*[*]

Organometallic "half-sandwich" molecular fragments of the type $(C_nH_n)ML_2$ (n=4, 5, 6, 7) having only 16 electrons in their valence shell play an important role as intermediates in organometallic chemistry. This is especially true of the chemistry of optically active $CpML^1L^2L^3$ systems[1]. The electronic structure and the dynamic behavior (inversion) of such 16-electron species generated by thermal or photochemical dissociation are of crucial importance in the mechanism (Scheme 1) of S_N1 substitution of these molecules *(1a, b)* *via* chiral intermediates *(2a, b)* which in some cases proceeds with retention.



Schema 1

(1a) *(2a)* *(3)* *(2b)* *(1b)*

Substitution etc.

With the aid of the model system $CpMn(CO)_2$, whose formation has been demonstrated on photolysis of tricarbonyl(η^5-cyclopentadienyl)manganese ("cymantrene")[2], it proves possible to settle the questions of a "planar" *(4a)* or "pyramidal" *(4b)* ground state geometry and of possible energy barriers in Scheme 1 ($L^2=L^3=CO$, M = Mn) in terms of molecular orbital calculations and[3, 5] and perturbation theory.

(4a) *(4b)*

The most suitable starting point for constructing the valence MOs of a "planar" $CpMn(CO)_2$ *(4a)* is an analysis of the

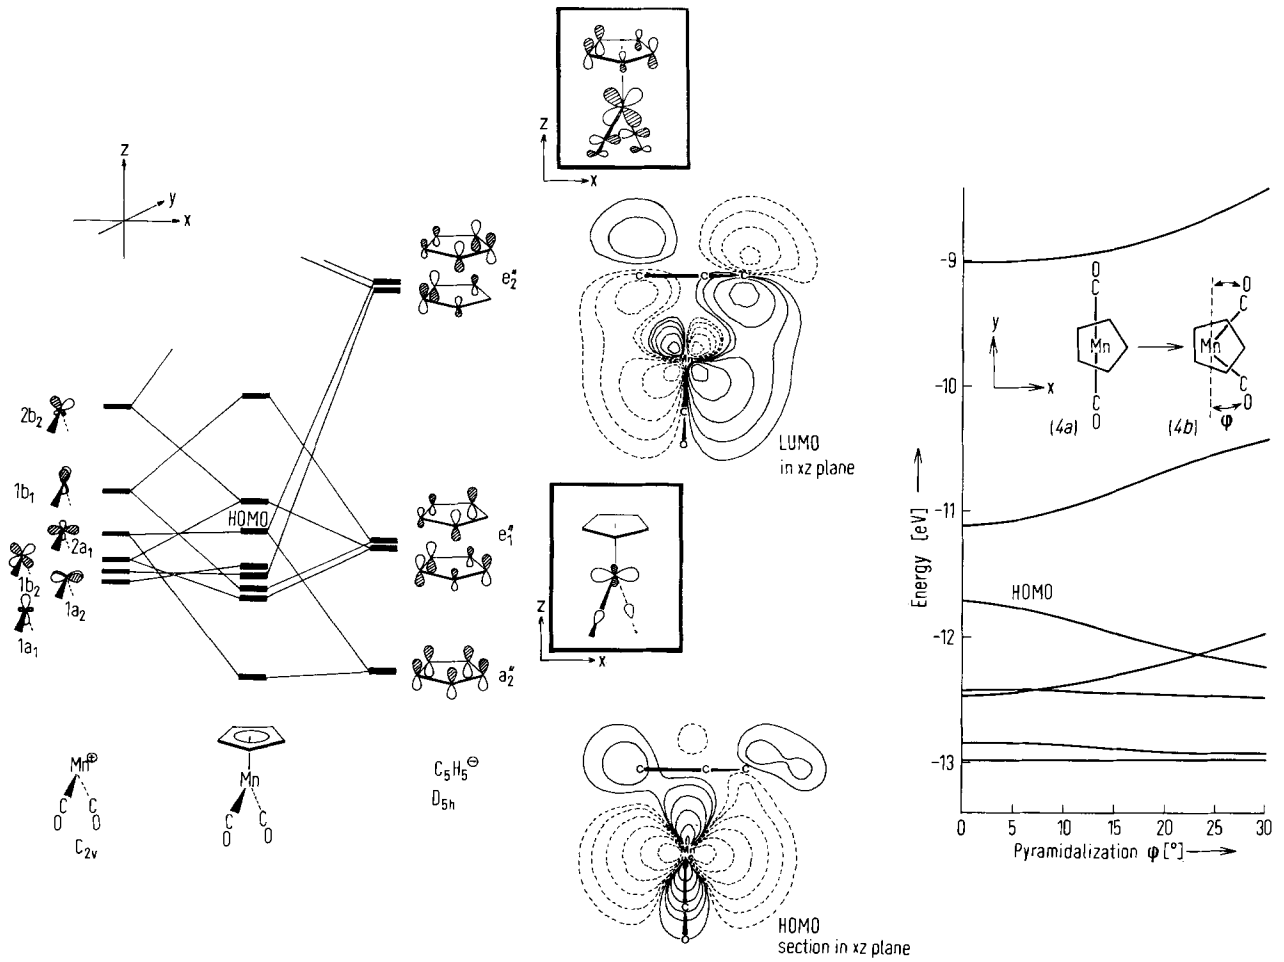

Fig. 1. Left: Interaction diagram for construction of the MOs of "planar" $CpMn(CO)_2$ *(4a)*.—Center: HOMO (below) and LUMO (above) for *(4a)*; contours at wavefunction values of 0.4, 0.2, 0.1, 0.05, 0.025, 0.0125.—Right: Calculated Walsh diagram for pyramidalization *(4a)* → *(4b)*.

interaction between the MOs of fragments constituting the complete molecule, for example between the orbitals of a $Mn(CO)_2^+$ moiety and the $C_5H_5^-$ ligand[6]. A corresponding diagram is shown in the left-hand third of Figure 1, the MOs of the metalcarbonyl fragment[7] are shown only qualitatively in their contribution at the metal center.

The small difference in energy between the HOMO and the LUMO is striking and relevant to our discussion. As shown by the calculated contour diagrams (Fig. 1, center) the HOMO is to be regarded as a nonbonding electron pair at the metal (*ca.* 90% Mn contribution), while the LUMO possesses mainly d_{xz} character at the manganese and has a large π^*_{CO} component. The model calculation of a Walsh diagram[8] for a transition to "pyramidal" geometry *(4b)* (Fig. 1, right-hand third) shows the pronounced increase in HOMO-LUMO separation expected from perturbation theory. The two frontier orbitals, of different pseudosymmetry in the "planar" system, start mixing on going from *(4a)* to *(4b)*. As a consequence the energy of the upper one increases and that of the lower one falls, and the overall stabilization leading to the "pyramidal" minimum is accompanied by rehybridization at the metal, charge shift into the CO groups, and strengthening of the Mn—C and weakening of the C—O bonds. The Walsh diagram reveals a planar structure for 18-electron systems such as $CpCo(CO)_2$, as is found experimentally for all molecules of that kind.

The energetically decisive lowering of the HOMO during the transition *(4a)* → *(4b)*, *i.e.* the barrier to inversion and hence the configurational stability of a $(C_nH_n)ML_2$ 16-electron system, therefore depends sensitively upon the distance to the LUMO in the planar geometry[9]. The metal and the ligands L as well as the C_nH_n ring accordingly exert a marked and predictable influence upon the ground state structure and inversion behavior of such molecular fragments.

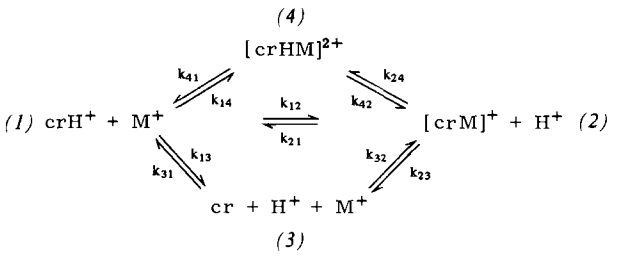
Kinetics of Alkali Metal Complex Formation by Bicyclic Cryptates

By *Karsten Henco, Burkhard Tümmler*, and *Günter Maass*[*]

The diazapolyoxa macrobicyclics (cryptands) synthesized by *Lehn et al.* have stability constants up to 10^5 l mol^{-1} and are therefore the strongest complexing agents presently known for alkali metal ions in aqueous solution[1]. The kinetics of complex formation has so far only been examined for the [2.2.2] cryptand, the methods of potentiometry, ^{1}H-NMR and ^{23}Na-NMR spectroscopy merely yielding overall dissociation rate constants for the complexes of [2.2.2][2].

[2.1.1]: m = n = 0
[2.2.1]: m = 1, n = 0
[2.2.2]: m = n = 1



We here report studies on the kinetics of complexation of nonprotonated and singly protonated cryptands with sodium and potassium ions. For this purpose we employed the temperature jump relaxation procedure which permits determination of the rate constants of both association and dissociation[3]. The relaxation processes were registered as absorptions between 225 and 250 nm as functions of the cryptand concentration. In the chosen wavelength range the free nonprotonated ligand absorbs much more strongly than its mono- and di-protonated forms and than the complex formed by the ligand and the metal ion.

In the basic range (pH = 12.5) a concentration-dependent relaxation time was found for recombination of metal ion and unprotonated ligand, corresponding to the bimolecular mechanism[3].

$$M^+ + L \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} [LM]^+$$

Numerical evaluation yields the rate constants $k_{12} = 9 \times 10^4$ l mol^{-1} s^{-1} and $k_{21} = 1.4 \times 10^2$ s^{-1} for the Na^+/[2.1.1] system and $k_{12} = 3 \times 10^7$ l mol^{-1} s^{-1} and $k_{21} = 2 \times 10^3$ s^{-1} for the K^+/[2.2.1] system. We interpret the experimental finding by assuming that the diffusion-controlled encounter of metal ion and ligand is followed by stepwise replacement of the water molecules in the inner hydration shell of the metal ion by the coordination sites of the ligand. It should be emphasized that unimolecular conformational transitions such as the *exo/endo* conformational equilibria discussed by *Lehn et al.* do not represent the rate-determining step of complexation. Interestingly, K^+ recombines about one hundered times faster with [2.2.1] than does Na^+ with [2.1.1], although the ratios of the ionic to cavity radius are equal ($r_{Na^+}/r_{211} = r_{K^+}/r_{221} = 1.2$)[1]. The rate constant measured for the K^+/[2.2.1] system is comparable with the value found for binding of alkali metal ions to sterically unhindered polydentate ligands such as ethylenediaminetetraacetic acid (EDTA)[4]. On the other hand, the lower flexibility and the greater bond angle opening in the case of the smaller [2.1.1] cryptands render optimal adaptation of the metal ion to the cavity of the ligand so difficult that the rate of association is drastically reduced.

The two complexes having the greatest stability, the sodium complex of the [2.2.1] cryptand and the potassium complex of [2.2.2] (both with lg $K = 5.4$) were examined at pH = 6.3 in cacodylate buffer and at pH = 7.5 in Tris buffer. The ligands exist in the mono- and diprotonated form at the chosen pH values. In the temperature jump experiments two relaxation times were always observed: the fast relaxation (10 to 100 μs) is assigned to proton transfer in the acid-base system buffer-cryptand, and the slow relaxation (10 to 100 ms) to the binding of the metal ion to the monoprotonated ligand. Analysis of the concentration and pH dependence of the latter relaxation time shows that binding of the metal ion may precede or succeed protolysis, *i.e.* complex formation may proceed by the dissociative or the associative mechanism[3]:

cr = Cryptand

In the neutral pH region the intermediate state *(3)* of the free nonprotonated ligand is populated only very slightly. On the other hand, we could deduce from the saturation behavior of the slow relaxation at higher concentrations of salt and ligand that the intermediate state *(4)* is present in larger than negligible concentrations in solution. This complex $[crHM]^{2+}$ has not yet been detected by NMR spectroscopy[1]. The overall rate constants for the forward and reverse reaction $\vec{k}$ and $\overleftarrow{k}$ are listed in Table 1.

Table 1. Rate constants of alkali metal complex formation of bicyclic cryptates.

Ligand	Cation	Stability constant lg K	Rate constants $\vec{k}$ [l mol^{-1} s^{-1}]	$\overleftarrow{k}$ [s^{-1}]
[2.1.1]	Na^+	3.2	$(9 \pm 1)\ 10^4$	$(1.4 \pm 0.1)\ 10^2$
[2.2.1]	Na^+	5.40	$(6 \pm 2)\ 10^6$	18 ± 2
[2.2.1]	K^+	3.95	$(3 \pm 1)\ 10^7$	$(2 \pm 1)\ 10^3$
[2.2.2]	K^+	5.4	$(2 \pm 1)\ 10^6$	9 ± 3

The values measured for the [2.2.2] complex are of the same order of magnitude as the constants published by *Lehn et al.*[2].

Synthesis and Structure Determination of a 1,4-Dialuminacyclohexadiene[**]

By *Heinz Hoberg, Vicente Gotor, Armin Milchereit, Carl Krüger*, and *Janine C. Sekutowski*[*]

Using (pentaphenyl)aluminacyclopentadiene[1], we have been able to investigate the influence of vinyl bound aluminum on the ligand properties of the C=C double bond towards transition metals[2]. We will now report on the synthesis, structure and some properties of a new type of model compound—1,4-diethyl-2,3,5,6-tetraphenyl-1,4-dialumina-2,5-cyclohexadiene *(1)*.

The reaction of the *cis*-dialuminum-ate complex *(2)*[3] with electrophiles should produce the intermediate *(3)* and, after the cleavage of R_3Al, either first *(4)* and then *(1)* or *(1)* directly. It was shown, however, that *(2)* can react with electrophiles in very different ways; reaction A occurs exclusively with alkyl halides (*e.g.* CH_3I) whereas reaction B is observed with $(CH_3)_3SiCl$ or $(C_2H_5)_2AlCl$ (molar ration 1:2) in polar solvents.

(2) *(3)* *(4)* *(1)*

In the second case a product is found in which Al:R = 1:1, this corresponds to *(4)* as well as to *(1)*. The molecular mass (560), which was determined vaporimetrically in benzene, decides in favor of *(1)*. Surprisingly, *(3)* cyclizes at as low a temperature as 20°C and not, as was at first expected, at a higher temperature. It still remains an open question as to whether the six-membered ring is formed according to the sequence *(3)* → *(4)* → *(1)* or to the sequence *(3)* → *(1)*.

The structure of the dialuminacyclohexadiene *(1)* was determined by an X-ray structural analysis from 3906 reflections (1644 unobserved). Cell data: $a = 10.0692(7)$, $b = 16.4599(9)$, $c = 12.0016(3)$ Å, $\beta = 68.708(3)°$. Since the space group is $P2_1/n$ where $Z = 2$, the molecule has a crystallographic inversion center. The Al_2C_4 ring (cf. Fig. 1) is planar, the Al atoms only deviate by 0.05 Å from the best plane and have a slightly deformed, tetrahedral coordination [CAlO 103.7(4), CAlC 114.5(8)°]. The Al—O [1.907(3) Å] as well as the Al—C [1.984(4) Å] bond lengths are similar to those found in (pentaphenyl)aluminacyclopentadiene[2b]. The C=C distance in *(1)* is 1.362(5) Å, the dihedral angle C10—C1C2′—C20′ is 7.52°, and the two phenyl rings are almost parallel with one another. The transannular distance Al1—Al1′ is 3.472(2) Å, *i.e.* there is no transannular bonding.

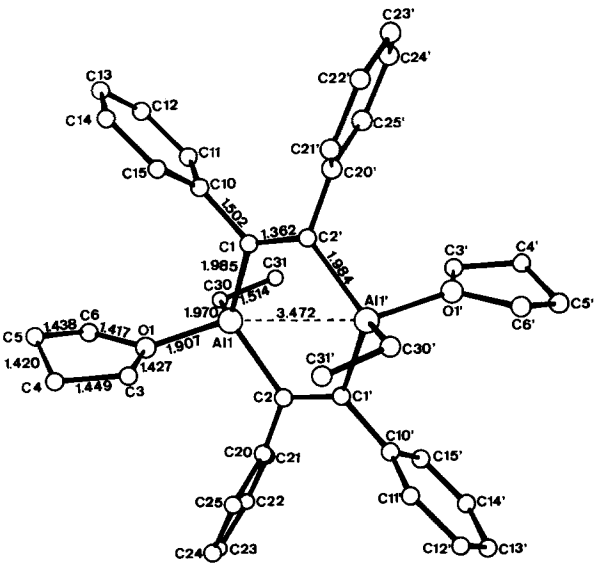

Fig. 1. Molecular structure of *(1)* and numbering of the atoms.

The organoaluminum compound *(1)* shows a striking behavior towards alkali metals in ether when *N,N,N′,N′*-tetramethylethylenediamine is added: *(1)* takes up four equivalents of lithium, during which neither elimination of Al[4] nor addition of Li to the C=C bonds[5] takes place but an *ortho*-metalation of the four phenyl groups occurs.

Experimental

A solution of trimethylchlorosilane (11.0 g, 101.8 mmol) in tetrahydrofuran (80 ml) is added drop by drop to *(2)* (23.0 g, 50.9 mmol)[3] in THF (250 ml) at 20°C over a period of 3 h. After approximately 15 h, the precipitated NaCl (5.8 g, 98 %) is filtered off; the solution is then concentrated under vacuum and the residue (17 g) is recrystallized from approximately 200 ml toluene. Yield: 13.7 g (88 %) *(1)*, m.p. 216 to 218°C.—^{1}H-NMR (C_4D_8O, 100 MHz, TMS int.): $\tau = 3.18$ (m; 20H, C_6H_5), 6.44 and 8.30 (m; 16H, $(CH_2)_4O$), 9.0 (t; 6H, CH_3—CAl).—MS: $m/e = 468$ [*(1)* − 2 THF].—Alcoholysis: after addition of 10 ml 2-ethylhexanol, 1.149 g (1.88 mmol) yield 80 Nml (3.57 mmol, 95 %) of ethane.—Hydrolysis: after addition of 20 ml 0.1 N H_2SO_4 and ether extraction, 0.68 g (3.78 mmol, 96%) *cis*-stilbene (GC) is formed from 1.2 g (1.96 mmol).

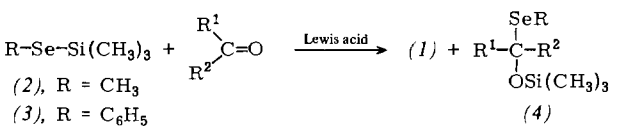
Synthesis of Diselenoacetals and *O*-(Trimethylsilyl)-monoselenoacetals

By *Willy Dumont* and *Alain Krief*[*]

Methods for the synthesis of selenoacetals from carbonyl compounds have already been described[1, 2], but all demand drastic conditions [bubbling of HCl gas for 1 to 2 h (Method A)]. Moreover, the classical HCl method for the synthesis of phenylselenoacetals from aldehydes does not proceed as simply as described in the literature[1]. We have found that concentrated sulfuric acid (Method B) can be used with advantage for the synthesis of pure selenoacetals from aldehydes and selenophenol (see Table 1).

Zinc chloride[3] proved to be a very effective and mild reagent (Method C). It affords pure selenoacetals *(1)* in about 80 % yield from aldehydes or ketones and selenol (see Table 1).



(1)

Table 1. Diselenoacetals *(1)* synthesized according to method B and method C.

[a] Yield of pure substance.

Methyl- and phenyl trimethylsilyl selenide [*(2)*[4] and *(3)*[5], resp.] do not react with carbonyl compounds at 25 °C or on heating (neither neat nor in solvents such as carbon tetrachloride, diethyl ether or acetonitrile). Selenoacetals are, however, obtained in high yield when half an equivalent of aluminum trichloride is added to a solution of two equivalents of *(2)* or *(3)* and one equivalent of the carbonyl compound in carbon tetrachloride. Interestingly, when magnesium bromide or, more so, when zinc chloride is used in place of $AlCl_3$, the *O*-(trimethylsilyl)monoselenoacetal *(4)* is also formed[6].

(2), R = CH_3
(3), R = C_6H_5

(4)

The hitherto unknown compounds of type *(4)* are also obtained on reacting carbonyl compounds and selenols in the presence of pyridine and chloro(trimethyl)silane[7] (see Table 2). These compounds can be used as starting material for the synthesis of α-halogenoalkyl selenides[8].

[a] Yield of pure substance.

Experimental

1,1-Bis(phenylseleno)heptane (method B): Concentrated sulfuric acid (6 ml) is added rapidly with stirring to a mixture of selenophenol (30 g, 0.19 mol) and heptanal (10.8 g, 0.094 mol) through which nitrogen is bubbled. The reaction is strongly exothermic and requires cooling with a water bath. After 30 min stirring, the mixture is diluted with ether (100 ml), washed with a dilute aqueous solution of sodium hydrogen carbonate, then with water, and finally dried over $MgSO_4$. To remove simultaneously formed diphenyl selenide an ethereal solution of the crude 1,1-bis(phenylseleno)heptane is slowly added under nitrogen and at 20 °C to a suspension of $LiAlH_4$ (1.5 g) in ether (150 ml). The mixture is refluxed for 30 min, cooled to 0 °C, and carefully treated with the minimum of an aqueous solution of KOH (50 %) until evolution of hydrogen has subsided. The mixture is rapidly filtered on celite and dried over $MgSO_4$. After purification (see below) and removal of ether there remains pure 1,1-bis(phenylseleno)-heptane in 73 % yield.

1,1-Bis(phenylseleno)heptane (method C): Heptanal (10.8 g, 0.094 mol) is slowly added under nitrogen to a solution of selenophenol (30 g, 0.19 mol) in CCl_4 (30 ml) in which is suspended anhydrous zinc chloride (6.8 g, 0.05 mol). After 3 hours' stirring at 20 °C the mixture is diluted with ether (100 ml), washed with an aqueous HCl solution (5 %) (2 times 50 ml), then with an aqueous solution of $NaHCO_3$, and finally with water. The organic phase is dried over $MgSO_4$, the solvent removed under vacuum and the crude product taken up in anhydrous ether. After treatment of the solution with $LiAlH_4$ as described above pure 1,1-bis(phenylseleno)heptane is obtained in 72 % yield.

1-Phenylseleno-1-(trimethylsiloxy)heptane: A solution of selenophenol (7.8 g, 0.05 mol) in pyridine (10 ml) is slowly added at 20 °C under nitrogen to a solution of anhydrous heptanal (5.7 g, 0.05 mol) and chloro(trimethyl)silane (7 g, 0.075 mol) in anhydrous pyridine (30 ml). After 12 hours' stirring at 20 °C, the mixture is diluted in carbon tetrachloride (100 ml), washed three times with 0.1 N NaOH, then with water, and finally dried over $MgSO_4$. Distillation of the filtrate affords 1-phenylseleno-1-(trimethylsiloxy)heptane in 80 % yield (b.p. 125–128 °C/0.1 torr).

α-Halogenoalkyl Selenides and α-(Phenylseleno)alkanide Anions

By *Willy Dumont, Mireille Sevrin*, and *Alain Krief*[*]

No general method for the synthesis of α-halogenoalkyl selenides *(2)*[1] has so far been described in the literature. We have found that these compounds can be obtained in quantitative yields by addition of gaseous HCl or HBr in benzene to vinyl selenides *(1)*[6]. (Method A, see Table 1) or by treatment of a mixture of an aldehyde and selenophenol with a saturated solution of gaseous HBr in benzene in the presence of anhydrous calcium chloride (Method B, see Table 2)[7].

[a] Determined by NMR analysis of the crude product mixture.

α-Bromoalkyl phenyl selenides *(4)* react rapidly (1 to 3 min) with n-butyllithium at −78 °C in tetrahydrofuran[3] with preferred cleavage of the Br—C bond and formation of the α-(phenylseleno)alkanide anions *(5)*[9]. On prolonged stirring of the reaction mixture at −78 °C these anions react with 1-bromobutane present in the medium to give *(6)*. The carbanion *(5)* in which R^1 and R^2 are both alkyl groups is much more reactive [90% yield of *(6)* after 1 h] than the parent compound *(5)* with $R^1 = R^2 = H$. Rapid hydrolysis of *(5)* or reaction with haloalkanes, which are more reactive than 1-bromo-n-butane, leads to variously substituted selenides.

Interestingly, aldehydes and ketones react much more rapidly with *(5)* than 1-bromo-n-butane. The β-(phenylseleno)-α-alkanols *(7)* are obtained in high yields (see Table 3). Olefins[10] and epoxides[11] are readily accessible from *(7)*. The advantages of this method starting from *(4)* are the ready accessibility of the starting material and the fact that the end product is not contaminated by undesirable butyl phenyl selenide (which is formed on reaction of selenoacetals with n-butyllithium).

(4) *(5)* *(7)* *(6)*

[a] Yield of pure substance.

Other α-halogenoalkyl selenides, including the closely related α-bromoalkyl methyl selenides and α-chloroalkyl selenides, react differently under the same reaction conditions. First results show that *n*-butyllithium attacks at the selenium atom, and thus indicate that this reaction could open a new synthetic route to carbenes.

Experimental

1-Bromoethyl phenyl selenide by Method A: To 10 ml of benzene saturated with anhydrous HBr is added 1 mmol of phenyl vinyl selenide dissolved in 2 ml of benzene. The mixture is stirred at 20 °C for 2 h. Evaporation of benzene under vacuum leads to NMR-spectroscopically pure 1-bromoethyl phenyl selenide in 95% yield. Attempts to distill or chromatograph compounds *(2)* (with the exception of the bromo- and chloromethyl phenyl selenides) resulted in complete decomposition of the products. The chloro derivatives are stable at 0 °C for 1 month; the bromo analogs, especially those with R^1 and R^2 = alkyl, are less stable.

1-Bromoethyl phenyl selenide by Method B: To 10 ml of benzene saturated with anhydrous HBr and containing calcium chloride (1 g) is added a mixture of acetaldehyde (1 mmol) and selenophenol (1 mmol) in benzene (2 ml). After 2 h at 20 °C the mixture is filtered and the benzene removed by evaporation under vacuum. NMR spectroscopically pure 1-bromoethyl phenyl selenide is obtained in 93% yield.

2-(Phenylseleno)nonan-3-ol: *n*-Butyllithium (1 mmol) (2 N in hexane, Merck) is added at −78 °C under nitrogen to a solution of 1-bromoethyl phenyl selenide (1 mmol) in anhydrous tetrahydrofuran (10 ml). After 3 min (−78 °C), heptanal (1 mmol) in THF (2 ml) is added and the resulting solution is stirred for 2 h at −78 °C and 1 h at 25 °C. After hydrolysis and preparative thin-layer chromatography the alcohol *(7)* is obtained in 69% yield.

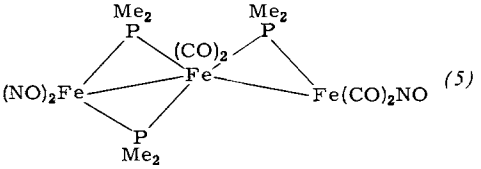
Phosphorus-Bridged Trinuclear Complexes Having Contiguous Metal-Metal Bonds[**]



By *Egbert Keller* and *Heinrich Vahrenkamp*[*]

The metal-metal bond lengths in phosphorus- and arsenic-bridged dinuclear complexes can be modified by variation of the nature and number of the ligands, thus permitting some degree of control of the reactivity of such complexes[1]. We have now attempted to synthesize the hetero-dinuclear complex *(3)*, for which we expect a particularly short metal-metal bond, from *(1)* and *(2)* by the propene elimination method[2].

However, the reaction did not lead to *(3)*, but instead, as a result of rearrangements and exchange reactions, to several mononuclear complexes and the two new trinuclear complexes *(4)* and *(5)*.

[*] Prof. Dr. H. Vahrenkamp, Dipl.-Chem. E. Keller
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Computing Center of the University.

The crystallographic data[3] and the molecular dimensions of *(4)* and *(5)* are almost identical. We thus have one of those rare cases in which analyses and spectra[4] are more significant in identifying the compounds than structure determination. The most important structural characteristic of *(4)* and *(5)* is the contiguous metal-metal bonding (bond angle of 160° at the central iron atom) and the three bridging dimethylphosphido ligands (Fig. 1).

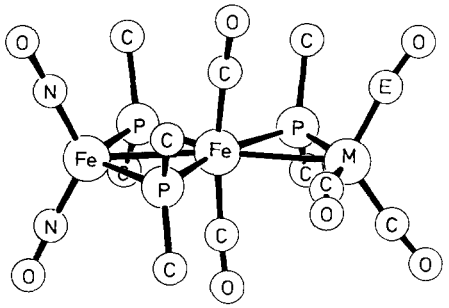


Fig. 1. Molecular structure of the trinuclear complexes *(4)* [M = Co, E = C; Fe—Fe = 2.67, Fe—M = 2.66 Å] and *(5)* [M = Fe, E = N; Fe—Fe = 2.66, Fe—M = 2.71 Å].

Neutral trinuclear complexes containing two consecutive base-bridged metal-metal bonds have not previously been reported. The stability of *(4)* and *(5)* seems to arise from the ability of the good π-acceptor ligands CO and NO to mop up the excess electron density caused by the bridging atoms which weakens the metal-metal bond[5]; other complexes of this kind[5, 6] require positive charges and 16-electron central metals for this purpose. The fact that all three metal atoms in *(4)* and *(5)* are coordinated differently is also unusual.

The failure of *(3)* to be formed is attributed, as in other cases[7], to the ligand sphere of this complex being too open, making it energetically less favorable than simpler complexes containing more ligands. On the other hand, a low number of ligands is an essential prerequisite for the aggregation observed in the formation of *(4)* and *(5)*. The formation of phosphorus-bridged clusters should therefore be feasible with *(1)* and *(2)* and reactants containing even fewer ligands.

Procedure

A mixture of *(1)* (2.5 g, 12 mmol) and *(2)* (2.0 g, 11 mmol) is stirred without a solvent for 2 d; 170 cm^3 of gas (propene, carbon monoxide) is evolved. After pumping off 1.3 g (70%) of $Co(NO)(CO)_3$ the reaction mixture is chromatographed on silica gel. Elution with cyclohexane successively gives $(CO)_4Fe(\mu\text{-}PMe_2)Co(CO)_3$, $[(CO)_3Fe\text{-}\mu\text{-}PMe_2]_2$, and $[(NO)_2Fe\text{-}\mu\text{-}PMe_2]_2$. The fourth, reddish-violet fraction eluted with benzene/cyclohexane (1 : 3) gives brown compound *(4)* (yield 420 mg, 13%; m.p. 182 °C) on recrystallization from benzene. The fifth, brown fraction gives the brown compound *(5)* (yield 15 mg, 0.7%; m.p. 162 °C) from hexane.

Molecular Structure of $[\eta\text{-}C_5H_5(CO)_2Re{=}C(C_6H_5)P(CH_3)_3][BCl_4]$ [**]

By *Fritz R. Kreissl* and *Peter Friedrich*[*]

Depending upon the ligand in the "*trans*-position" to the carbyne ligand, neutral or cationic carbonyl-carbyne complexes of chromium, molybdenum, tungsten, manganese, and rhenium[1] react with trimethylphosphane to give η^1- and η^2-ketenyl derivatives[2], dinuclear complexes with ylide bridges[3], or neutral or cationic, metal-substituted phosphorus ylides[4]. Spectroscopic data for the last-named organometallic compounds indicate predominance of structure *(1)* in the resonance hybrid[4].

(1a), M = Mn
(1b), M = Re

This kind of bonding has now been verified for *(1b)* by what we believe to be the first X-ray structure analysis[5] of a cationic transition-metal-substituted phosphorus ylide (cf. Fig. 1).

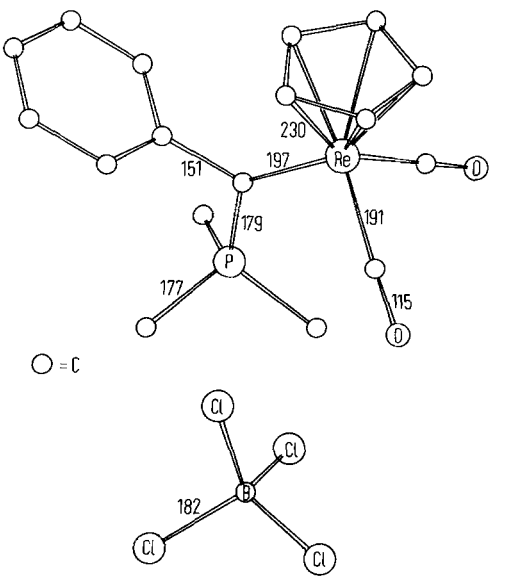

Fig. 1. Structure of the ylide complex *(1b)* (distances in pm).

[*] Dr. F. R. Kreissl, Dipl.-Chem. P. Friedrich
Anorganisch-chemisches Institut der Technischen Universität
Arcisstrasse 21, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

In *(1b)* the rhenium atom exhibits pseudooctahedral coordination, the bond angles and the distances to the carbonyl groups and to the cyclopentadienyl ring having the usual values[6].

The pronounced double bonding character of the M=C linkage suggested by the ^{13}C-NMR signal of the methylene carbon atom [$\delta = 262.2$ ppm, $^1J(^{31}P\text{-}^{13}C) = 14.7$ Hz] is confirmed by the rhenium-carbon distance of 197(1) pm. This bond is shorter than the tungsten-carbene carbon bond (213–215 pm[7]) found by *Casey et al.* for the isoelectronic complex $(CO)_5WC(C_6H_5)_2$, and can likewise be explained in terms of $d(M)_\pi$-$p(C)_\pi$ interaction. The sp^2-hybridized methylene carbon atom is almost coplanar with rhenium, phosphorus, and C-1 of the phenyl substituent. Opening of the Re—$C_{methylene}$—P bond to 128.2° is probably due to steric hindrance between the $C_5H_5(CO)_2Re$ unit and the $(CH_3)_3P$ group.

The phosphorus-methylene carbon bond length of 179(1) pm in *(1b)* is considerably greater than that of the corresponding bond in $(C_6H_5)_3P{=}CH_2$, *i.e.* 166.1 pm[8]; it is comparable with the three P—C_{methyl} bonds [176(2) to 180(2) pm] within the standard deviation and can be regarded as a single bond.

A New *cis*-Stereospecific β-Lactam Ring Closure[**]

By *Edgar Raude* and *Dieter Hoppe*[*]

4-Thia-2,6-diazabicyclo[3.2.0]hept-2-en-7-ones ("azetidinone-thiazolines") *(1)* are of utility in the synthesis of cephalosporins and penicillins[1], since the thiazoline ring protects acylamino and thio groups and, moreover, fixes them in a *cis*-orientation. We have now synthesized a compound of this type in only two steps from a Δ^2-thiazolin-5-one.

4-Methyl-2-methylthio-Δ^2-1,3-thiazolin-5-one *(3)*, obtained by cyclodehydration of 2-[(methylthio)thiocarbonylamino]-propionic acid[2] *(2)* with dicyclohexylcarbodiimide[3], was subjected to pyridine-catalyzed condensation with *O*-ethyl *N*-phenylformimidate[4] *(4)* to give the imine[5] *(5)* [67% yield; IR (film): 1725 (C=O), 1635 and 1550 cm^{-1} (both C=N); ^{1}H-NMR ($CDCl_3$): $\tau = 2.37$ (s, CH), 7.42 (s, SCH_3), 8.33 (s, CH_3)]. On heating with a suspension of sodium imidazolide (prepared *in situ* from imidazole and sodium hydride), *(5)* rearranges to the β-lactam[5] *(8)*, yield 88%. The IR data [(film): 1750 (C=O), 1540 (C=N)], the ^{1}H-NMR spectrum [($CDCl_3$): $\tau = 4.39$ (s, 5-H), 7.49 (s, SCH_3), 8.26 (s, CH_3)], as well as the loss of phenyl isocyanate in the mass spectrum[6], all evidence structure *(8)*.

Presumably, primary cleavage of the thiazolinone *(5)* gives the acylimidazolide *(6)*, which is in equilibrium with its (diastereomeric) cyclic tautomers *(7)*, of which only *cis*-*(7)* reacts further to give the bicyclic *(8)*. We interpret formation of the 5-amino-Δ^2-thiazoline-4-carboxamide[5, 7] *(9)* by irreversibly occurring addition of *tert*-butylamine and *(5)* (30 min at 25 °C, in dichloromethane) as indicating the above reaction course.

Experiments are in progress with the aim of extending this β-lactam synthesis to those formidic esters whose nitrogen atoms bear groups that are either suitable for cyclization or replacement by hydrogen.

4-Methyl-2-methylthio-4-(N-phenylimino)methyl-Δ^2-1,3-thiazolin-5-one: A solution of freshly distilled[8] *(3)*[3] (8.1 g, 0.05 mol), *(4)*[4] (7.5 g, 0.05 mol), and pyridine (0.8 g, 20 mol %) in anhydrous benzene (100 ml) is distilled over a packed column for 18 h, a benzene/ethanol mixture being drawn off at the head of the column (*ca.* 10 ml/min). The volume is maintained above 50 ml by addition of benzene. Rapid short-path distillation of the residue gives compound *(5)* (8.8 g, 67%), b.p. 145 to 148 °C/0.05 torr, as a viscous oil.

Dichloronitronium Hexachloroantimonate, $ONCl_2^{\oplus}SbCl_6^{\ominus}$

By *Kurt Dehnicke, Henning Aeissen, Marianne Kölmel*, and *Joachim Strähle*[*]

The dichloronitronium ion, which is isoelectronic with phosgene, was until now unknown. We have now synthesized this cation in the form of its hexachloroantimonate by reacting nitrogen trichloride with antimony pentachloride in the presence of sulfinyl chloride:

$$NCl_3 + SbCl_5 + SOCl_2 \xrightarrow{CCl_4} ONCl_2^{\oplus}SbCl_6^{\ominus} + SCl_2$$
(1)

The salt *(1)* forms shining, pale-yellow, hygroscopic crystals which are sparingly soluble in CCl_4 and stable up to 145 °C. Vacuum thermolysis yields nitrosyl hexachloroantimonate with the cleavage of chlorine:

$$ONCl_2^{\oplus}SbCl_6^{\ominus} \rightarrow NO^{\oplus}SbCl_6^{\ominus} + Cl_2$$

We have characterized *(1)* by elemental analysis, IR and Raman spectra as well as by a crystal structure analysis. It is the first NCl_2 compound with a pentavalent nitrogen atom.

The crystal structure (1817 symmetry-independent reflections, R = 4.26 %)[1] consists of almost undistorted $SbCl_6^{\ominus}$ octahedra and nearly completely planar $ONCl_2^{\oplus}$ ions (maximum deviation from the plane 0.038 Å). The unit cell contains two symmetry-independent sorts of cations, the differences between which lie within the range of their standard deviations (Table 1).

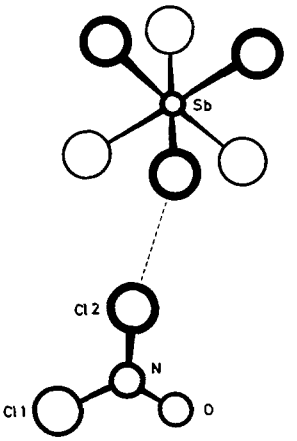

Fig. 1. Representation of an ion pair $NOCl_2^{\oplus}SbCl_6^{\ominus}$ in parallel projection [100]. The symmetry-independent ion pairs contained in the unit cell differ only very slightly from one another, therefore only the type II cation and the anion belonging to it are shown.

Table 1. Bond lengths [Å] and bond angles [°] of the $ONCl_2^{\oplus}$ ion.

Bond lengths, angles	Type I	Type II
N—O	1.30 (2)	1.32 (2)
N—Cl1	1.61 (2)	1.64 (2)
N—Cl2	1.72 (2)	1.69 (2)
Cl1—Cl2	2.857 (7)	2.851 (7)
O—Cl1	2.570 (15)	2.605 (16)
O—Cl2	2.599 (16)	2.590 (16)
Cl1—N—Cl2	118 (1)	118 (1)
O—N—Cl1	124 (2)	124 (1)
O—N—Cl2	118 (1)	119 (1)

The NO bond length in $ONCl_2^{\oplus}$ is 1.31 Å and lies between the length of a NO double bond (NO gas: 1.151 Å)[2] and that of a NO single bond (H_2N—OH: 1.47 Å)[3]; when compared with $OCCl_2$ (CO bond length = 1.166 Å)[4a], this represents a significant reduction in the π bond contribution. On the other hand the NCl bond lengths, with a mean value of 1.665 Å, are noticeably shorter than those in NCl_3 (1.75 Å)[5] and *N*-chlorosuccinimide (1.69 Å)[6], so that the NCl bond has a π bond contribution. The different sizes of the N—Cl1 and N—Cl2 bond lengths (1.63 and 1.71 Å respectively) are worthy of note, they produce the C_s-symmetry of the $ONCl_2^{\oplus}$ ion and are caused by a cation-anion interaction as indicated in Figure 1. The Cl atom of the long N—Cl bond is an average distance of 3.33 Å away from one of the Cl atoms of the $SbCl_6^{\ominus}$ ion—a distance which is smaller than the van der Waals bond length (3.5—3.6 Å) and corresponds to an ion pair. The effect is comparable with the intermolecular Cl...Cl interactions as observed in the crystal structures of Cl_2 (3.34 Å)[7], NCl_3 (3.37 and 3.42 Å)[5] and Cl_3VNCl (3.25 Å)[8].

The vibrational spectrum of *(1)* is in agreement with the crystallographic findings (Table 2). The bands expected for the O_h symmetry of the $SbCl_6^{\ominus}$ ion are observed [Raman: 330 (A_{1g}), 278 (E_g), 171 cm^{-1} (F_{2g}); IR: 347 cm^{-1} (F_{1u})].

In accordance with the reduced π bond contribution of the NO bond as compared to the CO bond in phosgene ($\nu CO = 1827\ cm^{-1}$)[4b], we observe the NO stretching vibration of the $ONCl_2^{\oplus}$ ion at 1650 cm^{-1} which resembles the situation

[+] Author to whom correspondence should be addressed.

Table 2. Raman spectrum of the $ONCl_2^{\oplus}$ ion.

$\tilde{\nu}$ [cm^{-1}]	Intensity	Assignment
1650 (IR)	m	νNO
747	m	$\nu_{as}NCl_2$
635	m	$\nu_s NCl_2$
420	w-m	δONCl
220	vw	δNCl_2

with the ONF_3 molecule (1690 cm^{-1})[9]. On account of the π bond contribution of the NCl bond, there should be a shift of the NCl stretching vibrations to shorter wavelengths as compared to the CCl vibrations of $OCCl_2$ (ν_{as} = 849, ν_s = 569 cm^{-1})[4b]; this shift is only observed in the symmetrical vibration, the asymmetrical vibration has bridging character as a result of the cation-anion interaction, and accordingly appears at a significantly longer wavelength (747 cm^{-1}) than in the phosgene molecule.

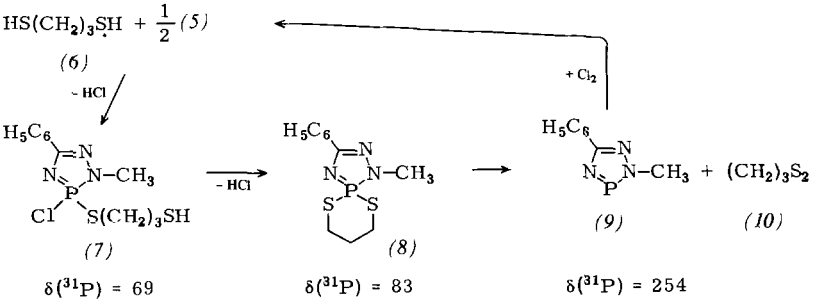
1,2,4,3λ^3-Triazaphospholes Synthesized by Reductive ($\sigma^4 \rightarrow \sigma^2$)-Elimination at Phosphorus[1]

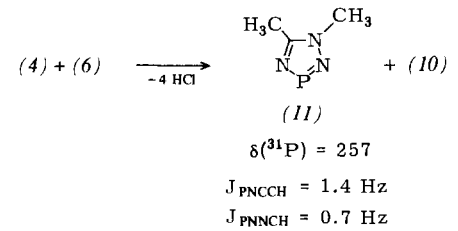
By *Alfred Schmidpeter, Jörg Luber*, and *Helmut Tautz*[*]

Reductive eliminations which lead to the formation of dicoordinated phosphorus from tetra-coordinated phosphorus,



are unknown with acyclicly bound phosphorus and have only so far been found to occur, indeed in large numbers, with phosphabenzenes[2]. These reactions are apparently limited to phosphorus in a cyclic 6π system and provide evidence in favor of the σ^2 as opposed to the σ^4 phosphorin system. We have now observed the first other case of such an elimination with 1,2,4,3-triazaphospholes. It similarly shows that the aromaticity of the azoles is better preserved in the σ^2 phosphaderivatives than in the σ^4 derivatives. In the extension of earlier studies[3] on the reaction of acylhydrazines with phosphorus pentachloride, we have found that the N^1 or N^2 monosubstituted amidrazone hydrochlorides [*e.g. (1)* or *(2)*[4]] condense with PCl_5 already at 0°C to give 3,3,3-trichloro-1,2,4,3λ^5-triazaphospholines, such as *(3)*, or their hydrochlorides, such as *(4)*. At room temperature *(3)* loses a further molecule of HCl and is converted into the 1,2,4,3λ^5-triazaphosphole dimer *(5)* whereas *(4)* is still stable at 100°C.

In all products phosphorus is penta-coordinated on account of the fact that it is incorporated into a five-membered ring[5]; the ^{31}P-NMR shifts to higher fields (negative sign) confirm this. 1,2,4,3λ^5-Triazaphospholes having a tetra-coordinated phosphorus atom are only formed when Cl is substituted by *O*, *N* or *S* bonded groups[6].



The reaction of *(5)* with 1,3-propanedithiol *(6)* (or 1,2-ethanedithiol) and triethylamine leads, *via* the spectroscopically identifiable substitution steps *(7)* and *(8)*, to a final, slightly slower, reductive elimination with the production of 1,2,4,3λ^3-triazaphosphole *(9)*[7]; typical product distribution after 3 h at 40°C in $CHCl_3$: 10% *(7)*, 40% *(8)*, 50% *(9)*.

1,2,4,3λ^3-Triazaphosphole *(11)* is formed in the same way from *(4)*. The products *(9)* and *(11)* were identified analytically and spectroscopically; the shift of the ^{31}P-NMR signal to very low field is especially characteristic.

(9) is chlorinated by PCl_5 or Cl_3CSCl and thus reconverted to *(5)*.

[*] Prof. Dr. A. Schmidpeter, Dr. J. Luber, Dipl.-Chem. H. Tautz
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

2-Methyl-5-phenyl-1,2,4,3λ³-triazaphosphole (9)

45 g 1-methylbenzamidrazone hydrochloride *(1)* is added portionwise to 50 g PCl_5 in 500 ml CH_2Cl_2. After 12 h at room temperature with brief refluxing if necessary, and the evolution of HCl, the mixture yields an almost clear solution which is then evaporated. The residue is boiled with 300 ml acetonitrile and filtered under suction: 42 g (71 %) *(5)*, colorless crystals, m.p. = 200 to 202 °C.—10.6 g *(6)* and 19.8 g triethylamine in 40 ml benzene are added to 24.3 g *(5)* in 250 ml benzene with ice-cooling. After stirring for 12 h at room temperature, triethylammonium chloride is filtered off under suction, the filtrate evaporated, and the residue distilled: 15.3 g (86 %) *(9)*, b.p. = 108 to 110 °C/0.1 torr.

1,5-Dimethyl-1,2,4,3λ³-triazaphosphole (11)

20.6 g 2-Methylacetamidrazone hydrochloride *(2)* is stirred with 34.8 g PCl_5 in 500 ml CH_2Cl_2 at room temperature. After 24 h the *(4)* formed is filtered off under suction: 40 g (91 %).—25.9 g *(4)* is allowed to react with 10.1 g *(6)* and 40.4 g triethylamine as described for *(5)*: 3.4 g (29 %) *(11)*, b.p. = 91 to 92 °C/13 torr, m.p. = 39 to 41 °C.

Structure of the First Four-Membered Cyclic Diorganyltin Chalcogenides[**]

By *Heinrich Puff, Rudolf Gattermayer, Rudolf Hundt*, and *René Zimmer*[*]

In the diorganyltin chalcogenides Ph_2SnS[1] and Me_2SnS[2] so far examined by X-ray analysis, puckered six-membered rings have been found. We have now synthesized di-*tert*-butyltin chalcogenides

(1a), X = S
(1b), X = Se
(1c), X = Te

for the first time by the following routes:

$$2\,t\mathrm{Bu_2SnCl_2} + 2\,\mathrm{Na_2X} \rightarrow 4\,\mathrm{NaCl} + [t\mathrm{Bu_2SnX}]_2$$

and[3]

$$[t\mathrm{Bu_2Sn}]_4 + 4\,\mathrm{X} \rightarrow 2[t\mathrm{Bu_2SnX}]_2$$

The di-*tert*-butyltin chalcogenides occur as dimers in the solid state and also in solution, and form flat four-membered tin-chalcogen rings[4].

The new compounds *(1)* form monoclinic crystals having two molecules in the unit cell:

	Lattice constants				Cell vol.	Space group
	a [Å]	*b* [Å]	*c* [Å]	β [°]	[Å³]	
(1a) [5]	11.05_0	16.50_0	6.31_5	96.2_4	1144.7	$P2_1\text{-}C_2^2$
(1b) [6]	8.77_3	12.25_8	12.01_4	114.8_4	1172.5	$P2_1/c\text{-}C_{2h}^5$
(1c) [7]	8.74_0	12.50_9	12.14_5	114.0_0	1213.1	$P2_1/c\text{-}C_{2h}^5$

The X-ray structural analysis[8] showed that the four-membered, tin-chalcogen ring of the selenium derivative *(1b)* ($R = 0.064$) has a rhombic form whereas that of the sulfur derivative *(1a)* ($R = 0.051$) is slightly deformed—probably due to packing effects—but is still planar. The four tertiary carbon atoms lie almost in the same plane which is nearly perpendicular to the plane of the ring.

	Bond lengths [Å]				Angles [°]		
	Sn—X		Sn—C		XSnX	SnXSn	CSnC
(1a)	2.49	2.38	2.21	2.17	94.3	84.0	114.4
	2.47	2.42	2.23	2.26	94.0	87.6	117.3
(1b)	2.55		2.16	2.20	97.5	82.5	115.1

The vibrational spectra (IR and Raman), measured with powders, confirm the molecular symmetry as determined by X-ray analysis. Molecular weight measurements in chloroform show that the four-membered ring remains when the compounds are dissolved. The NMR spectra (^{1}H-, ^{13}C- and ^{119}Sn-NMR at room temperature, ^{1}H-NMR also at −100 °C) demonstrate that the molecular geometry in solution is the same as that in the solid state. In the mass spectra of the homologous compounds *(1)*, the molecular ion was observed in all cases; the distribution of the isotopes agrees with the calculated values.

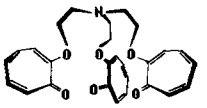
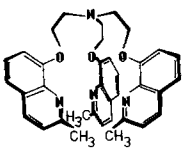
Noncyclic Cryptates[1]

By *Fritz Vögtle, Walter M. Müller, Winfried Wehner*, and *Egon Buhleier*[*]

Cryptates have been defined as complexes in which a bicyclic or larger neutral ligand of the crown ether type encloses a central ion in three dimensions[2]. We will now describe a new type *(1)* of neutral ligand for alkali metal ions which is not cyclic but still shows cryptand properties as regards the complete envelopment of the ion as well as the strength and selectivity of its complexation.

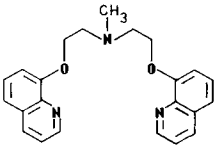


(1)

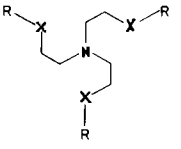


(2)

The topology of open chain cryptands is given by consequent combination of the polypode[2] ("octopus" molecule[3]) and terminal group concepts[4, 5].



(3)



(4)

As is shown in Table 1, readily crystallizing complexes are formed with alkali, alkaline-earth, and heavy metal ions.

A first index of the cryptand-analogous complexation of *(1)* compared with that of the crown ether type dipode *(5)*, is provided by the clearly stronger phase transfer of solid $KMnO_4$ and (aqueous) Na and K picrates into organic phases; this phase transfer surpasses that of dibenzo[18]crown-6. The participation of the terminal quinolyl groups of *(1)* in cation complexation is supported by the similar ^{1}H-NMR spectra of all three quinolyl groups in the *(1)*·KSCN complex and of the OCH_3 protons in the *(2b)*·NaSCN complex; further support comes from the considerably lower phase transfer capacity of the comparable compound *(2a)* which has a phenyl group as donor atom free terminal group.

(5)

(6)

Potentiometric data confirm and specify these findings (Table 2).

Table 1. Noncyclic cryptands and their cryptates.

[a] Correct analyses and/or high resolution mass spectra were obtained for all ligands and their complexes.
[b] No crystalline complexes could be produced from these ligands with the following salts: NaSCN, KSCN, RbI, $Co(ClO_4)_2$, $Ni(ClO_4)_2$, $Cu(ClO_4)_2$.
[c] Stoichiometry—ligand : salt : H_2O.
[d] Temperature at the beginning of sintering is given in brackets.

Of all the noncyclic ligands examined, *(1)* shows the highest complexation constants for alkali metal ions (in methanol/water); attention should be drawn to its preference for Na^+ over K^+ (and Li^+) and also to its high selectivity for divalent

[*] Prof. Dr. F. Vögtle, W. M. Müller, Dipl.-Chem. W. Wehner, Dipl.-Chem. E. Buhleier

Table 2. Acidity and complex stability constants (log K) of selected ligands [potentiometric in methanol/H_2O (88:12); temperature 293 K; ionic strength: tetraethylammonium bromide; 10-fold salt excess of the ion to be measured].

Ligand	pK_a	Li^+	Na^+	K^+	Cs^+	Mg^{2+}	Ca^{2+}	Sr^{2+}	Ba^{2+}
(1)	7.02	<2	2.6	2.0	<2	2.06	2.14	2.7	3.2
(2a)	6.01	<2	<2	<2	<2	<2	<2	<2	<2
(2b)	6.40	<2	2.2	2.3	<2	<2	<2	2.0	2.1
(3)	5.92	<2	<2	<2	<2	<2	<2	3.3	3.6
(4)	7.09	<2	<2	<2	<2	<2	<2	<2	<2
(5)	7.78	<2	<2	<2	<2	<2	<2	<2	<2

ions, especially Ba^{2+} and Sr^{2+}. The even higher complexation constants of the pseudocryptand *(3)* for these divalent cations is especially striking; this compound has three terminal tropolone ether groups. In agreement with this, a BaI_2 complex of *(3)* could be isolated but a KSCN complex could not. In contrast, the complex stabilities for the smaller Li^+ and Ca^{2+} ions are clearly lower. We attribute this selectivity, on the basis of studies with space-filling models, to the fact that the pseudocavity cannot become sufficiently small to form a "skin-tight" wrapping around the small cations for steric reasons. Only *(1)* also has a log K value which is greater than 2 for Mg^{2+}.

In contrast with the favorable complexation by the terminal 8-quinaldyl group in spirally wound, open chain crown ethers[4], the OCH_3 groups of the three-armed compound *(2b)* seem rather to block the pseudocavity; here the $KMnO_4$ transfer and the complex stabilities for all cations are lower. In agreement with this concept of open chain cryptates, even lower complex stabilities are found with *(2a)* which has terminal phenyl groups.

In the ^{1}H-NMR spectra of the NaSCN and KSCN complexes of *(4)*, the methyl protons are shifted to higher fields ($\Delta\delta = 0.78$ and 0.88 respectively in $CDCl_3$) than those of the free ligand; on the basis of studies with models, this can be accounted for by a propeller-like twisting of the three quinaldyl groups. This interpretation is corroborated by the finding that the CH_3 shift of the K^+ complex to higher fields is larger than that of the Na^+ complex ($\Delta\Delta\delta = 0.1$): in the first case the CH_3 protons appear to lie further in the anisotropic region of the quinaldyl system than in the second, due to the larger volume of the metal ion.

The description and stereochemical formulation of *(1)* as an open chain cryptand also appears to be justified by the comparatively low complex stability of the analogous noncyclic crown ether *(5)* which also has terminal quinolyl groups: although *(5)* is capable of forming crystalline complexes (Table 1), its complexation constants are an order of magnitude smaller than those of *(1)* (Table 2); selectivity towards divalent ions is not observed.

Open chain cryptands such as *(1)* (whose topography is characterized by the tetrahedral arrangement of its four nitrogen atoms and which resembles that of *Lehn*'s "soccer ball" cryptands[6]), *(2b)* and *(4)* may collectively have the greatest complexation capacity of all neutral ligands so far investigated when the simplicity of their synthesis and the price of the starting materials are taken into account.

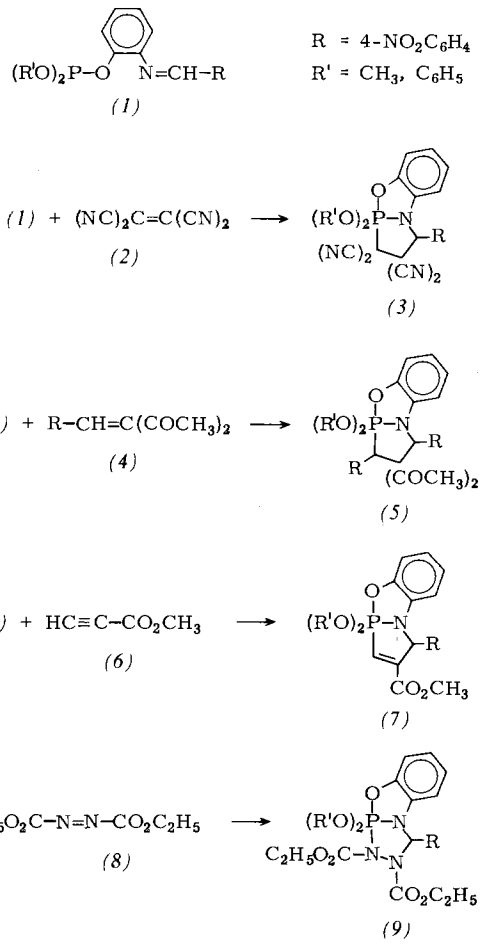
Double Ring-Closure Additions to *o*-(Methyleneamino)-phenyl Phosphites[1]

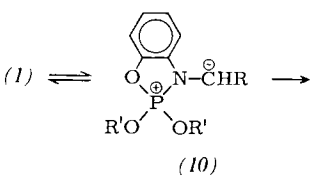
By *Alfred Schmidpeter, Josef Helmut Weinmaier*, and *Elmar Glaser*[*]

Methyleneaminophosphanes react with electron-deficient double- and triple-bond systems by [3+2]-cycloaddition[2] in which the induced charges are cancelled out by the formation of a λ^5-phosphazene:



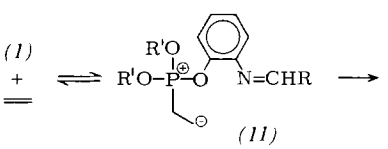
In the case of *o*-(methyleneamino)phenyl phosphites *(1)* however, the formal insertion of the three-membered *o*-oxyphenylene chain separates the two reaction centers—λ^3-phosphorus and the methylene carbon atom—into 1,6-positions from one another and makes a π bond-mediated compensation of charges impossible. In spite of this, these compounds again react with unsaturated systems in fundamentally the same way *i.e.* by 1,6-addition to P and C. Here, the charges equal out *via* a σ bond between P and N. Bicyclic σ^5-phosphoranes are the products.

2-(4-Nitrobenzylideneamino)phenyl dimethyl and -diphenyl phosphites *(1)* react with tetracyanoethylene *(2)* at 0°C and also (amongst other compounds) with 4-nitrobenzylideneacetylacetone *(4)*, methyl propiolate *(6)* or ethyl azodicarboxylate *(8)* after heating for several hours in benzene, to yield crystalline 1:1-adducts.



The ^{31}P-NMR shifts of *(3)*, *(5)* and *(7)* are found at $\delta = -35$ to -50 and those of *(9)* at $\delta = -50$ to -65 (to high field); they confirm the pentacoordination of the phosphorus. The ^{1}H-NMR spectra verify, on the basis of the diastereotopy of the *P*-methoxy groups, the addition to the benzylidene carbon atom of *(1)*; the values of the ^{31}P-^{1}H- and ^{1}H-^{1}H

[*] Prof. Dr. A. Schmidpeter, Dipl.-Chem. J. H. Weinmaier, E. Glaser
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)



couplings also confirm the direction of addition in the formation of *(5)* and *(7)*.

It would seem obvious to interpret the reactions as [3+2]-cycloadditions to a 1,3-dipolar equilibrium form *(10)* of the phosphites *(1)*:

The direction found for the additions leading to *(5)* and *(7)* which, as far as can be discerned, is followed exclusively, speaks against this route and in favor of a preceding bimolecular equilibrium; in this equilibrium the reaction partner attacks the phosphorus electrophilically and thus forms the 1,3-dipolar intermediate *(11)* which can then react further in an intramolecular [3+2]-cycloaddition:

The reactions presented here profit from the fact that the intramolecular ring-closure is kinetically especially favorable[3] and that pentacoordination of phosphorus is especially easy to reach in the bridgehead position of the *bicyclo*octane framework[4]. However, double additions to phosphites which are bimolecular in both steps and which lead to *monocyclic* σ^5-phosphoranes, are apparently limited to carbonyl compounds[5].

Experimental Procedure

A solution of $(R'O)_2PCl$ (0.1 mol) in benzene (50 ml) is added to a solution of *p*-nitrobenzaldehyde *o*-hydroxyanil (0.1 mol) and triethylamine (0.1 mol) in benzene (100 ml). After 2 h at room temperature the triethylammonium chloride is filtered off, the filtrate evaporated and the residue recrystallized. Yellow crystals: *(1a)*, $R' = CH_3$, m.p. = 151 to 152 °C (from chloroform), 55 % yield; *(1b)*, $R' = C_6H_5$, M.p. = 94 to 96 °C (from benzene), 71 % yield.

Equivalent quantities of *(1a)* or *(1b)* and the reaction partner *(4)*, *(6)* or *(8)* are refluxed for 48 h in benzene. The oily residue remaining after evaporation is then purified by column chromatography and/or recrystallization from acetonitrile. Colorless to yellow crystals, 30—80 % yield.

Synthesis of *N*-Protected ω-Amino Acids with the Aid of Stannyl Azides[**]

By *Hans R. Kricheldorf, Gerd Schwarz*, and *Jürgen Kaschig*[*]

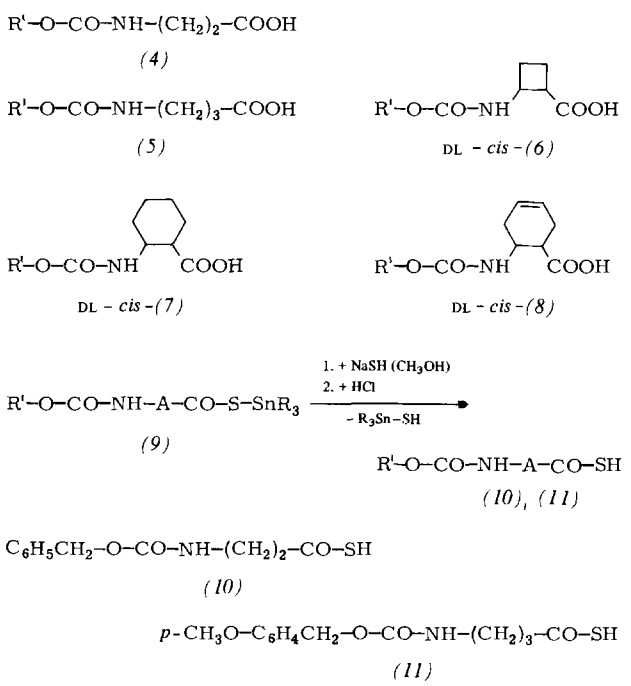
Acyl chlorides as well as carboxylic anhydrides and thioanhydrides can all be converted into isocyanates with stannyl azides. However, stannyl azides also add to isocyanates to form readily decomposable *N*-stannylcarbamoyl azides. This

[*] Dr. H.-R. Kricheldorf, Dipl.-Chem. G. Schwarz, Dipl.-Chem. J. Kaschig
Institut für makromolekulare Chemie der Universität
Stefan-Meier-Strasse 31, D-7800 Freiburg (Germany)

[**] We wish to thank the Schering A. G. (Bergkamen) and CIBA Geigy AG (Marienberg) for supplying us with chemicals used in this work.

side reaction can be avoided by first acylating the stannyl azides, *e.g.* with equimolar amounts of dicarboxylic anhydride, at 25—35 °C and subjecting the resulting acyl azides *(1)* to Curtius degradation. In this way the stannyl esters of ω-isocyanatocarboxylic acids are formed almost quantitatively. Since stannyl esters are resistant to alcoholysis, in contrast to silyl esters, alcohols can be added to the isocyanate group of *(2)* without side reactions. Hydrolysis of the resulting *N*-alkoxycarbonyl-ω-amino stannyl ester *(3)* gives the *N*-protected ω-amino acids, *e.g.* *(4)* to *(8)* (see Table 1), which usually crystallize well.

This method has the following advantages:



1) The synthesis can be carried out as a single-pot process.

2) ω-Amino acids are not required as starting materials.

3) The distannoxanes formed on hydrolysis of the stannyl esters *(3)* can easily be transformed by thionyl chloride into stannyl chlorides, which give stannyl azides with sodium azide[1, 2].

4) The preferred reagent tri-*n*-butylstannyl azide is not explosive, not sensitive to hydrolysis, not particularly toxic, stable on storage, and readily accessible in larger quantities[1, 2].

Succinic and glutaric thioanhydrides were reacted in the same way as the cyclic anhydrides[3]. The intermediate thioamino *S*-stannyl esters *(9)* were thiolyzed with sodium hydrogen sulfide solution in order to avoid hydrolysis of the CO—S bond. The yields of the thio amino acid derivatives thus obtained, *(10)* and *(11)* (see Table 1), were nevertheless lower than those of the analogous amino acid derivatives *(4a)* and *(5b)*, due primarily to the sensitivity of the sulfur compounds to oxidation and to their reluctance to crystallize.

Procedures

D,L-*cis*-6-(*tert*-Butyloxycarbonylamino)-3-cyclohexene-1-carboxylic acid *(8d)*, dicyclohexylammonium salt: Tri-*n*-butylstannyl azide (0.1 mol) and *cis*-4-cyclohexene-1,2-dicarboxylic anhydride (0.1 mol) are stirred in anhydrous dioxane (50 ml) for 20 min at 30—35 °C. The IR spectrum then displays two azide bands of approximately equal intensity at 2090 and 2150 cm^{-1}. The reaction mixture is heated until vigorous evolution of N_2 starts and the exothermic reaction kept under control by cooling if required. After the reaction has subsided the mixture is heated for 40 min at 80—90 °C, *tert*-butanol (0.15 mol) and 1,4-diaminobicyclooctane (0.5 g) are added, and warming to 50—60 °C continued overnight. The isocyanate band at 2275 cm^{-1} provides a check on whether addition is complete. The reaction mixture is then stirred with 1 N sodium hydroxide solution (120 ml) for 30 min and diluted with dichloromethane (150 ml). The aqueous phase is separated off and re-extracted with dichloromethane (50 ml). After stirring of the aqueous phase with citric acid (20 g) and ethyl acetate (150 ml), the organic phase is separated off and treated with diethyl ether (200 ml) and dicyclohexylamine (0.1 mol). The pure product crystallizes overnight from the ethereal solution at 0 °C.

Table 1. Properties of *N*-protected ω-amino acids of types *(4)* to *(8)* and *(10)*, *(11)* prepared with the aid of tri-*n*-butylstannyl azide. *(a)*: $R' = C_6H_5CH_2$ (R'—O—CO=Z); *(b)*, $R' = p\text{-}CH_3—C_6H_4CH_2$ (R'—O—CO=Z(OMe)); *(c)*, $R' = p\text{-}NO_2—C_6H_4CH_2$ (R'—O—CO=Z(NO_2)); *(d)*, $R' = C(CH_3)_3$ (R'—O—CO=Boc); *(e)*, $R' = CCl_3CH_2$ (R'—O—CO=Troc).

[a] Crystalline crude products.
[b] Recrystallized from ethyl acetate + petroleum ether; the results of C, H, N analyses agree with the calculated values (±0.3 %).
[c] Dicyclohexylammonium salt.

N-Benzyloxycarbonylthio-β-aniline *(10)*: Succinic thioanhydride[3] (0.1 mol) and tri-*n*-butylstannyl azide (0.1 mol) are dissolved in anhydrous dioxane (500 ml) and heated to 20—25 °C for 10 h, 40—45 °C for 20 h, and 80—90 °C for 40 min. 30 min after addition of benzyl alcohol (0.1 mol) the reaction mixture is concentrated in vacuum. The residue is dissolved in methanol (100 ml) and a small amount of phenolphthalein is added. An approximately 5 M solution of NaSH in methanol is then added under N_2 until a persistant red color appears. The solution is concentrated *in vacuo* and the residue dissolved in ethyl acetate (150 ml) and extracted twice under N_2 with water (2 × 80 ml). The aqueous extracts are acidified to pH = 1 with conc. hydrochloric acid. The precipitate is dissolved in ethyl acetate (200 ml) and partly induced to crystallize after concentration of the solution by addition of petroleum ether and cooling to −20 °C in the course of three days. The oily fraction obtained after concentration of the mother liquor at 10^{-3} torr shows the same IR and ^{1}H-NMR spectrum as the crystalline fraction.

6,7-Diphenyl-2,3-dihydro-1,4-dioxocin[**]

By *Gerd Kaupp* and *Michael Stark*[*]

Irradiation of 1,2-diphenylcyclobutene derivatives generally leads to elimination of diphenylacetylene (α-cleavage) or to oxidative formation of cyclobuta[*l*]phenanthrenes (dehydrocyclization)[1, 2]. The reaction course depends upon whether the phenyl groups can undergo free rotation after excitation of the *cis*-stilbene chromophore, or whether the partial rotations are sterically hindered[3]. We now report a β-cleavage, a rare event in photolyses of cyclobutenes[1, 4], which permits a ready synthesis of dihydrodioxocin *(4)* starting from the bicyclic *(3)*.

(1) *(2)* *(3)* *(4)* *(5)*

Photoaddition of diphenylacetylene *(1)* to *p*-dioxene *(2)*[5] affords *(3)* [^{1}H-NMR (CCl_4): δ = 7.75—7.15 (10H, m), 4.95 (2H, s), 4.0—3.5 (4H, sym. AA'BB')][6]. *cis*-Linkage of the rings in *(3)* is confirmed by catalytic hydrogenation to the symmetrical (^{1}H- and ^{13}C-NMR spectra) derivative *(5)* (m.p. 134—135 °C)[6]. Compound *(3)* displays a UV spectrum having pronounced fine structure [CH_3CN: $\lambda_{max}(\varepsilon)$ = 225 (22500), 229 (sh, 20500), 294 (16600), 298 (sh, 16500), 315 (sh, 10400), 319 nm (sh, 8500); EPA, 77 K: 228, 233, 236.5, 284 (sh), 296.5, 309, 322 nm] and an intense fluorescence spectrum showing only a hint of fine structure even at 77 K [cyclohexane: λ_{max}^{corr} = 383 nm, Φ_{fl} = 0.32; EPA, 77 K: *ca.* 355 (sh), 369, *ca.* 385 nm (sh)]. Disrotatory opening of the bicyclic *(3)* to the eight-membered ring *(4)* with a quantum yield Φ = 0.33 competes with fluorescence. The symmetrical structure of *(4)* is confirmed by the ^{1}H-NMR spectrum [CCl_4: δ = 7.2—6.9 (10H, m), 6.53 (2H, s), 4.08 (4H, br s, $\Delta\nu_{1/2}$ = 2 Hz)][6]. The UV spectrum [CH_3CN: $\lambda_{max}(\varepsilon)$ = 230 (sh, 16300), 244 (18400), 277 nm (sh, 5500)] also complies with expectations. Secondary photolysis of *(4)* to *(3)* and other products can largely be avoided. The complete absence of α-cleavage on photolysis of *(3)* is surprising.

1,6-cis-7,8-Diphenyl-2,5-dioxabicyclo[4.2.0]oct-7-ene (3)[6]:

Compound *(1)* (2.0 g, 11.2 mmol) is dissolved in *(2)* (90 g) and irradiated for 3 d with eight low-pressure mercury lamps (253.7 nm) in a Rayonet reactor at 30 to 35 °C. Excess *(2)* is distilled off, and compound *(3)* (1.05 g) crystallizes from the oily residue at −20 °C after addition of CH_3OH (50 ml). Chromatography of the mother liquor on SiO_2 (300 g) with benzene (5 l) yielded unreacted *(1)* (320 mg), *(4)* (100 mg), and *(3)* (860 mg; total yield 64%; m.p. 88 °C, CH_3OH).

6,7-Diphenyl-2,3-dihydro-1,4-dioxocin (4)[6]:

A solution of compound *(3)* (1.0 g, 3.8 mmol) in benzene (500 ml) is irradiated for 1 h with a high-pressure mercury lamp (Hanau TQ 150) through a Pyrex filter under N_2 at 25 °C. After concentration, compound *(4)* (850 mg) crystallizes from CH_3OH (15 ml) at −20 °C. The mother liquor still contains 30 mg of *(4)* (total yield 88%; m.p. 114 °C, CH_3OH) and 30 mg of *(3)*.

Hydrogenolysis of Trisubstituted Dichlorophosphoranes—A New Method for Deoxygenation of Oxophosphoranes

By *Mitsuo Masaki* and *Noboru Kakeya*[*]

Although tertiary phosphanes are versatile reducing agents, their use in industry is very limited, mainly owing to the lack of economical methods for regenerating the reagents from oxophosphoranes, *i.e.* from their oxidation products. We recently reported a convenient method for the reduction of the oxophosphoranes[1], involving their treatment with oxalyl chloride and reduction of the resulting dichlorophosphoranes with thiols in the presence of trimethylamine[2]. We have now found an even simpler method, which is illustrated by equations (a) and (b).

$$\underset{(1)}{R_3PO} + Cl_2 + CO \rightarrow \underset{(2)}{R_3PCl_2} + CO_2 \qquad (a)$$

$$\underset{(2)}{R_3PCl_2} + H_2 \rightarrow \underset{(3)}{R_3P} + 2HCl \qquad (b)$$

Table 1. Reduction of oxophosphoranes *(1)* to phosphanes *(3)*.

	R_3PO *(1)*	Yield of *(3)* [%]	Recovery of *(1)* [%]
(a)	$(n\text{-}C_4H_9)_3PO$	90	10
(b)	$(n\text{-}C_8H_{17})_3PO$ [a]	92	8
(c)	$(C_6H_5)_3PO$ [b]	86	14

[a] Chlorination and hydrogenolysis were performed under conditions similar to the case of *(1a)* (see Experimental).
[b] Chlorination conditions: 1 h at 60 °C and then 1.5 h at 100 °C; hydrogenolysis conditions: 180 °C, 2 h.

When tri-*n*-butyl(oxo)phosphorane *(1a)* is treated with an equimolar amount of chlorine under carbon monoxide pressure in carbon tetrachloride at room temperature, an exothermic reaction occurs to give tri-*n*-butyl(dichloro)phosphorane *(2a)* and carbon dioxide. The formation of *(2a)* was confirmed by treatment of the reaction mixture with aniline and triethylamine to give tri-*n*-butyl(phenylimino)phosphorane [isolated in 94% yield based on *(1a)*].

The dichloro compound *(2a)* underwent hydrogenolysis at 160 °C and *ca.* 98 bar of hydrogen without any catalyst to give tri-*n*-butylphosphonium chloride, which was easily converted into the free base *(3a)* either by neutralization with sodium hydrogen carbonate or by thermal dissociation in refluxing toluene (further examples are shown in Table 1).

Oxo(triphenyl)phosphorane *(1c)* is known to be converted into the corresponding dichloro compound *(2c)* by phosgene[3]. The reaction of eq. (a) takes place with ease even under conditions where phosgene is scarcely formed from carbon monoxide and chlorine without catalyst. When a solution of chlorine in carbon tetrachloride is treated with *ca.* 59 bar of carbon monoxide at 60 °C for 1 h, neither phosgene nor oxalyl chloride was formed and the major amount of chlorine is recovered.

Experimental

A glass cylindrical vessel containing a solution of *(1a)* (2.18 g, 10 mmol) and chlorine (0.71 g, 10 mmol) in carbon tetrachloride (15 ml) was charged in an autoclave, which was then pressurized with CO to *ca.* 59 bar at 25 °C. The reaction mixture was shaken for 10 min, during which the temperature of the mixture rose to 60 °C at the highest by an exothermic reaction. The reaction mixture in the vessel was stripped of solvent and toluene (50 ml) was added. Some (*ca.* 35 ml) of the toluene was evaporated to remove the remaining carbon tetrachloride. The vessel containing the resultant toluene solution of *(2a)* was charged in an autoclave, which was pressurized with hydrogen to *ca.* 98 bar. The mixture was shaken at 160 °C for 1.5 h, and then neutralized with aqueous $NaHCO_3$. According to gas chromatography the reaction mixture contained 1.82 g of *(3a)* and 0.21 g of *(1a)*.

Amino Sugars and *N*-Glycosides by Oxyamination of Unsaturated Carbohydrate Derivatives[**]

By *Ingolf Dyong, Quan Lam-Chi, Gerhard Schulte, Bert Fraser-Reid*, and *John L. Primeau*[*]

The synthesis of amino sugars has so far remained a difficult problem. Only 2-amino-2-deoxyaldoses have become more readily accessible through studies by *Lemieux et al.*[1], but in the case of all other amino sugars (*e.g.* 3-amino-3-deoxyaldoses) recourse is still being made to tedious multi-step syntheses. As has been found independently by each of our research groups, the single-step *cis*-oxyamination of olefins developed by *Sharpless et al.*[2] provides a particularly useful and widely applicable method in carbohydrate chemistry for the synthesis of nitrogen-containing sugar derivatives.

3,4,6-Tri-*O*-acetyl-D-glucal *(1)* reacts with chloramine-T, the sodium salt of *N*-chloro-*p*-toluenesulfonamide, in the presence of catalytic amounts of OsO_4[2] to give the four products *(2)*—*(5)*, which can easily be separated by chromatography on silica gel with toluene/diisopropyl ether/2-propanol (20:4:1) and are readily isolable in crystalline form. *(2)* [m.p. 159—160 °C, $[\alpha]_D^{21} = +70.9°$ ($CHCl_3$), yield 10.3%], after acetylation to *(2a)* [m.p. 125—126 °C, $[\alpha]_D^{24} = +74.4°$ ($CHCl_3$)], is identical with the known 1,3,4,6-tetra-*O*-acetyl-*N*-toluenesulfonyl-α-D-glucosamine[3]. Compounds *(3)*—*(5)* are tri-*O*-acetyl-*N*-tosyl-α-D-glucosylamines [total yield 30.6%]. Reac-

[**] Synthesis of Biologically Important Carbohydrates, Part 12. This work was supported by the Landesamt für Forschung des Landes Nordrhein-Westfalen, the Fonds der Chemischen Industrie, and the National Research Council of Canada.—Part 11: *I. Dyong, R. Knollmann, N. Jersch, H. Luftmann*, Chem. Ber., in press.

tions typical for sugars containing a free 1-OH (glycosidation, halogenation) do not occur, and on acetylation *(3)*, *(4)* and *(5)* each afford the same 2,3,4,6-tetra-*O*-acetyl-*N*-tosyl-α-D-glucosylamine *(6)* [m.p. 132—133 °C, $[\alpha]_D^{21} = +35.7°$ ($CHCl_3$)][4]. The oxyamination of *(1)* is thus strongly regioselective and most likely stereospecific, since no products having the *manno* configuration have so far been detected[5].

Earlier attempts to *cis*-hydroxylate ethyl 4,6-di-*O*-acetyl-α-D-hex-2-enopyranoside *(7)*[6] with OsO_4 led exclusively to the corresponding mannose derivative[7], and, as expected, *(7)* reacts within 40 h at 40 °C to give the amorphous ethyl 4,6-di-*O*-acetyl-*N*-tosyl-α-D-mannosaminide *(8)* [m.p. 48—54 °C, $[\alpha]_D^{25} = +14.5°$ ($CHCl_3$), yield 16%] and the ethyl 4,6-di-*O*-acetyl-3-deoxy-3-*N*-tosylamino-α-D-mannoside *(9)* [m.p. 146—148 °C, $[\alpha]_D^{25} = +43.7°$ ($CHCl_3$), yield 37 %]. *(8)*, *(9)* and unreacted *(7)* can be separated with chloroform/cyclohexane/2-propanol (6:10:1). The markedly different mass spectra of *(8)* and *(9)* are consistent with positional and not configurational isomers. Thus the mass numbers of the strong H_1^+ fragments[8] [*(8)*: $m/e = 241$ TosHNCH=CHOEt$^+$; *(9)*: $m/e = 88$ HOCH=CHOEt$^+$] appear with only low intensity in the spectrum of the other isomer. The main product *(9)* can be converted almost quantitatively into *(10)* [m.p. 168—170 °C, $[\alpha]_D^{25} = +61.9°$ (CH_3OH)] by the method of *Zemplen*, and into the hydrochloride *(11)* [m.p. 225–227 °C $[\alpha]_D^{25} = +59.7°$ (CH_3OH)] by reaction with sodium in liquid ammonia after treatment with acid. Cleavage of aglycon from *(11)* with 4 N HCl leads to a product that gives a negative Elson-Morgan test, *i.e.* a product which cannot be a 2-amino-2-deoxy sugar[9a]. The data of the crystalline hydrochloride are consistent with those of 3-amino-3-deoxy-D-mannopyranose hydrochloride *(12)* [decomp. pt. 165—167 °C, $[\alpha]_D^{25} = +15.2°$ (3 min) → $+5.8°$ (2 h; H_2O)], which hitherto was accessible only by multistep synthesis[9b].

$K_6[Si_2Te_6]$—Synthesis and Structure of the First Tellurodisilicate

By *Günter Dittmar*[*]

While thio and seleno analogs of silicates have long been known[1], corresponding tellurium compounds have not yet been prepared.

It has now proved possible, by melting a stoichiometric mixture of the elements in an evacuated quartz tube, to obtain the compound $K_6[Si_2Te_6]$ as grayish black crystals having a metallic sheen, which are sensitive to air and moisture. Its structure was solved by complete X-ray analysis (space group C2/m, $Z = 2$; $a_0 = 965.2$, $b_0 = 1362.1$, $c_0 = 890.2$ pm, $\beta = 117.34°$; 1305 observed relexion data recorded with a four-circle diffractometer; unweighted R value for anisotropic temperature factors 6.1 %).

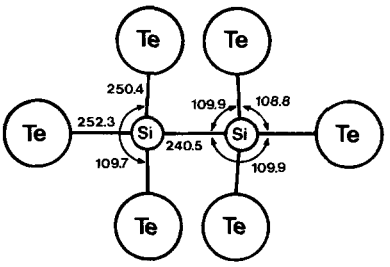

Fig. 1. Structure of hexatellurodisilicate(6−). Bond lengths [pm] and angles [°].

In contrast to Si_2Te_3[2], where the Si_2Te_6 units are linked two-dimensionally to form infinite double layers, the disilicate groups are isolated in $K_6[Si_2Te_6]$ (Fig. 1). The bond lengths have the values expected for covalent bonds. The Si_2Te_6 has 2/m symmetry but deviates only slightly from the ideal $\bar{3}$ 2/m symmetry. The bond angles at silicon indicate almost ideal tetrahedral coordination. The K atoms link the Si_2Te_6 groups in a deformed octahedral or trigonal-prismatic environment to form a three-dimensional network without any preferred planes of cleavage.

Procedure

Si (0.1680 g), K (0.7015 g), and Te (2.2892 g) are weighed into a quartz ampoule ($d = 20$ mm, $l = 50$ mm), which is then evacuated and sealed. The ampoule is heated in a corundum crucible to 630 °C (sillite furnace). After 1 h the temperature is slowly lowered to 280 °C over a period of 6 h, and cooling allowed to proceed further. Short grayish black prism isolated from the regulus can be stored under anhydrous liquid paraffin.

Catalyzed Rearrangement of Nitrile Oxides to Isocyanates[**]

By *Georg Trickes* and *Herbert Meier*[*]

The rearrangement of nitrile oxides *(1)* to isocyanates *(2)* is of particular interest because of the simultaneous shift of two ligands along a CN unit. This long-known reaction[1] has recently been studied in some detail by *Grundmann et al.*[2]. Use of the thermal rearrangement *(1)* → *(2)* is severely restricted by the competing dimerization of *(1)* to the furoxanes *(3)*.

While studying the photochemistry of 1,2,3-thiadiazole 1,1,2-trioxides[3] we discovered a catalytic process permitting the rearrangement *(1)* → *(2)* to be performed under such mild conditions that dimerization is avoided. A suitable catalyst is sulfur dioxide, which participates in the reaction as a dipolarophile.

(2) directly from *(1)* 70-95%
(7) directly from *(1)* 68-93% *(7)* from *(2)* 78-98%
(5) directly from *(1)* 81-94% *(5)* from *(2)* 98%

In this way the rearrangement of nitrile oxides *(1)* to the isocyanates *(2)* in excellent yields can be accomplished directly in boiling anhydrous benzene; however, 1,3,2,4-dioxathiazole 2-oxides *(4)* can also be isolated as intermediates[4]. Compounds *(4)* are extremely sensitive to moisture and quantitatively afford hydroxamic acids *(5)* on treatment with water at room temperature. The first published synthesis of *(4)*[5] utilized the reverse reaction of *(5)* with sulfinyl chloride.

If work-up is carried out in aqueous medium at 70—80 °C, compounds *(2)* yield the symmetrical urea derivatives *(7)* *via* the amines *(6)*.

Carbene Addition to Dicarbonyl(η-cyclopentadienyl)cobalt[1]

By *Manfred L. Ziegler, Klaus Weidenhammer*, and *Wolfgang A. Herrmann*[*]

Oxidative addition with elimination of CO occupies a special place in the chemistry of dicarbonyl(η-cyclopentadienyl)cobalt *(1)*[2]. The reason for this is the low coordination number of the metal atom, which facilitates nucleophilic attack at the center of the molecule.

While aliphatic diazo compounds readily react with *(1)* on heating to give dinuclear μ-methylene cobalt complexes[3], we have now also been able to synthesize mononuclear derivatives—*via* a photochemical route starting from the dialkyl diazomalonates *(2a)* and *(2b)*. The green crystalline compounds *(3a)* and *(3b)*, obtained in *ca.* 60 % yield, are moderately air-stable, diamagnetic, and readily dissolve in strongly polar solvents. According to total elemental analysis and osmometric molecular weight determinations they have the empirical formulas $C_{12}H_{11}CoO_6$ and $C_{14}H_{15}CoO_6$, respectively. Since the mass spectra show no molecular ions, and the IR, ^{1}H-NMR and ^{13}C-NMR spectra (Table 1) provide only proof of the structure $(\eta^5\text{-}C_5H_5)Co(CO)L$ but no conclusive evidence about the constitution of the ligand L, we have carried out a crystal structure analysis on the ethyl derivative *(3b)*[4]. The presence of a five-membered metallacycle proves that the reaction

[a] τ values; TMS int.; +33 °C. [b] δ values; 22.63 MHz; TMS int.; +32 °C; *ca.* 1.5 M solution in CD_2Cl_2; "remaining C": assignments uncertain.

proceeds *via* the unusual 1,3-addition of bis(alkoxycarbonyl)-carbene : $C(CO_2R)_2$ to the substrate *(1)*. Linking of a carbene carbonyl oxygen atom to the metal atom and conversion of an M—CO— group into an M—Acyl function increases the coordination number of the central metal atom, which is finally located in a distorted tetrahedral environment. To our knowledge [2+3]-carbene additions of this type have hitherto not been observed in organometallic chemistry.

Experimental[5]:

A solution of *(1)* (3.60 g, 20 mmol) and *(2a)* (3.79 g, 24 mmol) or *(2b)* (4.50 g, 24 mmol) in tetrahydrofuran (200 ml) is irradiated (Hg high-pressure lamp TQ 150) for 10 h at −25 °C in a pyrex immersion-lamp apparatus furnished with internal and external cooling. The green reaction solution is concentrated by evaporation under high-vacuum at +20 °C and then purified by column chromatography (Kieselgel 60, Merck 7734; Act. II—III; 48 × 2 cm; 10 °C). The carbene adducts *(3a)* and *(3b)*, respectively, are eluted with acetone as rapidly migrating deep-green zones. The oily residue remaining after evaporation of the eluate is crystallized from ether/CH_2Cl_2 (10:1) at −35 °C. The dark green crystals have a metallic luster. After washing them with 3 × 10 ml ether they are recoverable in analytically pure form. *(3a)*: 3.60 g (58%); m.p. 145—149 °C. *(3b)*: 4.13 g (61%); m.p. 118 to 119 °C.

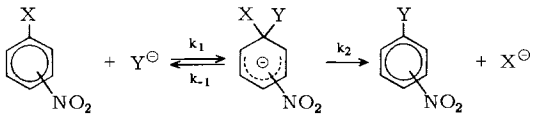
(2), X = R = H

Syntheses and rearrangements of 5-substituted pyrimidine nucleosides and nucleotides are reviewed in an article by *T. K. Bradshaw* and *D. W. Hutchinson* with particular emphasis on the derivatives of uridine *(1)* and cytidine *(2)*. X in *(1)* can, for example, be Cl, Br, NO_2 or CH_2OH, while with *(1)*, R = PO_3H or $(PO_3H)_2H$, 5-hydroxy derivatives are also obtained. Halogen derivatives of *(2)*, R = H, are also known; 5-hydroxymethyl compounds are not formed. In all syntheses the result strongly depends upon substitution pattern. Mechanisms are suggested for substitution at C-5 and for exchange reactions. Biochemically interesting in this connection is the mode of action of the thymidylate synthetase. [5-Substituted Pyrimidine Nucleosides and Nucleotides. Chem. Soc. Rev. *6*, 43—62 (1977); 110 references]

[Rd 956 IE—F]

The photochemistry of imines forms the theme of a review by *A. C. Pratt*. Especially dealt with are imines of the type $R^1R^2C{=}NR^3$, in which R^3 is alkyl, aryl or acyl. Typical reactions are, *inter alia*, geometrical isomerization, photoreduction to amines, photocyclizations of *N*-benzylideneanilines

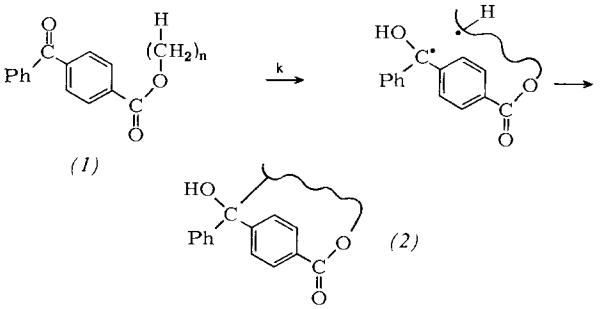


(2)

such as *(1)* to phenanthridine derivatives *(2)*, and the α-cleavage of *N*-acylimines. [The Photochemistry of Imines. Chem. Soc. Rev. *6*, 63—81 (1973); 59 references]

[Rd 957 IE—F]

Nucleophilic substitution—with emphasis on linear free energy relationships between reactivity and physical properties of leaving groups and substrates—is the subject of a review by *G. Bartoli* and *P. E. Todesco*. In a nucleophilic substitution, a nucleophile ($Y^{\ominus}$) replaces a nucleofugic (leaving) group X; an example is



There is no order of precedence for $Y^{\ominus}$ and X that is valid under all conditions. Interactions between $Y^{\ominus}$, X and the rest of the substrate must be taken into consideration. In the case of halo-arenes and -heteroarenes it can be shown that the polarizability of the halogen and of the nucleophile (*e.g.* $C_6H_5S^{\ominus}$ and $CH_3O^{\ominus}$) play a decisive role. [Nucleophilic Substitution. Linear Free Energy Relationships between Reactivity and Physical Properties of Leaving Groups and Substrates. Acc. Chem. Res. *10*, 125—132 (1977); 48 references]

[Rd 958 IE—L]

Stereoselectivity in the binding of transition-metal chelates to nucleic acid constituents is reported on by *L. G. Marzilli* and *T. J. Kistenmacher*. It is known, for example, that ions such as Cu^{2+} destabilize the DNA double helix because they disrupt base-pairing through their binding to heterocyclic bases; in contrast, ions such as Mg^{2+} increase the stability of the double helix, since they minimize repulsion between negatively charged groups through their binding to phosphate chains. Which factors then determine the selectivity, *i.e.* determine which binding centers will be preferred by a given metal chelate? In this connection rules could be derived by systematically varying the geometry of the metal (particularly Cu(II) and Co(III)) and the size and hydrogen-bonding potential of chelate ligands (*e.g.* ethylenediamine, 2,4-pentanedionate, glycyl glycinate). Noteworthy are the strong hydrogen-bonding interactions involving exocyclic groups on the purine and the pyrimidine ring. These bonding interactions, coupled with repulsive nonbonded interactions, can influence the stability of the complex. [Stereoselectivity in the Binding of Transition-Metal Chelate Complexes to Nucleic Acid Constituents: Bonding and Nonbonding Effects. Acc. Chem. Res. *10*, 146—152 (1977); 29 references]

[Rd 959 IE—L]

Determination of the conformation of hydrocarbon chains in solution by photochemical probes is discussed in an article by *M. A. Winnik*. In such chains conformational equilibrium is reached in about 10 ns. The phosphorescence lifetimes of benzophenone derivatives such as *(1)* are of the order of 10—100 μs. Chemical reactions which quench the excited state, *e.g.* cyclization to *(2)*, shorten this time. The constant *k*

was measured in CCl_4, acetic acid, acetonitrile and other solvents; its value increases monotonically with the chain length. Compounds with $n<9$ do not cyclize. The basis of calculations was a diamond lattice model for the hydrocarbon chain. [Photochemical Probes of Hydrocarbon Chain Conformation in Solution. Acc. Chem. Res. *10*, 173—179 (1977); 35 references]

[Rd 960 IE—L]

The study of metal clusters can, according to *E. L. Muetterties*, provide a valuable insight into chemisorption and catalytic processes on surfaces. Metal clusters are discreet molecular species in which three or more atoms form a triangular or polyhedral array; the center position is almost always vacant and the periphery is usually enveloped by ligands. The range of examples extends from $Os_3(CO)_{12}$ and $Pd_3(CNR)_6$ through species having 4 to 10 or 12 metal atoms up to the ion $Pt_{15}(CO)_{30}^{2-}$. A cluster molecule may be regarded as a little piece of metal with chemisorbed species on the periphery. The chemistry of this molecule allows conclusions to be drawn about the processes taking place in heterogeneous catalysis. [Molecular Metal Clusters. Science *196*, 839–848 (1977); 75 references]

[Rd 961 IE—F]

Neutron Activation Tables. By *G. Erdtmann*. Vol. 6 of the series edited by *K. H. Lieser*. Verlag Chemie, Weinheim—New York 1976. 1st edit., 146 pp., 15 figs., bound, DM 78.—.

A brief introduction to the "Neutron Activation Tables" is followed by very clear definitions of the tabulated values.

The tables are set out clearly in the order of the mass numbers. Data are given for the following reactions of all stable elements and for a large number of synthetic elements: a) with slow reactor neutrons (mostly n, γ) reactions with thermal and epithermal neutrons, b) with fast reactor neutrons, and c) with 14.5 MeV neutrons. In each case the tables show the starting nuclide and its isotopic abundance, the reactions, the half-life of the product, the reaction cross section, the activities for all six irradiation times, and the strongest gamma lines and their intensities. The appendix provides information on the complex disintegration series of some radionuclides formed in neutron reactions.

Along with the very clear arrangement of the tables it should be particularly noted that the author has taken great care to collect and select the best-attested values from the most recent records of nuclear data. This is therefore a valuable reference work for daily use in the laboratory and will certainly be of use not only for the nuclear physicist, chemist, or physician but also for all those who are only occasionally concerned with neutron activation. Production and printing match the high quality of its contents.

R. Henkelmann [NB 372 IE]

An Introduction to the Chemistry of Heterocyclic Compounds. By *R. M. Acheson*. John Wiley & Sons Ltd., New York—London 1976. 3rd edit., xvii, 501 pp., bound, £ 17.75.

As the author states in the preface, the present book attempts to give the student a brief outline of the most important properties and chemical reactions of heterocyclic systems in about 500 pages. It is therefore intended as a bridge between the current original publications too specialized for the beginner and textbooks of organic chemistry in which, in the author's opinion, heterocyclic chemistry is frequently dealt with too summarily.

After a short introduction to the nomenclature, heterocycles, arranged predominantly in order of their ring size, are treated in ten main chapters. For all the more important representatives of the various classes exhaustive information is given on physical and chemical properties, reactivities, mechanisms, and approaches to syntheses. A pleasing feature is that almost every chapter section ends with interesting examples of substances, taken mostly from the chemistry of natural products. Each chapter contains an exhaustive bibliography, and at the end of the book there is a comprehensive subject and compound index.

The book represents the state of heterocyclic chemistry at the beginning of 1975. The wealth of results and new developments that have appeared since the last 1967 edition is suitably taken into account. Thus, classes or substances such as the benzotriazoles, relatively large ring systems (azonines, azocines, and diazepines) and the 1,2-dioxetanes (important in photochemical processes), new syntheses, spectroscopic results, and mechanistic ideas have now been included in the new edition. However, some interesting compounds, such as α-lactones, benzene trioxide, and benzene triimine, have been omitted. The use of the obsolete method using letters (instead of the clearer method of showing skeletons) and the unjustified rotation of formulas in synthetic schemes are a didactic weakness, but this does not diminish the scientific value of this work. The book does complete justice to the aim mentioned at the beginning, although it is rather expensive for the student.

Heinrich Wieland Centennial: His Lifework and His Legacy Today[**]

By Bernhard Witkop[*]

Many of *Heinrich Wieland*'s friends and disciples remember all too well his sixtieth, sixty-fifth[1], seventieth, and eightieth birthdays; the last-named one was observed quietly on June 4, 1957[2]. He thanked us all with the Goethe quotation, behind which he tried to hide his emotion[3]. Of the two colleagues in Munich who were *Wieland*'s very close friends, *Hans Fischer*, in *Wieland*'s words, paraphrased from *Goethe*'s Faust, "could not be held back by the ringing of the Easter Bells from taking his own life, on Saturday, March 31, 1945"[4], but *Walter Gerlach* is with us today as a living link to a tradition so great and unique that the present student generation may have difficulties in grasping its true dimensions. It seems appropriate to let physics, as the more logical and mathematical science, lead us to an evaluation which would also facilitate a re-interpretation of the history of chemistry. In doing so, as a useful exercise in epistemology, let us look at the famous experiment of *Stern* and *Gerlach* (1920–1923) when the two scholars used a beam of silver atoms to prove the quantization of space and to measure the magneton[5–7]. These memorable experiments[8] were the turning point in the study of the mechanics of the atom, leading, eventually, to the electron spin, the development of molecular beam technique by *I. I. Rabi*, magnetic resonance, maser and laser and related work in pure physics[9]. In this presentation we are looking, as it were, at the "fine structure" of a small segment of the spectrum of physics. Will it be possible to transfer this kind of analysis to the historical development of modern organic chemistry and to the contributions of *Heinrich Wieland*, who always considered "biochemistry an area neglected by organic chemists"[10]?

Heinrich Wieland [photograph by *B. Witkop* at Starnberg in 1953].

Munich's tradition as the origin and nursery of great ideas and men of science began with *Liebig*, who passed the "olympic fire" on to *Adolf von Baeyer*, *Richard Willstätter*, *Heinrich Wieland*, and many others (Fig. 1)[11]. Just as our old master is very much present and with us at this moment, so are the disciples who, in the words of *A. W. von Hofmann* "have preceded us"[12]. *Liebig* continued his studies on silver fulminate, begun with *Kastner*, in Paris with *Vauquelin*: in 1832 *Gay-Lussac* presented the results to the Academy in the presence of *Alexander von Humboldt*. Thanks to *Humboldt* and *Gay-Lussac*'s sponsorship, *Liebig* was appointed

[**] Commemorative lecture under the auspices of the Gesellschaft Deutscher Chemiker at the Fall Meeting in Munich, September 13, 1977.

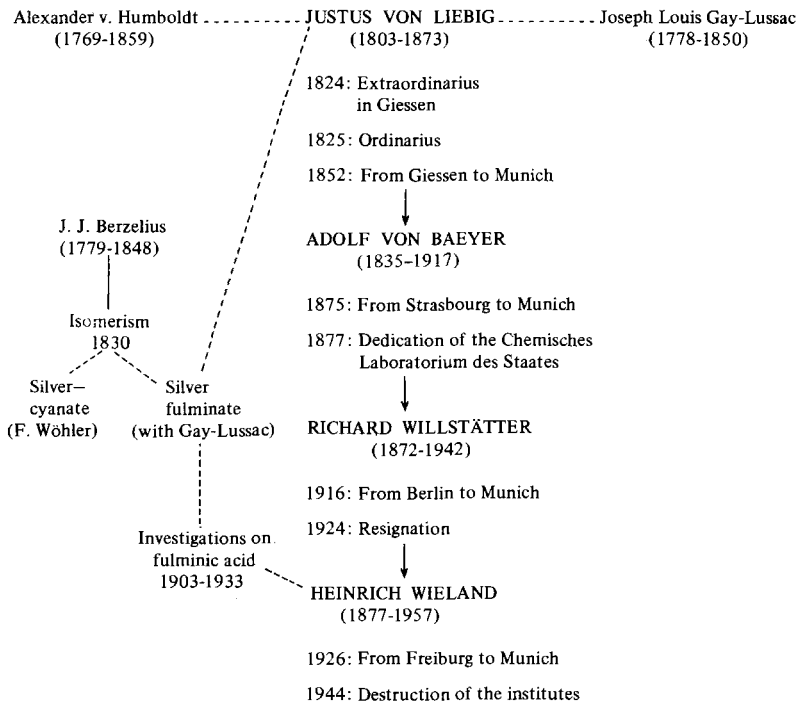

Fig. 1. The Munich Chair of Organic Chemistry in the course of history.

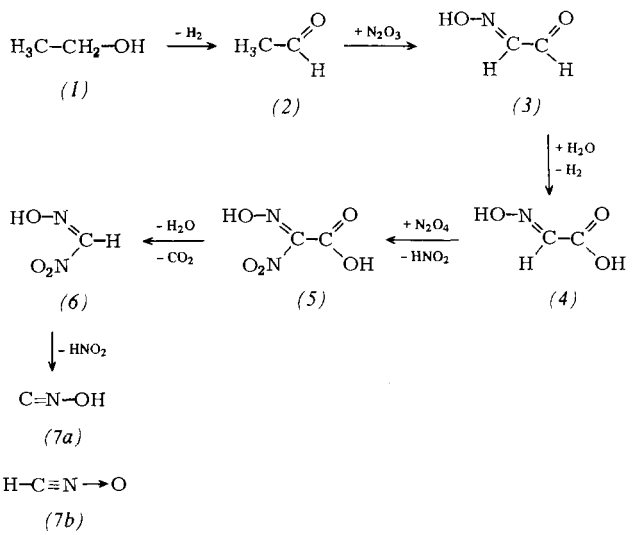

Fig. 2. Formation of fulminic acid *(7a)* or *(7b)* from alcohol, nitric acid, and mercury.

Extraordinarius for philosophy at Giessen in 1824[13]. *Liebig* performed an accurate analysis of silver fulminate. *Wieland*'s contribution to this highly traditional field came in 1903 when he elucidated the formation and polymerization of fulminic acid. He showed methylnitrolic acid *(6)* to be the key intermediate in the classical preparation of fulminic acid *(7)* from alcohol *(1)*, nitric acid, and mercury (Fig. 2).

Liebig's fulminic acid or 2-nitromalonamidonitrile *(11)* arises by dimerization of free fulminic acid through partial hydrolysis of the mercury salt. *Nef*'s formulation of fulminic acid as formoxime *(7a)* has recently been changed to that of formonitrile oxide *(7b)*[14]. Dimerization leads to (hydroxyimino)acetonitrile oxide *(8)* which adds more fulminic acid to yield furoxanaldoxime *(9)* that then rearranges to 4-nitro-Δ^4-isoxazolin-5-imine *(10)*, *Grundmann*'s prefulminuric acid *(10)*[15]. Ring opening of *(10)* leads to fulminuric acid *(11)*. Thus, *Wieland*'s essentially correct reaction mechanism of the oligomerism of fulminic acid was not revised until very recently. The identical composition of silver fulminate and silver cyanate was recognized by *Liebig* and prompted *Berzelius* to coin the term *isomerism* in 1830. *Wieland*'s extensive investigations on nitrogenous compounds have been reviewed by *Friederich Klages* and later by *Rolf Huisgen*[1] who by the use of modern methods and the entire armamentarium of electronic theory, quantum mechanics, and NMR spectroscopy expanded and completed his mentor's heritage in a manner hardly foreseeable.

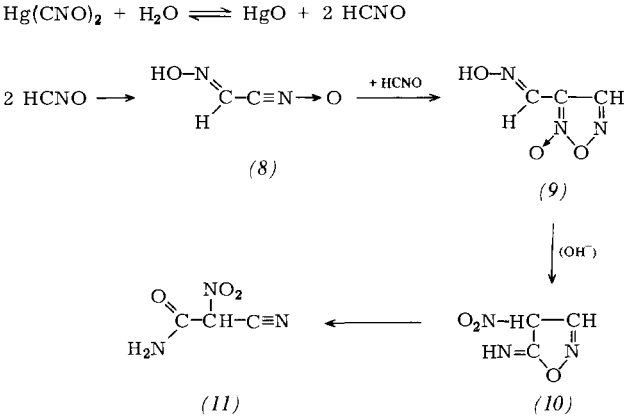

Fig. 3. Dimerization of fulminic acid *(7)* to fulminuric acid *(11)*.

Wieland himself enjoyed remembering his predecessor by telling the famous story of *Liebig*'s "Abendvorlesung" on February 12, 1853, when, in the presence of their majesties, King Maximilian II and the Queen of Bavaria, accompanied

by Princes and Princesses, a violent explosion injured not only *Liebig* but also members of the Royal Court[16]. According to *Wieland*, the beauteous Princess *Mary* saved the situation when she got up and returned, with a curtsy and a smile, a piece of equipment that had landed on her lap to the dumbfounded *Liebig*. *Frederick Schönbein*, a close friend of *Liebig*, characterized Munich in those days[17]: "Of all the cities in Europe, Munich probably has the largest number of eminent chemists. If I am not mistaken, there are no less than seven professors who teach their discipline and head their own laboratories".

In our historical analysis we now come to the dichotomy of style: classical *versus* romantic. Among *Liebig*'s scientific progeny we have proponents of both attitudes. We would certainly consider *Warburg* on the side of strict form, fact, reason, and rigid deduction. *Wieland*, on the other hand, shows in his work an artistic streak, is intuitive and guided more by emotion and imagination. During his student days he had trouble renting a room in Munich because he was an undaunted piano player to the extent that he enjoyed the reputation of a "forte-pianist" throughout the neighborhood. In the selection of his topics, especially among natural products (see Charts I and II), he was guided by his closeness to, and love of, nature. The details of this part of his research have been adequately described, but the latent underlying principles require some elaboration. Nowadays we face the question of classification of natural products: clearly *Wieland* was attracted by physiological activity rather than by taxonomy, but to some extent he had a sixth sense for the subtle aspects of biogenesis, as we know it today. From the tacky industrial yeast mother liquors of ergosterol production

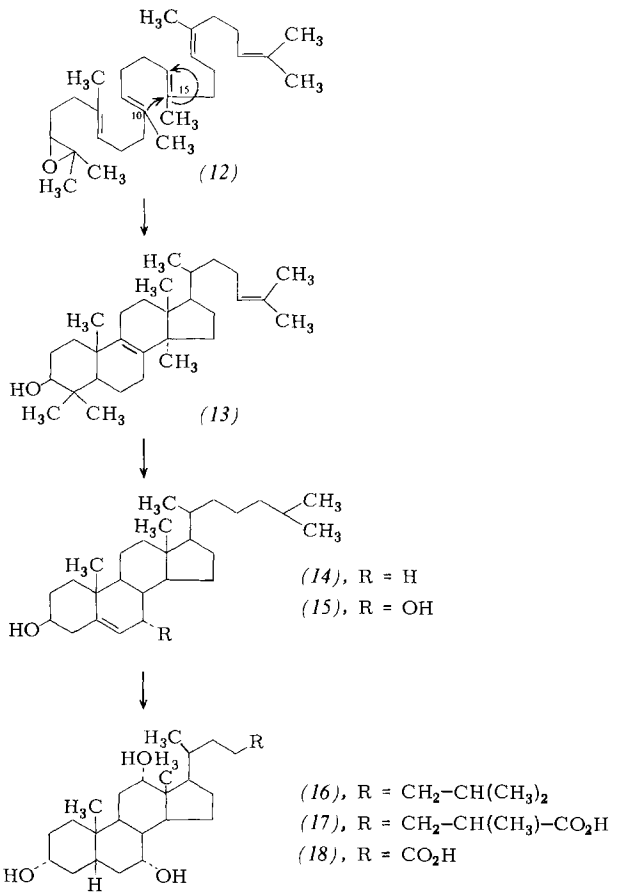

Fig. 4. Biosynthesis of cholic acid *(18)* by enzymatic stereoselective cyclization of squalene 2,3-epoxide *(12)* *via* lanosterol *(13)* and cholesterol *(14)* with intramolecular migration of the methyl groups at C-10 and C-15.

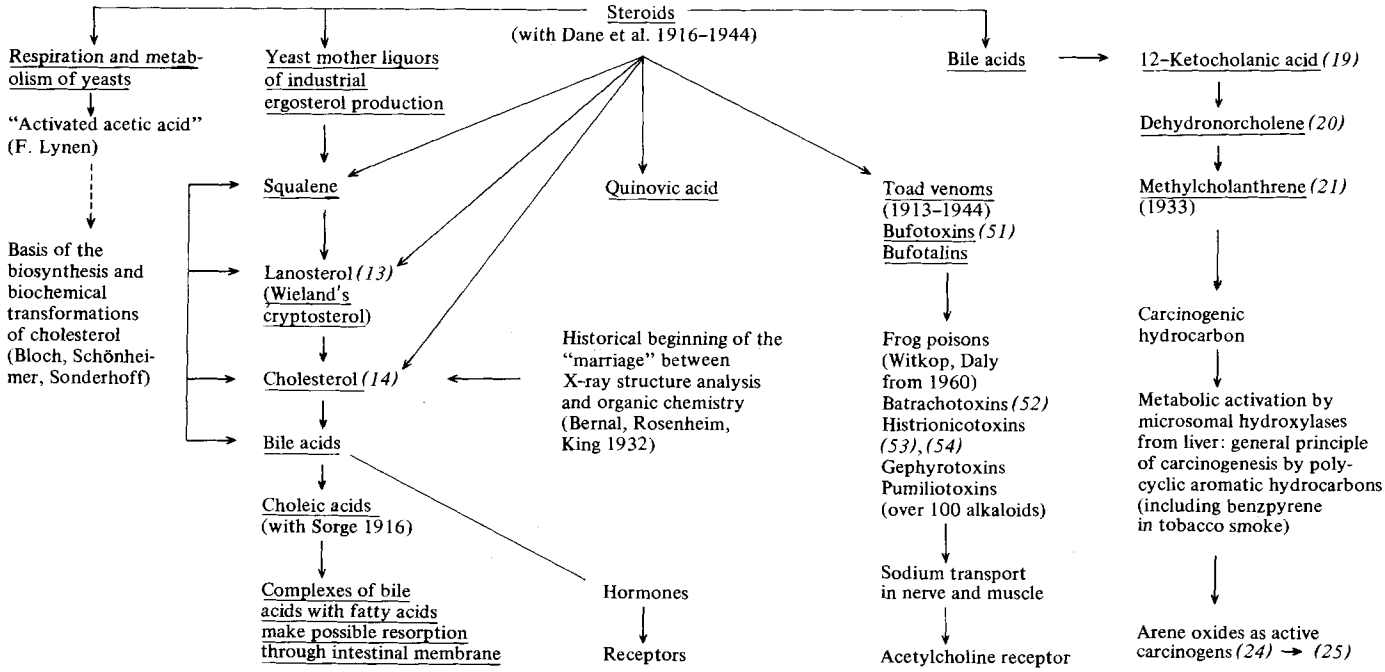

Chart I. *Wieland*'s work on natural products: juxtaposition of the static classical chemistry of natural products performed by *Wieland* and the dynamic biochemistry of metabolic processes that resulted therefrom. *Wieland*'s classical approach to natural products chemistry is apparent from the isolation and structural elicidation of key compounds, such as squalene, cryptosterol, and cholesterol from the yeast mother liquors of industrial ergosterol production. It was not until the 1940's that *Konrad Bloch*, *Rudolf Schönheimer*, and (in 1937) *Wieland*'s student *Robert Sonderhoff* introduced isotopic labeling, which permitted elucidation of the biosynthesis of cholesterol and the bile acids. Likewise, forty years elapsed between *Wieland*'s synthesis of the carcinogenic hydrocarbon methylcholanthrene and proof of the connection between formation of labile arene oxides in the liver or lung and carcinogenesis. The only compound that has not yet served as the basis for biochemical developments is quinovic acid, a pentacyclic triterpene from the mother liquors of quinine production. *Wieland*'s first foray into biochemical dynamics was his work on metabolism and respiration of yeast. These studies led to the concept of "activated acetic acid" and—through *F. Lynen*—to its structure.

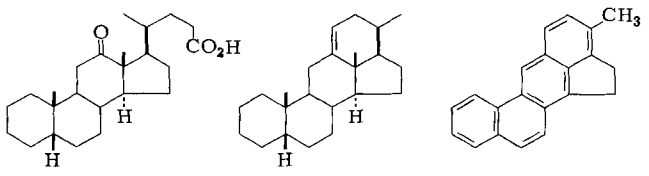

he hoped to isolate intermediates in steroidal biosynthesis. Indeed, he demonstrated the presence of squalene and "cryptosterol", *i.e.* lanosterol *(13)*; however, these precursors were not related with cholesterol *(14)* until *Konrad Bloch*[18] (Fig. 4) established a most fascinating concerted stereoselective intramolecular cyclization of squalene 2,3-oxide *(12)*, followed by oxidative rearrangement to cholesterol *(14)*.

The introduction of radioactive markers or deuterium goes back to *Rudolf Schönheimer*[19] who established the concept of the dynamic state of body constituents[20], and to *Wieland*'s laboratory, especially *Robert Sonderhoff*[21], the promising young biochemist who had such an early, tragic death. The new isotopic label technique showed clearly that *e.g.* cholic acid *(18)* arises from cholesterol *(14)* *via* intermediates *(15)*, *(16)*, and *(17)*. These transformations form the basis of concepts on the etiology of atherosclerosis as they were developed by *Ludwig Aschoff*, *Rudolf Schönheimer*, and others (Fig. 5).

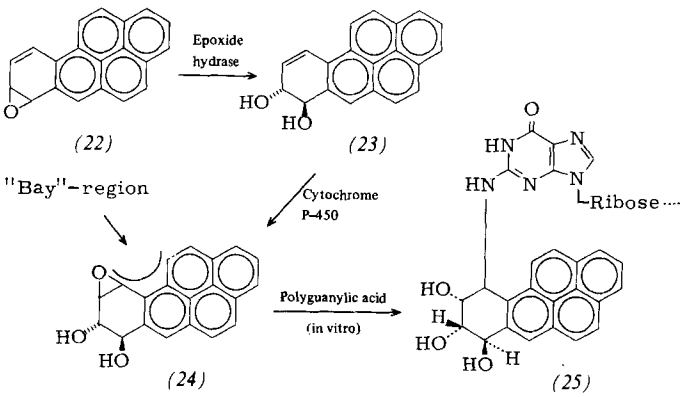
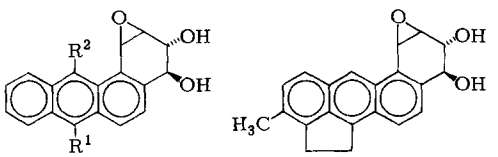
Fig. 5. Work on cholesterol metabolism and atherosclerosis [19].



Wieland and *Dane* obtained methylcholanthrene *(21)* by distillation of 12-ketocholanic acid *(19)* and selenium dehydrogenation of dehydronorcholene *(20)* (Fig. 6). This hydrocarbon was soon found to be highly carcinogenic, and represents the starting point in a long search for a mechanism of carcinogenesis by polycyclic aromatic hydrocarbons. The mechanism would have delighted *Wieland*, because it shows how strongly reactions of an initially purely academic nature are involved in intermediate metabolism.

(19) *(20)* *(21)*

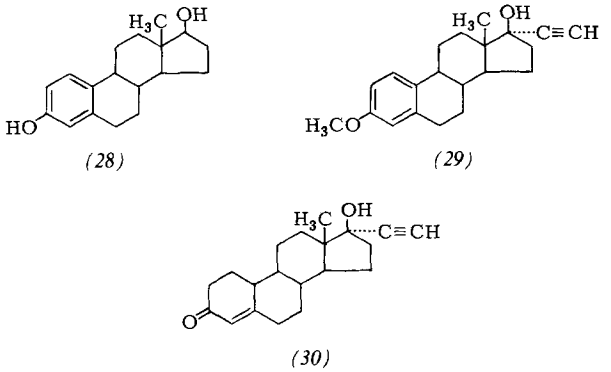
Fig. 6. Formation of methylcholanthrene *(21)* from 12-ketocholanic acid *(19)* *via* dehydronorcholene *(20)*.



Metabolic activation starts with hepatic hydroxylase P-448 (P-450) to yield, by insertion of an oxygen atom, (autoxidizable) phenols[22] or, by addition of oxygen to a double bond, (labile) arene oxides[23] that open up to *trans*-dihydrodiols with the aid of epoxide-hydrase. Thus benzo[*a*]pyrene would initially form the epoxide *(22)*, easily opened to the (synthetically accessible) optically active highly mutagenic and carcinogenic *trans*-diol *(23)*, presumably the precursor of the "ultimate carcinogen" *(24)* by a second epoxidation at the so-called

(22) *(23)* *(24)* *(25)*

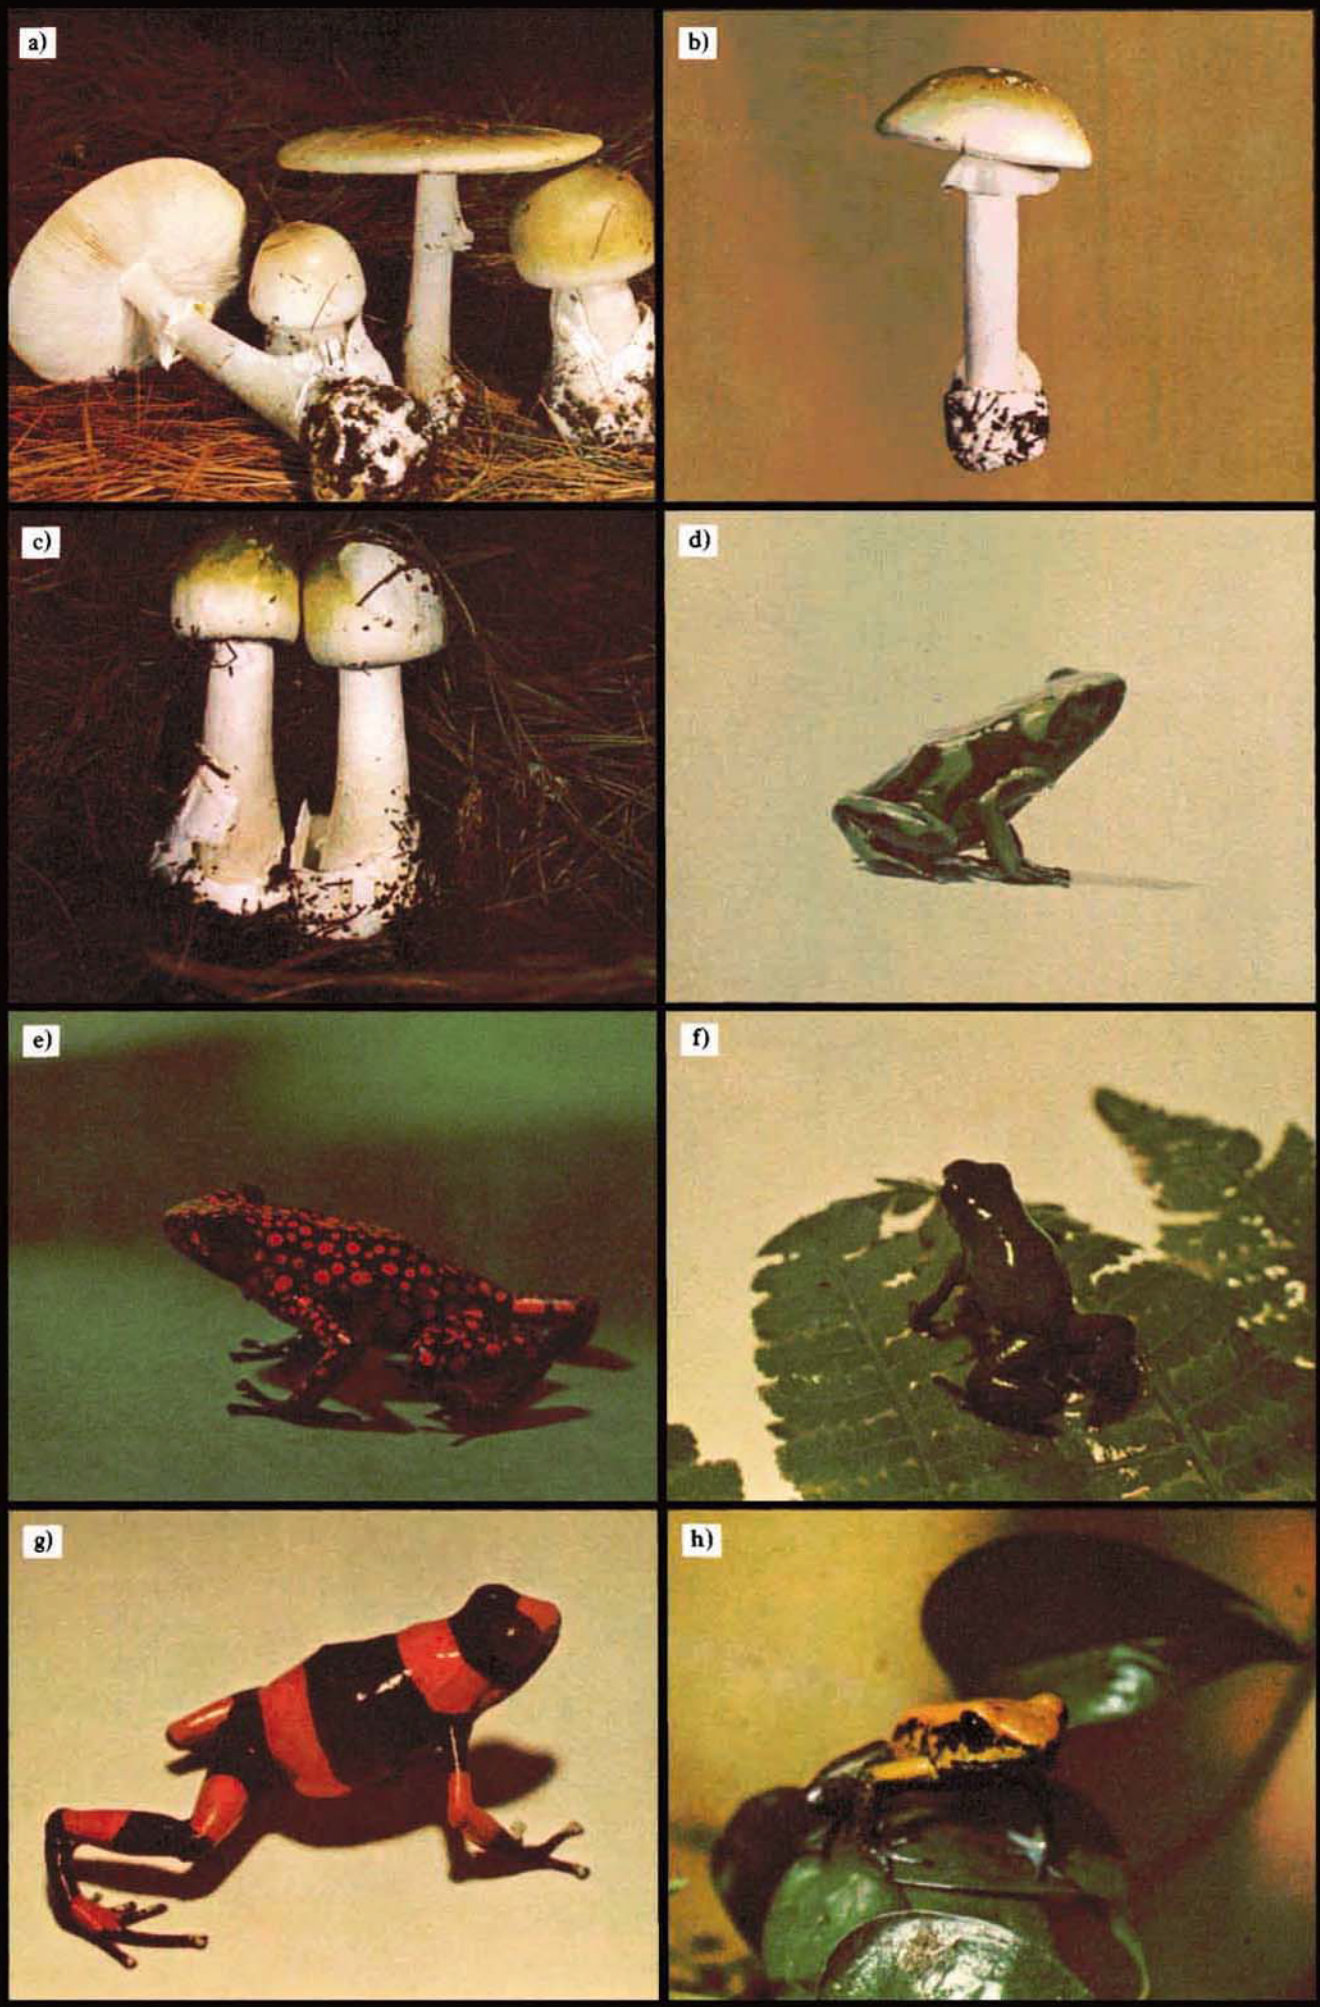
Fig. 7. Mechanism of carcinogenesis by a carcinogenic aromatic hydrocarbon.—An intermediate aliphatic epoxide is likewise postulated in the case of aflatoxin B_1 which causes liver cancer. However, it reacts with guanine units of DNA to form 2-(N^7-guanyl)-2,3-dihydro-3-hydroxyaflatoxin B_1 [26a].



bay region (Fig. 7). Opening of this short-lived diol-epoxide *(24)* *in vitro* by the 2-amino group of polyguanylic acid or *in vivo* by similar electrophilic groups (or phosphate residues) of DNA[24] leads to adducts *(25)* which probably introduce errors in transcription, unless the faulty nucleic acid sequence is removed by excision with the help of special enzymes and repair mechanisms[25]. The active mutagens and probably carcinogenic metabolites of benzanthracene and of 3-methylcholanthrene are similarly formulated as *(26)* and *(27)* (Fig. 8)[26].

(26) *(27)*

Fig. 8. Presumably carcinogenic metabolites of benzanthracene *(26)* and methylcholanthrene *(27)*.



Through *Wieland* and *Windaus* we learned about steroids. Subsequently steroidal hormones such as estradiol *(28)* (Fig. 9) were systematically modified to give new estrogens (*e.g.* mestranol *(29)*) and developed from there into antifertility, agents (*e.g.* norethindrone *(31)*).

(28) *(29)* *(30)*

Fig. 9. Stepwise modification of the estrogenic properties of estradiol (*28*) *via* mestranol *(29)* to the contraceptive norethindrone *(30)*.

The introduction of contraceptive steroids has slowed down the population explosion and changed the culture and morals of the present generation. This provides a straightforward and impressive example for the interdependence of science

and culture. Immunosuppression through corticoids has made possible a new technology of organ transplantation. The intricate action of steroid hormones on their target cell nuclei has only recently been elucidated[27]. Accordingly, cell function is modified by hormonal action in six steps (Fig. 10).

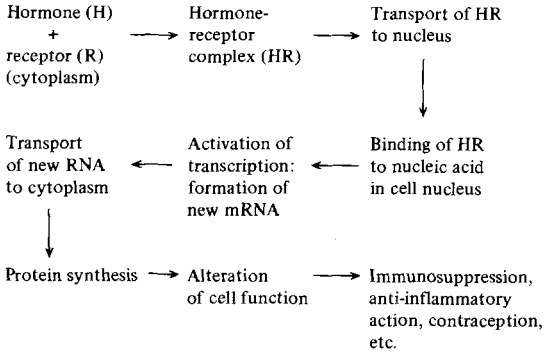

Fig. 10. Mechanism of action of steroidal hormones [27].

The first formulation *(31)* of the bile acids and cholesterol (Fig. 11) rested on an overuse of the so-called Blanc rule and led to an "intelligent error" (in ecclesiastical terms: *oh felix culpa*). The transition from the old *(31)* to the new formulation *(33)* is easier to follow by looking at the somewhat unusual presentation *(32)*.

A highly historical event occurring in the year 1932 was the fortunate consequence of this error, namely, the "marriage" of X-ray crystallographic analysis with "the ocean of organic chemistry" (Fig. 13), in a manner reminiscent of "*Lo Sposalizio Di Venezia Col Mare*" as the beginning of Venice as a great Mediterranean power[28]. This wedding

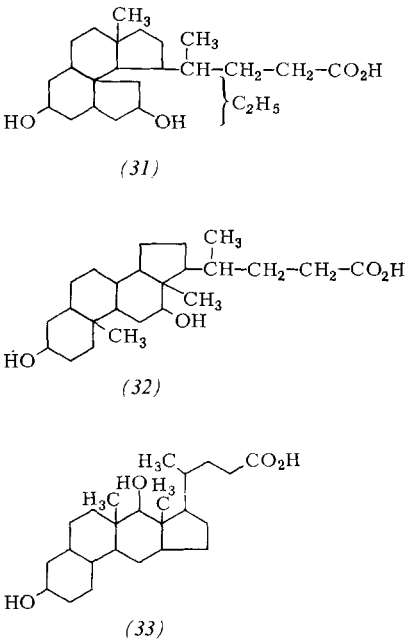

Fig. 11. Comparison of the old formula of deoxycholic acid *(31)* with the revised formula *(33)* via a helpful intermediate way of writing *(32)*.

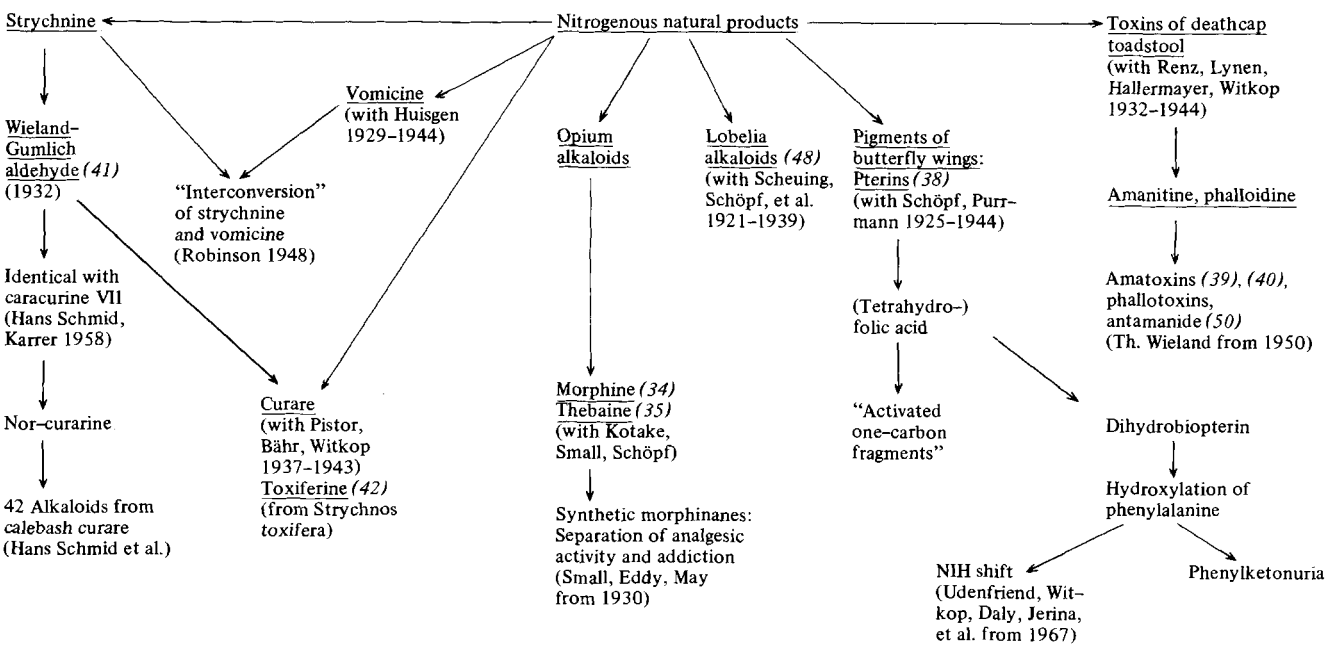
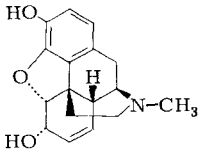
opened a new era, initially recognized and accepted by classical organic chemists with considerable reluctance. To the crystallographer *Bernal*, and the interpreters *Rosenheim* and *King*, *Wieland*'s old structure *(31)* should be a "thick molecule". But the crystalline dimensions of deoxycholic acid called for a "thin, lath-like molecule" as represented by the flat tetracyclic structure *(33)* which *Wieland* and *Dane* by 1932 had independently deduced from new chemical evidence. Thereafter, important natural compounds, precious by virtue of





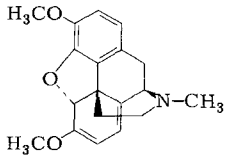


Chart II. *Wieland*'s studies on nitrogenous natural products have had a lasting effect on developments in biochemistry. For example, work on the pigments of butterfly wings with *Schöpf* and *Purrmann* provided the basis of the chemistry of pterins, from which the entire dynamics of the folic acid components of important enzymes can be derived, and also the mechanisms of enzymatic hydroxylation which led to the discovery of the NIH shift. The toxins of the deathcap toadstool have been further investigated by *Wieland*'s son *Theodor*, and utilized in various ways in molecular biology. The antamanides were used by *Isabella Karle* in X-ray studies on the folding and unfolding of cyclic peptides. Synthetic work on the opium alkaloids was continued in Bethesda by *Wieland*'s student *L. F. Small*, *E. Mosettig*, and *E. L. May*, and resolved into addictive and analgetic components. In *Paul Karrer*'s laboratory, *Hans Schmid* (1917—1976) demonstrated how the Wieland-Gumlich aldehyde obtained from strychnine by oxidation could be transformed into alkaloids from calebash curare also investigated by *Wieland*. (*Wieland*'s fields of study are underlined in Chart II.)

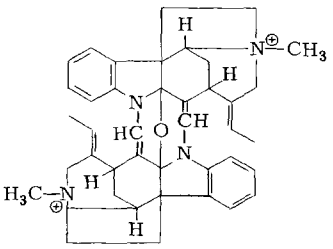
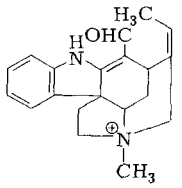
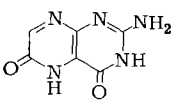
their paucity, became fully known up to the last conformational detail and their absolute stereochemistry. *Dorothy Hodgkin*'s very personal, charming, and lucid account of her brilliant X-ray analysis of vitamin B_{12}[29] is essential and pleasurable reading for every chemist[30]. Further examples are selected (Fig. 12) with a strong *pro domo* attitude and an explicable admiration for the pioneering work of *Isabella* and *Jerome Karle*, the inventors of the "symbolic addition procedure"[31].



At this juncture, we should return first to *Wieland*'s work on "alkaloids" (Chart II) that covers a wide range from basic



(34)



(35)

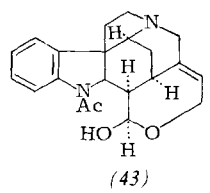
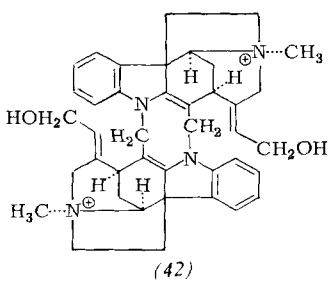
plant products—strychnine, vomicine, lobelines *(38)*, morphine *(34)*, thebaine *(35)*, calabash curare alkaloids *(36)*—to non-basic butterfly wing pigments *(38)* and cyclic peptides *(39)* and *(40)*[32] from *Amanita phalloides*, the most poisonous mushroom known (Figs. 12 and 16).

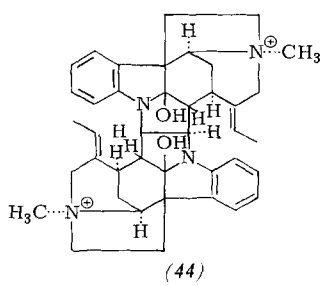


Wieland's intuition and "prepared mind"[33] in selecting topics for his research, recalls *Goethe*'s way of linking good fortune or serendipity to merit: "Wie sich Verdienst und Glück verketten, das geht den Toren niemals ein, wenn sie den Stein der Weisen hätten, der Weise mangelte dem Stein."[34] Historians and sociologists must examine "cases of serendipity gained and serendipity lost"[35]. In *Wieland*'s work, such gains and losses often merge, become latent or dormant and then surface again to produce spectacular results. The most striking example in this respect is a rather academic degradation product of strychnine (Fig. 13), the so-called Wieland-Gumlich aldehyde *(41)*[36]. It was probably standing on the shelf when *H.-J. Pistor*, *K. Bähr*, and I started postdoctoral work on calabash curare in *Wieland*'s private laboratory in 1950. We then isolated, from the bark of *Strychnos toxifera* toxiferine-I *(42)*, one of the most toxic alkaloids known[37]. It was not until 1958 that this alkaloid was recognized in *Paul Karrer*'s laboratory by *Hans Schmid* and his collaborators as the product of a condensation and dimerization of the Wieland-Gumlich aldehyde or its methobase[38–41]. The *N*-acetyl derivative of the Wieland-Gumlich aldehyde occurs as diabolin *(43)* in calabash curare as well as its methochloride. Over 40 tertiary and quaternary alkaloids [*e.g.* C-calebassin, *(44)*] were separated and isolated from calabash curare by *H. Schmid* and *P. Karrer* using cumbersome column chromatography. X-Ray analysis finally confirmed the complex structures based on chemical reactions[42].

The lobelia alkaloids *(48)* were introduced into pharmacology as respiratory stimulants by *Wieland*'s brother *Hermann*[43], into industrial production by an intriguingly simple synthesis[44] at C. H. Boehringer, Ingelheim, by *Georg Scheuing*[45]; they helped to start postpartum respiration for *Wieland*'s first grandchild.



Racemic lobeline (Fig. 14) or *cis*-2,6-diphenacyl-*N*-methylpiperidine *(48)* is easily obtained by catalytic hydrogenation



(41)

(43)

of the methosulfate of 2,6-diphenacylpyridine *(45)*, whereas its hydrochloride yields lobelanidine *(47)*, and its free base the pyridine-dicarbinol *(46)* on hydrogenation.

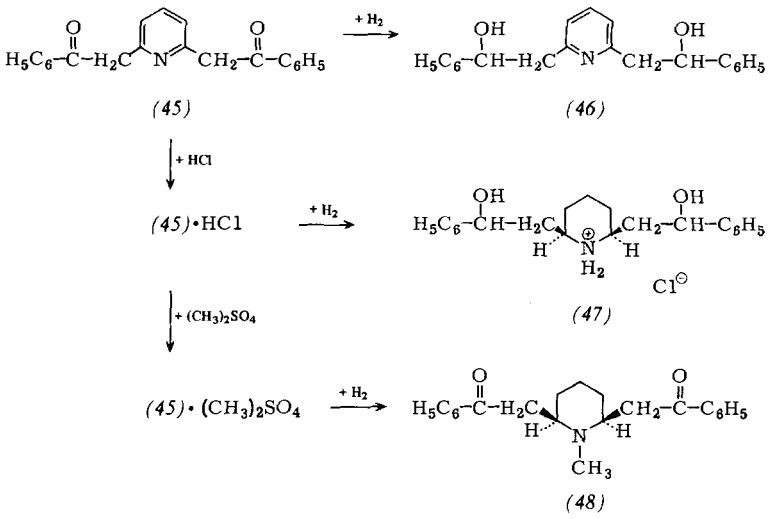

Fig. 14. *Scheuing*'s synthesis of norlobelanidine *(47)* and lobeline *(48)* by catalytic reduction of the hydrochloride and methosulfate of 2,6-diphenacylpyridine *(45)*.

Lyndon F. Small, from *Wieland*'s laboratory, brought back to the United States an interest in opium alkaloids and in their replacement by nonaddictive synthetic analgesics. More than 40 years later, thanks to the efforts of the late *Nathan B. Eddy* and *Everette May*, the search for a better analgesic[46] has come to a point at which separation of analgesic power from undesirable morphine-type drug dependence holds more than promise. On optical resolution of a 5,9-dialkylbenzomorphane a levorotatory antipode *(49)* was obtained (Fig. 15) which was a better analgesic than morphine, was not addicting in rhesus monkeys and, like desmethyl-*N*-allylmorphine (nalorphine), was an antagonist of morphine. The reversal of the two alkyl groups in 5-methyl-9α-propyl-6,7-benzomorphane also gave long-acting opiate antagonesis[47,48]. Further development of this principle of optical resolution has led in the case of *N*-tetrahydrofurfurylnoroxymorphones to compounds suitable for clinical testing[48a].

Here we enter the new area of opiate receptors in the brain[50] and of endogenous analgesic peptides, such as endorphin, derived from β-lipotropin[49].

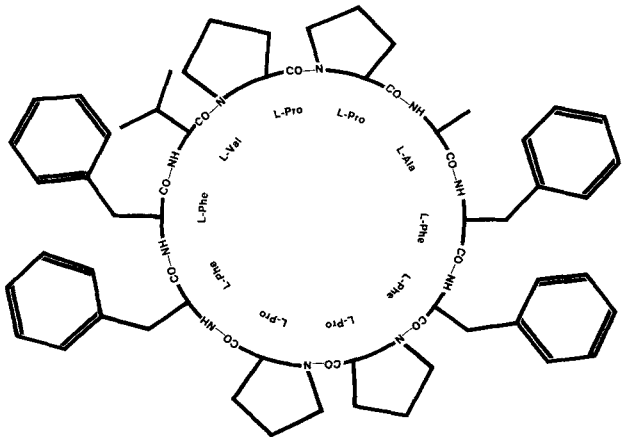
Physical dependence capacity	0	strong
Antagonism (nalorphine = 1)	0.2	0

"The new truths of science begin as heresy, advance to orthodoxy, and end up as superstition"[51]. This description, by *T. H. Huxley*, not necessarily in the same sequence, may be applied to some of the stages in *Wieland*'s work on pterins. When *Wieland*, in 1925, followed a suggestion of his disciple *Clemens Schöpf* to resuscitate *F. G. Hopkins*' work (1889—91) on butterfly pigments, he had, as pointed out more than once in this paper, an intuitive preconception of some metabolic significance of the pterins, especially when his student *Koschara* found xanthopterin *(38)* as a regular urinary metabolite[52]. For a while, especially during the war, pterin research was salvaged by giving it the label of "studies on the antipernicious anemia factor". From the vantage point of hindsight we now recognize the importance of *Wieland*'s work on pterins, to which his student *Robert Purrmann* contributed some crucial ideas and experiments. In a similar way research on curare was salvaged during the war by giving it the label of "relevance to surgery", because the toxiferines are strong muscle relaxants. These memories have gained significance because "the relevance of scientific research" has again been questioned today. *Wieland*'s work is ample proof that highly qualified research is always "relevant"[52a].

We are fully aware of the importance of the activated one-carbon units[53] in metabolism and of tetrahydrofolic acid and dihydrobiopterin as prosthetic groups of essential enzymes whose absence in genetic defects creates grave metabolic problems, such as phenylketonuria[54]. The search for rapid assays of enzymes involved in the biosynthesis and metabolism of catecholamines[55] led to the discovery of the "NIH-shift", the existence of arene oxides as extremely labile intermediates in the hydroxylation of aromatic substrates[56,57], and an understanding of the carcinogenic action of aromatic polycyclic hydrocarbons, such as the above-mentioned methylcholanthrene.



My entrance into *Wieland*'s private laboratory in 1938 required, as initiation fee, the work-up of half a ton of *Amanita phalloides* (Fig. 16), the deathcap, Europe's most poisonous and most fatal mushroom. The constant contact with these mushrooms, partly fresh, partly dried and powdered, led

Fig. 16. In the field of natural products, *Wieland's* legacy has proved extremely fruitful in two particular areas: *Theodor Wieland* has shown that constituents of the deathcap (toadstool) are important tools in molecular biology, and the first acetylene derivatives found in animals have been isolated from *Dendrobates histionicus.*—Most of the photographs of frogs were supplied by Dr. *C. W. Myers*, American Museum of Natural History, New York. (a) to (c): Deathcap toadstools *(Amanita phalloides)* at various stages of growth. They contain amatoxins [cf. *(39)*], phallotoxins and antamanide *(50)*. The photographs were provided by Dr. *D. M. Simons*, Wilmington, Delaware. (d): *Dendrobates histrionicus.* It contains the spirocyclic acetylene derivatives *(53)* and *(54)*. (e): *Dendrobates auratus.* It occurs in Panama, Costa Rica, Nicaragua, and Colombia and contains numerous pumiliotoxins which are all derivatives of *cis*-decahydroquinoline and in some cases bear acetylenic substituents. (f) *Dendrobates viridis.* Newly discovered species from western Colombia which mainly contains pumiliotoxin B. (g) *Dendrobates Lehmanii.* Newly disovered species [64a] containing about eight pumiliotoxins. (h): *Phyllobates aurotaenia*, a variant of the classical poison dart frog containing the extremely poisonous batrachotoxins *(52)*. (See p. 563.)

to unpleasant dermatitis and conjunctivitis, discomfitures which, in those days, were endured with a sense of pride to be in the vanguard of scientific battle. *Wieland* himself encouraged such an attitude. When *Rudolf Hallermayer*, shortly before the crystallization of amanitin, complained in 1941: "Herr Geheimrat, this morning it took about ten minutes until I was able to open my festering eyelids," the rejoinder came with ill-concealed satisfaction: "At long last we seem to be getting very good enrichment!"[58]

The crystallization of phalloidin by *F. Lynen* and *U. Wieland*, preliminary results on its hydrolysis, the crystallization of "amanitin"—these events are the beginning of a long natural product saga[59], an inheritance that took *H. Wieland's* second son *Theodor* a quarter of a century to explore completely and bring to full bloom[60]. In reprospect there is seen to be a continuity between work on phalloidin, its cleavage to secophalloidin by *Theodor Wieland*, and the general exploitation of such neighboring group effects for the extremely useful, selective nonenzymatic cleavage of peptides and proteins with cyanogen bromide—extending up to the sequence determination of immunoglobulin (molecular weight 148000 with more than 1200 amino acids)[60a].

The amatoxins *(39)* and *(40)*[32] are selective inhibitors of nucleotide polymerase B in the cell nucleus, while the related phallotoxins selectively bind to the actin of hepatocytes. The lipophilic cyclic decapeptide, antamanide, *(50)* has affinity to membranes which then are protected from the toxic effects of phalloidin. The natural and synthetic antamanides form complexes with lithium, sodium, and calcium ions. The alkali

(50)

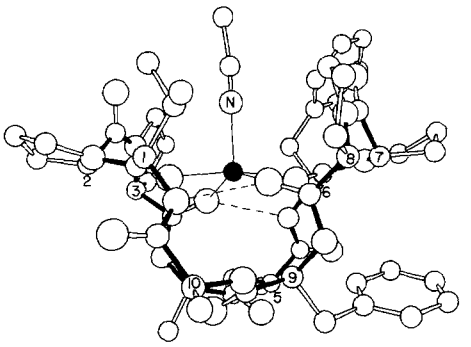


Fig. 17. In the lithium complex of natural antamanide the pentacovalent metal ion sits on the cyclic decapeptide folded to a saddle and bears a molecule of solvent as a "cap" (acetonitrile). In this structure the peptide carbonyls are directed towards the interior of the molecule, and the amide groups towards the exterior [61].

in the pentacovalent complexes sits in a saddle (Fig. 17) and has, as a cap, a molecule of solvent[61]. *Isabella Karle* extended this beautiful X-ray analysis to the uncomplexed antamanide in which the peptide backbone is turned inside out, more unfolded and held in place by a pair of intramolecular hydro-

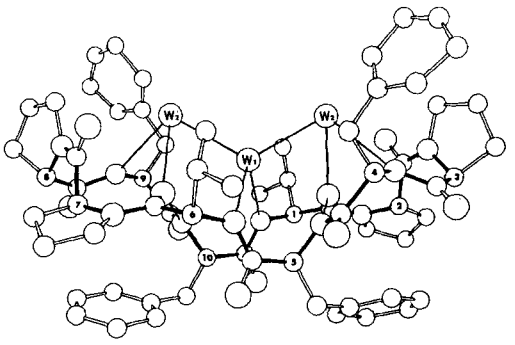

Fig. 18. In the uncomplexed trihydrate of synthetic [Phe^4,Val^6]antamanide the unfolded decapeptide is stabilized by three molecules of structural water (W). The amide groups are now directed to the interior of the molecule and the peptide groups to the exterior [63].

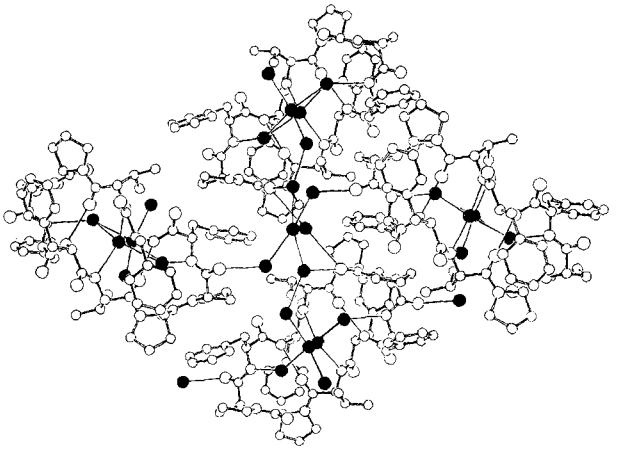
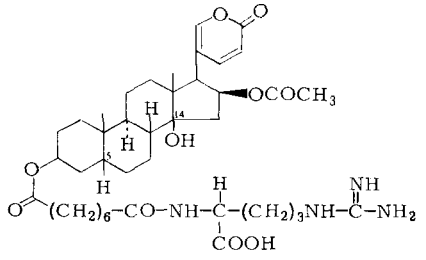
gen bonds of the (5→1) type[62] as well as by three[63] strategically placed molecules of structural water (Fig. 18). The uncomplexed synthetic [Phe^4, Val^6]antamanide exists, with little conformational change, also as a dodecahydrate (Fig. 19)[64].





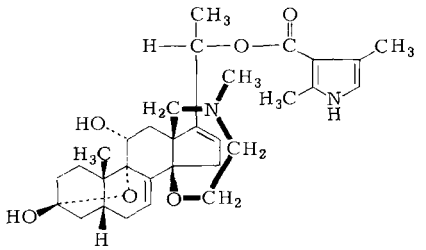


Fig. 19. In the uncomplexed dodecahydrate of synthetic [Phe^4,Val^6]antamanide the arrangement of the four antamanide molecules shown leaves channels in the crystal structure which are filled with structural water (solid circles) of varying degree of association. Such structures might possibly serve as models for explaining the unusual properties of water molecules in proteins and cell membranes [64].

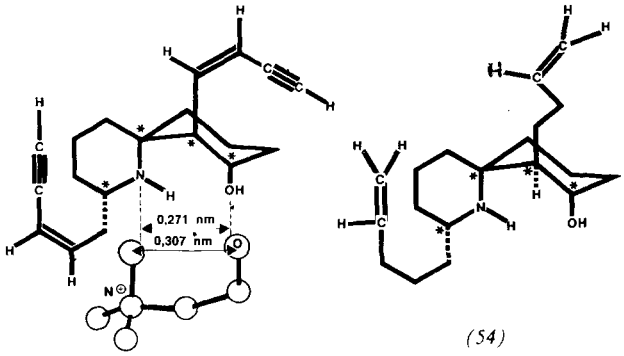
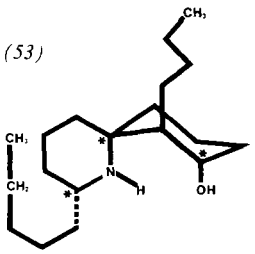
The crystal lattice in this case contains cavities and channels that are filled with water molecules of various degrees of associative binding. Here one is reminded of the lipophilic peptide part of trans-membrane proteins, such as the surface glycoprotein of human erythrocytes, glycophorin, and in that respect the organization of water in the antamanide lattice gains in significance for membrane models and for understanding its protective action against phalloidin in the membranes of liver cells.

The digression from *Wieland*'s toad venoms [bufotoxin *(51)*] to frog toxins [batrachotoxin *(52)*] conceptually seems to be only a small step (Fig. 20): the disciple varies a theme given by the "*magister ludi*". When it comes to methodology and detail, the comparison shows up the great progress made since *Wieland*'s isolation of the cardiotonic bufotoxin in 1913. Just the initial phase, the process of collection, demonstrates this point: most of the toads *(Bufo vulgaris)*, about 27000, were "milked" and set free again by schoolchildren in the pleasant Black Forest area, and the result was 21 grams of crystalline bufotalin and bufotoxin *(51)*[65]. Bufotoxin *(51)* is a conjugate of an unusual steroid with suberylarginine linked at the 3-hydroxyl, originally formulated by *Wieland* as attached to the 14-hydroxyl. In addition, there is a β-acetoxy group at carbon 16, previously assigned to C(5). By contrast, the tiny poison dart frogs *(Phyllobates aurotaenia)* of Western Colombia, were collected in an impenetrable jungle with an annual rainfall of 12 meters. Transportation is only possible on the rivers by launch or balsa raft[66]. The frogs weigh only 1—2 grams and contain 50 micrograms of toxins, which the frog inactivates under stress or on death. One of the four components, batrachotoxinin A, the steroid moiety of batrachotoxin, was eventually crystallized and established a



(51)



(52)

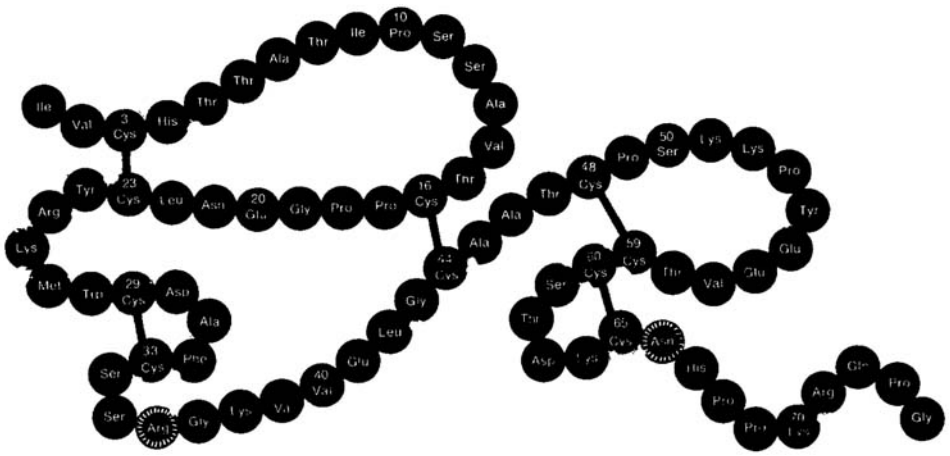


Fig. 20. The principal venom of the toad *Bufo vulgaris* is bufotoxin *(51)* which was formulated by *Wieland* as the conjugate with suberyl-arginine in position 14 and with an acetoxy group in position 5 instead of 16. The principal toxin of the frog *Phyllobates aurotaenia* is batrachotoxin *(52)* which shares the steroidal skeleton and some stereochemical features with bufotoxin.

(53) *(54)*

(55)

(56)

Fig. 21. The histrionicotoxins *(53)*, *(54)*, *(55)* show reversible binding to the ion conductance modulator of the acetylcholine receptor, while the snake venom, bungarotoxin *(56)* binds irreversibly to the recognition site of this receptor. A molecule of choline is shown under the formula of molecule *(53)* for comparison.

record for *Isabell Karle* as the smallest crystal, length 1/10 mm, which supplied all the X-ray data required for complete structure analysis[67]. In the ester, batrachotoxin *(52)*, we meet the familiar steroid skeleton with unprecedented new features, such as a new heterocyclic ring sharing a common axis with rings C and D in the manner of the propellanes. Ten years later batrachotoxin *(52)* has become one of the most useful tools in electrophysiology for the study of the properties of the sodium channel in axons, synapses, and muscle[68]. It opens up irreversibly and selectively the "gate" of sodium channels while its antagonist, the less toxic tetrodotoxin, the poisonous principle of the puffer fish, closes these sodium channels in a reversible manner.

Another frog, *Dendrobates histrionicus* (Fig. 16d), which occurs in many colorful varieties in Colombia, Ecuador, and Peru has given us the first acetylenic alkaloids [*(53)* and *(54)*] (Fig. 21) of animal origin[69]. They have proven their value in the study of receptor mechanisms: tritiated perhydrohistrionicotoxin *(55)* does not bind like bungarotoxin *(56)*, a powerful snake venom, to the recognition site of the acetylcholine receptor but to a special protein subunit, hopefully identifiable with the ion translocation site[70]. In all there are now known to be present more than 100 different novel alkaloids in the many *Phyllobates* and *Dendrobates* species of South America.

The contributions of the organic chemist, *John W. Daly*, and of the herpetologist-taxonomist, *Charles W. Myers*, have added up to more than the sum of their parts[71]. The significance of the frog toxins for the study of receptors, membranes, and ion transport may eclipse that of the toad and salamander *(Clemens Schöpf)* venoms, but the thematic origin clearly goes back to the old master, *Heinrich Wieland*.

When one mentions *Wieland*'s name to present-day biochemists, they remember him for his theories on the "activation of hydrogen" that brought him into—at times violent—opposition to *Warburg* (1883—1970), another founder of modern biochemistry[72]. *Wieland* "diminished" the role of oxygen to that of an acceptor for activated hydrogen by replacing O_2 by quinones, metals, or methylene blue[73]. *Warburg*'s feelings toward this hypothesis and its originator are best characterized by his reaction to reading his own obituary in the Times (of London) of January 12, 1938: "An error had occurred: he had been mistaken for a distant relation, the distinguished botanist and Zionist leader, also called *Otto Warburg* (1859—1938). The error was corrected on the following day with appropriate apologies. *Warburg* was mildly amused and mildly annoyed when, as a subscriber to the Times, he read the news of his demise; annoyed because he thought that deliberately no reference had been made to what he considered to be one of his most important discoveries, that of nicotinamide in the coenzymes of dehydrogenases and the chemical nature of its reversible reduction and oxidation. He commented: 'it looks as if the obituary was written jointly by poor old *Heinrich Wieland* and poor old *Torsten Thunberg*'. These two scientists had published much work on dehydrogenations without establishing the chemical mechanism and, quite wrongly, *Warburg* considered them his adversaries"[72]. Since the departure of *Wieland* and *Warburg*, we can now see the two scientists in the same historical perspective as *Isaac Newton* (1642—1727) and *Christian Huygens* (1629—1695): light, in its ambivalence, is understandable both in undular and corpuscular terms. Likewise the unity of biochemistry[73] now reigns in the close coupling of oxido-reduction mechanisms and of "anabolic *versus* catabolic, amphibolic and 'anaplerotic' processes"[74]. At the time of their controversy, their fascination by models, the surface of platinum[76] or of charcoal[77], served well as a formal basis for polemics, but action was not restored until *D. Keilin* turned to the living wax moth *(Galleria mellonella)* to establish the physiological role of cytochrome reactions[78].

There was then little reason to suspect that *Wieland*'s favorite two enzymes for—putatively metal-free—model dehydrogenations, *viz.* the "Schardinger enzyme", xanthine oxidase, and the "Thunberg enzyme", succinate dehydrogenase, would turn out to be multi-centered iron-sulfur-containing flavoprotein complexes[79]. In xanthine oxidase the iron-sulfur centers act as an electron reservoir serving to maintain molybdenum as Mo^{VI} (for efficient reduction) and flavin as $FADH_2$ (for efficient oxidation) as visualized by the plausible but unproven intermediates observable under anaerobic conditions[80]. The reaction of xanthine oxidase with oxygen involves both paired and unpaired electronic transition states between xanthine, oxygen, and reduced flavin adenine dinucleotide ($FADH_2$). A new form of active oxygen, the superoxide anion, $O_2^{\ominus}$, suspected by neither *Warburg* nor *Wieland*, enters the enzymatic arena[81].

The most recent investigations on the mechanism of biological oxidation, *Wieland*'s lifelong theme and quest, make use of the classical Schardinger enzyme, xanthine oxidase, in order to produce superoxide anion required for the activity of indoleamine 2,3-oxygenase, a novel catabolic enzyme discovered by *Hayaishi* (Fig. 22). In this system methylene blue, utilized

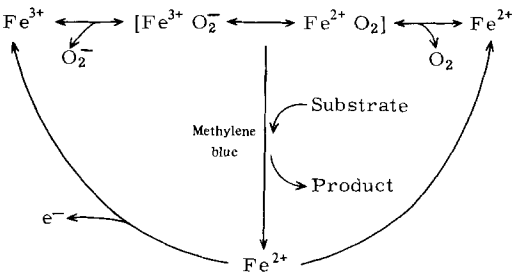

Fig. 22. The action of indoleamine 2,3-oxygenase involves a catalytically active ferric heme-superoxide complex that is in resonance equilibrium with the ferrous heme-dioxygen complex and, in the presence of substrate, is converted to product and ferrous heme-enzyme. Methylene blue, a cofactor, is required for maximum enzyme activity [82].

so often by *Wieland* as a substitute for oxygen in model reactions, surprisingly enough assumes the role of a new cofactor required for maximal enzymatic activity.

We approach the end of our excursion through the garden of *Wieland*'s natural products. We, the later generation, have accumulated enough knowledge through biosynthetic studies with labeled or radioactive precursors to recognize or predict the gross biogenetic origin of practically all natural products discussed so far[83]. Again, *Wieland* had anticipated much of this development. It was in his laboratory that studies on yeast, previously agitated under oxygen and, therefore, "verarmt"[84] (depleted) by combustion of intracellular ingredients, led to the discovery of an "induction time" until added acetic acid was further metabolized. This experiment furnished

information which did not become transformed into knowledge until *Feodor Lynen* provided the correct interpretation. "When does information become knowledge?" is a pertinent question[85] to ask especially in an age of the production of more data than the human brain is capable of grasping. *Lynen*'s postulate of an "activated acetic acid"[86] rested on a proper interpretation of the induction phenomenon and on the fact that on addition of an easily combustible substrate, such as a small amount of ethanol, the induction time became shorter. The further development has become history: *Lynen*'s discovery of the nature of active acetic acid as Acetyl-CoA, the biotin carboxylase ("aktivierte Kohlensäure"), the "doubly activated acetic acid" ("aktivierte aktivierte Essigsäure"), *viz.*, malonyl-CoA, the multienzyme complex of fatty acid synthesis, all these discoveries led directly to breath-taking new vistas impressively described in his Nobel lecture[87].

When we now compare the impact of *Wieland*'s example and discoveries on the growth and expansion of organic chemistry in its widest interpretation, *i.e.*, encompassing biochemistry and molecular biology, we could construct a tree somewhat comparable to the one based on the Gerlach-Stern experiment[9] with which we started this historical critical essay. "In a centenary celebration, the rich heir complacently goes over the treasure which past centuries have distilled"[88]; if we heed *Ortega*'s advice, expressed in 1932 as a reaction to what he then considered "the breakdown of the university in the face of men's present needs", we have to do more than worship the past or more than putting *Wieland* on a pedestal. "There is but one way left to save a classic: to give up revering him and use him for our own salvation... bring him close to us to make him contemporary, resurrect our classic by immersing him in life once more"[88].

There are types of excellence that involve doing something well and types that involve being a certain kind of person. *Wieland* excelled in both respects and both faculties grew commensurate with the risks and responsibilities. It is not everyone that finds the age he deserves. Perhaps he might have been worthy of a better century, but then we would not know how he met the challenges of his time.

We must not forget that at a time when, in the words of *Karl Jaspers*, the German universities had lost their dignity, students looked up for courage and help to their teachers. Barely a hundred years earlier another man had dishonored the constitution and broken the instruments of law, namely the narrow-minded and opinionated *Ernst August*, King of Hanover. Against his tyranny rose the "Seven Professors of Göttingen" as one man, among them the intrepid *Jacob Grimm* for whom "science meant the search for the metaphysical ethos in the physical world". To him doctrine and science were one, in the same way as thought and action formed an indissoluble unity. Thus, at the age of 52 years, he courageously faced an uncertain exile[89].

One hundred years later this bright example was followed by a great darkness fortunately illuminated by "professores" (confessors), such as *Kurt Huber* and *Heinrich Wieland*, who had the courage to stand up and be counted. *Wieland*'s student *Hans Carl Leipelt*, because of his allegiance to *Kurt* and *Clara Huber*, was arrested by the Gestapo on October 8, 1943, and hanged on January 29, 1945[90]. At the mock trial of *Leipelt*, *Wieland*, invited as a witness, defied the dreaded *Roland Freisler*, "President of the Folk Tribunal" by walking up to the helpless defendant and by exchanging a handclasp of deep sympathy and approval.

In today's agonizing world of constant redefinitions of old standards and values, he would not have seen a problem in reconciling excellence with democratic principles, *i.e.* equality with quality. He would have quoted *William Learned:* "The conception of a democratic education as one leveled to a colorless mediocrity is as grotesque an interpretation of democratic principles as (a conception) of health in which abounding vitality ... is deprecated on the ground that only average health is fair to the community. No one believes this."[91] "The right of competition may only be limited in order to preserve it. For excesses of competition lead to monopoly, as excesses of liberty lead to absolutism."[92]

We admire the scientist who uses his intellectual gifts in the service of one of the highest values of our civilization—the search for truth. At a time when many intellectuals place their gifts in the service of chicanery and lend themselves to the cause of tyranny and brutality, this requires great fortitude.

In Germany, more so than in the United States, the period of institutional crises, especially of the University, is not yet over. Many students in their radicalism laid claim to ownership of "their" university as an instrument for social change or experimentation. *Wieland*, as a protagonist of a correctly defined elitism[93], if called upon to express his opinion today, would have challenged such a claim: "Yes, the university is indeed owned. There are proprietors. They are not listed in your catalog. They are not students, faculty members, or alumni. Rather they are, especially for Munich, *Fraunhofer*, *Liebig*, *Baeyer*, *Willstätter*, *Thomas Mann*, *Max Weber*, *Karl Vossler*, *Kurt Huber*, and you may go back further to *Plato*, *Aristotle*, and *Confucius*. They are the proprietors. The rest of us hold the University in trust for them and for those whose names have yet to join this timeless throng."

Today we are happy in the knowledge that *Heinrich Wieland*, a faithful trustee during his lifetime, has entered the ranks of the scholarly proprietors.

institutionalization of science began with *Liebig* as convincingly depicted by *Joseph Ben-David* in his study "The Scientist's Role in Society". Prentice-Hall, Englewood Cliffs, New Jersey 1971: "Toward the end of the century the laboratories of some of the professors became so famous that the ablest students from all over the world went there for varying periods of time. The list of students who worked in such places often included practically all the important scientists of the next generation. ... These unplanned and unexpected developments were an even more decisive step in the organization of science than the early nineteenth century reform. Research started to become a regular career, and scientists in a number of fields started to develop into much more closely knit networks than ever before. Their nuclei were now university laboratories training large numbers of advanced students, thus establishing between them personal relationships, highly effective means of personal communication, and the beginning of deliberately concentrated and coordinated research efforts in a selected problem area." (pp. 124—125.)

[28] This event dates back to AD 1000 and was celebrated on August 15, La Sensa, *i.e.* L'Ascensione or L'Assunta, by the Doge sailing out into the Adriatic on his Maesta Nave (after 1311 *il Bucintoro*, probably from *Navilium Ducentorum Hominum*) to drop a golden ring, consecrated by the Pope, into the sea with the words: "*Desponsamus te, mare*" (we wed thee sea).—On his way from his home in Starnberg to the station, *Wieland* often passed a house with a big fresco of the "Buzentaur", a replica of the Bucintoro, used by *Ludwig* II of Bavaria for aquatic pageants on the lake with the inscription: "Schön war die Vergangenheit, schöner noch wird die Zukunft Starnbergs sein." At least for *Wieland*, Starnberg became his haven after the destruction of his house, Arcisstrasse 1, and his laboratory in 1944.

[30] "The structure of vitamin B_{12}, as we think of it today, is based on a fascinating complex of evidence obtained by X-ray analysis and by more traditional chemical means. We have reached a position in which we can almost say we "see" the molecule—if not quite as clearly, perhaps, as we should like. We can assign positions in space to the atoms of this very large molecule within less than half an Ångstrom unit in two different crystal structures. We know its absolute configuration and the exact stereochemistry of all the different asymmetric centres present. Yet most of this knowledge rests on a way of using X-ray diffraction effects which is very far from rigid in its application. Part, at least, of our evidence that our method works at all is the character of the structure it has given us for B_{12}—a structure that fits in an extraordinarily reasonable way with such a variety of observations, chemical and stereochemical and biogenetic, that it is impossible not to believe it is essentially correct." [52a] Today's gigantic research effort is endangered precisely because of a too narrow interpretation of relevance; it can hardly be avoided that an increasingly centralistic bureaucracy will insist that research be directed towards the solution of certain national problems, or that certain areas, such as genetic engineering, be placed under state supervision. In his study "The Logic of Liberty" (London 1951), *Michael Polansky* pleads for freedom of research: "What technical inventions were the discoveries of the Nobel Laureates Planck, Einstein, Perrin, Millikan, Michaelson, Rutherford, Aston, Chadwick, Barkla, Heisenberg, Compton, Frank, G. Hertz, Rubens, Laue, Joliot, Fermi, Urey, Anderson, W. H. and W. L. Bragg, Schrödinger, Dirac, etc., unconsciously intended to produce? No one can tell—so the new theory of science must pass them over. One wonders how the great physicists in the list above would have fared if, before embarking on their investigation, they had to get a certificate of its social usefulness from a scientific directorate, as contemplated by Marxist scientists and their friends. To what conflicts may not have led their "arrogant pretence" to be the sole judges of their own preference!" (pp. 82—83).

Concerning the possible presence of calcium ions in the crystal lattice, *Isabella Karle* expressed her views in a personal communication as follows: "The question arises as to the whereabouts of the Ca^{++} ions present in the crystallizing solution. Are they still in the mother liquor surrounding the crystal? Or is it possible that some of the sites in the inner core of the channel are partially occupied by Ca^{++} rather than by H_2O? The X-ray diffraction data cannot distinguish between the type of ion or atom occupying a site when dealing with partial occupancies, since the occupancy and the weight of an atom are not independent variables. The distances between the sites in the inner core and the H_2O in the bound layer are compatible with $Ca^{++}\cdots O$ ligands."
[64a] On booking at this frog, one is reminded of *Charles Darwin*'s description in The Voyage of the Beagle (1831), Chap. 5: "Amongst the Batrachian reptiles I found only one little toad *(Phryniscus nigricans)*, which was most singular from its color. If we imagine, first, that it had been steeped in the blackest ink and then, when dry, allowed to crawl over a board freshly painted with the brightest vermilion so as to color the soles of its feet and parts of its stomach, a good idea of its appearance will be gained. If it had been an unnamed species, surely it ought to have been called *Diabolicus*, for it is a fit toad to preach in the ear of Eve." Charles Darwin and the Voyage of the Beagle. Electrocyclic Ring Opening Reactions of Ethylene Oxides[**]

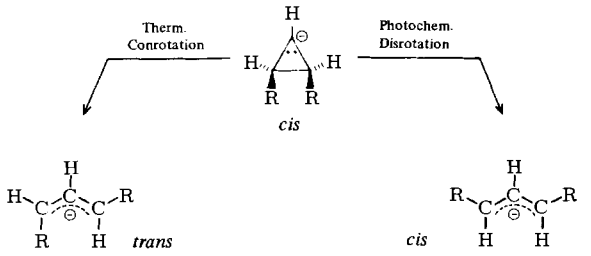
By Rolf Huisgen[*]

Substituents capable of stabilizing negative charge endow ethylene oxides with the ability to undergo electrocyclic ring opening at the CC bond; heating or irradiation generates small equilibrium concentrations of carbonyl ylides which can engage in 1,3-dipolar cycloadditions. Apart from the normal conrotatory mode of ring opening, predicted by the Woodward-Hoffmann rules, the disrotatory process, forbidden by orbital symmetry, also appears to occur in the case of α-cyano-*cis*-stilbene oxide. Kinetic studies on α-cyano-*trans*- and -*cis*-stilbene oxide permit construction of the energy profile for electrocyclic ring opening to give the stereoisomeric carbonyl ylides and for their recyclization and rotation.

1. Ring Opening of the Cyclopropyl Anion



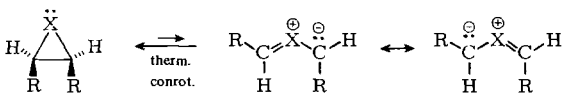
One of the most stimulating ideas to have permanently influenced our concept of the reaction event during the past decade is the principle of the conservation of orbital symmetry. The initial publication of the *Woodward-Hoffmann* rules in 1965 spurred an enormous number of experimental and quantum-chemical studies; the stream of relevant publications has not receded to this day.

Any formation or cleavage of a bond proceeds with conservation of orbital symmetry. This principle can be demonstrated for electrocyclic reactions, cycloadditions, and sigmatropic shifts. These processes involve the breaking or forming of several bonds coupled in a single step.

[*] Prof. R. Huisgen
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

[**] Extended version of the Roger Adams Award Address, National Organic Symposium of the American Chemical Society, Fort Collins (Col.), June 24, 1975, and a plenary lecture delivered at the GDCh General Meeting at Cologne, Sept. 9, 1975.

Electrocyclic reactions are ring openings or closures in which a σ bond is transformed into a π bond, or *vice versa*. *Woodward* and *Hoffmann* advanced predictions about the steric course of such one-step processes[1]. The principle of conservation of orbital symmetry requires that ring opening of a cyclopropyl anion to an allyl anion occurs as a thermal conrotation or a photochemical disrotation.

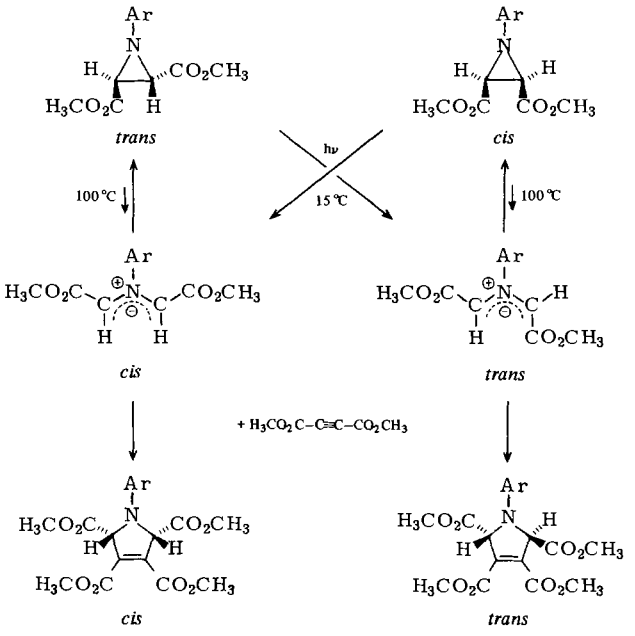


The substituents located in positions 2 and 3 of the cyclopropyl anion *in front of* or *behind* the plane of the ring rotate into the plane of the three C atoms on ring opening. The term "conrotation" refers to the steric course in which *cis* substituents move into the *endo* and *exo* positions of the allyl anion. On completion of "disrotation", on the other hand, the former *cis* substituents both appear in the *exo* position or—less likely—in the *endo* position of the allyl anion.

Numerous examples of electrocyclic ring opening reactions of cyclopropyl anions to form allyl anions have been reported; however, a clearcut, unequivocal experiment confirming the steric course has yet to be performed, twelve years after the original prediction.

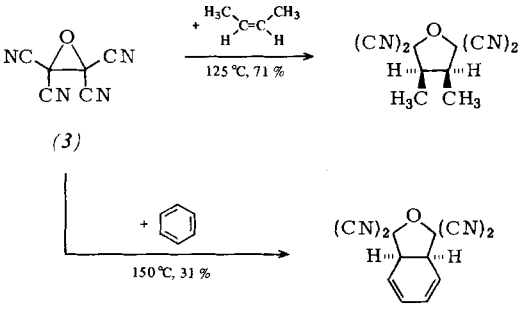
2. Isoelectronic Analogs of the Cyclopropyl Anion

A remarkable new ring opening of substituted ethylenimines at the CC bond was observed independently by three research groups[2–4] in 1965/66. On heating, a small equilibrium concentration of a species arises which undergoes 1,3-dipolar cycloadditions *in situ* with suitable dipolarophiles.



(1) *(2)*

X = NR, O

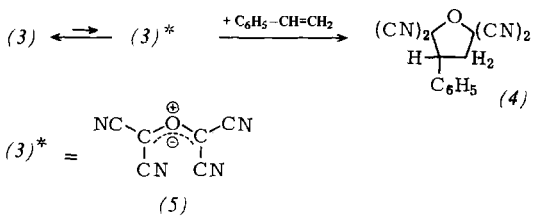


Ethylenimines (aziridines) *(1)*, X = NR, and ethylene oxides (oxiranes) *(1)*, X = O, possess a lone pair at the heteroatom and are isoelectronic with the cyclopropyl anion; in contrast to the last-named species, they have no net charge. Electrocyclic ring opening should lead to the hetero analogs *(2)* of the allyl anion in which the uncharged central carbon atom is replaced by an immonium or oxonium function. The negative charge is distributed over the terminal carbon atoms as in the allyl anion itself.

The hypothetical ring opening products *(2)* are 1,3-dipoles in the sense of the 1,3-dipolar cycloaddition concept[5]. 1,3-Dipoles are defined as "zwitterionic heteroallyl anions"; their 1,3-cycloadditions to dipolarophilic multiple bonds follow the ring-size classification 3+2→5, and they are symmetry-allowed concerted processes[6, 7]. The ring-opened valence tautomers *(2)* of aziridines and oxiranes should be *azomethine ylides* and *carbonyl ylides*, respectively[*]; these species are symbolized either as resonance structures as in *(2)* or with delocalized negative charge. Several entries into the class of azomethine ylides were developed previously[8, 9].

Scheme 1

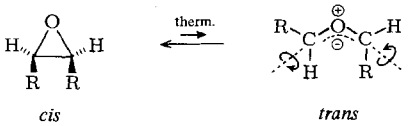
The steric course of the novel aziridine ring opening precisely follows the pathway allowed by orbital symmetry. The reactions of Scheme 1, published in 1967[10], permitted the first verification of *Woodward* and *Hoffmann*'s prediction for the cyclopropyl anion. The aziridine-*trans*- and -*cis*-dicarboxylic esters undergo reversible conrotatory ring opening at 100 °C. In the process, the *trans*-diester yields the *exo,exo*-substituted *cis*-azomethine ylide; this product is trapped *in situ* by acetylenedicarboxylic ester as a dipolarophile to form the 3-pyrroline-*cis*-2,5-dicarboxylic ester. Conversely, the aziridine-*cis*-dicarboxylic ester gives an adduct having *trans* ester groups in positions 2 and 5. The reactions are highly stereospecific; no mutual contamination of the diastereomeric adducts could be detected. On irradiation a disrotatory ring opening of the aziridine was observed. In this case the relative configura-



(3)

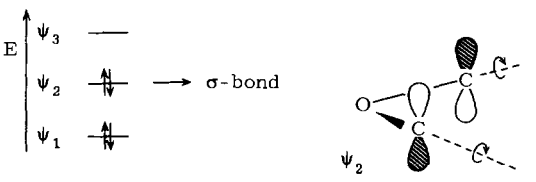
[*] These trivial names[5] have become accepted; see, *e.g.*, *R. M. Kellogg*, Tetrahedron *32*, 2165 (1976). Systematic names for these species are 2-azonia- and 2-oxoniaallyl anions.

tion of the ester groups is retained on going from the three- to the five-membered ring.



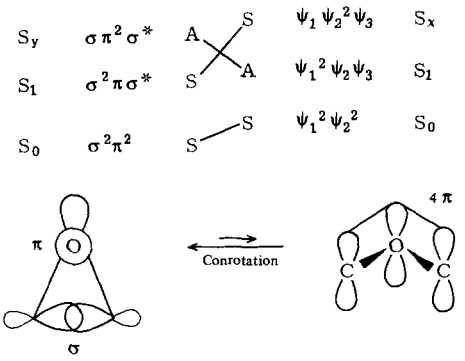
Whereas electrocyclic ring opening of aziridines meanwhile ranks among the thoroughly documented reactions, much less is known about the CC bond opening of ethylene oxides.

According to *Linn* and *Benson*[11], tetracyanoethylene oxide (oxiranetetracarbonitrile) *(3)* can add at elevated temperature to olefins, acetylenes, and even to benzene, forming 2,5-dihydro- and tetrahydrofuran derivatives. The configuration of the olefinic dipolarophile is retained.



A kinetic study revealed that cycloaddition of tetracyanoethylene oxide *(3)* to styrene to give *(4)* is preceded by a first-order reaction[12]. Today there is no doubt that the "activated species" *(3)** is the carbonyl ylide *(5)*. In contrast to the irreversible electrocyclic ring opening of the cyclopropyl anion, aziridines and oxiranes are strongly favored at equilibrium with azomethine ylides and carbonyl ylides, respectively.

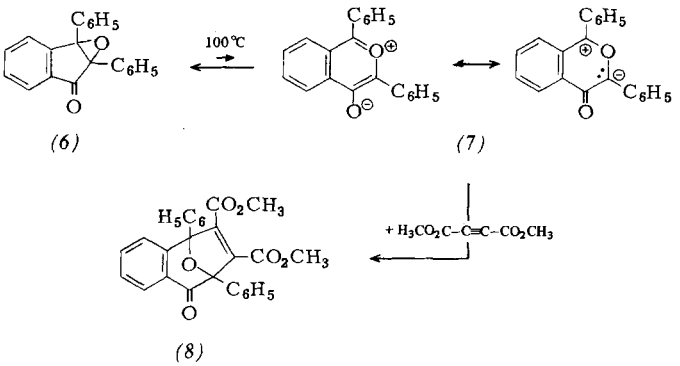
3. Orbital Control of Oxirane Ring Opening



Electrocyclic ring opening at the CC bond entails 90° rotations about the two CO bond axes. In conrotation these motions occur in the same sense, both clockwise or both anticlockwise. A twofold symmetry axis passing through the O atom and the center of the oxirane CC bond is the molecular symmetry element dominating the conrotatory process. However, the symmetry concerned is only local; it applies to the bond system participating in the reaction and not to the substituents.

Scheme 2

The simplest application of the principle of conservation of orbital symmetry to the stereochemistry of electrocyclic ring closure consists in inspection of the symmetry properties of the HOMO, the highest occupied molecular orbital[1]. This is illustrated for the oxirane cyclization in Scheme 2. As in the allyl anion, the two lowest π molecular orbitals are occupied in the carbonyl ylide. The electron pair in ψ_2 is utilized to form the σ bond between the terminal carbon atoms. In order to achieve phase-consistent overlap, two 90° rotations in the same sense are required, *e.g.*, both clockwise, if the white half-orbitals are to undergo σ interaction.

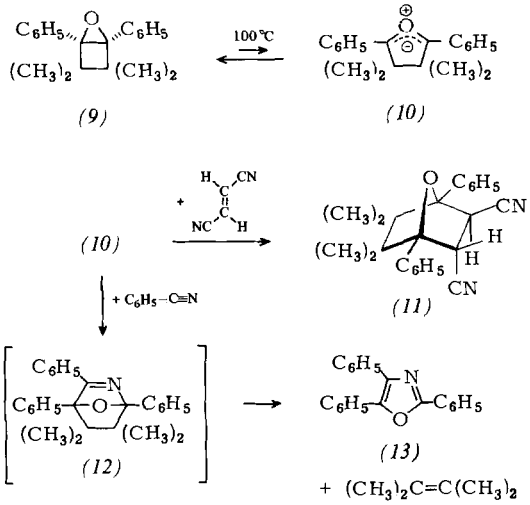


Scheme 3

A more sophisticated approach to orbital symmetry is provided by the correlation diagram of molecular states[13]. This leads to a correlation of the singlet ground states of oxirane and carbonyl ylide in the conrotatory process (Scheme 3). In an alternative model of orbital control due to *Evans*, *Zimmerman*[14], and *Dewar*[15], the 4π electron system of the allyl anion is characterized by a phase discontinuity in the transition state of the conrotatory process.

4. Cyclic Carbonyl Ylides

Since tetracyanoethylene oxide *(3)* contains four identical substituents, no experimental conclusions about the stereochemistry of ring opening can be drawn from the cycloadducts of *(5)*. The only examples providing information about the spatial course of the reaction concern cyclic carbonyl ylides.



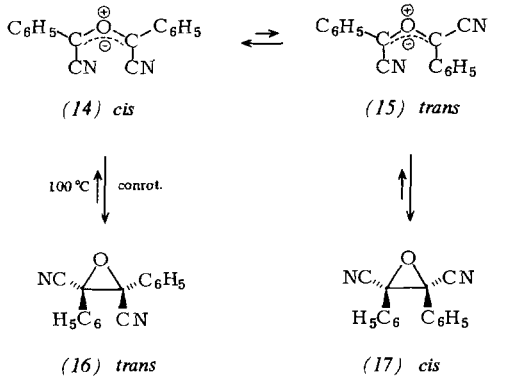
On heating 2,3-diphenylindenone 2,3-oxide *(6)* to 100°C, *Ullman* and *Milks*[16] observed reversible thermochromism; they attributed the red color to the benzopyrylium-olate *(7)* which can easily be recognized as a carbonyl ylide. Cycloadducts were obtained at 135—175°C with dimethyl acetylenedicarboxylate, norbornadiene, and cyclohexanone.

Thermal equilibrium according to *(6)*⇌*(7)* requires orbital symmetry-forbidden disrotatory processes. The ring skeleton exerts a geometrical constraint precluding conrotatory ring opening of *(6)*; the product would have to contain a phenyl group inside the hetero ring! The activation energy of ring opening is 29 kcal/mol[17].

UV irradiation leads to a photoequilibrium *(6)*⇌*(7)*. The first singlet excited states should be linked by symmetry-

allowed disrotatory processes. However, quenching and sensitization experiments, as well as quantum yields, suggested to *Ullman* and *Henderson*[17] that not the electronic excited states, but the vibrationally excited ground states were responsible for equilibration.

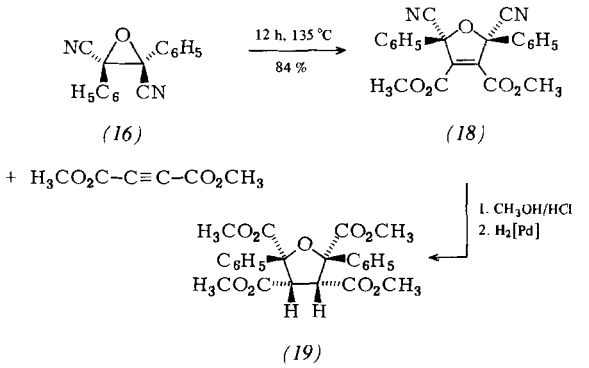
(9) *(10)* *(11)* *(12)* *(13)*



Arnold and *Karnischky*[18] attributed the purple-red color assumed by a solution of the bicyclic oxirane *(9)* at 100°C or on irradiation (253.7 nm) to the cyclic carbonyl ylide *(10)*; the color disappears at 22°C with a half-life of 8 min. Trapping with fumaronitrile affords the 1:1 adduct *(11)*, while the benzonitrile adduct *(12)* suffers spontaneous retro-Diels-Alder reaction to give triphenyloxazole *(13)*.

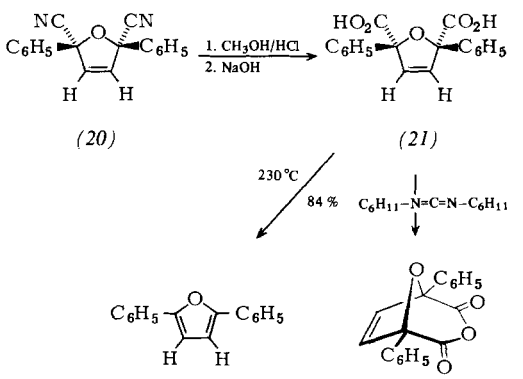
The feasibility of forbidden thermal disrotations in the cases *(6)*⇄*(7)* and *(9)*⇄*(10)* may be due, respectively, to the aromatic stabilization of *(7)* and to the enormous ring strain of *(9)* (57 kcal/mol for bicyclo[2.1.0]pentane).

5. Reactions of α,β-Dicyano-*trans*- and -*cis*-stilbene Oxides



5.1. Cycloadditions and Stereochemistry of Ring Opening

The choice of an appropriate and representative model is of crucial importance in solving a problem. An example of an unfortunate choice of model may be quoted: The clarification of the *Walden* inversion was impeded for half a century by the use of α-halocarboxylic acids. This class of compounds abounds with complications which obscured conclusions on the mechanism of nucleophilic substitution[19].

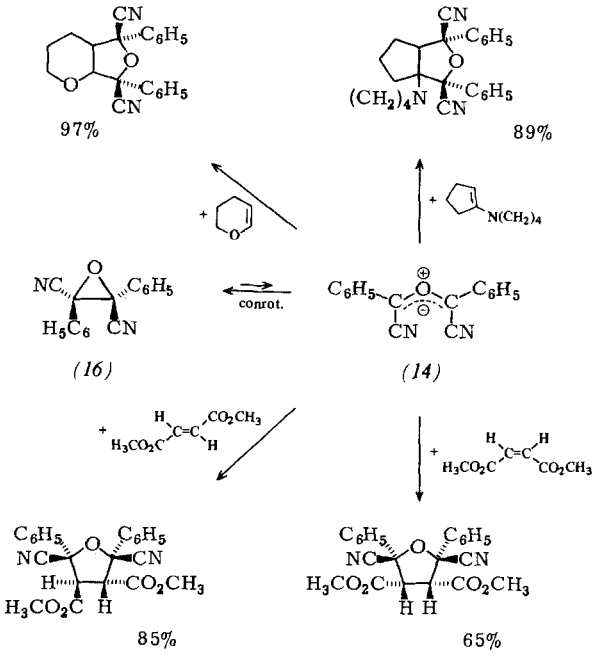


(14) cis *(15) trans* *(16) trans* *(17) cis*

Monocyclic oxiranes having two chiral centers are suitable objects for studying the steric course of the electrocyclic reaction. Our first models were α,β-dicyanostilbene oxides *(16)* and *(17)*[20], which equilibrate at as low a temperature as 100°C without acid or base catalysis to give a mixture of 85% *trans* and 15% *cis* form[21]. Dipole moments of 0.9 and 6.5 D confirm the *trans* and *cis* configurations of *(16)* and *(17)*, and correct an earlier structural assignment[22]. The two carbonyl ylides *(14)* and *(15)*, related by rotation about the CO axis, are plausible intermediates of isomerization; the overall activation energy for *(16)*→*(17)* is 27.2 kcal/mol[21].

(16) *(18)* *(19)*

As expected, the *trans*-oxirane *(16)* develops 1,3-dipolar activity above 100°C. *In situ* reaction with dimethyl acetylenedicarboxylate gives an 84% yield of the crystalline 2,5-dihydrofuran derivative *(18)*[21]. Conversion of the nitrile groups into ester groups and catalytic hydrogenation—known to involve *cis* addition of hydrogen—afford compound *(19)*, shown by its ^{1}H-NMR spectrum to possess a plane of symmetry. Hence the *cis*-carbonyl ylide *(14)* must have reacted, suggesting a conrotatory ring opening of the *trans*-oxirane *(16)*.

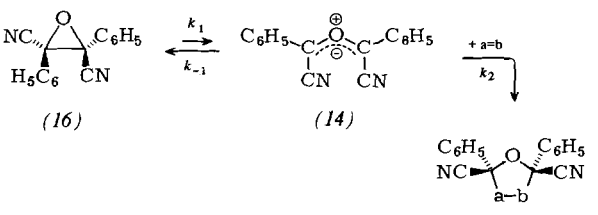


(20) *(21)*

Reaction of acetylene itself with *(16)* in cyclohexanone produces 91% of the adduct *(20)*[21]. The corresponding dicarboxylic acid *(21)* contains the functional groups in *cis* orientation, as demonstrated by anhydride formation on treatment with carbodiimide. Dehydrogenation with concomitant elimination of carbon dioxide occurs at 230°C. Formation of 2,5-diphenylfuran proves the CC ring cleavage of the oxirane *(16)* in contrast to the classical rupture at the CO bond.

The *trans*-oxirane *(16)* combines *via (14)* with various kinds of olefinic substrates to give tetrahydrofuran derivatives[21]. In Scheme 4, dihydropyran and *N*-(1-cyclopentenyl)-pyrrolidine serve as examples of electron-rich double bonds,

whereas dimethyl fumarate and maleate represent electron-poor olefins. Phenylated ethylenes and norbornene also give good yields of adducts. The nitrile groups display a *cis* orientation in all the adducts.



Scheme 4

Does this constitute proof of conrotatory ring opening? Alas, no: for the same cycloadducts are obtained starting from dicyano-*cis*-stilbene oxide *(17)* as from the *trans*-oxirane *(16)*[21]. An *ad hoc* hypothesis is readily conceived: the *trans*-carbonyl ylide *(15)* undergoes rotation to the *cis*-ylide *(14)* faster than cycloaddition. Comfort is even sought in the van der Waals interaction of *endo* substituents in the carbonyl ylide *(15)* being greater than in *(14)*, thus giving the latter an energetic advantage. However, this might all be a figment of the imagination, an attempt to save the conrotatory ring opening.

We clearly have to change our model. The first has failed to give the desired stereochemical information. Before going any further, however, we shall gather some kinetic information.

5.2. Rate Constants of Cycloadditions of α,β-Dicyano-*trans*-stilbene Oxide as Measured by Dilatometry

Adduct formation from the oxirane *(16)* involves a reversible system of first order, followed by a second order reaction; in the presence of a large excess of dipolarophile (designated as a=b) the cycloaddition becomes of pseudo-first order.

$$\frac{d[\text{Adduct}]}{dt} = k_1[\text{Oxirane}]\frac{k_2[a{=}b]}{k_{-1}+k_2[a{=}b]} = k_d[\text{Oxirane}] \quad (a)$$

$$k_d = \frac{k_1 k_2[a{=}b]}{k_{-1}+k_2[a{=}b]} \quad (b)$$

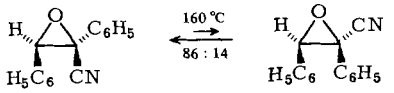
The value of k_d measured by dilatometry[23] is the first order overall rate constant for adduct formation. The material reaching the high-energy intermediate *(14)* at rate k_1 is rapidly channeled into recyclization (k_{-1}) and cycloaddition ($k_2[a{=}b]$). The fraction occurring in equation (a) is called the partition coefficient; it represents the mole fraction of carbonyl ylide *(14)* which leads directly to the cycloadduct. According to eq. (b), k_d is a function containing the dipolarophile concentration [a=b] in both the numerator and the denominator. k_d is a linear function of [a=b] only when $k_{-1} \gg k_2[a{=}b]$.

$$k_d = \frac{k_1}{k_{-1}} k_2[a{=}b] \quad (c)$$

These special conditions as defined by eq. (c) are fulfilled in the reaction of *(16)* with dimethyl fumarate (Table 1); the three values of k_d are proportional to the fumaric ester concentrations. Hence it is demonstrated that the electrocyclic ring opening equilibrium is completely established and that 1,3-dipolar cycloaddition is a slow subsequent reaction[24].

Table 1. Dilatometric rate constants of α,β-dicyano-*trans*-stilbene oxide *(16)* (40 mmol/l) to various dipolarophiles a=b in *o*-dichlorobenzene at 139 °C [24].

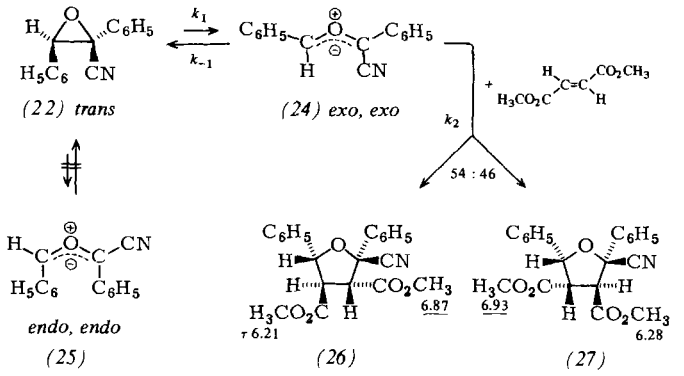
Dipolarophile a=b	[a=b] [mol/l]	$10^5 k_d$ [s^{-1}]	$10^5 k_d/[a{=}b]$ [$l \cdot mol^{-1} s^{-1}$]
Dimethyl fumarate	0.300	3.77	12.6
	0.522	6.51	12.5
	0.601	7.57	12.6
Diethyl maleate	0.501	0.50	0.99
N-Phenylmaleimide	0.527	4.86	9.2
Maleic anhydride	0.589	2.26	3.8
Cyclopentene	0.589	1.88	3.2
Norbornene	0.567	6.51	11.5
N-(1-Cyclopentenyl)-pyrrolidine	0.646	12.1	18.7



The k_d values of several dipolarophiles compiled in Table 1 are proportional to the cycloaddition rate constant k_2 after division by the dipolarophile concentration [a=b], and thus constitute a measure of the dipolarophilic activity for a given 1,3-dipole. Table 1 lists compounds with electron-poor double bonds, normal alkenes, and an enamine as an example of an electron-rich system. Dimethyl fumarate is 13 times more active than dimethyl maleate; *trans* disubstituted ethylenes are superior to the *cis* compounds in 1,3-dipolar cycloaddition[25] and Diels-Alder reaction[26] for obvious reasons. The angle-strained double bond of norbornene with its non-equivalent π-orbital lobes[27] reacts with *(14)* 3.6 times faster than cyclopentene.

On comparing dimethyl fumarate, cyclopentene, and *N*-(1-cyclopentenyl)pyrrolidine it is notable that both electron-withdrawing and electron-releasing substituents enhance dipolarophilic activity. A useful classification of 1,3-dipoles is based on the decisive HOMO-LUMO interaction according to *Sust-*

mann[28]. The above behavior classifies the carbonyl ylide *(14)* as a Sustmann type II species characterized by two HOMO-LUMO interactions of comparable strength. The narrow overall spread of the k_2 values corresponds to expectations for the bottom of a paraboloid function attained by plotting $\log k_2$ against the lowest ionization potential of the dipolarophiles[29].



6. α-Cyano-*trans*-stilbene Oxide and Dimethyl Fumarate

6.1. Stereochemistry of Cycloaddition

(22) trans *(23) cis*

Monocyanostilbene oxides, prepared from benzaldehyde and α-chlorophenylacetonitrile and potassium *tert*-butoxide, turned out to be superior models for studying the stereochemistry of electrocyclic ring opening. In this case a temperature of 160 °C is necessary to establish the thermal *trans,cis* equilibrium [86% *(22)* and 14% *(23)*] with $t_{1/2} = 7.2$ h[30].

(22) trans *(24) exo, exo* *endo, endo* *(25)* *(26)* *(27)*

Scheme 5

Heating the *trans*-oxirane *(22)* in an excess of molten dimethyl fumarate to 130 °C produces the two cycloadducts *(26)* and *(27)*[30] in 99% yield. The NMR spectra—some of the τ values are entered in Scheme 5—permit assignment of configuration, the high τ value of the ester methyl located *cis-vicinal* to phenyl being an important criterion. Both adducts contain *cis* phenyl groups in positions 2 and 5, and *trans* ester groups in positions 3 and 4. The configurations of 1,3-dipole and dipolarophile are retained in the concerted cycloaddition. Thus, the carbonyl ylide involved must be the *exo,exo*-diphenyl isomer *(24)* expected as the product of conrotatory ring opening. The carbonyl ylide *(25)*, which would also account for the stereochemistry of the adducts, is energetically disqualified by the interaction of two large groups on the *endo* side.

6.2. Kinetics of Cycloaddition

The carbonyl ylide *(24)* fails to appear in spectroscopically detectable concentrations. It can be shown kinetically, however, that cycloaddition is preceded by reversible formation of a high energy intermediate. The aforementioned dilatometric study of cycloadduct formation with a variable excess of dimethyl fumarate affords the pseudo-first order k_d values defined in eq. (a) and (b). If these are plotted against the molar concentration of fumaric ester, then curves are obtained for various temperatures which approach plateau values (Fig. 1 A). This demonstrates that in eq. (b) the recyclization constant k_{-1} and the cycloaddition constant k_2[a=b] are of similar magnitude[31].

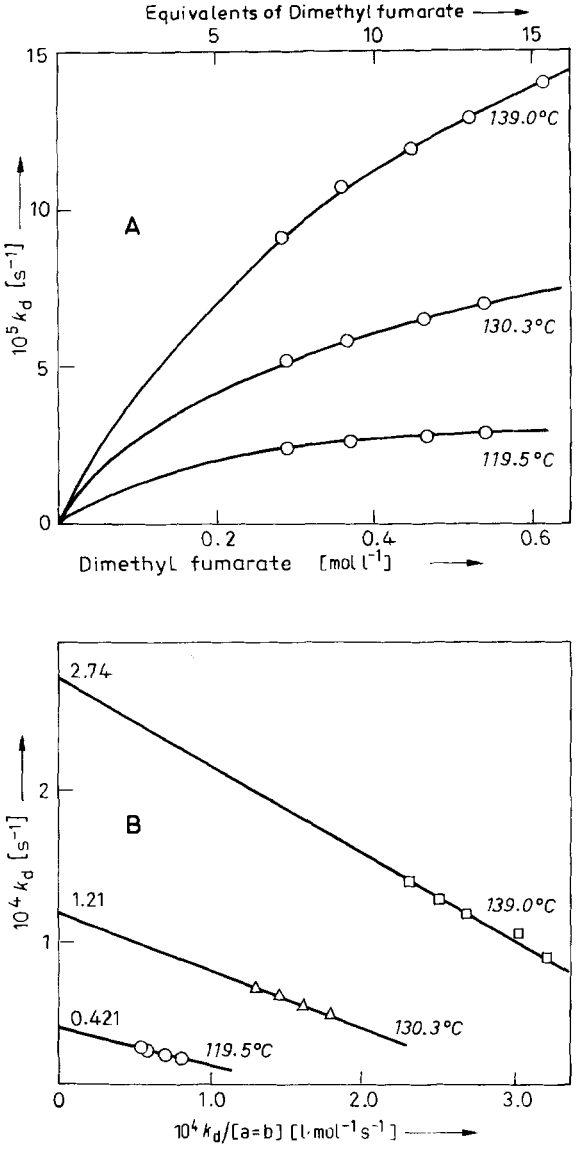


Fig. 1. Dilatometric rate measurements of the cycloaddition of α-cyano-*trans*-stilbene oxide *(22)* (40 mmol/l) with dimethyl fumarate in *o*-dichlorobenzene [30]. A) Plot of k_d *vs.* dimethyl fumarate concentration [a=b]. The curves were calculated with the values k_1 and k_{-1}/k_2 determined from Fig. 1 B. B) Plot of k_d *vs.* k_d/[a=b].

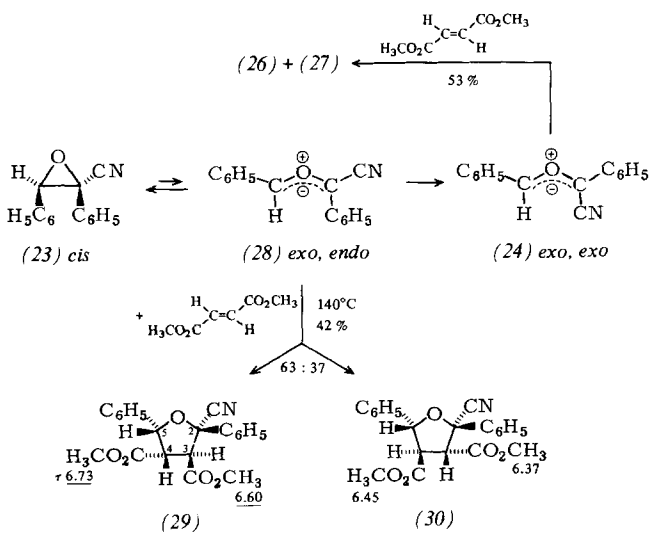
Equation (b) having the dipolarophile concentration [a=b] in the numerator and in the denominator can be transformed into the equation of a straight line by representing k_d as a function of k_d/[a=b]. When plotted according to eq. (d), the experimental values do indeed define straight lines (Fig. 1 B). The intercept is identical with the ring opening constant

$$k_d = k_1 - \frac{k_{-1} k_d}{k_2[\text{a=b}]} \qquad \text{(d)}$$

k_1. The Eyring activation parameters can be determined from the temperature dependence of this rate constant. The activation enthalpy amounts to 30.1 kcal/mol; the change in entropy, $\Delta S^{\neq} = 2$ cal K^{-1} mol^{-1}, is negligibly small, as expected for the conversion of the rigid oxirane *(22)* into the rigid carbonyl ylide *(24)*.



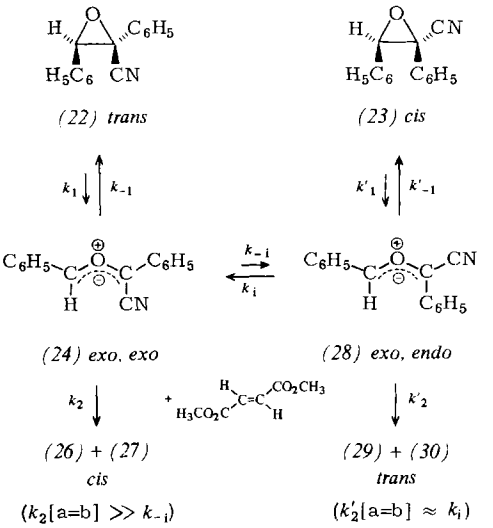
The slopes of the straight lines in Figure 1B correspond to the rate ratios of the reactions competing for the carbonyl ylide (k_{-1}/k_2). The increase in slope with temperature results from k_{-1} having a higher temperature coefficient than k_2. The intramolecular cyclization *(24)*→*(22)* should possess as small an activation entropy as the reversal *(22)*→*(24)*; hence $\Delta H^{\neq}$ accounts for virtually all the free energy of activation. In contrast, 1,3-dipolar cycloadditions display modest enthalpies of activation, but large negative entropies of activation[25]; k_2 consequently shows a much smaller dependence upon temperature than k_{-1}.

It should be mentioned in passing that *(22)* also undergoes cycloadditions with other olefinic and acetylenic dipolarophiles[24, 30].

7. α-Cyano-*cis*-stilbene Oxide and Dimethyl Fumarate

7.1. Stereochemistry of Addition

Reaction of the *cis*-oxirane *(23)*—*cis* and *trans* refer here to the orientation of the phenyl groups—in a dimethyl fumarate melt at 140°C furnishes 42% of two new adducts besides 53% of the cycloadducts *(26)* and *(27)* with *cis*-2,5-phenyl groups already discussed. All four diastereomeric tetrahydrofuran derivatives were separated by layer chromatography and characterized[30]. The ^{1}H-NMR spectra (some τ values shown in Scheme 6) leave no doubt that the phenyl groups in positions 2 and 5 of the new adducts *(29)* and *(30)* are *trans* located. The 63:37 ratio of *(29)* and *(30)* is remarkable in that the phenyl and the ester group twice appear in *cis-vicinal* positions, corresponding to a relatively high van der Waals strain. The reason lies in the more extensive π overlap of the reactants in the transition state leading to *(29)*.



Scheme 6

The *trans*-2,5-diphenyl adducts *(29)* and *(30)* must originate from cycloaddition of the carbonyl ylide *(28)* which has an *exo*- and an *endo*-phenyl group.

7.2. Cycloaddition *versus* Rotation

A tentative interpretation: α-cyano-*cis*-stilbene oxide *(23)* opens conrotatorily to the *exo,endo*-diphenyl carbonyl ylide *(28)* which is only partly trapped by 1,3-dipolar cycloaddition to give *(29)* and *(30)*. Part of the carbonyl ylide *(28)* escapes by isomerization to the more stable *exo,exo*-diphenyl isomer *(24)*, which in turn is converted by fumaric ester into the *cis*-diphenyl adducts *(26)* and *(27)*.

Why is the *exo,exo* form *(24)* more stable than *(28)*? In the *exo,endo* isomer *(28)* the planar conformation is prohibited by the proximity of the *endo*-phenyl and the *endo*-hydrogen, whereas the conjugation is unimpaired in the *exo,exo*-isomer *(24)*.

Scheme 7

What support can we derive for the working hypothesis of partial trapping of *(28)*? In Scheme 7, α-cyano-*trans*- *(22)* and -*cis*-stilbene oxide *(23)* are interconnected by rotation *via* the stereoisomeric carbonyl ylides. Starting from the *trans*-oxirane *(22)*, reaction with dimethyl fumarate exclusively affords the *cis*-2,5-diphenyl adducts *(26)* and *(27)*. There is no concomitant rotation of the *exo,exo*-carbonyl ylide *(24)*, *i.e.* k_2[a=b], the rate of cycloaddition, is much greater than k_{-i}. In contrast, cycloaddition to give the *trans*-diphenyl adducts *(29)* and *(30)*, and rotation proceed at similar rates in the less favored *exo,endo*-carbonyl ylide *(28)*. Since the carbonyl ylide *(24)*, which arises by rotation with the rate constant k_i, does not return to *(28)* in the presence of dimethyl fumarate, k_i constitutes the product-determining step for the formation of the *cis*-diphenyl adducts *(26)* and *(27)* from the *cis*-oxirane *(23)*.

$$\frac{\textit{cis}\text{-Adducts } (26)+(27)}{\textit{trans}\text{-Adducts } (29)+(30)} = \frac{k_i}{k'_2[\text{a=b}]} \qquad \text{(e)}$$

The large negative entropy of activation of concerted cycloadditions and the only modest activation enthalpy has already been mentioned. In contrast, rotational barriers such

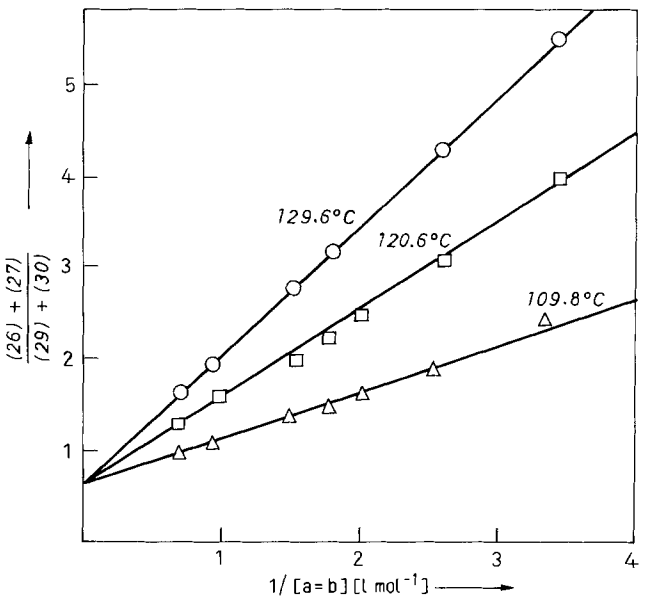
as those between the carbonyl ylides *(28)* and *(24)* are associated with activation entropies close to zero; a higher temperature coefficient should arise from the higher enthalpy of activation.

Table 2. Cycloadditions of α-cyano-*trans*- *(22)* and -*cis*-stilbene oxide *(23)* to dimethyl fumarate (excess, melt); temperature dependence of the ratio of *cis* and *trans*-2,5-diphenyl cycloadducts, *(26)*+*(27)* and *(29)*+*(30)* [30].

	Temp. [°C]	Conversion [%]	Reaction time	*cis* : *trans* *(26)*+*(27)* : *(29)*+*(30)*
trans *(22)*	130	99	45 h	100 : 0
cis *(23)*	100	26	30 d	31 : 69
cis *(23)*	120	87	14 d	44 : 56
cis *(23)*	130	80	130 h	49 : 51
cis *(23)*	140	95	120 h	57 : 43

The temperature dependence of the *cis*:*trans* cycloadduct ratio indeed fits eq. (e) (Table 2)[30]. In experiments with the *cis*-oxirane *(23)* in molten dimethyl fumarate at 100–140°C the proportion of stereospecifically formed *trans*-2,5-diphenyl adducts drops from 69 to 43%. Rotation gains ground, as confirmed by the increasing percentage of *cis* adducts, formed non-stereospecifically *via* rotation. The inadequate rate of ring opening precludes studies at lower temperatures; even at 100°C only 26% conversion takes place within 30 days.

Starting from the *cis*-oxirane *(23)*, competition between bimolecular cycloaddition (k'_2[a=b]) and unimolecular isomerization (k_i) for the carbonyl ylide *(28)* should depend upon the concentration [a=b] of the fumaric ester. If the ratio of *cis* to *trans* adducts is plotted against the reciprocal of the fumaric ester concentration, then eq. (e) predicts a straight line of slope k_i/k'_2.



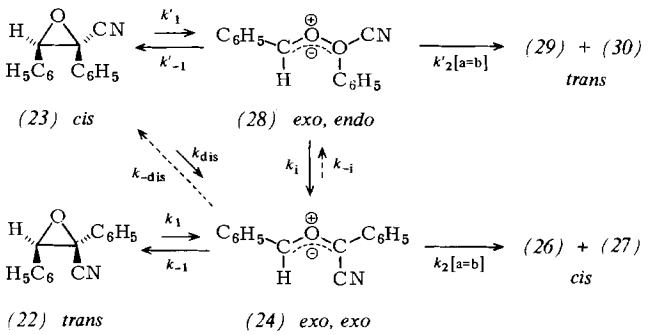


Fig. 2. Reaction of α-cyano-*cis*-stilbene oxide *(23)* with an excess of dimethyl fumarate in *o*-dichlorobenzene; dependence of the ratio of *cis*- and *trans*-2,5-diphenyl cycloadducts (*(26)*+*(27)*)/(*(29)*+*(30)*) upon the concentration [a=b] of fumaric ester [32].

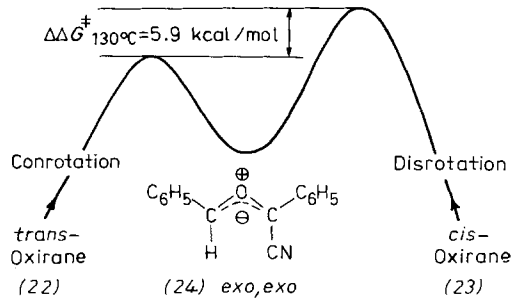
The ratio of *cis*- to *trans* adducts was determined by NMR spectroscopy for several concentrations of fumaric ester in *o*-dichlorobenzene at various temperatures[32]. The experimental ratios define straight lines in Figure 2, thus indeed establishing the competition of first order isomerization with second order cycloaddition. For the reasons mentioned, the slope of the straight lines (k_i/k'_2) increases with temperature.

7.3. Two Pathways Leading to Nonstereospecific Cycloadducts

A blemish: the three straight lines of Figure 2 do not pass through the origin as required by eq. (e), but intersect the ordinate at the value 0.56. What does this mean? Even at an infinitely great concentration of fumaric ester (corresponding to 1/[a=b] = 0) 36% of *cis* adduct is formed alongside 64% of *trans* adduct; 36/64 is 0.56. The unavoidable conclusion: only 64% of the material is actually subjected to competition between unimolecular isomerization and bimolecular cycloaddition. How, then are the remaining 36% of *cis* adducts formed from the *cis*-oxirane *(23)* circumventing the *exo,endo*-carbonyl ylide *(28)*?

Only the most likely pathway from a total of four possibilities[32] will be considered, *viz.* the disrotatory pathway leading directly from the *cis*-oxirane *(23)* to the *exo,exo*-carbonyl ylide *(24)*. In trying to interpret this minor participation of symmetry-forbidden disrotation in ring opening, it should be borne in mind that disrotation already becomes effective at 100°C in the case of the bicyclic oxiranes *(6)* and *(9)*.

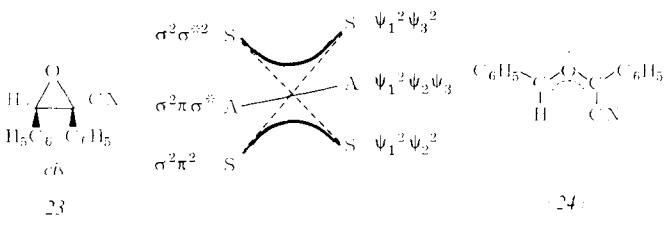
Scheme 8



Thus Scheme 7 is replaced by Scheme 8 which includes disrotatory ring opening. Since the *cis*-2,5-diphenyl cycloadducts *(26)* and *(27)* are obtained exclusively from the *trans*-oxirane *(22)* (Scheme 6), k_{-i} and k_{-dis} must be negligibly small in the presence of fumaric ester. Treatment of the remaining complex reaction according to *Bodenstein*'s *quasi*-steady state principle affords eq. (f). Once again, the ratio of *cis*- to *trans*-2,5-diphenyl cycloadducts, *(26)*+*(27)* to *(29)*+*(30)*, is a linear function of 1/[a=b], the reciprocal of the fumaric ester concentration. The intercept, k_{dis}/k'_1, is the ratio of the rate constants of disrotatory and conrotatory ring opening of *(23)*. Its value of 0.56 means that the allowed conrotation is only about twice as fast as the forbidden disrotation.

$$\frac{\textit{cis}\text{-Adducts}}{\textit{trans}\text{-Adducts}} = \frac{k_{dis}}{k'_1} + \frac{k_i k'_1 + k_{dis} k'_{-1} + k_i k_{dis}}{k'_1 k'_2} \cdot \frac{1}{[a=b]} \qquad (f)$$

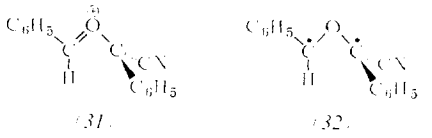
7.4. Orbital Symmetry-Allowed and -Forbidden Ring Opening



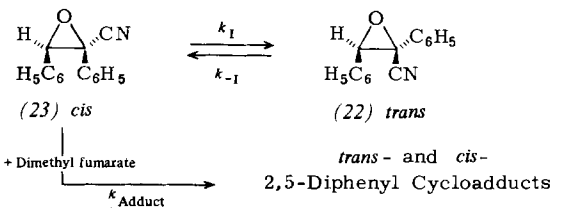
We should not forget that ring opening of the *trans*-oxirane *(22)* occurs by conrotation exclusively. The *cis* oxirane *(23)*

enters into the forbidden disrotation, because conrotation leads to the energetically less favorable of the two carbonyl ylides. A fairer comparison of symmetry-allowed and symmetry-forbidden is provided by the formation of one and the same *exo,exo*-carbonyl ylide *(24)* from the *trans*-oxirane *(22)* by conrotation and from the *cis*-oxirane *(23)* by disrotation (Scheme 8); the transition states of endothermic formation of the carbonyl ylides should structurally resemble the latter more closely than the oxiranes.

Scheme 9



Let us compare orbital symmetry with laws in human society. Forbidden acts do occur, but they require a higher activation energy. As derived below, the transition states leading from *(22)* and *(23)* to the *exo,exo*-carbonyl ylide *(24)* differ in their free energy by 5.9 kcal/mol at 130°C (Scheme 9). Conrotatory ring opening should accordingly be 1600 times faster than the forbidden disrotation. $\Delta\Delta G^{\neq}$ of allowed and forbidden reactions is, however, smaller than in the few cases which have been successfully subjected to experimental measurement. In the electrocyclic ring closure of *trans,cis,cis,trans*-2,4,6,8-decatetraene to form 7,8-dimethyl-1,3,5-cyclooctatriene conrotation and disrotation differ by 12 kcal/mol in $\Delta G^{\neq}$ at 170°C[33]; in the case of 2,3,4,5-tetraphenyl-2,4-hexadiene, disrotatory ring closure to the cyclobutene derivative requires >7 kcal/mol more energy than the conrotatory mode[34].



Scheme 10

The nature of "forbidden" processes is one of the toughest mechanistic problems of our time. The hard nut has not been cracked, neither here nor in any other case. One-step and two-step reactions have been considered.

The orbital symmetry correlation diagram of the molecular states for concerted disrotation is shown in Scheme 10. Formally, the ground state of the oxirane *(23)* should be correlated with the second excited singlet state of the carbonyl ylide *(24)*. However, configuration interaction prevents the crossing of correlation lines which connect states of the same symmetry. Correlation of the ground states, *(23)* → *(24)*, goes by way of an energy peak representing the forbiddenness of the process. It can be readily demonstrated that the energy gap between ψ_2 and ψ_3 should be smaller for the carbonyl ylide than for the azomethine ylide (Scheme 1) or the allyl anion, which could imply a reduced $\Delta\Delta G^{\neq}$ for conrotation and disrotation[24].

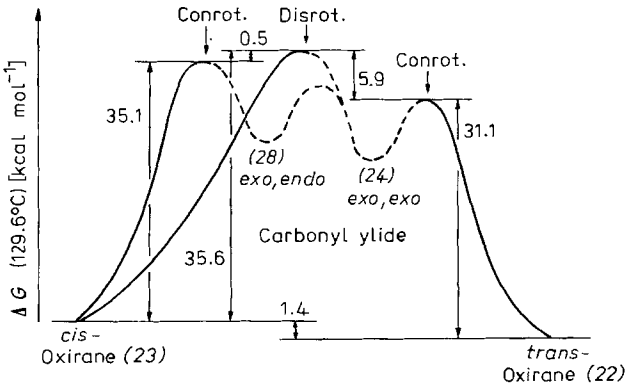
An attractive nonconcerted process is visualized in a ring opening which involves only one 90° rotation. Whether or not the oxonium ylide *(31)*—possessing no allyl anion orbital—and the diradical *(32)* are different species, is unsettled. *Dewar* and *Kirschner*[35] found in MINDO/3 calculations that the energy requirements of conrotatory and disrotatory ring opening of the cyclopropyl anion differ by a mere 9 kcal/mol, assuming the disrotation to involve two successive 90° rotations. The oxonium ylide *(31)* is an octet structure stabilized by substituents.

Temp [°C]	$10^6 k_I$ [s^{-1}]	$10^6 k_{Adduct}$ [s^{-1}]
130	1.17	1.15
170	5.32	5.39

Scheme 11

Determination of the energy difference of 5.9 kcal/mol in Scheme 9 is based on further kinetic information: The overall isomerization constant k_I of *cis*- to *trans*-oxirane, *(23)* → *(22)*, virtually equals the overall constant of cycloaddition in the presence of dimethyl fumarate[31] (Scheme 11). Hence it follows that the transition states of conrotatory and disrotatory ring opening of the *cis*-oxirane *(23)* represent the highest mountain passes in the entire energy panorama.

The free energy profile of Figure 3 is now accessible; the solid lines refer to experimental ΔG values at 130°C. The difference of 5.9 kcal/mol between the transition states of dis-



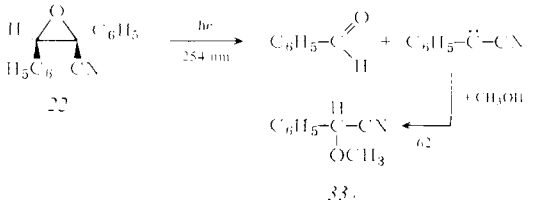


Fig. 3. Free energy profile for *cis,trans* isomerization of the α-cyanostilbene oxides *(23)* and *(22)* *via* the carbonyl ylides *(24)* and *(28)* [32].

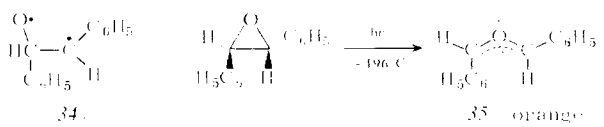
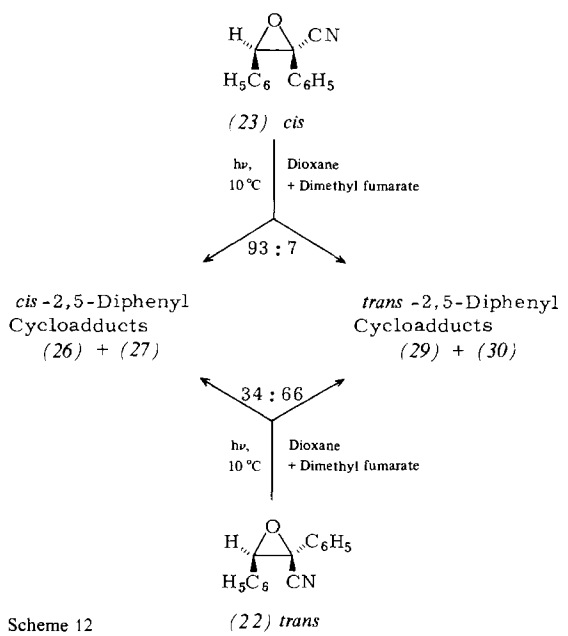


rotation and conrotation, both leading to carbonyl ylide *(24)*, is the result of a thermochemical cycle.

How deep are the energy valleys in which the carbonyl ylides hold their brief sojourn before reacting further? Solution of this problem requires an excursion into photochemistry.



8. Photochemical Ring Opening of Oxiranes

Griffin et al.[36] observed an interesting photofragmentation of *vic*-diaryloxiranes into carbonyl compounds and carbenes; formation of *(33)* from *(22)* serves as an illustration[37]. Irradiation of *trans*- and *cis*-stilbene oxide in a matrix at −196 °C produces an orange and a deep-red color with absorption maxima at 490 and 510 nm, respectively. A diradical *(34)* arising from CO bond rupture was initially preferred for the colored species[38]; *Do-Minh*, *Trozzolo*, and *Griffin*[39]

later attributed the colors to the carbonyl ylides, *e.g. (35)*, which are formed by a disrotatory process. Carbene formation presumably results from photolysis of the carbonyl ylide[36] or from a second photoprocess starting from the oxirane.

Scheme 12

The experiments of Scheme 12, performed in 1972, offer a "missing link". On irradiation of α-cyano-*cis*- and -*trans*-stilbene oxides in dioxane with a mercury low-pressure lamp at 10 °C, the carbonyl ylides generated can be intercepted with dimethyl fumarate[40]. The principal products isolated are *cis*-2,5-diphenyl cycloadducts from the *cis*-oxirane *(23)* and *trans*-2,5-diphenyl adducts from the *trans*-oxirane *(22)*. The preferred ring-opening pathway, if not the only one operative, appears to be the disrotatory mode which is symmetry-allowed for the first singlet excited state. On the other hand, it is probably the singlet ground state of the carbonyl ylides which combines with dimethyl fumarate; the adduct ratios *(26)/(27)* and *(29)/(30)* match those from thermally generated carbonyl ylides (54:46 in Scheme 5, 63:37 in Scheme 6).

Why is the stereoselectivity in Scheme 12 not greater? The sequence of photochemical disrotatory ring opening and thermal conrotatory cyclization constitutes a *trans,cis* isomerization of the oxirane which precludes stereochemical purity. After irradiating the *trans*-oxirane *(22)* in the presence of fumaric ester, one isolates alongside 46% of cycloadducts some oxirane which contains *(22)*:*(23)* = 85:15[40]. Photoisomerization of the carbonyl ylides *(24)*⇌*(28)*, would provide a further source for stereochemical leakage.

Recently, also *Griffin et al.*[41] and *Lee*[42] described trapping reactions of photogenerated carbonyl ylides by [3+2→5] cycloadditions. The stereoselectivity observed by *Lee* on photoaddition of *cis*- and *trans*-stilbene oxide to methyl acrylate or maleic anhydride corresponds to that found by us. The complexity of oxirane photolysis is evidenced by the observation that triplet sensitizers enhance the yield of cycloadduct and produce identical adduct mixtures from *cis*- and *trans*-stilbene oxide; nevertheless, singlet carbonyl ylides appear to be the species entering into cycloaddition[41,42].

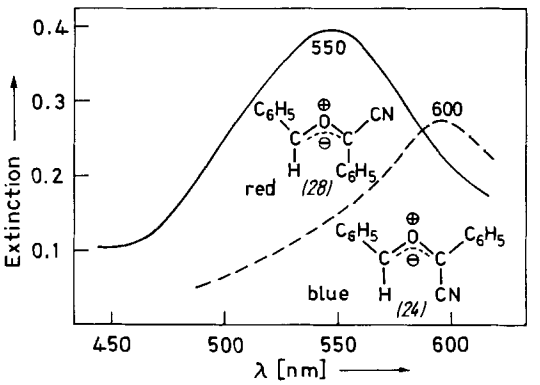


Fig. 4. Flash photolysis of α-cyano-*cis*- *(23)* and -*trans*-stilbene oxide (22). Matrix of isopentane/ether (6:1) at −196 °C, 25-joule argon flash, measurement with xenon lamp [43]. Extinction in arbitrary units.

In cooperation with the Max-Planck-Institut für Kohlenforschung we subjected the oxiranes *(22)* and *(23)* to flash photolysis in an isopentane/ether matrix at −196 °C. We attribute the colors observed (Fig. 4) to the carbonyl ylides *(28)* and *(24)*. The longer wavelength absorption measured in the experiment with the *cis*-oxirane *(23)* is attributable to the *exo,exo*-diphenyl isomer *(24)* with its unhindered carbonyl ylide conjugation[43].

The colors disappear with half-lives of 5 and 2.5 s, respectively, at −196 °C, corresponding to thermal recyclization of the carbonyl ylides. Flashing of oxirane solutions at room temperature does not lead to detectable colors; no absorption

was registered in the visible range even one microsecond after the flash. Thus, the carbonyl ylides must disappear with a half-life shorter than 0.5×10^{-6} s at 25 °C, indicating $\Delta G^{+} < 12.5$ kcal/mol for recyclization. A check on these results and supplementary measurements in the intermediate temperature range are required.

9. Energy Profile for the *cis,trans*-Isomerization of α-Cyanostilbene Oxide

Further kinetic data and relations—see ref. [24] for details—help to define reasonable maximum and minimum values for the rate constants of Scheme 8. These estimates provide the basis for the free energy profile of Figure 5 which offers upper and lower limits for the depth of the energy troughs corresponding to the carbonyl ylides *(28)* and *(24)*. The disrotatory ring opening of the *cis*-oxirane *(23)* has been omitted for the sake of clarity.

about the CO bond, the energy barrier is actually quite small. Indeed, significantly higher barriers to rotation, *viz.* 20—26 kcal/mol, were found for azomethine ylides having similar substitution patterns[44,45]. *Ab initio* calculations with the 4—31 G program[46] do in fact confirm that the resonance energy of the azomethine ylide is greater than that of the carbonyl ylide, both being considered as the unsubstituted parent compounds; *Hehre*[47] calculated the rotational barrier of the azomethine ylide as 29 kcal/mol and that of the carbonyl ylide as 14 kcal/mol.

In a different approach, *Hayes* and *Siu*[48] treated the structure of some 1,3-dipoles by a SCF configuration interaction technique in which the percentage of mixing of a doubly excited with a ground configuration was calculated. Twice that percentage is defined as "π diradical character" which in the case of azomethine ylides and carbonyl ylides amounts to 30 and 38 %, respectively. We suppose a decreasing rotational barrier with increasing "π diradical character".

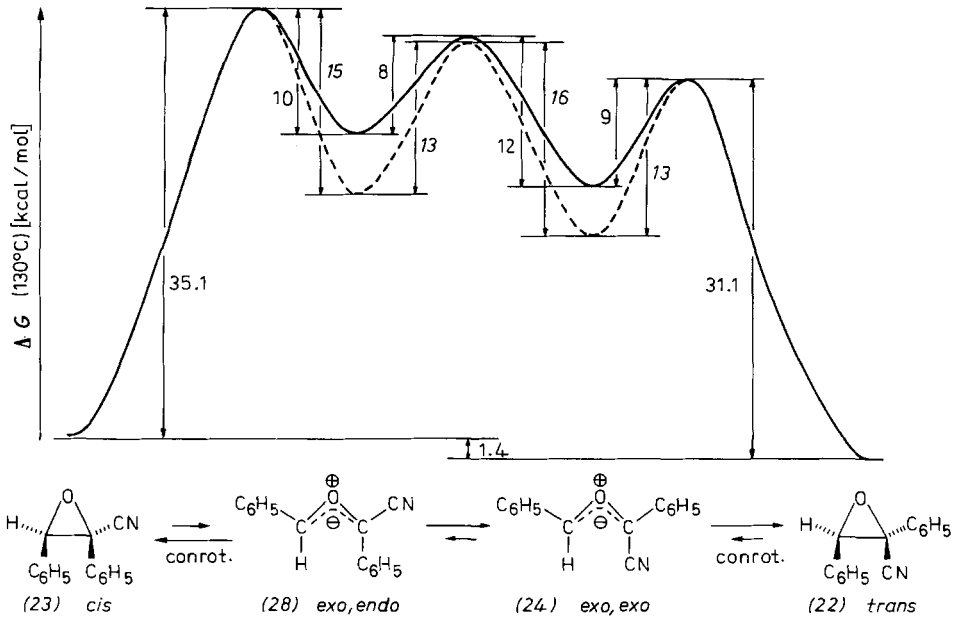

Fig. 5. Free energy profile (130 °C) for thermal *cis,trans*-isomerization of α-cyanostilbene oxides; maximum (in italics) and minimum ΔG^{+} values for the carbonyl ylides [43].

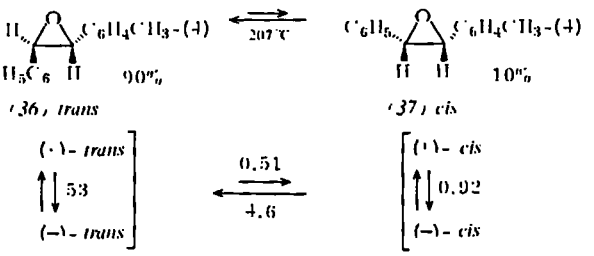
The energy profile clarifies why the carbonyl ylides are not visible in thermal equilibrium with the oxiranes. They lie roughly 20 kcal/mol above the energy level of the oxiranes. One should expect only one carbonyl ylide molecule per 10^{11} oxirane molecules at 130 °C. It is an enticing aspect of this study that indirect information on structure and reactivity of such high-energy intermediates can be acquired.



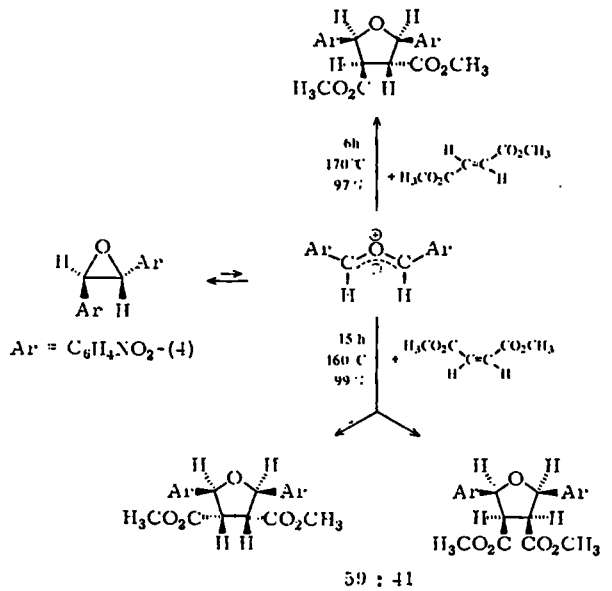
As the result of van der Waals pressure of the *endo*-phenyl and the *endo*-H, the energy level of the *exo,endo*-diphenyl-carbonyl ylide *(28)* is 3—4 kcal/mol above that of the *exo,exo*-isomer *(24)*. The recyclization barriers are 8—13 and 12—16 kcal/mol, respectively. The low rotational barrier for *(28)* → *(24)* is responsible for the lack of stereoselectivity observed in the 1,3-dipolar cycloadditions of *(28)* (Table 2, Fig. 2).

In view of the fact that the allyl anion resonance of the carbonyl ylide must be temporarily sacrificed on rotation

Is it permissible to use *free energy profiles* for picturing the reaction event, as done in Figures 3 and 5? Is not the standard enthalpy a better measure for the fictitious potential energy of the single molecule or collision complex? After critically examining the graphical representations of complex reactions, *Johnston*[49] concludes that the ordinate of the usual plots corresponds neither to the potential energy nor to the enthalpy, nor to the free energy in the strict sense. Nevertheless: "It cannot be said that these plots are meaningless. It can be said that they are an artificial, conventional, short-hand notation for complex reactions. Some people are able to communicate with each other using these symbols..."

Have we chosen a good model for the mechanistic study? It has provided the deepest insight so far into the stereochemistry and energetics of the electrocyclic oxirane ring opening including the energy requirements of the orbital symmetry-allowed and symmetry-forbidden courses. The limited 1,3-

dipolar activity of the *exo,endo*-carbonyl ylide *(28)* was disadvantageous; the cycloaddition could not suppress the rotation completely.

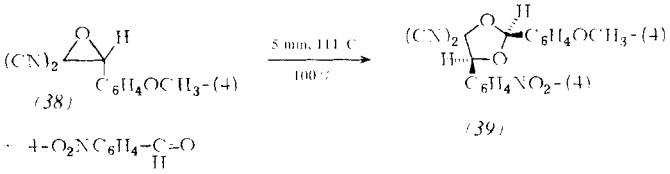


Scheme 13

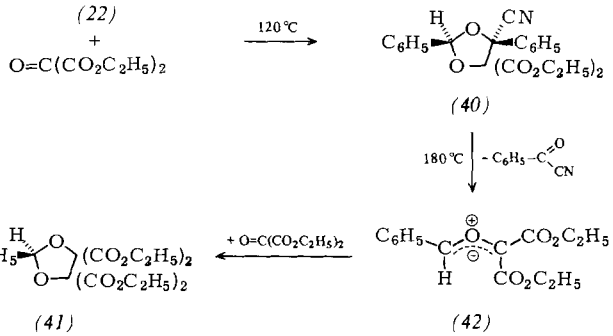
A model used by *MacDonald* and *Crawford*[50] adds welcome evidence. The *trans* isomer *(36)* of the optically active 2-phenyl-3-*p*-tolyloxirane racemizes 60 times faster than the *cis* form *(37)*; the rate constants at 207 °C are given as $10^6 k$ $[s^{-1}]$ in Scheme 13. The intermediate carbonyl ylides possess a plane of symmetry. The preference of the *trans* isomer *(36)* in racemization rate is due to conrotatory ring opening to form the *exo,exo*-diaryl-carbonyl ylide, the energetically more favorable of the two open-chain species. The *trans,cis* isomerization proceeds *via* rotation of the carbonyl ylide. The *exo,endo*-carbonyl ylide arising from the *cis*-oxirane *(37)* displays the greater tendency to undergo rotation.

Comparison of the ring opening rates of *(36)* and *(37)* with those of α-cyano-*trans*- *(22)* and -*cis*-stilbene oxide *(23)* reveals that the additional nitrile group accelerates 540- and 1400-fold (extrapolation to 130 °C).

10. Synthesis of Heterocycles with Carbonyl Ylides

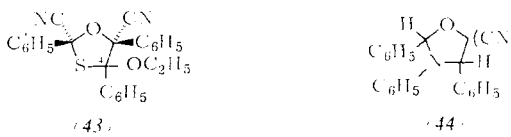


A brief outline of the preparative use and synthetic utility of carbonyl ylides may supplement the mechanistic study.



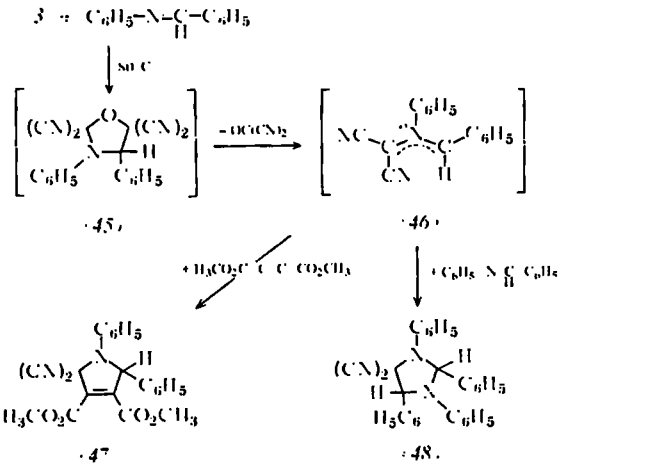
Scheme 14

How does the ability of oxirane to undergo thermal ring opening depend upon the number and nature of the substituents? The allyl anion character of the ring-opened species requires substituents capable of stabilizing negative charge. Tetra- and trisubstituted ethylene oxides have been examined so far. Just two substituents suffice in the case of *p,p'*-dinitro-*trans*-stilbene oxide, which reacts with dipolarophiles at 160—170 °C. Satisfactory yields of tetrasubstituted tetrahydrofurans are obtained with dimethyl fumarate and maleate (Scheme 14)[24].

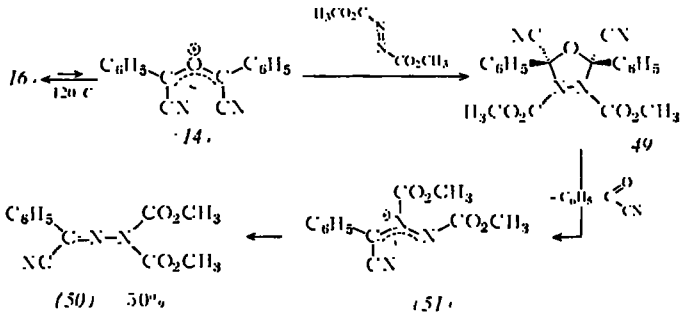


Photochemical oxirane ring opening also demands several activating substituents, of which at least one must be an aryl group, probably to ensure adequate long-wave absorption.

Apart from olefinic and acetylenic bonds, numerous hetero multiple bonds as dipolarophiles accept carbonyl ylides. *Robert et al.*[51] prepared 1,3-dioxolanes from 2-aryl-3,3-dicyanooxiranes and aromatic aldehydes, *e.g. (39)* from *(38)* and *p*-nitrobenzaldehyde in boiling toluene.



Addition of α-cyano-*trans*-stilbene oxide *(22)* to diethyl mesoxalate to form *(40)* is followed by a 1,3-dipolar cycloreversion; the new carbonyl ylide *(42)* adds afresh to the mesoxalic ester, yielding tetraethyl 1,3-dioxolanetetracarboxylate *(41)*[52].



Addition of carbonyl ylides to the highly dipolarophilic CS double bond furnishes 1,3-oxathiolanes. Thus, α,β-dicyano-*trans*-stilbene oxide *(16)* combines with *O*-ethyl thiobenzoate at 120 °C to give 65 % of *(43)* (two diastereomers)[52]. Azomethines of the *N*-benzylideneaniline type add the carbonyl ylide from 1,1-dicyano-2-phenyloxirane at 111 °C to form 65 % of *(44)*[53].

In contrast, addition of tetracyanoethylene oxide *(3)* to *N*-benzylideneaniline is succeeded by elimination of mesoxalonitrile leading to the azomethine ylide *(46)*. The latter combines either with a second molecule of *N*-benzylideneaniline to give the imidazolidine *(48)* or with added dimethyl acetylenedicarboxylate, whereupon 62 % of the "mixed" product *(47)* is obtained. This observation reported by *Linn* and *Ciganek*[54] indicates interesting specificities. In a mixture of

benzylideneaniline and dimethyl acetylenedicarboxylate the tetracyanocarbonyl ylide *(5)* reacts preferentially with the first dipolarophile, but the intermediate azomethine ylide *(46)* faster with the second one. The role of dimethyl acetylenedicarboxylate as trapping reagent for *(46)* can also be played by fumaric ester, *N*-phenylmaleimide, and other electron-poor dipolarophiles[55].

A proclivity towards 1,3-dipolar cycloreversion is also found in the 1,3,4-oxadiazolidine *(49)*, which is formed from α,β-dicyano-*trans*-stilbene oxide and dimethyl azodicarboxylate at 120 °C. After elimination of benzoyl cyanide, the azomethine-imine *(51)*, a new 1,3-dipole, rearranges by an ester group shift to form the dimethyl hydrazonedicarboxylate *(50)*[56].

11. Conclusion

The chemistry of carbonyl ylides is still in its infancy. The electrocyclic ring opening of substituted ethylene oxides served so far as the main port of entry into this class of 1,3-dipoles. Reaction of carbonyl compounds with carbenes probably constitutes another general approach[57]; the intramolecular version was successfully applied by *Ibata et al.*[58] to make cyclic carbonyl ylides available. The synthetic potential of carbonyl ylides and their cycloadditions is far from being exhausted.

A sincere word of thanks goes to the author's young associates who dedicated their skill, enthusiasm and energy to the problem: they are Drs. Helmut Hamberger, Alexander Dahmen, and Volker Markowski. Dr. Horst Hermann of the Max-Planck-Institut für Kohlenforschung at Mülheim/Ruhr, Abt. Strahlenchemie, directed the flash spectroscopic studies.

Macrolides. Recent Progress in Chemistry and Biochemistry

By Satoru Masamune, Gordon S. Bates, and (in part) John W. Corcoran[*]

Dedicated to Professor R. B. Woodward on the occasion of his 60th birthday

The progress of macrolide chemistry and biochemistry over the past several years has indeed been remarkable. This review attempts to cover the important contributions which have been made in the fields of structural and synthetic chemistry as well as in the biosynthesis and mode of antimicrobial activity of the "polyoxo" macrolide antibiotics. Emphasis has been placed on the recent synthetic achievements in this field.

1. Introduction

The chemistry of macrolide antibiotics originated with the isolation of pikromycin by *Brockmann* and *Henkel* in 1950[1]. Soon afterward *Streptomyces* organisms yielded several other antibiotics which appeared to be chemically and antimicrobially related to pikromycin. By the end of 1957 the elegant execution of classical chemical degradations of these antibiotics had led to the disclosure of the gross structures of methymycin[2], erythromycin A[3] and B[4], and carbomycin A (magnamycin)[5-8], demonstrating that each of them contains a lactone incorporated in a medium- or large-ring system. As the number of lactonic natural products has increased to well over one hundred, the word, "macrolide", originally[5] restricted to the above antibiotics *(vide infra)* has gradually been used in a broader sense and in some cases overextended to cover even a macrocyclic lac*tam* of plant origin[9,10]. Structural, stereochemical, and conformational studies of representative members of this steadily growing family have been actively pursued for the past two decades mainly by means of X-ray crystallographic, ^{1}H- and ^{13}C-NMR, and mass spectroscopic techniques[11], and our knowledge of the macrolides is quite rich in these respects. A few excellent reviews have already appeared[12-16]. Since it is not the purpose of this article to compile a complete documentation of the work, we intend to outline only the major course of development as far as the structure and stereochemistry are concerned. However, in order to provide interested readers with updated information a rather extensive list of macrolide compounds is included in Table 1, Section 7.

In contrast to a plethora of structural studies that have appeared in the past 25 years, it is only in recent years that we have witnessed major synthetic accomplishments in the field of macrolides, and efforts to further enrich our knowledge in this area are gaining momentum at an ever increasing rate. It is interesting to consider why we have had to wait so long for this development. In the last decade expertise in organic synthesis has already proved to be highly sophisticated, and general approaches, at least in principle, for syntheses of a vast number of important groups of compounds such as steroids, terpenes, and alkaloids, were available. In the field of antibiotics, total syntheses of penicillins and cephalosporins, and tetracyclins had already been completed by the end of the sixties. Thus, the macrolides were the only remaining major family of antibiotics which presented an academic challenge to synthetic organic chemists. We saw at least two major, general problems associated with the macrolide synthesis: one was the construction of a medium- or large-size lactone and the other involved the introduction of chiral centers into a straight chain aliphatic acid—say—through a *stereospecific* aldol condensation or acylation. There was a need to devise new synthetic methods for both problems. The first problem now has acceptable solutions, which have made possible the first total synthesis of methymycin[17], and of pyrenophorin[18], vermiculine[19], and nonactin[20,21]. The second problem presents much to be further investigated and still demands creativity and imagination for its satisfactory answer. In this article emphasis is placed on the synthesis

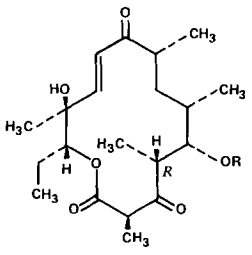
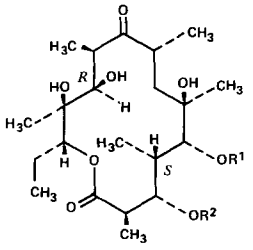
of macrolides in order to define the present and future problems in this area[22]. The macrolide antibiotics have also received due attention from the viewpoints of both their biosynthesis[23] and mode of antimicrobial activity[24, 25] and these subjects are updated in Section 6.

2. Structure and Classification

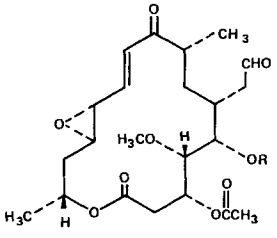


Because of the vast number of lactonic natural products commonly referred to as macrolides, a classification of these compounds into subgroups would now appear to be in order.

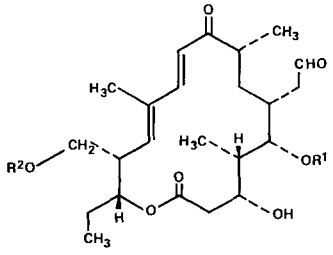
2.1. "Polyoxo" Macrolides



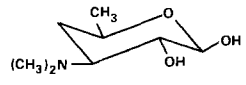
Categorized in this major subgroup are at least 50 antibiotics whose structures meet the criteria originally implied by *Woodward* in 1957 to include several antibiotics then available[5]. The lactones are normally 12-, 14-, or 16-membered. Other features are (1) an array of substituents uniquely and systematically (see Section 3) attached to the ring system and (2) the linkage of one or more sugars, very often one of them being nitrogen-containing. Methymycin *(1)* is the only member whose lactone is 12-membered. Typical "polyoxo" macrolides are pikromycin *(2)*, erythromycin A *(3)*, carbomycin A *(4)*, and tylosin *(5)*[26].



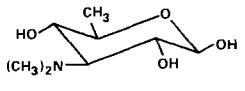
Methymycin *(1)*
R = Desosaminyl



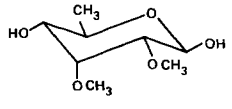
Pikromycin *(2)*
R = Desosaminyl



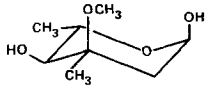
Erythromycin A *(3)*
R^1 = Desosaminyl
R^2 = Cladinosyl



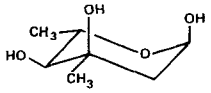
Carbomycin A *(4)*
R = (Isovaleryl)-mycarosyl-mycaminosyl



Tylosin *(5)*
R^1 = Mycarosyl - mycaminosyl
R^2 = Mycinosyl

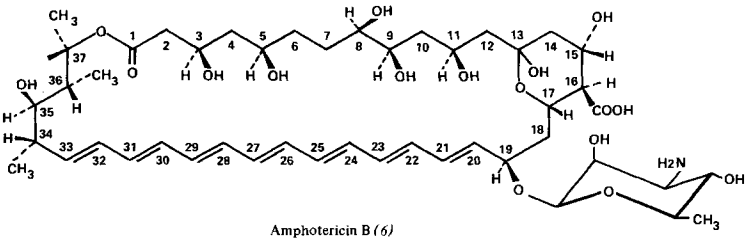


D-Desosamine



D-Mycaminose

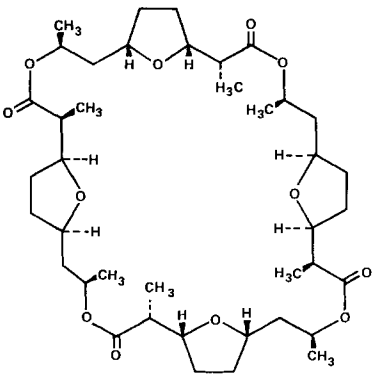
D-Mycinose



L-Cladinose

L-Mycarose

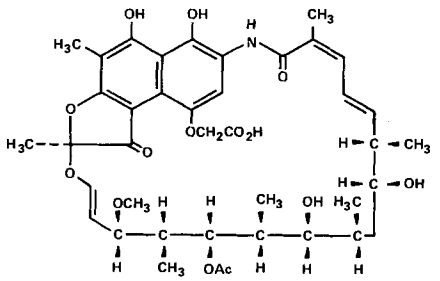
2.2. Polyene Macrolides[13]



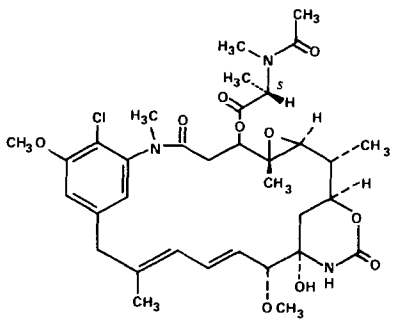
Characteristic of this group is the feature that the lactone ring carries few alkyl (mostly methyl) substituents and accommodates a conjugated polyene containing up to as many as seven *E* double bonds. Accordingly the size of the lactone enlarges to 38 members in some compounds. Most of these compounds are antifungal and not antibacterial agents. Amphotericin B *(6)* is a representative member and its structure has been fully elucidated[27].

Amphotericin B *(6)*

2.3. Ionophoric Macrolides



Macrolides of this group contain two or more lactone groups (oligonolide) in a very large ring system. An antibiotic of this group has a hydrophilic "hole" capable of binding an alkali metal cation and thus of transporting ions in biological systems. Nonactin *(7)*[15, 28] and boromycin[29] are included in this group. Several structurally similar antibiotics in an open (seco-acid) form have been isolated.

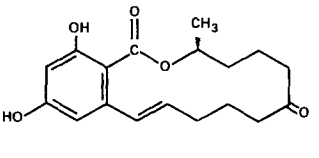


Nonactin *(7)*

2.4. Ansamycin[9, 10, 30, 31]

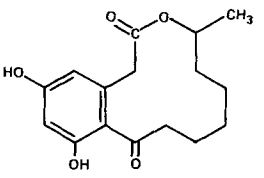
More than 10 antibiotics possess a unique structure in which two non-adjacent positions of an aromatic nucleus are connected by a long aliphatic bridge through an amide linkage (lactam). Therefore this group does not belong to the macrolides in the correct sense, but is included herein because of the close similarity of the aliphatic chain in structure and stereochemistry to that of the "polyoxo" macrolides (see Section 3). Rifamycins, *e.g.* rifamycin B *(8)*, and streptovaricins are typical representatives; most of the ansamycins are noted for their broad spectra of antibacterial activity and

Rifamycin B *(8)*



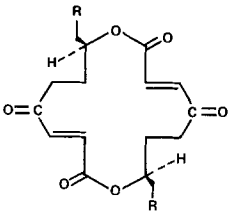
Maytansine *(9)*

are also interesting as potential antitumor agents. Also included in this class is maytansine *(9)*, which is unique in that it is *possibly* of plant origin[9, 32].

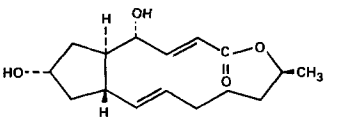


2.5. Other Macrolides

Under this heading are listed several lactonic compounds of medium-ring size which have not thus far grown into large families. Most of these lactones are of either mold or bacterial origin and exhibit varying biological activities. Examples are zearalenone *(10)*[33] (from *Gibberella zeae*), curvularin *(11)*[34] (from a species of *Curvularia*), pyrenophorin *(12)*[18, 35] (from *Pyrenophora avenae* and *Stemphylium radicinum*), vermiculine *(13)*[19, 36] (from *Penicillium vermiculatum*), and brefeldin A *(14)*[37] (from *Penicillium*, *Curvularia*, and *Ascochyla*).



Some members of the cytochalasan family[38], cytostatically[39] active metabolites, possess 13- or 14-membered lactone rings, which are derived from the corresponding carbocyclic ketones through a Baeyer-Villiger type oxidation at a late stage of biosynthesis[40]. Because of this origin of the lactone and lack of similarity of these compounds to other macrolide antibiotics in structure and physiological activity, the cytochalasans are only briefly dealt with in this review (see Section 5.3).

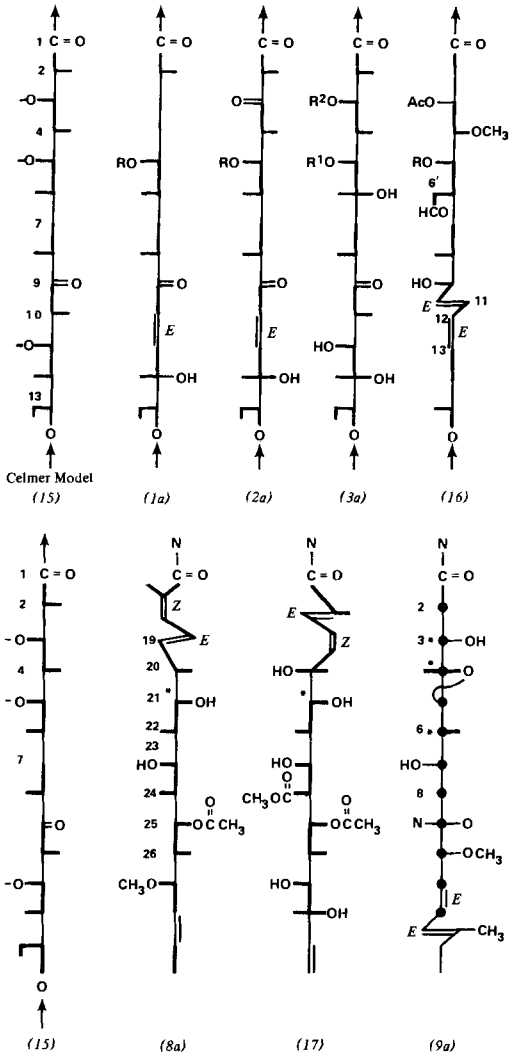


Zearalenone *(10)*

Curvularin *(11)*

Pyrenophorin *(12)*, R = H
Vermiculine *(13)*, R = $COCH_3$

Brefeldin A *(14)*



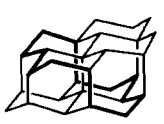
The above classification reflects our view and is not one that has already received general acceptance. There are certainly other ways to categorize the macrolide family. Some "polyoxo" macrolides are further subdivided according to their biological activities.

3. Stereochemistry

The stereochemistry of the "polyoxo" macrolide antibiotics is beautifully correlated in terms of what is commonly referred to as *Celmer*'s stereochemical model[14], expressed in the Fischer projection formula *(15)*. 12-Membered methymycin *(1a)* [missing C(2), C(3) or C(3), C(4)] and the 14-membered macrolides, whose stereochemistry has been elucidated, all pattern after the model *(15)*, and so-called "extra" hydroxy groups such as those at C(6) and C(12) of erythromycin A and C(8) of oleandomycin *(137)* (see Section 6.1) are apparently introduced at these carbon atoms at a late stage of biosynthesis with retention of the original stereochemistry (front side oxidation). The model has served to detect previously misassigned stereochemistry on several occasions, and, remarkably, thus far there have not been any observed irregularities.

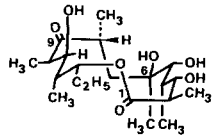
Information is also available concerning the stereochemistry of leucomycin *(16)*, a 16-membered macrolide. X-ray analyses of desmycarosyl-"*iso*"-leucomycin A_3[41] and diacetyl-3,6'-bicycloleucomycin A_3[42] have shown beyond reasonable doubt that *(16)* has the stereochemistry shown above[43], and thus that model *(15)* is still valid. The extra 2 achiral carbon atoms [C(10) and C(11)] are inserted between C(9) and C(10) of the model. Carbomycin B has already been related to *(16)* chemically[14]. The stereochemistry of tylosin shown in structure *(5)* adopts the model for this compound and remains to be confirmed experimentally[44].

More interestingly, inspection of the stereochemistry of ansamycins[10, 30, 31] reveals that *Celmer*'s model applies even to these antibiotics, but with reversal of stereochemistry at C(21) (ansamycin numbering), which corresponds to C(5) in *(15)*, as shown in the formulas for rifamycin *(8a)* and streptovaricin *(17)*. An exception is maytansine *(9a)*[9, 45] where several chiral centers appear to possess the opposite absolute configuration compared to that in *(15)*. Of course this last comparison is subject very much to our arbitrary choice



The center asterisked does not match with that of *(15)*.

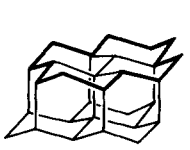
of reference points. Some portions of acyclic compounds related to the ionophoric macrolides (cf. Section 2.3) may be stereochemically correlated with *(15)* as well.



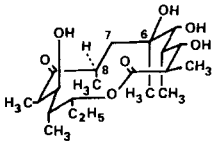
4. Conformation

Elaborate analyses of various spectroscopic data have been performed in order to define the conformation of 14-membered macrolide antibiotics in solution[46]. The conformational problems associated with molecules of this complexity arouse chemical interest and also undoubtedly have an important bearing on the structure-biological activity relationship of the antibiotics. We select herein only a few representative, most-studied molecules for discussion.

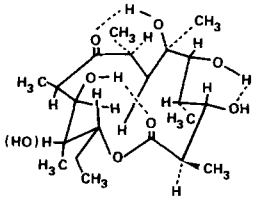
Basically patterning after the diamond lattice conformation *(18)* (bold line) proposed earlier for cyclotetradecane by *Dale*[47], *Celmer* advanced in 1965[48] a model



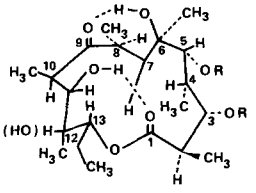
(18)



(19)



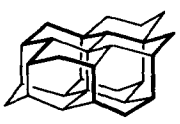
(19) for a preferred conformer of erythronolide B, the aglycone of erythromycin B [C(12)—OH missing in *(3)*]. Although the Celmer-Dale model *(19)* was in reasonable agreement with the ^{1}H-NMR data, mainly in terms of dihedral angles derived from the Karplus equation, it soon became apparent that further refinement was needed to remedy several major drawbacks. The earlier X-ray analysis of erythromycin A *(3)*[49] had demonstrated several important features: (1) The C(6)—OH, C(9)=O, and C(1)=O (lactone) groups are *syn*-oriented in space, and all the C—O axes of these groups are nearly parallel. In model *(19)*, the C(6)—OH and C(9)—C=O groups are *syn* to each other, but are *anti* to the lactonic C=O, and all to the C—O axes are oriented in different directions. (2) The crystal structure also shows, contrary to what is implied by model *(19)*, that the overall shape of the antibiotic is rather flat. Using the CPK molecular model we attempted unsuccessfully to close the lactone ring of the erythronolide B seco-acid constructed in the manner suggested in model *(19)*, mainly because of the non-bonded interaction of the three hydrogen atoms directed inside of the ring system and also because of the *syn*-periplanar oriented C(4)- and



(20)

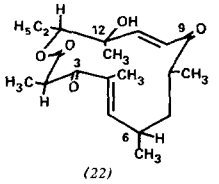
(19a)

(19b)



(19c)

C(6)-methyl groups. (Formula *(19)* is unrealistically stretched horizontally in comparison with the CPK model.) These arguments are subject to the usual criticism, such as more conformational freedom present in solution than in the lattice, and therefore by themselves do not invalidate *(19)*. However they deserve serious attention. Further studies demonstrated that with most of the macrolides or their derivatives, all of the vicinal proton-proton coupling constants fell in the range of either 10—12 Hz or 0—2 Hz and remained constant over a wide range of temperature and in a variety of solvents[50]. This implies that the ring system is rigid and its conformational freedom in solution is restricted *(vide infra)*. Therefore there were no strong reasons to believe that the preferred conformer differs greatly in geometry from the crystal structure. These considerations led to the proposal of a second diamond lattice model [as shown in *(20)* and *(19a)*], which removed most of the deficiencies of model *(19)*. Further modification involving a limited rotation along the C(7)—C(8) axis led to the *syn*-orientation of both C(9)=O and C(6)—OH and at the same time eliminated the disadvantageous 1,3-interaction between the C(4)- and C(6)-methyl groups. The resulting Perun model *(19b)* appears to accommodate quite well the ^{1}H-NMR



and CD data for erythronolide B, as well as the possible hydrogen bondings between C(6)—OH and C(9)=O, and between C(11)—OH and C(1)=O as suggested by its ^{13}C-NMR spectral parameters[51-53]. For the derivatives of both the C(3)—OH and C(5)—OH groups, such as erythromycin A *(3)* or B *(134)*, or the 3,5-diacetate of erythronolide B, the *syn*-periplanar disposition of the groups attached at the 3 and 5 positions (which is favored through hydrogen bonding is the case, as judged from the spectral data [cf. *(19c)*][52,54]. from model *(19b)* to avoid the non-bonded repulsion, if the ring system is still flexible enough to afford limited rotations about the C(4)—C(5) and C(5)—C(6) axes. Apparently this is the case, as judged from the spectral data [cf. *(19c)*][52,54]. After all this, model *(19c)* is now essentially the same as that demonstrated by the X-ray analysis of *(3)*[49]. Macrolides have only little, if any, conformational freedom in solution except in very few cases.

Extremely useful and somewhat surprising to us at the outset of our involvement in this project was the fact that the above conformational conclusion, reached after the above rather lengthy discussion, was revealed by relatively simple inspection of the CPK models built for these antibiotics. Thus, almost invariably when one succeeds in lactonizing the model of a seco-acid, the conformation of the resulting macrolide corresponds roughly to *(19b)* or *(19c)*. Moreover, the model exhibits some flexibility around the bonds discussed above. Of course if one chooses a differently substituted macrolide, the preferred geometry accordingly deviates from *(19b)* or *(19c)*.

Ogura et al.[55] have recently proposed another diamond model [*(21)* and *(22)*] for kromycin, a dehydrated aglycone of pikromycin *(2)*, more or less implying that the molecule is L-shaped [cf. *(22)*]. Both its X-ray analysis[56] and CPK-model studies indicate that two fragments including C(3)

(21)

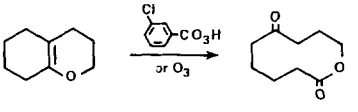
(22)

through C(6) and C(9) through C(12) are nearly coplanar, with a very shallow dihedral angle between the planes, and that the ring system as a whole is flat (flatter than erythronolide) as a consequence of trying to link together the two coplanar segments. It has been already noted that the Perun model *(19b)* itself does not exactly follow a diamond framework, but deviates from it with varying substituents. For kromycin, the concept of the diamond lattice almost loses its meaning because of the relatively highly unsaturated lactonic system. Since some of the carbon atoms do not even lie close to the points of the lattice of *(21)*, it would appear to us that there is no *pressing* need to adhere to the diamond lattice concept in this case.

In summary, we have now reached the general agreement that a ("polyoxo") macrolide molecule is rigid and its most preferred conformation in solution is essentially the same or nearly the same as its crystal structure. The X-ray result in effect constitutes an important "backbone" for conformational arguments. It should also be pointed out that CPK models are very instrumental and vividly demonstrate the interesting structural feature that virtually all the O-containing substituents (OH and sugar) are located on one side of the aglycone and all alkyl groups on the other side (*e.g.*, erythronolide A and B).

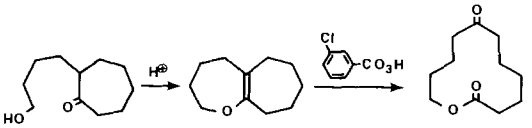
Although spectral data of several 16-membered macrolide antibiotics[57] have been recorded, there are very few convincing arguments about their conformations. Thus far, no X-ray analysis of any *intact* antibiotics or aglycones has been recorded.

5. Synthesis



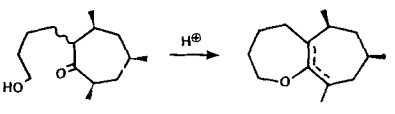
5.1. General Strategy

A macrolide synthesis unavoidably meets with two major problems—(1) the construction of a medium- or large-sized lactone and (2) the stereochemical control of numerous chiral centers embedded in the ring system of an aglycone—in addition to that of attachment of a sugar or sugars to the aglycone. In order to evaluate the overall synthetic scheme of each reported approach it appears logical to first examine the method of ring construction, very often illustrated by model studies, and then to consider its applicability to more stereochemically complex systems such as the naturally occurring macrolides.



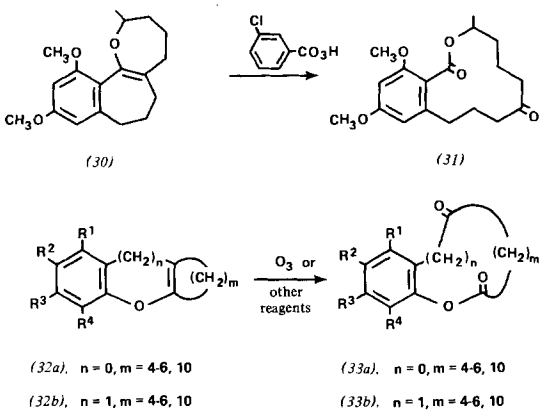
5.1.1. Rupture of the Fused Bond in a Bicyclo[*m.n.*0] system

Grob-type fragmentation of the single bond between the ring junctures [C(1) and C(m+2)] of a bicyclo[*m.n.*0] system or oxidative cleavage of the fused double bond leads to a monocyclic ($m+n+2$) membered ring. If the bicyclic precursor contains a lactone group as such or in a latent form, the above operation results in the formation of a macrocyclic lactone.

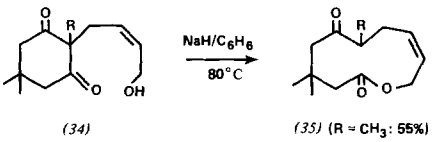


The method developed by *Borowitz et al.* involves oxidative cleavage of the vinyl ether *(23)*[58]. The reaction proceeded satisfactorily to yield *(24)*, and the method appeared encouraging. In principle it creates two crucial functional groups of methynolide, C(7)-ketone and C(1)-lactone, simultaneously with the ring opening, if applied to an appropriate precursor. Acid-catalyzed dehydration of *(25)* afforded *(26)* in good yields with subsequent cleavage (72%) to *(27)*[59]. However,

(23) *(24)*

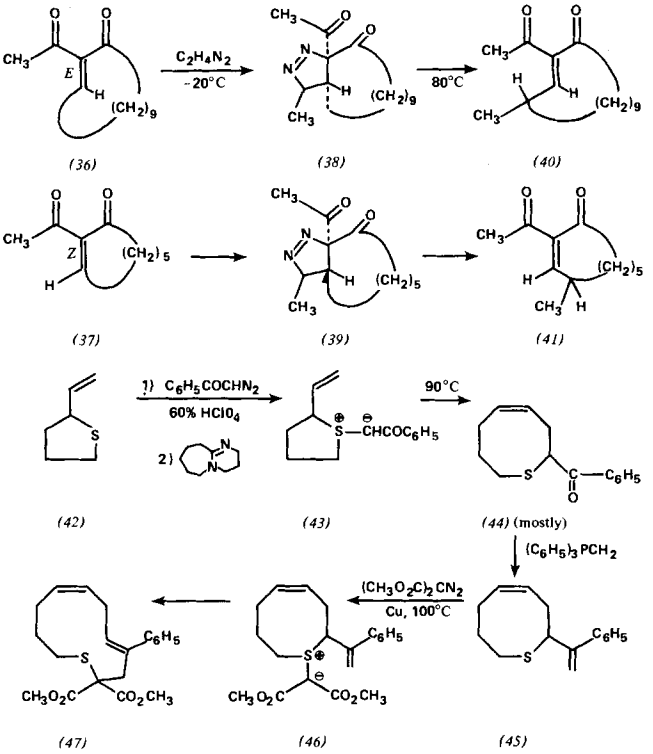


(25) *(26)* *(27)*



(28) *(29)*

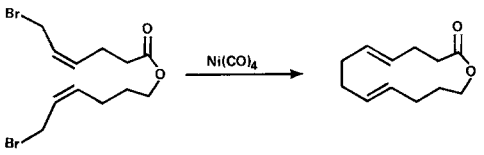
with substituted ketones only poor yields of product were obtained. Thus, in the case of *(28)* cyclization "occurred to a minor extent" affording small amounts of a mixture of isomeric enol ethers *(29)*[60]. The behavior of the seven-membered ring system is unique and very often unpredictable because of our limited knowledge of this system. Obviously, modifications of *Borowitz*'s original procedure are required for the construction of structurally complex macrolides. However, in the original form it has found uses in several cases. Thus oxidative cleavage of vinyl ether *(30)* led to a compound *(31)*, which turned out to be isomeric to the dimethyl ether of curvularin *(11)*[61]. The benzofurans *(32a)* and benzopyrans *(32b)* were analogously converted into the corresponding oxolactones, *(33a)* and *(33b)*, respectively[62].



A novel example of the cleavage of a fused-bond involves an intramolecular retro-Dieckmann reaction as exemplified in the conversion of *(34)* to *(35)*[63], but obviously the application of this method to the synthesis of a particular compound of this type is limited.

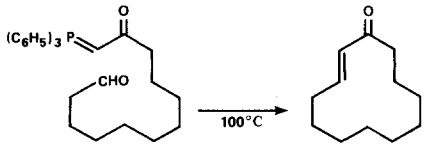
The scope of the concept discussed in this section has by no means been fully explored and a clever use of *Grob*-type fragmentation on a properly functionalized system may possibly provide an ingenious solution to a specific synthetic problem. However, this approach very likely involves several complicated problems associated with the seven-membered or larger ring systems, and it is rather doubtful that it will become generally applicable to the synthesis of a large number of macrolides.

5.1.2. "Ring Growing" Reactions[64]



A "ring growing" process normally consists of two or three consecutive steps. A small carbon unit is formally inserted into a functionalized starting ring system, and this process can be repeated several times. The ring enlargement of a cyclic ketone using diazomethane is one of the most common examples. As a model experiment for macrolide syntheses, at least two such reactions have recently been reported. Addition of diazoethane to the *E*- and *Z*-enediones *(36)* and *(37)* affords the corresponding pyrazolines *(38)* and *(39)*, both of which undergo thermal elimination of N_2 to yield products *(40)* and *(41)*, respectively[65]. Repetition of the sequence creates stereochemical complications at both the pyrazoline and final stages, but apparently the stereochemistry of starting material and/or product determines the course of reactions to provide a single isomer at each step. Hence, this ring growing reaction shows high (and possibly predictable) stereoselectivity, which can be cleverly utilized, *if* the reaction happens to provide a product with the proper stereochemistry.

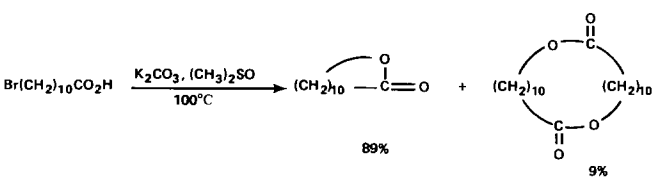
Another ring growing method is more efficient in the sense that it inserts a three-carbon unit in one sequence, uniquely employing a [2,3] sigmatropic rearrangement. Examples are the rearrangements of *(43)* to *(44)*, and *(46)* to *(47)*[64]. Thus by suitable choice of five-, six-, or seven-membered starting materials, syntheses of any desired medium- or large-size carbo- and heterocyclic systems can, in principle, be achieved. If they are to be utilized in the macrolide synthesis, these two methods, like the one discussed in Section 5.1.1, would create additional major stereochemical problems associated with medium-size ring systems during the course of each ring growth. Precise control of reaction courses would indeed be a challenging task.



5.1.3. Cyclization of an Acyclic Precursor

Probably the first example of this type of approach reportedly aimed at the synthesis of a natural macrolide molecule utilized tetracarbonylnickel(0) to close the diallylic bromide termini of an ester-containing acyclic precursor[66], a reaction which has been successfully employed in the preparation of the 11- and 14-membered terpenes, humulene[67] and cembrene[68]. A model reaction is the cyclization of *(48)* to *(49)*. Proper modifications on *(48)* and further conversion of *(49)* (in particular, creation of chiral centers at the double bonds which is very likely to be necessitated) do not appear to

(48) (49)

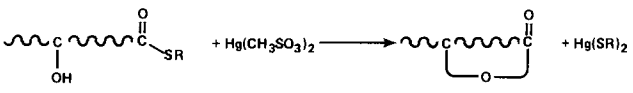


be readily executable operations. Use of a stabilized Wittig reagent effects carbon-carbon bond formation under near-neutral conditions and has been used with success in many cases for construction of medium- and large-size rings. In fact conversion of *(50)* into *(51)* proceeded in acceptable yields[69].

(50) (51) (20-30%)

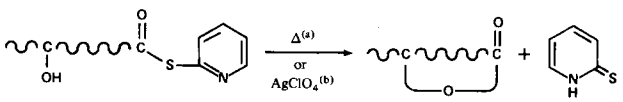
At this stage one must consider whether it is possible to effect direct lactonization of the seco-acid corresponding to a natural macrolide. In this respect *Stoll*'s classical work concerning intra- *versus* intermolecular formation of esters from straight chain aliphatic ω-hydroxyacids[70] is truly discouraging. Indeed it is for this reason that the other methodologies for the ring construction discussed above have been sought, despite the fact that inclusion of lactone formation at a late stage of the synthesis would seem a more obvious approach than to resort to a scheme involving carbon-carbon bond formation or rupture for construction of the ring. The biosynthesis of a macrolide antibiotic also very likely proceeds through a final lactonization stage before the formation of the aglycone is completed (if the introduction of "extra" hydroxy groups is not involved). In addition, this lactonization approach offers an undisputable advantage: the already discussed stereochemical problems associated with medium- and large-ring systems no longer confront us and the entire synthesis is largely simplified.

Let us review two aspects of lactonization reactions. A well-known general problem associated with intra- *versus* intermolecular cyclization of a bifunctional acyclic compound obviously concerns the competition between reactions of the first and second order, *providing* the chain is long and *conformationally flexible*. The most common way in which to promote the intramolecular reaction is by the high dilution technique. In cases where a desired reaction proceeds with high efficiency, one can effectively realize the condition of high dilution by subjecting a reactant slowly to a reaction condition (for instance, by slow addition), so that reaction of the first portion is essentially complete before a second portion is introduced. Thus, controlled (one-hour) addition of 11-bromoundecanoic acid *(52)* (0.08 mol) to hot dimethyl sulfoxide (1 l) containing



(52) (53) (54)

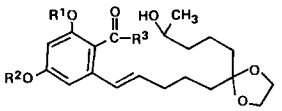
K_2CO_3 provides the monocyclic lactone *(53)* in excellent yields[71].



The other important aspect is the effect of the numerous substituents of the seco-acid. As already elaborated in Section 4, most of the "polyoxo" macrolide antibiotics are conformationally rigid molecules, and inspection of their CPK atomic models further predicts that the corresponding seco-acids would retain, to a large extent, the rigidity of the macrolides because of the bulky substituents. Thus the rotational freedom along most of the C—C bonds of the chain would be suppressed—a condition that favors an intramolecular cyclization. These considerations lead to an encouraging, nonetheless extremely risky prediction. Our project, a synthesis of methymycin *(1)* (see Section 5.2.1), was initiated against this background a few years ago, despite the adverse situation that the seco-acid could only be obtained by synthesis and not through a conversion of the natural product (world supply at that time was *ca.* 500 mg).

In the meantime intensive studies in this sector have led to the development of three efficient methods for the synthesis of the ester (and lactone). One of them (Method 1) utilizes activation of a hydroxycarboxylic thiol ester *(55)* with a thiophilic, soft metal ion such as Hg^{II} or Cu^{II}[72]. Another

(55) Method 1 (56)



method is *Corey*'s "double activation" method[73], patterned after *Mukaiyama*'s procedure for formation of peptide linkages (Method 2)[74, 75]. Prolonged refluxing of a dilute solution of the thiol ester *(57)* in a relatively high-boiling, inert solvent such as xylene or toluene is normally required to complete the lactonization. However, $AgClO_4$ considerably accelerates this reaction, as reported by *Gerlach* (Method 3)[76], and thus

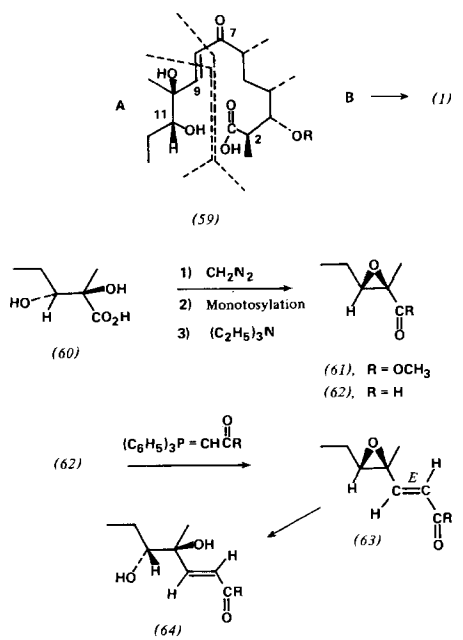
(a) Method 2
(b) Method 3

(57) (56)

the cyclization is completed within an hour at room temperature. The effectiveness (and selectivity; see Section 5.3.1) of these newer methods becomes evident from the recent reports[72, 73] on high-yield lactonization of the seco-acid derivatives *(58a)* and *(58b)* of zearalenone *(10)*, as compared with a rather low-yield cyclization previously reported[77]. [*(58a)*, Method 1, 25 °C, 5 min: 90 % zearalenone dimethyl ether ethylene ketal; *(58b)*, Method 2, benzene, reflux, H^+: 75 % *(10)*]. The scope and limitations have now been relatively well defined and are discussed in some depth in Section 5.3.

(58a), $R^1 = R^2 = CH_3$, $R^3 = SC(CH_3)_3$

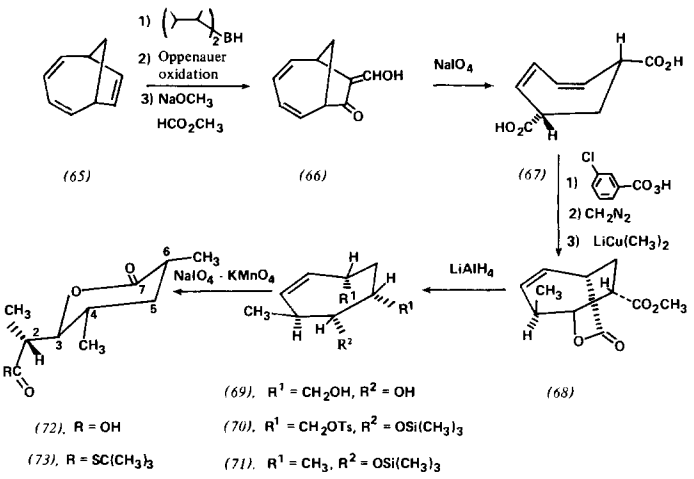
(58b), $R^1 = H$, $R^2 = THP$, $R^3 = OH$



Having achieved the task of the lactone closure, one must consider the construction of the seco-acid. Although imaginative fragmentation reactions of a ring system to lead to an 11 to 15 C-atom seco-acid with the correct stereochemistry are not impossible, it appears more practical to dissect the seco-acid into two (or three) fragments. Since all of these fragments are chiral compounds, the problem arises of combining the proper set of each enantiomorphic isomers for the synthesis of a macrolide. There are at least three ways to achieve this: (Route 1) both segments are resolved or asymmetrically synthesized and combined, (Route 2) one segment is resolved and used as a resolving agent for the other, and (Route 3) the stereochemical information is directly transmitted to the other *via* chemical reactions. This last route is most attractive in that new chemistry would very likely emerge in pursuing this approach. Use of templates is highly tempting, and if one succeeds in this venture organic synthesis will be a step closer to the enzymatic reaction. Needless to say, the combination of the two (or three) segments which are often already highly sensitive toward both acid and base must be performed under mild conditions. Let us see how a few total syntheses have thus far been achieved.

5.2. Total Syntheses

At the time of writing this Review, syntheses of methymycin *(1)* (polyoxo macrolide), nonactin *(6)* (ionophoric macrolide), pyrenophorin *(12)*, vermiculine *(13)* in addition to zearalenone *(10)* and curvularin *(11)* (other macrolides) had been recorded, and those of several other, more complicated macrolides appear to be near completion.

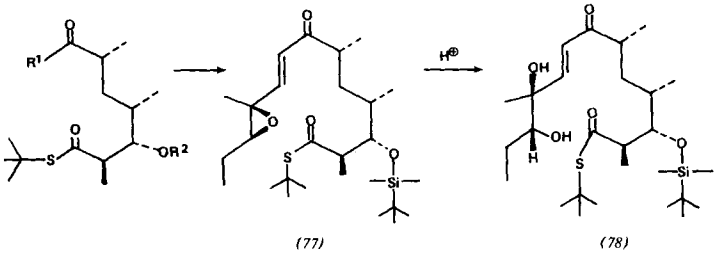


5.2.1. Methymycin[17]

The scheme used involves the condensation of optically pure segment A [C(9) through C(11)] and racemic segment B [C(1) through C(7)], to provide the seco-acid *(59)*. Segment A was prepared in a straightforward manner. Readily available (+)-(2*R*,3*R*)-2,3-dihydroxy-2-methylvaleric acid *(60)*[78] was converted by a standard route into the epoxy-ester *(61)*,

which upon reduction with $(i\text{-}C_4H_9)_2AlH$ yielded the corresponding aldehyde *(62)*. Wittig reaction of *(62)* with an acylmethylenephosphorane provided an *E*-α,β-unsaturated ketone *(63)* (R = CH_3, for example) which underwent epoxide ring opening under mild acidic conditions to the corresponding dihydroxyketone *(64)* with retention of configuration at the γ position. The neutral conditions of the Wittig reaction and the stereochemical course of the ring opening qualify *(62)* as a synthetic unit.

The construction of segment B is a little more involved and uses bicyclo[4.2.1]nona-2,4,7-triene *(65)* as starting material[79]. Selective hydroboration, oxidation, and formylation of *(65)* yielded a hydroxymethylene compound *(66)*,

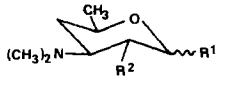


which was oxidatively cleaved to give *cis*-dicarboxylic acid *(67)*. Subsequent reactions on *(67)*, epoxidation, esterification, and finally methylation with $LiCu(CH_3)_2$, all proceeded reasonably well to afford a key intermediate lactonic ester *(68)*. $LiAlH_4$ reduction converted *(68)* into the corresponding triol *(69)*. The two primary hydroxy groups were tosylated, and the secondary one was trimethylsilylated to produce *(70)*. Lithium dihydrocuprate[80], a reagent developed for the reduction of tosylates and halides into hydrocarbons, cleanly removed the tosyl groups (without elimination of the homoallylic tosyl group), and the resulting cycloheptene *(71)* was subjected to the Lemieux-Rudloff oxidation to afford, after acidification, a C_{10}-acid *(72)* identical with a key degradation product of methynolide previously obtained by *Prelog*[81] and *Djerassi*[2].

The confirmation of the stereochemistry of a synthetic intermediate at this stage is highly desirable, and *(72)* also provides a means of distinguishing between the two carboxylic acids, one of them being masked as a δ-lactone. The 2,2-dimethylpropanethiol ester which tolerates quite well both mild acidic and basic conditions was used for the protection and later activation of the C(1)-carboxylic acid of *(72)*. Since the δ-lactone is at least several hundred times more readily hydrolyzed with alkali than a normal methyl ester[82], the thioate *(73)* very rapidly consumed 0.95 equivalent of KOH at 20 °C to afford the hydroxycarboxylate *(74)*, which was then transformed into the imidazolide *(75)*. Treatment of *(75)* in a dilute solution (0.01 M) with 1 equivalent of salt-free methylene(triphenyl)-phosphorane in benzene led to the desired Wittig reagent *(76)*[83, 84]. Model experiments using the imidazolide of 2-deu-

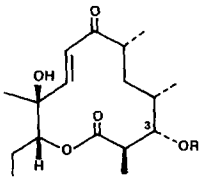
terio-2-ethylhexanoic acid confirmed that no epimerization occurred under these conditions. Refluxing a toluene solution of (±)-*(76)* (1 equivalent) and (+)-aldehyde *(62)* (3 equivalents) brought about successful condensation to yield a diastereoisomeric (presumably 1 : 1) mixture of epoxythiol esters *(77)* which was converted on mild acid treatment into the desired methynolide seco-acid derivative *(78)*.

The crucial step of lactonization was achieved by employing Method 1 (described earlier in Section 5.1.3). Treatment with $Hg(CF_3CO_2)_2$ or preferably $Hg(CH_3SO_3)_2$ in the presence of Na_2HPO_4 at room temperature effected cyclization to *(79)* in 30% yield. Compound *(79)* was quantitatively converted into *(80)* with tetrabutylammonium fluoride[85].



The final stage of the methymycin synthesis involved glycosylation of the aglycone with desosamine *(81)*. The presence

(74), R^1 = OK, R^2 = H

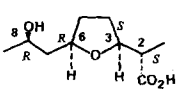


(75), $R^1 = C_3H_3N_2$, $R^2 = Si(CH_3)_2C(CH_3)_3$

(76), $R^1 = CH{=}P(C_6H_5)_3$, $R^2 = Si(CH_3)_2C(CH_3)_3$

(81), R^1 = β-OH, R^2 = OH

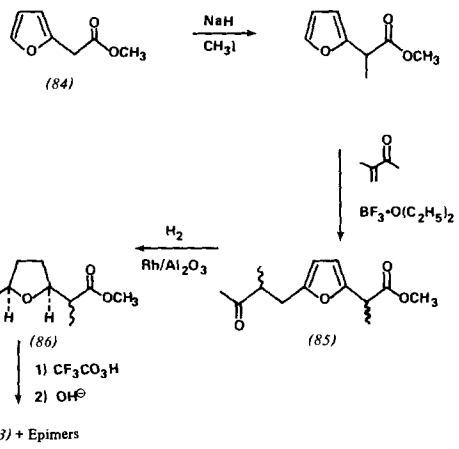
(82), R^1 = α-Br, R^2 = $OCOCH_3$



(79), R = $Si(CH_3)_2C(CH_3)_3$

(80), R = H

of the dimethylamino group in *(81)* and also the congested substituents around the C(3) hydroxy group of *(80)* restricted the selection of reagents and reaction conditions applicable for this operation. However, use of α-bromo-2-acetyldesosamine hydrobromide *(82)*·HBr and lutidine (which is too weak to liberate the amine which normally induces complicated side reactions) successfully led to a 5:1 mixture of β- and α-glycosides of methynolide. Deacetylation with methanol and triethylamine and separation of the β-isomer from the α-isomer completed the synthesis of *(1)*.



5.2.2. Nonactin *(7)*

This 32-membered ionophoric macrolide is comprised of four nonactic acid *(83)* subunits arranged in an alternating enantiomorphic (+ − + −) order. Therefore *(7)* is an achiral molecule. The structure of *(7)* immediately suggests a logical synthetic approach, consisting of (i) the preparation of *(83)*, (ii) tetramerization of its enantiomers in the proper sequence, and finally (iii) lactonization to the macrocycle *(7)*. Of several schemes reported for the first step, one starting with furan or a furan derivative and later creating the *cis*-stereochemistry at the C(3) and C(6) positions of *(83)* is most representative and has been used by four groups. *Beck* and *Henseleit*[86] utilized as starting material methyl furan-2-acetate *(84)* which, after monomethylation, was condensed with 3-methyl-3-buten-2-one to provide a 2,5-disubstituted furan *(85)*. Catalytic

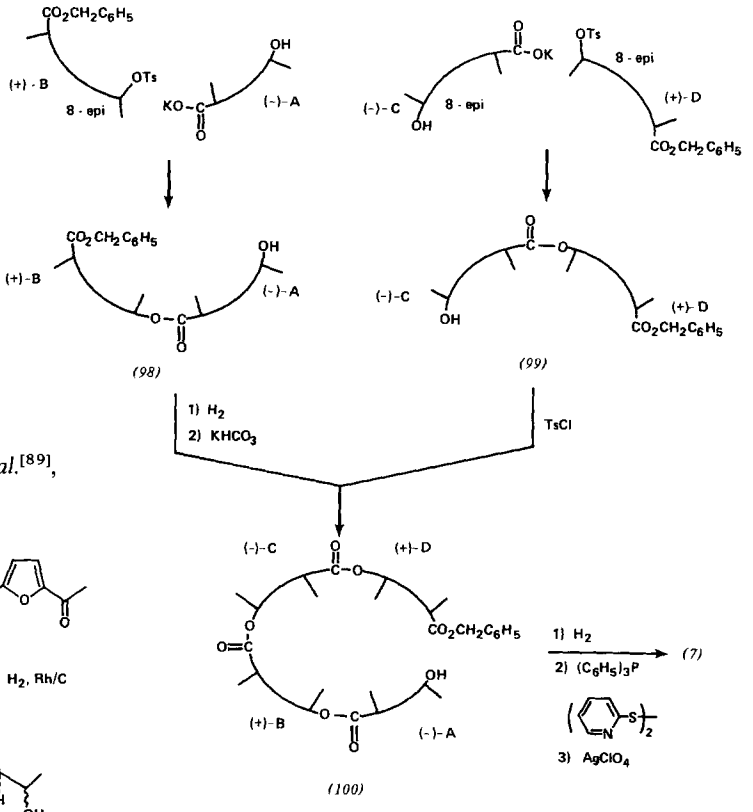
hydrogenation of *(85)* with Rh introduced *cis*-oriented hydrogen atoms at the 2- and 5-positions of the furan and led to a mixture of four stereoisomers *(86)*. Subsequent conversion of the acetyl group into a hydroxy group afforded *(83)* and its diastereoisomers.

The scheme adopted by *Gerlach* and *Wetter*[87] also suffers from a similar drawback: non-stereoselective introduction of the two chiral centers of the side chains. Condensation of

(87)

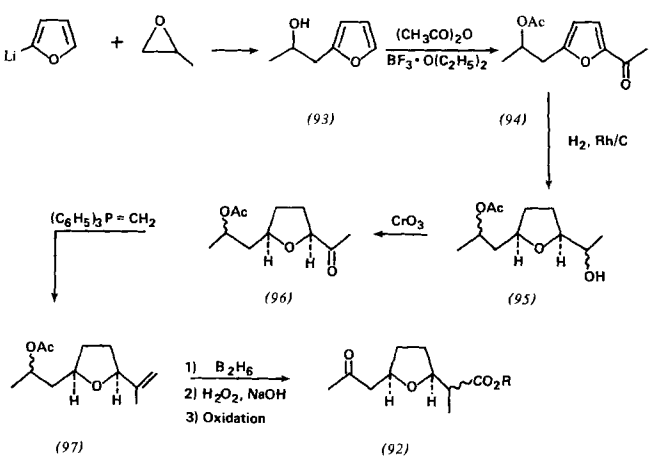
(88)

(89)



(90)

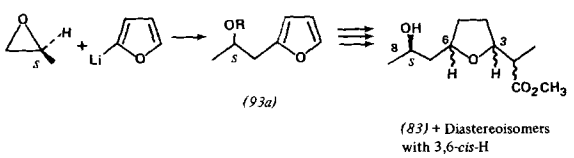
(92) + 2-epi



(91)

(83) + 8-epi

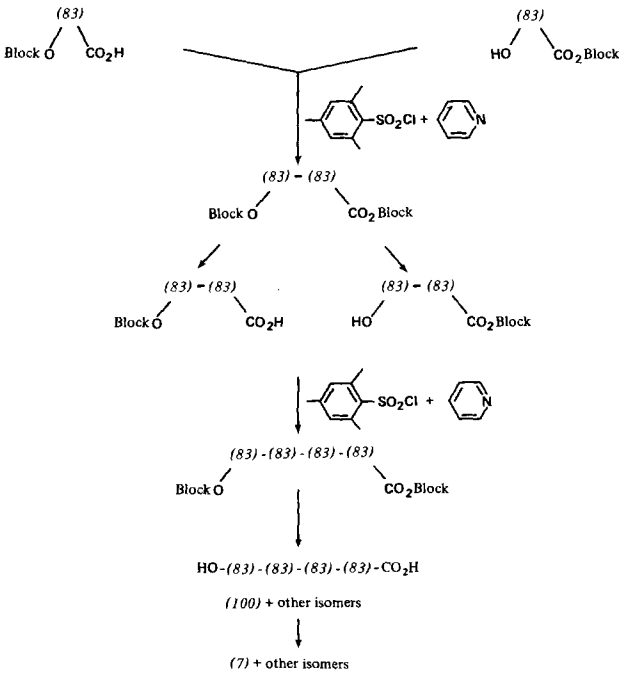
acetonylfuran *(87)* with chloronitrone *(88)*[88] and subsequent hydrolysis of the condensate *(89)* and oxidation of aldehyde *(90)* gave a ketoester *(91)*. The ensuing operations, catalytic hydrogenation and sodium borohydride reduction, led to the formation of four separable compounds isomeric at the 2- and 8-positions of *(83)*.

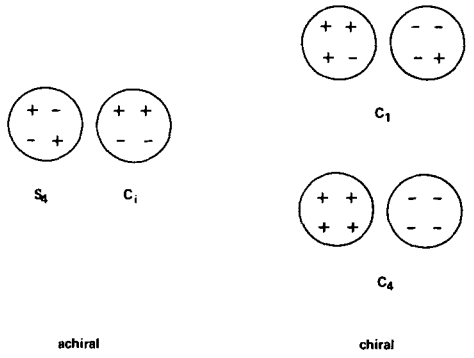


A further synthetic variant, reported by *White et al.*[89], involves intermediates *(93)*—*(97)* and leads to *(92)*.

Somewhat earlier, *Schmidt et al.*[20,90] described a method in which (−)-(*S*)-propylene oxide (rather than the racemate) [obtained from (+)-L-lactic acid] was used as starting material. Through a sequence of reactions, similar to those described above and preserving the original chiral center, they managed to obtain (−)-(2*R*,3*R*,6*S*,8*S*)-nonactic acid [(−)-*(83)*], and its three isomers: (2*S*,3*R*,6*S*,8*S*), (2*R*,3*S*,6*R*,8*S*), and (2*S*,3*S*,6*R*,8*S*). A Walden inversion proceeded smoothly on treatment of the 8-tosylate of this last isomer with potassium acetate to yield (+)-(2*S*,3*S*,6*R*,8*R*)-nonactic acid [(+)-*(83)*]. In this way, a series of compounds, (+)-*(83)*, (−)-*(83)*, and their 8-epimers were prepared.

The non-selectivity encountered in the above four schemes[91] is not as discouraging as it appears, because the



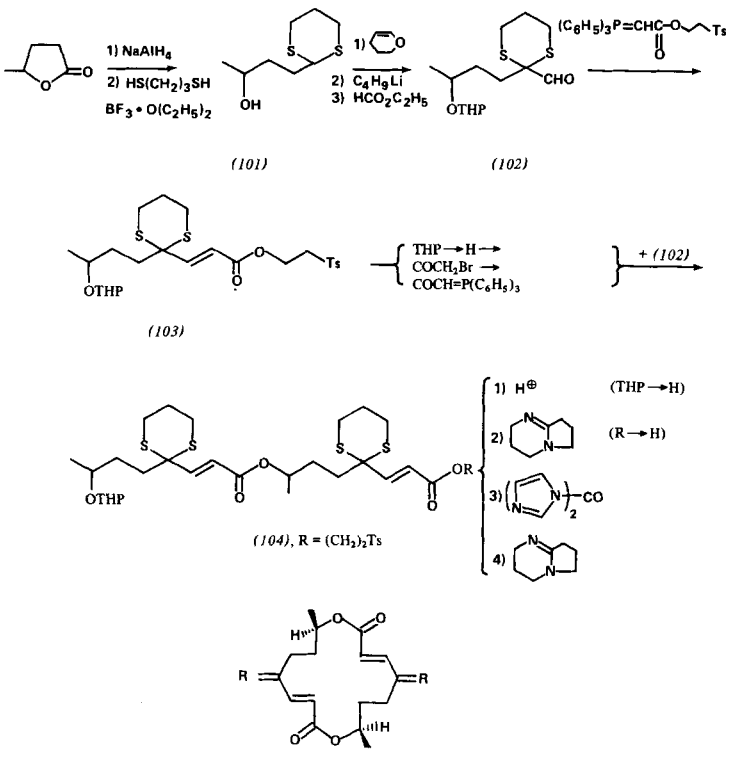


(83) + Diastereoisomers with 3,6-*cis*-H

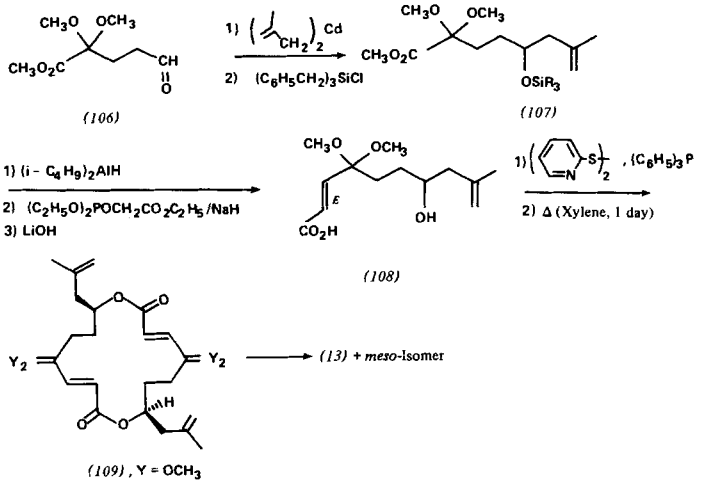
2-epimers can be equilibrated to give a mixture of the normal and epi-series (which are separable). Moreover, 8-epi-*(83)* can be used for the synthesis of *(7)*.

The second and third steps of the nonactin synthesis proceeded in the following way[20]: an S_N2 displacement of the tosylate of (+)-8-epi compound (B) with the (−)-nonactate anion (A) and similarly that of D (= B) with (−)-8-epi-hydroxy-nonactate anion (C) afforded two esters *(98)* and *(99)*, respectively. After debenzylation of *(98)* and tosylation of *(99)*, the two fragments were condensed in the same manner as above. The final lactonization of the resulting tetra-ester *(100)* proceeded, after hydrogenolysis of the benzyl ester, in 20% yield by use of the Gerlach procedure (Method 3).

Gerlach et al.[21] started with racemic *(83)*, properly blocking and deblocking the carboxylic acid (*tert*-butyl and CF_3CO_2H) and the OH groups (benzyl and hydrogenolysis), and forming the ester linkage with the aid of 2,4,6-benzenesulfonyl chloride and pyridine to obtain a mixture of statistically



possible stereoisomers corresponding to *(100)*. Cyclization of the mixture using their method gave rise to several cyclic isomers in 20% yield, from which racemic *(7)* (of symmetry S_4) was isolated. The other possible isomers, an achiral compound of C_i, and two racemates of C_1 and C_4 symmetry, had apparently also been formed in this cyclization.

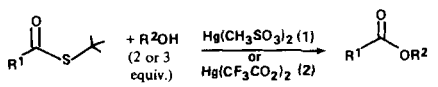


5.2.3. Pyrenophorin *(12)* and Vermiculine *(13)*

Since these 16-membered diolides which are composed of two identical hydroxyacids are optically active, the two chiral centers of each component must have the same absolute configuration. *Colvin, Purcell,* and *Raphael*[118] were able to synthesize *(12)*. The authors emphasized the importance of the

β-tosylethyl group for the protection of the carboxylic acid[92,93], which was liberated from *(104)* without cleavage of the central ester linkage. Treatment of the hydroxyacid corresponding to *(104)* with carbonyldiimidazole cleanly afforded the imidazolide of the hydroxyacid (the hydroxy group normally is less reactive to this reagent), which underwent base-catalyzed lactonization[94]. The generation of the keto

groups provided a separable mixture of (±)- and *meso-(12)*. This synthesis, first reported in 1972, could be somewhat simplified in view of other more recent techniques already described above. It appears possible to achieve one-step double lactonizations, as exemplified in the following synthesis of vermiculine. *Corey et al.*[119] condensed the aldehyde *(106)* (which was prepared by partial reduction of the corresponding glutarate) with bis(methallyl)cadmium to yield compound

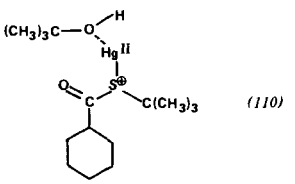


(107), in which the terminal methylene group served as a masked ketone and imparted base-stability to subsequent intermediates. A standard two-carbon chain extension of *(107)* provided a key intermediate *(108)*, and refluxing a xylene solution of its 2-pyridinethiol ester effected double cyclization to give a mixture of stereoisomeric diolides *(109)*. Further operations including OsO_4-$NaIO_4$ oxidation converted *(109)* into (±)-vermiculine *(13)* and its *meso*-isomer.

5.3. Further Remarks on Macrolide Synthesis

The total syntheses described in Section 5.2 reveal the two important problems of macrolide synthesis: ester and lactone formation, and control of the stereochemistry. Rather extensive studies have been performed in order to define the scope and limitations of several potentially useful reactions (see Section 5.1.3). A summary of this development is given in the following sections.

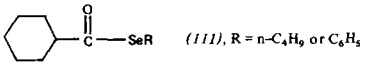
5.3.1. Ester and Lactone Formation



Method 1 (Section 5.1.3), utilizing a thiophilic metal ion to activate a thiol ester, offers some distinctive advantages. Firstly, as is described in the synthesis of methymycin *(1)* [see the processes for converting *(73)* into *(78)*], the 2,2-dimethylpropanethiol ester serves as an excellent protecting group, surviving both relatively mild alkaline and acidic conditions. Its stability toward OH^- and H^+ is comparable to that of normal alkyl esters. (However, the thiol ester does react readily with an amine in conformity with the hard-soft principle.) Secondly, reaction of a metal ion, such as Hg^{II}, with the thiol ester formally creates a trivalent sulfur molecule, a highly reactive species, and thus ester (and lactone) formation proceeds very rapidly at room temperature or below. More importantly, bulky substituents or double bonds located near

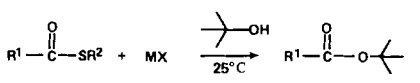
R¹	R²	Reagent	Buffer	Yield [%]
		1 or 2	Na_2HPO_4 (or none)	100 %
		1		90 %
		1 or 2		85 %
		1	Na_2HPO_4	90 %

the reaction centers—namely the hydroxy and acyl groups—do not impede the reaction[72, 95]. Thus *tert*-butyl pivalate and *tert*-butyl crotonate are prepared in excellent yields.



In the absence of alcohols, *tert*-butyl cyclohexanemethanethioate reacts with $Hg(CF_3CO_2)_2$ to form cyclohexanecarboxylic trifluoroacetic anhydride. Reaction of this anhydride with *tert*-butyl alcohol to give the ester, however, proceeds *ca.* 10 times slower than the above Hg^{II}-catalyzed ester formation[96]. Since intermediacy of the corresponding ketene has been ruled out[96], it would appear that the metal-catalyzed ester formation proceeds mostly through coordination of the alcohol to the metal. The possible intermediate *(110)* subsequently collapses into the ester and mercuric salts with retention of stereochemistry at carbon a to the carboxy group. The present method is not free from disadvantages: the electrophilicity of Hg^{II} toward

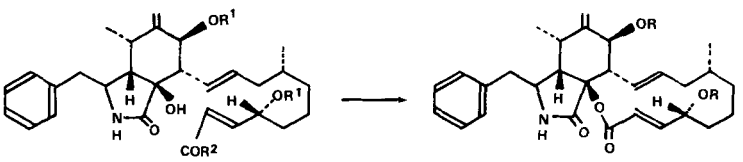
(110)



reactive alkenes[97] may be a problem sometimes. However, in most cases the reactivity of Hg^{II} with sulfur exceeds significantly that with ordinary or electron-deficient (C=C—C=O) double bonds, and we have thus far encountered only one case (cyclization of cytochalasin-B seco-acid, *vide infra*) where this problem is detrimental to the execution of successful lactonization, free from side reactions.

There are two obvious ways of modifying the procedure. Because of the comparatively weak bonding between carbon and selenium, selenol esters such as *(111)*[98] appeared to be good candidates for a more reactive species than the thiol ester. However, conversion of these *Se*-esters into *O*-esters

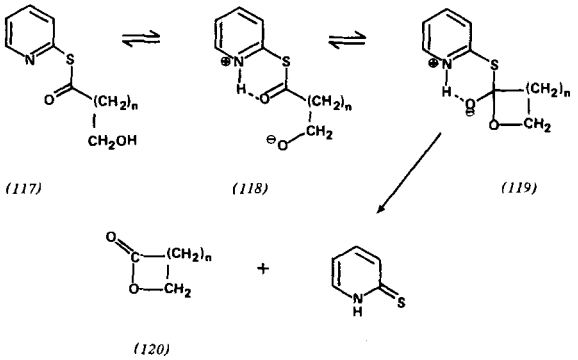
(111), R = n-C_4H_9 or C_6H_5



with transition metal cations which are inert to the C=C bond, [*e.g.*, Ag^I, Cu^I] were rather discouraging, and we have concluded that selenol esters do not offer any advantages for this purpose over thiol esters. Moreover, Hg^{II} was still needed to effect the reaction.

(112) *(113)*

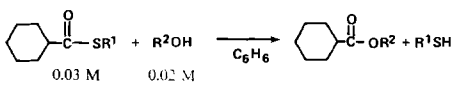
R¹	R²	MX	Solvent	Time	Yield [%]
		$Cu(CF_3SO_3)$	C_6H_6/THF	10 min	95
		$Ag(CF_3CO_2)$	C_6H_6	10 min	100
		$Cu(CF_3SO_3)$	C_6H_6/THF	5 h	80
		$Cu(CF_3SO_3)_2$ $Ag(CF_3CO_2)$ $AgBF_4$	CH_3CN C_6H_6 (Δ) C_6H_6 (Δ)	1.5 h 1.5 h 1 h	24 100 <5
		$Ag(CF_3CO_2)$ $Cu(CF_3SO_3)$ $Cu(CF_3SO_3)_2$	C_6H_6 (Δ) C_6H_6/THF CH_3CN	1.5 h 5 h 30 min	100 90 100



Another modification involves a variation of R^1 and R^2 in *(112)* and also that of MX. The more acidic the reacting thiol R^2SH is, the less thiophilic the metal cation needs to be to effect the reaction, and in many cases Cu^I, Cu^{II}, and Ag^I were even superior to Hg^{II}. The presence of electro-inductive groups such as the C=C bond and protected hydroxy groups somewhat retards the ester formation. All these observations appear to conform with the hard and soft acid and base principle of *Pearson*. Further it is now clear that *Gerlach*'s method (Method 3, Section 5.1.3), the use of $AgClO_4$ or $AgBF_4$ to activate 2-pyridinethiol esters, is fully in accord with this

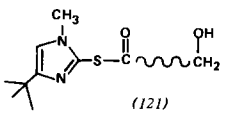
(114), $R^1 = CH_3CO$, $R^2 = OH$
(115), $R^1 = CH_3CO$, $R^2 = SC_6H_5$

(116), R = H

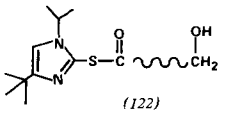


trend. In this way we have recently succeeded in cyclizing diacetylcytochalasin-B seco-acid *(114)* to the corresponding lactone, which yields cytochalasin-B *(116)* upon mild alkaline hydrolysis[95]. The ester *(115)* and $Ag(CF_3CO_2)$ (but not $AgClO_4$) have been the only combination able to achieve this task. (For the preparation of thiol esters see [74, 96, 99–101].)

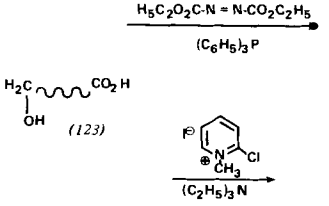
(117) *(118)* *(119)*



(120)



In contrast to Method 1, *Corey*'s "double activation" procedure (Method 2, Section 5.1.3) does not necessitate use of an external reagent to activate the functional group; cyclization (*e.g. (117)* to *(120)*) is accomplished by heating a solution of the 2-pyridinethiol ester of a hydroxyacid for a prolonged period of time. Several pieces of evidence point to the intermediacy of *(119)* in this lactonization[102]. If one accepts this mechanism, then it follows that a thiol ester substituted heavily near the reaction centers (hydroxy and acyl groups) would encounter a high energy barrier in the process leading to *(119)*. We have confirmed this inference: the rate of ester formation is progressively retarded as the steric hindrance increases, and is extremely slow with *tert*-butyl alcohol, although addition of Ag^I completes the reaction within 10

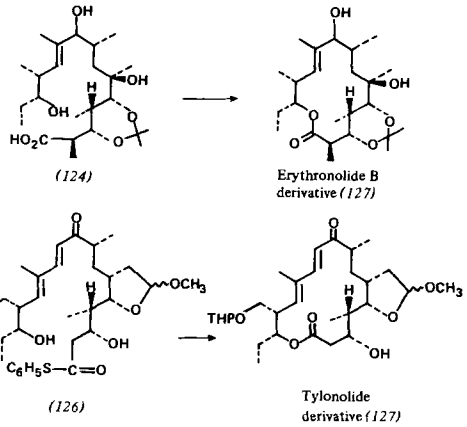


R^1	R^2	T [°C]	Time (h)	Yield of O-Ester [%]
	n-$C_9H_{19}CH_2$—	25	4	51
			20	96
		50	1	63
			4	91
	n-C_4H_9—CH(—CH_3)—	80	1	49
			4	98
	$(CH_3)_3C$—	80	24	18
			72	38
	n-$C_9H_{19}CH_2$—	50	1	7
			20	18
	n-C_4H_9—CH(—CH_3)—	80	2	2
			30	6
	$(CH_3)_3C$—	80	24	0

minutes. This steric retardation of the reaction constitutes a major drawback to Method 2. We have failed to cyclize the seco-acids of methynolide and cytochalasin derivatives [*(59)* and *(114)*, resp.] by this method. In fact, in most of the examples thus far reported[103] substances possessing either a primary hydroxy or primary carboxylic acid group were cyclized, whereas in model studies straight chain aliphatic ω-hydroxyacids are employed. Some improvement has been made, however, and the latest version of this method[104] involves the use of esters of the type *(121)* and *(122)*, which undergo cyclization 100 times faster than the corresponding 2-pyridinethiol ester. Other cyclization reactions include the

(121)

(122)

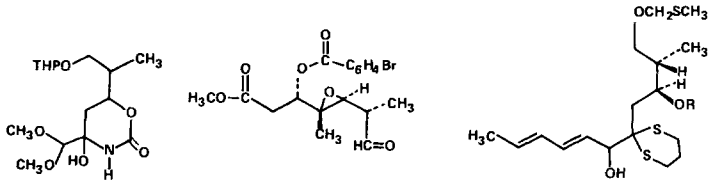


reaction of diethyl azocarboxylate and triphenylphosphane with an aliphatic hydroxyacid *(123)*[105] and use of 2-chloro-*N*-methylpyridinium iodide and triethylamine[106].

(120)

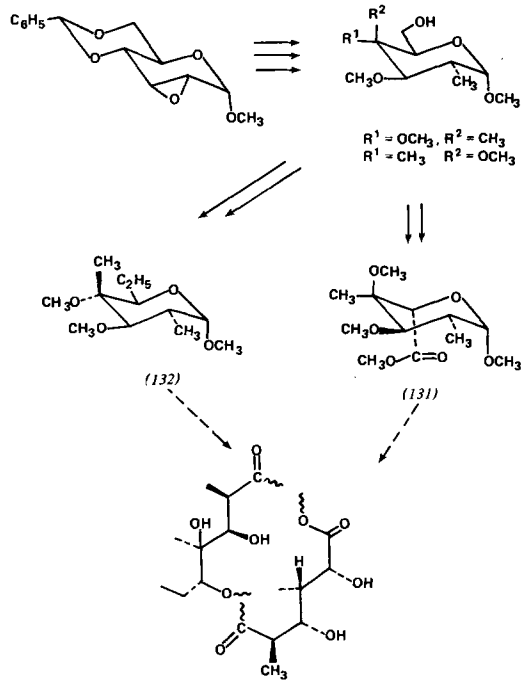
Staab's imidazolide method, which was successfully utilized in the synthesis of pyrenophorin *(12) (vide supra)* and in a model study for erythronolide B[107], requires a catalytic amount of strong base, which normally destroys sensitive "polyoxo" macrolide seco-acids and/or causes epimerization unless they are properly protected.

Other examples of the lactonization of seco-acids derived from natural macrocyclic compounds are: *(124)*→*(125)*



(Method 2, yield not specified)[103a], *(126)*→*(127)* (Method 1, 17%)[101] and the successful cyclizations, according to Method 2, of bistetrahydropyranyl ethers of A-brefeldinoic seco-acid to the corresponding brefeldin A derivative (70%) [cf. *(14)*], of *N*-benzyloxycarbonylcarpamic acid to bisbenzyloxycarbonylcarpaine (> 50%), and of vertalin seco-acid to vertaline (67%)[103a].

5.3.2. Stereochemical Considerations



The subunit of pyrenophorin *(12)* or vermiculine *(13)* contains only a single chiral center and no effort has been made in the synthesis to selectively combine the two identical enantiomers of the subunit. Nonactin *(7)* obviously presents more stereochemical problems. Of the four asymmetric centers of nonactic acid *(83)*, only two (possibly three) were stereospecifically introduced in synthetic intermediates. Tetramerization of (+)- or (−)-*(83)* adopted either Route 1 (see Section 5.1.3) or a random combination of (±)-*(83)*, followed by chromatographic separation of the desired macrocycle (±)-*(7)* from other isomers. In the synthesis of methymycin *(1)* both fragments A and B were stereospecifically or selectively synthesized and were combined by Route 2. Although a few newer methodologies permitted efficient execution of some crucial transformations involved in the scheme, the overall control of stereochemistry relies upon conventional, well-known techniques which utilize a ring system to establish the *cis* or *trans* relationship of two specific substituents. Can we "stretch" this type of approach to a more complicated system? Can we devise a new methodology to create a chiral center in an aliphatic acid in a manner a step closer to the enzymatic process? These are questions we are seriously asking in the synthesis of tylosin *(5)*, a 16-membered macrolide antibiotic. These questions arise when we consider a few processes, (1) addition of one propionate unit to a preformed chiral fragment, (2) matching two different subunits, and in particular (3) creation of a new asymmetric center or centers concurrently with this matching.

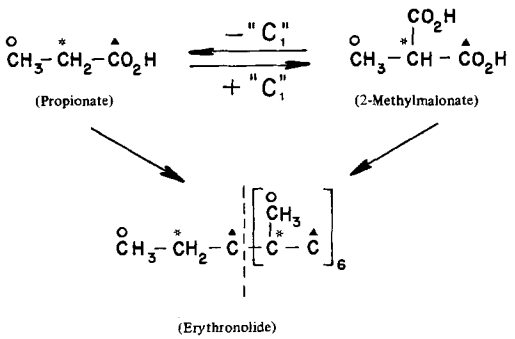
Two years ago two groups reported syntheses of fragments, *(128)*[108], *(129)*[109], and *(130)*[110], from which it was

(128) *(129)* *(130)*

intended to form the 19-membered lactam of maytansine *(9)*. Clearly it is not a simple matter to link these fragments together in the proper manner. The view that polyoxo macrolide antibiotics are "big" cyclic sugars naturally suggests the idea that a sequence of transformations of commonly available monosaccharides would yield fragments required for a macrolide synthesis. This approach becomes particularly attractive for erythronolide A, whose structure possesses hidden symmetry. *Hanessian* and *Rancourt* have prepared the C(1)—C(6) *(131)* and C(9)—C(13) *(132)* fragments of erythronolide A

from glucose through a sequence of some ten steps[111]. This approach is neat and clever, and if macrolide syntheses were commercially important and viable, this would be the route to be chosen.

It is our view that synthetic organic chemists are still challenged by the above, as yet unsolved, fundamental problems associated with stereochemistry and when one accepts this challenge, new chemistry will undoubtedly emerge.



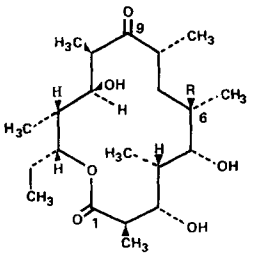
6. Biochemistry[*]

6.1. Biogenesis

Five representative "polyoxo" macrolides [*(1)*—*(5)*] are described in Section 2.1. Although there are common features in the biogenesis of all five, there are many differences. Early studies were mainly concerned with erythromycin A *(3)* and are summarized in several review articles[23, 112–114]. Apparently, these "polyoxo" macrolide antibiotics and also the polyenes (Section 2.2) and the bridge system of the ansamycins (Section 2.4) are formed from simple metabolic intermediates like acetate, propionate, malonate, 2-methylmalonate, butyrate (or 2-ethylmalonate), much in the same manner as saturated long-chain fatty acids are synthesized. Monomers with activated carboxyl groups (thiol esters of coenzyme A or a polyenzyme synthase) condense in rapid stepwise fashion with their carboxylated derivatives (malonate, 2-methylmalonate, and 2-ethylmalonate derivates) to yield a long-chain polyoxo fatty acid which after a minimum of one biological reduction can form a lactone. Structural analysis of the known macrolides shows that the process of chain extension or growth proceeds independently of whether modification of the β-oxo function introduced at each step of chain extension occurs or not. This feature distinguishes the formation of macrolide lactones from that of saturated fatty acids, but it would appear that the latter is the special case.

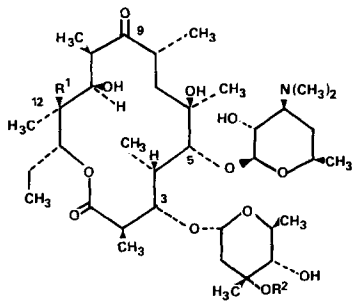
Most of the lipid-derived structures found in nature are built from carbon chains derived from the same monomers cited above (as well as others) and their structures show the retention of variable amounts of these same oxygen atoms. It seems that most lipids, including those of the macrolide group, are formed by General Fatty Acid Synthases (GFAS's) and the saturated acids (*e.g.*, palmitic) found in cell membranes and neurological tissues are formed by Specialized or Saturated Fatty Acid Synthases (SFAS's). (These abbreviations will be used here together with the abbreviated names of the substrates believed to be used by the synthase.)

The aglycones (erythronolides) of the erythromycins are synthesized by a GFAS:Pr, 2-MeMal; all available evidence shows that they are made from one *pr*opionate and six *2-meth*-



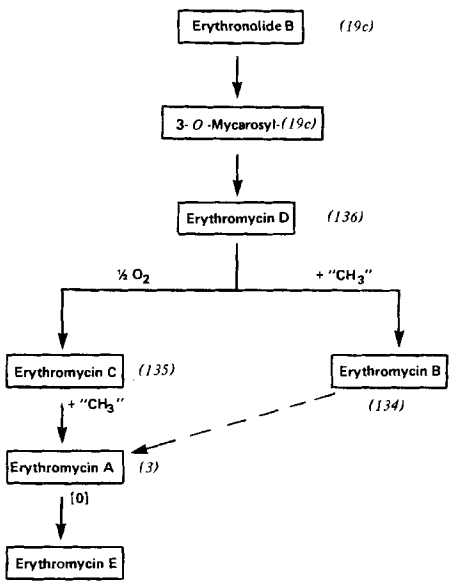
(Propionate) (2-Methylmalonate)

(Erythronolide)



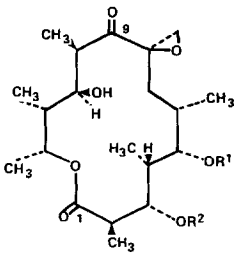
*yl*malonate units. This conclusion came from work using radioactive substrates and has been confirmed by ^{13}C-NMR studies which have added proof for the stepwise route of synthesis[115, 116]. Erythronolide B *(19c)* is the final lactone formed prior to glycoside formation. Its presence as well as that of its penultimate precursor, 6-deoxyerythronolide B *(133)*, was shown initially by studies with blocked mutants of *Streptomyces erythreus*[117, 118]. A most interesting soluble hydroxylase system which is dependent on a cytochrome P_{450} component is required for the transformation of *(133)* into *(19c)*[119]. The work with mutants also showed that a neutral monoglycoside, 3-*O*-mycarosyl-erythronolide B is the next isolable intermediate. This structure accepts either activated

[*] This section is contributed by *J. W. Corcoran.*



Erythronolide B *(19c)*, R = OH
6-Deoxyerythronolide B *(133)*, R = H

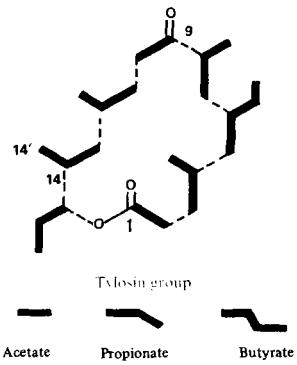
D-desosamine or some precursor yielding the first biologically active bis-glycoside, erythromycin D *(136)*[120–122]. This



Erythromycin	R^1	R^2	
A	OH	CH_3	*(3)*
B	H	CH_3	*(134)*
C	OH	H	*(135)*
D	H	H	*(136)*

intermediate *(136)*, the key substance in the biosynthesis, can be either hydroxylated to yield erythromycin C *(135)*[123] or directly receive an activated methyl group from *S*-adenosyl-L-methionine to give erythromycin B *(134)*[124]. The same transmethylase will react with *(135)* to give the common A form *(3)*[125] of erythromycin. Under some conditions, *(134)* may be hydroxylated to the A form *(3)* directly, although this has yet to be demonstrated with the cell-free enzyme system used to elucidate the terminal steps in erythromycin formation. Oxidative degradation of erythromycin A *(3)* occurs, yielding at least one further substance, the E form, with an ortho ester linkage between oxidized L-cladinose and C(3) of the ring[126].

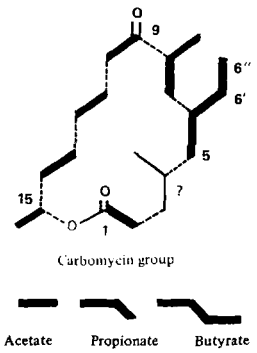
There is some biosynthetic "crossover" between closely related pathways in the macrolide area. Thus *S. erythreus* modified lactones derived from erythronolide B *(19c)* often accept L-mycarose. The products are novel monoglycosides which usually do not serve as acceptors for D-desosamine[127]. In general this has not proved to be a useful route to new antibiotics. A notable exception is the transformation of the 11-*O*-methyl ether of erythronolide B *(19c)* into 11-*O*-methylerythromycin B[128]. A second exception is the case of the 9-oxime of erythronolide A, where, in a mixed fermentation using *S. antibioticus* which is normally a producer of oleandomycin *(137)*, a new antibiotic is formed. It is 3-*O*-oleandrosyl-



Oleandomycin *(137)*
R^1 = Desosaminyl
R^2 = Oleandrosyl

5-*O*-desosaminyl erythronolide A 9-oxime, which contains the typical sugar residues of oleandomycin and the lactone ring of erythromycin A[129].

Additional examples of "interspecies" cross-over are the formation of mycaminosyl derivatives of narbonolide and 9-dihydronarbonolide when these 14-membered aglycones are added to cultures of *Streptomycetes* that normally produce 16-membered macrolides[130]. *Martin et al.* have also isolated derivatives of erythronolide B *(19c)* in which non-branched neutral sugars are present instead of L-mycarose[131]. Clearly the future should see much more use of mixed fermentations which produce "hybrid" macrolide structures.

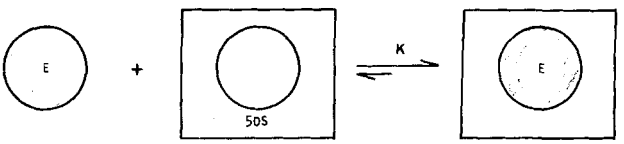


A large number of other macrolides similar to the erythromycins include, *inter alia*, methymycin *(1)*, pikromycin *(2)*, narbomycin [12-deoxy-*(2)*], and oleandomycin *(137)*. These antibiotics are not exclusively derived from propionate/2-methylmalonate but contain one unit that originates from acetate/malonate. This conclusion is based on isotopic and NMR evidence. The reasons for this are obscure, but a given microbial strain gives a single predominant product together with trace amounts of other possible products which differ more in oxygen atom substitution patterns from the major component than in the carbon skeleton of the lactone[132]. The finding that *S. Venezuelae* can form either the 12-membered methymycin system or the 14-membered pikromycin structure according to the culture medium is fascinating and awaits a rational explanation[133] (cf. discussion of the magnamycin-type of macrolide, *vide infra*).

The 16-membered macrolides tend to either of two structural extremes. The tylosin group (*e.g.*, rosamycin and cirramycin) are largely derived from propionate with the added feature that one biogenetic unit comes from butyrate/2-ethylmalonate (GFAS: Pr, Mal, 2-MeMal, 2-EtMal)[134, 135]. These structures are thus biogenetically somewhat similar to the erythromycin group. The methyl position of the butyrate is oxidized to an

aldehyde group in most known cases (except for platenolides, *vide infra*). The sugars of tylosin *(5)* are similar to those of erythromycin, but are present as a disaccharide, and a third sugar residue is attached to a hydroxylated methyl group [C(14')].

The other group of 16-membered macrolides is typified by carbomycin A (magnamycin) *(4)* and includes, *inter alia*, the leucomycins [cf. *(16)*], niddamycin, platenomycin, spiramycin, *etc.* These structures are formed biologically from acetate/malonate with the use of only one propionate/2-methylmalonate unit and the same butyrate/2-ethylmalonate building block as that for the tylosin group. The origin of C(3) and C(4) of the carbomycin ring system is as yet unclarified[136]. In the case of tylosin these same two positions are derived from 2-methylmalonate, and thus "can in principle" be formed from an acyl intermediate. This portion of the macrolide ring system seems more variable than the other,



and perhaps is formed after the 15-oxo or 15-hydroxy acid leaves the GFAS responsible for its formation (cf. ref. [112]). Such variability might also explain how either a 12- or 14-membered lactone could stem from a common producing organism (cf. methymycin *(1)*, *vide infra*). The platenolides[137] differ from most 16-membered macrolide aglycones in retaining the methyl group [C(6'')] of the butyrate/2-ethylmalonate precursor which constitutes C(5), C(6), C(6') and C(6''). They are produced by blocked mutants of *S. platensis* which normally produces the platenomycins, 16-member macrolides of the carbomycin type with an aldehyde group at C(6'')[138].

Very few cell-free studies have been carried out on the enzymes involved in the biogenesis of 16-membered macrolides. Hence it is difficult to do more than speculate on the steps involved in assembling these complex molecules. Sugar-free lactones have been identified both in normal fermentations and in fermentations with blocked mutants, and it is likely, as with erythromycin, that some sugar-free lactone is released from the GFAS system, which then accepts either the preformed disaccharide L-mycarosyl-D-mycaminose plus the third sugar (when present) or all the sugars in stepwise fashion. The times of acylation of the L-mycarosyl moiety and the ring system are also unknown.

6.2. Mode of Action

The mode of action of the macrolides was initially studied with erythromycin A *(3)*, and a comparison has been made with a limited number of other macrolides[24,139-141]. Also, a large number of semi-synthetic macrolide antibiotics have been studied, mostly in comparison with erythromycin[141-144]. There appears to be general agreement that all macrolide antibiotics affect protein synthesis in susceptible bacteria—mostly the gram-positive group. However, cell-free studies have shown that erythromycin inhibits protein synthesis in systems from gram-negative bacteria. When the intracellular concentration of the antibiotic is high enough (*ca.* 10^{-4} M), intact cells of both groups are inhibited. The difference seems to lie in their ability to accumulate the drug, and there even seems to be some "barrier" to this process in highly sensitive gram-positive cells[145]. The mechanism of accumulation has not been studied.

Erythromycin A *(3)* inhibits the growth of bacteria and the mechanism of action involves a stoichiometric binding of high affinity of one molecule of the erythromycin to a highly specific "site" on the 50S ribosomal subunit. It appears that this occurs only, or at best, when the 50S unit is in the free state, and that the erythromycin/50S ribosomal adduct is able to form ribosomal assemblies (70S and polysomes) which may function in the synthesis of bacterial protein. On the average, however, these assemblies do not behave normally and overall cellular protein synthesis is disturbed[140,145].

E = Erythromycin. For *Bacillus subtilis* 168, $K \approx 3 \times 10^{-7}$ l/mol [140].

There is some controversy as to which part of the ribosome cycle is the primary target of the disturbance. Some macrolides appear to inhibit the action of peptidyl synthetase, an enzyme activity which promotes the formation of a new aminoacyl bond in the growing polypeptide chain. Other studies, especially those with erythromycin, have suggested that the primary disfunction in protein synthesis concerns the GTP-dependent translocation[146]. This may be an academic difference, since the assays used to study the mode of action are extremely non-physiological and very much influenced by experimental design. The study of erythromycin action used radioactive antibiotics of high specific activity, and most comparisons with other macrolides have depended on their ability to displace this erythromycin from its binding site on the 50S ribosomal unit[140,141]. Thus far this activity has agreed well with independent studies of the potency of the second macrolide.

In principle, the macrolide antibiotics should be capable of inhibiting mammalian mitochondrial protein synthesis, as this process is very similar to that in bacteria. Apparently erythromycin (and presumably other useful macrolides) is unable to penetrate the mitochondrial membrane and for

Table 1. Macrolide antibiotics.

Damavaricin	23		[316, 317]		[316]	[316, 317]
Geldanamycin	19				[318]	
Halomycin B	25	[319]	[320]			
Maytansine	19	[9, 45] [e], [32, 321]	[321, 322]	[108—110, 323]		[32]
Mikamycin B	19					[324]
Naphthomycin	29	[325]				
Protostreptovaricin	23	[326]				
Rifamycin	25	[30a, 327, 332], [328—331] [d]	[30c, 30d, 329, 333—339]	[320]	[30b, 340]	[332—346]
Streptovaricin	23	[347, 349, 350], [348, 351] [e]	[352, 353]	[316]	[354]	[353, 355]
Tolypomycin						[356—360]
Other macrolides						
Aplysiatoxin	14	[361]				
Aspicilin	17	[362]				
Axenomycin	34	[363, 364]				
Brefeldin A	13	[365] [e]		[182]	[366]	[365]
Chlorothricin	14	[367] [e], [368]	[368]			
9-Decanolide	10					[369]
(*Z*)-4-Decen-9-olide	10					[369]
Evorin		[370]	[370]			
11-Hydroxy-5-tetradecen-13-olide	15					[369]
9-Oxotridecanolide	13			[371]		
Macrolidine	14	[372]				
Milbemycin	16	[373]				
Primycin	36	[374—376]				
Pyrenophorin	16	[35b]		[18]		
Roridin	18				[377, 378]	[379, 380]
Trichothecane	18				[381]	
Venturicidine	20	[382] [e]	[382]			
Vermiculine	16	[36a] [e], [36b]		[19]		
Verrucarin	18				[377, 378]	[379, 380]
Vertisporin	18	[383, 384]				
Virginiamycin	23					[385, 386]
Zearalenone	14			[72, 73]		[33]

[a] The "polyoxo" macrolides are listed by family name only. There are thus many more individual compounds than these listed here. For example, there are at least 11 leucomycin variations and 3 spiramycins. Some families have a common aglycone but have various sugars attached which modify their physiological activity. The spiramycins, neospiramycins and the forocidins share a common 16-membered aglycone.—Acumycin, amaromycin, azalomycin, bandamycin, forocidin, griseomycin, macrocin, megacidin, miamycin, neospiramycin, relomycin, sekazin, tertimycin. B-58941 see [12—16]. Ring size: 16 or unknown.

[b] From the point of view of chemical and biological properties, these antibiotics might be intermediate in position between the "polyoxo" and the polyene macrolides.

[c] The figure in brackets following the name of the polyene macrolide is the number of conjugated double bonds present in the aglycone—aurenin (5) (ring size: 24), crytocidin (6), hepcin (7), hexamycin (6), monicamycin (7), Ac_2 435 (4), MM 8 (3), PA 150 (7), PA 153 (5), PA 166 (4), 2814 H (7) see [12—16].

[d] Conformational analysis.

[e] X-Ray analysis.

[f] Sugar part.

this reason it is not a cytotoxic agent[140]. This is in contrast to some other antibiotics with a similar mode of action (*e.g.*, chloramphenicol).

Clinical resistance to erythromycin is fairly common. Several possibilities exist as to its mechanism. In certain cases, mutation leads to a change in the binding constant for the erythromycin/50S ribosome adduct. In others, the erythromycin seems to "induce" an enzyme (an adenine methylase) that introduces a methyl-adenine moiety into the ribosomal RNA and this in turn affects the ability of the antibiotic to bind to the ribosome. No resistant microorganism has shown enzymatic destruction of erythromycin or other macrolides.

7. Concluding Remarks

We believe that the preceding sections have covered most of the significant developments in this area over the past seven years. The number of natural macrolides defined in a broad sense will undoubtedly increase and the emergence of new types of compounds is a distinct possibility. Powerful instrumental techniques are now at our disposal and will help elucidate the structures, configuration, and conformation of newly discovered substances very efficiently and almost automatically. In the field of synthesis, despite recent notable successes, there are important, as yet unsolved problems asso-

ciated with the stereochemistry of macrolide molecules (see Section 5.3). Obviously the biochemistry of macrolide antibiotics is extremely complicated, and understanding biological phenomena at the molecular level requires extensive research. The macrolides, because of their importance to chemistry, biochemistry, and medicine, will continue to attract both academic and practical interest for many years to come.

Since the submission of this paper several other publications in this sector have appeared in the literature. These will be reserved for a future review article.

The authors wish to express their appreciation to M. Aratani, W-K Chan, A. Greiner, Y. Hayase, and R. Sobczak who have aided in the compilation of the references cited in this article and also to those who have made their unpublished results available to us. Two of the authors (SM and GSB) are grateful to the National Research Council of Canada for financial assistance.

Principles of Osmotic Desalination

By K. W. Böddeker[*]

Salt solutions can be separated into pure water and concentrated salt solution by reverse osmosis using semipermeable membranes. The distinct features and limitations of osmotic separations are developed from a consideration of the pertinent solution properties and the conditions inherently to be met by the membranes, seen as interacting barrier phase in a process which substantially separates water from water.

1. Introduction

Osmosis is a natural phenomenon directed at equalizing concentration differences of solutions with common solvent. Reverse osmosis, by an analogous mechanism, increases solution concentration differences and thus is a separation phenomenon. Both effects depend on the presence of a semipermeable barrier which is permeable to the solvent but more or less completely impermeable to the solute. Generally speaking, therefore, the terms osmosis and reverse osmosis indicate directions of solvent flow across a semipermeable barrier separating two solutions of different concentration: from dilute to concentrated (osmosis) or from concentrated to dilute (reverse osmosis). The discussion of osmotic effects amounts to an analysis of the driving forces for solvent flow.

The importance of osmotic effects is best illustrated by noting that the cell walls of living tissue have semipermeable properties, *i.e.* they are permeable to water (life being an aqueous system) and impermeable—or in a sophisticated way partially permeable—to the solutes of the cell or body fluids. Osmosis has been called the physics of life.—Reverse osmosis, using artificial semipermeable membranes, is a barrier separation process best known in its application to the desalination of brackish waters and seawater. The discussion to follow will therefore deal with aqueous electrolyte solutions.

As a barrier separation process reverse osmosis belongs to the general class of filtration operations, of which it forms one limiting case on a scale whose opposite end is the classification of gravel on a sieve. The difference in operation between a semipermeable membrane and a sieve, however, is rooted far deeper than is suggested by simply picturing a perforated wall with pore sizes ranging down to molecular dimensions. The unique feature of reverse osmosis is that it does not really involve the separation of a dissolved species from the solvent but actually differentiates between thermodynamic activities of the solvent itself: water is separated from water. The properties of the dissolved species—including their size—are quite irrelevant except for their effect on the activity

[*] Dr. K. W. Böddeker

Postfach 160, D-2054 Geesthacht (Germany)

of the solvent. A clear recognition of this situation could have spared much futile speculation on the salt rejecting capability of pores invoked to retain the notion of a "filter". In the proximity of "ideal" semipermeability no pores are needed, for water may pass a barrier phase by diffusion.

2. Osmotic Properties of Aqueous Solutions

Regardless of the mode of transport, any separation relies on some physical difference between the species to be separated, from size in ordinary filtration to minute mass effects in diffusive isotope separation. In reverse osmosis, then, the relevant difference is not that between salt and water—obviously large—but the much more subtle difference between water containing salt and pure water. This difference reveals itself in the so-called colligative properties, namely osmotic pressure, lowering of vapor pressure, elevation of boiling point, and lowering of freezing point, which are strictly properties of the solvent reflecting the change in free energy or chemical potential of the solvent as its activity is (invariably) lowered on introduction of solute:

$$\mu = \mu^0 + RT \ln a_w \tag{1}$$

μ^0 is the standard potential of the pure solvent at $a_w = 1$. Again, the nature of the solute is of no relevance as the colligative properties depend upon particle concentration only (ions in the case of electrolytes).

The lowering of potential at $a_w < 1$ (which, by dimension, is "energy" or "work") represents the minimum thermodynamic energy required to desalt water by removing pure water isothermally from an essentially infinite body of salt solution. As applied to seawater, for example, which contains about 3.5 % of total dissolved salt (TDS), the minimum energy requirement at room temperature is nearly 0.7 kWh per metric ton of water. At a recovery of 50 % the figure is around 1 kWh per ton. In actual seawater desalination by reverse osmosis the energy requirement is an order of magnitude higher, and still higher in distillation. Any cost figures quoted as being below this minimum are wishful thinking.

The physical boundary between the solution and pure water which localizes the chemical potential difference between adjoining regions of different activity is, of course, the semipermeable membrane. It will allow water to cross under the driving force of its own chemical potential drop, but represents something like an infinite resistance (if ideally semipermeable) to the potential difference of the solute. Since the solution always has a lower potential than the pure solvent the direction of flow is into the solution, as if drawn by the solute: osmosis. If the solution, *i.e.* the potential sink, is confined in volume, the solvent influx will result in a pressure increase. This well-known phenomenon, which, for example, makes ripe fruit burst after a shower, establishes a link between solute concentration and pressure. Both affect the activity of the solvent; however, whereas solutes lower the solvent potential, external pressure raises it.

The formal connection between concentration and pressure is best visualized by a model experiment in which one mole of water is first allowed to pass by osmosis from the pure water side into a solution (wherein it occupies the partial molar volume $\bar{v}$), and subsequently is driven out again by applying a pressure p. The work involved is $p\bar{v}$, and the complete expression for the chemical potential of the solvent becomes

$$\mu = \mu^0 + RT \ln a_w + p\bar{v} \tag{2}$$

Allowing now also for pressure differences across the semipermeable membrane, the direction of solvent flow apparently depends on the relative magnitude of the two effects. Reverse osmosis then is the situation in which the lowering of potential due to solute concentration is over-compensated by an external (hydrostatic) pressure, resulting in a net solvent flow away from the solution. Desalination by reverse osmosis is thus a misnomer since it actually is a de-watering scheme (as, incidentally, is distillation). Or, by the same token, a method to concentrate a solution (isothermally) (see Fig. 1).

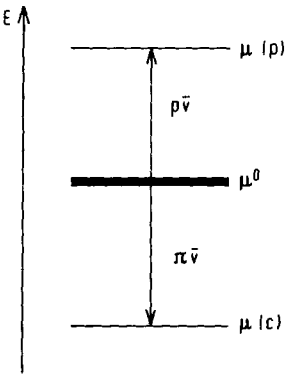

Fig. 1. The chemical potential of water. μ^0 = standard potential of pure water; p = external pressure, π = osmotic pressure. $\bar{v}$ = partial molar volume.

Of particular interest is the equilibrium situation in which the two opposing effects of solute concentration and pressure just balance each other. The corresponding pressure is, by definition, the osmotic pressure of the solution, π. It is one of the colligative properties of the solvent and as such is properly expressed in terms of the solvent activity. With $p = \pi$ at $\mu = \mu^0$ Eq. (2) gives for the osmotic pressure

$$\pi = -\frac{RT}{\bar{v}} \ln a_w \tag{3}$$

At $a_w = 1$ (pure water) the osmotic pressure is zero. Using this equation (or analogous expressions for the other colligative properties) the activity of the solvent—which is a somewhat hidden quantity—is experimentally accessible. Of more importance, however, is a direct relation between the analytical solute concentration and the corresponding osmotic pressure. For dilute solutions such a relationship may be constructed by observing that both the solvent activity and its mole fraction (x_1 for solvent concentration) are close to unity, implying that $\ln a_w \approx \ln x_1$. Simple mathematics then leads to the mole fraction of the solute (x_2, which, for dilute solutions, is proportional to other concentration units)

$$\ln a_w \approx \ln x_1 = \ln(1 - x_2) \approx -x_2 \tag{4}$$

As far as the approximation "dilute" holds, the desired relation between osmotic pressure and solute concentration is as follows:

$$\pi = \frac{RT}{\bar{v}} x_2 \text{ or } \pi\bar{v} = RTx_2 \quad (5)$$

This is the van't Hoff limiting law for osmotic pressure. It resembles the ideal gas law, giving rise to the alluring but erroneous notion that the osmotic pressure has the same kinetic origin as gas pressure, *viz.* particles bouncing against the walls of their container. In fact, as follows from a consideration of surface tension, electrolytes in solution even tend to stay away from the solution boundaries (an observation leading at one time to the suggestion that all that is required to desalt water is to skim its surface).

Since the colligative properties are a function of particle concentration, numerical calculations have to account for electrolyte dissociation (ν = number of moles of ions produced per molar entity of salt at "infinite dilution"). Furthermore, using molality to express the solute concentration (m_2 = moles of solute per kg of solvent, one kg of water representing 55.5 moles), the customary equation for the osmotic pressure is

$$\pi = \frac{RT\nu m_2}{\bar{v}\ 55.5}\phi \quad (6)$$

in which ϕ is the empirical "osmotic coefficient" correcting the naive expression (5) for ionic interactions (for example, incomplete dissociation at "actual dilution"). Its value has been tabulated for most salts of interest in desalination. At the concentrations in question here, it usually differs little from unity[1].

In the context of the approximations used here, even seawater with a total salt content of about 3.5 % may be considered a dilute solution. Its osmotic pressure at room temperature is about 26 bar, at 2 °C about 23 bar. Such pressures, of course, are encountered in the depths of the oceans, ready-made (in principle) to drive a perpetual fountain of fresh water in a device known as an "osmotic pump". This is a pipe open at the top but capped by a semipermeable membrane at the bottom, lowered straight down into the ocean (which, for all practical purposes, is a solution of uniform concentration and temperature, with a surface density close to 1.03 g/cm^3). A pressure difference of 23 bar across the membrane is reached at a depth of around 230 m; it corresponds to the osmotic pressure of the seawater. Any excess pressure on further lowering the pipe is reverse-osmotically compensated by fresh water rising inside the pipe, always maintaining a constant Δp of 23 bar at $\Delta\mu = 0$ across the membrane. Since the density of the fresh water is lower than that of seawater (both, of course, increasing with increasing depth), the fresh water inside the pipe does not simply remain at the 230 m-mark but actually rises until—at a calculated depth of the pipe of 8750 m—it reaches the surface[2].

In practice, pressurizing pumps are more convenient. Even then the desalination of seawater by single-pass reverse osmosis, though demonstrated on a pilot plant scale, is still more challenge than business. Solutions with lower salt concentrations and lower osmotic pressures are easier to handle. A physiological sodium chloride solution, which is adjusted to the osmotic pressure of the blood (7.6 bar) has an NaCl concentration (0.95 %) comparable to that of a "thick" brackish water—at present, the realm of applied reverse osmosis.

The osmotic pressure of the feed water is something like a basic design factor for the reverse osmosis process. First of all, there is obviously no reversal of solvent flow until the osmotic pressure is exceeded by an external pressure acting on the solution. This places an upper limit on the solution concentration that may reasonably be treated by this process. Secondly, while ordinary filtration may be carried out to the point of dehydration, reverse osmosis has to work against an increasing osmotic pressure as solvent is removed from a finite feed water reservoir. This limits the practical yield or recovery of the process and, by implication, renders the designed output a function of the initial feed water concentration.

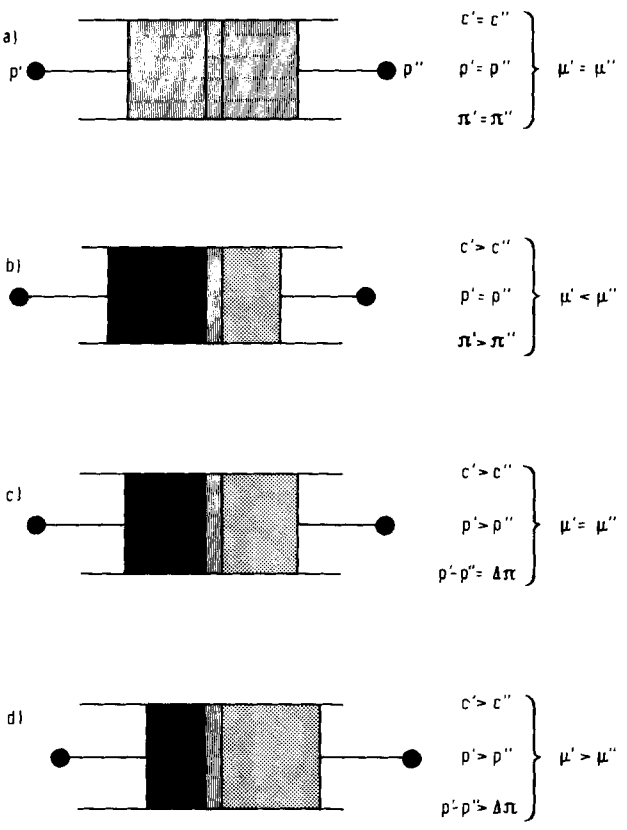

Fig. 2. Summary of the osmotic situations. a) Natural equilibrium, b) osmotic volume flow, c) osmotic equilibrium, d) reverse osmosis.

A summary of the four osmotic situations is presented in Figure 2[3]. It is understood that solvent flow from a given solution can likewise be effected by lowering the activity (raising the osmotic pressure) of the counter solution beyond the point of flow reversal, by concentrating the counter solution with anything soluble. This is the principle of dialysis at ambient pressure (osmotic extraction). If "anything soluble" is a nutrient, like saccharose, the principle might be useful for supplementing emergency water at sea in an osmotic flow extractor[4]. Another suggestion aims at producing hydro-electricity from the Dead Sea, osmotically linked to the Jordan River: Dead Sea water, being pumped to a hydroturbine, "absorbs" the Jordan through semipermeable membranes, thereby increasing—as in the above flow extractor—not the pressure head, but the total liquid volume delivered[5].

3. Membranes and Membrane Model

The discussion so far has assumed an "ideal semipermeable membrane" governed by the activity of the solvent only, with no inference as to the mechanism of transport or selection across the membrane. The next best real thing to the ideal limit is a "diffusion controlled solubility membrane", the model of which is pictured as a homogeneous (*i.e.* pore-free) phase in which all solution components are soluble to various degrees and have a certain diffusive mobility[6]. Even the model version of this membrane expressly allows for salt passage, as dictated by reality. Selectivity is interpreted as arising from differences in solubility and mobility of the components in the membrane phase, that is, in terms of measurable and even adjustable membrane properties. The only assumption involved in the model treatment is that there is no coupling between the flow of water and of salt through the membrane, thus allowing the transport of the two to be considered independently. Although this model is still a limiting case confined to "dense" membranes of high salt rejecting capacity, it comes very close to describing real membranes of this type. Any sizeable departure from simple solution-diffusion behavior is indicative of a pore flow mechanism and should be regarded as ultrafiltration (or else as a membrane imperfection) rather than reverse osmosis.

By combining the osmotic principles with the tangible features of the solution-diffusion model, the equations of flow constituting the "instructions for use" of applied reverse osmosis may now be derived. In a general way the diffusive flow (or flux) F_i of a species i through a homogeneous membrane is given by the concentration of that species *in* the membrane phase (c_i), its mobility *in* the membrane phase ($m_i = D_i/RT$, with diffusion coefficient D_i), and the driving force acting on that species across the membrane (grad μ_i, the gradient of the chemical potential within the membrane boundaries)[7]:

$$F_i = c_i \times m_i \times \operatorname{grad} \mu_i \tag{7}$$

Viewing this relation as a generalized ohmic law, the product $c_i \times m_i$ represents the "conductivity" of the membrane phase. The potential is represented by external concentration and pressure differences, with the thickness of the membrane in between included in the conductivity part (Δy, the geometry of the conductor). For the present purpose Eq. (7) thus becomes

$$\underset{\text{flux}}{F_i} = \underset{\text{conductivity}}{\frac{c_i D_i}{RT\Delta y}} \times \underset{\text{potential}}{\Delta\mu_i} \tag{8}$$

The specific features of reverse osmosis emerge on analysis of the driving forces involved, $\Delta\mu_i$. For the solvent, indicated by the subscript i = 1, this is straightforward: The activity term of Eq. (2) can be expressed by the corresponding osmotic pressure according to Eq. (3) to yield

$$\mu_1 = \mu_1^0 - \pi\bar{v}_1 + p\bar{v}_1 \qquad (2), (3)$$

and

$$\Delta\mu_1 = \bar{v}_1(\Delta p - \Delta\pi) \tag{9}$$

For the chemical potential of the solute, subscript i = 2, (as for any component of a mixture) an equation analogous to Eq. (2) applies, *i.e.*

$$\mu_2 = \mu_2^0 + RT\ln c_2 + p\bar{v}_2 \tag{2'}$$

Partial differentiation of μ_2 with respect to c_2 and p (observing that $\partial\mu/\partial p = \bar{v}$, and with $\mathrm{d}\ln c = c^{-1}\mathrm{d}c$) yields

$$\Delta\mu_2 = \frac{RT}{c_2}\Delta c_2 + \bar{v}_2\Delta p \tag{10}$$

By coincidence, the partial molar volumes of water and sodium chloride, $\bar{v}_1$ and $\bar{v}_2$, are nearly the same, 18 ml/mole (neglecting compressibility). If a high concentration difference is maintained across the membrane, as is the case in high rejection reverse osmosis, the contribution of pressure to the driving force is negligible, amounting to roughly 1 % of the total solute potential difference.—The concentration c_2 refers to the *external* solution, whereas $c_i = c_2$ in Eq. (8) is the salt concentration *within* the membrane. The ratio $c_{membrane}/c_{solution}$ is in effect a distribution coefficient between membrane phase and solution phase, denoted K.

By incorporating these driving forces into the general flow equation (8) the transport equations for water and salt in the approximation of the solution-diffusion model take on the form[6]:

$$\text{Water (solvent):}\quad F_1 = \frac{c_1 D_1}{RT\Delta y}\bar{v}_1(\Delta p - \Delta\pi) \tag{11}$$

$$\text{Salt (solute):}\quad F_2 = \frac{D_2 K}{\Delta y}\Delta c_2 \tag{12}$$

The immediate results of this treatment may be summarized as follows: a) the rate of permeation of water is linearly dependent on the excess pressure over and above the osmotic pressure of the feed; b) the rate of permeation of salt is completely independent of the pressure; it is a function of the salt concentrations only, or more precisely, of the salt concentration at the respective solution-membrane interface; c) there is no interdependence between the two flows: neither does the permeating water carry salt, nor is the permeating salt accompanied by water.

A peculiarity of reverse osmosis becomes apparent when the salt rejection is considered (R). Next to the permeate flow rate (F_1) it is the most important quantity characterizing a separation process. It is conveniently defined in terms of the analytical salt concentrations of feed (') and permeate ('') as

$$R = \frac{c_2' - c_2''}{c_2'}; \qquad R \times 100 \triangleq \% \tag{13}$$

or as the desalination ratio c_2'/c_2''. Since, according to the model, the rate of salt permeation is independent of the pressure-driven water permeation, the rejection increases with increasing pressure, simply because an increase in water flux results in a correspondingly lower analytical salt concentration on the product side. In contrast to ordinary filtration, even if pressure-assisted, the "success" of reverse osmosis separa-

tions can thus be influenced by the operating pressure, which so far is the only process variable outside the inherent membrane properties. The rejection, incidentally, is independent of the membrane thickness, since the permeate salt concentration is given by the ratio of the two flows [Eq. (14)].

A graphical presentation of flows and resultant rejection in the simplified scheme of this, as it is, near-realistic model is given in Figure 3. As an orientational aid, order-of-magnitude values pertaining to the desalination of seawater by current reverse osmosis technology are included. (In terms of specific output, the membrane area is roughly comparable to the heat exchange surface of distillation plants.) Again, both F_1 and R are pressure dependent, but F_2 is not.

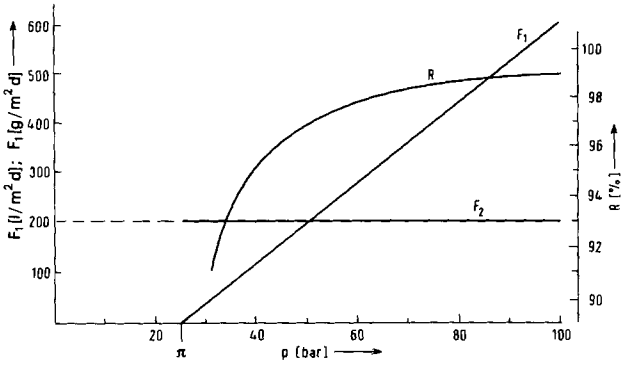

Fig. 3. Seawater desalination in the approximation of the solution-diffusion model. F_1, F_2 diffusive flow of water and salt, respectively; R = salt rejection; p = external pressure; π = osmotic pressure.

As a rule, the operating pressure of applied reverse osmosis is 3π, that is, it is adjusted to the salt content of the feed water to meet rejection requirements (about 75 bar in case of seawater). The salt concentration "seen" by a membrane in operation is, unfortunately, higher than the bulk concentration, c_2', because rejected salt accumulates at the solution-membrane interface as desalted water is withdrawn. The adverse effects of this "concentration polarization" are best seen by referring to the flow equations: As the osmotic pressure increases the net pressure (effective pressure) decreases with consequent reduction in flux [Eq. (11)]; secondly, a concentration build-up at the solution-membrane interface raises the level of salt passage, [Eq. (12)]. Essentially, the process of reverse osmosis separation is a polarization in itself, with much the same effects occurring gradually along the feed flow passage across any serial pattern of membrane surface. The only way to control concentration polarization is to maintain a reasonably high feed velocity across the membranes—which is a problem of hydraulic design.

It appears from this treatment that diffusion-controlled reverse osmosis may be of universal application conceptually, but faces some peculiar limitations when it comes to practical separations. First of all, as already mentioned, the process is confined to dilute solutions, there is no chance to desalt the Dead Sea (osmotic pressure > 200 bar) by reverse osmosis. It is perhaps more than coincidence that membrane performance is at its best at "physiological" salt concentrations (around 1 %), for this suggests that artificial (technical) membranes are not altogether different (though certainly less refined) than biological membranes. By a similar argument, and on first sight unexpectedly, it is not even desirable to do much better than nature: The higher the permeation rate of water through the membrane, the steeper the increase in concentration polarization. For hydraulic reasons, present-day apparatus will not handle more than about $2\,m^3$ of product water per square meter of membrane area and day. With certain brackish water membranes this limit is already being approached; seawater membranes rarely exceed a production rate of $500\,l/m^2\,d$. A final limitation, which only reluctantly has been accepted as a basic problem of reverse osmosis, concerns the fact that natural waters invariably contain particulate matter, living and dead, accumulating in a surrounding of high electrolyte concentration at the solution-membrane interface. It is the diminution in time-dependent flux due to membrane fouling which limits the availability of technical reverse osmosis installations.

4. Membrane Properties

Returning again to the conceptually possible, an intriguing question is whether, given a suitable transport model, membranes may be tailored to specific separation problems. If the solution-diffusion model does not really tell us how a membrane functions (much less so any "black box" treatment), it does provide some guidance in the orderly search for osmotic membranes. This involves two problem areas, which must be investigated separately: Finding a (polymeric) material that will discriminate permeability-wise between the solution components under consideration,—and making this material into a film of realistic productive capacity and mechanical strength.

In terms of the flow equations [Eqs. (11, 12)] the "conductivity" of a candidate membrane material for solvent and solute is represented by the permeabilities $c_1 D_1$ and KD_2, respectively, determined by absorption-desorption experiments. The most thoroughly investigated families of compounds for purposes of osmotic desalination are the cellulose acetates and the aromatic polyamides, the permeabilities of which towards water and sodium chloride are given in Table 1[8,9].

Table 1. Water and salt permeabilities in homogeneous membrane films. CA = cellulose diacetate; CTA = cellulose triacetate; PA = an aromatic polyamide.

Membrane	Acetyl [%]	H_2O c_1 [g/cm³]	H_2O D_1 [cm²/s]	NaCl K [a]	NaCl D_2 [cm²/s]
CA	33.6	0.29	5.7×10^{-6}	0.17	2.9×10^{-8}
CA	37.6	0.20	2.9×10^{-6}	0.060	4.3×10^{-9}
CA	39.8	0.16	1.6×10^{-6}	0.035	9.4×10^{-10}
CTA	43.2	0.12	1.3×10^{-6}	0.015	3.9×10^{-11}
PA	—	0.49	1.5×10^{-6}	0.2	1.2×10^{-10}

[a] K = (g NaCl/cm³ film)/(g NaCl/cm³ solution).

Selectivity rests primarily with the relative mobilities, which—in the case of the cellulose acetates—are also the most sensitive towards degree of acetylation with consequent effect on the potential salt rejection.—The permeation rate of water is directly related to the water content of the membrane phase, c_1, thus limiting the candidate membrane materials to hydrophilic polymers. Since it eventually governs the output of the process, the fractional water content is a highly important design variable. It is also open to some terminological confusion: A membrane material may contain two kinds

of water, *viz.* primary water as molecular constituent of the polymer matrix, and secondary water in the form of droplets or pore fluid, as in a sponge. While the total liquid transport clearly depends on both kinds, primary water will not enhance salt passage whereas secondary water does. With no coupling between the flows of water and salt, as postulated by the solution-diffusion model, the water term of Eq. (11) and Table 1 is strictly primary, the onset of pore formation with increasing total water content registering as a sudden increase in salt flow[10]. The occasional reference to the total (analytical) water concentration as "porosity" is, therefore, quite misleading.

Given the permeability data it is possible to calculate a "theoretical" or "intrinsic" salt rejection of a candidate membrane material for assumed conditions of concentration and pressure. The permeate salt concentration, c_2'', is determined by the relative flows of salt and water, *i.e.*

$$c_2'' = \frac{F_2}{F_1} c_1'' \tag{14}$$

implying that the salt rejection is independent of the membrane thickness, Eq. (13). The resultant expression in terms of the present model is

$$R = \left[1 + \frac{K D_2 R T}{c_1'' D_1 \bar{v}_1 (\Delta p - \Delta\pi)}\right]^{-1} \tag{15}$$

where c_1'' is the water concentration of the permeate, essentially 1.0 g/cm^3. For example, a membrane of CA-39.8 (cf. Table 1) applied to a 3.5 % sodium chloride solution at a gross pressure of 100 bar has a theoretical salt rejection of 99.8 %,—intrinsically, that is[11].

If the search for suitable osmotic materials has at least some rational basis, making membranes thereof remains largely an empirical task—it is an art illuminated by scattered experience. Since the flow of water, Eq. (11), is inversely proportional to the membrane thickness (Δy) with no effect on rejection, the efforts concentrate on making the membranes as thin as possible without incurring imperfections. This is achieved by a most disparate set of recipes, always to the effect that the membranes are reduced to a skin-layer covering one surface of an otherwise porous substrate film. If "integral-asymmetric", the layered structure emerges in a closed manufacturing process involving one and the same polymer throughout; if "composite-asymmetric", the skin-layer constituting the membrane proper is applied separately, either in the form of an ultra-thin homogeneous polymer film or by coverage with a polymeric or reactive monomeric solution. With integral-asymmetric membranes, of which the now classical cellulose acetate membranes of *Loeb-Sourirajan*[12] are a typical example, skin thickness ranges down to perhaps 1000 Å (0.1 μm); composite membranes, in particular the recent aromatic polyamide varieties[13], may reach an effective thickness of 200 Å. These are in fact the most promising classes of compounds (and the only ones to be used commercially) out of a vast and varied number of candidates evaluated to date[14]. Their success is not exclusively due to their superior intrinsic properties, but is likewise a result of the fact that these properties may be realized in the configuration of a membrane.

The concept of the "intrinsic membrane" is deceptive, for it completely ignores all manufacturing and operational circumstances. Experimentally, it is approximated by the "initial performance" of a laboratory membrane in short term reverse osmosis tests with clean salt solutions under conditions of zero recovery. The "actual performance" of production membranes is subject, not only to the limitations inherent in an osmotic separation, but also to the engineering design of the apparatus in which they are used.

The principal design concepts of applied reverse osmosis—referred to as module concepts—are summarily represented

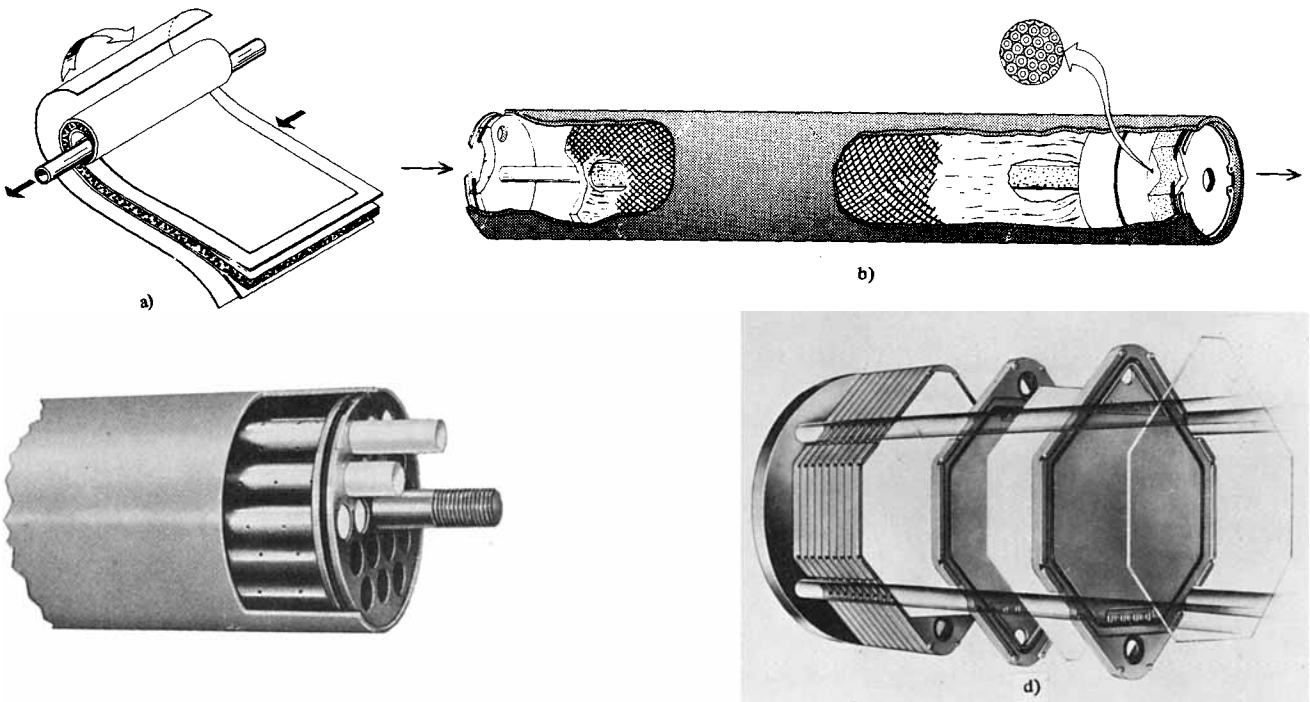

Fig. 4. Principal design concepts of applied reverse osmosis. Closed systems with prefabricated elements of a) spiral wound flat membranes or b) bundled hollow fibers; open systems with accessibly mounted membranes in c) tubular form or as d) flat sheets in serial arrangement [15].

in Figure 4[15]. The various designs are more than just geometrical isomers of membrane accomodation, each implying a certain mode of operation, and each adapting differently to environmental water conditions. Generally speaking, closed systems (Fig. 4a and 4b) requiring an elaborate feed water pretreatment are preferably used under conditions which favor a continuous quantity operation, while open systems (Fig. 4c and 4d) are less sensitive towards difficult feed water conditions and more versatile in small scale operation.

5. Conclusion

Reverse osmosis represents a highly attractive separation principle, whose somewhat uncertain credibility as a technical unit operation is due, not to a lack of basic development, but to overoptimism in projecting the intrinsically possible onto the harsh reality of actual feed waters. Future developments will have to focus on overall reliability rather than selectively on miracle membranes.

Molecular States and Molecular Orbitals[1, 2]

By Hans Bock[*]

Dedicated to Professor Erich Hückel on his 80th birthday and on the occasion of the 450th Anniversary of the foundation of Marburg University.

Molecules change their properties on acquisition or loss of energy. The state of a molecule can be characterized by the difference between its energy and that of the preceding initial state or that of the subsequent final state, as well as by the respective charge distribution. Molecules in their various energy states each display a particular structure and characteristic properties, and it is these entities which the chemist uses as synthetic building blocks.—The best model hitherto available for describing molecular states is the molecular orbital representation. Molecular orbitals are especially suitable for comparing mutually corresponding molecular states of similar compounds, and thus provide a manifold and stimulating overview of large areas of chemistry.—An attempt will now be made to point out important characteristic parameters of molecular states and to explain the rules governing their description by molecular orbitals, while circumventing mathematical barriers. A principal objective is the comparison of states of "chemically related" molecules with regard to the connection, the arrangement, and the potential of their atoms. The simple models employed for this purpose, whose inherent limitations and potential expansions are discussed, have meanwhile become valuable tools in the hand of the chemist.

Between 1789 and 1793, Georg Christoph Lichtenberg made the following entry in his Sudelheft No. I: "Wir sehen in der Natur nicht Wörter, sondern immer nur Anfangsbuchstaben von Wörtern, und wenn wir alsdann lesen wollen, so finden wir, daß die neuen sogenannten Wörter wiederum bloß Anfangsbuchstaben von anderen sind".[**]

1. To Measure or to Calculate?

The tetra-atomic molecule thioformaldehyde $H_2C{=}S$[3], detected in interstellar space, can be prepared pure by thermal elimination of HCl from methanesulfenyl chloride and subsequent deposition of NH_4Cl with ammonia (Fig. 1:A) and subjected to spectroscopic analysis (Fig. 1:B). Computer simulation of an almost superposable photoelectron spectrum[4] (Fig. 1:C) takes about 2 CPU hours (IBM 360/91).

Procedures such as PNO/CI (*P*seudo*n*atural *O*rbital/*C*onfiguration *I*nteraction) and CEPA (*C*oupled *E*lectron *P*air *A*pproach) developed by *Meyer*[5], or the GF method (many-

[**] "In Nature we see not words but only the first letters of words, and when we wish to read we find that the new so-called words are once again mere first letters of other words".

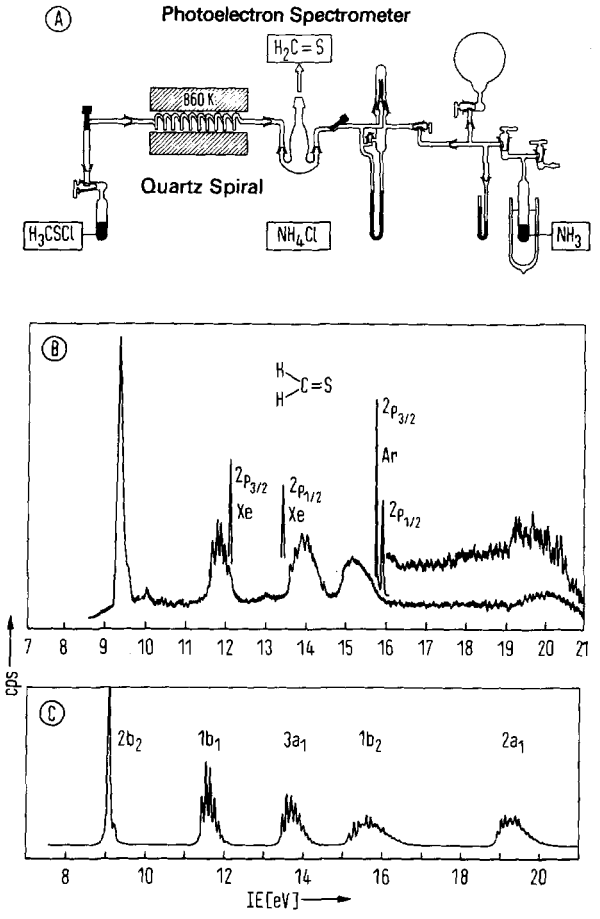

Fig. 1. For gas-phase preparation (A) of thioformaldehyde [3], methanesulfenyl chloride is passed through a quartz spiral heated to 860 K. Hydrogen chloride can be removed from the resulting gas mixture by deposition as ammonium chloride on reaction with ammonia introduced from a storage system *via* a fine-control valve. The reaction conditions such as furnace temperature or ratio of the gaseous reactants H_3CSCl to NH_3 are best adjusted with the aid of a photoelectron spectrometer, *i.e.* on the basis of the appearance and disappearance of the known ionization bands of HCl and NH_3. The PE spectrum (B) also provides a check on the purity of $H_2C{=}S$. Additional calculation [3, 4] of the ionization band pattern (C), a "fingerprint" of the molecule, also permits unequivocal identification of the reaction product $H_2C{=}S$.

body Green Functions)[4] utilized for reproduction of the PE spectrum (Fig. 1:C) permit calculation of some state data of gaseous, *i.e.* isolated, molecules up to the size of, say, *para*-difluorobenzene $C_6H_4F_2$[6] with a surprising degree of accuracy, *e.g.* ionization energies to within deviations of less than ± 0.3 eV[7].

Thus it is possible today to reproduce individual properties, especially those of small molecules, to within the limits of experimental error[7, 8] by calculation; or, generalizing, to satisfactorily approximate solutions of the Schrödinger equation by numerical methods[9]. This achievement has various consequences[10] which will come to affect the interrelationships between experimental practice and the application of theoretical tools. Some of these aspects[10] are presented in the simplified flowsheet of Figure 2[2c, d].

The provocative question "To measure or to calculate?" is probably best answered by pointing out how successful and stimulating a combination of the two can be. Thus correlation of experimental and calculated data, and especially the comparison of measured data for given states of chemically related molecules, will continue to promote the chemist's

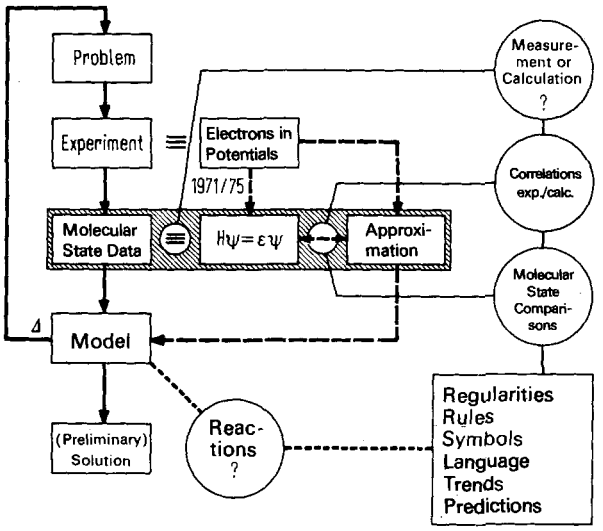

Fig. 2. Experimental investigation of a chemical problem (→) leads to individual experimental data which are generally compared with other results, *i.e.* verified by comparison with an (empirical) model. This cycle can be advantageously coupled with a loop (----→) in which the observations, after correlation with the behavior of electrons in potential fields, can be described in appropriate approximations, thus providing important information about the basic properties and scope of models. In particular, acting as their own computer, molecules "print out" complete solutions of the Schrödinger equation $H\psi=\varepsilon\psi$ (which cannot be solved exactly for many-particle systems) in the form of their measured data. Even simple approximations such as those proposed by *E. Hückel* in his epoch-making [11] work on π-systems [12] permit comparison of numerous individual data and derivation of far-reaching consequences and predictions from the resulting models.—The recent breakthrough achieved in numerically approximating solutions of the Schrödinger equation with newly developed calculating procedures [9] also enhances the importance of other correlations between experimental and calculated quantities and of comparisons between states of chemically related molecules. This could represent the starting point for a more intense development of a metatheory [10] providing a unified description of regularities, permitting manifold predictions, and also yielding models suitable for application to reaction courses as more and more detailed knowledge becomes available.

understanding of the substances with which he is dealing. In addition, however, greater effort could be invested in the development of a metatheory which facilitates an overall view of the material and energetic multiplicity by describing regularities and setting up rules, provides a unified set of symbols and a common language, reveals tendencies, and supports predictions to a greater extent than was formerly possible[10]. More attention should also be directed to theoretical calculation of quantities not readily accessible to experimental determination, *e.g.* on energy or reaction surfaces[13]. This would provide a means of incorporating the reactivity of chemical compounds in improved models as increasingly detailed knowledge becomes available concerning the course of reactions.

The following remarks about molecular states and their description by molecular orbitals, together with the examples largely selected according to their didactic value, are intended to arouse the preparative chemist's interest in exploiting the tools put at his disposal by theory.

2. Properties of Molecules in Their Various States

If energy is supplied to or withdrawn from a molecule it goes into another state. If, in addition, electrons are acquired or released during this transition then molecular ions, which may also be radicals, are formed as new particles which can themselves exist in numerous states of various energies. The

energy differences can be recorded by a variety of measuring techniques (cf., *e.g.*, Fig. 3) and show that the total energy of the individual molecular states increases on going from those of a stable radical anion $M^{\bullet\ominus}$ *via* those of the neutral molecule M to those of the radical cation $M^{\bullet\oplus}$ (Fig. 3).

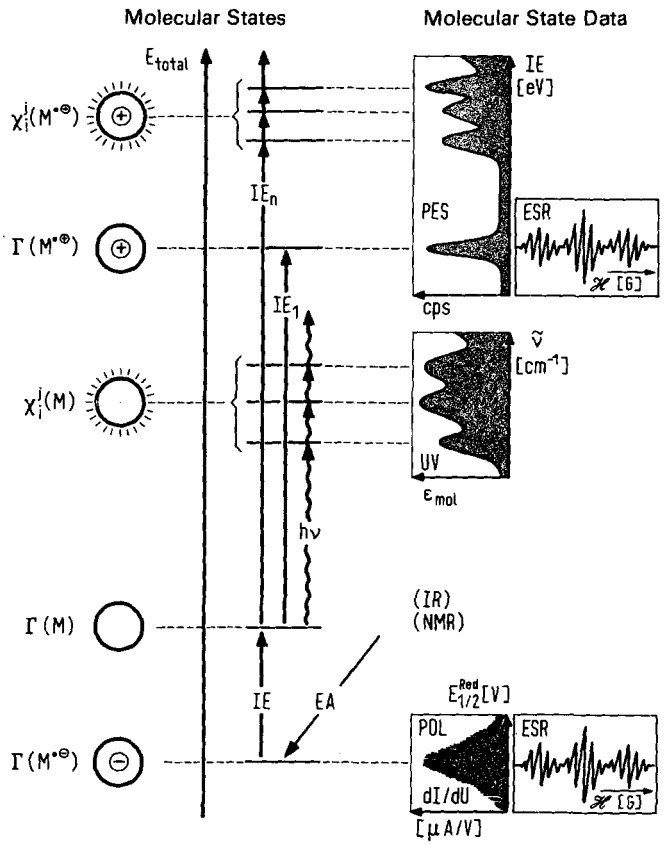

Fig. 3. A neutral molecule M in its ground state $\Gamma(M)$ can take up certain amounts of energy; thus on absorption of UV radiation $E = h\nu$ it is transferred into one of the numerous electronically excited states $\chi_i^j(M)$. Larger amounts of energy may lead to loss of an electron, for example to form the radical cation $M^{\bullet\oplus}$: the first ionization energy IE_1 generates its ground state $\Gamma(M^{\bullet\oplus})$; the higher ionization energies $IE_{n(>1)}$ likewise observable in the photoelectron spectrum (PES) produce its electronically excited states $\chi_i^j(M^{\bullet\oplus})$. In contrast, on acceptance of electrons to form a stable radical anion $M^{\bullet\ominus}$, *i.e.* given a positive electron affinity EA, the total energy becomes more negative; the ionization reaction $\Gamma(M^{\bullet\ominus}) \rightarrow \Gamma(M) + e^{\ominus}$ requires energy. In solution, radical anions can be stabilized by ion-pair formation with the counterion and by solvation; their energy difference relative to M can be measured polarographically (POL) as the half-wave reduction potential $E_{1/2}^{Red}$. Information concerning the spin-, and hence charge-density in the radical ions $M^{\bullet\oplus}$ and $M^{\bullet\ominus}$ can be gained from high-resolution electron spin resonance (ESR) spectra. For the nomenclature of molecular states, cf. ref. [14].

Radical cation states of molecules are especially suitable for an introductory discourse: they can be observed by the straightforward and direct technique of photoelectron spectroscopy[2c–e, 15], are characterized by a typical electron hole, and as shown below can usually be interpreted on the basis of simple models. A wealth of information about the properties of radical cations can be gleaned from PE spectra[2e, 15b, c]; this will be illustrated by clear-cut examples of relatively small molecules which in some cases experience only slight structural deviations (Figs. 4 and 6) and in others even undergo changes in structural type (Figs. 5 and 6).

In the PE spectrum of HBr[15a, 16] (Fig. 4) the first two ionizations can be assigned to the bromine electron pairs perpendicular to the molecular axis. Two radical cation states $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ result which are, however, not "degenerate",

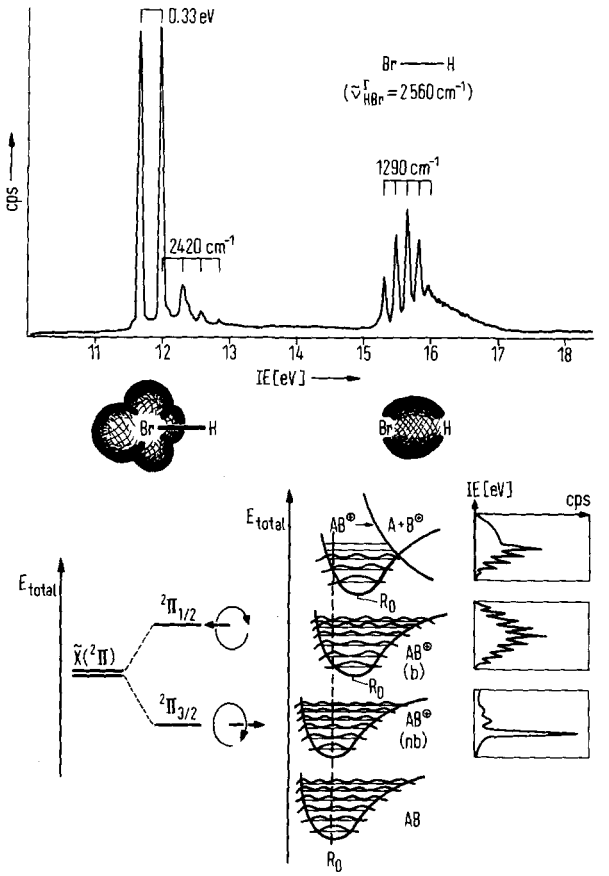

Fig. 4. In the photoelectron spectrum of HBr [15a, 16] a total of 4 ionizations are observed—corresponding to the presence of 8 valence electrons. Of the three lowest energy ionizations shown, the bands at 11.68 and 12.01 eV can be assigned to the Br electron pairs, and that at 15.60 eV to the BrH bond: in the nomenclature of spectroscopy [14] the two (spin/orbit) coupled radical cation states are designated as $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$, and the simple one as $^2\Sigma^+$. They differ, among other things, in their stretching frequencies $\tilde{\nu}_{HBr}^{\oplus}$, which are hardly changed ($^2\Pi$) and almost halved ($^2\Sigma^+$), respectively, relative to that of the uncharged molecule $\tilde{\nu}_{HBr}$. This result can be interpreted, together with the differing band shapes, in terms of the potential energy curves as follows: if the equilibrium distance R_0 remains unchanged during the vertical transition to the radical cation state, *i.e.* if an (almost) nonbonding electron (nb) is ionized, then $\tilde{\nu}_{AB}^{\oplus} \approx \tilde{\nu}_{AB}$ and owing to the most frequent $0 \rightarrow 0$ transition a needle-shaped principal band will result. If R_0 increases, *i.e.* if a bonding electron (b) is removed, then $\tilde{\nu}_{AB}^{\oplus}$ becomes smaller relative to $\tilde{\nu}_{AB}$ and the most frequent vertical transition now appears near the center of the band. If the resulting radical cation $AB^{\oplus}$ is unstable, *e.g.* towards dissociation into $A^{\bullet} + B^{\oplus}$, then the vibrational fine structure vanishes—the curve of the dissociative state and that of the binding state cross in the potential energy diagram—as in the present case for $HBr^{\bullet\oplus}$, which decomposes into $H^{\bullet} + Br^{\oplus}$ at 15.85 eV [16].

i.e. of equal energy, but owing to different kinds of orientation of spin and orbit angular momentum[15b, c, 17] are split by 0.33 eV (Fig. 4). The vibrational fine structure recognizable following the second main band exhibits a frequency which is only slightly lower than the stretching frequency in the neutral HBr molecule: hence the electron hole arising on ionization of a "nonbonding" electron from the bromine electron pairs hardly exerts any significant effect on the force constants $f_{HBr}^{\oplus} \sim f_{HBr}$, and the equilibrium distance $R_0^{\oplus}$ accordingly remains practically unchanged compared with R_0[16]. In contrast, the third PE band, assignable to ionization from the σ_{HBr} bond, displays an approximately halved radical cation vibrational frequency $\tilde{\nu}_{HBr}^{\oplus}$ (Fig. 4)—corresponding to a diminished force constant $f_{HBr}^{\oplus}$ and an increased equilibrium distance $R_0^{\oplus}$ in this state. That each individual molecular state exhibits characteristic properties and possibly a specific

reactivity, is apparent from the dissociation $HBr^{\oplus} \rightarrow H^{\bullet} + Br^{\oplus}$ occurring in the third radical cation state above 15.85 eV—recognizable from the disappearance of vibrational fine structure (Fig. 4).

The experimental data for $HBr^{\bullet\oplus}$ demonstrate that molecular states have different kinds of charge distributions depending upon their energy, and hence also different properties including different kinds of reactions. In molecules containing more than two atoms, the overall structure, which is not necessarily linear, can therefore change according to the state, as will now be exemplified in more detail for certain radical cation states of disilane (Fig. 5) and ammonia (Fig. 6).

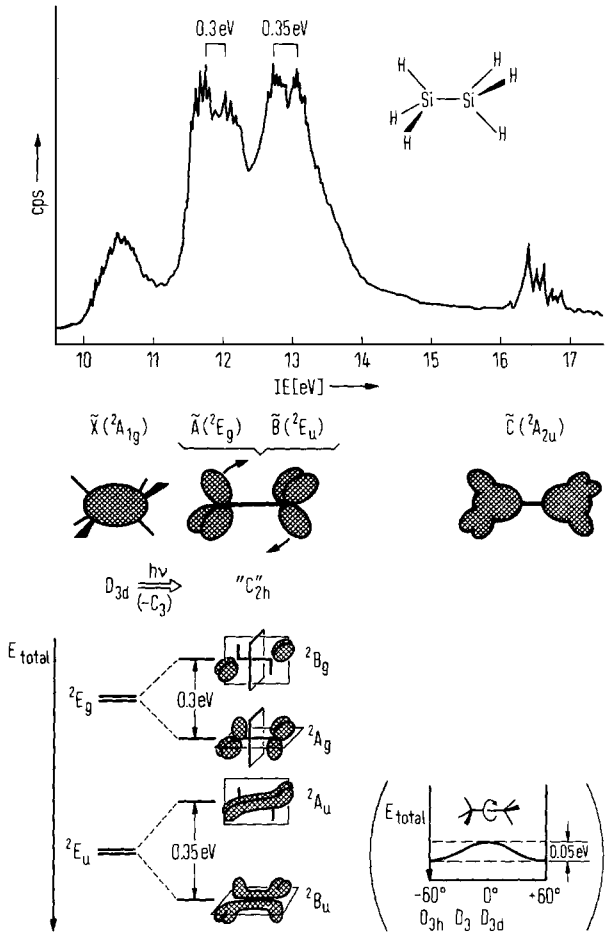

Fig. 5. In the photoelectron spectrum of Si_2H_6 [18] 7 ionizations are expected, corresponding to 14 valence electrons. Of these ionizations 2 each should lead, in the preferred staggered conformation of D_{3d} symmetry, to energetically degenerate radical cation states. Thus a total of 5 PE bands are predicted, assignable to the following $H_3Si—SiH_3^{\bullet\oplus}$ states given in the order of increasing energy (concerning nomenclature, cf. [14, 19]): σ_{SiSi} ionization $\rightarrow \tilde{X}(^2A_{1g})$, σ_{SiH_3} ionization $\rightarrow \tilde{A}(^2E_g)$ and $\tilde{B}(^2E_u)$, and the ionizations having large $3s_{Si}$ components $\rightarrow \tilde{C}(^2A_{2u})$ and $\tilde{D}(^2A_{1g})$, with the latter outside the range of measurement. It is observed, however, that the second and third PE bands are split by 0.3 and 0.35 eV, respectively. This is because the energetic equality of the degenerate states $\tilde{A}(^2E_g)$ and $\tilde{B}(^2E_u)$ is removed by a "Jahn-Teller distortion" of $H_3Si—SiH_3^{\bullet\oplus}$: two SiH bonds probably bend, the threefold symmetry axis vanishes ($-C_3$), the structure of the resulting radical cation belongs to the C_{2h} symmetry group, and the degenerate states split ($^2E_g' \rightarrow {}^2B_g + {}^2A_g$; $^2E_u \rightarrow {}^2A_u + {}^2B_u$). The splitting of the second and third PE bands cannot be attributed to a conformational rotation ($D_{3d} \rightarrow D_3 \rightarrow D_{3h}$) about the SiSi bond since the threefold axis and thus the degeneracy would be retained in the process; furthermore, the rotational barrier amounts to only 0.05 eV [18].

Assuming the species to have the same structure as the neutral molecule, the disilane radical cation $H_3Si—SiH_3^{\bullet\oplus}$ is expected to display two sets of two degenerate states of equal energy: the pertinent bands should therefore have double intensity but only one maximum. However, the PE spectrum of disilane (Fig. 5) tells a different story: the second and third PE bands are split by 0.3 and 0.35 eV, respectively[18]. This observation cannot be attributed to a conformational change since the degeneracy of the states would be conserved on rotation about the SiSi bond and the energy barrier for such a rotation is a mere 0.05 eV. Rather, a structural change must have taken place which destroys the threefold axis, *e.g.* by analogy with the $H_3C—CH_3^{\bullet\oplus}$ cation[18], by deformation of SiSiH angles (Fig. 5). Restructuring of the $\tilde{A}(^2E_g)$ and $\tilde{B}(^2E_u)$ states of the disilane cation is not a unique occurrence: degenerate radical cation states of non-linear molecules are generally unstable towards such a "Jahn-Teller distortion". The energy gap arising on removal of degeneracy can exceed 1 eV[15b,c].

Information like this read off from PE spectra is open to generalization: during mono-ionization from the ground state of a molecule having n valence electrons to generate one of the possible $n/2$ radical cation states (Fig. 3), both the molecular structure and other molecular properties can undergo drastic changes. This is impressively demonstrated by a comparison of vibrational frequencies of the tetraatomic molecules NH_3, PH_3, and PF_3 and those of their radical cations $NH_3^{\bullet\oplus}$, $PH_3^{\bullet\oplus}$, and $PF_3^{\bullet\oplus}$[2e, 20] (Fig. 6).

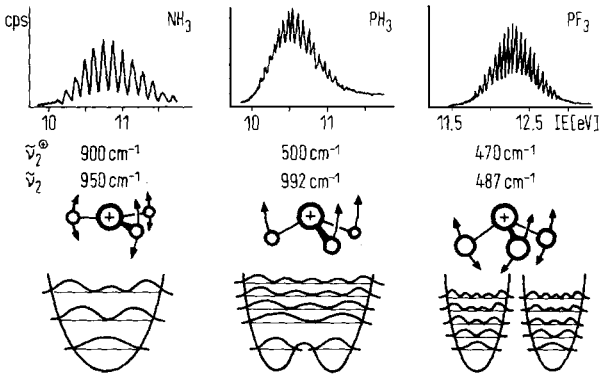

Fig. 6. The first band of the photoelectron spectra of NH_3, PH_3, and PF_3 [20], which is assigned to ionization from the n_N or n_P electron pair, exhibits a marked vibrational fine structure. Some 20 peaks are recognizable, from which the frequency of the symmetrical deformation $\nu^{\oplus}$ of the radical cation can be determined to within $\pm 20\,cm^{-1}$. On comparison of $\tilde{\nu}^{\oplus}$ with the ground state frequency of the neutral molecule $\tilde{\nu}$, a constant (NH_3, PF_3) or halved value (PH_3) is found [2e, 20]. Constant values result when no molecular inversion occurs, as a consequence of flattening of the molecular skeleton yielding the planar $NH_3^{\bullet\oplus}$ species or of an excessively high inversion barrier in pyramidal $PF_3^{\bullet\oplus}$. Halving of frequency [21] occurs at low inversion barriers, *e.g.* in the flattened pyramid of $PH_3^{\bullet\oplus}$. In the potential energy diagrams (cf. Fig. 4), these results are described in terms of a common potential trough ($NH_3^{\bullet\oplus}$), two extensively overlapping potential troughs ($PH_3^{\bullet\oplus}$), or two completely separate potential troughs ($PF_3^{\bullet\oplus}$) [2e, 20].

The first ionization of the pyramidal compounds XH_3 and XF_3 occurs from the electron pairs n_x[2e, 20–22]. Comparison of the symmetrical deformation vibrations of the neutral molecule (Fig. 6: $\tilde{\nu}_2$) and the radical cation (Fig. 6: $\tilde{\nu}_2^{\oplus}$) demonstrates just how diverse the changes in properties can be, which arise on removal of an almost nonbonding electron: in the planar[20] species $NH_3^{\bullet\oplus}$ no inversion can occur and the (slightly lower frequency) deformation vibration can be described by a single potential trough (Fig. 6). The ionization $PH_3 \rightarrow PH_3^{\bullet\oplus} + e^{\ominus}$ widens the HPH angle from 93.3° to about 110°[20]; the halving of frequency observed in the PE spectrum (Fig. 6: $\tilde{\nu}_2^{\oplus} \approx \frac{1}{2}\tilde{\nu}_2$) is explicable as due to extensive interpenetration of the potential troughs corresponding to the two inverto-

mers[21b]. In contrast, the molecular structure is largely retained on electron ejection from $PF_3 \rightarrow PF_3^{\bullet\oplus} + e^{\ominus}$, and the high inversion barrier describable by two distinct potential troughs[20] prevents frequency halving of the symmetrical deformation vibration $\nu_2^{\bullet\oplus}$.

Even in the case of constant electron occupancy in the initial and final states a supply of energy might effect a drastic redistribution of charge: frequently cited structural modifications[21c, 22] accompanying transitions into other electronic states include the mutual twisting of the two halves of the molecule of ethylene and the bending of acetylene in the lowest excited state, as well as the bending of carbon dioxide or the stretching of water on absorption in the vacuum UV region (Fig. 7).

From the sheer number of structural modifications of molecules known to occur on uptake of energy and—more generally—from the accompanying modifications of molecular properties caused by redistribution of charge it follows that:

The chemist's synthetic building block with a particular structure and characteristic properties is always a molecule in a state of specific energy and charge distribution.

Reactions are likewise not typical for a molecule but—as already emphasized for $HBr^{\bullet\oplus}$ (Fig. 4)—for a particular molecular state. This is strikingly confirmed by the different kinds of reaction pathways emanating from different kinds of photochemically excited states[23], *e.g.* from the $^3(n\rightarrow\pi^*)$ triplet state and from the $^1(\pi\rightarrow\pi^*)$ singlet state of adamantanethione[24] (Fig. 8).

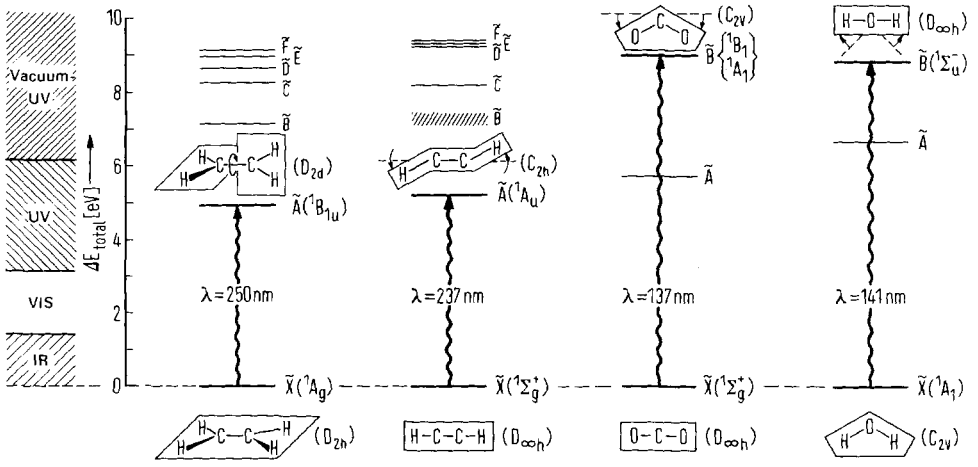

Fig. 7. The structure of a molecule can also be modified after energy transfer through a photon if the number of electrons remains constant (cf. Figs. 3 to 6). Thus ethylene is twisted on $\pi\rightarrow\pi^*$ excitation in the UV region; at the minimum of the potential energy curve of the excited state $\tilde{A}(^1B_{1u})$ [14] the two H_2C halves of the molecule are mutually perpendicular (D_{2d} symmetry). Linear in its ground state $\tilde{X}(^1\Sigma_g^+)$, acetylene is doubly bent in the first electronically excited state $\tilde{A}(^1A_u)$. Excitation with short-wave light ($\lambda = 137$ nm) bends carbon dioxide; in contrast, water is stretched in its 2nd excited state $\tilde{B}(^1\Sigma_u^-)$ in the vacuum UV region. In the other states shown ($\tilde{A}, \tilde{B}, \tilde{C}, \tilde{D}$...) there is either no structural change [21, 22] or the geometry of the excited state is (still) unknown.

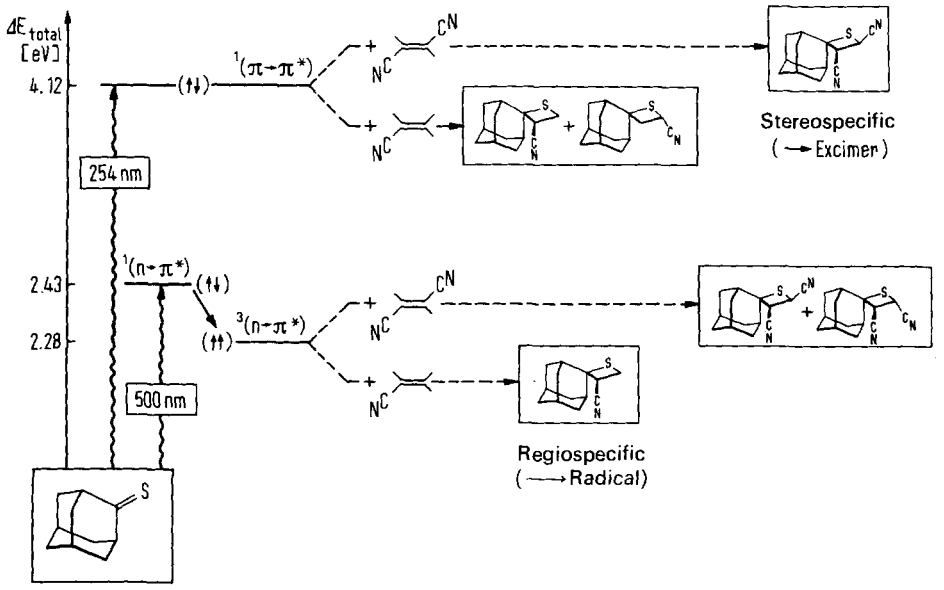

Fig. 8. Adamantanethione exhibits $^1(\pi\rightarrow\pi^*)$ and $^1(n\rightarrow\pi^*)$ electronically excited states separated by 1.69 eV; the latter undergoes radiationless transition into the lower-energy triplet state $^3(n\rightarrow\pi^*)$ with two unpaired ($\uparrow\uparrow$) electron spins [24]. Reaction with acrylonitrile or fumaronitrile on irradiation with 254-nm light ($\pi\rightarrow\pi^*$) or 500-nm light ($n\rightarrow\pi^*$) therefore lead to different reaction types and reaction products [24]: the $^3(n\rightarrow\pi^*)$ diradical reacts regiospecifically with acrylonitrile *via* the radical intermediate of most favorable energy. In the $^1(\pi\rightarrow\pi^*)$ singlet state with paired electron spins ($\uparrow\downarrow$) addition of fumaronitrile occurs stereospecifically *via* an excimer complex [24].

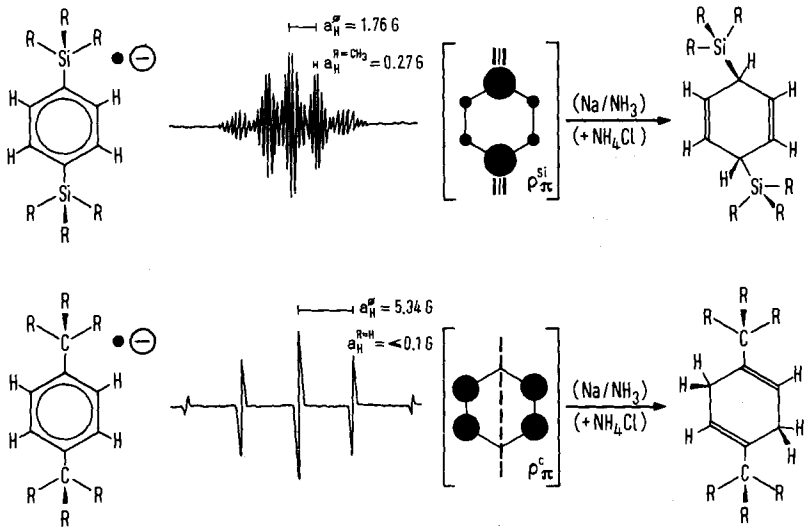

Fig. 9. 1,4-Bis(trimethylsilyl)benzene can be reduced to the radical anion by potassium in dimethoxyethane. Its ESR spectrum [25] displays the quintet of 4 phenyl protons with a gap of 1.76 G between the corresponding signals, which are further split by the 18 equivalent methyl protons ($R = CH_3$) (intensity ratio outer line: inner line = 1:48620). The *p*-xylene radical anion ($R = H$), on the other hand, yields an ESR spectrum which, while revealing a more strongly split quintet of the 4 phenyl protons, gives no evidence for additional coupling with the methyl protons: hence the substitution sites must lie in a nodal plane in which the spin density ρ_π is approximately equal to zero. The charge density is consequently also low and preparative protonation by treatment with NH_4Cl after prior Birch reduction (Na/NH_3) accordingly proceeds exclusively a positions 2 and 5. As indicated by the drop in the phenyl proton coupling constant a_H^{ar} from 5.34 to 1.76 G, the electron density in these positions is lower in the trimethylsilyl derivative which is protonated solely in positions 1 and 4 [26] where a high spin, and hence a high charge density is now evidenced by the clearly resolved coupling of the methyl protons $a_H^{R=CH_3}$.

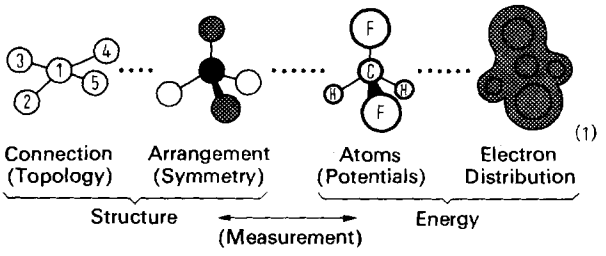
As shown by the excitation and reaction scheme for adamantanethione, the reactions starting from the $^3(n\rightarrow\pi^*)$ triplet state proceed by a radical mechanism[24] and involve the radical intermediate of most favorable energy: they are therefore regiospecific but not stereospecific. In contrast, formation of an excimer complex is observed to follow excitation into the $^1(\pi\rightarrow\pi^*)$ singlet state[24]: acrylonitrile is not longer added regiospecifically, while fumaronitrile does undergo stereospecific addition.

Experimental evidence for the variety of reactions for various charge distributions is supplied by, *e.g.*, combined ESR[25] and preparative studies[26] on the reduction of 1,4-dialkyl- and of 1,4-bis(trimethylsilyl)benzene derivatives (Fig. 9).



From the ESR spectra of benzene radical anions (Fig. 9) we can deduce coupling constants a_H^π which are directly proportional to the π-spin populations ρ_π at the relevant π centers[27,28]. They furnish the following information about the distribution of the additional electron in variously substituted reference compounds: in the trimethylsilyl derivative the substitution sites 1 and 4 bear the greatest charge, whereas in the *p*-xylene radical ion these positions lie in a nodal plane of negligible spin density (Fig. 9). The ESR evidence can be tested and exploited preparatively: protonation with NH_4Cl after prior Birch reduction with Na/NH_3 always occurs at the centers of greatest electron density. In full accord with the charge distribution estimated from the ESR spectra, the 1,4-bis(trimethylsilyl) compound is hydrogenated only in positions 1 and 4 to yield the corresponding cyclohexadiene, whereas the *p*-xylene radical anion is protonated solely at positions 2 and 5[26] (Fig. 9).

These examples, selected from a wealth of similar ones, document that the molecules in their individual states exhibit specific properties, including a specific reactivity. The number of building blocks available for chemical syntheses is multiplied several-fold by this energetic diversification: the number of 10^7 compounds so far known to result from variation of constituent elements and connections has to be increased for molecules containing N atoms and n valence electrons to include $3N-6$ vibrational modes, at least $n/2$ ionizations, far more than $(\frac{n}{2})^2$ electronic excitations, as well as states arising by other processes. In order to gain some kind of overview of such an enormous variety, to recognize inherent trends and regularities, and to formulate predictions the chemist needs a model containing the parameters of importance for molecular states (Fig. 3) in suitable form, and which is also flexible and open to extension (Fig. 2).

The best model hitherto available for a comprehensive description of molecular states is the molecular orbital representation[29].

3. Description of Molecular States by Molecular Orbitals

What demands does the chemist place on a model for molecular states? As illustrated for H_2CF_2, it must contain the number of atoms, their connection (topology) and their arrangement (symmetry):

(1)

Furthermore, potentials have to be defined for the individual centers, representing various kinds of atoms, in such a way that the resulting electron distribution reproduces all important details of molecular structure such as distances and conformation. The energy must be included in the model as a parameter of molecular state, and changes in characteristic molecular properties should be determinable as a consequence of changes in energy (Fig. 3). For the chemist it is important that such a model permits comparison of experimental data applying to corresponding states of chemically related molecules (Fig. 2).

In simple molecular orbital models, whose utility and limitations will now be considered for various examples, the procedure is to determine the distribution or motion of an electron in the time-averaged field of the atomic nuclei and the other electrons of a molecule. In order to answer the question "when and with what probability will an electron be located at which site?", the $3N$-dimensional total function resulting for N electrons is approximated by a product of three-dimensional functions having particular qualities[30-32]. The (one-electron)

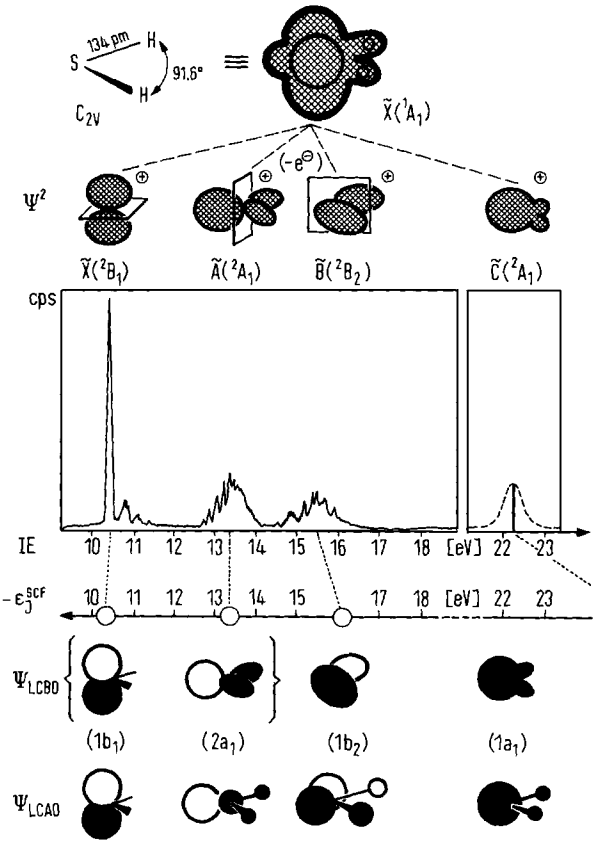


Fig. 10. In the gas phase the HSH molecule has a C_{2v} structure; the electron density distribution in the ground state $\tilde{X}(^1A_1)$ is totally symmetric and almost spherical. Ionization of one of the 8 valence electrons leads to the ground state $\tilde{X}(^2B_1)$ or one of the three excited states [14, 19] $\tilde{A}(^2A_1)$, $\tilde{B}(^2B_2)$, or $\tilde{C}(^2A_1)$ of the radical cation $HSH^{\bullet\oplus}$, which exhibit 0 or 1 zero site planes with respect to the resulting electron hole. All four states of $HSH^{\bullet\oplus}$ are observed in the PE spectrum between 10.47 and 22.2 eV in the HeII region [35]. The ionization energies can be satisfactorily correlated with SCF orbital energies according to *Koopmans* ($IE_n^v = -\varepsilon_j^{SCF}$) [36]. The relevant orbital diagrams can be qualitatively depicted by symmetry-adapted linear combinations (*LC*) of *B*ond *O*rbitals ψ_{LCBO} or of *A*tomic *O*rbitals ψ_{LCAO}. The resulting molecular orbitals ψ frequently change their sign (○|●); the resulting nodal planes of C_{2v} symmetry types (b_1), (a_1), and (b_2) are retained as zero site planes (⊛|⊛) in the squared functions [2]. These can be compared with the electron-hole zero site planes of the radical cation states such as would result from the difference electron densities of the HSH ground state and the individual $HSH^{\bullet\oplus}$ radical cation states.

molecular orbitals thus obtained are especially suitable for discussions of one-electron properties such as the states of radical cations $M^{\bullet\oplus}$ arising on ionization of an electron, in which the electronic interaction and electron distribution still resemble those in the ground state of the neutral molecule M. In such cases *Koopmans'* theorem[33] is valid

$$\Delta E_{total} = IE_n^v \equiv -\varepsilon_j^{SCF} \qquad (2)$$

according to which the vertical ionization energies IE_n^v measured by photoelectron spectroscopy, *i. e.* the energy differences between the particular states ΔE_{total} for ejection of an electron $M + h\nu \rightarrow M^{\bullet\oplus} + e^{\ominus}$ (Fig. 3), can be correlated with calculated (one-electron) orbital energies $-\varepsilon_j^{SCF}$ of "*S*elf *C*onsistent *F*ield" quality[32-34]. Let us therefore begin our description of molecular states by molecular orbitals with the didactically advantageous example of the four states of the triatomic radical cation $HSH^{\bullet\oplus}$ resulting on valence electron ionization and discussible in terms of theorem (2) (Fig. 10).

Ejection of a valence electron from the HSH molecule, which exhibits an almost spherical charge distribution in the ground state, leads to four states of the radical cation $HSH^{\bullet\oplus}$ observable in the PE spectrum. In these states the distribution of the electron hole can be described by calculating the difference electron density between the initial state and pertinent final state (Fig. 10): evidently, zero site planes can result whose positions relative to the molecular skeleton are reflected by the symmetry classification[19] of the radical cation state[14]. If *Koopmans'* theorem (2) applies—*i. e.* if the redistribution of charge (relaxation) and changes in the mutually dependent motion of electrons (correlation) accompanying the ionization process are negligibly small[15b,c]—then the electronic arrangements (configurations) in the individual states can be described by a single set of molecular orbitals ψ. Such a set can be approximately constructed by linear combination of bond or atomic orbitals (Fig. 10). There result symmetry-adapted molecular orbitals ψ which are themselves not experimental observables; however, their squares ψ^2 can be correlated with experimental electron densities. The electron-hole zero site planes in the radical cation states apparently correspond to those of the squared functions ψ^2 and thus to the nodal planes resulting from changes of sign in the molecular orbitals ψ (Fig. 10). The utility of such molecular orbitals ψ or of their squares ψ^2, sketched by hand or plotted by computer, will now be demonstrated by PE spectroscopic comparison of the iso-valence electronic compounds HSH and HOH (Fig. 11).

HSH and HOH differ primarily in the higher effective nuclear potential of the oxygen and in the larger HOH angle. Under the assumption, corroborated in the following, that no essential structural change will occur on ionization to the radical cation ground state $\tilde{X}(^2B_1)$[32], the potential difference can be accounted for by shifting one of the two PE spectra along the ionization energy scale (Fig. 11). The angle opening effects which then become clearly recognizable were correctly predicted by *Walsh* in 1953[37]—ten years before the discovery of PE spectroscopy: $\Delta IE_{1,2}$ decreases and $\Delta IE_{2,3}$ increases. This situation is a consequence of the optimum electron distribution in the individual radical cation states, which depends upon the given potential and can be qualitatively interpreted with the aid of the relevant molecular orbi-

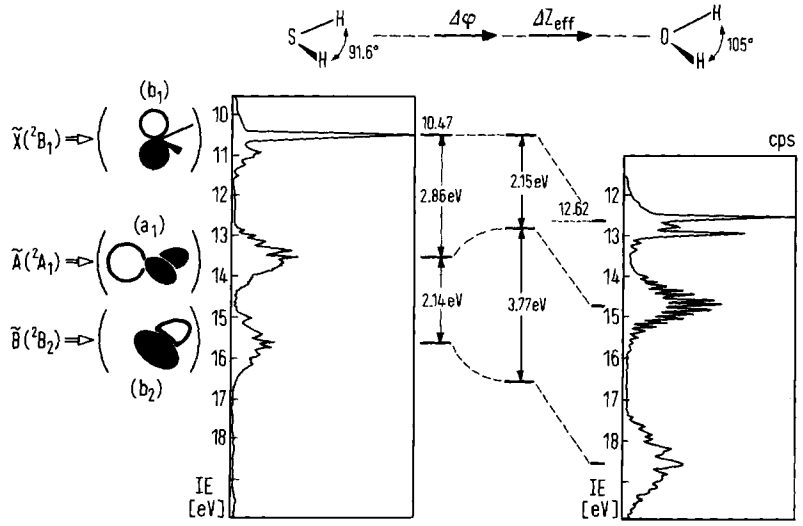

Fig. 11. On comparison of the first three radical cation states $\tilde{X}(^2B_1)$, $\tilde{A}(^2A_1)$, and $\tilde{B}(^2B_2)$ of the iso-valence electronic triatomic molecules HSH and HOH particular attention has to be focused on the change of the bond angle $\Delta\varphi$ and the differing effective nuclear charge ΔZ_{eff} of sulfur and oxygen. Assuming the first ionization, assigned to the nonbonding electron pair, to constitute a suitable internal standard, ΔZ_{eff} can be compensated by a relative shift of the PE spectra [35] by $12.62-10.47=2.15$ eV. The opening of the angle $\Delta\varphi$ can be discussed on the basis of the molecular orbitals (b_1), (a_1), and (b_2) as follows [37]: diminution of the bonding interaction and augmentation of the antibonding interaction in (a_1) raises (destabilizes) this orbital, while diminution of the antibonding interaction in (b_2) lowers (stabilizes) that orbital. There results an experimental Walsh diagram [37] which permits comparison of the radical cation states of the chemically related molecules HSH and HOH.

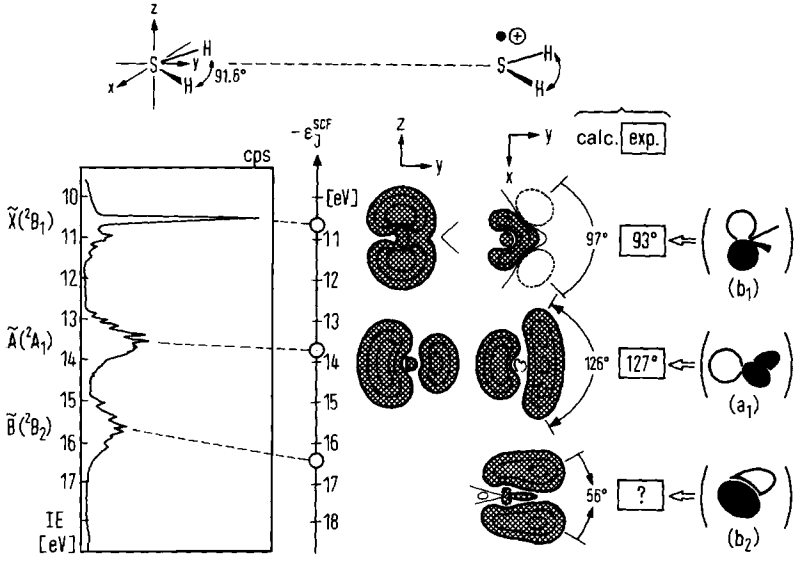

Fig. 12. The radical cation $HSH^{\bullet\oplus}$ expectedly shows structural changes (cf. Figs. 4 to 6) in some of its states. In the ground state $\tilde{X}(^2B_1)$ the angle φ remains almost constant relative to HSH. For the 1st electronically excited state $\tilde{A}(^2A_1)$ an opening to 127° is found spectroscopically [35] and for the 2nd excited state a closing to 56° is calculated [36]. The distribution of the unpaired electron, corresponding to that of the electron hole, follows from the spin population contour diagrams in the zy and xy planes calculated for optimized geometry [36]; negative spin densities are merely shown as dashes. There is satisfactory overall agreement between experimental and calculated data $IE=-\varepsilon_j^{SCF}$ and φ (*ab initio* open shell with STO 3G basis set [36]). Qualitative molecular orbital considerations predict the following angle changes in the $HSH^{\bullet\oplus}$ states: roughly constant according to (b_1) because of the node in the HSH plane; widened according to (a_1) by reduced antibonding interaction and analogously narrowed according to (b_2).

tals[37]: if the bonding interactions characterized by like signs in a molecular orbital increase then the orbital is stabilized, and if the antibonding interactions characterized by a change in sign increase then destabilization occurs (Fig. 11). Conversely, the applicability of such perturbation arguments to the comparison of states of chemically related compounds *via* molecular orbitals according to (2) shows that we are dealing with comparable states having comparable properties; it therefore supports the assignment of the PE spectra and can be extended to other AH_2 compounds which may also have a different number of electrons[37]. In sum, correlation diagrams according to *Walsh*[37], which reproduce changes in

orbital energies accompanying changes in structural parameters, furnish a far-reaching overview of numerous molecular states.

The perturbation arguments also permit prediction of structural modifications in the individual radical cation states of a particular molecule, if these relax towards the potential minima after vertical excitation (cf. Fig. 4): if ionization generates a radical cation state whose representative molecular orbital—now occupied by only one electron—is dominated by strong bonding or antibonding interactions then structural changes mitigating these interactions are expected. The optimum charge distribution in the individual states can be discussed in these terms as will also be demonstrated for $HSH^{\bullet\oplus}$ as example (Fig. 12).

The calculated optimum charge distributions in the individual $HSH^{\bullet\oplus}$ states[36], rationalizable in terms of qualitative molecular orbital perturbation arguments, are in accord with spectroscopic structural parameters[35]: ionization of the nonbonding sulfur electron pair leaves the HSH angle unchanged; in the subsequent first excited state it is opened to 127°. In this context, it should be mentioned as a further example of changes occurring in energetically higher states (cf. Figs. 4 to 7) that both spectroscopic evidence[35] and calculations[36] show the water radical cation $HOH^{\bullet\oplus}$ to be linear in the first electronically excited state (cf. Fig. 12: $\tilde{A}(^2A_1)$).

The above discussion of radical cation states of HSH and HOH (Figs. 10, 11, and 12) demonstrates that *ab initio* SCF spin populations and the "qualitative" molecular orbitals in qualitative agreement therewith, satisfactorily describe the electron distribution and structure, respectively, and thereby facilitate extensive comparison of these chemically related molecules. A further example will illustrate the feasibility of such a state correlation also for characteristic molecular subunits such as π bonds and the way in which the symmetry-adapted qualitative MO models can be energetically parametrized with the experimentally determined energy differences between the states. The π-ionization energies of norbornene, norbornadiene, isopropylidenenorbornadiene, and isopropylidenenorbornane determined by PE spectroscopy represent the starting point of our discussion[38] (Fig. 13).

Three π ionizations are expected and observed in the PE spectrum of isopropylidenenorbornadiene[38] (Fig. 13: $M^{\bullet\oplus}$).

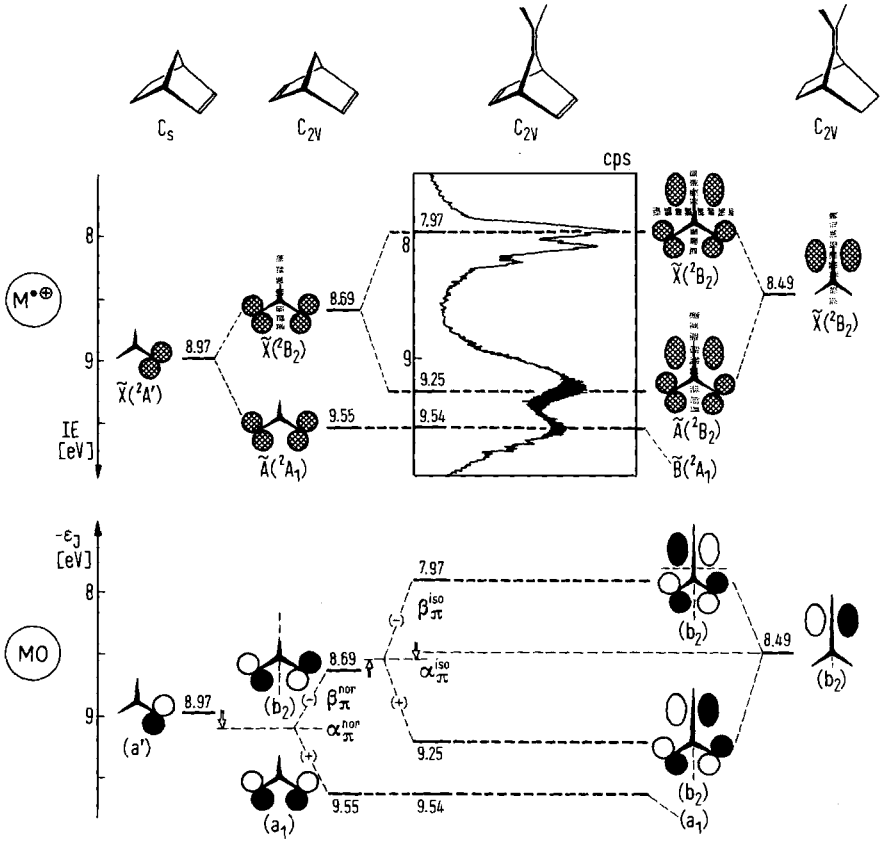

Fig. 13. Comparison of radical cation states $M^{\bullet\oplus}$ of chemically related molecules is a valuable aid in the assignment of PE spectra such as that of isopropylidenenorbornadiene: the first ionization of norbornene (C_s symmetry) and of isopropylidenenorbornane (C_{2v} symmetry) leads to the π-radical cation ground state $\tilde{X}(^2A')$ and $\tilde{X}(^2B_2)$, respectively. Norbornadiene has two $\pi^{\bullet\oplus}$ states, $\tilde{X}(^2B_2)$ and $\tilde{A}(^2A_1)$. Of the three π states of isopropylidenenorbornadiene the highest one $\tilde{B}(^2A_1)$ has the same energy as the $\tilde{A}(^2A_1)$ state of norbornadiene; the two lower ones $\tilde{X}(^2B_2)$ and $\tilde{A}(^2B_2)$ are of the same symmetry type and are split to lower and higher ionization energies relative to the $\tilde{X}(^2B_2)$ states of norbornadiene and isopropylidenenorbornane of equal symmetry.—This situation can be transparently illustrated with π molecular orbitals MO [38, 39]: in norbornadiene the two π orbitals (a_1) and (b_2) split about an average value α_π^{nor} which roughly corresponds to the π level of norbornane ($\Downarrow$). Of the two norbornadiene π orbitals only (b_2) has the correct symmetry to mix with the $\pi(b_2)$ orbital of isopropylidenenorbornane, which leads to the two $\pi(b_2)$ molecular orbitals split about the average value ($\Uparrow\Downarrow$) α_π^{iso}. The third π molecular orbital (a_1) cannot interact with any other orbital of same symmetry and therefore its orbital energy expectedly resembles that of the $\pi(a_1)$ orbital of norbornadiene. The interaction parameters β_π^{nor} and β_π^{iso} can be determined from the PE spectroscopic ionization energies (see text).

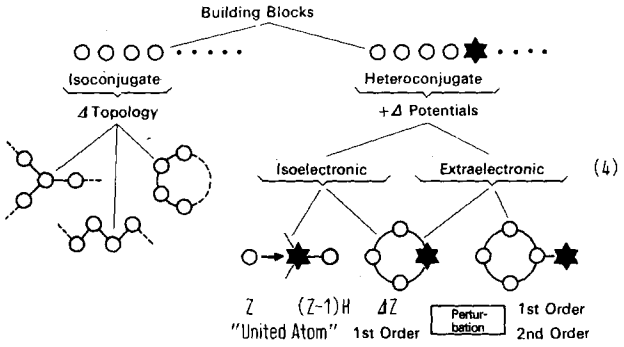
The radical cation ground state exhibits a relatively low energy, and the two excited states lie close together. Comparison with the $\pi^{\bullet\oplus}$ states of other bicyclo[2.2.1] hydrocarbons reveals how the varying energy differences can be interpreted: doubling the number of π electrons on going from norbornene to norbornadiene leads to states of type $^2A_1$ and $^2B_2$ and introduction of another exocyclic double bond of the same symmetry type to splitting of the two $^2B_2$ states about their average value. This state correlation can be translated into through-space interaction[39] within the framework of a qualitative MO model (Fig. 13: MO) and described by construction of linear combinations of appropriate symmetry. Only π orbitals of same symmetry mix with each other—in full accord with the PE spectroscopic finding that the same ionization energy must be expended to generate the $^2A_1$ states of norbornadiene and isopropylidenenorbornadiene (Fig. 13: $M^{\bullet\oplus}$).

The qualitative MO model whose molecular orbitals reflect the symmetry classification[19] of the radical cation states (Fig. 13) can be energetically parametrized as follows: The Coulomb integrals α_π[40], which represent the energy of electrons in a given potential, can be determined in the present case by taking the average of the π-ionization energies of norbornadiene or of the two $^2B_2$ states of norbornadiene and isopropylidenenorbornane (Fig. 13: α_π^{nor} and α_π^{iso}). In many calculation procedures—*e.g.* the HMO approximation—overlap integrals S are not explicitly accounted for but included by definition in the interaction parameter β[40]. The latter can be calculated from the determinant (3), which contains the connection of individual centers or of subunits in the system and permits calculation of the pertinent eigenvalues ε_J[40] by insertion of the relevant ionization energies. For instance, the interaction of the two π units in norbornadiene with $\alpha_\pi^{nor} = (8.69+9.55)/2 = 9.12\,eV$ and with $\varepsilon = IE_1 = 8.69\,eV$ (Fig. 13) is given by

$$\begin{vmatrix} \alpha_\pi^{nor}-\varepsilon & \beta_\pi^{nor} \\ \beta_\pi^{nor} & \alpha_\pi^{nor}-\varepsilon \end{vmatrix} = 0;$$

$$\beta_\pi^{nor} = -\sqrt{(\alpha_\pi^{nor}-\varepsilon)^2} \qquad (3)$$
$$= -\sqrt{(9.12-8.69)^2} = -0.43\,eV$$



When calculating the analogous parameters β_π^{iso} for isopropylidenenorbornadiene it must be borne in mind that three π subunits are interacting[40]. The resulting parameters α_π and β_π command more general interest because they can be compared with values for other π systems[2c] and can be inserted in qualitative MO models[41] for analogous compounds.

The satisfactory description of radical cation states by molecular orbitals (Figs. 9 to 13) confirms that the requirements specified above (1) concerning the reproduction of atom connection and arrangement, as well as electron distribution in the existing potentials, are fulfilled. Even the qualitative linear combinations of bond orbitals which are readily compatible with chemical intuition can be symmetry-adapted[19] and parametrized in a transparent way with experimental state data. The predictions of such simple MO models can be supported by the results of calculations of varying degrees of sophistication right up to the numerical reproduction of state data (Fig. 1). As repeatedly emphasized, there is one particular application of particular interest to the chemist:

Mutually corresponding states of chemically related molecules can advantageously be compared on the basis of molecular orbitals.

4. Comparison of Molecular States Based on Molecular Orbitals

Practically every chemist attempts to organize his set of individual compounds by some definition of chemical relatedness, *e.g.* by principles of homology or by substituent effects. Starting from (1), the following classifications are recommended for molecular state comparison:

Depending upon the relative change, the distinction between iso- and hetero-conjugate, and between iso- and extra-electronic systems is of course a flexible one. The extent of perturbation often also determines the scope of a model, and, within this scope, its quality, *i.e.* the deviations in correlations between observed and calculated quantities.

From thousands of published state comparisons some exemplifying (4) will now be presented. They are chosen to illustrate how entire classes of compounds can be surveyed by application of a network of general rules (cf. Fig. 2).

4.1. Topology-Based Comparison of States

In the approximate solution of the Schrödinger equation applying the variation principle, a secular determinant of type (3) is passed[40] which incorporates the topology of the molecule (4). Thus in the HMO approximation[28] for unbranched polyene chains (Fig. 14) the principal diagonal contains the energy terms $(\alpha-\varepsilon)$ and the adjacent diagonals contain the π interactions β_π assumed to be equal between the connected centers ①–②, ②–①, ②–③ ... (μ)–(μ−1). The solutions of the corresponding eigenvalue polynomials can be derived in closed form[28] (Fig. 14).

From the HMO eigenvalue schemes of linear π systems (Fig. 14) one infers for their state comparison: neutral compounds with odd-numbered polyene chains in which one electron occupies the non-bonding molecular orbital of eigenvalue $\varepsilon_J^{HMO} = \alpha$, are radicals with a doublet ground state. In compounds with even-numbered π systems, the energy difference $\Delta E = h\nu_\pi$ between the ground state and the first $(\pi \rightarrow \pi^*)$ excited state can be compared, in a crude approximation, with the distance between the inner molecular orbitals $\Delta\varepsilon_J^{HMO}$, and the color of polyenes thereby satisfactorily predicted. Moreover, all unbranched polyene chains belong to the alternant π systems[28, 42–44], whose molecular orbitals show pairwise correspondence (Fig. 14: $\varepsilon_J^{HMO} = \varepsilon_{n-J+1}^{HMO}$) and always display

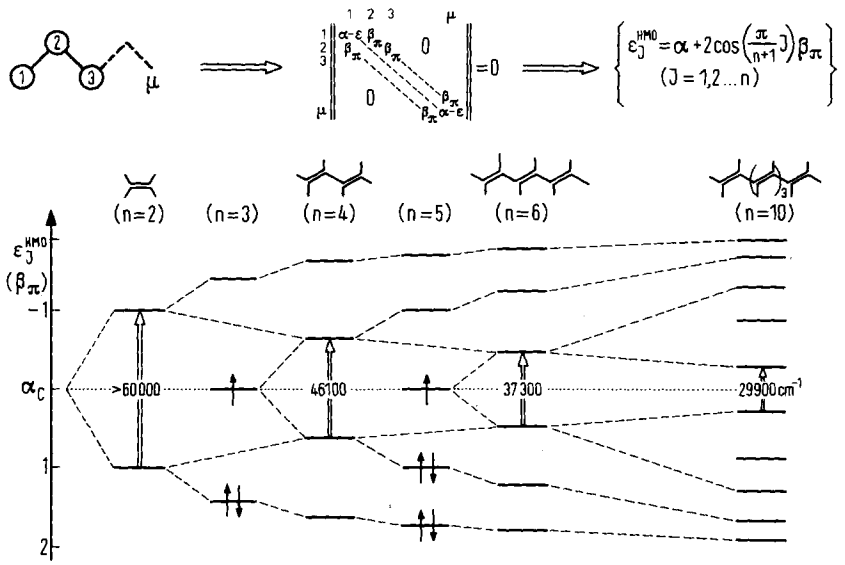


Fig. 14. The HMO model [28] for linear π-electron systems with $\mu = n$ centers, assumes in a simplifying way that all π interactions β_π are equal. A closed formula for the eigenvalues ε_J^{HMO} can be derived *via* the determinant [40] || || containing the connections of the individual centers. The eigenvalue schemes in units of the parameter (β_π) permit a comparative discussion of numerous properties of linear polyenes. Thus all odd-numbered compounds are radicals owing to the occupation of the non-bonding molecular orbital $\varepsilon_J^{HMO} = \alpha$ by only one electron (↑). For even-numbered π systems the distance between the inner orbitals decreases with increasing number of centers and a linear regression is obtained for the wave number $\tilde{\nu}_\pi$ [cm^{-1}] of the longest wavelength absorption, *i.e.* $\tilde{\nu}_\pi = 14800 + 25400\,\Delta\varepsilon_J^{HMO}$ [28], from which the color of long-chain polyenes can be predicted. From the alternancy, *i.e.* from the pairwise arrangement of the molecular orbitals ψ_J and ψ_{n-j+1} relative to α_C, it follows, among other things [28], that the charges q_μ at all centers μ amount to $q_\mu = 1$ and, therefore, the π-dipole moment μ_π must be identical to zero, $\mu_\pi = 0$.

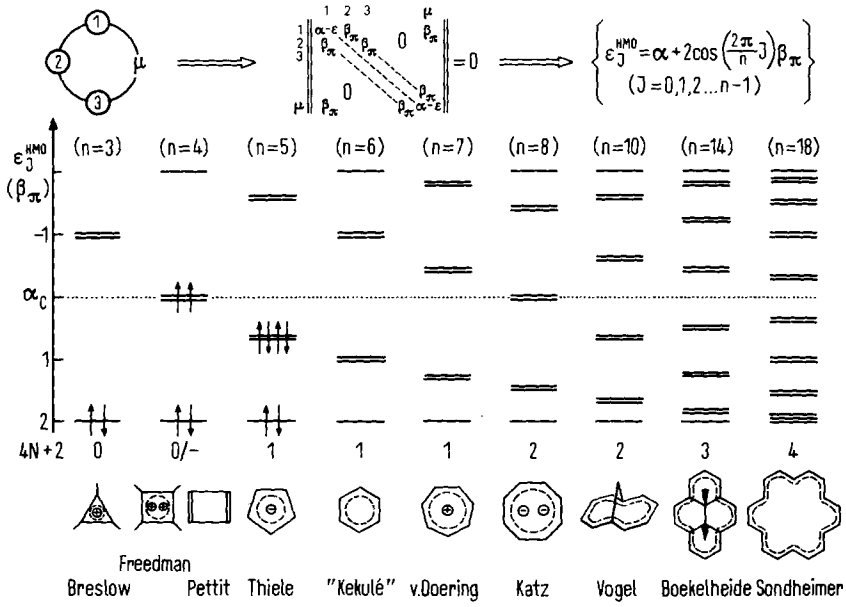

Fig. 15. For cyclic π-electron systems [28] the interactions β_π occurring on ring closure 1—μ have to be included in the HMO determinant [40] || || in addition to the linear systems (Fig. 14). The general formula resulting for the eigenvalue ε_J^{HMO} furnishes energy-level schemes in units of β_π which display the following features: regardless of the number of centers $J = n$, an eigenvalue $\varepsilon_0^{HMO} = \alpha + 2\beta$ is always obtained for $J = 0$; pairs of degenerate eigenvalues $\varepsilon_J^{HMO} = \varepsilon_{n-J}^{HMO}$ result from the cosine term for values $0 < J < n-1$; and finally $\varepsilon_{n-1}^{HMO} = \alpha - 2\beta$ follows for $J = n-1$ in all even-numbered, and hence alternant, primeters. On introducing the electrons one recognizes that closed shells with spin-paired electrons (↑↓) are obtained only if their number satisfies the Hückel rule $4N+2$. The corresponding compounds may be charged, exhibit characteristic properties, and have been systematically synthesized in large numbers [45].

a π charge $q_\mu^{HMO} = 1$ at all centers μ; hence a π dipole moment $\mu_\pi = 0$ is predicted for the compounds in the ground state[28].

The classical example for ground state comparisons with the aid of MO models is found in cyclic π systems known as perimeters[28,42–45]. Their topologically determined secular determinants[40] additionally contain the π interactions $\beta_{1\mu}$ and $\beta_{\mu 1}$ owing to cyclization of the chain by connecting centers 1 and μ (Figs. 14 and 15). The resulting polynomials again yield general solutions ε_J^{HMO} (Fig. 15).

As follows from the HMO eigenvalue schemes (Fig. 15), stable nonradical π systems with closed valence shells are obtainable only if $4N+2$ electrons ($N = 0, 1, 2, 3\ldots$) are sup-

plied. This conclusion, reached by *E. Hückel*[46], led to one of the greatest successes of MO theory: not only was the tropylium ion $C_7H_7^{\oplus}$, for example, predicted in 1931[46], long before it was ever isolated (1954) as a salt, but a large number of compounds such as [10]-, [14]-, and [18]annulenes (Fig. 15) have been systematically synthesized since 1950 as a consequence of the $(4N+2)$ rule[28, 42–46]. Numerous other observations on the ground states of molecules having π perimeters find a ready explanation[28, 42–46]: these include the Jahn-Teller distortion $D_{4h} \rightarrow D_{2h}$ of the cyclobutadiene diradical, and the oxidizability of its tetraphenyl derivative to the dication, or the flattening of the boat conformation of cyclooctatetraene on reduction to the dianion. On the other hand, caution should be exercised when dealing with all more or less arbitrary and artificial supplementary definitions of "aromatic", "nonaromatic", or even "antiaromatic" character of compounds[28, 47].

It should also be pointed out that even-numbered perimeters are also alternant systems[28, 42–44]. The fascinating topological criterion for alternancy can be formulated such that labeling of the individual centers of a system with "*" or "○" leads only to "*—○" connections. Among the numerous consequences of such a connection[28, 42–44], the pairwise occurrence of the molecular orbitals ψ_J and ψ_{n-J+1} for linear π-electron systems (Fig. 14) or ψ_{n-J} for even-numbered cyclic π-electron systems (Fig. 15) is especially striking. In this context one might also emphasize that the calculated virtual unoccupied molecular orbitals can also be correlated with experimental data, as demonstrated here for ESR, PE, and ET spectra (Fig. 16, 17, and 18).

The ESR coupling constants $a_X^{\ominus}$ and $a_X^{\oplus}$ of radical ion ground states (Fig. 3) can usually be satisfactorily correlated with calculated spin populations $\rho_\mu^{\ominus,\oplus}$, *i.e.* with the squares of the coefficients $c_{J\mu}^2$ from the relevant linear combinations $\psi_J = \sum_\mu c_{J\mu}\phi_\mu$[40], which represent the electron densities, according to the relation derived by *McConnell*[27]

$$a_{\mu,X}^{\ominus,\oplus} = |Q_X|\rho_\mu^{\ominus,\oplus} = |Q_X|c_{J\mu}^2| \tag{5}$$

Only in the case of alternant systems, owing to the pairing properties of ψ_J and ψ_{n-J+1} or ψ_{n-J}, are the radical cation and radical anion ground states of one and the same molecule expected, and found experimentally, to display (almost) the same spin populations and thus (almost) the same coupling constants (Fig. 16)[27].

On correlation of σ ionization energies with bond orbital models[19], all the orbitals of the latter are doubly occupied. For radical cation states of alternant σ systems, owing to the pairwise correspondence of the eigenvalues ε_J and ε_{n-J+1} or ε_{n-J}, it is expected and observed PE spectroscopically that the σ ionization energies of, say, methylpolysilanes[48] are equally distributed to both sides of a reference state (Fig. 17).

The PE ionization pattern of decamethyltetrasilane corresponds to the fully occupied eigenvalue scheme of the chain with $n=3$ (Fig. 14), and that of dodecamethylcyclohexasilane

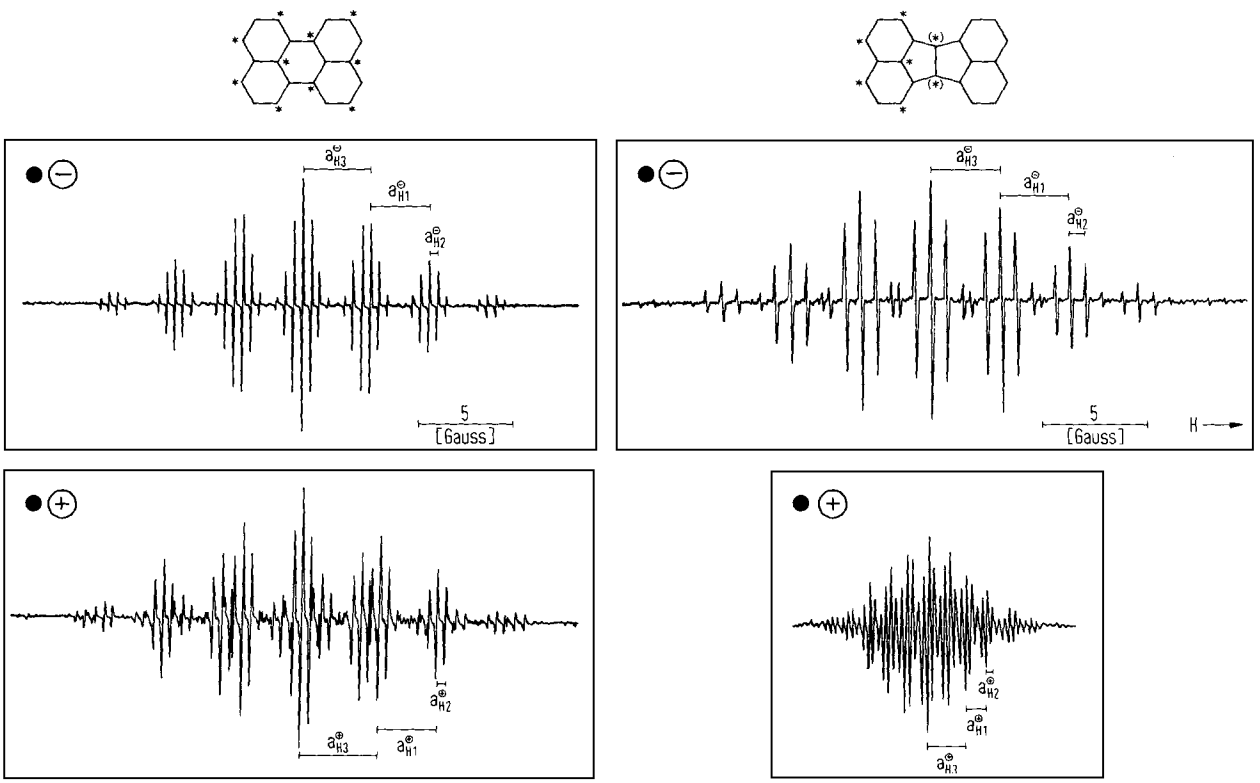

Fig. 16. In alternant π systems, *i.e.* those whose centers can be alternately starred, the pairing properties of their molecular orbitals ψ_J and ψ_{n-J+1} (Fig. 14: linear systems) or ψ_{n-J} (Fig. 15: even-numbered cyclic systems) imply that the coefficients $c_{J\mu}$ of the linear combinations $\psi_J = \sum_\mu c_{J\mu}\phi_\mu$ [40] differ in sign but not in magnitude [28, 42—44]. The squares of the coefficients $c_{J\mu}^2$, which can be correlated (5) with the ESR coupling constants $a_{\mu,X}^{\ominus,\oplus}$, are identical. The ESR spectra of the radical cation and the radical anion are therefore expected to be equal for the same alternant compound, but to differ considerably for nonalternant compounds, *e.g.* those with odd-numbered rings (*—*). This is indeed the case, as demonstrated by the ESR spectra of the radical ions of perylene and acenaphtho[1,2-*a*]acenaphthylene [27].

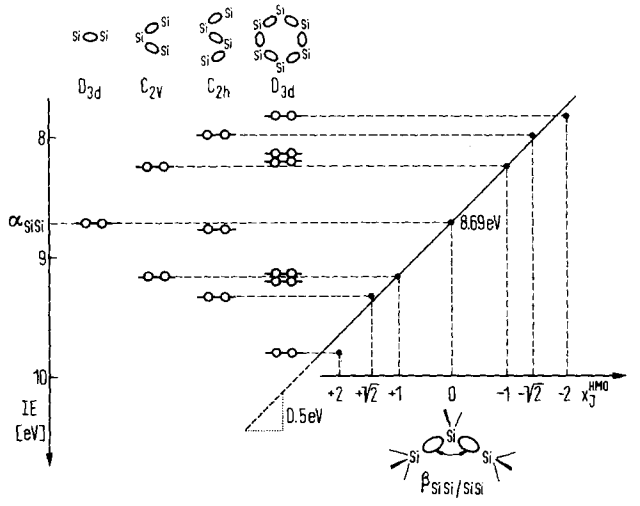

Fig. 17. Comparison of the lowest PE ionization energies of methylpolysilanes $R(SiR_2)_nR$ and $(SiR_2)_n$ yields as center of gravity α_{SiSi} the 1st ionization energy of hexamethyldisilane. The splitting patterns correspond to the HMO eigenvalue schemes of isoconjugate (4) chains (Fig. 14) and rings (Fig. 15) with fully occupied orbitals; insofar as they are not already included in the parameter α_{SiSi}, the SiC and CH orbital components can, to a good approximation, be neglected. Correlation with the eigenvalue coefficien x_j^{HMO} defined according to $\varepsilon=\alpha+x_j^{HMO}\beta$ leads to a regression line with only a slight standard deviation; its slope affords the interaction parameter $\beta_{SiSi/SiSi}=0.5$eV. The alternancy of the SiSi bond skeleton is already included in the HMO model: if Koopmans' theorem (2) is extended to $\Delta\varepsilon_j^{HMO}\sim\Delta IE_n$, the object/mirror image arrangement of the ionization energies about the disilane center of gravity fully confirms the above premise.

to that of the perimeter with $n=6$ (Fig. 15). Comparison of the radical cation states of methylpolysilanes on the basis of an LCBO-MO model is at the same time a good example of parametrization of the Coulomb integral α and resonance integral β[40] with the aid of ionization energies (Fig. 17).

The topological concept of alternancy can also be illustrated for certain isoconjugate π systems by inclusion of the radical anion states[49]. The energy differences from the ground state of the neutral molecule up to the resonance states generated by transient take-up of an electron are accessible by the refined[49] experimental technique of electron transmission spectroscopy (ETS)[50] (Fig. 18).

If electron transmission spectroscopy is regarded as complementary to photoelectron spectroscopy, and if the electron affinities taken from the ET spectra[50] are compared with unoccupied orbitals in an extension of (2) and contrasted with the ionization energies[15], there results the pairwise correspondence of orbital energies relative to a common center of gravity expected (Fig. 18) for alternant linear and cyclic π systems (Figs. 14 and 15).

Summarizing: Comparisons of states on the basis of topologically designed MO models emphasize the connection of the centers in the molecule, are of considerable utility owing to their extensively generalizable predictions—consider *E. Hückel's* $(4N+2)$ rule[46]—and also lead to further insights, as shown for the example of "alternancy"[28,42-44]. These insights apply strictly only to isoconjugate systems (4) such as unsaturated hydrocarbons[28,42-46] and, approximately, to σ systems with characteristic subunits such as peralkylated polysilanes[18,48], boranes[51], or interhalogen compounds[28,52]. However, the basic principles can also be transferred to hetero systems, *e.g.* after modification by the potential perturbations mentioned in Section 4.2.

4.2. Potential-Based Comparison of States

Although they may contain different kinds of building blocks, hetero-conjugate molecules *(4)* can nevertheless display the same kind of connection, comparable geometry (1), and possibly the same number of (valence) electrons. As already discussed for HSH and HOH (Figs. 10 to 12), however, the varying potentials of the central atoms lead to a different electron distribution, and thus to deviating molecular properties. If the changes remain in the range of validity of the

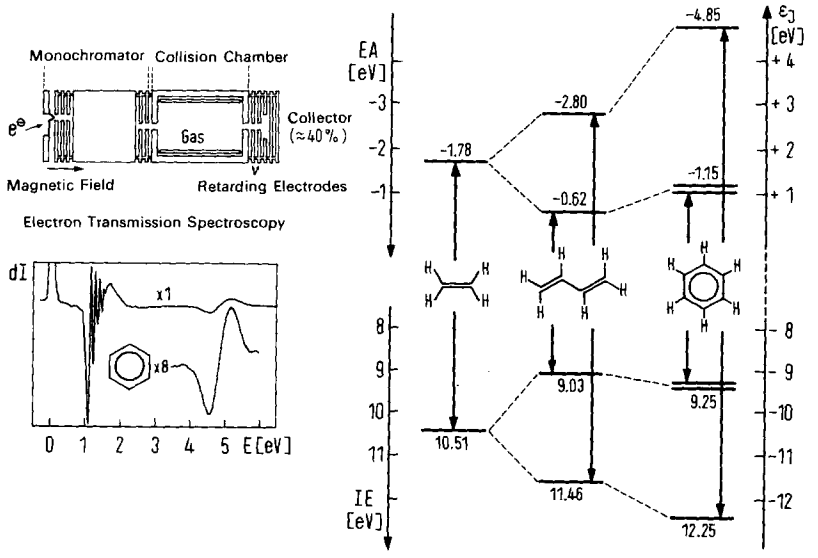

Fig. 18. On recording an electron transmission spectrum, a monochromatic electron beam of variable energy is scattered by the gaseous compound [49, 50]. The resonance (current) fluctuations dI measurable in the unscattered residual transmission beam indicate the intermediate formation of short-lived radical anions. If the electron affinities *EA* [eV] of the resonance states thus determined are plotted together with the PE ionization energies *IE* [eV] on an orbital energy scale ε_j [eV] one obtains the object/mirror image arrangement of the energy differences between the states expected from the alternancy of the π systems (Figs. 14 and 15).

MO model used, then the perturbations[28, 39, 42] can be profitably used for comparison of molecular states.

Potential-based models, which compare the states of chemically related molecules with (largely) similar structures on the basis of changes in potential, may open up interesting vistas. This is demonstrated, for instance, by the photoelectron spectra of the isoelectronic species AH_n of a group (constant n), and also within a period of the system of elements (Fig. 19), with one proton after the other with nuclear charge $Z=1$ being withdrawn from the nucleus Z. An approximation of this kind is designated as the "united atom" model (4) and is also known as *Grimm*'s "hydride shift" rule[54]. In the place of the ambiguously definable and far too imprecise quantity "electronegativity"[55], a suitable parameter for comparing the effective potential is the average ionization energy of all n valence electrons of the central atom $\overline{IE}^{\text{atom}}_{\text{valence}} = [IE_1(A)+IE_1(A^{\oplus})+IE_1(A^{\oplus\oplus})\ldots+IE_1(A^{+n-1})]/n$[56] which also serves for estimating effective nuclear charges according to *Slater*[28, 31] (Fig. 19).

The determining influence of the core potential of the central atom A in the compounds AH_n is clearly revealed by a comparison of the atomic and molecular ionization energies $\overline{IE}^{\text{atom}}_{\text{valence}}/IE^{\text{v}}_n(AH_n)$ (Fig. 19). Thus the sum of all PE ionization energies for argon and water are almost identical. Two regions are easily recognized: the energetically higher states with s holes and the band of the p-type radical cation states, which are to be assigned to the ionizations of electron pairs n_A or to the symmetry-adapted bond combinations σ_{AH} (Figs. 4 and 10). It appears, for example, that the AH_2 compounds display energetic centers of gravity which rise slower than the ns_A ionization energies (Fig. 19), corresponding to the expectation that s electrons, being on average closer to the nucleus, are more susceptible to changes in potential at center A.

In topology-determined systems, potential changes by substituents within the scope of the model can profitably be described as perturbations. One distinguishes between first- and second-order perturbations—as discussed here for the two highest occupied, degenerate benzene orbitals $\pi(e_{1g})$[28, 42, 43] (Fig. 20).

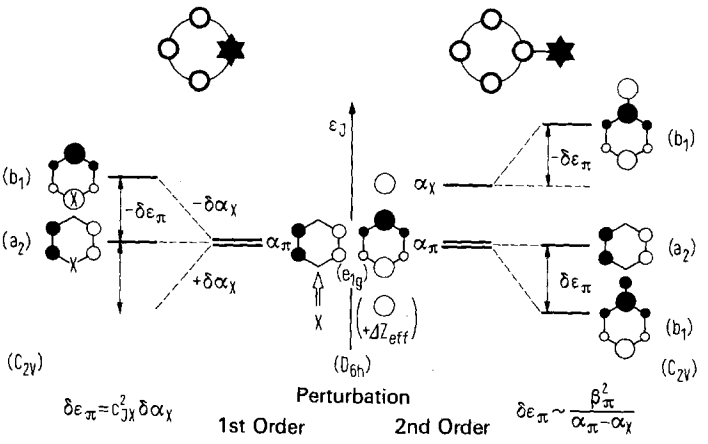

Fig. 20. Substitution in and on the benzene ring lowers the molecular symmetry, *e.g.* $D_{6h}\rightarrow C_{2v}$, thereby removing the degeneracy of the e_{1g} orbital.

1st order perturbation occurs in the HMO approximation [28] *via* a change in potential $-\delta\alpha_X$ (X = donor) or $\delta\alpha_X$ (X = acceptor) and leads to a raising $-\delta\varepsilon_\pi$ or lowering $\delta\varepsilon_\pi$ of the perturbed molecular orbital, whose composition is regarded approximately as unchanged. On substitution in a nodal plane, *i.e.* coefficient at center $c_{JX}=0$[57], $\delta\varepsilon_\pi$ remains equal to zero (cf., however, Fig. 23). 1st order perturbations are frequently isoelectronic (4), *i.e.* an atom X or a group of atoms X–(Y) at the center concerned is replaced by another atom or another group of atoms of different nuclear charge Z_X.

2nd order perturbation occurs in the HMO approximation [28] on mixing of orbitals of the same symmetry class, *i.e.* construction of the linear combination $\psi=c_J\psi_J\pm c_K\psi_K$ for the complete system. The change in orbital energies $\pm\delta\varepsilon_\pi$ is directly proportional to the square of the perturbing interaction β^2_{JK} and inversely proportional to the separation of the orbitals $\alpha_\pi-\alpha_X$. 2nd order perturbations are usually extra-electronic (4), *i.e.* the system is extended by one or more centers.

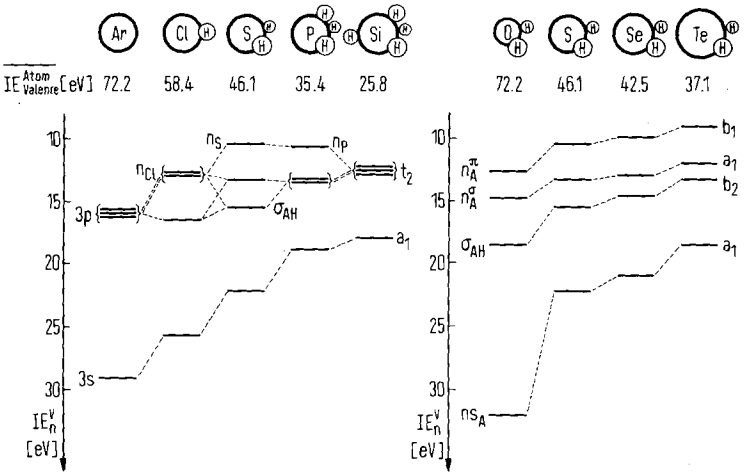

Fig. 19. Comparison of PE spectroscopic ionization energies IE^{v}_n [53] for 3rd row AH_n species, starting from the 3s and from 3p states of the argon atom shows: the 3s electrons in the proximity of the nucleus become more readily ionizable with decreasing effective nuclear charge, represented here by the average ionization energy of the valence electrons of atom A $\overline{IE}^{\text{atom}}_{\text{valence}}$ [56]. The p electrons, which are on average farther away from the nucleus, expectedly prove less susceptible to the influence of the potential of atom A; their levels split to the radical cation states typical of the compounds which are assignable to ionizations from n_A electron pairs or symmetry-adapted combinations of σ_{AH} bonds (Figs. 4 and 10).—In the hydrogen compounds AH_2 of group 6 the energy of the radical cation states $AH_2^{\oplus}$ decreases on going from O to Te, the rate of decrease being all the greater the higher the ionization energy IE^{v}_n, and thus the influence of the effective nuclear charge ($\overline{IE}^{\text{atom}}_{\text{valence}}$).

PE spectroscopy furnishes—*via* Koopmans' theorem (2)—didactically excellent examples of 1st and 2nd order perturbation[2d]: these include phosphabenzene[2e, 58] and 1,4-bis(methylthio)benzene[2c, 59] and their homologous derivatives (Figs. 21 and 22).

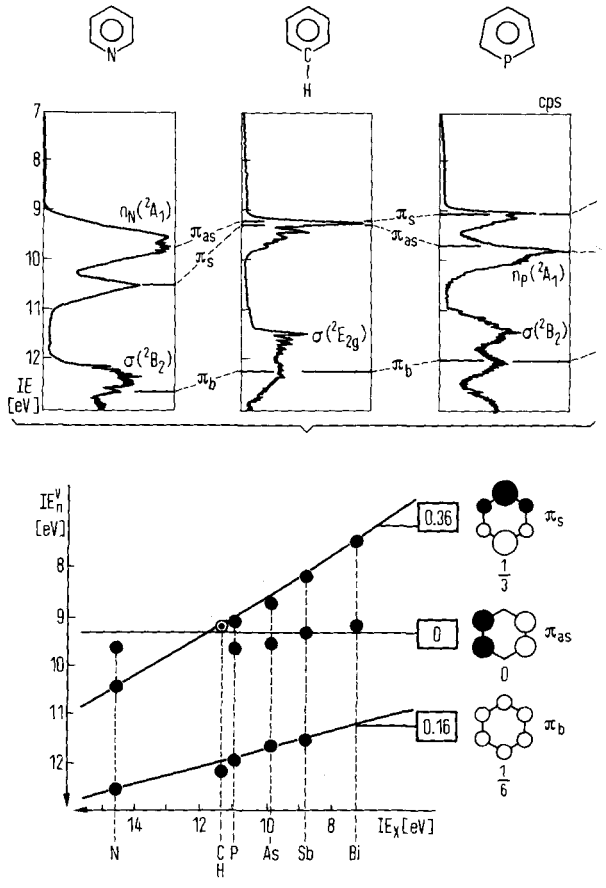

Fig. 21. In the PE spectra of benzene and its hetero derivatives C_5H_5X with X = N, P, As, Sb, Bi [58], the three π ionizations are observed below 12 eV and, in addition, radical cation states which are assigned to the electron pair $n_X(^2A_1)$ and to the benzene skeleton $\sigma(^2B_2)$ [58]. In the benzene π orbitals the coefficients [57] at the substitution centers are 1/3 (π_s), 0 (π_{as}), and 1/6 (π_b). On correlation of the 1st order perturbations due to the potential changes $\delta\alpha_X$—approximated by the valence ionization energies IE_X ($^4S_{3/2} \rightarrow {}^3P_0$) of the atoms X—with the PE ionization energies of the C_5H_5X molecules then, according to (2) $\Delta IE \sim \Delta\varepsilon_J$ and to $\delta\varepsilon_J = c_{J\mu}^2 \delta\alpha_X$ (Fig. 20), regression lines result as expected with slopes of about 1/3, 0, and 1/6. This molecular state comparison at the same time confirms the PE band assignment for the π ionizations.

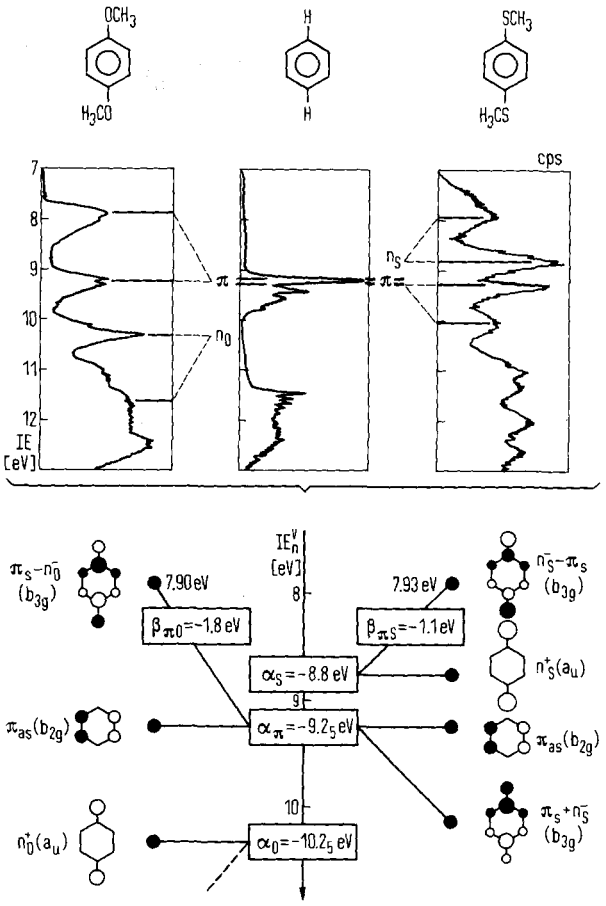
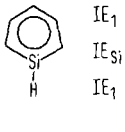
The radical cation state comparison of benzene and its aza, phospha, arsa, stiba, and bismuta derivatives[58] demonstrates the elegance, quality, and utility of potential-based 1st order perturbation models as follows (Fig. 21): of the three model parameters two are accessible by comparison with experimental data, the difference in eigenvalues $\delta\varepsilon_\pi$ according to Koopmans' theorem (2) from differences in molecular π ionization energies, and the perturbations of the potential $\delta\alpha_X$ from the 1st ionization energies of the atoms X[56]. The varying slopes of the resulting regression lines expectedly correspond to the various orbital contributions[57] $c_{\pi X}^2$ at the substitution center X (Fig. 21). The quality of the regression (6) is very good[58], and one of the possible applications should be to predict the 1st ionization energy of the hitherto unknown species silabenzene:





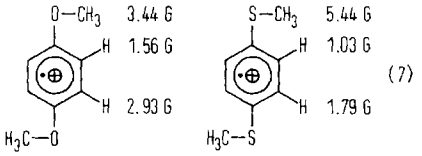


Fig. 22. The PE spectra of benzene and its *p*-bis(methylthio)- and *p*-dimethoxy derivatives contain ionizations to $\pi^{*\oplus}$ states as the lowest 2, 4, and 3 ionizations. In the MO model, *e.g.* for the dithio π system, $n_S^+(a_u) \equiv \alpha_S$ and $\pi_{as}(b_{2g}) \equiv \alpha_\pi$ represent internal standards which are of unique symmetry type and do not mix with any other orbitals in the same energy region. Mixing of symmetry-equivalent orbitals $n_S^- \pm \pi_s(b_{3g})$ leads to mirror image splitting $\pm\delta\varepsilon_\pi$. Parameters $\beta_{\pi X} = -\sqrt{(IE_2 - IE_1)(IE_3 - IE_1)}$ show that $2p_C/2p_O$ interaction effects a larger 2nd order perturbation than $2p_C/2p_S$ interaction.

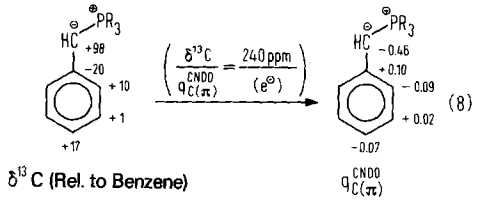
$$IE_1 = 5.24 + 0.362\ IE_{Atom}\ [57]$$
$$IE_{Si} = 8.15\ eV\ [56] \qquad (6)$$
$$IE_1 \approx 8.2\ eV$$

External extraelectronic (4) substitution on the benzene ring, *e.g.* with XCH_3 groups whose electron pairs n_X extend the π system, can usually be satisfactorily described by 2nd order perturbation models. *Para*-disubstituted benzene derivatives[58] constitute an appropriate example (Fig. 22): mixing of the symmetry-equivalent orbitals can be parametrized with PE ionization energies, the orbitals of unique symmetry class serving as internal standards α_S and α_π. It warrants mention that numerical agreement of the 3rd ionization energy of the dithio compound (α_π) and the 1st benzene π-ionization energy, *i.e.* the constancy of the π_{as} orbitals confirms the applicability of a 2nd order perturbation model. Parametrization by analogy with (3) yields $\beta_{\pi O} > \beta_{\pi S}$, and thereby provide the information that the π interaction $2p_C/2p_O$ causes a larger perturbation than $2p_C/3p_S$.

Considering the many known examples it is pointed out that perturbation models, once established, also reflect other molecular properties suitable for modeling: thus the measured ESR spin populations of the corresponding radical cations

(7)



must, according to the McConnell relation (5), at least qualitatively reproduce the orbital mixing ratio $\pi_s \pm n_{\tilde{X}}$ (Fig. 22). Accordingly, a large ring contribution π_s is expected and observed for the dimethoxy derivative, but a large electron pair contribution n_s for the bis(methylthio) derivative[59].

1st and 2nd Order perturbation models of the kind discussed in this section are commonly encountered in the literature, *e.g.* for unsaturated hydrocarbons[28, 38, 41, 42, 60] (cf. also Fig. 13), their halo[61] or pseudohalo derivatives[62], and also for saturated hydrocarbons and their derivatives[17, 63]. The parameters α_X and β_{XY} determinable from experimental data—especially ionization energies—can also be used in other models and are therefore of predictive value (6) with regard to model-determined molecular properties of chemically related compounds.

4.3. Computer-Assisted Comparison of States

The question "to calculate or to measure?" has already been answered in Section 1 by pointing out just how successful and stimulating a combination of the two turns out to be. Computer assistance is usually also valuable for setting up models for comparison of states, a whole arsenal of various procedures[64] presently being available—ranging from the optimum parametrization of MO models from a set of experimental data[62,63] *via* EHMO[65] (*E*xtended *H*ückel *MO*) as the simplest σ calculation procedure[64] and numerous so-called semi-empirical procedures[64] such as CNDO (*C*omplete *N*eglect of *D*ifferential *O*verlap) and INDO[34, 66] (*I*ntermediate *N*eglect of *D*ifferential *O*verlap) or MINDO[67] (*M*inimum *N*eglect of *D*ifferential *O*verlap) to *ab initio* calculations[64, 68]. In the HMO approximation[28, 42], for example, the complete secular determinant[40] containing all the centers and all the interactions is solved instead of the incomplete perturbation determinant of type (3). Experience shows computational aids to be indispensable for molecules of low symmetry and special cases, *e.g.* for extreme perturbations[69] (Fig. 23).

In the PE spectrum of the phenyl-substituted phosphorus ylide (Fig. 23) the characteristic benzene band at 9.25 eV (shown as dashed line) that would have to be assigned to the π_{as} ionization (Figs. 20 to 22) is conspicuously absent. The suspected gross perturbation of the benzene π system by the neighboring "ylidic" carbon electron pair $n_c^{\ominus}$ is clearly revealed by CNDO calculations (Fig. 23): the computer-simulated C—C connection of the two molecular moieties without allowing for π interaction raises the two benzene $\pi(e_{1g})$ orbitals to different degrees by σ charge transfer. Additional splitting leads to the final sequence of molecular orbitals. As may be gathered from the PE spectrum (Fig. 23), the π_{as} molecular cation state is stabilized by 0.9 eV relative to benzene by the neighboring carbanion center—this is one of the strongest substituent effects known[2e]. The model derived by CNDO simulation of an experimentally inaccessible intermediate can be substantiated by state comparisons with other phosphorus ylides; the charges $q_{C(\pi)}^{CNDO}$ also calculated for the benzylidene carbon atoms by the CNDO program correlate satisfactorily with ^{13}C-NMR data[69]:

(8)

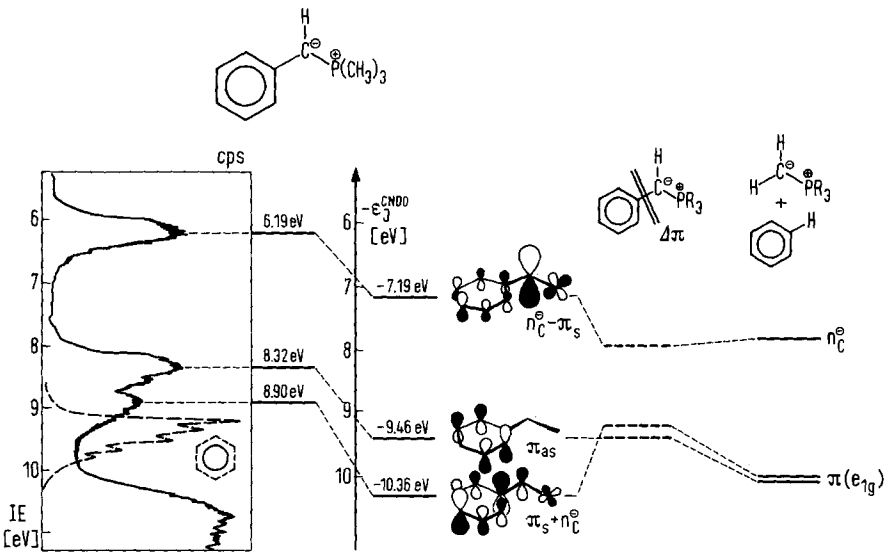


Fig. 23. The PE spectrum of benzylidenetrimethylphosphorane surprisingly no longer shows a band typical for benzene derivatives at 9.25 eV (---) [69]. This finding becomes understandable in the light of CNDO calculations: if the partial systems benzene and methylenetrimethylphosphorane are connected together without permitting π interaction (Δπ) then a considerable raising of the π_s orbital, and also of the π_{as} orbital, is calculated. π interaction mixes the initial orbitals $n_c^{\ominus} \pm \pi_s$, whereas π_{as} remains unchanged. The PE ionization energies are assigned thus: IE_1 ($n_c^{\ominus} - \pi_s$), IE_2 (π_{as}), and IE_3 ($\pi_s + n_c^{\ominus}$). The benzene radical cation state represented by the orbital π_{as} is therefore stabilized to the extent of 9.25 − 8.32 = 0.93 eV by the ylide substituent.

As demonstrated by the perturbation model (Fig. 23), the phenyl ring acts as an acceptor and assists in distributing the neighboring carbanion charge over the ylide molecule.

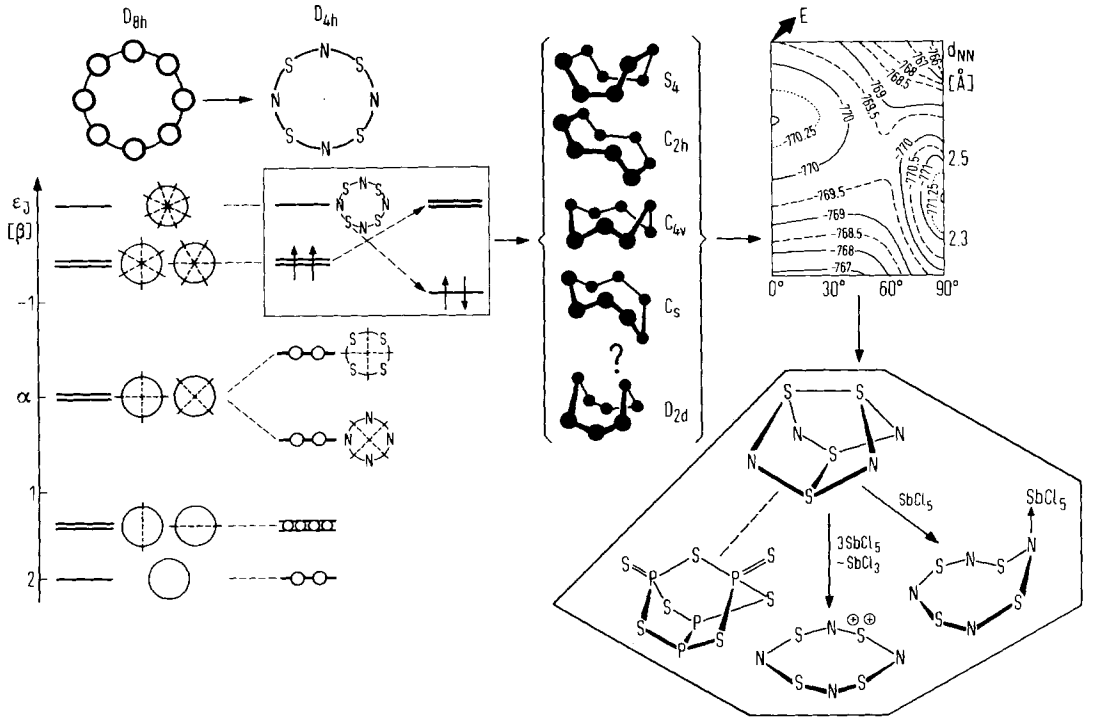
Generally speaking, state comparisons *via* computer-assisted perturbation models were, and still are, frequently utilized for detecting dominating effects and possibly defining them as model parameters—for example, the concepts of through space and through bond interactions[39, 70] (cf. also Fig. 13[38]) or of hyperconjugation[2c, 71]. As a rule, the computer programs used also calculate further data for comparison such as in (8). Among these data, particular interest attaches to the total energies E_{tot} and the charges q_μ on the individual centers μ, which, in the HMO approximation for example, are made up of the contributions of the individual orbitals ψ_J each occupied by b_J electrons:

$$E_{tot}^{HMO} = \sum_J b_J \varepsilon_J \qquad (b_J = 0,1,2) \qquad (9)$$
$$q_\mu^{HMO} = \sum_J b_J c_{J\mu}^2$$

These data are obtained independently by semiempirical procedures[34, 42, 64] and can be profitably employed in computer-assisted perturbation models. Ylides have already been discussed as examples for charge distribution q_μ^{CNDO}[69] (cf. (8) and Fig. 23); the use of EHMO total energies will be illustrated by a description of the cage structure of S_4N_4[72] (Fig. 24).

The starting point for a discussion of the S_4N_4 cage structure[72] is provided by the molecular orbitals of the [8]perimeter (Fig. 15). Perturbation by S and N potentials merely removes the degeneracy of the nonbonding orbital pair, owing to the position of the nodal planes. Each nitrogen atom contributes one π electron, and each sulfur atom two π electrons; filling with a total of twelve π electrons affords a reactive triplet state with two unpaired electrons. A stable singlet state could be achieved if the highest orbital could be lowered, by additional transannular interactions, beneath the next-highest pair (Fig. 24). Among several possible deformations, EHMO calculations show the D_{2d} structure with S—S bonds to have the lowest total electron energy[72]. This calculated result agrees with the S_4N_4 structure determined by X-ray methods. The computer-assisted perturbation model is also valid for the ground state of other cage compounds such as P_4S_7, in which the P—P connection leads to a greater interatomic distance, and permits understanding of further molecular properties: thus addition of the Lewis acid $SbCl_5$ generates a perturbation sufficient to stabilize opening to the singlet ground state[72] (Fig. 24). A planar structure was predicted by the MO model[72] for the dication $S_4N_4^{2\oplus}$ in 1970—in full accord with the recently published X-ray structure analysis[73].

Quite intentionally, the examples cited so far have not aimed at closest possible numerical reproduction of experimental data by calculated values (Fig. 1), but were instead selected to provide an insight into the dynamic behavior of molecules under the influence of perturbations for comparisons of states of chemically related compounds. For the sake of completeness, however, it should be mentioned that the comparison of experimental data and model quantities has not only often permitted parametrization of the latter (cf., *e.g.*, Fig. 13 and (3), Figs. 17, 21, or 22), but frequently leads to significant correlations for calculated model quantities, permitting



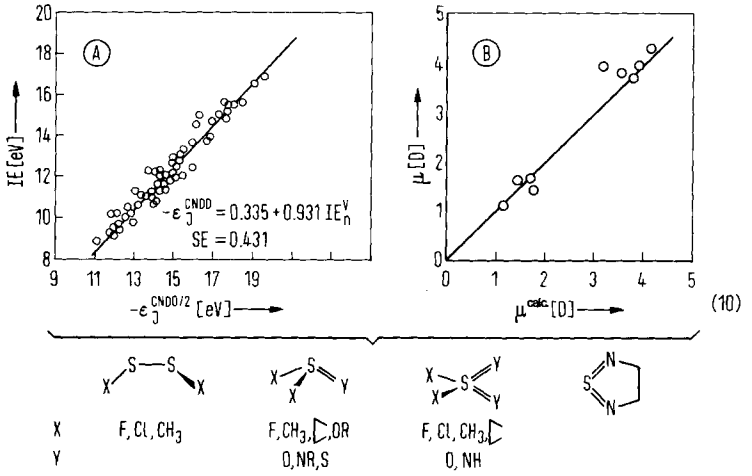


Fig. 24. The MO description of the three-dimensional cage structure of S_4N_4 [72] starts from the isoconjugate [8]perimeter (Fig. 15). Lowering of the symmetry $D_{8h} \rightarrow D_{4h}$ merely removes the degeneracy of the orbitals $\varepsilon_{4,5} = \alpha$ by different 1st order perturbation (Fig. 20). Occupation by 1N and 2S electrons shows that a planar S_4N_4 molecule would have to be a diradical. Between the numerous possible structural distortions, which would either interchange the uppermost orbitals or cancel the degeneracy of the second from top pair of orbitals, no adequate qualitative distinction seems possible. Calculation of an energy surface E_{tot}^{EHMO} as a function of distances such as d_{NN} shows that a D_{2d} cage should be the most stable S_4N_4 structure. The model can also be applied to other cage molecules such as P_4S_7 or to cage opening by perturbation in the $SbCl_5$ adduct. X-Ray structure analysis recently proved [73] the cation $S_4N_4^{2\oplus}$ to be planar—as would be expected from occupation of the eigenvalue scheme by two electrons less.

predictions within their confidence limits. Points to watch will become clear in simultaneous correlations of energy $-\varepsilon_J^{CNDO}/IE_n^V$ according to *Koopmans* (2) and of dipole moments $\mu^{calc.}/\mu^{exp.}$ covering 15 sulfur compounds of four different types, some exhibiting extreme substituents (F) and some with extreme ring strain ($\sphericalangle$CSC *ca.* 50°)[74].

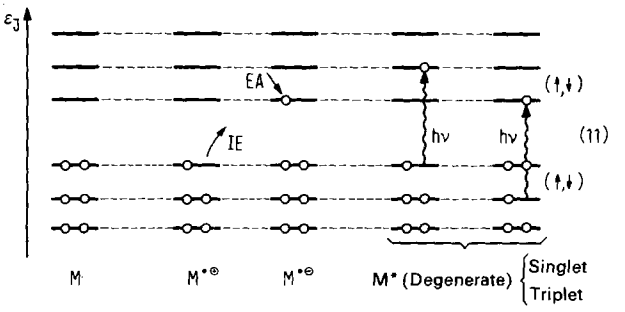
(10)

The regression line of the Koopmans correlation (10: A) neither passes through the origin nor exhibits a slope of 1, and its standard deviation is relatively large. The known gas-phase dipole moments are correlated directly with the calculated values: the regression line (10: B) of slope 1 passes through the origin. Taken together, the two correlations show the calculation procedure used to be suitable, within the limitations mentioned[28], for interpretation and for prediction of model properties of such sulfur compounds. However, the reader is earnestly warned against all fortuitous numerical coincidences based on single "hit and run" calculations without extensive testing of confidence limits (10), or in which "home-spun" parameters defined more or less arbitrarily, like "aromaticity", are backed up with some kind of calculated figures.

To summarize:

By virtue of their inherent concepts (topology, symmetry), of their input parameters (potentials, number of electrons), and of their flexibility (perturbation), molecular orbital models provide a manifold and stimulating overview of types and classes of compounds.

5. Limits of the Molecular Orbital Description of Molecular States



Experimental molecular state data and calculated molecular orbital parameters can be correlated in various ways: energy differences such as ionization or excitation energies can be compared with eigenvalues (cf. (2), (10), or Figs. 10, 13, 17, 18) or their differences (cf. Figs. 14, 20, 21, 22). Changes in charge such as demonstrated by ESR spin populations or resulting from substituent perturbations can be correlated with squared eigenfunctions (cf. (5), (7), or Figs. 12, 16, 20, 21). Furthermore, "summed-up" parameters such as total energies or total charges (9) provide a basis for discussing numerous other molecular properties such as structures (Fig. 24), dipole moments (10), or NMR signal shifts (8). However, the accompanying loss of transparency often leads to the limits of easily tractable MO models. Beyond these limits, the description of molecular states on a molecular orbital basis has made enormous progress within the discipline of theoretical chemistry—even reaching as far as the reproduction of spectra of small molecules (Fig. 1). In what cases should the average consumer of quantum chemistry become cautious and consult a theory producer?

All the MO models presented are based on the implicit assumption that the distribution or motion of an electron can be described within the time-averaged field of the atomic nuclei and the other electrons of a molecule (1). Such one-electron MO models describe the properties of molecules in a particular state, in each case on the basis of a single electronic configuration (11): for instance, all radical cation states according to *Koopmans* by means of a single set of molecular orbitals (Fig. 25).

In conclusion, the limited validity and some possible extensions of one-electron MO models will be illustrated for important aspects: change in electron energy with or without changes in the number of electrons, structural changes or reactions, and the description of large molecules of low symmetry.

5.1. Changes in Electron Energy Due to Changes in the Number of Electrons

One-electron MO models for molecules M with closed electron shells in the ground state (11: M) generally also permit

(11)

description of the properties of radical ions (11: $M^{\bullet\oplus}$ and $M^{\bullet\ominus}$) with a modified number of electrons (Fig. 25). Numerous correlations of various experimental data with calculated parameters of the respective singly occupied molecular orbital

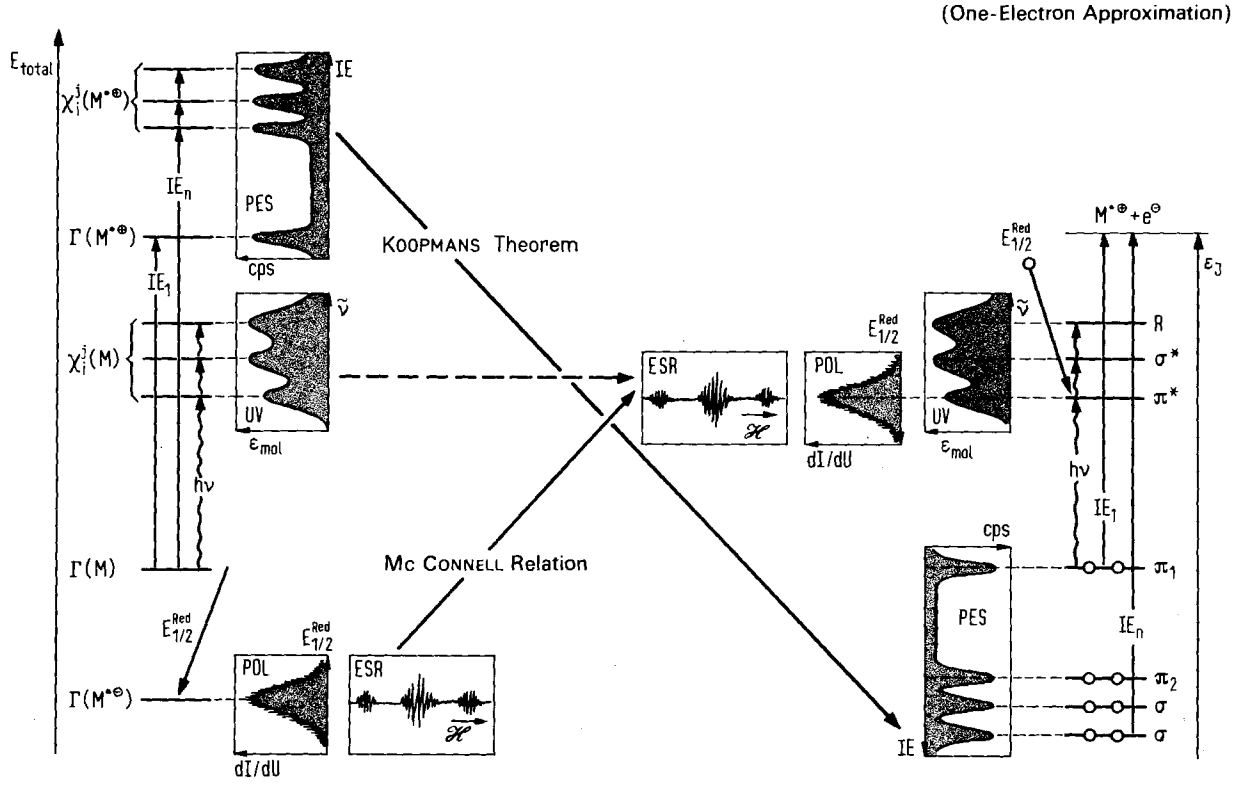


Fig. 25. Energy differences between, and charge distributions in the various states of a molecule can be determined by a variety of experimental methods, of which some are mentioned (cf. Fig. 3). Interpretation of experimental data with one-electron MO models is based on the fundamental assumption of Koopmans' theorem $IE_n^v = -\varepsilon_j^{SCF}$ (2) or the McConnell relation $a^{\bullet\oplus,\ominus}_{\mu,X} = |Q| c^2_{J\mu}$ (5), *i.e.* that the electron distribution can be established with a single electron configuration. Ionization energies or half-wave reduction potentials can then be compared with the eigenvalues ε_J, ESR coupling constants with the squares of the orbital coefficients $c_{J\mu}$ at the centers μ of the singly occupied molecular orbital ψ_J of type σ, π, π^*, σ^* or R. In some (a few) cases the UV excitation energies $\Delta E = h\nu$ can be expressed as the eigenvalue differences $\Delta\varepsilon_J$ between the initial and final orbitals (cf. Fig. 14). The limitations of describing states by one-electron MO models are clearly apparent from the crossovers (→) of the individual correlations.

confirm[27, 28, 42–44] that the electron distribution can usually be described satisfactorily by a single electron configuration (11: $M^{\bullet\oplus}$ and $M^{\bullet\ominus}$).

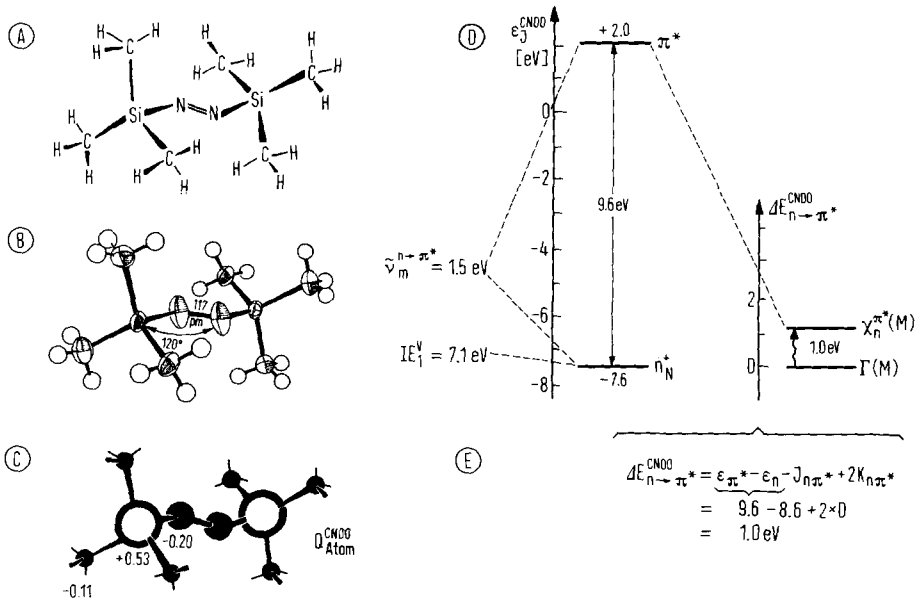
The applicability of one-electron approximations requires not only a comparable molecular structure but also that changes in the charge distribution (relaxation) and in mutually dependent electron motions (correlation) may together be neglected[15b]. Thus the molecular structure remains essentially constant during the *ca.* 10^{-16} s duration of vertical ionization (cf. Fig. 4: HBr potential curves), and the deviations from Koopmans' theorem appearing in a particular method of calculation will be all the smaller the less the charge distribution and electron correlation change during the ionization process[33]. Far better agreement with experimental data is yielded by the many-electron approximative solutions of the Schrödinger equation mentioned in the introduction (cf. Fig. 1), in which the total energies of the individual states are calculated separately and subtracted from one another according to (2): calculated values ΔE_{total} and vertical ionization energies IE_n^v generally differ by less than ± 0.3 eV[3–7]. Nevertheless, application of these highly sophisticated methods to larger molecules still remains in the precinct of the theoretician.

5.2. Changes in the Electron Energy not Involving Changes in the Number of Electrons

As documented by many of our examples (Figs. 10, 13, 18, 21, or 23), ionizations can usually be described, starting from a single electron configuration (11: $M^{\bullet\oplus}$), by one of the so-called canonical orbitals[64] which are adapted to the symmetry of the molecule and satisfy Koopmans' theorem (2). The electron hole generated can thus be characterized according to the orbital type and the electronic interaction regarded approximately as unchanged. For excitations in which the number of electrons remains constant, *i. e.* none of the electrons is ejected, a description of the molecular state based on just a single electron configuration (11: M) is generally inadequate (Fig. 26).

As in the case of the blue compound bis(trimethylsilyl)diimine[76] (Fig. 26), the ionization energies are usually reproduced satisfactorily by MO calculations *via* Koopmans' theorem (2), while reproduction of the excitation energies usually requires consideration of the modified electronic interaction—in the present case electron repulsion is approximately accounted for by Coulomb terms J as well as spin pairing effects by exchange terms K[77].

Generally, one-electron MO approximations, *i.e.* those which treat electrons as being independent of one another, are unsuitable for describing electronically excited states $\chi_i^j(M)$ of neutral molecules; simple regressions between UV maxima and eigenvalue differences, as shown in Figure 14, therefore represent exceptions valid only for certain excited states of particular series of compounds[28, 44]. Thus it is impossible, with a single electronic configuration, to establish either the energy differences between singlet and triplet states (11: ↑↓ and ↑↑) or the different excitation energies to such states of like symmetry (11: $h\nu \neq h\nu'$), for which degeneracy would be predicted



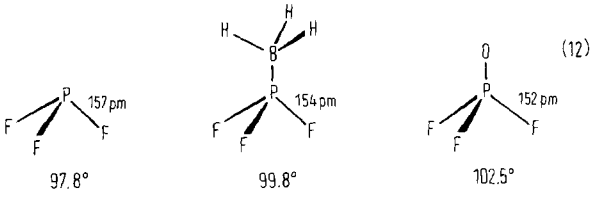


Fig. 26. *Bis(trimethylsilyl)diimine* (A) *is a blue (!) azo compound* [76], *whose long-wave* $n\rightarrow\pi^*$ *band appears at the edge of the IR spectral range, which exhibits a first ionization energy of only 7.1 eV, and whose unusually short NN bond length (B) amounts to only 117 pm (azobenzene 125 pm,* N≡≡N 111 pm). The MO description in terms of the charges Q_{atom} (C) suggests that silicon ($Q_{Si}^{CNDO} = +0.53$) acts as a strong electron donor towards nitrogen ($Q_N^{CNDO} = -0.2$). The CNDO calculations also satisfactorily reproduce the first ionization energy $IE_1^V = 7.1$ eV (D); the eigenvalue of the highest occupied orbital n_N^+ amounts to $\varepsilon_{30}^{CNDO} = 7.6$ eV. The $n\rightarrow\pi^*$ excitation energy $E_m^{n\rightarrow\pi^*} = 1.5$ eV, on the other hand, cannot be related to the gap $\Delta\varepsilon = 9.6$ eV to the lowest unoccupied π^* orbital. Only after approximate consideration of the modified electronic interaction [17], as expressed in the large Coulomb term $J_{n\pi^*}$, can the $n\rightarrow\pi^*$ excitation energy be roughly reproduced (E) with $\Delta E_{n-\pi^*}^{CNDO} = 1.0$ eV.

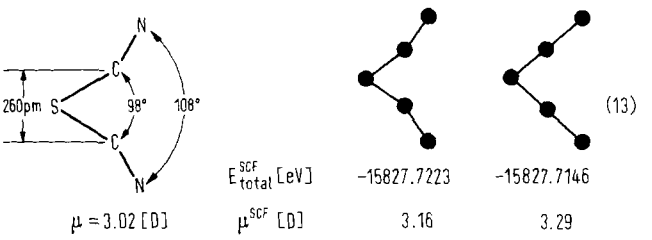

without inclusion of configurational mixing[31, 32, 44, 78, 79]. Numerous other experimental results such as negative spin densities (Fig. 12) can only be explained after inclusion of electronic interaction.

5.3. Changes in the Electron Energy Accompanying Changes in Molecular Structure

Molecular orbital models are usually based on a given, unchanged molecular geometry—frequently an illegitimate assumption[37]. Rather, changes in the structure of a molecule are known to occur on transition to another molecular state (Figs. 5, 6, 7, 12 or 24) and also within series of chemically closely related compounds (cf. *e.g.* Fig. 11). In many cases, *Gillespie*'s electron pair repulsion model[80] proves very useful in discussing possible changes; thus, along the series

widening of the FPF angle and shortening of the FP bond can be explained by increasing electron withdrawal F→P, which is also observed in the PE spectra[2e]. Precise calculation of the geometry of states requires considerable computational effort because the differences between large energy contributions ΔE_{total} have to be calculated. The bending of the S—C—N bond in $S(CN)_2$ is illustrative[81]:

Obviously, the $S(CN)_2$ structure as determined by microwave spectroscopy, and also the dipole moment, are satisfactorily reproduced by *ab initio* calculation with an extensive basis[81]; the slight SCN bending can be attributed to the calculated electron density between the two carbon atoms. However, the minor differences in total energy on bending (13: $\Delta E_{total}^{SCF} = 0.0077$ eV) show how much caution should be exercised when considering numerical data, *e.g.* from semiempirical procedures.

In polyatomic molecules, structure determinations via the minimum of the total energy require calculation of a multidimensional energy surface; attempts are made to avoid prohibitive costs, *e.g.* by fixing some coordinates, using fast computer programs, and optimization of coordinates (Fig. 27).

The total energy surface for rotation of SH about the CS axis in thiphenol[27], comprising 595 individual CNDO calculations (Fig. 27), and also considering deflections of C—SH, requires some 2 hours of computing time on a medium-size computer. It may be seen that no other conformation is preferred apart from the minima in the total energy for planar geometry. In spite of reservations towards individual numerical results from semiempirical calculations, such a comparison of total energies should, in general, correctly reproduce the energetically favored conformers.

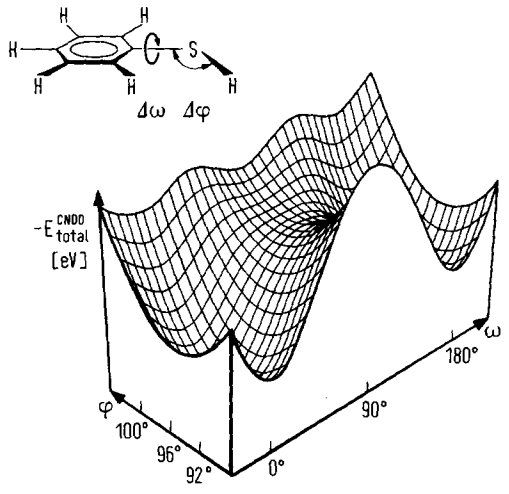

Fig. 27. The total energy surface for SH rotation in thiophenol [82], is made up of $17 \times 35 = 595$ individual CNDO calculations. In addition to twisting about the CS axis (Δω), deflections of C—S—H (Δφ) have also been considered, especially on passing of the *ortho* hydrogen atoms of the benzene ring. It is seen that no minima of the CNDO total energy occur except for planar arrangements ($\omega = 0°$ and 180°).

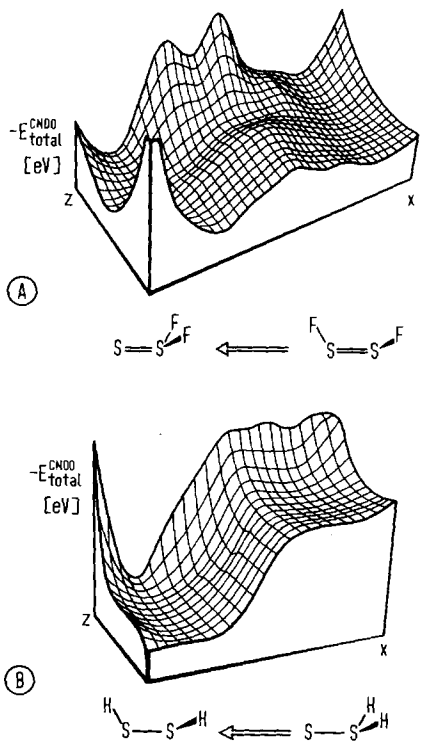

Fig. 28. The two isomers FSSF and F_2SS can be prepared separately; F_2SS is the thermodynamically more stable of the two. This situation—like PE ionization energies (10: A) or dipole moments (10: B)—is reproduced by CNDO calculations. On this basis, the isomerization energy surface FSSF⇆F_2SS(A) can be approximated assuming the occurrence of an intramolecular 1,2 fluorine shift: the FSS fragment is considered fixed and the second fluorine atom migrates along the SS axis x through 12 sectional planes z each with 144 screening points. The geometry is completely optimized only in the region of the minima; configuration interaction is neglected. The surface made up of 1728 CNDO total energies clearly exhibits the energetically preferred potential valley corresponding to isomerization. Close to the saddle point a shallow minimum is calculated for an almost planar three-membered ring arrangement F—S(—F)···S. The CNDO total energy for the more stable isomer F_2SS is only slightly more negative than that for FSSF; a relatively high barrier is found between the two. Corresponding energy surfaces for the H_2S_2 system, and likewise for Cl_2S_2 too [74], predict the XSSX isomer with C_2 symmetry to be the thermodynamically and kinetically stable species.

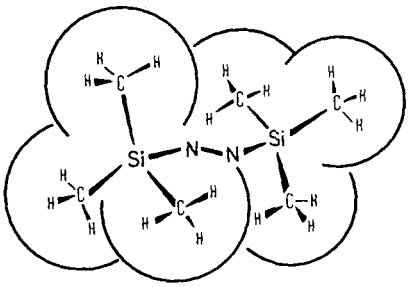
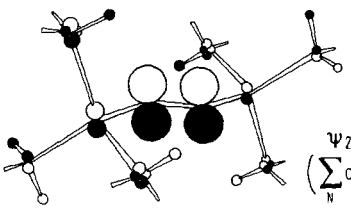
5.4. A Special Case: Molecular Reactions

As sketched out in the previous Section, changes in the geometry of molecules can often be satisfactorily approximated by point-for-point calculation and comparison of the total energy. Intensive efforts are currently being invested in the calculation of such energy surfaces also for molecular reactions in many places[13, 83, 84]. One of the many prerequisites of such calculations is that either experimental information about the detailed reaction course is available, *e.g.* from molecular beam studies[83], or plausible assumptions are possible, as for the presumably intramolecular isomerizations of compounds S_2X_2[74] (Fig. 28).

Accepting the various assumptions and simplifications given the following conclusions concerning the isomerizations $XSSX \rightleftarrows X_2SS$ can be drawn from the calculated energy surfaces[74] (Fig. 28), in complete accord with experimental evidence: both F_2S_2 isomers must be isolable; F_2SS is more stable than FSSF; only the HSSH and ClSSCl isomer, respectively, should be capable of existence in the H_2S_2 and Cl_2S_2 systems.



What general statements can be put forward concerning reactions between molecules of medium size $K_kL_lM_m + R_rS_sT_t \rightarrow$? For instance, how do the successful collisions occur in the gas phase? What is the structure of the molecular collision complex at the saddle point of maximum energy? Are there any intermediates? How is the course of reaction affected by the environment, *e.g.* in a solvent or at a catalyst? Numerous questions require experimental elucidation[83]—apart from further development of suitable calculating procedures[83, 84] (Fig. 2).



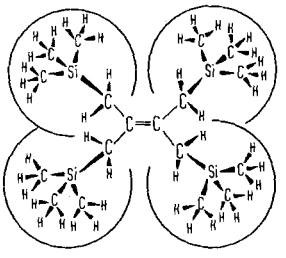
In this context, some attempts at mapping reaction coordinates warrant mention: thus comparison of X-ray structure analyses furnishes information about mutually coupled changes in molecular structures, such as angular deviation as a function of distance[85]; the "hyperspace" $H_2 + H^{\oplus}$ has already been calculated[84]; *ab initio*[68, 83] and MINDO/NDDO procedures[67, 83] compete with each other[86, 87], *e.g.* in calculation of hydrocarbon reactions; a qualitative illustrative model for reactions from singlet and triplet excited states[88] proves to be useful[23]; and, last but not least, the orbital symmetry rules of *Woodward* and *Hoffmann*[90], which are based on configuration diagrams[89], have found wide application in organic chemistry[91].

5.5. Large Molecules of Low Symmetry

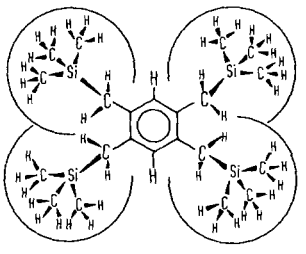
A further limitation of MO models is that characteristic orbitals are generally no longer obtained for molecules with more than 15 to 20 atoms and structures of low symmetry. In particular, proximate (canonical[75]) orbitals of the same symmetry class usually undergo extensive mixing. For instance, the 28-atom molecule of bis(trimethylsilyl)diimine (Fig. 2) is calculated to have the following orbital as the seventh-from-highest of 30 occupied molecular orbitals:

Although ψ_{24} appears to represent the π_{NN} bond[24], its contributions at the nitrogen centers $\sum_N c^2_{24,N}$ amount to only about

(14)



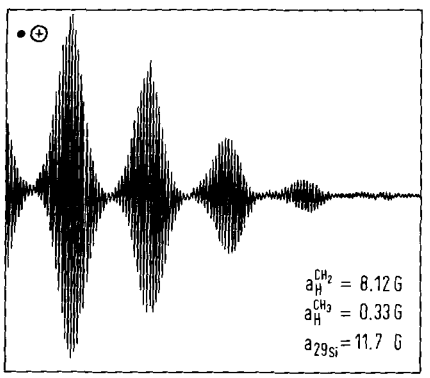
50 %[76]. Integrated quantities such as the total atomic charges (9) are often much more suitable for describing the states of such molecules. Thus the calculated high electron densities in the NN bond of azo compounds such as bis(trimethylsilyl)-diimine (Fig. 26), which are due to Si→N polarization, can be correlated with the low first ionization energies[76].



This example also marks a boundary beyond which a direct qualitative discussion of molecular states offers several advantages. For instance, comparably low first ionization energies are predicted for the 66- and 72-atom ethylene and benzene derivatives in the gas phase (Fig. 29) as a consequence of their identical substitution pattern of four tetrahedrally arranged $(H_3C)_3SiCH_2$ groups, and of the excellent stabilization of the roughly spherical radical cations. Similarly ESR spectra with extensive coupling are predicted as a result of complete delocalization of the electron hole over the molecule on oxidation in solution[92]—regardless of whether the central π system is ethylene or benzene, comparable 1st ionization energies and radical cation spin populations are observed for the similarly substituted molecules $[(H_3C)_3SiCH_2]_2$-π-$[CH_2Si(CH_3)_3]_2$ (Fig. 29). These compounds are already very large for a conventional description of their states in terms of molecular orbitals; nevertheless, in this case too—as in the discussions of Sections 5.1 and 5.4—there is a possibility of extending the available methods, for example by applying calculating techniques developed for the solid state.

6. Conclusion and Outlook

The selection of examples presented in this report should corroborate the following statement:



Chemical building blocks with defined structure and properties are molecules in particular states which can be characterized by their energy and their charge distribution. The best models yet available for their description are molecular orbitals, which are especially suitable for comparison of corresponding molecular states of chemically related compounds. By virtue of their inherent topology and symmetry, the potentials and numbers

$IE_1 = 7.15$ eV

$IE_1 = 7.10$ eV

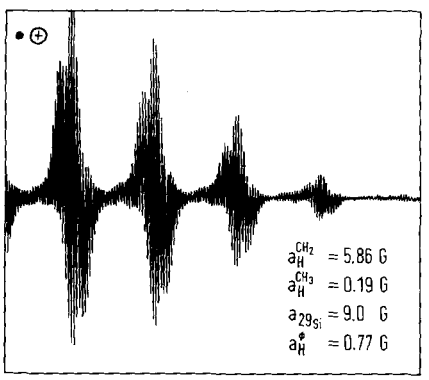


Fig. 29. In the tetrakis(trimethylsilylmethyl)-substituted ethylene and benzene derivatives $C_{18}H_{44}Si_4$ and $C_{22}H_{46}Si_4$ the central systems are surrounded in similar manner by four $(H_3C)_3SiCH_2$ groups. The energy differences between the ground states of the neutral molecule and the radical cation are in close agreement at 7.10 and 7.15 eV [92]. Their ESR spectra (1850 and 1988 lines, respectively) are characterized by the nonet of the methylene protons, of which five groups of signals are shown starting from the midpoint of the spectrum. The coupling constants for the 36 methyl protons $a_H^{CH_3}$, for the ^{29}Si doublet ($I^{29}_{Si} = 1/2$, abundance 4.70%) and the phenyl protons $a_H^{\oplus}$ can be confirmed by spectral simulation [92]. Obviously, $a_H^{CH_2}$ and a^{29}_{Si} decrease on switching from the ethylene derivative to the large benzene compound, providing further evidence for complete delocalization of the unpaired electron over the entire molecule.

of electrons to be inserted, and their flexibility towards perturbations, they provide a manifold and stimulating overview covering wide areas of chemistry.

How will molecular states be interpreted ten years from now? Ten years ago expeditions had just started into the *terra incognita* of σ molecular skeletons, with photoelectron spectra and all-electron calculations as navigational aids. Time and again, MO models have done great service in the interpretation of new experimental data—some 20 years ago in the case of the newly developed ESR technique and likewise just recently in the novel chemical application of electron transmission spectroscopy. The stimulation of preparative work by MO models is manifested by all those studies which are based on the stability of cyclic compounds with $(4N+2)$ electrons or on orbital symmetry in concerted reactions. The snowball-like increase in application of MO models during the past 15 years is a classical example of the influence of large computers in the natural sciences, and even the very next generation of computers can provide fresh impetus for advances and innovations in calculating procedures.

Last but not least, MO models offer—in the face of the increasing complexity and incredibly fast expansion of chemical sciences—an opportunity of gaining, and retaining, a general understanding and overall view of chemistry.

This is an appropriate place to express my gratitude to Professor Edgar Heilbronner, who introduced me to the "HMO model and its application". The work of the Frankfurt group cited above would not have been possible without the untiring efforts of dedicated co-workers, especially Dr. Hartmut Alt (deceased), Dr. Hans Seidl, Dr. Bahman Solouki, Dr. Klaus Wittel, Dr. Gerhard Wagner, Dr. Herbert Stafast, Dr. Walter Ensslin, Georg Brähler, Wolfgang Kaim, Shamsher Mohmand, Karl-Alexander Ostoja-Starzewski, and Abbas Tabatabai. Generous support of our work by the Deutsche Forschungsgemeinschaft, the State of Hesse, Hoechst AG, the Fonds der Chemischen Industrie, the Max-Buchner-Stiftung, and the Stiftung Volkswagenwerk is gratefully acknowledged. Scientific contacts with numerous colleagues have always had a stimulating effect; for suggestions and critical discussion comments I wish to thank especially Prof. E. Heilbronner, Dr. K. Wittel, Prof. G. Binsch, Prof. W. Kutzelnigg, Dr. P. Rosmus, and Dr. A. Semkow.

Received: June 29, 1977 [A 180 IE]
German version: Angew. Chem. *89*, 631 (1977)

[1] Based on a lecture delivered at the invitation of the Gesellschaft Deutscher Chemiker on the occasion of the Chemiedozententagung, Marburg, March 22, 1977.

[2] 6th Essay on "Molecular Properties and Models".—The following articles are to be considered as the 1st to 5th essays, respectively: a) "Color and Constitution of the Azo Compounds", Angew. Chem. *77*, 469 (1965); Angew. Chem. Int. Ed. Engl. *4*, 457 (1965); b) "Die Störung von π-Systemen als Molekülsonde für Substituenteneffekte", Jahrb. Akad. Wiss. Göttingen *1969*, 13; c) "Photoelectron Spectra of Nonmetal Compounds and Their Interpretation by MO Models" (with *B. G. Ramsey*), Angew. Chem. *85*, 773 (1973); Angew. Chem. Int. Ed. Engl. *12*, 734; d) "Photoelectron Spectroscopy: An Experimental Approach to Teaching Molecular Orbitals" (with *P. Mollère*), J. Chem. Educ. *51*, 506 (1974); e) "Photoelectron Spectra and Bonding in Phosphorus Compounds", Pure Appl. Chem. *44*, 343 (1975).

[14] Molecular states are generally designated Γ for the ground state and χ_i^j for electronically excited states generated by excitation $i \rightarrow j$; the charge is also given (in parentheses), *e.g.* as $M^{\bullet\oplus}$, M, or $M^{\bullet\ominus}$.—IUPAC rules have been published [Pure Appl. Chem. *21*, 29 (1970)] for specific cases. The individual states of a particle M or $M^{\bullet\oplus}$ are denoted therein by $\tilde{X}$ (ground state) and successively by $\tilde{A}$, $\tilde{B}$, $\tilde{C}$... (excited states), and also by their multiplicity $m=s+1$, *i.e.* the number s of spin-uncoupled electrons (singlet: $s=0$, $m=1$; doublet: $s=1$, $m=2$, *etc.*) as well as their symmetry type within the symmetry group of the molecular structure [19].

[15] From the wealth of review literature about photoelectron spectroscopy the following have been selected (with contents): a) *D. W. Turner, C. Baker, A. D. Baker, C. R. Brundle:* Molecular Photoelectron Spectroscopy. Wiley-Interscience, London 1970 (reproductions of numerous spectra, literature covered up to 1969); b) *C. R. Brundle, M. B. Robin* in *F. C. Nachod, J. J. Zuckerman:* Determination of Organic Structures by Physical Methods. Vol. III. Academic Press, New York 1971, pp. 1ff. (introduction with the aid of selected examples); c) *J. H. D. Eland:* Photoelectron Spectroscopy. Butterworths, London 1974 (principles, information from PE spectra, general interpretation, literature covered up to 1972); d) *J. P. Maier*, Annu. Rep. Prog. Chem. *B 71*, 75 (1974) (survey of recent developments). Cf. also refs. [2c, 2e].

of the iso(valence)electronic ethane radical cation is calculated by *A. Richartz, R. J. Buenker, P. J. Bruna, S. Peyerimhoff*, Mol. Phys., in press. Cf. also the survey by *C. Sandorfy:* Chemical Spectroscopy and Photochemistry in the Vacuum Ultraviolet. Reidel, Dordrecht 1974.

[19] For designation of symmetry of states the reader is referred to the introduction in ref. [21c] and to *F. A. Cotton:* Chemical Applications of Group Theory, Wiley-Interscience, New York 1966. A simple procedure for determining the symmetry of all radical cation states of a molecule is illustrated for the case of disilane (see Scheme at foot of p. 635):
① Definition of the coordinate system and bond classification; change in sign occurs for units such as π bonds or electron pairs extending over more than one center. Performance of all symmetry operations ③ belonging to the symmetry group ② of the molecule in order to determine the number ④ of "bond basis functions" transforming into "+" or "−" themselves. The product of the resulting characters ④ of the "reducible" representation Γ⑤ and the characters of the individual "irreducible representations" ⑥ of the group concerned ② are added together ⑦ and divided by the number of symmetry operations ⑧ performed. One obtains the symmetry types ⑨ of all radical cation states that can be generated by (mono)ionization of the valence electrons of molecule ①.

[29] Review: *W. C. Price, S. S. Chissick, T. Ravensdale:* Wave Mechanics—the first fifty years. Butterworths, London 1973.

[30] An important condition [31, 32] is *Pauli*'s principle of antisymmetry: The overall (wave) function of a many-electron system must be antisymmetric on simultaneous exchange of site and spin coordinates $\vec{x}_i$ of two electrons $\psi(\vec{x}_1,\vec{x}_2,\vec{x}_3\ldots)=-\psi(\vec{x}_2,\vec{x}_1,\vec{x}_3\ldots)$. Two electrons of a system therefore cannot exhibit identical coordinates $x_1=x_2=x$ since $\psi(x,x,x_3)=0$ would then hold.

[31] Among the many introductions to the principles of quantum mechanics, one of the most recent ones is: *W. Kutzelnigg:* Einführung in die Theoretische Chemie, Vol. I. Verlag Chemie, Weinheim 1975.

[32] A comprehensible qualification of spectroscopic states and their discussion on the the basis of electron configurations is found in *K. Wittel, S. McGlynn*, "The Orbital Concept in Molecular Spectroscopy", Chem. Rev. 1977, in press.

[33] *T. Koopmans*, Physica *1*, 104 (1933). The scope is discussed, *e.g.*, in [15b, c] and by *E. Heilbronner* in *R. Daudel, B. Pullman:* The World of Quantum Chemistry. Reidel, Dordrecht 1974, pp. 211ff.

[40] Approximate solution of the Schrödinger equation $H\psi=\varepsilon\psi$ is discussed at length, *e.g.*, in ref. [31]. For the simplest case with most extensive simplifications—a homonuclear two-center system in the HMO approximation—the procedure [28] is as given below: in order to solve the differential equation with the two unknown eigenfunctions ψ and eigenvalue ε, an approximate linear combination $\psi^0_{1,2}=c_1\phi_1\pm c_2\phi_2$ is assumed which is made up of atomic orbitals ϕ and initially unknown coefficients c for each of the two centers. The best possible fit of ψ^0 to ψ within the framework of the approximation procedure, *i.e.* determination of the coefficients c_1 and c_2, is performed with the expanded and rearranged equation:

$$\varepsilon^0_{1,2}=\frac{\langle\psi^0_{1,2}|H|\psi^0_{1,2}\rangle}{\langle\psi^0_{1,2}|\psi^0_{1,2}\rangle}\approx\frac{\langle c_1\phi_1\pm c_2\phi_2|H|c_1\phi_1\pm c_2\phi_2\rangle}{\langle c_1\phi_1\pm c_2\phi_2|c_1\phi_1\pm c_2\phi_2\rangle}$$

the individual integrals being defined as parameters in the following way:

Type	$\langle\phi_i\|H\|\phi_j\rangle$	$\langle\phi_i\|\phi_j\rangle$
$i=j$	α_i (Coulomb)	1 (Normalization)
$i\neq j$	β_{ij} (Resonance)	S_{ij} (Overlap)

Determination of the energy minimum as a function of the coefficients $\delta\varepsilon/\delta c=0$ leads, *via* a system of so-called secular equations $\{\}$ and the corresponding secular determinant $\|\ \|$, initially to the eigenvalues $\varepsilon_{1,2}$:

$$\left.\begin{aligned}c_1(\alpha_1-\varepsilon)\pm c_2(\beta_{12}-S_{12}\varepsilon)&=0\\ c_1(\beta_{21}-S_{21}\varepsilon)\pm c_2(\alpha_2-\varepsilon)&=0\end{aligned}\right\}\Rightarrow\left\|\begin{matrix}\alpha_1-\varepsilon & \beta_{12}-S_{12}\varepsilon\\ \beta_{21}-S_{21}\varepsilon & \alpha_2-\varepsilon\end{matrix}\right\|=0$$

$$\psi^0_1=c_{11}\phi_1+c_{12}\phi_2 \qquad \varepsilon^0_{1,2}=\frac{\alpha\pm\beta}{1\pm S}$$
$$\psi^0_2=c_{21}\phi_1-c_{22}\phi_2$$

Insertion of the eigenvalues $\varepsilon_{1,2}$ into the secular equations finally affords the coefficients $c_{1,2}$ and hence the molecular orbitals $\psi_{1,2}$.

[55] The electronegativity is defined by *Pauling* and *Mulliken* as an energy, and by other authors as a force or a dimensionless ratio. The entire range of chemistry is embraced by $\Delta EN=3.54$ units (Fr 0.86 and Ne 4.40 [54]) and the effect of the central atom in various substituent groups (C in CH_3, CN, or CF_3) is not accounted for. Cf. *J. Hinze*, Fortschr. Chem. Forsch. *9*, 448 (1968).

[57] Orbital diagrams as shown in Fig. 20 are advantageously [28] drawn such that the radii of the circles round the sites are numerically equal to the coefficients $c_{J\mu}$. The areas of the circles $F=\pi c^2_{J\mu}$ are then directly proportional to the squares of the coefficients $c^2_{J\mu}$.

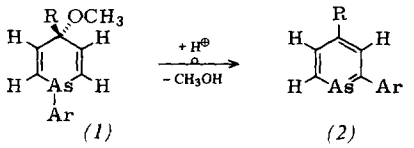
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

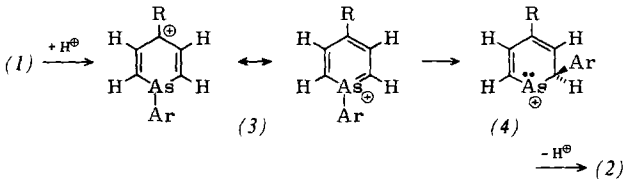
1-Aryl-4-methoxyarsacyclohexadiene→2-Arylarsabenzene Rearrangement—An Organoelement Analog of the Cyclohexadienol→Benzene Rearrangement



By *Gottfried Märkl* and *Rainer Liebl*[*]

The cyclohexadienol→benzene rearrangement[1] has been demonstrated on numerous occasions[2]. In the present communication we report the first analogous organoelement rearrangement.

The pronounced tendency of phospha- and arsacyclohexadienes to rearrange into phospha- and arsabenzenes is well known[3]. We have now been able to show that the 4-substituted 1-aryl-4-methoxyarsacyclohexadienes *(1)*[4], readily



[*] Prof. Dr. G. Märkl, R. Liebl
Chemisches Institut der Universität
Universitätsstrasse 31, D-8400 Regensburg 1 (Germany)

accessible by cycloaddition of arylarsanes to 3-substituted 3-methoxy-1,4-pentadiynes, smoothly rearrange to give the 4-substituted 2-arylarsabenzenes *(2)* in good yields on reaction with catalytic amounts of strong acids, *e.g.* *p*-toluenesulfonic acid in boiling benzene, or with boron trifluoride ether in benzene at room temperature. The rearrangement *(1)*→*(2)* thus constitutes a novel, preparatively extremely facile entry to the arsabenzenes.

(1) *(2)*

The initial step is cleavage of allyl ether from *(1)*, which is additionally facilitated by the heteroatom. Most likely the pyridinium ion analogs, the previously unknown 1-arylarsabenzenium ions *(3)* (1-arylarseninium ions) of tetravalent arsenic with coordination number 3[5], are formed first and then undergo the 1,2 aryl shift to give *(4)*, and finally deprotonation to give the arsabenzenes *(2)*.

(3) *(4)*

The intermediate *(4)* has the structure of a σ-complex formed as product of the electrophilic aromatic substitution of the arsabenzene ring (in position 2) and thus provides strong supporting evidence for the existence of non-aromatic complexes derived from arsabenzenes. Electrophilic aromatic substitution reactions of arsa- or phosphabenzenes have so far not been reported in the literature.

That also the difficultly accessible 4-substituted 1-arylarsacyclohexadien-4-ols undergo acid catalyzed rearrangement in the expected fashion to give the 2-arylarsabenzenes was demonstrated with 1,4-diphenylarsa-2,5-cyclohexadien-4-ol, which under analogous reaction conditions rearranges to 2,4-diphenylarsabenzene in 85% yield. Since the arsabenzenes cannot be arylated or alkylated in position 2[7] similarly to the Ziegler alkylation and arylation of pyridine[6] by reaction with organometallic compounds RLi or RMgX, the rearrangement mentioned here constitutes the first preparatively useful method for the synthesis of 2-arylarsabenzenes[8]. Some examples are listed in Table 1.

Procedure

2,4-Diphenylarsabenzene *(2a)*: A solution of *(1a)* (1.60 g, 5.0 mmol) (as a mixture of *cis/trans* isomers, in which the amount of one component is about 90—95%)[4] in anhydrous benzene (50 ml) is boiled under reflux in the presence of 20 mg *p*-toluenesulfonic acid for 3 h. The cooled reaction mixture is washed several times with water, dried over $MgSO_4$, and the solvent removed in a water-jet vacuum. Distillation of the residue in a rotating bulb-tube (air-bath temperature 180°C) at 10^{-3} torr affords 1.36 g *(2a)* (94%) as a pale yellow oil, which crystallizes on rubbing with petroleum ether in the presence of some ethyl acetate. Colorless crystals (from ethyl acetate/petroleum ether), m.p. 75—77°C. All operations must be carried out under highly-pure nitrogen.

[8] The synthesis of 2-phenylarsabenzene described by *A. J. Ashe III, W. T. Chan, E. Perozzi* (Tetrahedron Lett. *1975*, 1083) is impaired by the poor accessibility of the 2-phenylstanna-2,5-cyclohexadiene as precursor.

Pentacarbonyl(dimesitylgermanediyl)chromium(0)[**]

By *Peter Jutzi* and *Wolfgang Steiner*[*]

Carbene analogous diorganogermylenes are extremely reactive species that are stabilized by formation of polygermanes and by insertion reactions[1]. Following the synthesis of complexes containing GeX_2 ligands (X = halogen, SR)[2], we have now been able to prepare a diarylgermylene complex.

Reaction of pentacarbonyl(tetrahydrofurandichlorogermanediyl)chromium(0) [compound *(1)*][3] with mesitylmagnesium bromide affords pentacarbonyl(dimesitylgermanediyl)-chromium(0) [compound *(2)*] in *ca.* 50% yield:

$$(CO)_5Cr{\leftarrow}GeCl_2{\cdot}THF + 2\ MesitylMgBr \longrightarrow$$

(1)

$$(CO)_5Cr{\leftarrow}Ge\left[\begin{array}{c}CH_3\\ \\ CH_3 \quad\quad CH_3\end{array}\right]_2 + \ldots$$

(2)

Complex *(2)* is isolable as a red crystalline powder which is surprisingly air-stable and only slightly sensitive towards hydrolysis. Noteworthy is its thermal stability (DTA: dec. pt. 80 °C). *(2)* readily dissolves in hydrocarbons, chlorinated hydrocarbons, carbon disulfide and, without complexation, also in tetrahydrofuran and diethyl ether. Its structure follows from elemental analysis and spectroscopic data. Mass spectrum and molecular weight determination (cryoscopically in benzene) confirm the complex to be monomeric.

The dimesitylgermylene ligand should be a good π acceptor. This is indeed evidenced by the position of the long-wave A_1 vibration in the νCO region. Assignment of the νCO vibrations is based on the assumption of local C_{4v} symmetry for the $Cr(CO)_5$ moiety [IR in CH_2Cl_2 (comp.): 2075 (m, A_1), 1995 (s, A_1), 1945 (s, E) cm^{-1}].

The germylene complex *(2)* can readily be transformed into the nitrogen-germanium ylide complex *(3)* with pyridine:

$$(2) + Pyridine \longrightarrow (CO)_5Cr{\leftarrow}Ge\left[\begin{array}{c}CH_3\\ \\ CH_3 \quad\quad CH_3\end{array}\right]_2$$

with a pyridine ring coordinated to Ge via N

(3)

Compound *(3)*: pale yellow needles, m.p. 114 °C; IR in CH_2Cl_2 (comp.): 2065 (m, A_1), 1945 (s, A_1), 1925 (s, E) cm^{-1}. No reaction takes place with bulky bases such as triphenylphosphane or benzothiazole.

Presumably steric effects are responsible for the unexpected stability of the dimesityl germylene complex *(2)*. Attempts to synthesize the analogous diphenylgermylene complex have so far met without success.

Procedure

Synthesis of *(2)*: A THF-solution of mesitylmagnesium bromide (10 mmol) is added dropwise with stirring to a solution of *(1)* (2.03 g, 5 mmol) in THF (50 ml) at −20 °C. The reaction solution is warmed to room temperature and stirred for 1 h. After removal of all the volatile components *in vacuo*, the remaining brown oil is chromatographed on silica gel (Merck 60) with benzene/petroleum ether 50/70 (1:1). The red zone contains the desired product. Recrystallization from petroleum ether 50/70 at −78 °C affords the analytically pure complex *(2)*. Yield: 1.22 g (48 %).—^{1}H-NMR (in CH_2Cl_2): δ = 6.8 (s, 4 aryl-H), 2.4 (s, 12 methyl-H), 2.3 (2, 6 methyl-H).

Synthesis of *(3)*: A solution of *(2)* (2.52 g, 5 mmol) in benzene (50 ml) is treated with pyridine (0.40 g, 5 mmol). After removal of solvent the yellow residue is recrystallized twice from petroleum ether 50/70. Yield: 3.01 g (91 %).—^{1}H-NMR (in CH_2Cl_2): δ = 6.85 (s, 4H), 2.3 (s, 18H), 7.2—7.9 (m, 5 pyridine-H).

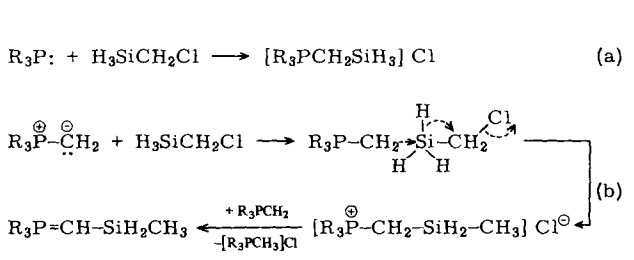
Anomalous Nucleophilic Substitution in (Chloromethyl)silane: 1,2-Hydride Shift[**]

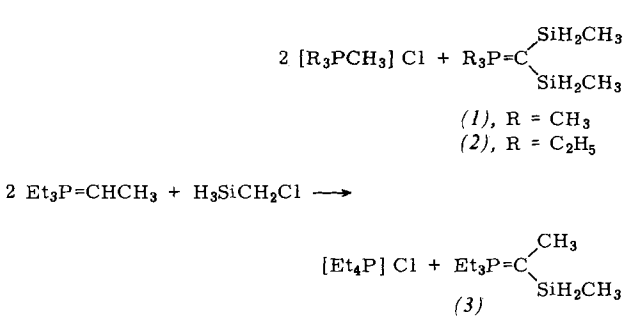
By *Hubert Schmidbaur* and *Beate Zimmer-Gasser*[*]

(Chloromethyl)silane is the β-Si analog of ethyl chloride:



$$\overset{\delta+}{H_3Si}-\overset{}{CH_2}-\overset{\delta-}{Cl} \qquad\qquad \overset{\delta+}{H_3C}-\overset{}{CH_2}-\overset{\delta-}{Cl}$$

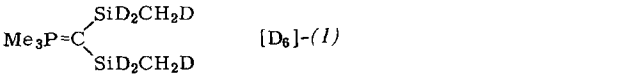
Spectroscopic investigations[1] have shown the "silaethyl chloride" to have a markedly reduced C—Cl polarity. Hence, in many cases substitutions in such a species ought to proceed differently from in the case of the "pure" alkyl compound. Whereas the previously studied quaternizations of phosphanes[2] showed no anomalies on account of the modest affinity of the phosphorus toward silicon [Reaction (a)], the first examples of the suspected alternative reaction mechanism [Reaction (b)] have now been observed in reactions with phosphorus ylides.



In contrast to trialkylphosphanes, the trialkyl(methylene)-phosphoranes have, in their ylidic carbanions, a nucleophilic center showing a high affinity toward silicon, the atom which it attacks preferentially on reaction with H_3SiCH_2Cl. The increase in coordination number of the silicon to 5 leads to destabilization of the Si—H bond, so that a hydride shift to the neighboring C-atom can follow with displacement of the Cl atom.

[*] Prof. Dr. H. Schmidbaur, Dipl.-Chem. B. Zimmer-Gasser
Anorganisch-chemisches Institut der Technischen Universität
Arcisstr. 21, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



The [(methylsilyl)methyl]phosphonium salt thus formed is transformed by transylidation with further ylide[3] into the [(methylsilyl)methylene]phosphorane end product. Since this reaction with H_3SiCH_2Cl can take place twice (until complete silylation of the ylide function), $Me_3P{=}CH_2$ and $Et_3P{=}CH_2$ respectively afford the bis(silyl)methylenephosphoranes *(1)* and *(2)* in almost quantitative yields. With $Et_3P{=}CHCH_3$ the reaction must terminate at the stage of the monosilyl compound *(3)*.

(1), R = CH_3
(2), R = C_2H_5

(3)

For proof of the 1,2 shift according to Eq. (b) we have synthesized D_3SiCH_2Cl and investigated its reaction with $Me_3P{=}CH_2$. NMR analysis of the product [D_6]-*(1)* confirmed the origin of one of the $SiCH_3$ hydrogen atoms from the SiH_3 group.

In the light of these findings a series of previously unexplained observations can now be clarified. For example, the instability or non-existence of silylmethyl-alkali metal and Grignard compounds $H_3SiCH_2^{\ominus}M^{\oplus}$ and of silylated ylides $H_3Si{-}CH{=}PR_3$[2,4]. Moreover, the prediction that alkylations of silylalkyl halides do not proceed in the usual sense, finds experimental support in the reaction of H_3SiCH_2Cl with *n*-butyllithium, which does not lead to pentyl- but to butylmethylsilane. This finding confirms the substitution mechanism suggested above and shows, as do experiments with fluorides and alkoxides as nucleophiles, that it is in no way restricted to ylidic reaction partners, but represents a general reaction principle.

Procedure

A solution of the ylide (20 mmol) in Et_2O (20 ml) is added dropwise at −78 °C to a stirred solution of $ClCH_2SiH_3$[5] (20 ml) in Et_2O (20 ml). The phosphonium salt formed immediately is filtered off and ether removed from the filtrate by evaporation. The resulting residue is then purified by distillation. B.p. [°C/torr]: *(1)* $30/10^{-1}$ (65/10); *(2)* $56/10^{-1}$; *(3)* $79/10^{-1}$.

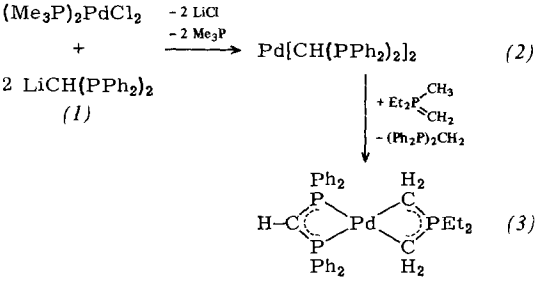
Diphosphinomethanide/Phosphoniumbismethylide: A Novel Ligand Combination for Transition Metals[**]



By *Hubert Schmidbaur* and *Johann R. Mandl*[*]

Under suitable conditions phosphorus ylides react with almost all metal centers to give metallocyclic compounds of type A, which on account of their interesting properties[1] have been the subject of numerous studies. In contrast, little is known about the related diphosphinomethanide complexes of type B, of which only a few of the previously reported[3] examples have been satisfactorily characterized structurally.

We have now found that the *combination of both ligand systems* leads to novel coordination compounds having a notably high tendency to formation and high thermal stability. The methods of synthesis and typical properties of such compounds are demonstrated here using a mononuclear palladium(II)- and a dinuclear gold(I)-complex as examples.

Reaction of $(Me_3P)_2PdCl_2$ with lithiated bis(diphenylphosphino)methane *(1)*[2] in tetrahydrofuran leads to formation of the orange-yellow insoluble palladium(II) bis[bis(diphenylphosphino)methanide] *(2)*, which reacts with diethylmethyl(methylene)phosphorane[4] with displacement of bis(diphenyl-

[*] Prof. Dr. H. Schmidbaur, Dr. J. R. Mandl

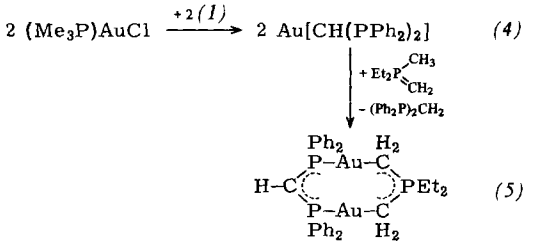
Arcisstr. 21, D-8000 München 2 (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

phosphino)methane to give the ylide/phosphinomethanide complex *(3)*.

The yellow crystalline diamagnetic product shows mass and IR spectra which reveal quite clearly the close relation to the precursor *(2)* on the one hand and to ylide complexes on the other.

^{1}H- and ^{1}H{^{31}P}-NMR spectra, but above all the ^{31}P{^{1}H}-NMR spectrum, support the proposed structure *(3)*; the latter shows a structurally diagnostic doublet/triplet pattern (2:1), which confirms the symmetrical bonding of the ligands.

In an analogous way reaction of $(Me_3P)AuCl$ and *(1)* affords the lemon-yellow insoluble gold(I) bis(diphenylphosphino)-methanide *(4)*, which is characterized by its ^{197}Au Mössbauer spectrum as a polymeric Au^I derivative with the metal atoms in a uniform environment (IS = 4.09, QS = 9.25 mm/s; 4 K)[5]. *(4)* reacts with the ylide to form the eight-membered heterocycle *(5)*, in which, unlike in *(3)*, neither the ylide nor the diphosphinomethanide assume a chelating function, serving instead as bridges between the metal atoms.

The colorless, crystalline compound *(5)*, which is soluble in benzene, was identified, like *(3)*, by mass, IR, and NMR spectra[6].

Procedure:

(1)→(2)→(3): To a suspension of $(Me_3P)_2PdCl_2$ (330 mg, 1 mmol) in THF (10 ml) is added a solution of *(1)* (2 mmol) in THF (20 ml). After 3 h the orange-yellow precipitate is filtered off, washed with THF and pentane, and dried at 60 °C/0.1 torr: Yield 830 mg (98 %) *(2)*, dec. pt. 190 °C.—A suspension of *(2)* (2.18 g, 2.5 mmol) in benzene (10 ml) is treated with $MeEt_2PCH_2$ (2.5 mmol) and stirred for 30 minutes. After removal of solvent the residue is taken up in toluene; *(3)* is then precipitated by addition of pentane. Yield 740 mg (50 %), m.p. 150 °C; MS: *m/e* = 608 [M^+(^{106}Pd)].

^{1}H-NMR ([D$_8$]-toluene, TMS int.): δC_2H_5 0.83 and 0.47, A_3B_2X, 10H; $\delta PdCH_2$ −0.35, m, 4H; δCH 2.9, "t", 1H, J_{HCP} 3 Hz; δC_6H_5 5.85, m, 20H.—^{31}P-NMR ([D$_8$]-toluene, H_3PO_4 ext.): δPPd 21.2, d, 2P; δPEt_2 −25.3, t, 1P, J_{PCPdP} 8.

(1)→(4)→(5): To a suspension of $(Me_3P)AuCl$ (308 mg, 1 mmol) in 10 ml THF is added a solution of the equivalent amount of *(1)* in THF. The yellow precipitate is washed with THF and pentane and then dried at 60 °C/0.1 torr. Yield 490 mg (85 %) *(4)*, dec. pt. 240 °C.—A suspension of *(4)* (480 mg, 0.82 mmol) in benzene (10 ml) is treated with 50 mg (0.43 mmol) $MeEt_2PCH_2$. After decoloration the solution is filtered and the filtrate evaporated down. *(5)* is precipitated by addition of pentane. Yield 275 mg (75 %), m.p. 186 °C (from toluene/pentane); MS: *m/e* = 894 [M^+]; IR: ν(AuC) = 550, ν(AuP) = 388 cm^{-1}.

^{1}H-NMR (C_6D_6, TMS ext.): δCH_3 0.87, dt, 6H, J_{HCCH} 7 Hz, J_{HCCP} 18; δCCH_2 1.25, m, masked by $\delta AuCH_2$ 1.10, d, J_{HCP} 9 (together 8H); δCH 2.50, "t", 1H, J_{HCP} 4.5; δC_6H_5 7.70, m, 20H.—^{31}P-NMR ([D$_8$]-toluene, H_3PO_4 ext.): δPAu −23.2, d, 2P; δPEt_2 −27.8, t, 1P, J_{PCAuP} 12.

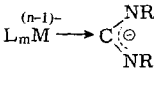
Carbodiimides as Source of Isocyanide and Carbonyl Ligands[**]

By *Wolf Peter Fehlhammer, Andreas Mayr*, and *Michael Ritter*[*]



Application of the Ugi reaction[1] to carbamoylmetal compounds (*C*-metalated formamides) leads to *isocyanide complexes* under extremely mild conditions[2]. Deprotonated carbamoyl complex species[3a], as formed by simple addition of isocyanates to carbonylmetalates[3b], may also be used as starting material. This synthetic principle, which is apparently of general validity for heteroallenes X=C=NR[4], is demonstrated for *carbodiimides*. In the presence of electron-rich metal compounds this heteroallene also proves to be a productive source of novel *carbene complexes*.

The reaction between carbonylmetal anion and carbodiimide, which requires from a few minutes at −78 °C [(I), *(1a)*] to several weeks at room temperature [(I), *(2b)*], can be followed by IR spectroscopy. The disappearance of the ν_{as}(NCN) band of the free carbodiimide is accompanied by

$$RN{=}C{=}NR + L_mM^{n-} \longrightarrow [L_mMC(NR)_2]^{n-} \quad (1)$$

L_mM = $Cr(CO)_5$ *(1)*, $C_5H_5Fe(CO)_2$ *(2)*
R = C_6H_5 *(a)*, C_6H_{11} *(b)*

the appearance of new bands in the region of 1500—1600 cm^{-1} which we assign to ν(N···C···N) vibrations of an adduct of the *C*-metalated formamidine type *(3)*. At the same time the ν(CO) bands shift to higher wavenumbers, indicating delocalization of the negative charge over the entering allene system.

Protonation of this adduct with HCl in tetrahydrofuran leads to the diaminocarbene complexes *(4)* and *(5)*, thus supporting formulation *(3)*.

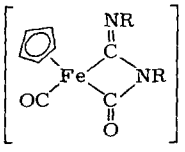
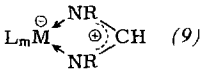
[**] Isonitrile Syntheses at the Metal, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 2: [2].

$(OC)_5CrC(NHR)_2$ (4) $[\eta^5\text{-}C_5H_5Fe(CO)_2\{C(NHR)_2\}]Cl$ (5)





As expected, on reaction with phosgene *(1a)* is split into the isocyanide complex *(6)* and $NC_6H_5^{2-}$, which occurs as phenyl isocyanate.

$$(1a) \xrightarrow[-2\,NaCl,\,-C_6H_5NCO]{COCl_2} (OC)_5CrC{\equiv}NC_6H_5 \quad (6)$$

This reaction clearly demonstrates the analogy between *(3)* and *N,N'*-disubstituted ureas, which react with phosgene to give two molecules of isocyanate[5]. Surprising, and inconsistent with the intermediacy of *(3)*, however, is the formation of the diisocyanide complex *(7)*.

$$(2) \xrightarrow[-NaCl,\,-CO_2]{COCl_2} [\eta^5\text{-}C_5H_5Fe(CO)(C{\equiv}NR)_2]Cl \quad (7)$$

For this reason we assume *(2)*, which can be isolated as yellow sodium salt, to have the chelate structure *(8)*, resulting from a primary product *(3)* by intramolecular nucleophilic attack of a carbodiimide nitrogen at the neighboring carbonyl ligand. In agreement with the suggested structure *(8)* the IR solution spectrum of *(2)* shows only one ν(CO) band (1886 cm^{-1}) accompanied by a remarkably intense structured band at *ca.* 1550 cm^{-1} [ν(N···C···N)+ν(C=O, carboxamide)].

Na [] *(8)*  *(9)*

A similar $\overline{FeC(NHR)N(R)C(NHR)}$ four-membered ring—product of addition of methylamine *via* two *cis* RNC ligands in hexakis(methyl isocyanide)iron(II)—has been confirmed X-ray crystallographically[6]. Most likely the isomerization carbamoyl(isocyanide)→carbonyl(carbene) complex[7] observed on addition of amine to $Mn(CO)_4(CNR)_2^+$ also proceeds *via* a four-membered ring as intermediate.

The reaction behavior of the iron adducts follows from their carboxamide structure *(8)*. Thus, protonation leads to cleavage of the four-membered ring at the CN carboxamide bond[3b], whereas phosgene attacks the exocyclic CO bond[2], causing ring opening in the formamidine moiety. In that case the carbodiimide molecule is completely used up for the construction of two isocyanide ligands, and the C atom required for mass balance is provided by a CO ligand.

Previously, complexes of type *(7)* were obtained only by substitution reactions, which naturally afford mixed products. The reaction of carbodiimides with carbonylmetalates and acids allows their direct synthesis and at the same time opens up a convenient entry to complexes such as *(4)* and *(5)*, which hitherto could not be synthesized by alternative routes.

Carbodiimides behave "quasi-ambivalent" toward metals: only the most electron-rich metal compounds obviously are capable of interacting with the weakly electrophilic carbodiimide carbon. In contrast, coordination to metals in higher oxidation states proceeds *via* one or even both nitrogen atoms, as observed, *e.g.*, in insertion products of type *(9)*[8].

Procedure

Adduct (2a): A solution of diphenylcarbodiimide (20 mmol) in THF (50 ml) is added with stirring at −78 °C to a solution of $Na[\eta^5\text{-}C_5H_5Fe(CO)_2]$ (20 mmol) in *ca.* 200 ml THF[9]. The mixture is allowed to warm to room temperature, stirred for a further 15 minutes, and then re-cooled to −78 °C.

$[\eta^5\text{-}C_5H_5Fe(CO)_2\{C(NHC_6H_5)_2\}]PF_6$ *(10a):* 50 mmol HCl in ether is added dropwise with stirring to a solution of *(2a)*. The mixture is evaporated to dryness, dissolved in water, and treated with NH_4PF_6 solution. Recrystallization of the resulting precipitate affords 5.5 g (53 % based on $[CpFe(CO)_2]_2$) ocher-colored crystals, m.p. 125 °C.

$[\eta^5\text{-}C_5H_5Fe(CO)(CNC_6H_5)_2]PF_6$ *(11a):* A 1 M solution of phosgene in THF (20 ml) is added dropwise with stirring to a solution of *(2a)* and the product isolated as in the case of *(10a)*. Recrystallization from ethanol yields 6.1 g (63 %) light-brown crystals, m.p. 142 °C.

Repetitive Peptide Synthesis with Insoluble Polymer-Bound Reagents and Solubilizing Macromolecular Peptide Carriers[**]

By *Gerhard Heusel, Günter Bovermann, Walter Göhring*, and *Günther Jung*[*]

For chain lengthening, peptides bound C-terminally to soluble polymeric carriers react quantitatively with activated *N*-protected amino acid esters which are bound to an insoluble matrix. We used the crystallizable polyoxymethylene introduced by *Bayer* and *Mutter*[1] for peptide synthesis as solubilizing peptide carrier and the N_α-*tert*-butyloxycarbonylamino acid ester of 2-nitrophenol[2] and 1-hydroxybenzotriazole[3] bound to crosslinked polystyrene as insoluble polymeric reagent (see Fig. 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

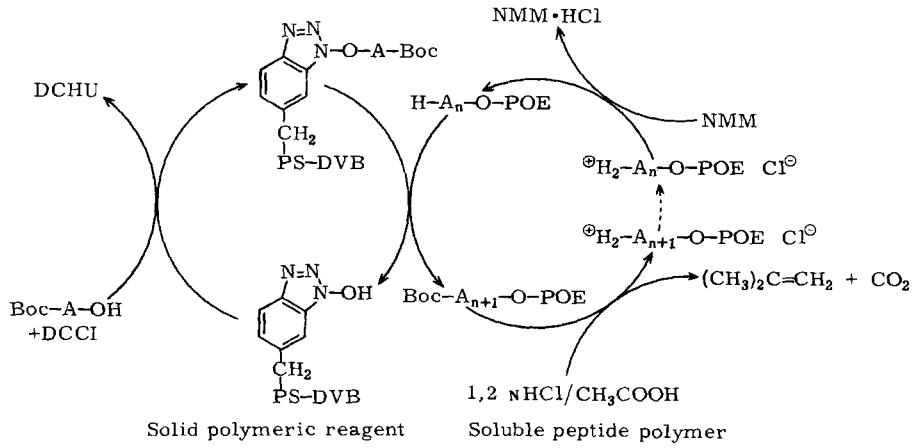

Fig. 1. Reaction scheme for peptide synthesis by coupling of polymer reagent with soluble peptide polymers. A = amino acid, Boc = *tert*-butyloxycarbonyl, DCCI = dicyclohexylcarbodiimide, DCHU = dicyclohexylurea, NMM = *N*-methylmorpholine, POE = polyoxyethylene, PS-DVB = 2% crosslinked polystyrene-divinylbenzene.

The synthesis of some oligopeptides[4] shows that, surprisingly, no complications arise in the inhomogeneous reactions of the two polymers. The advantages of the liquid-phase synthesis[1] (no reduced solubility of the growing fully-protected peptide chain, precise control of conversions) and the polymeric reagents (maintenance of supply of activated, *N*-protected building units, regeneration, favorable process engineering in batch or continuous column processes) are retained. Our repetitive peptide synthesis leads to fundamental simplification and improvement, since for the first time in peptide coupling, neither are side-products formed, nor do excess coupling components have to be removed.

General procedure:

A mixture of amino acid polyoxyethylene ester with free amino groups (molecular mass 6000, loading at least 0.2 mmol g. H-A-O-POE) in CH_2Cl_2 (5 ml) and *N*-Boc-amino acid-1-hydroxybenzotriazole ester bound to solid polystyrene (5 g) (loading about 1 mmol/g) is stirred for 2 h at 20 °C; the pH is maintained at 7—8 with *N*-methylmorpholine (NMM). The solution of the peptide-polymer Boc-A_2-O-POE is removed from the polymeric reagent by filtration. After determination of the coupling yield by titration or dansylation of the liberated amino groups, recoupling is continued until less than 0.1% free amino groups are detectable. After removal of solvent the Boc group of the dipeptide polymer is cleaved in the usual way with 1.2 N HCl/glacial acetic acid. The next coupling to the *N*-protected tripeptide polyoxyethylene ester can then be carried out. Considerably shorter coupling times and smaller excess quantities of reagent are required with the polymer-bound 1-hydroxybenzotriazole derivatives than with the corresponding 2-nitrophenol derivatives[4] (Fig. 2).

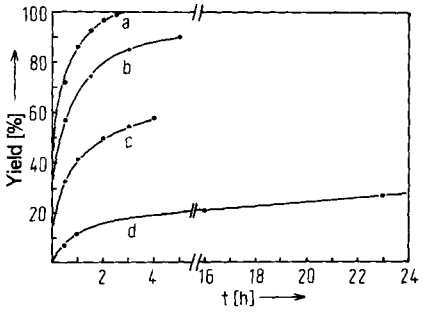

Fig. 2. Comparison of the coupling of Boc-L-Ala-O-(polystyrenehydroxybenzotriazole) with H-L-Val-O-POE of mol. masses 6000 (a), 10000 (b), and 20000 (c), and of Boc-L-Ala-O-(polystyrene-2-nitrophenol) with H-L-Val-O-POE of mol. mass 6000 (d). A threefold excess of polymeric reagent was used in each case.

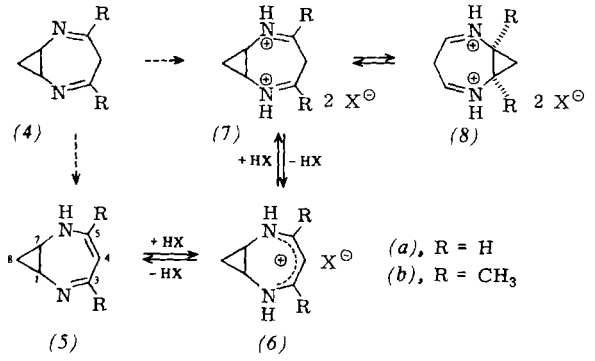
Degenerate Cope Rearrangement of the 2,6-Bisazoniabicyclo[5.1.0]octa-2,5-diene Dication[**]

By *Helmut Quast* and *Josef Stawitz*[*]

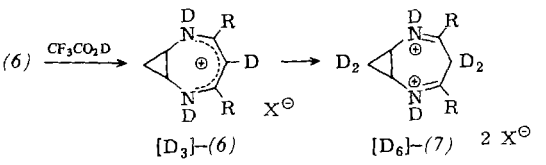
In memoriam Professor Hans Schmid

None of the non-classical semibullvalenes and diazasemibullvalenes with delocalized, bishomoaromatic ground states as proposed by *Hoffmann*[1] and *Dewar*[2], has yet been synthesized. In the search for realistic models for one of these compounds, 3,7-diazasemibullvalene *(1)*[2], we recently investigated the Cope rearrangement of the bisimines *(2)* resulting in the diazepines *(3)*[3]. We report here on the Cope rearrangement of 2,6-bisazonia-bicyclo[5.1.0]octa-2,5-diene dications *(7)*.



(1) *(2)* *(3)*

Diaza-3,4-homotropilidenes *(4)*, which are closely related to 3,7-diazasemibullvalene *(1)*, should not exist as such but are expected to tautomerize to their more stable tautomers *(5)*[4]. Their double protonation should however regenerate the structure *(4)* and produce the dications *(7)* having the structural prerequisites for a Cope rearrangement.



[*] Prof. Dr. H. Quast, Dipl.-Chem. J. Stawitz
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie. The results are taken from the planned dissertation of *J. Stawitz*.

(5b) (92%) is obtained in aqueous, acetate-buffered solution from the dihydrochloride of *cis*-1,2-cyclopropanediamine[5] and 2,4-pentanedione after 45 h at 75 °C, followed by basification and ether extraction; it is formed as pale yellow crystals (m.p. 161—164 °C) which sublime at 100—120 °C/10^{-5} torr. The structure of *(5b)* and its perchlorate *(6b)*, X = ClO_4, is based on IR, UV, ^{1}H-NMR (Table 1) and mass spectra.

The unsubstituted *(6a)* is less readily accessible than *(6b)* since the formation of a formal dimer with a 14-membered ring[6] competes with the ring closure yielding *(6a)*. Indeed the 14-membered ring[6] alone is formed from *cis*-1,2-cyclopropanediamine and malondialdehydedianil perchlorate[3,4] which has successfully been used in the synthesis of 2,3-dihydro-1*H*-1,4-diazepines having unsubstituted 5-, 6- and 7-positions, such as *(3)*. Only in rather dilute solution (5×10^{-3} to 6×10^{-3} M) in water/ethanol (1:1) did the sodium salt of malondialdehyde and the dihydrochloride of *cis*-1,2-cyclopropanediamine afford the cation *(6a)* free from dimer and decomposition products. It was isolated as the tetraphenylborate (yield 49%) which crystallized from dioxane, together with one mol of dioxane, as light-sensitive, pale yellow crystals with m.p. 226—228 °C. Its structure was established by IR, UV and ^{1}H-NMR spectra (Table 1).

as is shown by the intact ABX_2 spectra of the cyclopropyl protons. Accordingly, under these conditions D^+ may add to *(6)*, but the Cope rearrangement of the dications, which are present only in minimal amounts, apparently cannot yet compete with the reverse reaction. Addition of an equal volume of [D_2]-sulfuric acid to the solution of [D_3]-*(6a)* in [D]-trifluoroacetic acid results in the immediate disappearance of the AB part of the spectrum which only exhibits two equally intense singlets for 1-H, 7-H and 3-H, 5-H and thus proves formation of [D_6]-*(7a)* as the result of a rapid, degenerate Cope rearrangement.

The Cope rearrangement of *(7b)* should be rendered more difficult by the two methyl groups on the cyclopropane ring[7] of *(8b)*. Indeed the formation of [D_6]-*(7b)* requires more severe conditions, namely the warming of [D_3]-*(6b)* in [D]-trifluoromethanesulfonic acid.

The ^{1}H-NMR spectra of the dications *(7a)* and *(7b)* (Table 1) in trifluoromethanesulfonic acid are temperature dependent. The AB spectrum of the protons 4-H and 4'-H of *(7b)* is already broadened at 30 °C, this being especially evident in the low-field half of the spectrum. At 90 °C, only a broad singlet is observed for one of the two protons while the signal of the other proton at lower field can no longer be recognized. The reason for this is the difference in the rates of exchange of the protons 4-H and 4'-H with trifluoromethanesulfonic acid which, at the higher temperatures, are comparable with the ^{1}H-NMR time scale. In contrast, the ABX_2 spectrum of the cyclopropane protons of *(7b)* remains unchanged up to 90 °C. There is even a certain sharpening of the ABX_2 spectrum.—In the ^{1}H-NMR spectrum of *(7a)* in trifluoromethanesulfonic acid, already at 30 °C only the broad signal of one of the two protons 4-H and 4'-H can be recognized. Their rate of exchange with trifluoromethanesulfonic acid approximately corresponds to that of *(7b)* at 90 °C. Contrary to the changes observed with *(7b)*, in the case of *(7a)* an increase in temperature causes a broadening of *all* signals due to the rapid, degenerate Cope rearrangement; the fine structure of the ABX_2 spectrum also disappears. Above 100 °C slow decomposition begins. The ^{1}H-NMR spectra of *(7a)* and [D_6]-*(7a)* can be used to estimate a coalescence tempera-

Table 1. Chemical shifts and coupling constants (Hz) in the 90 MHz ^{1}H-NMR spectra of 2,6-diazabicyclo[5.1.0]octa-2,4-diene *(5)* and of the cations *(6)* and *(7)* derived therefrom. The data of the ABX_2 spectra of the cyclopropane protons were optimized using the LAOCOON III program.

[a] Internal standard TMS = 0.
[b] Internal standard [2,2,3,3-D_4]-3-trimethylsilylpropionic acid = 0.
[c] External standard TMS (50 percent in CCl_4).
[d] Broadened.
[e] 7-H still coupled with 6-H.

2,3-Dihydro-1*H*-1,4-diazepinium cations, *e.g.* *(3)*·H^+, already show rapid H/D exchange at their 1-, 4- and 6-positions[4] in [D]-trifluoroacetic acid. If the two methylene groups in *(7)* were to become equivalent due to a Cope rearrangement, then in deuterated strong acids the [D_6]-bisazonia-3,4-homotropilidene dications [D_6]-*(7a)* and [D_6]-*(7b)* should be formed from *(6a)* and *(6b)*, respectively.

In [D]-trifluoroacetic acid however, only the trideuterated cations [D_3]-*(6)* are observed in the ^{1}H-NMR spectra,

ture of 110±10°C for the signals of 1-H, 7-H and 3-H, 5-H and thus an activation barrier of $\Delta G_c^{\neq} = 73 \pm 2$ kJ/mol ($\Delta\nu = 409$ Hz) for the degenerate Cope rearrangement (assuming that all of *(7a)* is present as the dication). The activation barrier is thus clearly larger than that of 3,4-homotropilidene[8] but very similar to that of disubstituted 3,4-homotropilidenes[9].

Formation of Chlorophenols by Microbial Transformation of Chlorobenzenes[1]

By *Karlheinz Ballschmiter, Charlotte Unglert*, and *Peter Heinzmann*[*]

Only chloropyrocatechols have hitherto been described as products of the microbial degradation of chlorobenzenes[2]. We have now investigated the microbial transformation of the monochloro- to pentachlorobenzenes *(1)* (Table 1) into chlorophenols *(4)*.

(1) *(2)* *(3)* *(4)*

Table 1. Microbial transformation of chlorobenzenes *(1)* into chlorophenols *(4)* (experimental conditions see text).

Chlorobenzenes *(1)*	Chlorophenols *(4)*	Ratio [a]	Chlorobenzenes *(1)*	Chlorophenols *(4)*	Ratio [a]
(1a) 1-	*(4a)* 2-			*(4g)* 2,3,4-	7
	(4b) 2,3-	2	*(1e)* 1,2,3-	*(4h)* 2,3,6-	1
(1b) 1,2-	*(4c)* 3,4-	1		*(4i)* 3,4,5-	[b]
	(4d) 2,6-	[b]		*(4j)* 2,4,5-	
	(4e) 2,4-	6	*(1f)* 1,2,4-	*(4k)* 2,4,6-	
(1c) 1,3-	*(4f)* 2,5-	1	*(1g)* 1,3,5-	*(4k)* 2,4,6-	
	(4d) 2,6-	[b]	*(1h)* 1,2,3,4-	*(4l)* 2,3,4,5-	
(1d) 1,4-	*(4e)* 2,4-	3	*(1i)* 1,2,3,5-	*(4m)* 2,3,4,6-	
	(4f) 2,5-	1	*(1j)* 1,2,4,5-	*(4n)* 2,3,5,6-	
			(1k) 1,2,3,4,5-	[c]	

[a] Ratio after 24 h; [b] detected after 100 h; [c] not detectable.

We used mixed cultures of soil bacteria—preferably gram negative, polar flagellated rods—precultured on benzene. In the mineral salt solution (pH = 6.8) the bacteria had access to further benzene as a source of C. 200 mg of benzene and 50 mg of one of the chlorobenzenes *(1a)* to *(1k)* were allowed to diffuse from a hard paraffin layer (2 g) into 200 ml nutrient medium, whereupon the concentration of the chlorobenzene in solution finally amounted to 10^{-6} to 10^{-7} M (*ca.* 20 to 200 ppb). After 24, 100, 240, and 500 hours' incubation at 28 °C the cells and nutrient medium were worked up for chlorophenols[3]. The chlorophenols were extractively esterified with acetic anhydride in 0.1 M K_2CO_3 solution and identified by comparison of the retention indices of the esters with those of authentic compounds (glass capillary gas chromatography with ^{63}Ni electron-capture detector; Carlo Erba, Model 2300)[4]. Combined GC-MS using glass capillaries enabled additional confirmation of structure.

The degradation of benzene to phenol and its further hydroxylation to diphenols was investigated in the same experimental setup. The reaction products phenol, pyrocatechol, resorcinol and hydroquinone were identified by comparison of the retention indices of their pentafluorobenzyl ethers[5] with those of the authentic substances. Usually it is assumed that dioxygenases are responsible for the microbial degradation of benzene[6].

Microbial degradation of the chlorobenzenes *(1)* can be assumed to proceed *via* attack by a monooxygenase, since the observed distribution of isomers can only be rationalized in terms of an intermediary chlorinated cyclohexadiene epoxide *(2)*. With epoxides as intermediates, a migration of the chloro substituents is possible[7].

After a while diphenols can be detected in the joint degradation of chlorobenzenes and benzene *(vide supra)*. Their mode of formation is still unclear.

The hydroxylation shows structural specificity. In four experiments with different cultures only 2-chlorophenol was formed from chlorobenzene. All chlorophenols up to 3,4-dichloro- and 3,4,5-trichlorophenol are formed by attack at the *ortho* position to the chlorine of a —CCl=CH group.

In assessing the occurrence of phenol and chlorophenols as pollutants not only their direct release into the environment must be taken into consideration but also their formation by microbial transformation of benzene and chlorobenzenes.

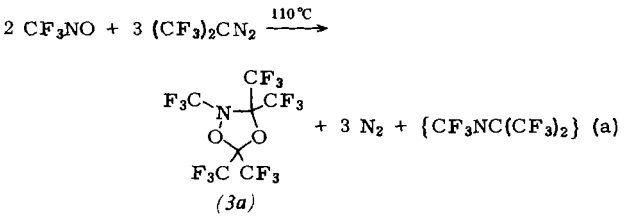
Synthesis of a Stable 1,3,4-Dioxazolidine[**]



By *Jürgen Varwig* and *Rüdiger Mews*[*]

Whereas 1,3,2-[1] and 1,2,4-dioxazolidines[2], compounds *(1)* and *(2)* respectively, are well documented, to our knowledge only the thermally unstable 1:1:1 adduct of *tert*-butyl isocyanide, 2-methyl-2-nitrosopropane and phenyl isocyanate has so far been assigned the 1,3,4-dioxazolidine structure *(3)*—purely on the basis of its mass spectrum[3].

(1) *(2)* *(3)*

We have now been able to synthesize the 2,2,4,5,5-pentakis-(trifluoromethyl)-1,3,4-dioxazolidine *(3a)* in 25% yield from bis(trifluoromethyl)diazomethane and trifluoronitrosomethane:

(3a)

Apparently hexafluoroacetone is formed as intermediate product in this reaction, the yield of *(3a)* being almost doubled due to reaction according to eq. (b):

The product *(3a)* is a water-clear liquid, b.p. 85°C. The new compound is extraordinarily stable, both thermally and chemically; concentrated alkalis and acids decompose it only slowly. *(3a)* was characterized by elemental analysis and by IR and mass spectra; ^{19}F- and ^{13}C-NMR spectra afforded proof of its structure[4]. The ^{19}F-NMR spectrum shows three signals in the intensity ratio 2:2:1 [$\delta(2,5\text{-}CF_3^A) = -73.37$, mult.; $\delta(2,5\text{-}CF_3^B) = -76.70$, sept., $J_{F(A)F(B)} = 4.2$ Hz; $\delta(NCF_3) = -64.58$, sept., $J_{FF(A)} = 9.18$ Hz], which do not permit unequivocal differentiation between *(3a)* and its 1,3,2-isomer *(1a)*, since similar intensity and coupling ratios are expected for *(1a)* for hindered inversion at nitrogen[5]. The ^{13}C-NMR spectrum, however, shows two nonequivalent quarternary carbon atoms [$\delta(C\text{-}2) = -100.89$, sept., $J_{CF} = 37.5$ Hz; $\delta(C\text{-}5) = -91.26$, sept., $J_{CF} = 36.1$ Hz] each bearing two trifluoromethyl groups [$\delta(2,5\text{-}C^A) = -119.76$, quart., $^1J_{CF} = 288.2$ Hz; $\delta(2,5\text{-}C^B) = -120.07$, quart., $^1J_{CF} = 288.3$ Hz; plus $\delta(NC) = -119.23$, quart., $^1J_{CF} = 270.0$ Hz.

Procedure

A mixture of $(CF_3)_2CN_2$ (17.8 g, 0.1 mol) and CF_3NO (9.9 g, 0.1 mol) is stirred in an autoclave at 110°C for 24 h. The product mixture is fractionally condensed *in vacuo* (−80°C, liq. air) and the contents of the trap (−80°C) finally distilled; yield 10.4 g (25%) colorless *(3a)*.—Analogous reaction of $(CF_3)_2CN_2$ (3.0 g, 0.017 mol), $(CF_3)_2CO$ (2.8 g, 0.017 mol) and CF_3NO (1.7 g, 0.017 mol) affords 3.7 g (53%) *(3a)*.—IR [gas, cm^{-1}]: 1382 w, 1348 w, 1305 s, 1280 vs, 1259 vs, 1230 s, 1202 m, 1170 s, 1123 s, 1091 m, 1002 m, 990 s, 923 w, 769 w, 752 w, 742 w, 723 m. MS [70 eV, (rel. int.)]: $m/e = 415$ M^+ (14), 69 CF_3 (100).

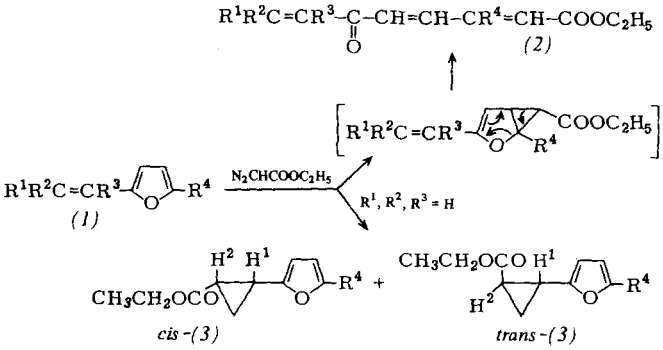
[5] The phosphorus analog of *(1a)*, prepared for comparison from $[(CF_3)_2COLi]_2$ and CF_3PCl_2 in tetrahydrofuran, shows three signals in the ^{19}F-NMR spectrum [$\delta(4,5\text{-}CF_3^A) = -66.7$, mult.; $\delta(4,5\text{-}CF_3^B) = -65.8$ mult.; $\delta(PCF_3) = -65.0$, dubl. of sept., $J_{CF_3\text{-}P} = 75.0$ Hz, $J_{CF_3\text{-}CF_3^B} = 6.2$ Hz]; the ^{31}P-NMR spectrum shows a quartet of septets [$\delta = +174.4$, $J_{P\text{-}CF_3^B} = 18.8$ Hz]. As in the case of the 4,4,5,5-tetramethyl-1,3,2-dioxaphospholane [*B. Fontal, H. Goldwhite*, Tetrahedron *22*, 3275 (1966)] no inversion is observed at the phosphorus.

Reaction of Alkenylfurans with Ethyl Diazoacetate



By *Oleg M. Nefedov, Viacheslav M. Shostakovsky*, and *Alexander E. Vasilvizky*[*]

Dedicated to Professor G. Wittig on the occasion of his 80th birthday

Whereas alkenylarenes (vinylbenzene, vinylnaphthalene) react with ethyl diazoacetate with exclusive formation of cyclopropane compounds, the alkenylfurans 2-isobutenylfuran *(1a)*, 2-(1-propenyl)furan *(1b)*[1] and 2-(1-methyl-1-propenyl)furan *(1g)* react with this reagent to give ethyl esters *(2)* of acyclic oxoalkatrienecarboxylic acids. The formation of the ester *(2)* can be explained by participation of the double bond of the furan ring[2] remote from the alkenyl substituent.

Neither the reaction temperature nor the manner of decomposition of the ethyl diazoacetate (catalysis, thermolysis or photolysis) influences the reaction path (Table 1). The properties of some of the esters *(2)* are listed in Table 2.

In contrast, reaction of 2-vinylfuran *(1c)* and 2-methyl-5-vinylfuran *(1d)* with ethyl diazoacetate leads mainly, and of 5-chloro-2-vinylfuran *(1e)* and 5-bromo-2-vinylfuran *(1f)*

[b] Adduct with maleic anhydride, prepared in boiling xylene (5 h), m.p. 172°C (from benzene).

exclusively, to the formation of ethyl esters of 2-(2-furyl)cyclopropanecarboxylic acids *(3)*. The adducts are 2.5—3:1 mixtures of *trans*- and *cis*-isomers (GLC and NMR data)[3]. Configurations of the isomers *(3)* were assigned by analysis of the ^{1}H-NMR spectra (multiplets of $—CH_2—O—$, H^1 and H^2) taking into account the magnetic anisotropy of the furan ring[4].

The different behavior of *(1a)*, *(1b)* and *(1g)*, on the one hand, and of *(1c)* to *(1f)* on the other, toward ethyl diazoacetate, correlates with the fact that the ratio of rate constants for addition to the vinyl double bond and for addition to the double bond remote from substituents in the furan ring decreases with increasing number of methyl substituents on the vinyl group. It can be largely explained in terms of steric factors. As competition reactions show (cf. Table 1), the double bond of the furan ring (remote from alkenyl substituents) in *(1a)* and *(1b)* is more reactive than the double bond in hexene.

Though the relative rate constants for the addition of ethyl diazoacetate to the double bond remote from alkenyl substituents do indeed depend upon the electronic character of the substituents [see *(1c)* and *(1d)* in Table 1], big differences in the values cannot be explained by steric and electronic factors only. Apparently the observed effect is connected with the ease with which the furan ring forms complexes.

Nickel(II)-Catalyzed Synthesis of Pyrroles from 2*H*-Azirines and Activated Ketones[**]

By *Pedro Faria dos Santos Filho* and *Ulf Schuchardt*[*]

3-Phenyl- and 2,3-diphenyl-2*H*-azirine[1], *(1a)* and *(1c)* respectively, react with dimedone at 145°C to give the pyrroles *(3d)* and *(3f)*[2]. We have now found that this reaction can be extended to a large number of activated ketones and that it is catalyzed by nickel(II) compounds.

(1) *(2)* *(3)*

The catalysis proves advantageous in that side-reactions are avoided. With sufficiently activated CH_2 groups in the ketone *(2)*, reaction with the azirine *(1)* proceeds to completion, even at room temperature; the pyrrole *(3)* can be precipitated in analytically pure form and in quantitative yield by addition of water (Table 1).

The versatility of this synthesis when *(2)* is sufficiently enolized would seem to be limited only by the number of known 2*H*-azirines *(1)*.

(3a), *(3c)*, *(3g)*, and *(3k)* were first prepared by *Knorr et al.* by reduction of the α-nitrosocarbonyl compounds with zinc dust in acetic acid in the presence of the corresponding ketone *(2)*[3]. We synthesized *(3b)*, *(3e)*, and *(3f)* in a similar

way in order to confirm their structures. However, in some cases purification of the product was demanding, and the yields were at most 50 %. It could be shown that the three-membered ring is opened only at the N=C double bond, and that an opening at the C—C single bond, as observed in the photolysis of *(1)*[1], does not occur. The reaction also proceeds *via* cleavage of N=C bond at 145 °C in the absence of catalyst. We prepared *(3a)*, *(3c)*, *(3f)*, and *(3l)* in this way, but the yields were less than 50 %; for purification of the products, chromatography on neutral aluminum oxide was necessary.

2,2-Dimethyl-3-phenyl-2*H*-azirine does not react with *(2)* in the presence of bis(2,4-pentanedionato)nickel at room temperature. The H atom in position 2 of *(1)* therefore seems to play an essential role in the reaction.

The reaction is not catalyzed by acids ($HClO_4$, $BF_3 \cdot Et_2O$). Reaction of *(1a)* with sodium acetylacetonate affords *(3a)* in only *ca.* 10% yield, the main products of the reaction being unidentified oligomers. The sodium salt of *(2)*, $R^3 = CO_2Et$, $R^4 = Ph$, reacts with *(1a)* to give 3-benzoyl-4-phenyl-2-oxopyrroline[4]; however, on reaction of this ketone *(2)* with *(1a)* in the presence of catalytic amounts of Ni^{II}, we obtained *(3l)*.

The reaction *(1)*+*(2)*→*(3)* is also catalyzed by other transition metal compounds.

General procedure

Bis(2,4-pentanedionato)nickel (15—20 mg, *ca.* 0.06 mmol) is added at room temperature to a solution of azirine *(1)* (5 mmol) and activated ketone *(2)* (5 mmol) in acetone (10 ml). After an induction period of 10—15 min the solution warms to 35—40 °C. For completion of reaction the mixture is stirred for 2–3 h at room temperature. The pyrrole *(3)* is then quantitatively precipitated with *ca.* 30 ml water. Precipitation with petroleum ether is also possible, but in the case of *(3a)*, for example, the yield is reduced owing to its significant solubility.

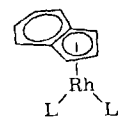
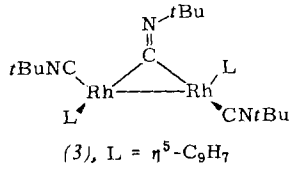
Reactivity of η^5-Indenylrhodium(I) Complexes; Cyclocotrimerization of Alkynes with Alkenes[**]



By *Peter Caddy, Michael Green, Edmund O'Brien, Lesley E. Smart*, and *Peter Woodward*[*]

$[MoX(CO)_3(\eta^5\text{-}C_9H_7)]$ (X = halogen) has a higher reactivity towards ligand substitution than the corresponding $\eta^5\text{-}C_5H_5$ system[1]. This difference is explicable in terms of the "slippage" of the indenyl ligand ($\eta^5\text{-}C_9H_7 \rightarrow \eta^3\text{-}C_9H_7$). The possible general synthetic consequences of this kinetic observation in the synthesis of transition metal organic compounds have been examined[1].



$[Rh(C_2H_4)_2(\eta^5\text{-}C_5H_5)]$ does not react with carbon monoxide, whereas the η^5-indenyl analog reacts instantaneously at room temperature to give $[Rh(CO)_2(\eta^5\text{-}C_9H_7)]$[2] ($\nu_{CO}$ = 2048 s, 1990 s cm^{-1}) in quantitative yield. Prolonged photolysis of $[Rh(CO)_2(\eta^5\text{-}C_5H_5)]$ affords two isomers of $[Rh_3(CO)_3(\eta^5\text{-}C_5H_5)_3]$, albeit only in low yield[3], while in refluxing heptane dicarbonyl(η^5-indenyl)rhodium is converted selectively in high yield into the dark-green trimer *(1)*[4] [ν_{CO} (CH_2Cl_2) 1852 s, 1805 s cm^{-1}].

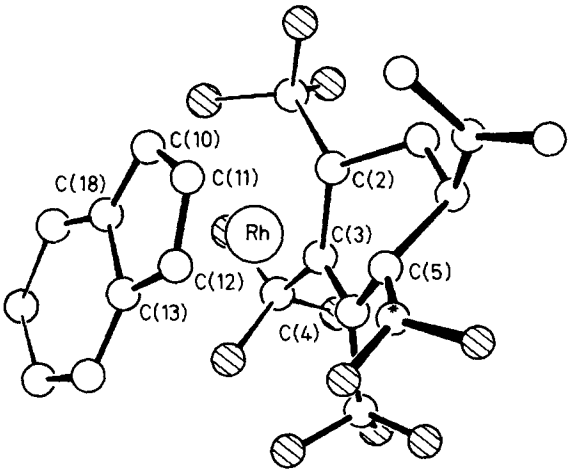
2120 cm^{-1}]. The ^{1}H-NMR spectrum of *(3)* indicates rapid bridged to terminal isocyanide exchange (cf. [5]). Ethylene can also be readily displaced from $[Rh(C_2H_4)_2(\eta^5\text{-}C_9H_7)]$ at room temperature by methylenecyclopropane, acrylonitrile and 1,3-dienes such as isoprene, cyclohexadiene or 1,3,5-cycloheptatriene forming respectively the crystalline complexes *(4)*, *(5)*, *(6)*, *(7)* and *(8)*. Similar reactions cannot, of course, be achieved with the $\eta^5\text{-}C_5H_5$ system[6].

The facile reaction of the η^5-indenyl complex with alkynes is of interest in terms of its relevance to recent comments[7] on the cyclocotrimerization of alkynes and alkenes. Reaction of $[Rh(C_2H_4)_2(\eta^5\text{-}C_9H_7)]$ with an excess of 3,3-dimethyl-1-butyne results in the rapid catalytic cyclotrimerization of the alkyne to 1,2,4-tri-*tert*-butylbenzene[8]. However, if the reaction is run at low alkyne concentration the complex (1,4-di-*tert*-butylcyclohexa-1,3-diene)(η^5-indenyl)rhodium *(9)* is obtained as yellow crystals, the diene being readily displaced by carbon monoxide.



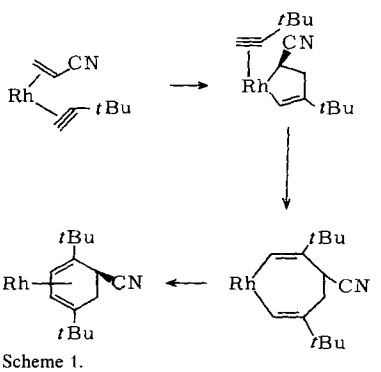


Fig. 1. Molecular structure of (η^5-indenyl)[5-isopropenyl-1,2,3,4-tetrakis(trifluoromethyl)-1,3-cyclohexadiene]rhodium(I) *(11)*. Space group Pbca, $a=16.962(3)$, $b=29.618(4)$, $c=8.596(4)$ Å, $V=4318.1$ Å^3, $Z=8$; Syntex four circle diffractometer; 2879 independent reflections ($I_0 \geq 1.0\sigma I$); $2.9° \leq 2\theta \leq 50°$ (Mo-K_α radiation); $R=0.063$. Rh—C(2): 2.15, Rh—C(3): 2.07, Rh—C(4): 2.09, Rh—C(5): 2.10, Rh—C(10): 2.18, Rh—C(11): 2.19, Rh—C(12): 2.18, Rh—C(13): 2.32, Rh—C(14): 2.31 Å; estimated mean standard deviation 0.01 Å.—For clarity the fluorine atom at * has been omitted.

Similarly, bis(acrylonitrile)(η^5-indenyl)rhodium *(5)* reacts with 3,3-dimethyl-1-butyne to give the cyano-substituted analog *(10)*. The reaction can also be extended to electronegatively substituted alkynes. Thus the isoprene complex *(6)* reacts at room temperature with hexafluoro-2-butyne to give *(11)* in the form of yellow orthorhombic crystals. According to X-ray structure analysis (see Fig. 1) the 1,3-diene part of the C_6-ring is planar; but the two carbon atoms originating from the isoprene bend away from the rhodium at a dihedral angle of *ca.* 132°. The propenyl group lies *endo* to the metal. The indenyl group is η^5-bonded to the Rh, but the atoms C(18) and C(13) are at greater bond distances from the rhodium than are C(10), C(11) and C(12).

Scheme 1.

Although the cyclocotrimerization of two alkyne molecules with an alkene molecule to form cyclohexa-1,3-diene derivatives has been the subject of a number of studies, with one exception[9] only the organic product has been isolated. The results reported here suggest the intermediacy of metallo-2-cyclopentenes[9] rather than metallocyclopentadienes[7], and that the incorporated alkene (ethylene or acrylonitrile) remains bonded to the metal throughout the reaction (see Scheme 1).

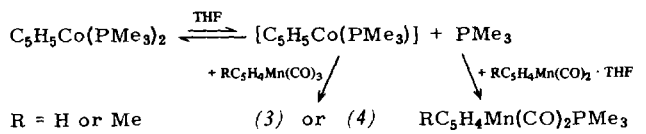
Synthesis and Reactivity of Hetero Dinuclear Complexes Containing a Mn—Co Bond[1]

By *Konrad Leonhard* and *Helmut Werner*[*]

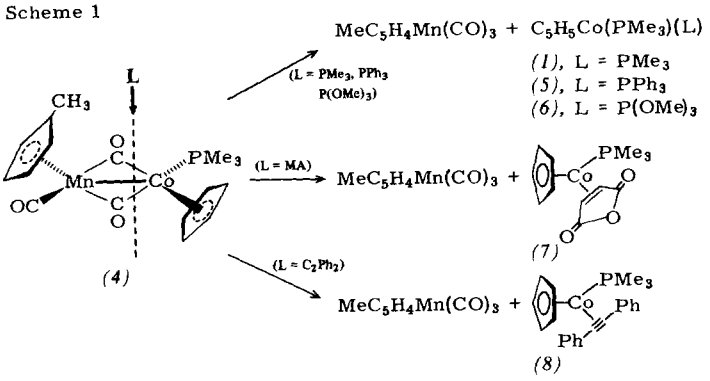
The compound $C_5H_5Co(PMe_3)_2$ *(1)*[2] recently synthesized by us is an extraordinarily strong nucleophile. It reacts not only with Brønstedt acids and with alkyl and acyl halides to give complex cations containing very stable Co—H and Co—C bonds[2] but also with Lewis acids such as $SnCl_4$, $ZnCl_2$, or $HgCl_2$ with formation of 1:1 adducts containing a metal-metal bond[3].



In order to test the reactivity of *(1)* toward Lewis acidic *transition metal* ligand fragments we have investigated the reaction of the cobalt compound with $C_5H_5Mn(CO)_2 \cdot THF$ (generated photochemically *in situ*, and present in THF solution together with $C_5H_5Mn(CO)_3$). Surprisingly, instead of the expected "adduct" *(2)* of the Lewis base $C_5H_5Co(PMe_3)_2$ and the Lewis acid $[C_5H_5Mn(CO)_2]$ we obtained the dinuclear complex *(3)*. Its composition and structure[4] are confirmed by elemental analysis, mass spectrum, IR, and NMR data (Table 1).

[*] Prof. Dr. H. Werner, Dr. K. Leonhard
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

$MeC_5H_4(CO)Mn(\mu\text{-}CO)_2Co(PMe_3)C_5H_5$ *(4)* could be synthesized in an analogous way.



We interpret the formation of the dinuclear complex in terms of intermediary formation of the 16-electron species $[C_5H_5Co(PMe_3)]$ (possibly solvated by THF) and subsequent reaction of this very reactive fragment with the inert tricarbonyl $RC_5H_4Mn(CO)_3$ (R = H, Me). This interpretation, which might seem very unusual at first sight, is supported by the finding that addition of $C_5H_5Mn(CO)_3$ to a *previously* irradiated solution of $MeC_5H_4Mn(CO)_3$ in THF (in which $MeC_5H_4Mn(CO)_2 \cdot THF$ is present as well as $MeC_5H_4Mn(CO)_3$ and *subsequent* reaction of this solution with *(1)* leads to formation of an isolable mixture of *(3)* and *(4)*, in which complex *(3)* predominates.

The formation and reactivity of 16e species of the type $[C_5H_5CoL]$ also underscores the result of the reaction of $C_5H_5Co(CO)_2$ with $MeC_5H_4Mn(CO)_2 \cdot THF$/ $MeC_5H_4Mn(CO)_3$. A (*Co—Mn*)-dinuclear complex is *not* formed, but a mixture of $(C_5H_5)_3Co_3(CO)_3$ and $(C_5H_5)_4Co_4(CO)_2$, thus indicating that the intermediate $[C_5H_5Co(CO)]$ reacts more rapidly with itself (or with $C_5H_5Co(CO)_2$) than with $MeC_5H_4Mn(CO)_3$. The Co_3- and Co_4-clusters so formed have already been synthesized photochemically[5, 6a].

(3) and *(4)* show pronounced reactivity toward Lewis bases L. For example, reaction of *(4)* with trimethylphosphane (in acetone or benzene at 30—50 °C) leads *quantitatively* to $MeC_5H_4Mn(CO)_3$ and *(1)*. In contrast, the *photolysis* of *(4)* in the presence of PMe_3 (in THF at room temperature) affords $MeC_5H_4Mn(CO)(PMe_3)_2$[7] and $C_5H_5Co(CO)PMe_3$. All other thermal reactions of *(3)* or *(4)* with L lead also to the complexes $RC_5H_4Mn(CO)_3$ (R = H, Me) and $C_5H_5Co(PMe_3)L$ *(5)—(8)*; particularly interesting is the reaction of the π donors maleic anhydride (MA) and tolane. "Mixed" cyclopentadienyl-bis(phosphane)- and -(phosphane)(phosphite)cobalt complexes such as *(5)* and *(6)* are to our knowledge unknown. These compounds could be useful starting materials for studies concerned with elucidating the mechanism of Co-catalyzed cyclotrimerizations of alkynes[8].

Scheme 1

We ascribe the *unsymmetrical* cleavage of the $Mn(\mu\text{-}CO)_2Co$ bridge fragment in *(3)* and *(4)* on reaction with Lewis bases (Scheme 1) to the *difference* in the metal atoms and their electron configurations. For equal distribution of the bonding electrons of the Mn—CO—Co bridges (taking into account a metal-metal single bond) the manganese would formally have 17 electrons and the cobalt 19 electrons in the valence shell. A "normal" 18e arrangement at both metal atoms would then be achieved, if 75 % of the two bonding electrons (= 1.5e) of each CO bridge belonged to the Mn and 25 % (= 0.5e) to the Co. As a consequence one would expect the Co—μ-CO bonds to be weaker than the Mn—μ-CO bond, as reflected by the reaction behavior of *(3)* and *(4)*. *Cotton et al.*[6] have demonstrated the presence of unsymmetrical CO bridges in the carbonylcyclopentadienylmetal complexes $(C_5H_5)_3Co_3(CO)_3$ and $(C_5H_5)_2V_2(CO)_5$; an unsymmetrical CO-bridge between two *different* metals has been found in $[FeCo(CO)_8]^-$ by *Bau et al.*[9].

Table 1. Spectroscopic data of the dinuclear complexes *(3)* and *(4)*.

Procedure

A solution of $MeC_5H_4Mn(CO)_3$ (1 mmol) in THF (200 ml) is irradiated with a mercury vapor lamp (Philips HPK 125 W) until evolution of gas has subsided. After switching off the lamp, the solution is treated with 1 mmol $MeC_5H_4Mn(CO)_3$ and 1 mmol *(1)* and then stirred for 16 h at room temperature. The oily residue obtained after removal of solvent *in vacuo* is washed several times with hexane and then recrystallized from THF/hexane: *(4)*, blue-black crystals, dec. pt. 121 °C; yield 330 mg (79 % w.r.t. *(1)*).

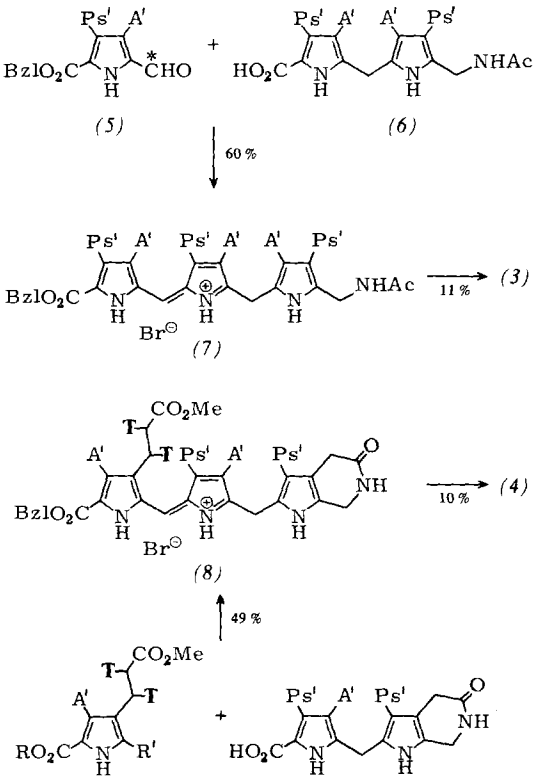
Total Synthesis of [^{14}C]- and [^{3}H]-Labeled Tripyrrole Precursors for Heme Biosynthesis[1]



By *Burchard Franck, Gregor Fels, Günter Ufer,* and *Arend Rowold*[*]

As has been demonstrated for heme *(2)*[2] and vitamin B_{12}[3] and is probably also the case for chlorophyll[4], uroporphyrinogen III *(1)* is a precursor of and key compound in the biosynthesis of biologically active porphyrins. Uroporphyrinogen III *(1)* is characterized by inversion of pyrrole nucleus D (in the dotted circle), together with its side chains. Isotopically labeled, biogenetically significant tripyrroles[5] are of importance for the elucidation of the biosynthesis of *(1)* from linear, oligopyrrole precursors, as well as for elucidation of the physiologically important "pyrrole inversion". We will now report the first total syntheses of the [^{14}C]- and [^{3}H]-labeled tripyrroles *(3)* and *(4)* respectively; each of them contains a terminal, inverted pyrrole nucleus and, of all the eight possible isomeric tripyrroles, these could well be the precursors preferred for biosynthesis.

On account of the complicated structure and high reactivity of the tripyrroles *(3)* and *(4)*, pathways for their syntheses were selected which, with extensive use of the convergence principle[6], yielded the stable well-protected depot compounds *(7)* and *(8)* from which *(3)* and *(4)* could be liberated by easy, mild reactions. Radioisotopes with different radiation energies were used to label the two tetrapyrroles so that when they were mixed, the individual rates of incorporation [of *(3)* and *(4)*] could be directly determined by measuring the radioactivities of the biosynthetic product, heme *(2)*. The positions of the labels were chosen so that the ^{14}C- and ^{3}H-isotopes (a) could be introduced into *(3)* and *(4)* respectively as late as possible in the multi-step synthesis, (b) would not be lost during biogenetic conversions, and (c) could be located in heme *(2)* by simple degradation.

The ^{14}C-labeled reactant for the synthesis of the tripyrrole *(7)* was pyrrolecarbaldehyde *(5)* which was obtained by Vilsmeier formylation with [^{14}CO]-dimethylformamide/$POCl_3$[7].

(5) was condensed with the dipyrrole derivative *(6)* with simultaneous decarboxylation in a single step (HBr/MeOH) to give the trinuclear compound *(7)*: m.p. 92—93 °C; FD-MS (12 kV): $m/e = 902$ (58 %, $M^{\oplus} - HBr$); ^{1}H-NMR ($CDCl_3$): $\delta = 13.22, 12.91, 10.36$ (3 s, 3 pyrrole-NH). Tritiated pyrrolecarbaldehyde *(9a)* condensed with the dipyrrole derivative *(10)* under the same conditions to yield *(8)*: m.p. 153—155 °C; FD-MS (11 kV): $m/e = 829$ ($M^{\oplus} - HBr + H$); ^{1}H-NMR ($CDCl_3$): $\delta = 11.36$ (2H), 10.02 (1H) (3 pyrrole-NH). The tritium was introduced catalytically into the pyrrolylacrylic ester *(9b)* with 5 Ci T_2/Pd and a 73 % yield of radioactivity. Subsequent transesterification and selective oxidation with sulfuryl chloride lead to the formation of *(9a)*.

The labeled tripyrroles *(3)* and *(4)* were prepared from the hydrobromides *(7)* and *(8)* respectively, with the yields specified, in four steps; these steps were conversion to the free base (NH_3), hydrogenolysis of the benzyl ester (H_2/Pd), decarboxylation (CF_3CO_2H, 0 °C), and alkaline saponification (2 N KOH, 20 °C).

Experimental

(7): A solution of *(5)* (418 mg, 1.08 mmol; 2.5 mCi) and *(6)* (624 mg, 1.08 mmol) in 25 ml methanol was mixed with 47 % HBr (0.8 ml) and stirred for 4 h at 20 °C. After 21 days in the refrigerator *(7)* (664 mg, 60 %) containing 1.45 mCi (58 %) had crystallized out.

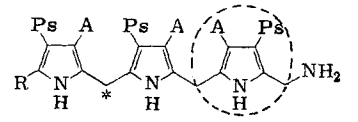
Heme Biosynthesis from [^{14}C]- and [^{3}H]-Labeled Tripyrroles[1]

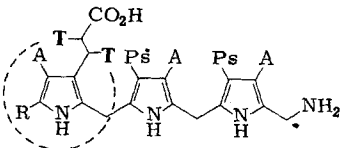
By *Burchard Franck, Gregor Fels*, and *Günter Ufer*[*]

The blood pigment heme [*(5)*, T=H] is biosynthesized *via* uroporphyrinogen III *(2)*[3] from four molecules of porphobilinogen *(1)*[2] under inversion of one of the pyrrole nuclei (in the dotted circle)[4]. The course of the condensation reaction yielding *(2)* from *(1)* and the point at which the vital[5] "pyrrole inversion" takes place are still uncertain[6, 7]. Tripyrroles have often been discussed as intermediates in heme biosynthesis. We have now been able to obtain informative experimental findings from biosynthetic studies with the [^{14}C]- and [^{3}H]-labeled tripyrroles, *(3a)* and *(4a)*[1], respectively.



(1) *(2)*

A = CH_2–CO_2H; Ps = CH_2–CH_2–CO_2H



Previous investigations of heme biosynthesis from isomeric dipyrroles and oligopyrroles gave inconsistent results[6, 8]. This can be attributed to the small quantities (nmol) of substances used, to variation in the enzyme activity in comparison experiments and a tendency for the reactive oligopyrroles to take part in non-enzymatic condensation ("chemical blank")[7]. In order to avoid such drawbacks, the multi-step syntheses of *(3a)* and *(4a)* were carried out in the mmol range. The two pyrroles were labeled with different isotopes so that they could compete for the heme-synthesizing enzyme in one experiment. A reliable determination of the "chemical blank"[8] was made possible by the observation that the carboxytripyrroles *(3b)* and *(4b)* which are also synthesized do not react with the enzyme system but behave as the tripyrroles *(3a)* and *(4a)* respectively in the chemical condensation.

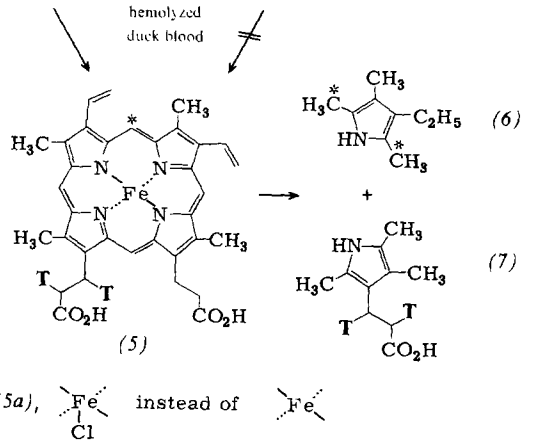
(3)



(4)

a: R = H; *b*: R = CO_2H; * = ^{14}C

(3a) + *(4a)* *(3b)* + *(4b)*

hemolyzed duck blood

(5) *(6)* *(7)*

(5a), instead of

In 17 separate experiments various quantities (0.5–4 mg) of mixtures of the tripyrroles *(3a)* and *(4a)* and of their carboxy derivatives *(3b)* and *(4b)* were incubated for 5 or 24 h at 32 °C with 25 ml of hemolyzed duck blood[3, 9]. The subsequently isolated hemin *(5a)* (90—117 mg) was purified until its level of radioactivity was constant.

Table 1. Competitive incorporation of the ^{14}C- and ^{3}H-labeled tripyrroles *(3a)* and *(4a)* and of *(3b)* and *(4b)* into hemin after 5 h.

Radioactivity of the tripyrroles [μCi]	Radioactivity of the hemin [μCi]	Incorporation of the radioactivity of the tripyrroles into hemin
(3a) ^{14}C: 2.37	^{14}C: 0.0122	^{14}C: 0.51 %
(4a) ^{3}H: 5.07	^{3}H: 0.0118	^{3}H: 0.23 %
(3b) ^{14}C: 4.09	^{14}C: 0.00034	^{14}C: 0.008 %
(4b) ^{3}H: 23.8	^{3}H: 0.00191	^{3}H: 0.008 %

The experimental results shown in Table 1 demonstrate that the two tripyrroles *(3a)* and *(4a)* are converted into heme significantly—*(3a)*, however, 2.2-fold faster. It follows from the low incorporation values of the "unnatural" carboxytripyrroles *(3b)* and *(4b)* that the "chemical blanks" can be neglected under the experimental conditions used.

The competitive incorporation of *(3a)* and *(4a)* has thus shown that, in addition to the preferred biosynthetic precursor, the enzyme system of duck blood can also use isomeric oligopyrroles. This could result in a partial diffusion of the ^{14}C- and ^{3}H-labeling of the tripyrroles *(3a)* and *(4a)* in the heme. It was confirmed by the chemical degradation of the hemin *(5a)*. The phyllopyrrole *(6)* formed after methylating cleavage (HI/CH_2O) contained, in addition to ^{14}C, 31 % of the ^{3}H-radioactivity of the hemin *(5a)* and the phyllopyrrolecarboxylic acid *(7)* contained, in addition to ^{3}H, 35 % of the ^{14}C-radioactivity.

As is the case with other natural products, the enzyme can use not only one but several intermediates for heme biosynthesis although these intermediates may be utilized with different efficiencies. This fact explains the apparently contradictory findings with other precursors[6-8].

A Trimeric Cyclopentadienone Derivative by Photolysis of 3,5-Diphenyl-4*H*-thiopyran-4-one 1,1-Dioxide with Daylight

By *Walter Ried* and *Hubert Bopp*[*]

Dedicated to Professor Friedrich Asinger on the occasion of his 70th birthday

Depending upon the nature of substitution, cyclopentadienone derivatives are known either as monomers or, through Diels-Alder reaction, as dimers[1]. The action of daylight on 3,5-diphenyl-4*H*-thiopyran-4-one 1,1-dioxide *(1)*, both in the solid state as well as in solution, led *via* the previously unknown 2,5-diphenylcyclopentadienone to formation of a trimer *(2)* by a double Diels-Alder reaction. Formation of a dimeric Diels-Alder product, as is usual for monomeric unstable cyclopentadienone derivatives, could not be observed. A photochemical synthetic route to monomeric substituted cyclopentadienones has been described by *Ishibe et al.*[2]: Irradiation of 2,6-bis(alkylthio)-3,5-diphenyl-4*H*-thiopyran-4-ones with a mercury lamp leads to loss of sulfur and formation of stable monomers.

The pentacyclic compound *(2)* is present in the *trans* form[3] and can be decarbonylated by briefly heating it to 190°C. The bicyclic product *(3)*[4], which can be regarded as normal decarbonylated dimeric cyclopentadienone, is formed. Confirmation of this retro-Diels-Alder reaction is provided by the decomposition of *(2)* in the mass spectrometer, since occurrence of the fragment $m/e = 435$ as base peak in the spectrum is consistent with the stability of *(3)*, while no fragment is observed that would correspond to the tricyclic decarbonylation product.

The ease of SO_2-extrusion from 4*H*-thiopyran-4-one 1,1-dioxides depends decisively upon the choice of substituents. Whereas, *e.g.* the 2,6-diphenyl[5] and the 3,5-dimethyl derivative[6] are completely stable in daylight, in the case of 3,5-diphenyl derivatives extrusion of SO_2 already begins after *ca.* 10 min. The 2,5-diphenylcyclopentadienone that is formed can be trapped with suitable dienophiles. It reacts with dimethyl acetylenedicarboxylate with loss of CO to give dimethyl 3,6-diphenylbenzene-1,2-dicarboxylate *(4)*[2].

t-1, t-4, c-5, c-8, t-8a, c-9a-Hexaphenyloctahydro-r-1,4:t-5,8-dimethanofluorene-9,10,11-trione (2): A solution of *(1)*[7] (2.96 g, 0.01 mol) in $CHCl_3$ (10 ml) is exposed to daylight for 10 d at room temperature. The solvent is removed in a rotary evaporator and the residue recrystallized from CH_3OH/acetone. 1.7 g (73 %) of colorless crystals, m.p. 143 °C (red coloration and decomposition).—IR (KBr): C=O 1770 (s), 1690 (s) C=C 1590 (s) cm^{-1}. UV (CH_2Cl_2): $\lambda_{max}(\varepsilon) = 232\ (3.5 \times 10^4)$, 260 (sh) nm ($1.6 \times 10^4$). ^{1}H-NMR ($CDCl_3$): $\delta = 4.32$ d (2), $J = 3$ Hz; 6.5 d (2), $J = 6$ Hz; 6.82 d (2), $J = 6$ Hz; 7.2—7.7 m (30). MS: $m/e = 696$ (2 %), M^+; 435 (100 %).

2,4,7,7a-Tetraphenyl-3a,7a-dihydroinden-1-one (3): *(2)* (1 g, 1.4 mmol) is heated in an oil-bath at 190 °C for 15 min. After cooling, the residue is recrystallized from acetone. 400 mg (64 %) pale yellow crystals, m.p. 186 °C.—IR (KBr): C=O 1705 (s), C=C 1590 (s) cm^{-1}. UV (CH_2Cl_2): $\lambda_{max}(\varepsilon)$ 230 (2.5×10^4), 335 nm (1×10^4). ^{1}H-NMR ($CDCl_3$): $\delta = 4.08$ d (1), $J = 2$ Hz; 6.65 and 6.82 AB-dd (2), $J = 7$ Hz; 7.1—7.7 m (21).

Dimethyl 3,6-diphenylbenzene-1,2-dicarboxylate (4): A solution of *(1)* (296 mg, 1 mmol) and dimethyl acetylenedicarboxylate (284 mg, 2 mmol) in $CHCl_3$ (10 ml) is exposed to daylight at room temperature. Separation of the reaction solution by column chromatography on silica gel (eluent benzene/ethyl acetate 10:1) affords—together with small amounts of *(2)*—160 mg (46 %) *(4)* as colorless crystals m.p. 192 °C (after recrystallization from methanol).

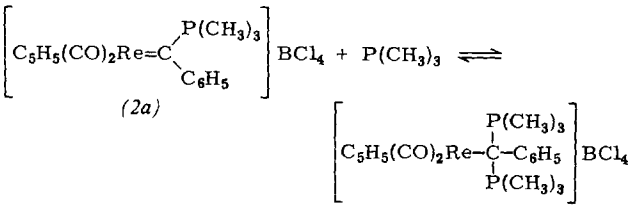
Bis[trimethylphosphorio(-onio)]methanide, A "Semi-Ylidic" Ligand in Transition Metal Complexes[**]

By *Fritz R. Kreissl, Karl Eberl,* and *Peter Stückler*[*]



Transition metal complexes of type *(3)* ought to be accessible, either by addition of an organyl to the ylide carbon atom in bis-ylide complexes *(1)*, or by addition of a phosphane to the sp^2 carbon atom in metal-substituted phosphorus ylides *(2)*.

(1) *(3)* *(2)*

M = metal carbonyl moiety

Occurrence of a comparable complex $[(CO)_5W{-}CH(PPh_3)_2]Cl$[1] as intermediate in the reaction of $(CO)_5WC(PPh_3)_2$ with HCl has been postulated but not isolated. We now report the first isolation and characterization of the phenylbis[trimethylphosphorio(-onio)]methanide complex *(3a)*, formed in the reaction of dicarbonyl(η-cyclopentadienyl)[α-(trimethylphosphoranediyl)benzyl]rhenium tetrachloroborate *(2a)*[2] with trimethylphosphane in dichloromethane.

(2a) *(3a)*

The thermolabile compound *(3a)*[3], which crystallizes with one molecule of CH_2Cl_2, is readily soluble in acetone but practically insoluble in ether or pentane. At room temperature it rapidly loses phosphane with regeneration of *(2a)*. The position of the two νCO bands of *(3a)* [KBr: 1885 and 1805 cm^{-1}] indicates a large σ-donor/π-acceptor ratio for the "semi-ylidic ligand". The ^{1}H-NMR spectrum shows four signals of relative intensity 5:2:5:18, which are assigned to the phenyl (δ = 8.03 and 7.53), methylene chloride (5.83), cyclopentadienyl (5.20), and *P*-methyl (2.38) protons; due to ^{31}P-^{1}H coupling the latter signal appears as an $A_9XX'A'_9$ system with $N = 12.0$ Hz[4] and proves the magnetic equivalence of all PCH_3 groups. The constitution of *(3a)* follows from the $^{13}C\{^1H\}$-NMR spectrum (CD_3COCD_3, −40 °C, δ rel. CD_3COCD_3 = 206.5 ppm, coupling constants in Hz): CO 208.01, C_6H_5 139.07 (2.4), 134.33 (7.3), 128.07, 127.64, C_5H_5 85.24, CH_2Cl_2 54.38, PCH_3 16.79 ($N = 61.0$), Re—C 6.16 (22.0 Hz). In contrast to the CO ligands, two aryl signals and the ylide carbon show triplet splitting, which rules out an attack by the phosphane on rhenium and clearly evidences formation of a semi-ylidic ligand. This finding also confirms the AXX′ system with $N = 61.0$ Hz expected for the PCH_3 carbon atom[5]. The $^{31}P\{^1H\}$-NMR spectrum (CD_3COCD_3) shows only one singlet at δ = 36.61, which once again underlines the equivalency and the ylidic character of the two phosphorus atoms.

Procedure

All operations must be carried out in anhydrous (Na, P_4O_{10}) solvents saturated with N_2. A solution of *(2a)*[2] (1.23 g, 2.0 mmol) in dichloromethane (20 ml) is treated with trimethylphosphane (0.25 g, 3.30 mmol) at −78 °C. A colorless precipitate is formed. After treatment with 20 ml ether and 20 ml pentane the supernatant liquor is decanted off and the residue washed with 5 × 10 ml pentane and 5 × 10 ml ether. Removal of solvent in a high vacuum (−78 °C, 48 h) furnishes colorless crystals; yield *ca.* 1.2 g (86 %).

Steric Enhancement of Chemical Reactivity. The Molecular Structure of Tris(*tert*-butyl)methyl *p*-Nitrobenzoate

By *Pei-Tak Cheng, S. C. Nyburg, Chacko Thankachan,* and *Thomas T. Tidwell*[*]

Significant steric accelerations have been observed both in reactions leading to formation of carbenium ions and in fragmentations to free radicals. Examples include carbenium ion formation by the solvolysis of *p*-nitrobenzoate esters or chlorides, and free radical formation from peresters, diazenes, and hexasubstituted ethanes[1–3]. Bulky substituents on these

reactants lead to rate accelerations that are sometimes quite large and the origin of these accelerations has been the subject of considerable discussion.

[*] Prof. Dr. T. T. Tidwell, Dr. P.-T. Cheng, Prof. Dr. S. C. Nyburg, C. Thankachan
Department of Chemistry, University of Toronto
Toronto, Ontario M5S 1A1 (Canada)

The rate enhancing factor which originally received the most attention was the mutual repulsion of the bulky groups R^1, R^2, R^3 in the ground state ("*B*ack-strain" effect) assumed to be relieved as the central carbon approached a trigonal geometry in the transition state. More recently it has been emphasized that as the bond to the leaving group lengthens in the transition state the repulsion between the alkyl groups and the leaving group ("*F*ront-strain" effect)[3a] will also be reduced; this may have major effects on the reactivity both in carbonium ion and free radical formation, but direct evidence for this phenomenon has so far not been obtained.

We have now determined the molecular structure of tris(*tert*-butyl)methyl *p*-nitrobenzoate *(1)* by X-ray crystallography, which vividly demonstrates the effects of both *B*- and *F*-strain (Fig. 1).

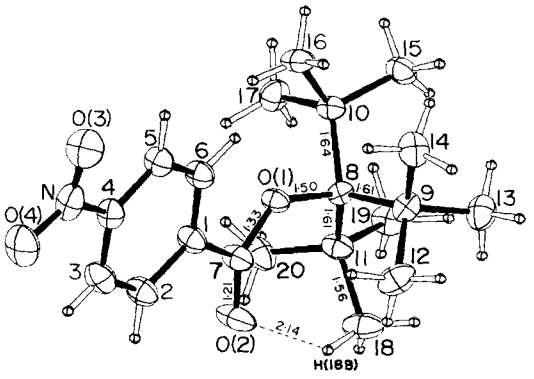

Fig. 1. ORTEP drawing of *p*-$NO_2C_6H_4C(O)OC[C(CH_3)_3]_3$ with bond distances given in Ångstroms (the average C—Me distance is 1.55 Å).

The crowding of the *tert*-butyl groups results in lengthening of the C8—C bonds to an average value of 1.62 Å, opening of the C—C8—C angles to an average value of 114°, and closing of the O—C8—C angles to an average value of 105°. There is also steric interference between the *tert*-butyl groups and the *p*-nitrobenzoate moiety, as evidenced by the H18B—O2 distance of 2.14 Å and the H16A—H6 distance of 2.20 Å. This interaction opens the C11—C8—O angle to 112.5°, whereas the other C—C8—O angles are 98.7 and 102.6°[4]. The C—O1—C angle is also opened to 132.8° by this crowding.

The bond angles of *(1)*, tris(*tert*-butyl)methane *(2)*[5], bis(*tert*-butyl)methyl oxalate *(3)*[6a], and bis(*tert*-butyl)methane *(4)*[6b] are listed in Table 1 for comparison.

Two competing effects may be envisaged to vary the relative geometry around the central carbon atoms of *(1)* and *(2)*: The increased steric pressure of the *p*-nitrobenzoate group in *(1)* will tend to compress the C—C—C angles, while the enhanced electronegativity of the oxygen in *(1)* would tend to increase the p character in the carbon orbital and hence increase these angles. The result of these competing effects for *(1)* is a 3.0° increase in the average X—C8—C angles, and a 2.2° decrease in the average C—C8—C angles.

Molecular mechanics has been used to calculate the geometries of the hydrocarbons *(2)* and *(4)*[5b,6b], and shows promise in predicting reaction rates of *p*-nitrobenzoates, chlorides, and peresters[3,7]. However, so far these methods have utilized hydrocarbons to simulate the reactants and fully formed intermediates with an sp^2 radical or cationic center to simulate the transition state. But, as the present study shows, ground state interactions between the leaving group and the rest of the molecule must also be taken into consideration.

Synthesis of Perdeuteriobenzo[*a*]pyrene[**]

By *Josette C. Seibles, Don M. Bollinger,* and *Milton Orchin*[*]

Benzo[*a*]pyrene is one of the most extensively studied chemical carcinogens[1]. There is substantial evidence implicating the electronically excited states of this and other polynuclear aromatic hydrocarbons in the initiation of the neoplastic process[2, 3]. When the hydrogens of aromatic hydrocarbons are replaced by deuterium, the photophysical properties are affected[4]. Perdeuteriated polycyclic arenes may thus be employed to test those hypotheses of chemical carcinogenesis which invoke the intermediacy of electronic excited states[5]. In one such study it was found that perdeuterio-7,12-dimethylbenz[*a*]anthracene was approximately twice as carcinogenic as the undeuterated compound[3].

Perdeuterated polycyclic arenes are currently prepared by two quite different procedures[6]. A suspension of the arene in D_2O is heated in the presence of reduced platinum in an autoclave at about 350 °C for several days, or, the exchange can be achieved in a homogeneous catalytic system. In the latter procedure the arene is dissolved in [D_6]-benzene, the exchange catalyst $C_2H_5AlCl_2$ is added and the solution is heated at about 90 °C for about 7 days[7]. In our procedure, the homogeneous exchange with [D_6]-benzene is achieved in 6 h using $AlBr_3$ as a catalyst.

Aluminum tribromide is vacuum sublimed and stored under nitrogen. To a 5 ml glass ampoule are added 2 ml of [D_6]-benzene and 1 µl of pure bromine. Approximately 20 mg of freshly sublimed $AlBr_3$ is added (in a dry box) to the preweighed reddish-orange solution in the ampoule, whereupon the solution turns yellow. The ampoule is capped and removed from the dry box, cooled in dry ice/acetone and flame sealed. The sealed ampoule is then heated (stirring is not necessary) in an oil bath in which it is immersed to about the liquid content level at 100 °C for 2 hours. The ampoule is opened (in a dry box) and its contents transferred by Pasteur pipette or syringe to a second 5 ml ampoule containing 100 mg of benzo[*a*]pyrene. A deep red color develops. The ampoule is sealed as before and heated in an oil bath without stirring at 110 °C for 6 h. The ampoule is cooled, opened, and 4—5 drops of distilled water added. The benzene layer is removed and transferred to a small round bottom flask. The reaction flask is washed several times with small additional amounts of benzene and the combined benzene solution evaporated to dryness *in vacuo*. The brown-yellow residue is transferred to a sublimation apparatus and vacuum sublimed. The light yellow sublimate is removed from the cold finger with a few ml of acetone and the acetone solution evaporated by a stream of nitrogen. The residue (87 mg) consist of pure benzo[*a*]pyrene containing 94.7 atom percent deuterium.

The deuterium content was determined by low voltage (7 eV) mass spectrometry using a Hitachi Perkin Elmer RMU7 mass spectrometer coupled with a VG Data System adapted to a PDP8 computer. Appropriate precautions to account for isotopic composition[8] were taken and analysis of the data (Amdahl 470 computer) afforded both atom percent and mole percent deuterium incorporation. The rate data (Table 1) indicate that six hours is probably the optimum time at 110 °C for maximum ^2H incorporation and minimum tar formation. These data were obtained by using a separate sample for each time interval. Using essentially the same procedure we also have prepared perdeuterated benz[*a*]anthracene, pyrene, chrysene, perylene, fluoranthene, carbazole, and triphenylene.

Further work is in progress to determine the rates of deuteration and dedeuteration at the various positions in benzo[*a*]pyrene.

Radical Cation of [2.2](9,10)Anthracenophane as a Model for Dimeric Anthracene Radical Cations[**]

By *Fabian Gerson, Gerd Kaupp,* and *Hiroaki Ohya-Nishiguchi*[*]

Oxidation of benzenoid hydrocarbons affords under certain conditions dimeric radical cations in which the π-spin population is evenly distributed between two equivalent aromatic moieties[1-3]. The most reasonable suggestion for the unknown structure of such paramagnetic species would be that the two π-systems involved lie in parallel planes, one above the other. Since no inclusion of solvent molecules is expected, the interplanar distance should amount to *ca.* 3 Å.

Suitable models for the dimers in question are therefore cyclophanes of D_{2h} symmetry, a distinct favorite being [2.2](9,10)anthracenophane *(1)*[4]. This compound not only contains two nearly parallel anthracene moieties in an essentially eclipsed arrangement and with an average distance of 3 Å[5], but it also readily forms a relatively stable radical cation $(1)^{\oplus\cdot}$. The ESR spectrum of such a radical cation is shown in Figure 1, along with that of the radical anion $(1)^{\ominus\cdot}$. The pertinent proton coupling constants are listed in Table 1, where they are compared with the analogous data for the radical ions and dimeric cations of anthracene *(2)* and its 9,10-dimethyl derivative *(3)*[2,3,6].

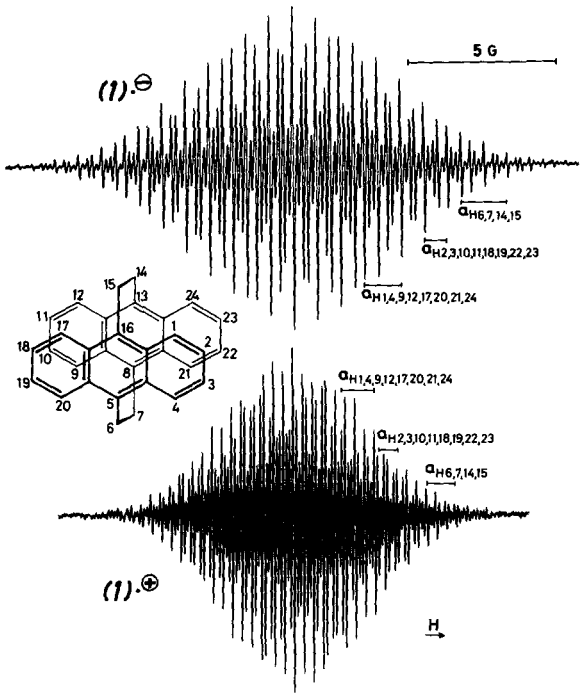

Fig. 1. ESR spectra of the radical ions of [2.2](9,10)anthracenophane *(1)*. Top: anion $(1)^{\ominus\cdot}$. Solvent: DME; counterion: $K^{\oplus}$; −10°C. Bottom: cation $(1)^{\oplus\cdot}$. Solvent: CH_3NO_2/CF_3COOH (*ca.* 10%)/$(CF_3CO)_2O$ (*ca.* 5%); counterion: $CF_3COO^{\ominus}$; +10°C.

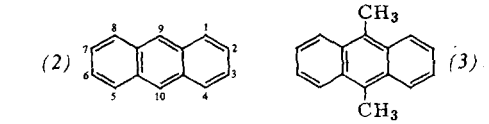

Table 1. Proton coupling constants (G) for the radical ions of [2.2](9,10)anthracenophane *(1)*, anthracene *(2)* and 9,10-dimethylanthracene *(3)*, in addition to those for the dimeric radical cations of *(2)* $[(2)_2^{\oplus}]$ and *(3)* $[(3)_2^{\oplus}]$.

Position:	1, 4, 9, 12, 17, 20, 21, 24	2, 3, 10, 11, 18, 19, 22, 23	6, 7, 14, 15	Ref.
$(1)^{\ominus}$	1.26	0.78	1.56 [a]	[7a]
$(1)^{\oplus}$	1.10	0.65	0.98 [a]	
Position:	**1, 4, 5, 8**	**2, 3, 6, 7**	**9, 10**	**Ref.**
$(2)^{\ominus}$	2.74	1.51	5.34	[2]
$(2)^{\oplus}$	3.08	1.38	6.50	[2]
$(2)_2^{\oplus}$	1.42	0.71	3.25	[2]
$(3)^{\ominus}$	2.90	1.52	3.88 [b]	[6]
$(3)^{\oplus}$	2.54	1.19	8.00 [b]	[6]
$(3)_2^{\oplus}$	1.22	0.66	3.51 [c]	[3]

[a] Eight methylene protons. [b] Six methyl protons. [c] Twelve methyl protons.

Assignment of the values 1.56 and 0.98 G to the eight equivalent methylene protons in $(1)^{\ominus}$ and $(1)^{\oplus}$, respectively, has been confirmed by the studies of the radical ions produced from [2.2](9,10)anthracenophane deuterated in all aromatic positions $(1-d_{16})$ (Fig. 2).

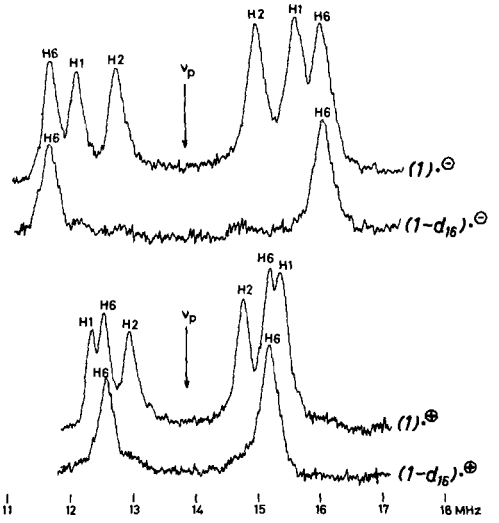

Fig. 2. ENDOR spectra of the radical ions of [2.2](9,10)anthracenophane *(1)* and its ring deuterated derivative $(1-d_{16})$. Top: anions $(1)^{\ominus\cdot}$ and $(1-d_{16})^{\cdot\ominus}$. Solvent: DME; counterion: $K^{\oplus}$; −80°C. Bottom: cations $(1)^{\oplus\cdot}$ and $(1-d_{16})^{\cdot\oplus}$. Solvent: CH_2Cl_2/CF_3COOH (*ca.* 10%)/$(CF_3CO)_2O$ (*ca.* 5%); counterion: $CF_3COO^{\ominus}$; −90°C. ν_p = free proton frequency.

The experimental finding that the coupling constants of the ring protons in $(1)^{\oplus\cdot}$, 1.10 and 0.65 G, strongly resemble the corresponding values in $(2)_2^{\oplus}$ and, in particular, those

[*] Prof. Dr. F. Gerson, Dr. H. Ohya-Nishiguchi

Doz. Dr. G. Kaupp
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Swiss National Foundation (Project 2.523.76) and by the Fonds der Chemischen Industrie.

in $(3)_2^{\oplus}$ points to almost identical π-spin distributions. Moreover, this result indicates that the structures of $(1)^{\cdot\oplus}$ and of both dimeric radical cations are also similar, since markedly differing spatial arrangements of the two anthracene-π-systems would lead to large differences in the coupling constants of the ring protons. (Cf., *e.g.*, Ref. [7]). Thus, the values presented in Table 1 provide an experimental support for the structures of $(2)_2^{\oplus}$ and $(3)_2^{\oplus}$ in which the two aromatic moieties are in an essentially eclipsed position and with an interplanar distance of *ca.* 3 Å.

It is noteworthy that the coupling constant of the methylene protons in $(1)^{\cdot\oplus}$ is considerably smaller than in $(1)^{\cdot\ominus}$, this decrease being presumably due to different conformational preferences.

Experimental

[2.2](9,10)Anthracenophane *(1)* was prepared according to a slightly modified[8] procedure of *Golden*[4]. The synthesis of the hexadecadeuterio derivative $(1-d_{16})$ started with perdeuterioanthracene which was converted into 1,2,3,4,5,6,7,8-octadeuterio-9,10-bis(chloromethyl)anthracene by the method of *Miller et al.*[9]. The latter compound yielded $(1-d_{16})$ in a reaction analogous to that described for *(1)*[4, 8].

The radical anion $(1)^{\cdot\ominus}$ was produced by reduction of *(1)* with potassium in 1,2-dimethoxyethane (DME), while the radical cation $(1)^{\cdot\oplus}$ resulted from oxidation of *(1)* in a mixture containing methylene chloride or nitromethane, trifluoroacetic acid (*ca.* 10%), and its anhydride (*ca.* 5%).

An Olefin with Unusually Large C—C=C Angles[**]

By *Otto Ermer*[*]

Experimental evaluation of the range over which the potential functions of force field calculations are valid[1] requires the investigation of severely strained molecules. We report here on the results of a crystal structure analysis of 2,2,5,5-tetramethyl-7,8;9,10-dibenzobicyclo[4.2.2]deca-3,7,9-triene *(1)* [Fig. 1a, b], a compound with high angle strain.

[*] Dr. O. Ermer
Abteilung für Chemie der Universität
Universitätsstrasse 150, D-4630 Bochum (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Calculations have shown that unsubstituted all-*cis*-bicyclo[4.2.2]deca-3,7,9-triene has an unusually large C—C=C angle of 137.8° at the double bond C(3)—C(4)[2]. For the 2,2,5,5-tetramethyl derivative *(2)* [Fig. 1c] a still somewhat higher value of 138.9° is calculated which exceeds the corresponding reference angle of 122.3° by 16.6°. The favored calculated conformations of these two olefins show C_{2v}-symmetry and not C_s-symmetry corresponding to a conformation *(3)* [Fig. 1d] as might be concluded from the consideration of Dreiding models.

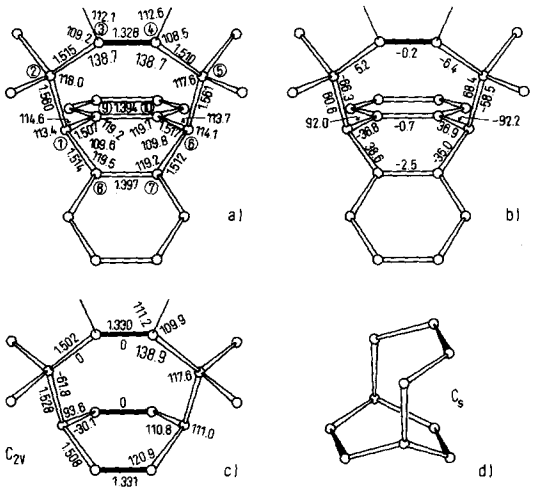

Fig. 1. a) Observed bond lengths [Å] and angles [°] and b) torsion angles [°] for the bicyclodecatriene framework of *(1)*; estimated average standard deviations: CC 0.003 Å, CCC 0.2, HCC 1.1, CCCC 0.4°. c) Calculated geometry of *(2)*. Distances and torsion angles are shown on the left-hand side of the diagram and bond angles on the right-hand side; corresponding information for the very similar geometry of the unsubstituted bicyclo[4.2.2]decatriene is given in [2]. d) Conformation *(3)* of bicyclodecatriene with favorable bond angles yet unfavorable torsion angles. *(3)* does not correspond to a potential energy minimum.

The crystal structure analysis of the dibenzo derivative *(1)* was performed in order to check the results of our force field calculations. The experimental results are of general interest as both our force field and those of other authors contain quadratic angle deformation potentials without anharmonicity corrections[1] whose suitability for the description of such large angle deformations as in the present case is questionable. The presence of the two benzene rings in *(1)* does not significantly impair the comparison between experimental and calculated results (see below).

Crystal data of *(1)*[3]: $a=9.132(5)$, $b=9.360(5)$, $c=12.914(6)$ Å; $\alpha=112.02$, $\beta=91.17(3)$, $\gamma=122.32(3)°$; space group $P\bar{1}$; $Z=2$. The intensities of 2997 independent reflections were measured on a Nonius three-circle diffractometer ($0.098\,Å^{-1}<\sin\theta/\lambda<0.617\,Å^{-1}$; graphite monochromator, MoKα-radiation, $\lambda=0.71069$ Å). A structural model was derived from a sharpened Patterson function of the crystal. 2239 reflections with $F_o>3\sigma(F_o)$ were used for the refinement of the carbon atoms (anisotropic temperature factors). The hydrogen atoms were refined with fixed carbon atom parameters excluding the reflections with $\sin\theta/\lambda>0.45\,Å^{-1}$ [1073 reflections; common isotropic temperature factors for the methyl hydrogen atoms (3.2 $Å^2$) and the remaining hydrogen atoms (1.4 $Å^2$)]. The final, conventional *R*-value was 0.048. Important structural parameters are given in Figure 1.

In the crystal, *(1)* has approximate C_{2v}-symmetry, although there are significant differences which tend towards a geometry analogous to *(3)* (cf. torsion angles in Fig. 1b). These differences could be due to crystal packing forces since they occur

mainly along the normal coordinate of the lowest calculated vibrational frequency of *(2)*[2] which amounts to only 51 cm^{-1}. The C—C=C angles at the planar, olefinic double bond of *(1)* are both 138.7° (Fig. 1a); to the best of our knowledge, these are the largest angles of this kind observed so far. The neighboring H—C=C and H—C—C angles (112 and 109°, respectively) are compressed accordingly. The length of the severely deformed double bond is normal (1.328 Å). The calculated results for *(2)* agree satisfactorily with these experimental findings (Fig. 1).

It is well known that, combined with excessive thermal motion parameters, apparent shortenings of bond lengths and increases of bond angles may result from crystal structure analyses. The large bond angles observed in the present case are not due to such an effect as is evident from the normal bond lengths and thermal parameters; the largest eigenvalue of the thermal motion tensors of C(2) to C(5) amounts to 4.8 $Å^2$.

The main reason for the approximate (exact in the calculations) C_{2v}-symmetry of the bicyclodecatriene framework lies in its favorable torsion angles as compared with conformation *(3)* which contains two eight-membered rings with unfavorable boat and chair conformations[2]. The severe opening of the two C—C=C angles and the less pronounced widening of the C—C—C ring angles at the quaternary carbon atoms are a consequence of the fact that the atoms C(1) to C(6) form an almost planar (exactly planar in the calculations) hexagon in which the olefinic double bond faces the long side C(1)...C(6).

A comparison between Figs. 1a, b and Fig. 1c, as well as the results from force field calculations for *(2)* with modified potential constants [increased reference lengths for C(7)—C(8) and C(9)—C(10); reduced rotation barrier around the C—C single bonds of the six-membered ring], indicate that the geometry of the olefinic double bond is only very slightly influenced by the fused benzene rings. A more significant influence may be noted for the non-aromatic, six-membered ring which is calculated to be somewhat flatter in *(2)* than that observed in the crystals of *(1)* (Figs. 1b and 1c). The bond lengths C(1)—C(2) and C(5)—C(6) measured for *(1)* exceed the corresponding calculated values for *(2)* by 0.03 Å. However, in view of largely normal non-bonded distances only small repulsive interactions are likely to occur between the benzene rings and the methyl groups.

A combination of energetically favorable changes of torsion angles around C—C single bonds may thus give rise to enormous changes of bond angles. Furthermore, the comparison of experimental and calculated results allows the conclusion that harmonic deformation potentials are useful for the description of relatively large widenings of C—C=C angles of up to about 17°. There are indications[4] that this also holds for similarly large widenings of C—C—C angles. It remains to be shown to what extent in such cases energetic and vibrational properties may be treated with simple, quadratic angle deformation potentials.

Crystal Structure of Barium Disilicide at High Pressures[**]

By *Jürgen Evers, Gilbert Oehlinger*, and *Armin Weiss*[*]

In the course of our high pressure studies on the behavior of disilicides and digermanides MSi_2 and MGe_2 of reactive divalent metals (M = Yb, Ca, Eu, Sr, Ba)[1] a high-pressure (HP)-modification of barium disilicide has been found. This phase is formed when $BaSi_2$ is heated to 1000 °C at 40 kbar in a belt apparatus[2]. On quenching to ambient conditions the HP-modification is storable as a metastable phase in the absence of air and moisture for several months without any noticeable change. Heating to approximately 400 °C at normal pressure (NP) leads to its complete retransformation into the orthorhombic NP-phase[3].

The powder diagram of the HP-phase can be indexed trigonal showing the characteristic sequence of reflections for the $EuGe_2$-type structure[4]. Crystallographic data are listed in Table 1. At low Θ-values very weak superlattice reflections were observed which were neglected in the trigonal indexing. Best agreement between observed and calculated intensities (27 reflections, Mo K_α radiation) was achieved with $z_{Si} = 0.432$; the minimum for the reliability facotr Q_R is flat (Table 2).

Table 1. Comparison of the crystallographic data of the high pressure (HP) and low pressure (NP) modifications of $BaSi_2$.

	HP-Phase	NP-Phase
Symmetry	trigonal	orthorhombic
Space group	D_{3d}^3-P$\bar{3}$m1	D_{2h}^{16}-Pnma (or C_{2v}^9-Pna2_1)
Axes [nm]	$a = 0.4047 \pm 0.0003$ $c = 0.5330 \pm 0.0005$	$a = 0.892 \pm 0.006$ $b = 0.675 \pm 0.006$ $c = 1.157 \pm 0.006$
Cell volume [nm^3]	0.07560	0.6966
Density [g/cm^3]		
exp.	4.2_6	3.54
calc.	4.251	3.68
Number of formula units	1	8
Atomic positions	1 Ba in 1a 2 Si in 2d	4 Ba^1 in 4c, 4 Ba^2 in 4c 4 Si^1 in 4c, 4 Si^2 in 4c, 8 Si^3 in 8d

Table 2. Reliability factor Q_R as a function of the parameter z_{Si} of the silicon atoms.

z_{Si}	0.400	0.425	0.430	0.432	0.434	0.450	0.475	0.500
Q_R	0.12_4	0.07_7	0.07_6	0.07_4	0.07_5	0.08_1	0.09_8	0.11_2

The $EuGe_2$-type structure in disilicides is already known from single crystal investigations on the NP-phase $Ca_{0.5}Sr_{0.5}Si_2$[5]. This type of structure differs from the AlB_2 type mainly with respect to the planarity of the metalloid atom layers; they are corrugated in the $EuGe_2$ type and planar in the AlB_2 type. Planar layers in the HP-phase of $BaSi_2$ would lead to Si—Si distances similar to those found in the HP-modification of $CaSi_2$[1b].

The packing density is about 13% higher in the HP-phase of $BaSi_2$ than in the NP-phase ($(V_{HP} - V_{NP})/V_{NP} = -0.13$). Referred to the elements silicon and barium the volume contraction for the HP-phase is 20%, for the NP-phase 7%. In the NP-phase the silicon atoms form isolated tetrahedra. According to the symmetry of the space group Pnma these tetrahedra are tilted against each other, the Ba-atoms lying

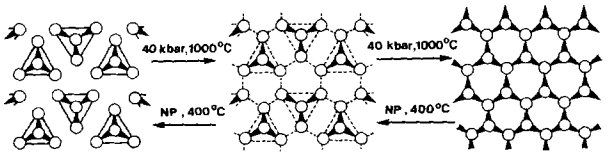

Fig. 1. Reconstruction of isolated Si_4-tetrahedra in NP—$BaSi_2$ into corrugated Si-layers in HP-$BaSi_2$ and *vice versa*.

between them. In the HP-phase the corrugated Si-layers could be reconstructed from the Si_4-tetrahedra by only slight displacements of the silicon atoms as illustrated schematically in Figure 1. In both modifications all the silicon atoms have three nearest Si-neighbors. However the $Si^{Si}Si$ bond angle is increased from approximately 60° in the NP-phase to $111.6°$ in the HP-phase. The Si—Si bond lengths are 0.24_5 nm in the HP-modification. The shortest Ba—Si distance is 0.32_8 nm, the shortest Ba—Ba distance 0.405 nm.

ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

Elemental sulfur and its reactions are surveyed by *Roland Mayer*. Sulfur has a pronounced tendency to react with itself and to form S—S bonds. Depending upon the external conditions, either chain or cyclic molecules can arise, which contain between two and over 10^5 sulfur atoms. S—S bonds can be homolyzed (by action of heat, radiation, or chemical energy) or heterolyzed (on nucleophilic attack). In particular, CH acids as well as organo-metallic, -boron, -silicon, -phosphorus, and -sulfur compounds should be able to react with elemental sulfur but knowledge about such reactions is, in some cases, limited. Among the reactions of elemental sulfur, thermal and base-catalyzed reactions with C—H bonds, reactions with S—H bonds, and base-catalyzed oxidations of C—Cl bonds are described. [Elemental Sulfur and its Reactions in *S. Oae:* Organic Chemistry of Sulfur. Plenum Press, New York 1977, pp. 33—69; 54 references]

[Rd 962 IE]

The vulcanization of natural and synthetic rubber with sulfur is the topic of a review penned by *M. Porter*. Natural rubber and seven synthetic rubbers can be vulcanized at temperatures between 20 and 200 °C with sulfur or sulfur donors (*e.g.* tetraalkylthiuram disulfide or dithiobismorpholine). Activators (zinc oxide, higher fatty acids, nitrogen bases) and accelerators (derivatives of 2-mercaptobenzothiazole or of a dialkyldithiocarbamidic acid) are usually also required. Analysis of structural modifications occurring on vulcanization is hampered by low concentrations, by the insolubility of the products, and by the difficulty of measuring degrees of crosslinking. Our knowledge about the vulcanization process has therefore been gained principally from studies of the reactions of sulfur and sulfur donors with olefins. [Vulcanization of Rubber in *S. Oae:* Organic Chemistry of Sulfur. Plenum Press, New York 1977, pp. 71—118; 91 references]

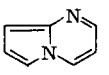
[Rd 963 IE]

Electronic energy transfer processes in organic molecules are reviewed by *N. J. Turro*. The article considers the most important processes which could contribute to an event of the kind

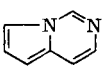
$$D^* + A \rightarrow D + A^*$$

the asterisk denoting an excited state, and the use of such processes to stabilize polymers or render them degradable. [Energy Transfer Processes. Pure Appl. Chem. *49*, 405—429 (1977); 26 references]

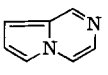
[Rd 969 IE]



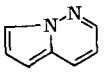
Polymers which become electrical conductors on irradiation represent the theme of an article by *J. M. Pearson*. Such materials have potential uses in electrophotography and for the development of inexpensive photocells for converting the sun's energy into electrical energy. However, only very few of the systems studied so far are active enough to compete with presently used inorganic materials. The reason lies mainly in the poor mobility of the charge carriers in organic polymers. Like the ease of generation of the charge carriers, it depends upon the electronic and morphological structure of the polymers. [Photoconductive Polymers. Pure Appl. Chem. *49*, 463—477; 42 references]



[Rd 972 IE]



The photooxidation of polymers is surveyed by *F. H. Winslow*. The light-induced oxidative degradation of polyolefins comprises a combination of radical and non-radical processes: singlet oxygen reacts with the polymer to form hydroperoxides



which decompose to radicals and thus lead to Norrish-type chain cleavage reactions. [Photooxidation of High Polymers. Pure Appl. Chem. *49*, 495—502 (1977); 25 references]

BOOK REVIEWS

Handbuch der Textilhilfsmittel (Handbook of Textile Auxiliary Agents). Edited by *A. Chwala* and *V. Anger* in collaboration with *Ch. Chwala*. Verlag Chemie GmbH, Weinheim—New York 1977. 1st edit., xvi, 1158 pp., 316 figs., 175 tables, bound, DM 440.—.

The task that the editors set before themselves, namely to bring out a new edition of *Chwala*'s "Textilhilfsmittel", required an entirely new concept for the book. In the interest of readers, an exhaustive treatment of the wide-ranging theme and the more important literature could be mastered only by drawing in competent specialists. This problem has been solved in the new edition in a remarkable manner, with the collaboration with 53 specialist authors.

The arrangement of this Handbook is clear and logical. The introductory chapters give the theoretical principles needed to understand textile auxiliary agents, with particular emphasis on the structural principles and the physicochemical properties of surface-active agents, but also with practical indications of interest to those working in this field. A detailed section is concerned with the structure of natural and synthetic textile fibers, providing a review of their construction and composition as well as of their chemical, physical, and dyeing characteristics. The main part of the book contains individual sections covering the whole spectrum of textile auxiliary agents and their application from the spinning process through intermediate treatments to the final preparation for the customer and the care of textiles. As examples we shall mention only the fiber preparation and coning oils, antistatics, bleaches and bleaching aids, sizes, finishing agents, high grade finishing agents, softeners, hydrophobic and oleophobic agents, optical brighteners, and flame-protection agents. Much space is devoted to dyeing and printing which present a diversity of problems. Special chapters deal with fiber-specific aids, of which we may mention wool protection and carbonizing agents, scouring and mercerizing agents, antimicrobiotics, and pest repellants.

A section on the use of organic solvents in initial preparation and final finishing demonstrates that recent trends are also taken into account, even if they have not yet achieved major importance. It should be specially emphasized that, along with the basic theme of the book—textile auxiliary agents and their application—special problems are also treated; for example, there are chapters on biological degradation of surfactants and on analysis; this underlines the importance of ecological knowledge for the use of textile finishing aids.

The description of an efficient system and its use with reference to a commercial product from a company with which the author is closely connected should generally be avoided in favor of an objective treatment. However, a review of the most important commercial products and their manufacturers is of value.

Treatment of many auxiliary agents, *e.g.* surfactants, in several sections, usually considered as duplication of effort, proves on closer examination to be a didactic advantage.

The literature references collected at the end of the individual chapters make it possible for interested readers to gain entry into primary literature. In a new edition it would be useful to consider the patent literature in each chapter; this should be attempted not only on the grounds of homogeneity but also because of the importance of patents as sources of information.

The publishers should be congratulated for the careful and readable printing and satisfactory make-up. The book can be recommended without any reservations.

Helmut Diery [NB 383 IE]

Recent Books

The Electro-Optical Kerr Effect in Conformational Analysis

New analytical methods (10)

By Manuel James Aroney[*]

Birefringence induced in a material by application of an electric field is known as the Kerr effect. The great sensitivity of this property to variations of molecular geometry and environment has made it the basis of a potent method for studying the conformations of molecules. It has, in addition, been effectively applied to investigations of the geometry of solvation and of solute aggregation. An outline is presented of the general technique of measurement of the Kerr effect, the extraction of directed effective polarizabilities of solute molecules and of structural groups, the calculation of theoretical Kerr constants for candidate structures of molecules, and the procedures used to determine solute conformations. The scope and limitations of the method are illustrated by specific conformational problems drawn from the literature. In the case of highly flexible molecules analysis of the measured Kerr constant is inhibited by uncertainties in conformational energy data. This paper is concerned mainly with the specification of detailed conformational features of molecules. Reference is made, however, to the utilization of pulsed orienting fields to study shapes and dimensions of biological macromolecules.

1. Introduction

If a strong, uniform electric field is applied to an aggregation of molecules in the gas or liquid state, a degree of order is imposed through interaction of the permanent and induced electric moments with the field **E**. A statistical equilibrium is attained in which the orienting interactions are counterbalanced by random thermal motion. The molecular system in the field becomes optically anisotropic. The refractive index measured in the direction of the field ($n_{\parallel}$) differs from that perpendicular to the field ($n_{\perp}$) and the substance is said to be birefringent. Experimentally the effect is usually studied by passing through the partly ordered system a beam of monochromatic, plane-polarized light arranged so that the plane of polarization is inclined 45° to **E**. The incident light vector can be regarded as the sum of two components in phase, which are respectively parallel and perpendicular to **E**. Since $n_{\parallel}$ and $n_{\perp}$ are unequal, the light components in these directions traverse the medium at different velocities and emerge out of phase; the light beam is now elliptically polarized (Fig. 1). The phase difference δ in radians is related to the birefringence Δn ($=n_{\parallel}-n_{\perp}$) by the equation

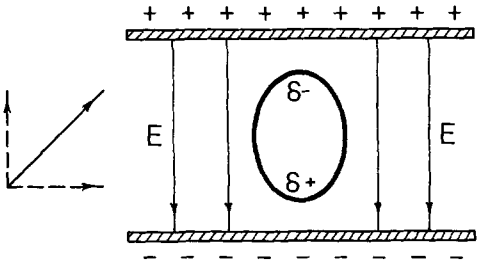

Fig. 1. Plane polarized light entering an "ordered" system of molecules. $n_{\parallel} \neq n_{\perp}$.

$$\delta = 2\pi l(n_{\parallel}-n_{\perp})/\lambda = 2\pi B l E^2 \qquad (1)$$

where l is the length of the light path through the birefringent medium; λ is the wavelength of the light; and B is the "Kerr constant" of the substance. This relation, derived from experi-

[*] Prof. Dr. M. J. Aroney
Department of Inorganic Chemistry, University of Sydney
Sydney, New South Wales 2006 (Australia)

ment, is called Kerr's Law after *John Kerr* who first reported the effect in 1875[1].

2. Measurement of the Kerr Effect

For gases and non-conducting liquids the Kerr constant B can conveniently be determined using the basic experimental arrangement shown in Figure 2[2]. A monochromatic light beam from ML is collimated by a lens L and passed through a polarizing Glan-Thompson prism P to give light polarized 45° to the static electric field E applied across two parallel electrodes of known dimensions in a Kerr cell KC; A is a second Glan-Thompson prism which is crossed with reference to P; PM is a photomultiplier. With the dielectric in the Kerr cell but no field applied, the light emerging from KC remains plane polarized and is absorbed by the analyzing prism A. If a high voltage is applied across KC (*ca.* $10^6\,V\,m^{-1}$ for a non-dipolar, non-conducting liquid such as benzene) the light emerges elliptically polarized; the intensity of light which penetrates the analyzer and is registered on the photomultiplier can be used, in conjunction with the incident light intensity, to determine the phase difference δ. Alternatively, a compensating device C (a mica sheet or a second Kerr cell containing a standard[3]) which causes a known phase change can be inserted between the Kerr cell and the analyzer and used to determine δ. Fuller descriptions of the components are given in ref. [2]. An alternative and highly sensitive method utilizes a quarter wave plate to convert the ellipticity into an optical rotation which is nulled by a Faraday coil arrangement[4]. The measurement of δ and thence B for a substance is normally made using light in the visible region but remote from absorption bands to avoid anomalous dispersion effects. Since B for a substance is dependent on λ [eq. (1)], the wavelength of light used for the measurement should be quoted. Pulsed voltages of short duration are also used to generate orienting fields. Pulsed birefringence techniques are generally less sensitive than static field compensation methods but they are more widely applicable in that they enable studies to be extended to conducting media[2, 5, 6].

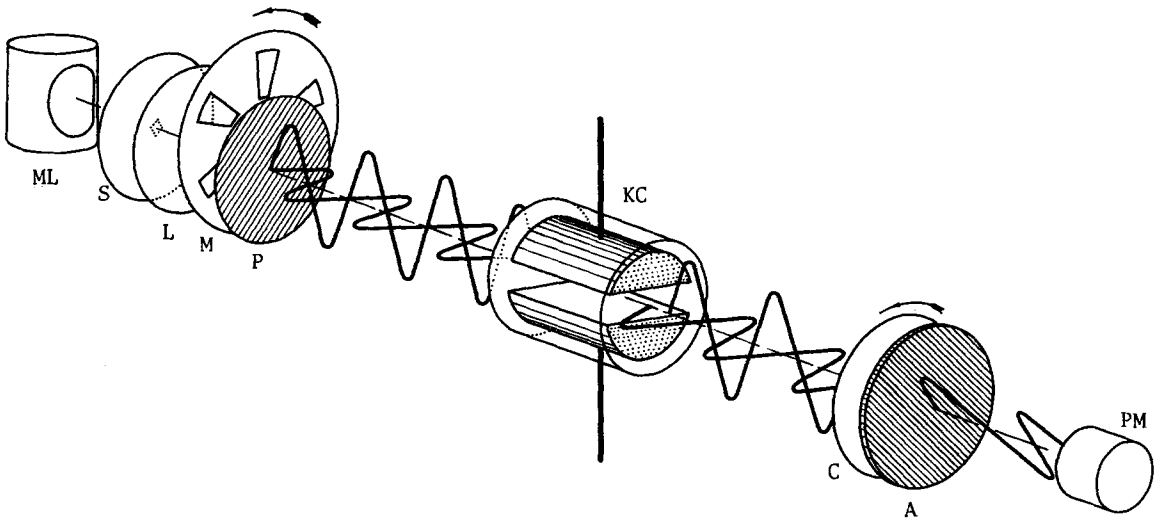

Fig. 2. Apparatus for measurement of the Kerr effect. ML monochromatic light source, S aperture, L lens, M modulator, P polarizer, KC Kerr cell, C compensator, A analyzer, PM photomultiplier.

The Kerr effect of a molecular substance is often expressed as the molar Kerr constant ${}_mK$ which is defined as

$${}_mK = 6\lambda n B M/(n^2+2)^2(\varepsilon_r+2)^2 d \qquad (2)$$

where n is the refractive index, ε_r the relative permittivity, M the molar weight, and d the density. The relation was initially applied to dilute gases. Physically ${}_mK$ is a measure of the difference, per unit field, of molecular refractions[*] $R_\parallel$ and $R_\perp$ measured parallel and perpendicular to the field direction[7]. For molecules in solution in a non-polar solvent the apparent solute molar Kerr constant at infinite dilution, designated ${}_\infty({}_mK_2)$, can be extracted from measurements of B, ε_r, d and n, for a graded series of dilute solutions[7].

3. Theoretical Concepts

3.1. Molecular Polarizability Anisotropy

Any molecule subjected to a uniform static electric field E undergoes deformation of its electrons and small displacements of the atoms relative to one another. A dipole moment **m** is induced in the molecule (additional to the *permanent* moment $\boldsymbol{\mu}$ which it may already possess) and, providing the field is not too great, the magnitude of the induced moment is in direct proportion to that of the applied field intensity.

$$m = \alpha E = (\alpha_E + \alpha_A) E \qquad (3)$$

The constant of porportionality α (*i.e.* the moment induced per unit field) is known as the mean polarizability of the molecule. It is composed of α_E and α_A, the electron and atom polarizabilities, respectively. With optical frequency fields only the electrons are sufficiently mobile to respond to the field and the induced moment now arises almost completely from α_E. The quantity α_E is directly related to the molar electron polarization ${}_EP$ of a substance by the well-known Lorentz-Lorenz equation[8]

$${}_EP = N_A \alpha_E / 3\varepsilon_0 \qquad (4)$$

where the constants N_A and ε_0 refer in turn to Avogadro's number and to the permittivity of a vacuum; ${}_EP$ is estimated

[*] The physical property of molecular refraction is defined by the relation $R_\lambda = (n_\lambda^2 - 1)M/(n_\lambda^2+2)d$. [8]

from refractivity (R_i) wavelength dispersion measurements by extrapolation procedures used to eliminate any atom polarization contribution[9].

The electrons in a molecule are generally not equally polarizable in all directions, *e. g.* the deformability of benzene electrons in the aromatic plane would be expected to be greater than that perpendicular to the aromatic plane. Thus we say that the polarizability of a molecule is *anisotropic* in that it varies with direction with reference to the molecular framework. A molecule may be regarded as having an *ellipsoid of polarizability* defined by the semi-axes b_1, b_2, b_3 in the directions of the principal axes *1*, *2*, and *3*. Thus b_1 is the moment induced by an electric field of unit intensity applied along the *1* axis; similarly b_2 and b_3 are moments induced by unit field along the axes *2* and *3*, respectively. The principal axes are such that one of them corresponds to the direction of maximum polarizability, another to the direction of minimum polarizability, and the three are mutually orthogonal (Fig. 3). The locations of the principal axes can sometimes be deduced from

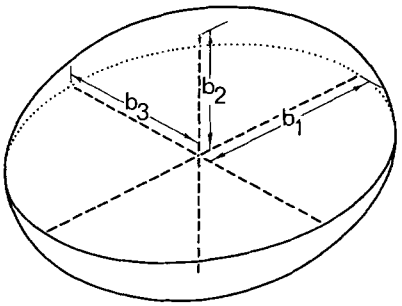

Fig. 3. Molecular polarizability ellipsoid.

symmetry considerations—an axis of symmetry must coincide with one, and a plane of symmetry must contain two, of the principal axes. It follows from eq. (4) that

$$_{E}P = N_A(b_1+b_2+b_3)/9\varepsilon_0 \qquad (5)$$

since α_E is the mean value of b_1, b_2, and b_3.

3.2. Interpretation of the Kerr Effect

The Kerr effect may be explained in terms of a partial orientational ordering by the applied field of molecules which are anisotropically polarizable[10, 11]. Thus the material as a whole becomes optically anisotropic and doubly refracting. Figure 4 shows the preferred molecular orientations for three specific types of interaction: (a) non-polar molecules such as benzene which tend to align themselves with the greatest polarizability axis, and hence the maximum induced moment, parallel to the field; (b) polar molecules with the permanent electric moment μ directed along the major polarizability axis; (c) polar molecules in which μ is located perpendicular to the major axis. Methyl chloride and chloroform are examples of (b) and (c), respectively. Since permanent moments are *ca.* 10^5 times greater than induced moments, the orientative action of a field on a polar molecule is overwhelmingly controlled by the disposition of μ within the molecular framework. This means that B and $_{m}K$ may, for polar molecules, be algebraically positive or negative depending on the location

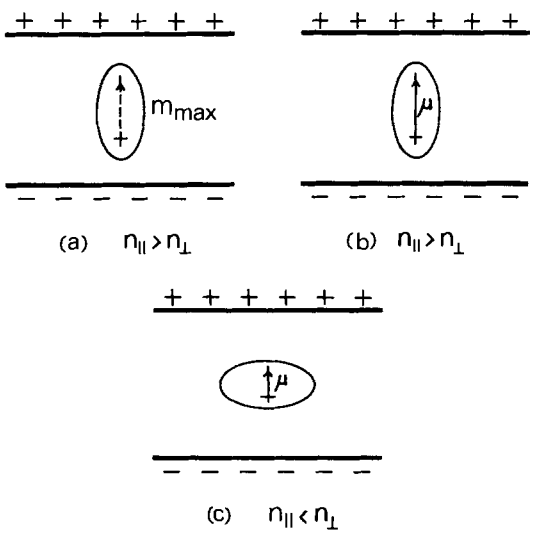

Fig. 4. Orientative action of a uniform electric field on non-polar (a) and polar molecules (b) and (c). For explanation see text.

of μ relative to the polarizability axes. For non-polar molecules the Kerr effect is positive but usually smaller in magnitude than for polar molecules. Of course if the molecules were isotropically polarizable (*i. e.* $b_1 = b_2 = b_3$) then the effect would be zero. Hence it is seen that the magnitude and sign of the Kerr constant must be related to the molecular polarizability anisotropy and to the magnitude and location of the permanent electric moment. Quantitatively this is expressed by eq. (6) which is a modified form[2] of the classical equations of *Langevin* and *Born*.

$$\begin{aligned} {}_{m}K = (N_A/810kT\varepsilon_0)\{({}_{D}P/{}_{E}P)[(b_1-b_2)^2+(b_2-b_3)^2+(b_3-b_1)^2] \\ +(kT)^{-1}[(b_1-b_2)(\mu_1^2-\mu_2^2)+(b_2-b_3)(\mu_2^2-\mu_3^2) \\ +(b_3-b_1)(\mu_3^2-\mu_1^2)]\} \end{aligned} \qquad (6)$$

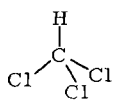
The molar distortion polarization $_{D}P$ is the sum of the molar electron and atom polarizations $({}_{E}P + {}_{A}P)$[12]. For polar organic substances the ratio $_{D}P/{}_{E}P$ is usually taken as 1.1 which is a satisfactory approximation since the second part of eq. (6) nearly always far outweighs the first. In cases where a more precise knowledge of the ratio is needed, $_{D}P$ is obtained by methods that are standard for dipole moment measurements[12]. The terms μ_1, μ_2, μ_3 are the vector components of the permanent moment along the principal axes *1*, *2*, and *3*, respectively; k is the Boltzmann constant; and T is the absolute temperature. For non-polar molecules the equation is simplified since terms involving μ_1, μ_2, and μ_3 vanish.

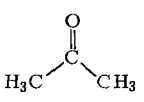
The derivation of eq. (6) assumes that polarizability is a linear function of the applied field intensity [(as in eq. (3)]. *Buckingham* and *Pople*[13] have modified the Langevin-Born approach to allow for a field-dependent polarizability:

$$m = \alpha E + \frac{1}{2}\beta E^2 + \frac{1}{6}\gamma E^3 + \cdots \qquad (7)$$

m is the induced moment; α is the normal low field polarizability; β, γ... are *hyperpolarizability* terms which describe the additional (non-linear) effects of strong fields. Both treatments apply strictly to molecules in the gas state at low pressure. The simpler (modified) Langevin-Born interpretation has been extensively used to derive "*effective*" *solute electron polarizabili-*

ties b from ${}_{\infty}({}_{m}K_2)$ measurements in non-polar solvents. Analysis of such data using the Buckingham-Pople approach is prohibitively complex for most molecules. The latter theory does, however, explain the observation of very small positive Kerr constants, attributed to field-induced distortions (γ term), for molecules such as carbon tetrachloride.





3.3. Principal Polarizabilities of Molecules as Solutes

For molecules such as ammonia, chloroform, or benzene, which have a three- or higher-fold symmetry axis, two of the principal polarizabilities (those in a plane perpendicular to that symmetry axis) are equal and the ellipsoid is one of revolution. In such cases eq. (5) and (6) can be used to solve for b_1, b_2, b_3. In the more general case where $b_1 \neq b_2 \neq b_3$, a third equation is necessary. This can be obtained from Rayleigh light scattering experiments.

If a beam of unpolarized monochromatic light is passed through a system of anisotropically polarizable gas molecules, the light scattered at 90° to the incident light path is imperfectly polarized. The degree of depolarization Δ_u[*] is related to the "molecular anisotropy" δ^2 of the molecules by $\delta^2 = 10\Delta_u/(6-7\Delta_u)$. From Δ_u measurements of solutions may be extracted the solute ${}_{\infty}\delta_2^2$ (at infinite dilution in non-polar solvents). The latter is related, by the derivation of *Le Fèvre* and *Rao*[14], to the effective solute polarizabilities b through eq. (8):

$$ {}_{\infty}\delta_2^2 = [(b_1-b_2)^2+(b_2-b_3)^2+(b_3-b_1)^2]/(b_1+b_2+b_3)^2 \qquad (8) $$

Table 1. Molecular principal polarizabilities [10^{40} b/C m^2 V^{-1}] [a] [b].

	8.27	9.89	5.97	[16]
	12.4	12.4	8.2$_8$	[17]
	16.4	14.0	9.1$_3$	[18]

[a] Expressed in SI units; the conversion factor to the c.g.s., e.s.u. system is: 1 C m^2 V^{-1} = 0.8988 × 10^{16} cm^3.
[b] From measurements at $\lambda = 589$ nm.

[*] Δ_u is measured as the ratio of the intensities of the light polarized in a horizontal plane (*i.e.* the plane defined by the incident and scattered beams) to that polarized in a vertical plane.

Eq. (5), (6), and (8) constitute three independent equations only if $\mu \neq 0$. It is implicit also that the symmetry of polar molecules should be such as to allow μ to be located with reference to the principal axes. Some examples of molecular principal polarizabilities so derived are listed in Table 1.

3.4. Polarizabilities of Bonds and Structural Groups

Bonded atom pairs and functional groups are known to have characteristic refractivities and mean polarizabilities[8, 19]. Directional polarizabilities have been attributed to individual bonds and groups and these can be deduced from analysis[8] of experimentally determined principal polarizabilities of molecules of known geometry. A selection of such values is given in Table 2. The term b_L for a bond represents the polarizability along the internuclear (longitudinal) axis; b_T and b_V (transverse and vertical polarizabilities) are normal to this axis. For example, an aliphatic C—C link is axially symmetric so that $b_L \neq b_T = b_V$; for C=O all three polarizabilities are unequal and, in cases like this, b_T is located in the plane of the trigonal carbon valencies with b_V perpendicular to this plane.

Table 2. Bond and group directional polarizabilities [10^{40} b/C m^2 V^{-1}] [a].

Bond or Group (AB)	b_L(AB)	b_T(AB)	b_V(AB)	Bond environment	Ref.

[a] From data at $\lambda = 589$ nm (1 C m^2 V^{-1} = 0.8988 × 10^{16} cm^3).
[b] *Le Fèvre, Orr,* and *Ritchie* [20] justified the isotropic b(C—H) values as appropriate for this scheme rather than the anisotropic α(C—H) estimates derived from Raman intensity studies of methane in the vapor state [24, 25].
[c] The polarizabilities quoted include, by the method of their derivation, contributions from the unshared electron pairs.
[d] b_L and b_T are the in-plane polarizabilities for the phenyl group.

It has been shown[2, 8] that this scheme of bond and group b values can be used to predict anisotropic polarizabilities and Kerr constants of molecules *providing the data are applied to molecular situations analogous to those from which they were derived.* The bond data are of course not constant throughout all molecular environments, *e.g.* conjugation in the halobenzenes results in C_{ar}—halogen polarizabilities which differ from those of the corresponding methyl halides[18]. In situations where bond polarizabilities are not accessible from Kerr effect measurements, approximate estimates may be obtained from empirical and semi-empirical relationships using atomic and bond dimensions[17, 26], vibration frequencies[27], or δ-function potentials[28].

4. The Kerr Effect Applied to Conformational Studies

The Kerr effect technique has been applied to a wide range of problems of conformation and configuration. In excess of three hundred publications have appeared in the literature on this subject since 1953. Substantive summaries of results are given in ref.[2, 8, 29, 30]. The procedure usually adopted involves measurement of the molar Kerr constant of the substance under investigation as a solute, *i.e.* the ${}_{\infty}({}_{m}K_2)$, and subsequent comparison with theoretical ${}_{m}K$ values computed for possible stereostructures. The approach is similar in principle to that used with dipole moments but the Kerr effect is much more versatile in that its application is not restricted to conformational situations requiring changes of relative disposition of *dipolar* groups. The techniques are often used in a complementary manner. Other physical methods, notably NMR and IR spectroscopy, frequently provide data which facilitate analysis of the Kerr effect through defining and/or limiting the range of conformational possibilities.

4.1. Calculation of Theoretical Molar Kerr Constants

The following data are needed to calculate the molar Kerr constant ${}_{m}K$ of a specific geometric form of a molecule: (a) the anisotropic polarizabilities of all component bonds or groups, (b) the permanent electric moments of all dipolar bonds or groups.

The molecular polarizability for a structure of specified geometry can be computed by additivity of the directed polarizabilities of the component structural units (cf. Table 2). The method may be illustrated with the simple case of an angular molecule A_2B composed of two A—B groups each having the polarizabilities b_L(A—B), b_T(A—B), b_V(A—B) (see Fig. 5). By symmetry the molecular principal axes *1* and *2* can be located as shown in Figure 5; *3* is perpendicular to the A_2B plane.

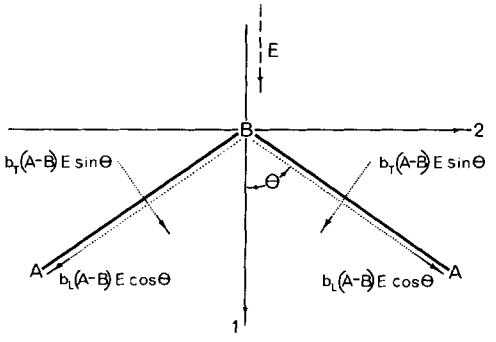

Fig. 5. Moments induced through polarization of the structural groups A—B by an electric field **E** applied in the direction of the axis *1*.

An electric field **E** of unit intensity, imagined to act along the molecular *1* axis has field components $E\cos\theta$ along the longitudinal axis of each A—B bond and moments b_L(A—B)$E\cos\theta$ are induced along these axes. The field has vector components $E\sin\theta$ along the transverse axis of each A—B bond and induces moments b_T(A—B)$E\sin\theta$ along each of these axes. The resultant induced moment for the molecule is $2b_L$(A—B)$\cos^2\theta + 2b_T$(A—B)$\sin^2\theta$ (electric field strength is unity) and this is directed along the *1* axes. Thus we have calculated the molecular b_1 which, by definition, is the moment induced along *1* by unit field acting in that direction. Similarly if the unit field is imagined to apply in turn along the *2* and *3* axes then b_2 and b_3 can be calculated by vector summation of the induced group moments. The procedure is the reverse of that used to obtain the bond and group polarizabilities (Section 3.4) from molecular principal polarizabilities. It is important to note that an electric field applied along a principal axis induces an overall resultant moment which is collinear with that axis. If the field were applied in a direction other than that of a principal axis, the resultant induced moment vector for the molecule would *not* coincide with the field.

With more complicated structures it is usually not possible to identify the locations of the molecular principal axes. We then choose any convenient set of orthogonal axes *X*, *Y*, *Z* within the molecule. A unit electric field imagined to act along *X* polarizes each structural group but the vector resultant of all induced moments for the molecule does not lie along *X* since this is not a principal axis. The resultant induced moment has vector components along *X*, *Y*, and *Z*, which are designated b_{xx}, b_{xy}, b_{xz}, respectively. Similarly, if a unit field were applied along *Y*, moments b_{yx}, b_{yy}, b_{yz} would be induced along *X*, *Y*, and *Z*; and finally if the unit field were directed along *Z*, moments b_{zx}, b_{zy}, b_{zz} would be induced along *X*, *Y* and *Z*. Thus the molecular polarizability specified with respect to our chosen set of axes *X*, *Y*, *Z*, has nine components, b_{xx}, b_{xy}, *etc.* Mathematically, or by trial and error, we can find that set of *X*, *Y*, *Z* axes for which all terms except b_{xx}, b_{yy}, b_{zz}, are zero. We know then that we have the principal polarizabilities b_1, b_2, b_3 and, as well, the location of the principal axes within the molecule. The latter information enables us to resolve all component group *permanent* electric moments along the principal axes to obtain μ_1, μ_2, μ_3. Substitution of the calculated quantities b_i and μ_i (i=1 to 3) in eq. (6) yields the theoretical molar Kerr constant for that geometric form of the molecule under study[*].

Two points should be noted: (a) Polarizability corrections are introduced into the additivity scheme if small exaltations are observed, *i.e.* if the experimental mean polarizability is found to exceed that expected from component group summation. Such exaltations, reflecting increased electron mobility in conjugated and hyperconjugated systems, are included in the calculations as additional increments of polarizability directed along the axis of maximum electromeric shift[8]. The group polarizability additivity scheme cannot, at this stage of knowledge, reasonably be applied to molecules such as conjugated polyenes in which extensive resonance interactions occur. (b) The permanent electric moment of a molecule under investigation is also measured. In many cases this assists in the analysis of molecular conformations from dipole vector

[*] We recognize here that polarizability is a symmetric tensor. It is more elegantly represented (with reference to a chosen set of reference axes *X*, *Y*, *Z*) in matrix form.

$$\mathbf{b} = \begin{bmatrix} b_{xx} & b_{xy} & b_{xz} \\ b_{yx} & b_{yy} & b_{yz} \\ b_{zx} & b_{zy} & b_{zz} \end{bmatrix} \xrightarrow[\text{transformation}]{\text{axes}} \begin{bmatrix} b_1 & 0 & 0 \\ 0 & b_2 & 0 \\ 0 & 0 & b_3 \end{bmatrix}$$

It is common practice in structural work to obviate the need for the axes transformation and to use instead a more general form of eq. (6) to calculate the theoretical ${}_{m}K$ directly from the terms b_{xx}, b_{xy}, *etc.* and μ_x, μ_y, μ_z— eq. (30), (35), (36) of ref. [8].

considerations alone. Often μ (observed) can be used to deduce μ_1, μ_2, μ_3 for eq. (6).

4.2. Some Applications

The method is best illustrated by considering some recent examples.

4.2.1. Carboxylic Esters

Many techniques including that of the Kerr effect have been applied to the study of the conformations of carboxylic esters—see review[31]. Recent investigations concern unsaturated esters. Vinyl formate, for example, was found to have an experimental dipole moment of 5.07[*] and $_\infty(_mK_2)$ of 48.1[*] in carbon tetrachloride solution[32]. Model conformations were specified by the interplanar angles θ and ϕ (see Fig. 6); θ is the dihedral angle between the O=C—$\overset{*}{O}$ and C—$\overset{*}{O}$—C planes and ϕ is that between the C=C—$\overset{*}{O}$ and C—$\overset{*}{O}$—C planes. The uniplanar s-*cis*-s-*trans* reference structure has both θ and ϕ equal to zero. From bond dipole additivity the predicted moments range from a minimum of 5.01 ($\theta=0°$) to a maximum of 11.67 ($\theta=180°$) clearly indicating that in solution the molecule has a s-*cis* $\theta=0$ geometry. This form is stabilized through antiparallel arrangement of C$\overset{*}{O}$C and C=O group dipoles. The molecular dipole moment is not sensitive to rotations ϕ. The calculated molar Kerr constant does, however, vary with ϕ since the vinyl group is anisotropically polarizable. Theoretical $_mK$ values for conformations defined by particular values of ϕ (retaining θ as 0°) are as follows:

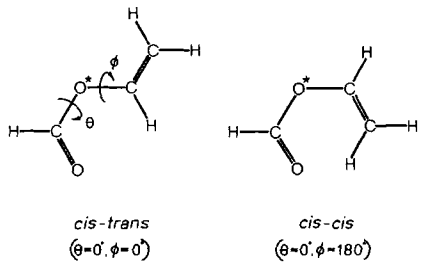

Fig. 6. Conformational models of vinyl formate.

ϕ	0°	30°	60°	90°	120°	150°	180°
$_mK$ (calc.)	+49	+38	+21	+22	+51	+90	+109

Agreement between observed and calculated Kerr constants occurs for structures with $\phi=ca.$ 0° or *ca.* 120°. The former is favored because of conjugative stabilization. It was concluded that vinyl formate in solution has a preferred s-*cis*-s-*trans* conformation ($\theta=0°\pm10$, $\phi=0°\pm10$). This result was reinforced by *ab initio* molecular orbital calculations[32] and is in accord with the result of an earlier microwave spectral study of the vapor[33]. A similar conclusion was drawn for vinyl acetate[32].

[*] Dipole moments and molar Kerr constants are given throughout in SI units as $10^{30}\,\mu$/C m and $10^{27}\,_mK/m^5\,V^{-2}\,mol^{-1}$, respectively. Conversion factors for comparisons with data in e.s.u. are: 1 C m = 0.2998×10^{30} D; $1\,m^5\,V^{-2}\,mol^{-1} = 0.8988\times10^{15}$ e.s.u. mol^{-1}.

4.2.2. Diaryl Disulfides

The skew configuration of the disulfide bridge in compounds R_2S_2 in solution has been verified by dipole moment and microwave dielectric loss measurements[34, 35]. For diphenyl disulfide the angle θ between the two R—S—S planes was determined as 85° from the measured dipole moment (6.07). The experimental $_\infty(_mK_2)$ was then analyzed to deduce that the phenyl groups are positioned such that each C_6H_5 is virtually coplanar with the adjacent $C_{ar}SS$ plane.

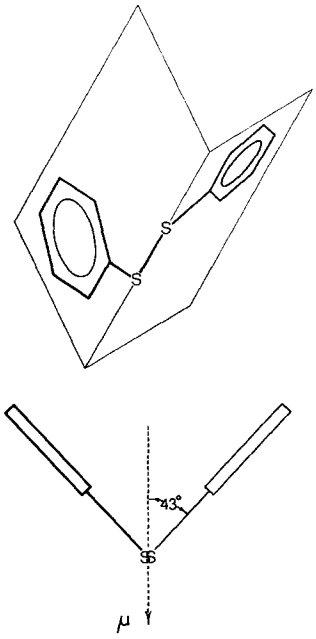

Fig. 7. Conformation of diphenyl disulfide.

The result is definitive since the observed value (−12.8) is close to the calculated value for the above model (−16) (see Fig. 7) and all rotations of one or both phenyl groups away from that model lead to a rapid increase in $_mK$ (calc.); *e.g.* for both phenyl groups perpendicular to their adjoining $C_{ar}SS$, $_mK$ (calc.) is 186. Di(4-pyridyl)- and di(2-pyridyl)-disulfide have also been shown, by similar arguments, to have skew structures in solution ($\theta=ca.$ 74°) with the pyridyl and contiguous $C_{py}SS$ groups nearly coplanar[36].

The approach outlined above has been applied as well to specifying solute conformations of the aromatic diketones such as benzil[37], di(2-pyridyl)-[38], di(1-naphthyl)- and di(2-naphthyl)diketones[39].

4.2.3. Conformational Equilibria

For molecules which exist in solution as equilibrium mixtures of two or more conformational isomers[40], the measured solute molar Kerr constant can be regarded as an average value connected with the molar Kerr constants of the individual forms by the relation

$$_\infty(_mK_2)=\sum_{i=1}^{n}N_i(_mK_i) \qquad (9)$$

where N_i is the molar fraction of the ith conformer and $_mK_i$ is the molar Kerr constant of that conformer. The analogous expression for dipole moments is given by eq. (10).

$$\mu^2_{exp.} = \sum_{i=1}^{n} N_i \mu_i^2 \quad (10)$$

The following condition also applies

$$\sum_{i=1}^{n} N_i = 1 \quad (11)$$

Equations (9) and (11) were used to determine *trans/gauche* ratios for molecules like the *n*-propyl halides[41] the dipole moments of which, unlike those of 1,2-dihalogenoethanes, are insensitive to conformational change. It must be assumed, however, that the geometry of each rotamer can be reasonably specified. Early work on conformational equilibria in the nitrogen heterocycles morpholine, piperazine, *etc.* (summarized in ref. [8]) did not take into account the strong solvent effect of benzene (see Section 4.3) and is being revised using molar Kerr constants and bond polarizability data from "non-interacting" solvent environments. More recently *Huang et al.*[42,43] examined a number of substituted ethanes in which the dipole moments as well as the molar Kerr constants vary appreciably with rotation about the ethane C—C bond. Equations (9)—(11) were used to interpret the experimental data in terms of two basic variables: the percentage of *gauche* population (χ) and the dihedral angle (θ) which defines the *gauche* conformer. For 2,2,3,3-tetramethylbutanedinitrile in carbon tetrachloride at 25° they found $\chi = 18\,\%$, $\theta = 85°$ and ΔE (the internal energy difference between the isomers) = 5.5 kJ mol^{-1} (see Fig. 8). *Huang et al.* sometimes use a graphical

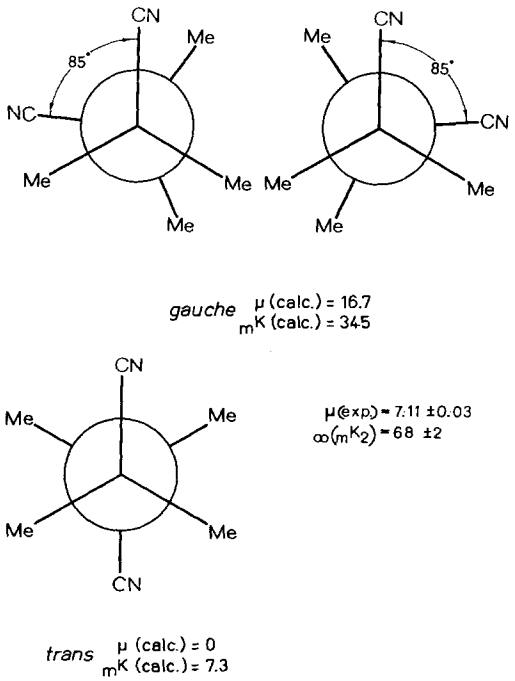

Fig. 8. Conformational isomers of 2,2,3,3-tetramethylbutanedinitrile.

procedure to derive χ and θ for such molecules. This is illustrated in ref.[43] with regard to 1,2-dibromopropane but the conclusions for this molecule are somewhat uncertain because the calculated molar Kerr constants for the two *gauche* conformers are not equivalent. The epihalohydrins (2-(halomethyl)oxiranes) provide examples of conformational equilibria between three characterized low energy forms[44]. Conformer distributions were obtained on this basis from the experimental dipole moments and molar Kerr constants by solution of equations (9)—(11)[45]. *Arbuzov et al.*[30,46] have extended such considerations to include light scattering studies (Δ_u in Section 3.3) which provide another conformation-dependent parameter. They describe a three dimensional graphical analysis, involving all three measured quantities, which they use to determine conformational equilibria in molecules such as the tetrahalonorcaranes (see Fig. 1 of ref.[46]). It is clear, however, that the method is in general limited in its application to molecules which have relatively few rotational isomers.

4.2.4. Substituted Cyclopropanes

The cyclopropyl group, because of its unsaturated character, has the ability to conjugate with adjacent π-electron systems. Phenylcyclopropane, for example, is known to have a resonance stabilized "bisected" structure (specified by $\phi = 0°$) with a mutually orthogonal disposition of the phenyl and cyclopropyl group planes[47], *i.e.* the C_6 group plane includes the CCC angle bisector (broken line in Fig. 9). Calculation shows

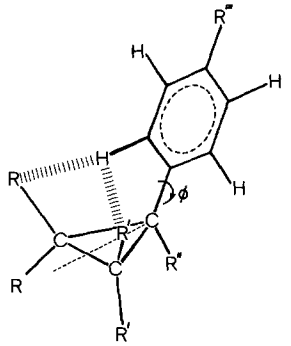

Fig. 9. Conformations ϕ of substituted arylcyclopropanes.

that the theoretical $_mK$ for this molecule is only slightly sensitive to rotations ϕ about the C(phenyl)—C(cyclopropyl)[48] bond. If polar groups are substituted in the cyclopropane ring, however, $_mK$ (calc.) acquires a wide range of values for $0° \leq \phi \leq 180°$. This occurs because rotations ϕ are associated with changes of orientation of the molecular dipole moment relative to the highly anisotropically polarizable aromatic group. A typical calculation, that for 1,1-dichloro-2-phenylcyclopropane, is reproduced graphically in Figure 10 as the theoretical $_mK(\phi)$ plotted against ϕ[49]. It is seen that the measured $_\infty(_mK_2)$ agrees with the calculated value if $\phi = ca.\ 60°$ or alternatively

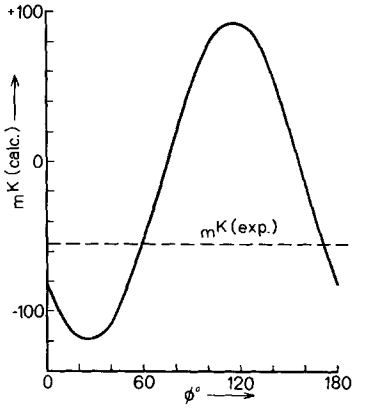

Fig. 10. Theoretical $_mK$ values for conformations $0° \leq \phi \leq 180°$ of 1,1-dichloro-2-phenylcyclopropane: ϕ is the angle of rotation from the bisected form (for which $\phi = 0°$) away from the CCl_2 group. (R = Cl, R′ to R‴ = H.)

ca. 170°; the latter model is precluded on steric grounds. There are, however, alternative interpretations[*].

The procedure adopted was to calculate analogous but independent ${}_{m}K(\phi)$ functions for a number of *para*-substituted 1,1-dichloro-2-phenylcyclopropanes. It was found that simultaneous agreement between theoretical and observed molar Kerr constants for the series is achieved only if $\phi = 60° \pm 5$. The variation of molecular geometry with different groups R, R′, R″ and R‴ (in Fig. 9) was investigated. It was shown that $\phi = ca.\ 6°$ for 1,1-difluoro-2-phenylcyclopropane[45] whereas the *cis*-halogen of the chloro- and bromo-analogs ($\phi = 67° \pm 6$ for the latter[48]) deflects the phenyl group beyond the eclipsed position with reference to the cyclopropyl methylene group. In the case of 1,1-dichloro-2-mesitylcyclopropane $\phi = ca.\ 76°$. By contrast with phenylcyclopropane, ϕ for *N*-phenylaziridine[50] was found to be *ca.* 90° (stabilized in this form by delocalization of the N-lone pair electrons into the phenyl ring).

This approach has been applied also to determining solute conformations of cyclopropyl methyl ketone[51] (bisected s-*cis* form as found also for the vapor by microwave spectroscopy[52]); cyclopropyl substituted-phenyl ketones[51], substituted bicyclopropyls[53], and aryl oxiranes[45]. Current work is directed to studying interactions between electron donor substituent groups and three-membered rings and the transmission of conjugation in polysubstituted cyclopropanes.

4.2.5. Substituted Pentafluorobenzenes

Specification of the pentafluorophenyl group polarizabilities[54] enabled the measured molar Kerr constants of decafluorobiphenyl, decafluorobenzophenone, and molecules of general formula C_6F_5R (R = OH, NH_2, CHO, $COCH_3$, OCH_3, SCH_3, CH_2CN) to be analyzed[55, 56]. The first of these is non-dipolar but the calculated molar Kerr constant varies rapidly with change of mutual disposition of the two C_6F_5 groups since they are highly anisotropically polarizable. A plot of ${}_{m}K$(calc.) against the dihedral angle ϕ is shown in Figure 11; $\phi = 0°$ for planar geometry. The experimental ${}_{\infty}({}_{m}K_2)$ in cyclohexane is 43.2 in agreement with that predicted for $\phi = ca.\ 62°$. This is close to the solute conformation (*ca.* 60°) from UV spectral studies in ethanol[57], the solid state structure (62°) from X-ray analysis[58], and the vapor state conformation (70°) by electron diffraction[59].

The results for molecules C_6F_5R are summarized in Table 3[56]; ϕ refers to the rotation of R from the resonance favored "planar" form. With each molecule C_6F_5R, ${}_{m}K(\phi)$ values were calculated for $0° \leq \phi \leq 90°$; the range is illustrated in columns 3 and 4. The ϕ estimates of column 5 designate, in each case, that conformation for which theoretical and measured molar Kerr constants are in agreement; in effect they represent average conformations. Column 6 lists similar ϕ values for

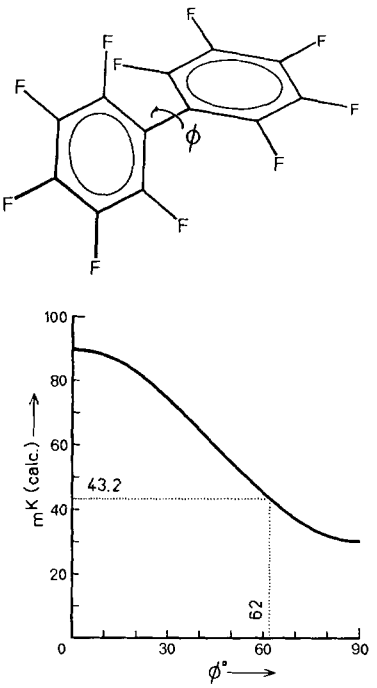

Fig. 11. Calculated molar Kerr constants for conformations ϕ of decafluorobiphenyl.

[d] The H···H line is parallel to the C_6 ring for $\phi = 0°$.

the corresponding C_6H_5R molecules determined also from Kerr effect data. Each of the molecules C_6H_5OH, C_6F_5OH, C_6H_5CHO, and $C_6H_5COCH_3$ was shown to exist in solution as a virtually planar form; for $C_6H_5NH_2$ and $C_6F_5NH_2$ the amino group disposition is given by $\phi = ca.\ 0°$. Anisole and *para*-substituted anisoles are, from Kerr effect evidence, planar or near-planar depending on the nature of the *para*-substituent[60]. An approximately planar structure for anisole was recently suggested from ^{1}H-NMR spectra of nematic solutions by *Emsley et al.*[61]; it should be noted, however, that these authors incorrectly quoted the Kerr effect results of ref. [60]. *Emsley et al.*[62] also examined pentafluorobenzaldehyde (in nematic solution) which, they deduce, has a planar "equilibrium structure". The ϕ values for C_6F_5R, where R = OCH_3, SCH_3, or CH_2CN, exceed those for the corresponding C_6H_5R compounds indicating greater steric/electrostatic repulsions of *ortho*-fluorine, relative to hydrogen, for each of these R groups. With R = CHO or $COCH_3$ the larger ϕ values in the pentafluorophenyl compounds are attributable to greater repulsions of R with *ortho* F and, in addition, to decreased

[*] The ${}_{\infty}({}_{m}K_2)$ should properly be regarded as the mean value for a population of conformations in torsional oscillation about one or more energetically favored geometric forms, *i.e.*

$$\langle {}_{m}K \rangle = \int_{-\pi}^{+\pi} {}_{m}K(\phi) \cdot \exp[-U(\phi)/kT]\,d\phi \Big/ \int_{-\pi}^{+\pi} \exp[-U(\phi)/kT]\,d\phi$$

$U(\phi)$ is the potential-energy function which determines the distribution amongst the various possible molecular conformations. This equation is not often applied since $U(\phi)$ functions are generally uncertain and speculative (see, however, Section 4.2.6).

resonance energy arising from inductive depletion of the aromatic π-system by the fluorine atoms.

4.2.6. Kerr Constants of Amides and Peptides

Flory et al.[63] have attempted to interpret the measured molar Kerr constants of some amides and peptides in dioxane solution using estimates of conformational energy data. With *N*-methylpropionamide, for example, theoretical ${}_mK$ values were calculated for rotations ψ of the CH_2—CH_3 group in the range $0° \leq \psi \leq 180°$ (see Fig. 12). The amide group was assumed to remain in the planar *trans* configuration. The average theoretical molar Kerr constant was computed by summing values of ${}_mK$(calc.) weighted according to conformational energies; the latter were calculated for various values of ψ as sums of non-bonded interactions and intrinsic torsional potentials for rotation about the central C—C bond[64]. Close agreement was obtained between the theoretical $\langle {}_mK \rangle$ and that from experiment. In the case of *N*-ethylacetamide, however, the experimental result is appreciably larger than that similarly calculated for rotations of the *N*-ethyl group. For each of the molecules the conformational energies are minimal when the rotating CH_2—CH_3 group is approximately perpendicular to the amide group plane. The approach was extended to glycyl, L-alanyl, and L-leucyl peptides of the type CH_3—CO—NH—CHR—CO—NH—CH_3 (where the peptide unit is defined by two torsional angles) and to oligoglycines and oligo-L-alanines. It was shown that the calculated average molar Kerr constants are sensitively dependent on conformational energies, but these, however, are not known at present with sufficient accuracy to allow quantitative calculations of $\langle {}_mK \rangle$ to be made. *Flory et al.*[63] also concluded that "the Kerr constant is an especially acute index of the average conformation".

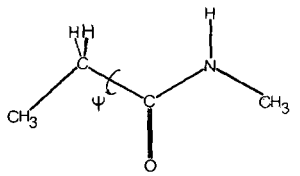

Fig. 12. Conformations ψ of *N*-methylpropionamide.

4.2.7. The Cotton-Mouton Effect

Another approach recently applied to conformational analysis involves the measurement of magnetic field induced birefringence (Cotton-Mouton effect) of diamagnetic organic molecules. The experimental method is identical to that of the Kerr effect except that the molecules in the cell are subjected to a strong uniform magnetic induction (*ca.* 2 Tesla). The molecules tend to be oriented by the magnetic field because of their magnetic anisotropy. Since each molecule is anisotropically polarizable the partly ordered system of molecules becomes optically anisotropic and birefringent. The molar Cotton-Mouton constant ${}_mC$, an intrinsic property of a molecule, is related to both the magnetic anisotropy and to the polarizability anisotropy [see eq. (1) and (4) of ref. [65]].

The procedure adopted in this work is analogous to that used in interpreting the Kerr effect in terms of solute conformations. The measured solute ${}_mC$ is compared with theoretical ${}_mC$(calc.) values for different possible geometric forms. The calculations are based on additivity of component group magnetic anisotropy and polarizability anisotropy data (as in Section 4.1). The Cotton-Mouton effect technique is generally not as sensitive a structural probe as that of the Kerr effect. This need not be the case, however, with some non-dipolar aromatic molecules such as 9-phenylanthracene or 1,3,5-triphenylbenzene where the range of calculated Cotton-Mouton constants for possible stereostructures exceeds that of the corresponding Kerr constants. With 9-phenylanthracene, for example, ${}_mC$(calc.) varies with rotations ϕ of the 9-phenyl group from 515 (for $\phi = 0°$, *i.e.* the planar form[*]) to 213 ($\phi = 90°$); the ${}_mK$(calc.) ranges from 244 ($\phi = 0°$) to 119 ($\phi = 90°$). The theoretical ${}_mC(\phi)$ and ${}_mK(\phi)$ functions when compared with the measured ${}_mC$ and ${}_mK$ (248 and 134, respectively, in carbon tetrachloride solution) each indicate an average conformation of $70° \pm 6$, a result in close agreement with the interplanar angle of 68° obtained from analysis of the electron spin resonance spectrum of the 9-phenylanthracene radical anion[66].

4.3. Solute-Solvent Interactions

With solutes in dilute solution, a non-linear concentration dependence of the electric birefringence may arise from solute-solute associations as for aniline[67] or through conformational changes induced by the reaction field of the medium[68,69] (the dielectric characteristics of the medium would vary of course with solute concentration). For structural investigations solute molar Kerr constants are determined at infinite dilution ideally in non-polar, "inert", and near-isotropically polarizable solvents, *e.g.* cyclohexane. Carbon tetrachloride has also been much used although it is known to interact with solutes such as amines[50,70]. For solutions in benzene, however, time-averaged non-random distributions of the highly anisotropically polarizable solvent molecules about the solute can result in apparent solute ${}_\infty({}_mK_2)$ values quite different to those from "innocent" solvents. The ${}_\infty({}_mK_2)$ of chloroform, for example, is -26.9 in carbon tetrachloride and -45.5 in benzene. The negative Δ_mK increment suggests that the benzene molecules within the solvent-cluster about $CHCl_3$ are organized such that the polarizability perpendicular to the solute dipole axis is augmented to a greater extent than in a direction parallel to that axis. This is compatible with *favored* transient $CHCl_3 \cdot C_6H_6$ associations, involving π-hydrogen bonding, in which the chloroform dipole moment lies perpendicular to the plane of the benzene molecule[71].

The Kerr constant of a solute, in common with its nuclear magnetic resonance spectrum, can be markedly affected by stereospecific interactions with aromatic solvents[72]. An extreme example is provided by the neutral metal complex *N*,*N*,*N*′,*N*′-tetramethylethylenediaminezinc(II) chloride for which the following apparent ${}_\infty({}_mK_2)$ values have been recorded: -7 (in "inert" solvent), -2450 (in benzene), $+5560$ (in hexafluorobenzene)[72]. Kerr effect measurements in benzene and other aromatic solvents present difficulties of interpretation as far as the analysis of solute conformations is

[*] Molar Cotton-Mouton constants are given here in SI units as $10^{26}\ {}_mC/m^5\ A^{-2}\ mol^{-1}$; $1\ m^5\ A^{-2}\ mol^{-1} = 0.6333 \times 10^{10}$ e.m.u. mol^{-1}.

concerned, but they undoubtedly provide a sensitive and potent method for investigating the geometry of solvation.

5. Electric Birefringences of Solutes in Water

Utilization of pulsed-voltage techniques has allowed extension of Kerr effect studies to conducting media. Small molecules and simple ionic species in water have not been much studied. A major difficulty is that of theoretical interpretation of the measured data, reflecting the inadequacy of existing dielectric theory. The experimental technique for such measurements is described in ref. [2]. A square-wave voltage pulse is applied to the molecular system which becomes birefringent. The light transmitted through the crossed prisms and the voltage applied are both simultaneously displayed on a double-beam oscilloscope (see Fig. 6.11 of ref. [2] for examples). The light intensity, measured as the height of the steady-state birefringence trace, is linearly dependent on E^4 if Kerr's law is obeyed. The Kerr constants B ($\lambda = 633\,\text{nm}$) for pure water and for a number of organic solvents were recently determined by this technique using voltage pulses of 70 μs duration and fields up to $15 \times 10^5\ \text{V m}^{-1}$ [73]. The extraction of anisotropic polarizabilities of glycine, *dl*-alanine, and α-aminoisobutyric acid from measured B values in water had earlier been attempted by *Orttung* and *Meyers*[74].

The electric birefringence technique has been much used in recent years for stereostructural investigations of biologically important macromolecules[5, 6, 75]. The duration of the orienting square voltage pulse is adjusted so that maximum orientation of the macromolecules is attained (evidenced by the horizontal section of the birefringence trace), but to minimize electrolysis, heating, and degradation, the pulse time must not be unnecessarily long. Macromolecular solutes commonly exhibit three regions of birefringence (Fig. 13): the build-up Δn_R (once the field is applied), the steady-state Δn_0, and the decay Δn_D (on sudden removal of the field). At high fields, saturation birefringence Δn_S may be attained, *i.e.*, a limiting value of the measured Δn with increase of the field intensity, and Kerr's law is no longer obeyed. The quantity Δn_S is related to the apparent solute polarizability anisotropy[76]. A complicating factor in such interpretations, particularly with solutions of polyelectrolytes, is the "interfacial polarizability" arising through displacement of counter-ions along the macro-ion by the applied field[77, 78]. *Benoit*[79] has shown that the birefringence decay of a monodisperse solution of particles of cylindrical symmetry is given by

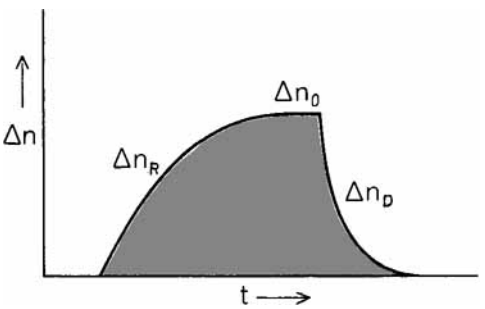

Fig. 13. Representation of the time dependent electric birefringence trace.

$$\Delta n_D = \Delta n_0 e^{-6\Theta t} = \Delta n_0 e^{-t/\tau} \quad (12)$$

where Δn_D is the birefringence at time t after removal of the field; Δn_0 is the birefringence value at the instant the pulse is quenched; Θ is a constant (the rotary diffusion constant); τ is the relaxation time of the particles. The term Θ is related to the particle dimensions[6]. For cylindrical, rod-like particles of length $2l$ and breadth $2m$

$$\Theta = 3kT[\ln(2l/m) - 0.8]/8\pi\eta l^3 \quad (13)$$

where η is the viscosity of the solvent. Thus the length of a long, rigid macromolecule can be deduced if an estimate of the axial ratio l/m is known, *e.g.* from viscosity measurements. The analysis of birefringence decay curves is, however, a complex and uncertain procedure with polydisperse solutes[75] or with flexible particles where the relaxation may occur by orientations of segments of the macromolecule. *Fredericq* and *Houssier*[6] have recently given an account of the dynamic electric birefringence technique as applied to biological macromolecules; they detail investigations on viruses, nucleic acids, nucleoproteins, fibrous proteins, and globular proteins. The interpretation is very rarely in terms of precise conformational features but the technique is of great value in exploring changes of shape and dimensions of biopolymers in solution with variation of temperature, pH, concentration, ionic strength, or of the applied field intensity.

6. Conclusion

The electro-optical Kerr effect is the basis of a highly sensitive yet relatively uncomplicated technique which has been extensively used to investigate the conformational preferences of molecules in non-polar solvents. The method has, in addition, been applied to the study of the geometry of solvation, solute aggregation[80], and the shapes and dimensions of biopolymers in solution. Problems of theoretical interpretation remain to be overcome particularly for polar and conducting dielectrics. The technique is gaining wider use despite the non-availability of commercial instruments.

I am grateful to Professor R. J. W. Le Fèvre, F. R. S. for his inspiration past and present, to Professor Dr. W. Lüttke for his very considerable encouragement, and to my many Sydney friends and colleagues, notably Dr. R. S. Armstrong, Dr. M. P. Bogaard, Dr. K. E. Calderbank, Dr. J. M. Eckert, Mr S. W. Filipczuk, Dr. R. K. Pierens, and Dr. G. L. D. Ritchie, for valued discussion. I thank also the Australian Research Grants Committee for financial support.

Oxometallates with Planar Coordination

By Hanskarl Müller-Buschbaum[*]

Oxo compounds whose coordination polyhedra have a planar structure are a rarity in solid state chemistry. The present state of this research area provides a wealth of interesting principles concerning one-, two-, and three-dimensional linkage of square-planar structural units. In certain cases the environment of these units in solids requires new conceptual models for the chemical bonding.

1. Introduction

During the last 15 years solid state chemistry has been enriched by a series of oxometallates with planar-coordinated ions such as Ni^{2+}, Cu^{2+}, Cu^{3+}, Pd^{2+}, Pt^{2+}, and Au^{3+}. Interest attaches not only to the chemical properties of these compounds but also to their structure, which has been studied by modern methods. The present article is intended as a review of the remarkable diversity of their characteristic structural principles—there have been only isolated investigations of their physical properties. Since important characteristics of the linkage of planar polyhedra[**] to one another are encountered in the halooxocuprates, this class of compounds has been included in the present review. While some of these substances exhibit deviations from the strictly planar coordination of the Cu^{2+} because the halogen provides a partial octahedral supplement to the planar metal-oxygen coordination, only those halooxocuprates will be included in which the copper in the planar bases of the distorted octahedra is surrounded by oxygen in quasiplanar manner.

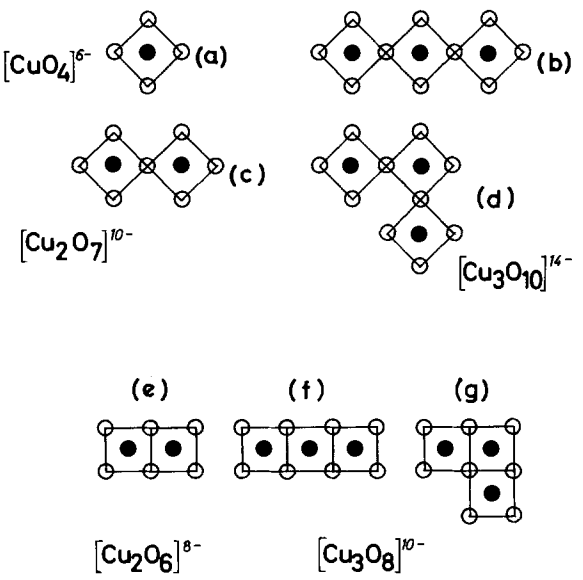

Fig. 1. Model representations of one-dimensional linking of square-planar polyhedra. (a) to (d) corner linking, (e) to (g) edge-linking (formulated for Cu^{2+}).

[**] If two corners of a regular octahedron are removed further and further from each other, or if a tetrahedron is compressed, these classical coordination polyhedra pass into planar configurations. Since such transitions are fluxional and the planar environment is a limiting case, the designation "square-planar polyhedron" is justified.

In this review the oxometallates are divided into the following two groups irrespective of their historical development: planar-coordinated oxometallates with one- or two-dimensional linkage of square-planar polyhedra, and planar-coordinated oxometallates with three-dimensional linkage of square-planar polyhedra.

In addition, two-dimensional linkage of the polyhedra can be subdivided characteristically into those in which the linkage is by the corners and those where it is by the edges, whereas the much more complicated three-dimensional linkage must still be presented *en bloc*. All the compounds belong to the class of solids *i. e.* their characteristic structure is restricted to the solid state and can be recognized only on consideration of the crystal structure. In the illustrations selected here the important structural principles are emphasized for clearer recognition.

2. Planar-Coordinated Oxometallates with One- or Two-Dimensional Bonding of Square-Planar Coordination Polyhedra

2.1. Square-Planar Polyhedra Occurring in Isolation

Figure 1 illustrates isolated, simply constructed, planar polyhedra. Cu^{2+} is regularly used as an example for the formulation of the chemical composition of anionic structural units, since oxocuprates provide examples of most of the structure types. The environmental relationships in the crystal structure are intentionally left out of consideration in this presentation. As can be seen from Figure 1, for structural units $[M_xO_y]$ with $x_{max}=3$ there are already seven possible, two-dimensional, isolated coordination polyhedra with exclusively corner or edge linkage. Of these seven possibilities only two have so far been observed in oxo compounds: the isolated square-planar structural unit (Fig. 1a) $[CuO_4]^{6-}$ found in Bi_2CuO_4[1-3] and Bi_2PdO_4[3,4]; and the edge-linked double square (Fig. 1e) $[Au_2O_6]^{6-}$ that is contained in the compounds Li_3AuO_3[5] and $Na_6Au_2O_6$[6] described by *Hoppe et al.*

Figure 2 shows, for Bi_2CuO_4, that in a tetragonal structure isolated square-planar structural units are stacked along the z-axis with a 45° twist. This structure is reminiscent of the almost identical arrangement of ligands in complexes such as $[Ni(CN)_4]^{2-}$. Bi^{3+} serves formally only as the linking element. In spite of its orthorhombic symmetry, Bi_2PdO_4[3,4] shows only very small deviations from Bi_2CuO_4, and these will not be discussed here any further. Nevertheless, these two compounds should be regarded as oxocuprate and oxopalladate and not as oxobismuthates, for which the formulations would be $CuBi_2O_4$ and $PdBi_2O_4$. This view follows from

experience with alkaline earth metal oxocuprates, where it can be seen that the Cu^{2+} is always square-planar coordinated even if it functions as a component in an anionic structural group[7].

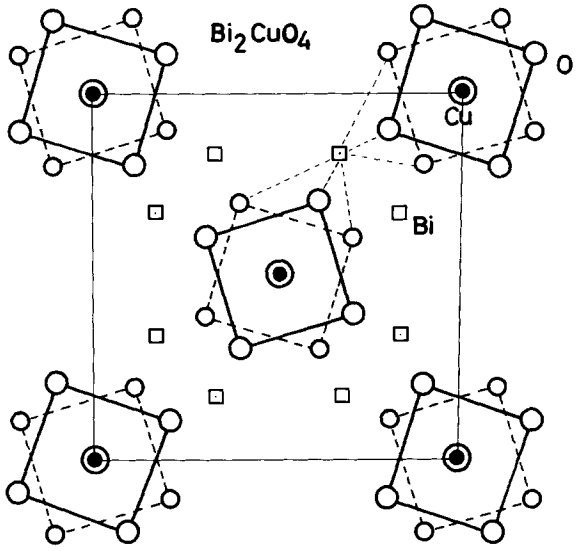

Fig. 2. Characteristic arrangement of square-planar CuO_4 polyhedra in Bi_2CuO_4; projective representation of the atomic distribution along [001] [2].

Li_3AuO_3 is a representative of double squares occurring in isolation[5], its typical structure being shown in Figure 3. The emphasized structural units $[Au_2O_6]^{6-}$, which are directly comparable with the structural units in dimeric gold chloride Au_2Cl_6, are here also stacked in an axial direction and are linked together only by tetrahedrally coordinated Li^+ ions. The compounds $Na_6Au_2O_6$[6] and Li_3CuO_3[8] are isotypic with Li_3AuO_3.

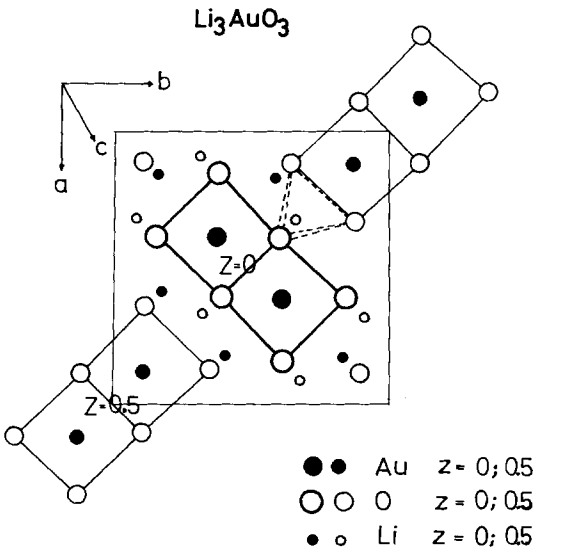

Fig. 3. Arrangement of $[Au_2O_6]^{6-}$ structural groups in Li_3AuO_3; projective representation of the atomic arrangement along [001] [5].

Although there is an apparent analogy between the structure of the solid compounds Bi_2CuO_4, Bi_2PdO_4, Li_3AuO_3, Li_3CuO_3, and $Na_6Au_2O_6$ and the well known structures of complexes or molecules, it cannot be derived therefrom under what conditions it would be possible to prepare other compounds with the still missing polyhedral groupings shown in Figure 1.

2.2. Infinite Linking of Square-Planar Coordination Polyhedra Having Exclusively Edge Linkage

2.2.1. One-Dimensional Infinite Chains

If for this type of polyhedra linkage we again chose to limit ourselves to the characteristic size of structural unit $[M_xO_y]$ with $x_{max}=3$, we obtain the polyhedral groupings shown in Figure 4. These begin with an extended isolated chain (Fig. 4a) and end with two flat arrangements of the structural unit $[Cu_3O_4]^{2-}$ (Figs. 4e and 4f). There are a number of interesting examples of the isolated extended chain shown in Figure 4a:

We shall first refer to Li_2CuO_2 and the compounds Li_2PdO_2, Na_2PtO_2, Li_2NiO_2, and Li_5AuO_4 isotypic with it. Li_2CuO_2 was first mentioned by *Scholder*[9] and was first obtained pure by *Klemm*, *Wehrmeyer* and *Bade*[10]. *Den Os*[11] designed the first model that described the structure. Finally, *Hoppe* and *Rieck*[12] determined the structure reproduced in Figure 5; this investigation yielded distinctly different parameters, especially for Li^+ and showed that the extended chains arranged in parallel, as emphasized in Figure 5, are a compromise with tetrahedral cross-linking through Li^{2+}, leading to stretching of the square polyhedra in the direction of the chain as well as to distortion of the tetrahedral coordination of O^{2-} around the Li^+.

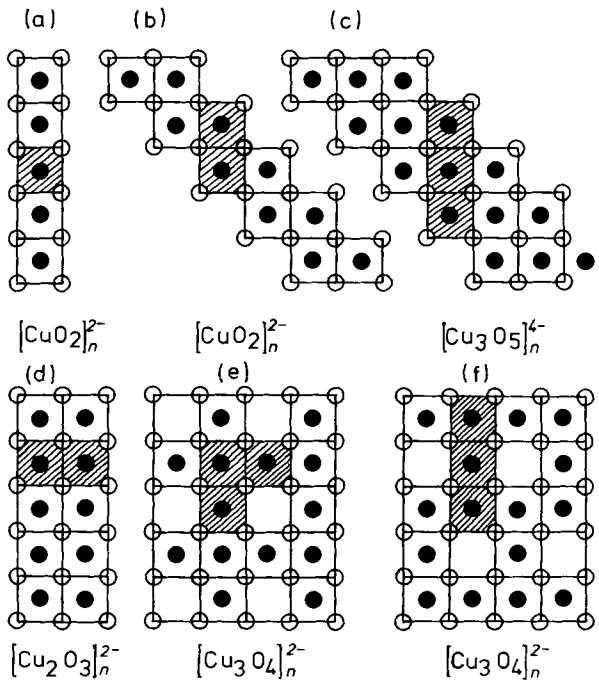

Fig. 4. Model representations of two-dimensional edge-linking of square-planar polyhedra (formulated for Cu^{2+}).

Directly comparable with Li_2CuO_2 are Li_2NiO_2[13] and the compound Li_2PdO_2, first prepared by *Scheer*[14] and investigated by X-ray analysis by *Dubey*, *Gard*, *Glasser*, and *West*[15] in ignorance of the already known crystal structure. Li_2PdO_2 has the structural characteristics described for Li_2CuO_2. What is remarkable, however, is that Na_2PtO_2 is isotypic with Li_2CuO_2, as observed by *Urland* and *Hoppe*[16]: Na^+ still has

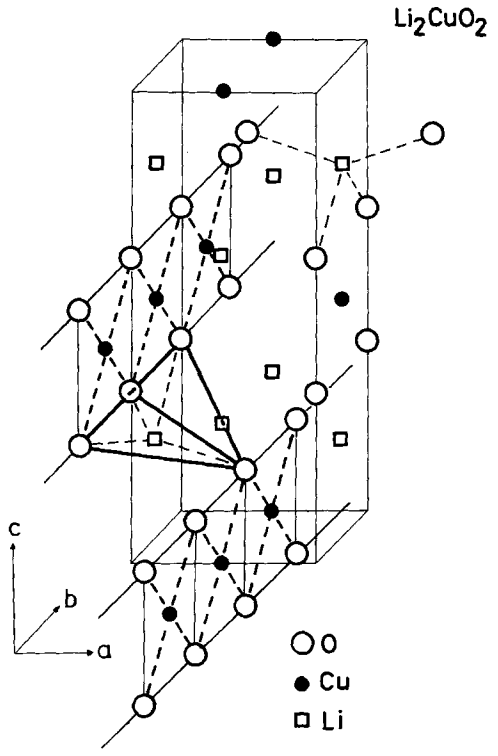

Fig. 5. Perspective representation of the arrangement of extended chains in Li_2CuO_2. The tetrahedral coordination of Li^+ is indicated [12].

tetrahedral oxygen coordination in spite of its relatively large dimensions, but the distortion of these tetrahedra and the stretching of the square-planar polyhedra around Pt^{2+} assume large values, so that the ideally right-angled O—Pt—O and Pt—O—Pt bonds are modified to 81 and 99°, respectively. Finally, the structural type Li_2CuO_2 includes a compound of formula Li_5AuO_4[5], which has the peculiarity that, statistically, part of the Li^+ occupies the metal positions in the stretched chains in common with Au^{3+} (cf. Fig. 5); the molecular formula Li_5AuO_4 should accordingly be altered to $Li_4(Li_{0.5}Au_{0.5})_2O_4$ or $Li_2(Li_{0.5}Au_{0.5})O_2$, whereby it becomes understandable also from the stoichiometry why the arrangement of the polyhedra is the same as in Li_2CuO_2.

However, the examples above do not exhaust the crystal chemistry of stretched chains of square-planar polyhedra. Figure 6 shows that, like Li_2CuO_2, the compounds $KCuO_2$, $RbCuO_2$, and $CsCuO_2$[10, 17, 18], as well as $RbAuO_2$[5] and probably $CsAuO_2$[5], also form stretched chains running parallel to one another, although these are not displaced in the lengthwise direction by half a polyhedron length. From these fine differences arise the trigonal-prismatic holes, emphasized in Figure 6, for K^+ (and Rb^+ and Cs^+, where relevant) which bind the stretched chains to one another. Clarification of the crystal structure by *Hoppe* and *Wasel-Nielen*[5] provided proof of the planar coordination of Cu^{3+} predicted by *Klemm*[10, 17] from magnetic measurements. Supplementing the structures shown in Figure 6, it is shown in Figure 7b that the parallel chains produced by crystallographic identity periods (*i.e.* without translation) can in the simplext case yield cubic polyhedra for large metal ions; this spatial arrangement of parallel stretched chains of polyhedra has been observed in $KAuO_2$[5]. If the right-angled $[AuO_2]_n^-$ chains arranged parallel to one another are distorted triclinically, there then results the cross-linking through octahedra observed with $NaCuO_2$[10, 19] (Fig. 7a). In addition to the findings reproduced in Figures 6 and 7, investigation of the crystal structure of K_2PdO_2[20, 21] shows that in parallel chains (cf. Fig. 22), and despite the same translation of the chains as in Li_2CuO_2 (cf. Fig. 5), not only tetrahedral but also prismatic holes for the linking alkali metal ions are produced.

The structural principles illustrated in Figures 6 and 7 give a substantially complete picture of isolated chains of edge-linked planar structural units. It remains to be shown that stretched chains of square-planar polyhedra arranged in parallel can, by chain cross-linking, afford all the coordination polyhedra of simple structure (tetrahedra, octahedra, trigonal prisms, and cubes) (a) on arrangement in crystallographically

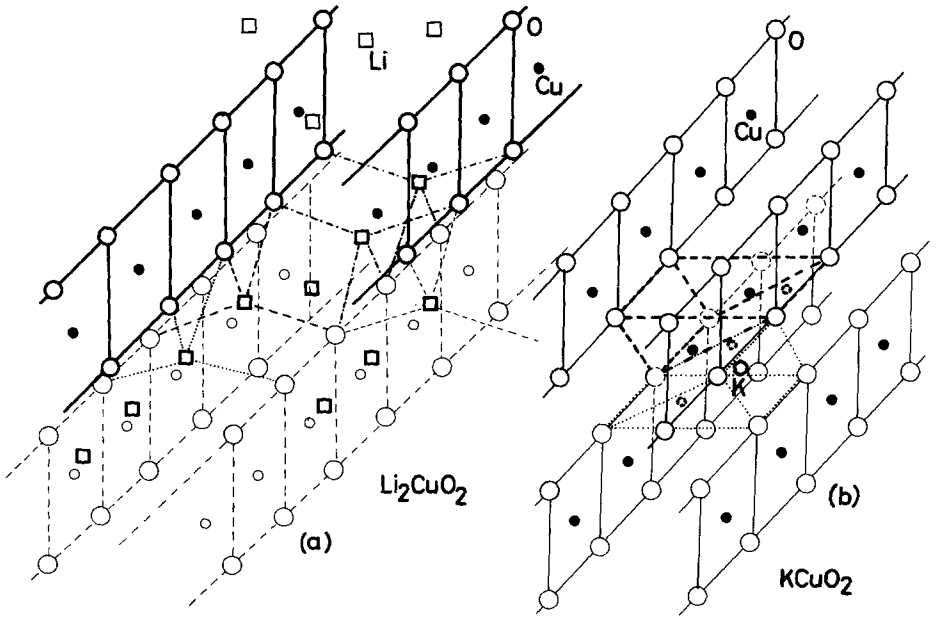

Fig. 6. Perspective representation of extended edge-linked chains in Li_2CuO_2 (a) with tetrahedral and in $KCuO_2$ (b) with trigonal-prismatic cross-linking [12, 18].

identical positions, and (b) by two-dimensional and (c) three-dimensional translation.

After the isolated stretched chains we turn to the zigzag chains of edge-linked square-planar polyhedra (Fig. 4b). Two isotypic compounds $SrCu_{0.75}Ni_{0.25}O_2$[22] and $SrCuO_2$[23] containing isolated zigzag chains have been known for some years. Figure 8 shows that every two rows of trigonal prisms (shaded triangles) of O^{2-} around Sr^{2+}, if linked in the long dimension, produce zigzag chains in the solid crystal structure. For a long time it seemed impossible to replace the Cu^{2+} in $SrCuO_2$ totally by Ni^{2+}, but recently we were able to prepare $SrNiO_2$ single crystals by a high-temperature/high-pressure technique (CO_2 laser, O_2 autoclave)[24], and this again confirmed the structure of $SrCuO_2$.

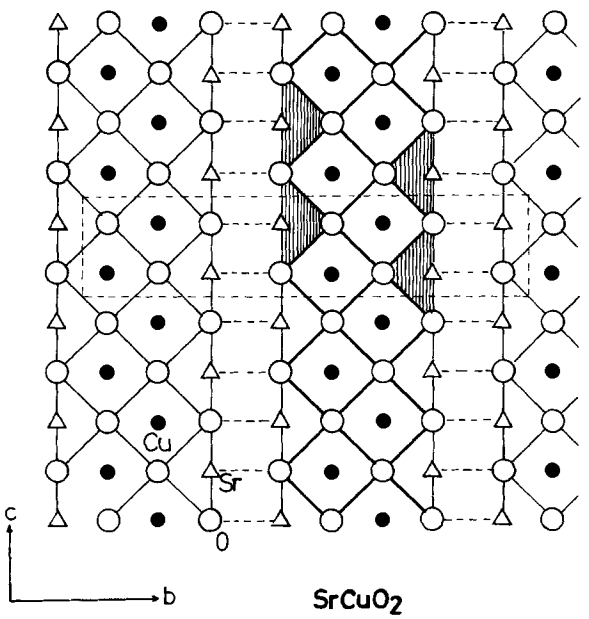

Fig. 8. Projective atomic distribution along [100] for $SrCuO_2$. The hatched surfaces are the view onto the triangular surfaces of trigonal prisms. One of the isolated square-planar zigzag chains is emphasized [22].

2.2.2. Formation of Two-Dimensional Planar Networks

The edge-linked patterns of Figures 4c and 4d are still hypothetical and until recently this was also true of the planar network formation of structural units $[Cu_3O_4]_n^{4-}$ (Figs. 4e and 4f). Recently we succeeded in preparing and determining the crystal structure of the chlorooxocuprate $Ba_2Cu_3O_4Cl_2$[25] and of the compounds $Sr_2Cu_3O_4Cl_2$[26], $Ba_2Cu_3O_4Br_2$[27, 28], and $Sr_2Cu_3O_4Br_2$[29] isotypic with it; this, surprisingly, gave the structural pattern shown in Figure 4e which was formulated previously by *Teske*[31]. Only half of the Cu^{2+} in these halooxocuprates is square-planar-coordinated; the other half of the square Cu/O polyhedra still present is supplemented by halogen to yield greatly tetragonally elongated octahedra. It should, however, be noted that all the oxygen in the four above-named compounds $M_2Cu_3O_4X_2$ belongs to the coordination sphere of the Cu^{2+}, an arrangement that justifies assigning these compounds to the edge-linked, two-dimensionally planar-coordinated oxo compounds (cf. Fig. 9). From the perspective representation in Figure 9 it can be seen that each Ba^{2+} is coordinated to four O^{2-} ions of a square (not occupied by Cu) in the $[Cu_3O_4]_n^{2-}$ pattern and also to four halide ions, thus forming a square antiprism. This halogen-barium configuration is also the reason why only the network scheme 4e is realizable for a $[Cu_3O_4]_n^{2-}$ group and not the other mode of linkage shown in Figure 4f[27]. The principle of alternating supplementation of square-planar Cu/O polyhedra by halide ions to give elongated octahedra is indicated separately in Figure 9 as a projection on the *a/b* plane; it can be seen that the regular pattern of square-planar structural groups is overlaid by a specific succession of octahedrally supplemented polyhedra corresponding exactly to those in $Sr_2CuO_2Cl_2$[32, 33], $Ca_2CuO_2Cl_2$[30, 33], $Sr_2CuO_2Br_2$[34], and $Ca_2CuO_2Br_2$[30]. Since these compounds for their part fall almost into the K_2NiF_4 type, there is also a loose relationship between the compounds $M_2Cu_3O_4X_2$ and the K_2NiF_4 type.

Figure 10 shows the typical great elongation at the apices of the octahedra in the structural types $M_2CuO_2X_2$ and $M_2Cu_3O_4X_2$ (M = Sr, Ba; X = Cl, Br), while the square-planar

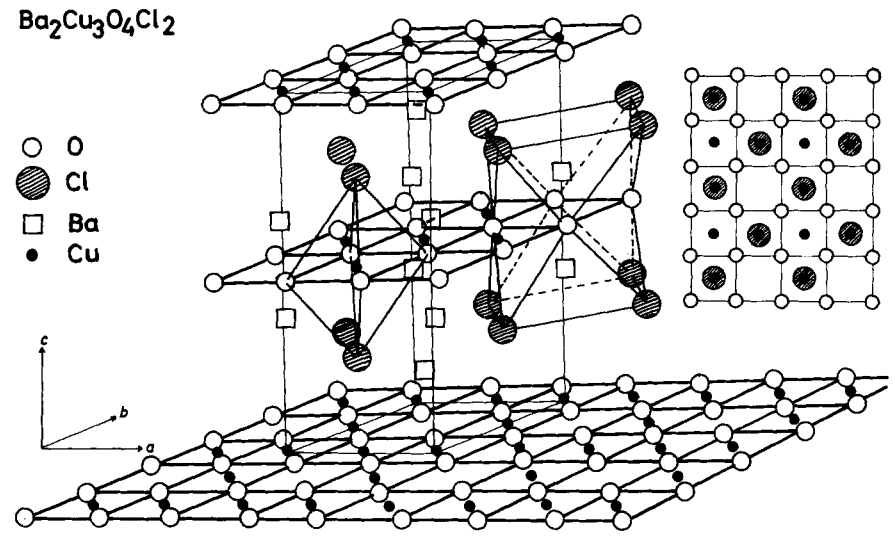

Fig. 9. Perspective representation of the atomic distribution in $Ba_2Cu_3O_4Cl_2$. The planar two-dimensional structure pattern, a planar polyhedron supplemented by Cl^- to afford an octahedron, and the coordination of Ba^{2+} are emphasized. The scheme for a series of alternating squares and octahedra is reproduced in projection on the right [25].

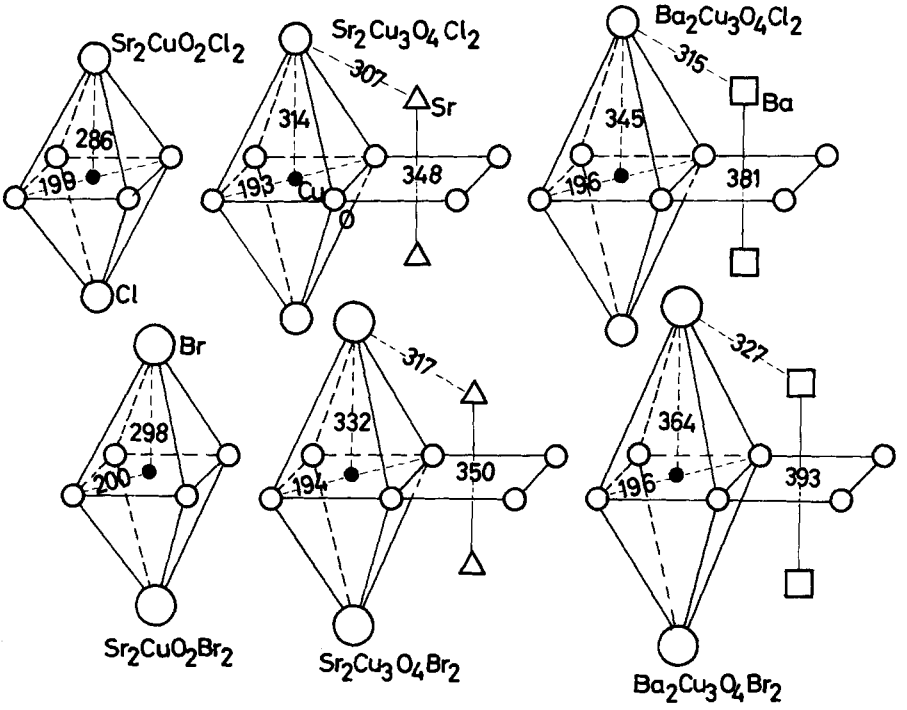

Fig. 10. Octahedral coordination polyhedra completed by halogen in the compounds $M_2CuO_2X_2$ and $M_2Cu_3O_4X_2$ (M = Sr, Ba, (Ca); X = Cl, Br). The distances are given in pm units [25—30, 32, 33].

Cu/O coordination remains almost constant. From the geometric relation in the crystal structure between metal ions (M—M) on the one hand and the experimentally determined separations d(Sr—Cl(Br)) and d(Ba—Cl(Br)) (cf. Fig. 10) on the other, it can be deduced that in the compounds $M_2Cu_3O_4X_2$ the large tetragonal distortion of the $[CuO_4X_2]$ octahedra cannot be explained by means of the Jahn-Teller effect alone; determining influence attaches rather to the relative atomic distances typical of the crystal structure, a feature that is discussed further for compounds $M_2CuO_2X_2$ in Section 2.3.2.

2.3. Infinite Linkages of Square-Planar Polyhedra with Exclusive Corner Linkage

2.3.1. One-Dimensional Infinite Chains

Figure 11 shows examples of edge-linking of square-planar structural groups. The simplest case in this type of linkage is the isolated one dimensional infinite chain (Fig. 11 a) which is present in the compounds Sr_2CuO_3[35], Ca_2CuO_3[36], and Sr_2PdO_3[37]. This rare form of a linear arrangement of isolated planar polyhedra, hitherto restricted to one crystal struc-

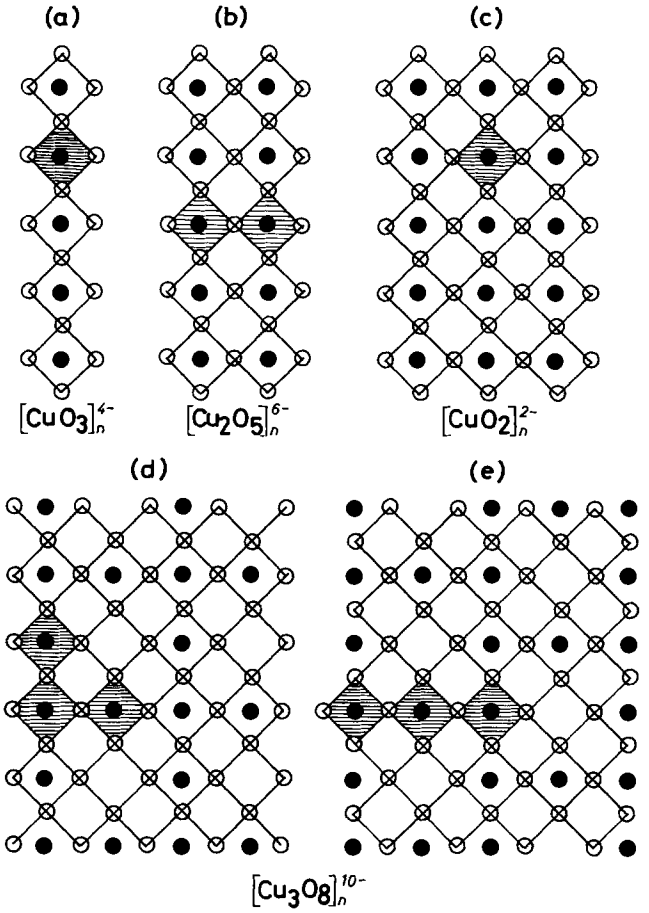

Fig. 11. Model illustrations of two-dimensional edge-linking of square-planar polyhedra (formulated for Cu^{2+}).

ture, is produced in the last-designated compounds by means of an Sr/O or Ca/O framework. Figure 12 shows in projection and perspective that the isolated corner-linked $[CuO_3]_n^{4-}$ chains span the triangular faces of trigonal prisms linked at every long edge.

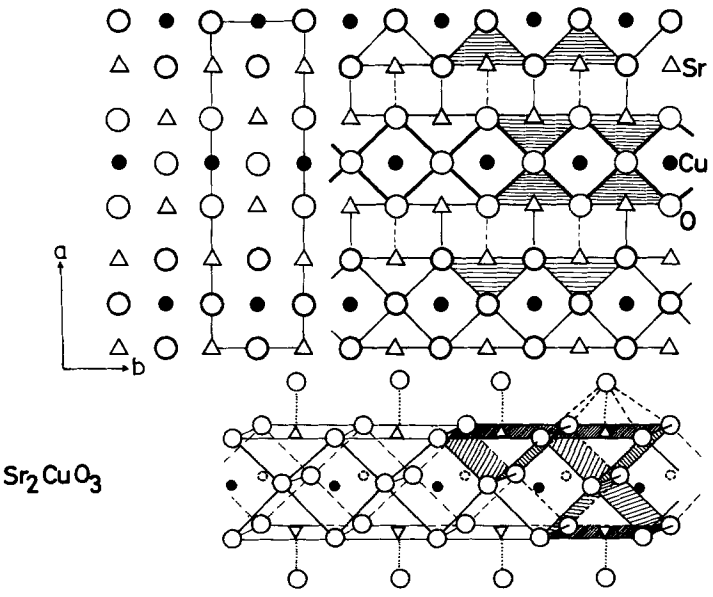

Fig. 12. Projective and perspective representation of the arrangement of polyhedra in Sr_2CuO_3. The hatched surfaces characterize trigonal prisms around Sr^{2+}; the isolated, extended, corner-linked, chain of planar $[CuO_3]^{4-}$ polyhedra is emphasized [35, 36].

In Sr_2CuO_3[35] each Cu/O polyhedron is exactly square and planar; in Ca_2CuO_3[36], because of the different atomic separations d(Cu—O) = 189 pm (2×) and 196 pm (2×), the polyhedra are merely planar. Finally, by a single-crystal X-ray structure study of Sr_2PdO_3[38] it was shown that, owing to the lowering of symmetry, even the central position of the Pd^{2+} in the planar polyhedron can be lost.

2.3.2. Two-Dimensional Planar Network Formation

The planar structural pattern of Figure 11 c has only recently been recognized, although many compounds with this polyhedral network have long been known. Thus, on the basis of X-ray powder diffraction all compounds of the chemical composition RE_2CuO_4 (RE = Pr^{3+}, Nd^{3+}, Sm^{3+}, Eu^{3+}, Gd^{3+}) were erroneously assigned to the K_2NiF_4 type[39–42], until *Müller-Buschbaum* and *Wollschläger*[43] proved on Nd_2CuO_4 single crystals that the Cu^{2+} in these is square-planar-coordinated and not octahedrally as in the K_2NiF_4 type. This surprising finding was later confirmed by an X-ray study of single crystals of Sm_2CuO_4[44], Gd_2CuO_4[45], and Eu_2CuO_4[46], which showed that octahedral coordination of the Cu^{2+} (K_2NiF_4 type) must also be rejected for these compounds.

Figure 13 shows the characteristic structure of Nd_2CuO_4. Comparison with the previously assumed K_2NiF_4 type[43] shows that the position of only one oxygen atom in this crystal structure needs to be altered, as a result of which Cu^{2+} is still only square-planar coordinated by O^{2-}. For the large cation (here Nd^{3+}) the trigonal-prismatic environment changes to cubic. Four of the eight neighbors of Nd^{3+} do not belong to the Cu^{2+} coordination sphere, and this explains why a stoichiometric composition such as Nd_2CuO_4 can nevertheless contain $[CuO_2]^{2-}$ groups. Nd_2CuO_4 was the first oxometallate in which it was observed that square-planar anionic structural units $[CuO_2]^{2-}$ are cross-linked not by ions but by cationic structural groups $[Nd_2O_2]^{2+}$. Figure 13 also shows that rejection of the K_2NiF_4 type is not valid for all rare earth metal oxocuprates: thus, La_2CuO_4[45] is the only compound in this series that contains not planar- but octahedrally-coordinated Cu^{2+}. This compound is thus not an oxometallate with planar structural units, but it must be mentioned here that it is the only compound containing Cu^{2+} undoubtedly in anionic structural units in spite of the octahedral coordination. Thus, the structure of La_2CuO_4 contradicts the thesis formulated in Section 2.1 above, namely that Cu^{2+} as a component of anionic structural groups is always square-planar-coordinated. Although this is so far the only exception, it is difficult to understand under what circumstances Cu^{2+} is planar- or non-planar-coordinated in oxometallates.

Compounds $M_2CuO_2X_2$ (M = Ca, Sr; X = Cl, Br) require discussion in connection with our consideration of oxocuprates that may be of the Nd_2CuO_4 or the K_2NiF_4 crystal-structure type. If one neglects the orthorhombic distortion of the crystal symmetry and the concomitant displacement (recognizable in Fig. 13) of the octahedron base in La_2CuO_4, the arrangement of octahedra and prisms is the same in La_2CuO_4 as in $M_2CuO_2X_2$. This makes it possible to discuss the experimentally observed large tetragonal elongation of the Cu/O octahedra. Figure 14 shows, for compounds of the type $M_2CuO_2X_2$

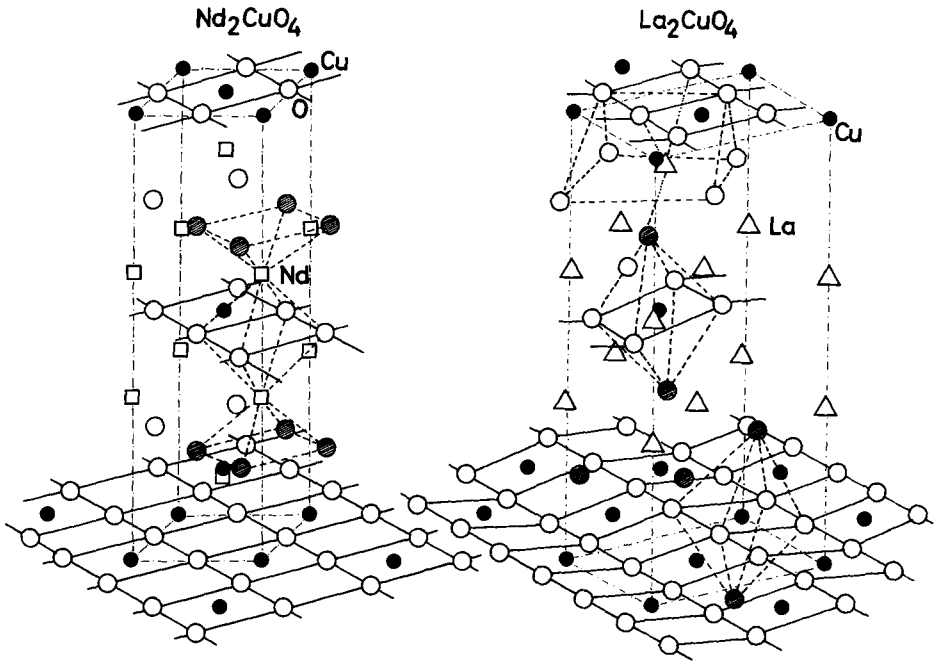

Fig. 13. Perspective representation of the two-dimensional linking of planar Cu/O polyhedra in Nd_2CuO_4, and the octahedral coordination (differing from it) of Cu^{2+} in La_2CuO_4 [43, 45].

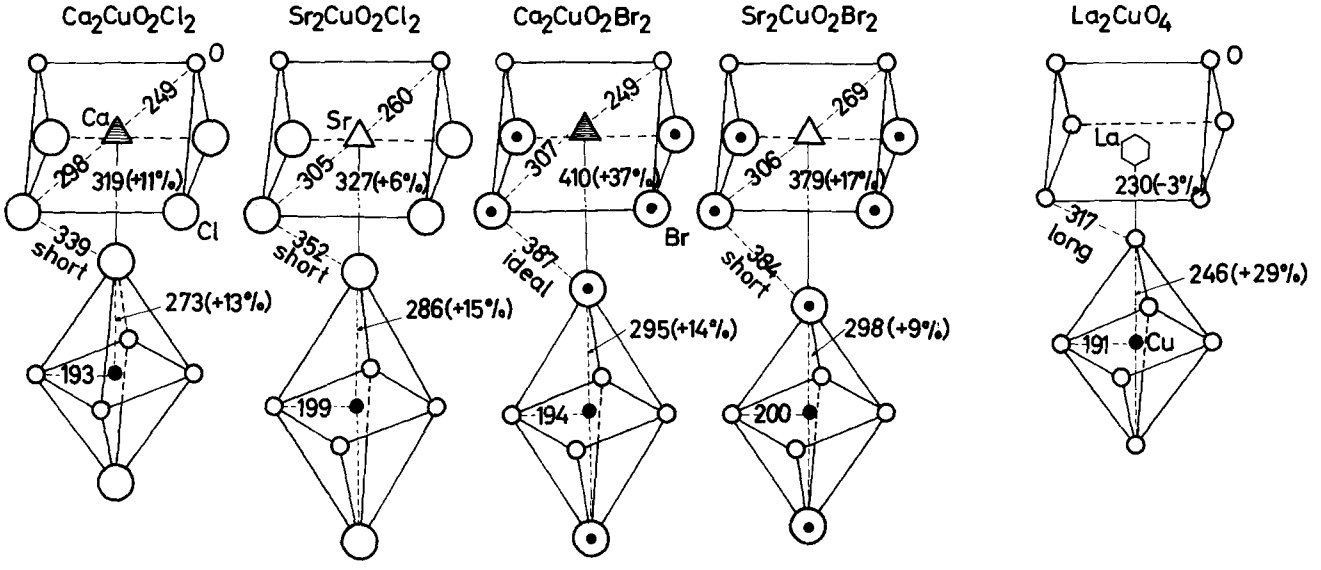

Fig. 14. Coordination polyhedra around Cu^{2+}, Ca^{2+}, and Sr^{2+} and their linkage in compounds of the type $M_2CuO_2X_2$ (M = Ca, Sr; X = Cl, Br). The analogous arrangement in La_2CuO_4 is added for comparison. The distances are in pm units [30, 32, 34, 35].

and for La_2CuO_4, the mode of linkage and the distance relationships between an octahedron around Cu^{2+} and the prismatic coordination of Ca^{2+}, Sr^{2+}, and La^{3+}. It can be seen that the distance between the Cu^{2+} and the peak or foot of the octahedron in halooxocuprates is about 14%, and in La_2CuO_4 about 29%, greater than the sum of the radii of the ions taking part in the bonding. In spite of the relatively short halogen-halogen separation (cf. Fig. 14), the Ca^{2+}/Sr^{2+}-halogen bonds in compounds of the type $M_2CuO_2X_2$ are in some cases considerably too long, so that undoubtedly a superposition of structural geometric effects falsifies the tetragonal Jahn-Teller distortion of the CuO_4X_2 octahedron or places it in doubt. The comparable distances in La_2CuO_4 are considerably different. Figure 14 shows that, in spite of the short separation $d(La^{3+}—O^{2-}) = 230$ pm in the direction of octahedral elongation, the apices of the CuO_6 octahedron are unusually greatly elongated which unequivocally indicates a Jahn-Teller effect at the Cu^{2+} ion. A recently concluded study of La_2NiO_4[34] confirms the assumption made here: since Ni^{2+} with the d^8 configuration does not undergo Jahn-Teller distortion, the octahedral elongation of about 18% observed for La_2NiO_4 is an effect due to the crystal structure; the higher degree of octahedral distortion in La_2CuO_4 must thus be considered as a Jahn-Teller-active contribution.

Each new structural type of planar-coordinated oxometallate raises the question as to which of the known structural principles nature has used in the formation of the compound. For substances with the formula $M_2CuO_2X_2$ (M = Ca, Sr;

X=Cl, Br) and for La_2CuO_4 this is the K_2NiF_4 type. For compounds of the general formula $M_2Cu_3O_4X_2$ (M=Sr, Ba; X=Cl, Br) (cf. Section 2.2.2) some influence of the K_2NiF_4 structural principles could also be detected. We shall now show that the structure types of Nd_2CuO_4, Sr_2CuO_3, and $SrCuO_2$ are simple variations of the K_2NiF_4 type. The original papers should be consulted for more complete understanding.

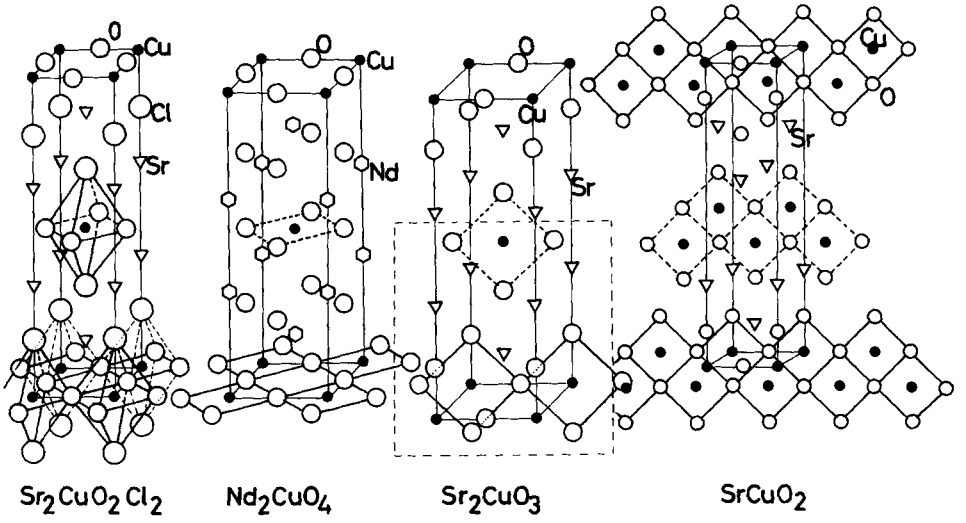

Fig. 15. Perspective representation of the relationships of the K_2NiF_4 structural type (exemplified by $Sr_2CuO_2Cl_2$) to Nd_2CuO_4, Sr_2CuO_3, and $SrCuO_2$ [24, 32, 43].

Figure 15 summarizes the results, and for comparison the distorted K_2NiF_4 type of $Sr_2CuO_2Cl_2$ is presented. If now, as explained previously, each position that forms a peak or foot of the octahedron on the *c*-axis is moved sideways, then one obtains around the Cu^{2+} the planar configuration shown in Figure 11c which is characteristic of the Nd_2CuO_4 type. If instead, starting again from the K_2NiF_4 type, an oxygen atom is formally removed from within the *a/a* plane, then the octahedral coordination again changes to square-planar around the Cu^{2+}, as is found in Sr_2CuO_3. That means that the structural type of Sr_2CuO_3 with its characteristic extended chain (cf. Fig. 11a) can be derived in a very simply way from the K_2NiF_4 type. Finally, the $SrCuO_2$ type can also be derived very simply from the Sr_2CuO_3 type by choosing a suitable section (Fig. 15, the broken line in Sr_2CuO_3)[24]. For this purpose the structural unit denoted by the broken line in Figure 15 is rotated through 180°, placed on an identical unit, and translated by *a*/2; the result is the isolated, edge-linked zigzag chain of Figure 4b. These examples show that the oxometallates with planar coordination polyhedra of known structure types can be referred back to three-dimensional coordination.

2.4. Two-Dimensional Infinite Linking of Square-Planar Polyhedra with Mixed Corner- and Edge-Linking

Figure 16 shows three designs for mixed corner- and edge-linking, the first of which, containing $[Cu_2O_3]^{2-}$ groups, has been observed in $CaCu_2O_3$[47] and $MgCu_2O_3$[48]. These oxocuprates form a two-dimensional infinite Cu/O network (cf. Fig. 17) which already is markedly wavy in the *a/b* plane (section perpendicular to Fig. 17)[47]. Thus, not only are the two compounds examples of the structural pattern in Figure 16, but also, because of the marked waviness of this $[Cu_2O_3]^{2-}_n$ network, they lie at the boundary of planar-coordinated oxometallates showing a spatial arrangement of planar polyhedra. Since, moreover, both compounds allow the octahedron peak and foot to be recognized, with graduated differences for Cu^{2+}, they also form a transition to the oxocuprates that

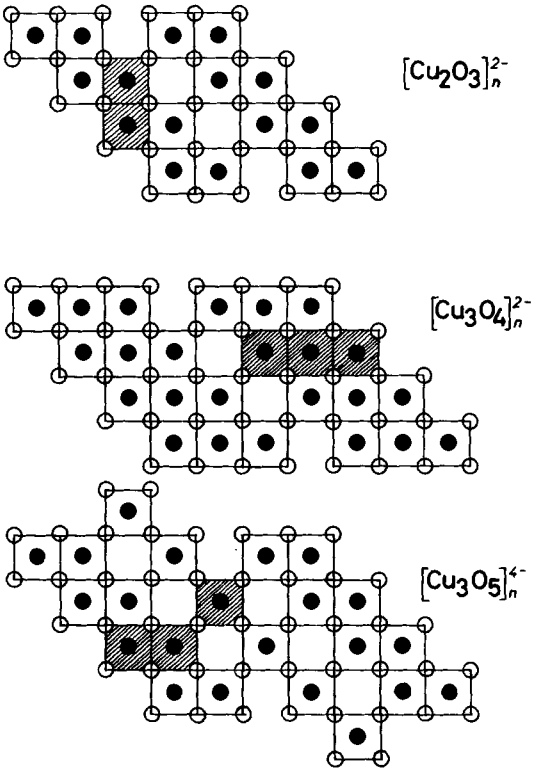

Fig. 16. Model representations of two-dimensional mixed edge and corner linkage of square-planar polyhedra (formulated for Cu^{2+}).

no longer contain planar-coordinated Cu^{2+}. Figure 18 shows that in $CaCu_2O_3$ the Cu—O separations are widely different in the planar base and in the peak or foot of the octahedron, whereas in $MgCu_2O_3$ they are so similar that the octahedral

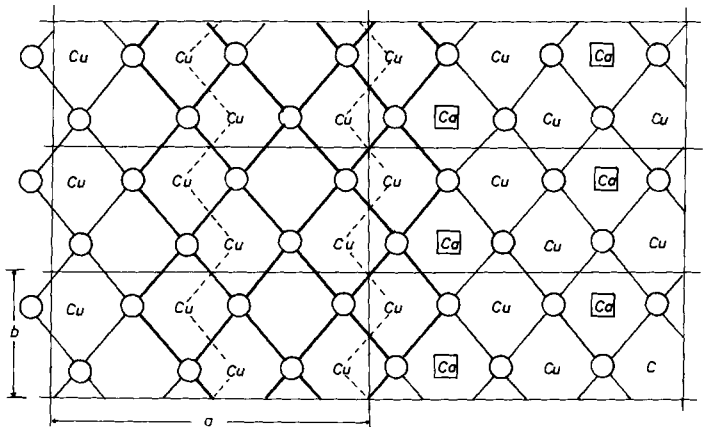

Fig. 17. Projective representation of flat, two-dimensional, endless linking of zigzag chains of square-planar polyhedra in $CaCu_2O_3$ [47].

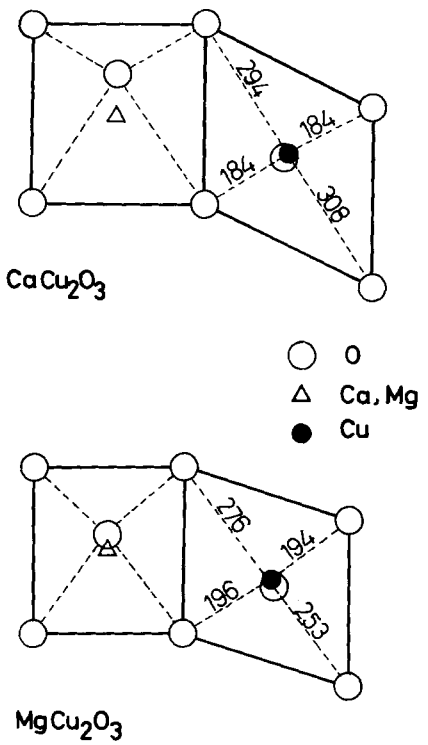

Fig. 18. Characteristic coordination polyhedra around Cu^{2+} and Ca^{2+} or Mg^{2+} in $CaCu_2O_3$ or $MgCu_2O_3$. The distances are given in pm units [48].

coordination of Cu^{2+} is evident. The harmonious transition recognizable in both compounds, from purely planar- to octahedral-coordinated Cu^{2+}, is a very good example of the change in the role of the copper from a component in anionic structural units to the function of a Cu^{2+} cation. Between the limiting states of 1) Cu^{2+} as component of anionic structural groups and 2) Cu^{2+} as cation there lies the intermediate region of mixed oxides, to which $MgCu_2O_3$ can be assigned with perhaps some justification; this supports *Zemann*'s view[49] that $MgCu_2O_3$ can be regarded as an NaCl variant in which half of the octahedra are distorted.

3. Oxometallates with Square-Planar Structural Groups in Three-Dimensional Linkage

Since systematics similar to those for the one- and two-dimensionally linked square-planar structural groups cannot at present be formulated for the three-dimensional case, this group of compounds will be arranged according to increasing degree of linkage. The Section ends with a discussion of compounds with isolated, three-dimensionally linked polyhedra.

The transition from one- and two-dimensional frameworks built up from planar polyhedra to three-dimensional linkage is not sharp but fluid. Similarly to $CaCu_2O_3$[47], in which an indication of the third dimension can be recognized in the waviness of its planar $[Cu_2O_3]_n^{2-}$ framework, the oxonicolate $BaNiO_2$ contains angled chains of the $[NiO_2]_n^{2-}$ type. This structure was clarified by *Lander*[50, 51], although it is still disputed[52–55]. The arrangement of the square-planar polyhedra in the compound $Ba_3Cu_2O_4Cl_2$ was shown in a recent study[56] to be definitely three-dimensional. Figure 19 demonstrates how an elongated, edge-linked chain, angled at nearly 90° runs through the crystal structure. In this chain, almost as in $Ba_2Cu_3O_4Cl_2$[25], every other planar polyhedron is supplemented on one side by halogen; the literature[56] should be consulted for a discussion of the Cu—Cl distance and the arrangement of the three different coordination polyhedra around the Ba^{2+}, not readily recognizable in Figure 19, which are necessary to link these isolated angled chains.

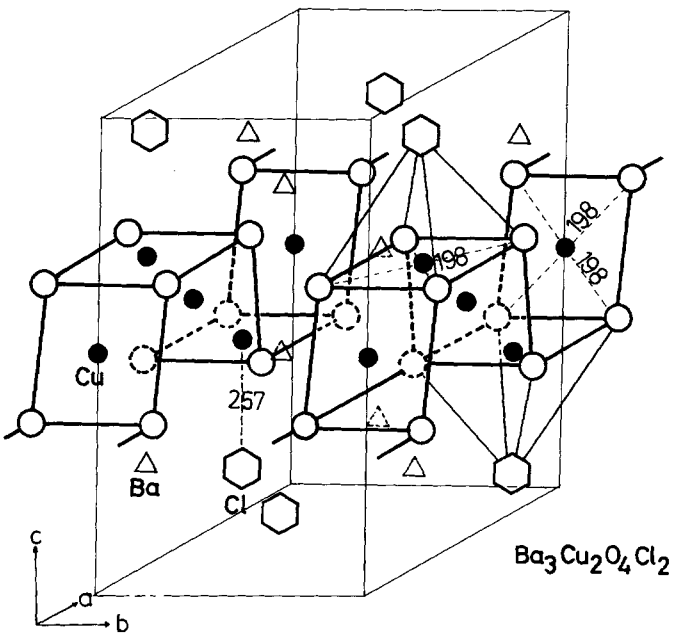

Fig. 19. Perspective representation of the angular edge-linked Cu/O chains in $Ba_3Cu_2O_4Cl_2$ [56].

As a special case, and therefore not mentioned in the Introduction, a (2+2)-coordination around Tl^{3+} in the compound $Sr_4Tl_2O_7$[57] contributes to the three-dimensional linkage of planar polyhedra. Although the different atomic separations d(Tl—O) = 208 pm (2×) and 250 pm (2×) previously led the discussion toward a strongly distorted (2+2)-coordination such as is recognizable in mercury compounds[57], here the planar character of the Tl/O polyhedra serves to include this compound in the discussion of planar-coordinated ions. $Sr_4Tl_2O_7$ is so far the only example of the perpendicular arrangement of linear, crossing, corner-linked chains shown in Figure 20. Owing to the crossing there appears a quasicyclic linkage of perpendicular planar polyhedra. The "rings" are

composed of $[Tl_2O_7]^{8-}$ structural units angled to about 90° to one another.

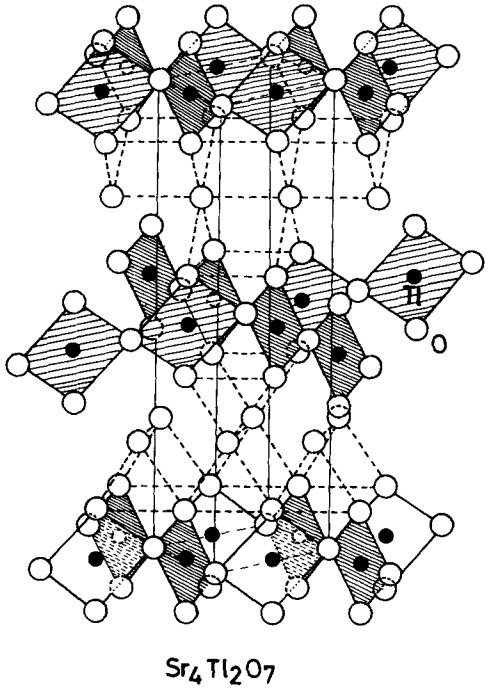

Fig. 20. Perspective representation of the quasi-square-planar (2+2)-Tl/O coordination in $Sr_4Tl_2O_7$. For the sake of clarity the positions of Sr^{2+} are not indicated; they lie within the hatched trigonal prisms [57].

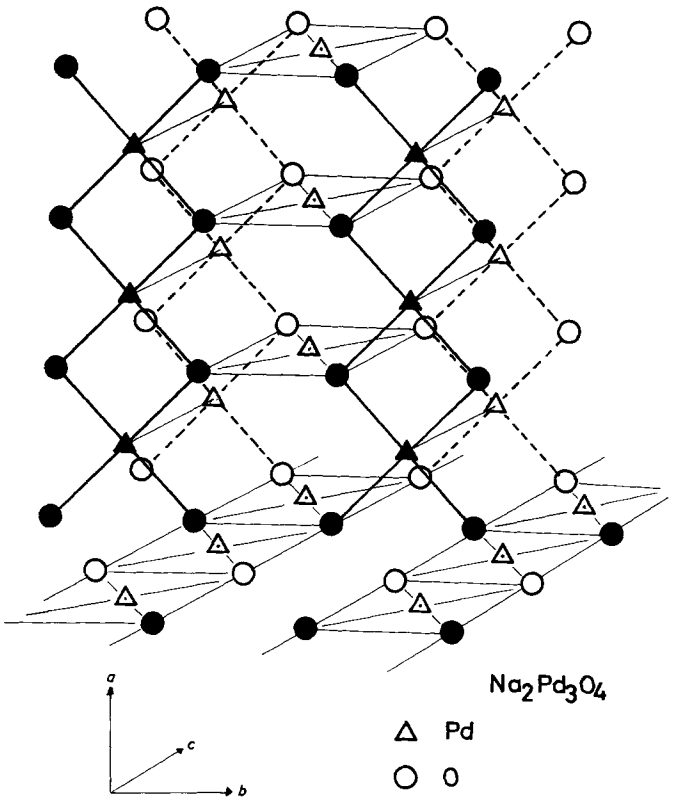

Fig. 21. Perspective representation of part of the linking of polyhedra in $Na_2Pd_3O_4$. The characteristic arrangement of linear extended edge-linked chains and their three-dimensional linkage by isolated square-planar polyhedra is shown [58].

An interesting kind of three-dimensional linkage of square-planar polyhedra was found by *Hoppe* and *Wilhelm*[58] in the compound $Na_2Pd_3O_4$. Figure 21 shows that in $Na_2Pd_3O_4$ elongated parallel chains, such as have been described for $KAuO_2$ (cf. Section 2.2.1), are cross-linked by individual square polyhedra around Pd^{2+}. In this compound we find a coexistence of linear chains and quasi-isolated single polyhedra that are not, as could be inferred from Figure 21, linked together unidimensionally and *ad infinitum* along [001]. Viewed in this way, there is a remarkable parallel between the three-dimensional linkage in $Na_2Pd_3O_4$ on the one hand and in $KCuO_2$ and K_2PdO_2 on the other. These three compounds have in common a combination of extended edge-linked chains with trigonal prisms around the alkali metal ion. Figure 22 shows the way in which trigonal prisms can

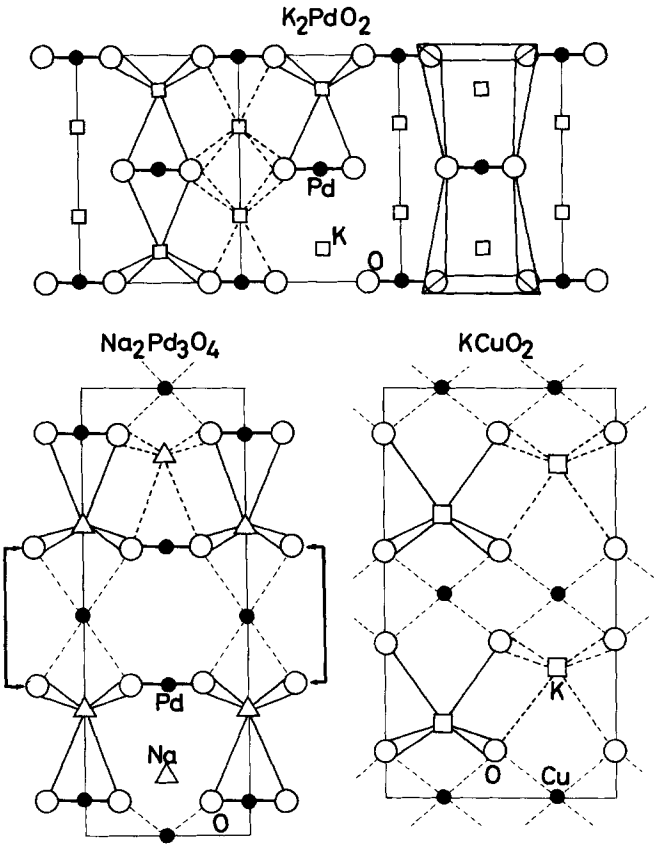

Fig. 22. Projective representation of the cross-linking of extended chains of planar polyhedra by trigonal-prismatic structural units in K_2PdO_2, $Na_2Pd_3O_4$ and $KCuO_2$ [21, 58, 18].

link parallel chains. K_2PdO_2 and $Na_2Pd_2O_4$ differ from $KCuO_2$ only in the orientation of the chain with identical arrangement of the prisms, this being due to the square structural units within the chains. On this basis it is easy to derive, for example, the structure of $Na_2Pd_3O_4$ from that of K_2PdO_2: if the cross-linking by isolated squares is removed from $Na_2Pd_3O_4$ (bracket in Fig. 22), then formally "Pd_2O_2" is removed from the formula unit $Na_2Pd_3O_4$ and together with the new chemical composition Na_2PdO_2 one obtains the polyhedral arrangement of K_2PdO_2. $KCuO_2$ contains a chain whose course is twisted by about 90° from that in K_2PdO_2 (cf. Fig. 22); in this case there is no sign of extension toward three-dimensional linkage.

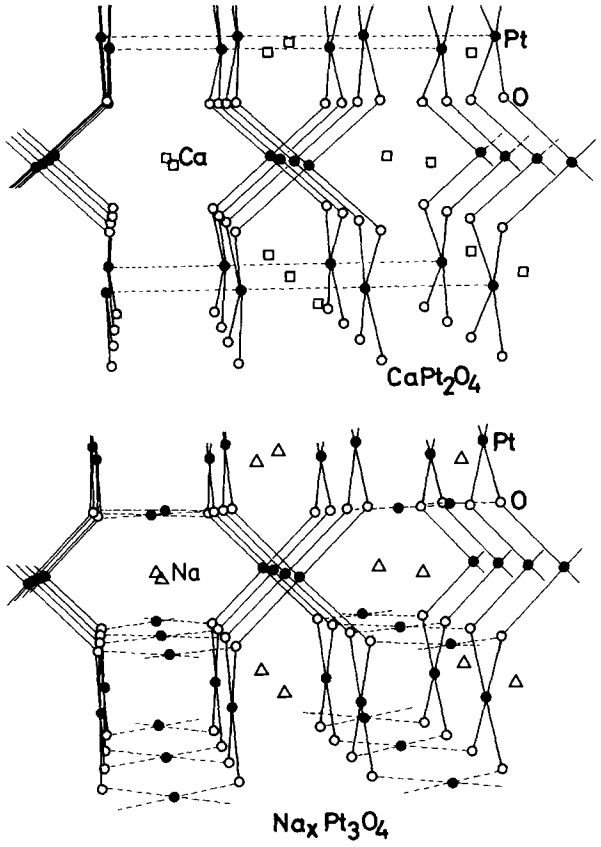

Fig. 23. Perspective representation of the three-dimensional linking of polyhedra in $CaPt_2O_4$ and $Na_xPt_3O_4$. Only the framework structure of square-planar polyhedra is shown [59].

The compound $CaPt_2O_4$[59] can be regarded as the precursor of a perfect three-dimensionally linked framework composed of individual square-planar polyhedra, such as were found in the interesting platinum bronzes of type $Na_xPt_3O_4$[60, 64]. A series of compounds such as $NaPd_3O_4$[61], $CaPd_3O_4$[62], $SrPd_3O_4$[66], $CdPd_3O_4$[63], $CdPt_3O_4$[59], $Cd_{0.3}Pt_3O_4$[59], $Ni_xPt_3O_4$[65], and $Pt_{0.4}Pt_3O_4$[68] is isotypic with $Na_xPt_3O_4$. Figure 23 shows the structure of $CaPt_2O_4$ and $Na_xPt_3O_4$. The high electrical conductivity due to the structure of the bronzes and the ability of the $[Pt_3O_4]$ framework to incorporate cations in widely varying amounts into the cubic holes are worth noting. In each case the partially tetravalent character of the platinum in Pt_3O_4 is changed to Pt^{2+}, a consideration that permits exclusively the oxidation state Pt^{2+} to be assigned to the $[Pt_3O_4]_n^{2-}$ framework in $Pt_{0.4}Pt_3O_4$[68].

Some very recently discovered oxocuprates and halooxocuprates contain limited areas of three-dimensional structural groups. Their peculiarity lies in the fact that these isolated structural groups are themselves constructed of square-planar coordinated Cu^{2+}. A characteristic example is provided by the compound $Ba_9Cu_7O_{15}Cl_2$[67] with a wealth of unusual coordinations. To provide a clearer picture, the interesting arrangements of polyhedra for Ba^{2+} and for the planar coordinated Cu^{2+} have been picked out in Figure 24 from the complicated over-all structure of this compound. A cyclic closed structural group $[Cu_6O_{12}]^{12-}$ can be recognized, which is constructed of planar polyhedra. Still more remarkable is the particle marked Cu_I in Figure 24: it has biplanar 12-fold coordination. This arrangement is reminiscent of the sandwich structures in molecular and complex chemistry. The Ba^{2+} occurs with 6-fold coordination to oxygen, supplemented by two Cl^-, in a previously unknown coordination polyhedron.

At present the most remarkable compound in the series of alkaline earth metal oxocuprates(II) is $BaCuO_2$[69]. Although the simple chemical composition does not lead us to expect anything unusual, this compound has no relation at all to the previously known $SrCuO_2$. In a large unit cell there are in all 90 $BaCuO_2$ formula units, so arranged that along the diagonal of the cubic space six-membered rings are formed from square-planar Cu/O polyhedra. These isolated structural units have been discussed in more detail above for $Ba_9Cu_7O_{15}Cl_2$ (Fig. 24). $BaCuO_2$ also has a 26-gon, formally constructed from Cu/O squares; the 26-gon is emphasized in Figure 25 as an important structural characteristic. This 26-gon occupies positions (000) and (1/2 1/2 1/2) and is linked by a complicated polyhedral framework around Ba^{2+}.

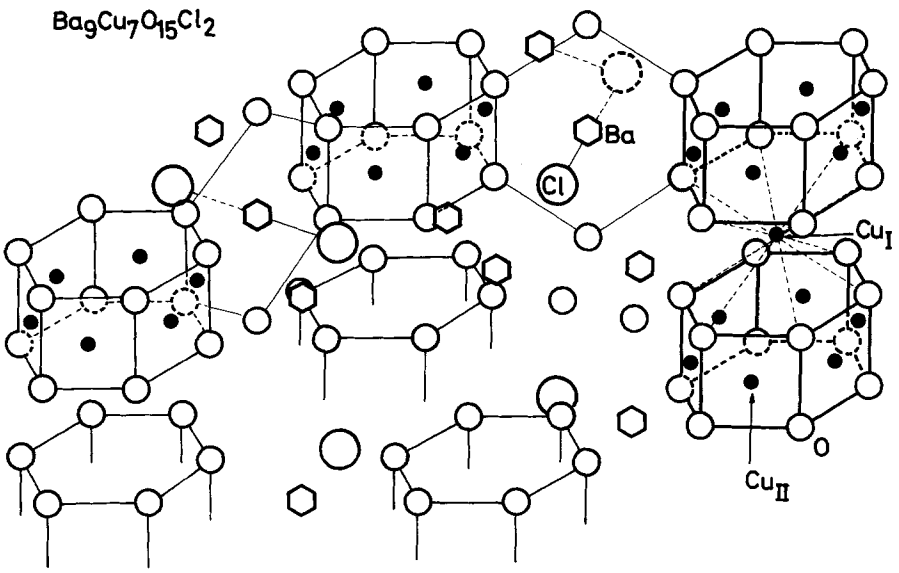

Fig. 24. Perspective representation of part of the linking of polyhedra in $Ba_9Cu_7O_{15}Cl_2$. The six-membered rings of square-planar polyhedra around position Cu_{II}, the biplanar 12-fold coordination around position Cu_I, and the (6+2)-coordination of O^{2-} and Cl^- (novel for Ba^{2+}) are emphasized [67].

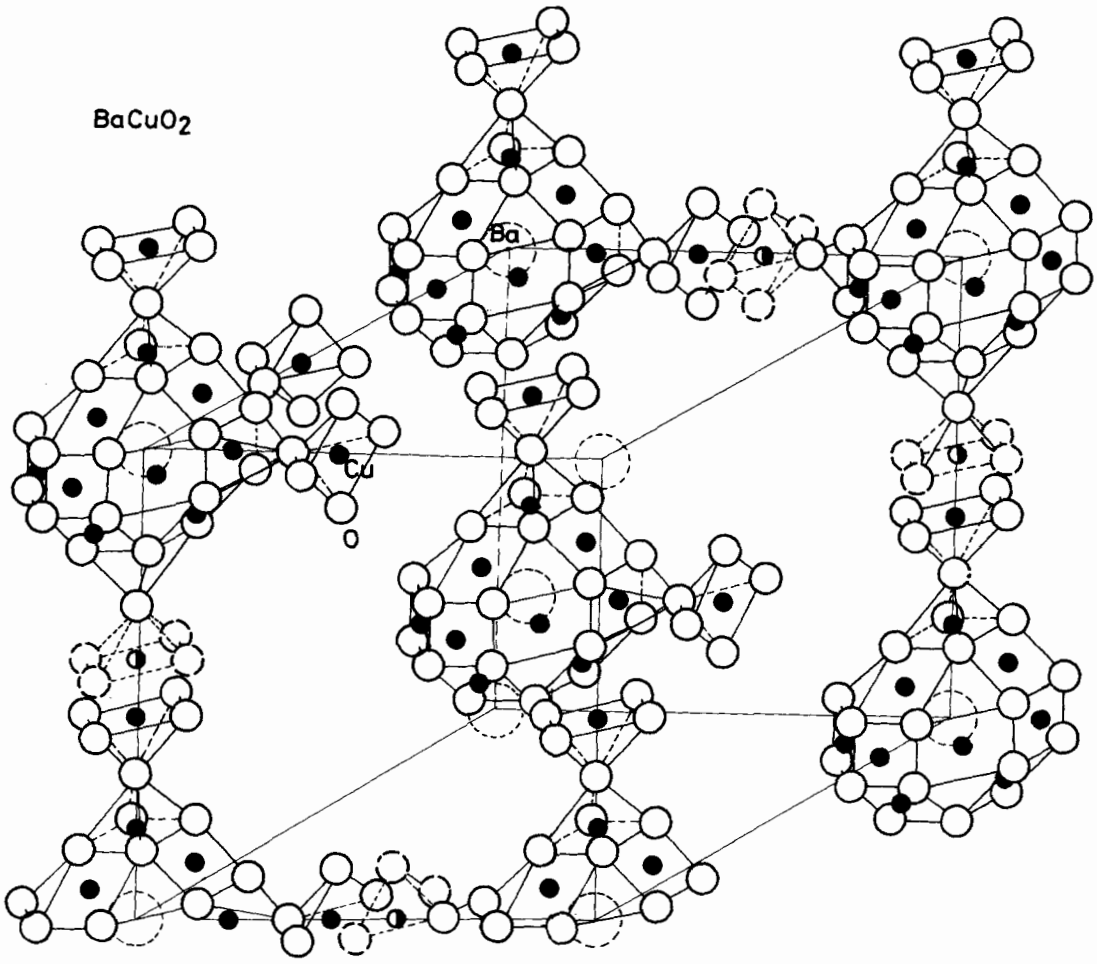

Fig. 25. Perspective representation of the 26-gon constructed from planar Cu/O polyhedra in $BaCuO_2$. Occupation of this quasispherical hollow body by Ba^{2+} is emphasized. Tetragonal pyramids around Cu^{2+} represented only by dotted lines denote a random distribution [69, 70].

The center of the 26-gon is $BaCuO_2$ is occupied by Ba^{2+}, which has the coordination number CN = 24 to O^{2-}, a number never observed before. In recently completed investigations of two structurally related halooxocuprates $Ba_{44}Cu_{45}O_{87}Cl_4$ and $Ba_{88}Cu_{88}O_{175}Br_2$[70], Cl^- or Br^-, respectively is observed at the center of the 26-gon instead of Ba^{2+}. This exchange is possible only because there appears to be an almost spherical coordination sphere with point-like distribution of positive and negative charges. It must, however, be pointed out that these environmental relationships are at present difficult to understand, in view of present concepts of chemical bonding, as in the sandwich-like incorporation of Cu^{2+} in $Ba_9Cu_7O_{15}Cl_2$ (cf. Fig. 24). For further detail, such as a Jahn-Teller distortion of some Cu^{2+} positions on occupation of the 26-gon by Br^- the literature[70] should be consulted.

This section would be incomplete without a reference to *Zemann*'s previous review of the crystal chemistry of copper[71]. Comparison of that review with the results presented above will demonstrate the appreciable progress made during the last 15 years, particularly for compounds with planar-coordinated ions.

4. Outlook

Oxo- and halooxometallates with planar coordination polyhedra are a recently discovered group of compounds, and few of their physical properties are known. Thus, only after further physical measurements will it be possible to answer questions about their electrical, optical, and magnetic behavior, about the chemical bonding, and about thermodynamic stability, questions that are important in connection with their practical application. Therefore, after recording the already known facts we shall turn to a few problems that still lie in the realm of speculation.

On the basis of presently available experimental material the structural systematics for one- and two-dimensional linking of planar-coordinated oxo compounds in the solid state can be considered as largely known. For the three-dimensional linking of planar-coordinated ions we need many more examples so that here too the basic structural principles may be recognized. What is certain is that the tetragonal elongation of the octahedra around Cu^{2+} in solids can seldom be unequivocally explained by the Jahn-Teller theory. In particular the halooxocuprates(II) show that crystal-chemical aspects (distribution of all atoms in each unit cell with consideration of the bond lengths, particle size, polarizability, *etc.*) are responsible for the elongated octahedra around Cu^{2+}. The few known examples of isotypic oxoniccolates(II) afford evidence against the validity of the argument that "Jahn-Teller effects determine the structural type". Oxo- and halooxoniccolates(II) are thus of great importance for theoretical understanding of deformed coordination polyhedra. Finally, it is remarkable that com-

pounds of the type $M_xPt_3O_4$ have a good electrical conductivity[72], which should be strongly anisotropic because of the stacking of square-planar structural groups at quasimetallic distances d(Pt—Pt) = 279—284 ppm. Oxometallates with these properties are comparable with the one-dimensional electrical conductors that are interesting physicists. In this connection the question arises whether oxocuprates(II), in which anisotropic metal-metal interactions could be expected on the basis of their known crystal structure, should be assigned to the group of one-dimensional conductors. It has been shown that in Bi_2CuO_4 the planar CuO_4 polyhedra are stacked unidimensionally (cf. Fig. 2) with distances d(Cu—Cu) = 290 pm longer than those in metallic copper. According to the band model, anisotropic conductivity in the stacking direction could arise on partial oxidation of Cu^{2+} to Cu^{3+}; however, the customary concepts about electron occupation of the 3d orbital of copper speak against this view. In the planar configuration Cu^{2+} has the ninth 3d electron always in the energetically unfavorable $d_{x^2-y^2}$-orbital. Even if partial oxidation to Cu^{3+} produced mobility of the charge carriers in the valence band, according to MO theory only the one $d_{x^2-y^2}$-electron can be affected. However, the orientation of this ($d_{x^2-y^2}$) orbital perpendicular to a one-dimensional metal chain excludes conductivity in the chain direction. In parallel with this, one must ask whether Bi_2PdO_4, which is related to Bi_2CuO_4 and contains a planar-coordinated d^8-element (Pd^{2+}), may not after all be a one-dimensional conductor.

Unlike Bi_2CuO_4, $Ba_3Cu_2O_4Cl_2$ contains an unfolded chain with partially planar-coordinated Cu^{2+}; the copper distances d(Cu—Cu) = 243 pm (cf. Fig. 19) are abnormally short. This compound thus contains one-dimensional isolated quasimetallic zigzag chains. Here too, according to concepts of orbital overlap along the zigzag chain only interactions of the d_{xy}- or d_{z^2}-orbital are possible, and neither of these is concerned in partial oxidation of the valence band of copper[73], *i.e.* electrical conductivity is excluded. For better understanding of such bonding it is important to measure the electrical conductivity as it is to prepare an isotypic compound $Ba_3Pd_2O_4Cl_2$, to which the same consideration might not apply.

The uncertainties in the prediction of conductivity are due not least to insufficient knowledge of the chemical bonding in these solid substances. On the one hand there are undisputed strong covalent interactions between Cu^{2+} and O^{2-}, which justify consideration of the situation according to the rules of MO theory, but on the other hand the observed coordination relationships seem explicable only on the basis of electrostatic interactions. Consider two examples.

In the compound $Ba_9Cu_7O_{15}Cl_2$ the situation of Cu_I (cf. Fig. 24) relative to the bonding of its $12\,O^{2-}$ neighbors is quite uncertain. If we apply orbital-overlap arguments it is not clear whether O^{2-} is bonded by $p_{x,y}$ to Cu_{II} and by p_z to Cu_I, or whether Cu_I is bonded by $12\,sp^3$ hybrid orbitals of oxygen with distances d(Cu_I—O) = 326 pm. It seems equally unsatisfactory to assume purely electrostatic interactions, since the identically charged but larger Ba^{2+} ion could, from the energy point of view, fill this large hole better than copper, whereas experimentally this is found not to occur.

Clearly, the inclusion of Ba^{2+}, Cl^-, and Br^- into the 26-gon of the $BaCuO_2$ crystal structure can be explained only by pure coulombic interactions (cf. Fig. 25). But how is one to visualize the bonds when ions occur at the center of a sphere with a uniform distribution of positive and negative charges on the surface? What is it that enables a Ba^{2+} ion to accept pointwise the $24\,O^{2-}$ particles on the surface of a 26-gon while refusing to accept 18 equidistant Cu^{2+} particles? If it seems reasonable to ascribe this to the different number of positive and negative charges, then the inclusion of Cl^- or Br^- becomes inexplicable.

These two examples show that the nature of the chemical bonding in solids must be reconsidered fundamentally if its growing separation from bonds in isolated molecules is not to continue.

Some Aspects of Antibiotics Research[**]

By Hans Zähner[*]

The era of spectacular developments in the field of antibiotics appears to be over. Ever greater efforts are needed to find ever fewer new antibiotics. The view that well-considered hypotheses can lead as successfully as proven results to further research is supported by the establishment of five theses. "Non-classical" screening methods and the search for secondary metabolites with unusual properties can provide a rich harvest.

Introduction

Antibiotics have been intensively investigated for more than 30 years. The successes, which in the early years followed one another in quick succession, have now become rarer. The effort required for progress has increased and the optimism has waned; some believe that the approach to new antibiotics is now asymptotic and that searching further for them is no longer worthwhile. Against this mood of skepticism I wish to put forward five theses, which have on purpose been phrased provocatively.

Thesis 1: Only a small part of the conceivable fields for the introduction of antibiotics has so far been covered.

Table 1 shows, in greatly simplified form, the relationship between the fields already covered and the partially covered to open fields.

Antibiotics are of course also used today in the fields designated here as open, but the latter are nevertheless thus described because the antibiotics used there are not satisfactory in every respect. For example, large quantities of antibiotics are used in animal feeds: insofar as they are used also in human medicine, they must be replaced. In practice, the only field described as wholly closed concerns infections by gram-positive bacteria in human medicine. The fields of protozoa, worms, and viruses are completely open; for the fields of tumors and systemic mycoses, antibiotics are only partially satisfactory.

One of the reasons for the uneven coverage of the various fields is that the correlation between the first screening tests and the desired action at the point of application is of very variable quality; the weaker this correlation, the more time-consuming and expensive is the work and the smaller is the prospect of success. The high cost of finding and preparing the antibiotics is, however, offset by the great economic interest.

Table 1. Possible fields for the introduction of antibiotics.

Fields covered	Fields partially covered	Open fields
Medical applications	Medical applications	Medical applications
Gram-negative bacteria	Gram-negative bacteria including multiresistant bacteria	Protozoa Systemic mycoses Worms Viruses Tumors
Nonmedical applications	Nonmedical applications	Nonmedical applications
	Phytopathogenic fungi	Phytopathogenic bacteria Phytopathogenic viruses Insects and mites Nematodes Snails Nutritive uses

According to a compilation by *Berdy*[1], 4076 antibiotics were known at the end of 1972. Each group concerned with the search for new antibiotics comes inescapably to the view that the proportion of new substances to those investigated is decreasing. For example, in the years 1954/55 we found one to three new antibiotics for every 1000 Actinomycetes strains tested, and only one out of 20 antibiotics actually investigated was new[2]. By 1958 the proportion of new antibiotics had fallen to less than one per thousand strains tested, and

[**] Based on a lecture at the Fifth International Fermentation Symposium, Berlin, July 1976.

not even every fiftieth antibiotic selected for study was new. These observations, together with the very large number of antibiotics described by then, have led to the view that we already know a large proportion of all existing antibiotics. To oppose this view I wish to present Thesis II.

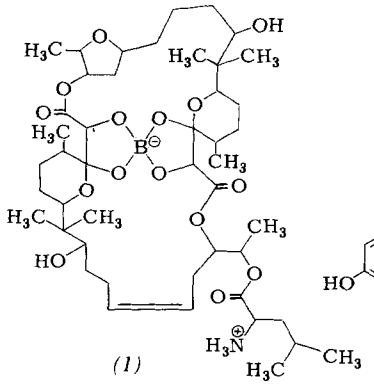
Thesis II: Only a small fraction of the natural antibiotics has so far been found

Up to a few years ago all antibiotics laboratories were using the same test methods and to some extent even the same test organisms. Only recently has the spectrum of the test methods become substantially wider. The classical methods are derived mainly from *Waksman*, and can be characterized by the following points:

there is an attempt to correlate the first test with later application as closely as possible;
all the tests depend on growth-inhibition or killing of the test organism;
all the tests are carried out under optimal conditions, *i.e.* with complex nutrient media;
all the tests are diffusion tests.

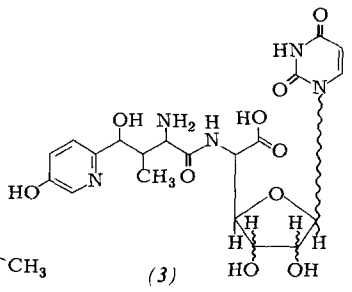
Two factors are decisive for the results of an antibiotic screening: the microorganisms and the test methods. Although this statement may be trivial, it has not been taken sufficiently into account, at least as far as the test methods are concerned. If one departs from the classical tests (see above), then quite a different selection of substances is obtained. In many antibiotics indications there is no satisfactory correlation between the first test and the desired action at the point of application. If this failure is regarded as a virtue and no account is taken of any correlation between the first test and the later application, *i.e.* if the first test is used only as a guide to the isolation of a new metabolite, then the other criteria of the classical test can also be disregarded.

The extent to which the test decides what will be found may be illustrated here by some examples from our own experience. Antifungal substances are still sought mostly by the classical method, with yeasts or fungal spores in a plate diffusion test; with actinomycetes one finds in this way a large number of polyenes as well as cycloheximide and antimycins. If the growth-inhibition criterion is replaced by the criterion of abnormal growth of the hyphae[3] or inhibition of zygospore formation[4], one then finds a wholly different spectrum of antifungal antibiotics from actinomycetes, namely compounds *(1)* to *(3)*.



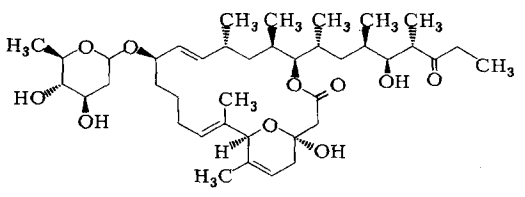
From its action, boromycin *(1)*[5], the first boron-containing natural product, belongs to the ionophoric antibiotics[7]. Its structure was clarified by *Prelog et al.*[6].

Venturidicin B *(2)* is an antifungal macrolide[8] whose structure was determined by *Keller-Schierlein et al.*[9]. Nikkomycin *(3)*, a nucleoside antibiotic related to the polyoxines[10], inhibits chitin synthesis[11].

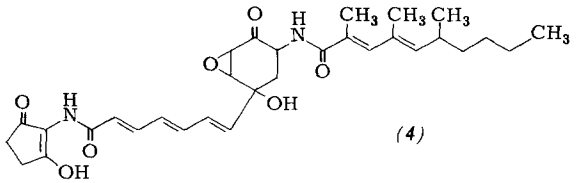


Simple and chemically well-defined media are used in the search for substances that show activity only in such simple media, and replacing the optimal complex nutrient media by such simpler ones leads to numerous antimetabolites[12] on the one hand and to some unusual new antibiotics on the other; examples of the latter are *(4)* to *(7)*.

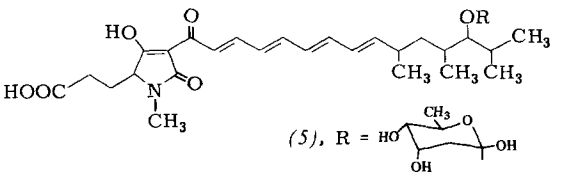
Manumycin *(4)*[13] is an antibiotic that interferes with protein synthesis of prokaryotic cells[14]. α- *(5)* and β-lipomycin *(6)*[15], together with oleficin[16], constitute a new group of antibiotics that interfere with lipids[17].



Chlorothricin *(7)*[18] is an unusual chlorine-containing macrolide that acts as an antagonist of acetyl-CoA[19] instead of inhibiting protein synthesis like the usual macrolides.

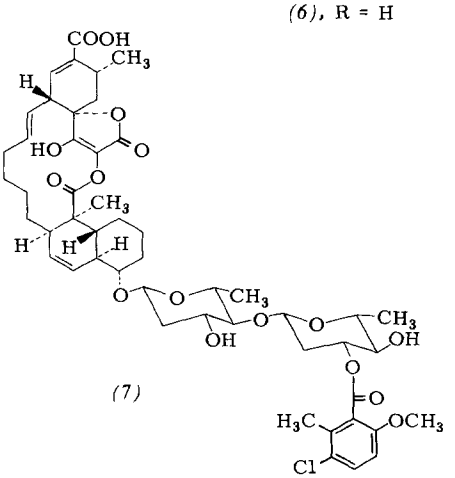


(1)



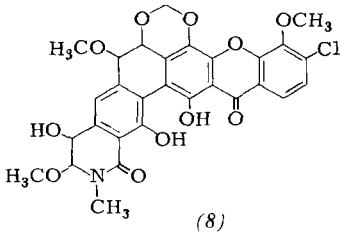
(3)

(2)



(4)

(5), R =



(6), R = H

(7)

If we now transfer our attention to antibiotics that diffuse only slowly—for which unfortunately there is still no generally

applicable test—we again find antibiotics that differ from those selected by the classical test procedures. As an example we may cite lysolipin I *(8)*[20] which, together with albofungin[21], forms a group of antibiotics whose mode of action and possible application have so far been little studied.

(8)

The modifications indicated above open up only a small fraction of the possible variations of the classical test procedures. New test methods are advantageously selected in such a way as to facilitate the identification or exclusion of known antibiotics. Examples of "nonclassical" screening are collected in Table 2.

Table 2. Some possibilities of "nonclassical" screening for microbial metabolites.

1. Search for antibiotics effective only under conditions nonoptimal for the test organisms, *e.g.* only on simple and chemically well-defined media or at nonoptimal temperatures
2. Use of permeation-damaged test organisms, *e.g.* extreme R-forms of *Enterobacteriaceae* or stable L-forms [a]
3. Use of extremely sensitive wild strains with consideration of antibiotics that are effective only against these "oversensitive" strains (narrow-spectrum antibiotics)
4. Search for antibiotics effective only in conjunction with detergents or ethylenediaminetetraacetic acid, *i.e.* antibiotics that require "help" for penetration
5. Cell-free systems of certain enzymes, *e.g.* proteases, dopa-decarboxylases, neuramidases, or chitin-synthetases and systems in which cell-free protein synthesis will occur, serve as indicators of activity
6. Application of criteria other than growth inhibition or death, *e.g.* action on differentiation and morphogenesis
7. Application of reactions for specific chemical groups as criteria, *e.g.* for reducing groups, amines, alkaloids, chlorine-containing or sulfur-containing metabolites
8. Application of methods from the field of "microbial transformation" [b]

[a] R-forms are gram-negative bacteria with incomplete lipopolysaccharides, L-forms are bacteria with either severely damaged or no cell wall.
[b] "Microbial transformation" means here the modification of organic compounds by microorganisms.

The new test methods indicated in Table 2 greatly increase the number of metabolites still to be discovered, although in such processes the boundary between antibiotics and other microbial metabolites begins to fade. If we combine the large number of possible new test methods with the almost unlimited number of microorganisms and consider that mutations increase the number of variations still further, we arrive at the thesis at the beginning of this section: so far we know only a small fraction of the natural antibiotics.

Thesis III: The problems of antibiotic transport have been neglected far too long

Antibiotics can be divided schematically into two groups: Group I, membranophilic antibiotics, and Group II, nonmembranophilic antibiotics.

The antibiotics of Group I attach themselves to or penetrate the cell wall of bacteria or fungi and there exert their activity; these antibiotics must not penetrate into the interior of the cell. To this group belong, among others, all the ionophoric antibiotics, polymyxins, colistins, lipomycins, and lysolipin I.

The antibiotics of Group II must penetrate into the cell, since their site of action is in the cell interior. Group II consists of antibiotics that attack primarily nucleic acid synthesis, protein synthesis, or the synthesis of metabolic intermediates. Examples are actinomycins, anthracyclines, tetracyclines, macrolides, aminoglycosides, and rifamycins, as well as chloramphenicol, cycloserine, and phosphonomycin. In the case of the gram-negative bacteria these antibiotics must pass through two membranes: the outer membrane and the cytoplasmic membrane.

The same possibilities are available for the uptake of antibiotics[22] of Group II into the cell as for the uptake of substrates, namely: a) active transport, b) facilitated diffusion, and c) passive diffusion.

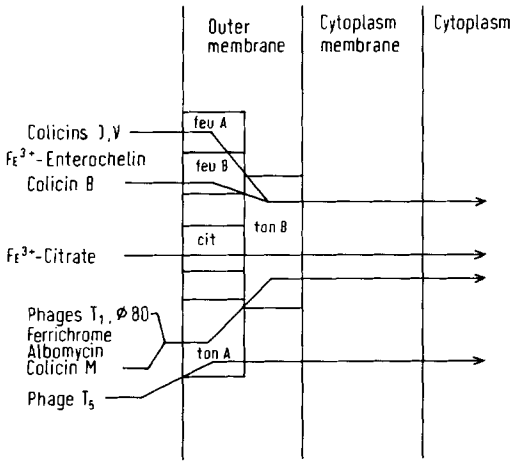
We shall concern ourselves in detail with active transport further below. The second possible mode of uptake, namely facilitated diffusion, cannot yet be exemplified; on theoretical grounds, however, it must be assumed that such systems require the uptake of large, not very lipophilic molecules. The third possibility, namely passive diffusion, is not conceivable according to the liquid mosaic model of membrane structure, at least not for large antibiotic molecules such as vancomycins, avilamycin/everinomycin, actinomycins, *etc.*

Owing to the several systems of active transport the bacterial cell can take up substrates even from highly dilute solutions. Failing such a system of active transport, *e.g.* as a result of mutation, much higher concentrations of the relevant substrate must be offered up to the cell to maintain the normal growth rate. Since antibiotics are sometimes active in extremely low concentrations, and in individual cases their enrichment in the cell has also been demonstrated, the suspicion arises that some of the antibiotic enters the cell by active transport; nevertheless, proof of enrichment is not yet proof of active transport, for even passive diffusion can lead to enrichment if there is a specific bonding site in the cell.

The transport systems for the substrates of bacterial cells are astonishingly specific. Since it cannot be assumed that special transport systems are set up for antibiotics, the question arises, which of the transport systems of the bacterial cell is drawn upon for this purpose. In other words, which substrate-transport system is misused by the antibiotic? Transport by way of the D-alanine system[23] has been demonstrated for cycloserine, and it has been shown that phosphonomycin is taken up both by means of the transport system for glycerophosphate and by means of an inducible transport system for glucose 6-phosphate[24]. Bacilysin can enter the cell by means of a dipeptide transport system[25]. The utilization of "normal" transport systems for the uptake of antibiotics will be illustrated here by three examples.

1. The Sideramine-Sideromycin Transport System

The sideramines, *e.g.* ferrichrome *(9)* and ferrioxamine B *(11)*, are microbial iron-transport compounds that are very soluble in water and permit optimal access of iron to the cell. Practically all microorganisms secrete either sideramines or related iron-complexing agents into the medium. Among



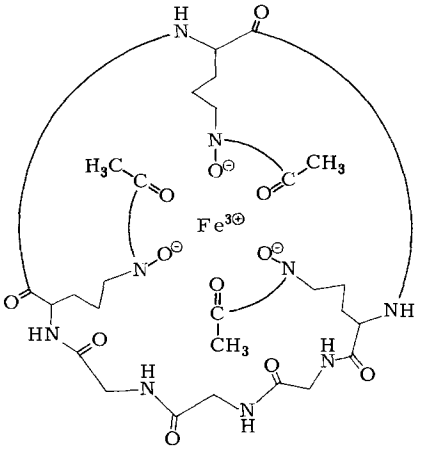


Fig. 1. System of Fe^{3+} transport in *Escherichia coli* [29]. For explanation see text.

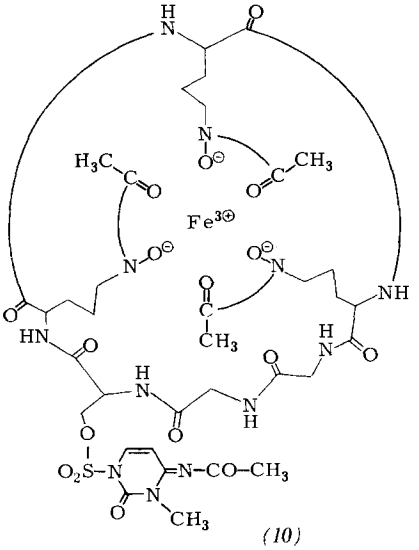
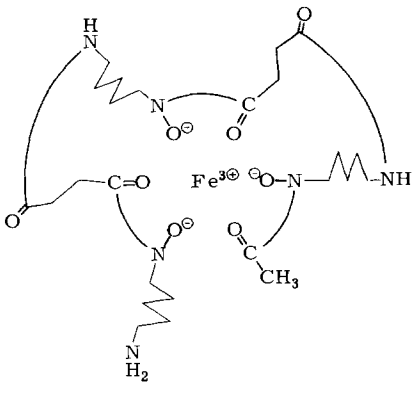
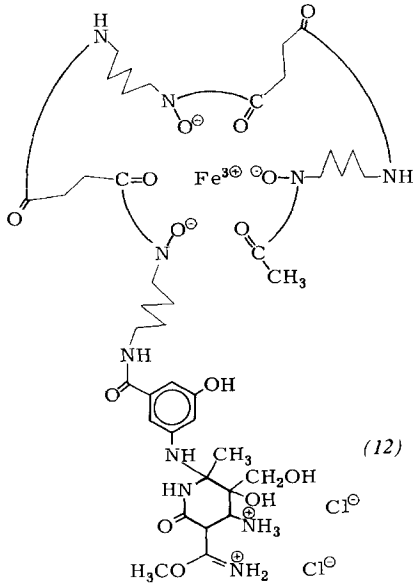


the sideromycins are included albomycin *(10)* and ferrimycin A_1 *(12)*. The antagonism between sideramines and sideromycins[26] rests on antagonism in transport[27,28]. *Hantke* and *Braun*[29] have investigated in detail the conditions for iron transport in *E. coli*, and have shown that ferrichrome *(9)* and albomycin *(10)* compete for bonding to the product of the gene ton A. The very complicated situation of the iron transport in *E. coli* is reproduced in Figure 1.

The product of the gene ton B is involved as well as the product of gene ton A in the ferrichrome uptake system. These gene products are proteins of the outer membrane of *E. coli* (from a chemical viewpoint these proteins deserve further investigation), whereas the genes ton A and ton B have already been mapped on the *E. coli* chromosome. This uptake system is used also by phages T_1 and ϕ 80 and by colicin M.



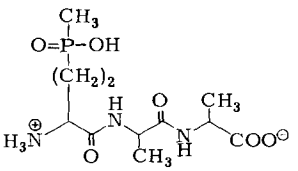
According to recent studies by *Wolf* and *Dengler*[34], the sideromycins inhibit protein synthesis in *E. coli* by inhibiting the transfer of certain amino acids to tRNA. The mode of the action of sideromycins thus has nothing to do with the antagonism to sideramines, *i.e.* to competition in transport.



(9)

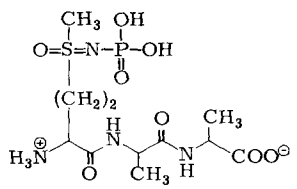
(10)

(11)



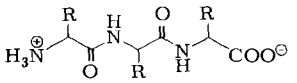
(12)

Sideramines are being investigated to an increasing extent[35], and a marked specificity in their formation and, in partial correspondence therewith, a specificity of transport, have become evident[36]. It is particularly interesting to note that specific sideramine-transport systems occur in organisms that themselves do not form sideramines. For example, *E. coli* synthesizes enterochelin as an iron-transport compound, but has a bonding protein specific for ferrichrome and can utilize the iron from ferrichrome. Higher cells too, *e.g.* bone marrow cells, are able to transport sideramines specifically and at mutually differing rates, and to utilize their iron for heme synthesis[37].



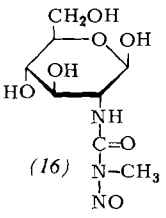
The close structural relationship between sideramines and sideromycins becomes clear if we contrast ferrichrome *(9)*[30] and albomycin *(10)*[31] with ferrioxamine B *(11)*[32] and ferrimycin A_1 *(12)*[33]. Ferrimycin A_1 *(12)* contains the complete molecule of ferrioxamine B *(11)*; the additional part has a molecular weight of more than 400. Albomycin *(10)* inhibits gram-negative and gram-positive bacteria; in both bacterial groups its action is antagonized by ferrichrome *(9)* and related sideramines. Ferrimycin A_1 *(12)* inhibits only gram-positive bacteria, and correspondingly ferrioxamine B *(11)* hinders the action of albomycin *(10)* only in gram-positive and not in gram-negative bacteria.

2. The Oligopeptide-Transport System

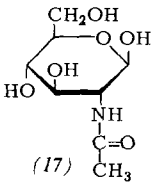


Payne and *Gilvarg*[39] have described a transport system for oligopeptides in *E. coli*. This system, which probably occurs widely in bacteria, transports tripeptides of the type *(15)*, tetrapeptides, and in some cases even pentapeptides, almost independently of their composition. We were recently able to show[38] that the tripeptide antibiotics phosphinothricylalanylalanine *(13)*[40] and phosphonomethioninesulfoximinylalanylalanine *(14)*[41] are conveyed by this transport system into the cell where they act as inhibitors of glutamine synthetase. In the cell they are split by a peptidase, with liberation in each case of the active component, which is always an unusual phosphorus-containing amino acid. Failure of the oligopeptide-transport system leads in *E. coli* to resistance to the two antibiotics.

(13)

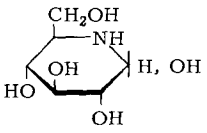


(14)

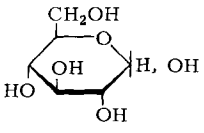


(15)

3. Transport of Antibiotics by the Phosphoenolpyruvate: Sugar-Phosphotransferase System



Schindler[42] has recently proved that streptozotocin *(16)*[43] and nojirimycin *(18)*[44] enter the cell by means of the phosphoenolpyruvate: sugar-phosphotransferase system[45]. This transferase system contains several enzymes. The protein designated as enzyme II recognizes the relevant sugar and is thus specific for certain sugars, whereas the remaining portions—enzyme I and a protein designated HPr—are the same irrespective of the sugars transported by the system. It is not yet clear whether phosphorylation occurs during the transport of streptozotocin *(16)* and nojirimycin *(18)*, or whether these antibiotics use the sugar-recognizing enzyme II and then penetrate into the cell more or less passively.



(16)

(17)

(18)

(19)

In the case of active antibiotic transport described above there is a clear relationship between the antibiotics, *e.g. (16)* and *(18)*, and the corresponding substrates, here *N*-acetylglucosamine *(17)* and D-glucose *(19)*, respectively. The same is true of the transport routes of cycloserine and phosphonomycin. For antibiotics of complicated structure no relationship to specific substrates can be seen, and proof of active transport is hardly possible in such cases. Nevertheless, it would be worthwhile to look for other actively transported antibiotics and to investigate their transport systems in detail. Further progress should follow better understanding of the antibiotic transport:

If it were known what transport system introduces complicated molecules into the cell, this system could perhaps also be misused for the transport of inhibitors of a different kind.

If the resistance is a resistance to penetration, as in the case of tetracyclines, it could perhaps be overcome by coupling the antibiotic with a carrier. In narrow-spectrum antibiotics the spectrum could perhaps be appreciably broadened by making derivatives designed to improve the transport properties.

Thesis IV: Antibiotics are secondary metabolites whose importance to the producer cell should be sought at the levels of primary metabolism, regulation, transport, and differentiation or morphogenesis rather than in defense against competitors

The wide distribution of antibiotics and the variety of their structures and points of attack lead repeatedly to the question

of the importance of antibiotics to the producer cell. In textbooks antibiotics are regarded as of major significance in competition between microorganisms, even if it is not assumed that microorganisms form antibiotics in order to keep other organisms away from the body. Several items of evidence lead us to doubt the "defense theory of antibiotics":

Many antibiotic-producing organisms are just as sensitive to their own antibiotics as are their competitors.

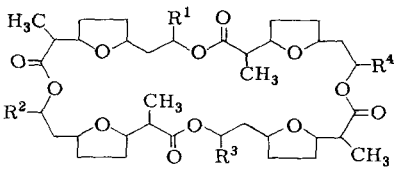
Some antibiotics are first produced at the end of the logarithmic phase of growth, often in connection with spore formation; if the spores are sensitive to the producer's own antibiotic, then clearly this must be degraded or inactivated by other organisms before germination is possible.

Only in exceptional cases can the presence of an antibiotic in its natural ecological niche be demonstrated.

The action spectrum of the antibiotics formed rarely coincides with the spectrum of the competitors.

We have declared antibiotics to be secondary metabolites that more or less accidentally possess antibiotic action. Next, we shall discuss the role of secondary metabolism. Are secondary metabolites really only waste products of primary metabolism or uneliminated residues of phylogenetic development[46]?

The development of organisms occurs at the levels of primary metabolism, metabolic regulation, material transport, differentiation, and morphogenesis. The driving force for further development is the interplay of increasing variation due to mutation with decreasing variation due to selection. Quite recently *Eigen* and *Winkler*[47] worked out afresh this interplay character of evolution. The extremely rigorous boundary conditions—the need to maintain reproductive and competitive capabilities—lead to the result that there is very little margin for the interplay between mutation and selection. One can thus imagine that latitude exists where the boundary conditions are less severe.



An example may clarify the gross difference in latitude between the primary and secondary metabolism. In primary metabolism a change in a product leads at once to death of the cell unless the new product can take over all the functions of the original product. In contrast, in secondary metabolism a product can be changed in any desired way so long as the change does not have an adverse effect at any of the above five levels. This has the result that in secondary metabolism there are often variations on a theme, *e.g.* a single strain may produce twenty anthracyclines.

This latitude of secondary metabolism should not be considered as isolated from the five levels of primary metabolism, metabolic regulation, material transport, differentiation, and morphogenesis. On the one hand the building units and various enzymes for secondary metabolism are derived from these levels, and on the other hand their results are taken up into a level if they are advantageous there. There are many substance groups that stand between secondary metabolism and one of the levels. Two examples will illustrate this point, and at the same time show the "fortuitousness" of antibiotic activity.

Sideramines, *e.g. (9)* and *(11)*, are assigned to iron transport; they occur in nature in great variety. On the one hand, there is a considerable specificity in sideramine formation, and on the other hand most sideramine-producers form many similar sideramines. For example, ferrioxamines A_1, A_2, B, C, D_1, D_2, E, F, and G can be isolated from the same Actinomyces strain[32]. Sideramines show the characteristics of both secondary metabolism (specificity of formation, variation) and of primary metabolism (function in iron transport). Of the nine ferrioxamines only the iron-free ferrioxamine E is active; it has been previously described as an antibiotic under the name nocardamine[48]. Its activity rests on the fact that it is a very strong iron-complexing agent and that many organisms are unable to remove the iron from the nocardamine-iron complex. The number of actinomycetes whose main component is ferrioxamine B (an antibiotically inactive component) is considerably greater than the number of actinomycetes that have nocardamine (iron-free ferrioxamine E) as the main component. It seems more or less accidental that, in addition to fulfilling its function in iron-transport in the producer cell, nocardamine also exerts an antibiotic effect on other microorganisms. In the fungal sideramine series of more than twenty individuals only one compound manifests antibiotic activity, namely deferritriacetylfusigen[49].

The observation that only one or a few members of a naturally occurring variation has or have antibiotic activity could be made much more frequently if antibiotic activity were not made the guideline for the isolation of secondary metabolites.

The second example is provided by the macrotetrolides *(20)*[50]. These are ionophoric antibiotics that have so far

(20a), $R^1 = R^2 = R^3 = R^4 = CH_3$, Nonactin
(20b), $R^1 = R^2 = R^3 = CH_3$, $R^4 = C_2H_5$, Monactin
(20c), $R^1 = R^3 = CH_3$, $R^2 = R^4 = C_2H_5$, Dinactin
(20d), $R^1 = CH_3$, $R^2 = R^3 = R^4 = C_2H_5$, Trinactin

been reported from only one, admittedly large, series of actinomycetes. Other microorganisms yield other ionophoric antibiotics. Biophysicists have found in them excellent models for the study of ion transport; whether they fulfil the same function in the producer cell is still an open question.

By using the nonactin-producing *Streptomyces griseus* as an example we can show that the producer may reap an advantage from its ability to produce such substances; mutants without this capability are at a disadvantage when the sodium-potassium ratios in the medium are unfavorable in comparison with the macrotetrolide producers[51]. Moreover, there are *Streptococcus faecalis* mutants[52] with a disturbed alkali-metal-ion transport; the wild strain also produces an ionophoric antibiotic[53], but it is not yet known whether this is absent from the above mutants. These ionophoric antibiotics show all the characteristics of secondary metabolites (specificity of formation, variation) and also play a part in the ion-economy of the producer; the antibiotic activity is connected with this more or less accidentally.

For some few examples it has been found[53] that at least part of the information for antibiotic synthesis can reside in the plasmids and not in the chromosome. Following this discovery it has been discussed how large is the proportion that resides in the plasmids compared with the total information on secondary metabolism. If this proportion is significant, then also on the genetic level the boundary conditions for the mutation/selection interplay would be less stringent in the secondary-metabolism area than in other areas. Plasmids can be duplicated more easily than portions of chromosomes and they can also reproduce outside the predecessor-successor chain. The transferability of plasmids to other organisms could appreciably accelerate the development and dissemination of a new possibility.

The hypothesis proposed here about the function of secondary metabolism as the "latitude" of phylogenetic development ascribes much greater importance to it than did earlier hypotheses. Secondary metabolism is thus the field where future developments will occur.

If secondary metabolism is in fact the "latitude" of biochemical evolution, then new metabolites, including new antibiotics, are continually being formed, and in numbers greater than we can describe. Thesis II as originally proposed, that we know only a small fraction of natural antibiotics, would then need to be amplified: we shall never isolate more than a small proportion of natural antibiotics.

Thesis V: Biological engineering processes also have their dangers

Here I should like to draw special attention to some dangers of the new possibilities offered by biological engineering in general and by antibiotics research in particular.

1. Highly impure water runs to waste from biological engineering processes. To purify it sufficiently for addition to the usual biological clarification plants requires more than mere neutralization or dilution; very probably special biological purification procedures will have to be included. Direct discharge into drainage systems or the sea must be ruled out.

2. Microorganisms can trigger off allergies. This is the case particularly with fungal spores, but also with certain constituents of microorganisms. These points must be borne in mind in the introduction of new biological engineering processes or in the reorganization of existing processes.

3. Microorganisms generally produce secondary metabolites, not only the desired ones, but often also undesirable and previously unknown ones. Most of the bio-engineering processes now in use have not yet been sufficiently investigated for the occurrence of undesirable secondary metabolites. Until proved innocent, each strain of *Penicillium* or *Aspergillus* should be examined for the formation of the extremely carcinogenic aflatoxins or other mycotoxins[53]. Most of the substrates used in biological engineering are ideal nutrient media for these fungi and are often massively contaminated with them. The control on mycotoxins must also be extended to the substrates of other processes if there is a possibility that one of the mycotoxins can make human contact[55].

4. In biological engineering processes increasing use is made of strains whose pathogenicity to man, animals, or plant life, and whose capacity to damage wood, textiles, or foodstuffs have been little studied. If, for example, we were to begin worldwide cultivation of edible fungi that have previously been grown only regionally, then a careful watch should be kept to see whether in their new environment they are not phytopathogenic or do not destroy wood. If the physiological properties of microorganisms are changed by mutation, *e.g.* the temperature optimum, then the pathogenicity must be rechecked. Changes in the action spectrum of weakly pathogenic strains should be taken into account just as much as the pathogenicity for a certain species.

It is true that the above-mentioned dangers are less spectacular in their effects than those that can arise from genetic engineering[54], but the likelihood of their occurrence is considerably higher. It is our responsibility to meet this danger with circumspection and care and to help to ensure that undesirable developments do not occur.

The work described in this article was carried out mainly within the framework of Sonderforschungsbereich 76 "Chemical Biology of Microorganisms". I am indebted to the Deutsche Forschungsgemeinschaft for generous aid, and to the many collaborators and partners without whose help this work could not have been accomplished.

Investigations of Mitochondrial Adenine Nucleotide Translocation by Means of Nucleotide Analogs

By Eckhard Schlimme, Karl Siegfried Boos, Dubo Bojanovski, and Joachim Lüstorff[*]

ATP and ADP are transferred across the inner mitochondrial membrane by means of a carrier (translocator), an inner membrane integral lipoprotein. Translocation of the adenine nucleotides occurs in two steps: specific binding and transport. By using substrate analogs with modified adenine, phosphate, or ribose moieties it is possible to check which structural properties of the substrate are essential for binding and transport.

1. Physiological Importance of the Adenine Nucleotide Carrier

Membrane bound processes are of fundamental importance for the function of living systems. In this context substrate transport is of special interest. For example, transfer of the adenine nucleotides adenosine 5′-*O*-triphosphate (ATP) and

adenosine 5′-*O*-diphosphate (ADP) across the inner membrane of the mitochondrion (Fig. 1a) is the key process in energy metabolism of aerobic cells. (The outer membrane is permeable to compounds of low molecular weight and can therefore be left out of consideration here.) Thereby, ADP is transferred[1–4] from the cytosolic side to the matrix side (*i.e.* from "outside" to "inside"), where oxidative phosphorylation occurs according to the reaction:

$$\text{ADP} + \text{Monophosphate} \rightleftarrows \text{ATP} + H_2O$$

By this phosphorylation process the energy liberated in numerous catabolic reactions is "chemically stored" in the

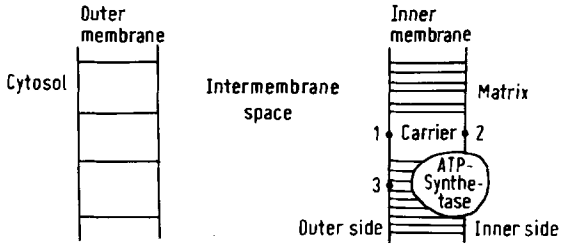

Fig. 1b. Schematic graph of the inner mitochondrial membrane
1: Carrier-dependent (specific) binding of ATP and ADP to the outer (cytosolic) side of the inner membrane; inhibitor is atractyloside;
2: Carrier-dependent (specific) binding of ATP and ADP to the inner (matrix) side of the inner membrane; inhibitor is bongkrekic acid;
3: Carrier-independent (unspecific) binding of ATP and ADP to the outer (cytosolic) side of the inner membrane; not inhibited by atractyloside.

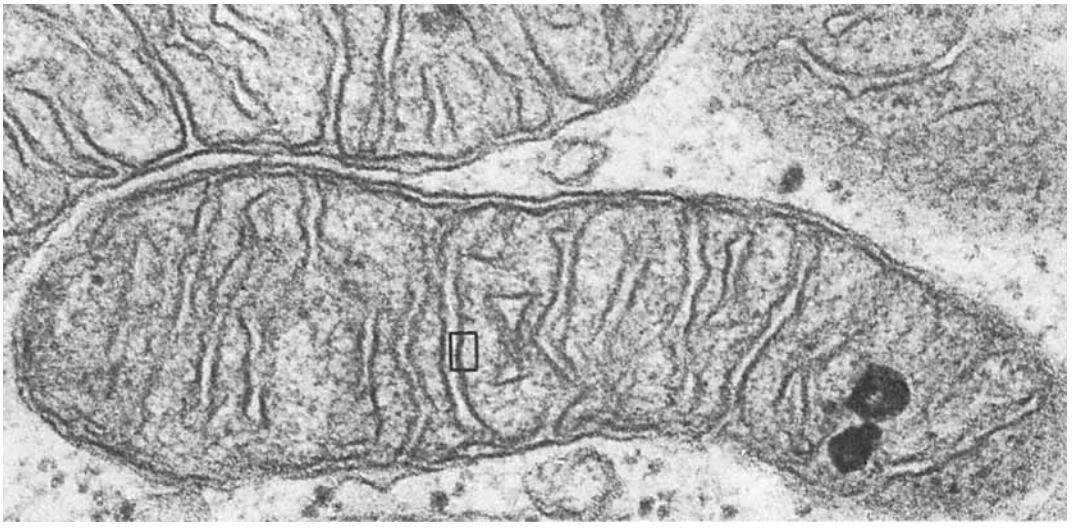

Fig. 1a. Electron-micrograph of a mitochondrion from a cell of mouse gall-bladder epithelium. The outer and the inner membrane surround the intermembrane space, while the inner membrane with numerous foldings (cristae) encloses the matrix space. The mitochondrion is surrounded with cytosol. The inset of the figure shows a segment of the inner membrane (cf. Fig. 1b).

ATP molecule *via* the respiratory chain to which the ATP-synthetase (F1-ATPase)—located on the matrix side—is coupled[5, 6]. ATP is then transported from the matrix to the cytosolic side, *i. e.* from "inside" to "outside". A substrate/product exchange thus occurs across the membrane.

This transport across the membrane can be specifically prevented by inhibitors (Fig. 1b). Atractyloside[7] and carboxyatractyloside, two cyclic triterpene glycosides from *Atractylis gummifera*, block the transport from the cytosolic side ($K_D \simeq 10^{-7}$—10^{-8} mol/l)[2,3,8-11], whereas bongkrekic acid, a lipophilic tricarboxylic acid from *Pseudomonas cocovenenans*, inhibits the transport mainly from the matrix side ($K_D \simeq 10^{-8}$ mol/l)[2, 3]. Other inhibitors are long-chain acyl-coenzyme-A esters, in particular palmitoyl-coenzyme-A[12-18]; their inhibitory effect may be physiologically important for the regulation of the adenine nucleotide transport.

The mode of action of the inhibitors pointed towards a carrier mediated active transport of ATP and ADP. This carrier molecule, which was isolated and characterized[19-29], is an integral component of the inner membrane (see Section 2) and represents about 10%[19-29] of the total mitochondrial protein. Some characteristic data for this transport system are summarized in Table 1.

The adenine nucleotide carrier preferentially transfers ADP from the cytosolic to the matrix side[2, 3]; in the reverse direction ATP transport is preferred[35, 36]. The translocation system thus operates asymmetrically, the asymmetry being due to the different postulated conformations of the carrier when oriented to the cytosolic ("c" state) and to the matrix side ("m" state) of the membrane, respectively[26, 28]. This property of the carrier system in particular guarantees rapid regulation of the cellular ATP level, the maintenance of which is a prerequisite for a steady state of energy-consuming processes. These are coupled either directly to ATP as the source of energy or to other nucleoside triphosphates (GTP, ITP, CTP, UTP) for whose syntheses ATP is again required as a donor of phosphoryl groups. The driving force of all of these processes is the free energy of hydrolysis of the nucleoside triphosphates. Under standard conditions (and at pH 7.0) the free energy for the hydrolysis of ATP is $\Delta G = -30.7$ kJ/mol; *in situ* this value can deviate widely from the standard value, and it can also vary within different cell compartments.

In addition to their function as central energy "transmitter" of the cell, adenine nucleotides in their role as allosteric effectors play an important role in regulation of the cell metabolism and are also substrates for anabolic processes.

Table 1. Some characteristic data for the mitochondrial adenine nucleotide translocator *in situ*.

Michaelis-Menten constants (K_M) [30—33]

K_M (ADP extramitochondrial, 2—5°C): 1—10 μmol/l
K_M (ATP extramitochondrial, 2—5°C): 1—150 μmol/l [a]

Maximal rate of translocation V

[μmol·min^{-1} per g of mitochondrial protein] [30—33]
V(ADP): 5 (2°C), 20 (5°C)
V(ATP): 2 (2°C), 7 (5°C)

Turnover [2, 34]

40—60 min^{-1} (2°C)
1600—2000 min^{-1} (20°C)

Activation energy [30, 31]

below 10°C: 176 kJ/mol
above 10°C: 69 kJ/mol

Topological findings

2×10^{13} translocator molecules per cm^2 of surface (inner mitochondrial membrane, rat liver) [34]

Molar ratio translocator: cytochrome a = (1.5—2.0):1 (rat liver mitochondria); = (2.5—3.0):1 (rat heart mitochondria) [2]

[a] Dependent on the energy state of the mitochondrion [32].

2. Structure and Mode of Action of the Carrier

Methods for the isolation and *in-vitro* characterization of the mitochondrial adenine nucleotide carrier were developed recently in several independent laboratories[20, 21, 24, 25, 27]. A review is given in Table 2.

According to the experimental findings, the macromolecule isolated from the inner membranes of heart and liver mitochondria (MW 29000 and 26000 respectively), as the substrate-

Table 2. Isolation and characterization of the mitochondrial adenine nucleotide translocator.

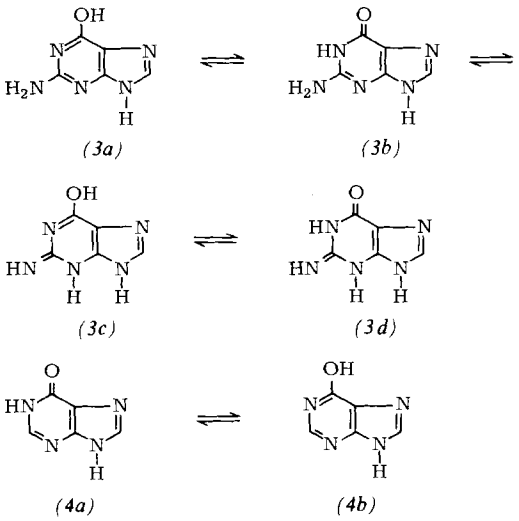
Liver mitochondria (rat) Brij 56	Soluble protein fraction in the exclusion volume of Sephadex G 25	—	Atractyloside-sensitive binding of ADP	[20]
Triton X 100 Emulphogen BC 720	Affinity chromatography on atractyloside-agarose	50000 to 60000	Binding of atractyloside	[21]
Sodium dodecyl sulfate	Affinity chromatography on carboxyatractyloside-agarose	26000 60000 (dimer)	Binding of atractyloside and inhibition of the ATP/ADP translocation in digitonin particles by antibodies against the isolated translocator protein	[23, 27]

and inhibitor-binding component, is an essential structural constituent of the adenine nucleotide carrier. The active carrier[26] is possibly the dimeric form of the isolated macromolecule[21,23,26,27]. Its translocation activity is largely characterized by interactions with the hydrophobic lipid environment. The carrier is a lipoprotein[27,37,38] consisting of: protein 85%, phospholipids 14%, and triacylglycerol 1%[27,38]; small-angle X-ray measurements on the isolated macromolecule[39] indicate a membrane-spanning structure with a largest distance of 7.3 nm and a radius of gyration of 3.1 nm.



Translocation of the substrates (S) ATP and ADP catalyzed by this carrier system (C) occurs in a reaction sequence of the type:

$$S_a + C \rightleftarrows S_a C \rightleftarrows CS_i \rightleftarrows C + S_i$$

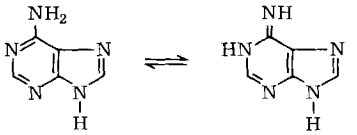
Association or dissociation reactions take place on both sides of the membrane (a = outer; i = inner). Transport of the substrate across the membrane can in principle be accomplished by two different means: 1) the nucleotide-carrier complex rotates within the membrane (rotation mechanism) so that the nucleotide ends up on the other side of the membrane; 2) the nucleotide is transferred from one side of the membrane to the other through a channel (pore mechanism) as a result of a conformational change of the nucleotide-carrier complex. Both processes are energy-dependent[26,29,40,41]. The general ideas about membrane transfer reactions[42-44], as well as the present knowledge of the structure of the adenine nucleotide carrier[27-29,38-47], favor a "pore mechanism" as the mode of ATP and ADP transport across the inner mitochondrial membrane.

3. Substrate Specificity of the Carrier

The carrier system is highly specific for ATP and ADP. None of the naturally occurring ribo- or deoxyribo-nucleoside 5-*O*'-tri(di)phosphates of guanine *(3)*, GTP, GDP, and dGTP, dGDP, of hypoxanthine *(4)*, ITP, IDP, and dITP, dIDP, of uracil, UTP, UDP, and of thymine, dTTP, dTDP, and of cytidine, CTP, CDP, dCTP, dCDP, are substrates for mitochondrial nucleotide transport[2,20,45].

(3a) *(3b)*

(3c) *(3d)*



(4a) *(4b)*

These findings emphasize again the role of ATP as the main donor of phosphoryl groups in the aerobic cell.

As in the field of enzyme-catalyzed reactions[46,47], substrate analogs proved to be of exceptional utility in the investigation of carrier-nucleotide interactions, especially those bound to the carrier but inappropriate for transportation. The two step nature of the process (binding and transport) can be experimentally proved by means of such analogs; furthermore, it can be shown which structural[48,49] properties of the adenine nucleotide molecule are essential for the specific binding (first step) and which are additionally required for inducing the transfer (second step).

3.1. Base-Modified Substrate Analogs

As mentioned above, replacement of adenine *(5)* in the nucleotide tri(di)phosphate by another purine or pyrimidine base leads to a loss of specific binding to the carrier. This may be due to the different electron distributions in the heterocyclic systems or to the different substitutions. In aqueous solutions guanine *(3)* and hypoxanthine *(4)* exist in the lactam forms *(3b)* and *(4a)*, while adenine exists in the amino form *(5a)*[50,51]. The different tautomeric equilibria and ionizations in the aqueous phase give rise to large physical differences between adenine on the one hand and guanine and hypoxanthine on the other.

(5a) *(5b)*

Figure 2 shows the reference systems for the orientation of heterocycle and sugar residue. The importance of an intact adenine base for binding to the carrier molecule and/or for

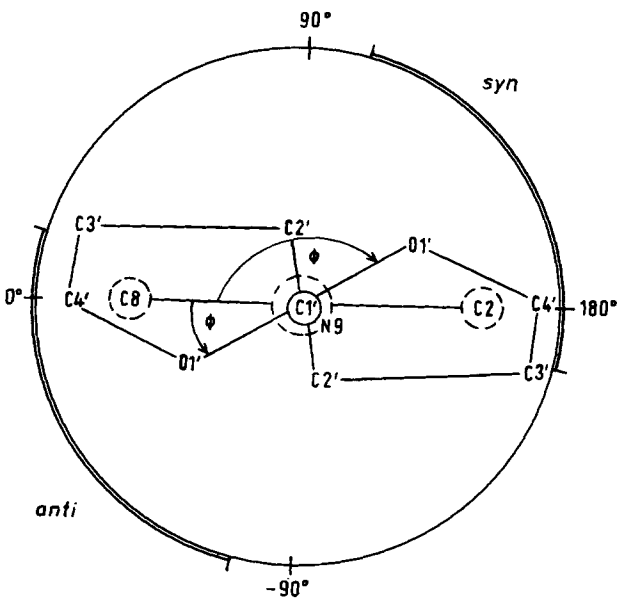


Fig. 2a. The position of the purine base relative to the sugar is described by the torsion angle φ (O1'—C1'—N9—C8) (cf. Fig. 3a). The base can be *syn*- or *anti*-positioned, where for a *syn*-conformation the angle φ is defined as 150±45° and for an *anti*-conformation as −30±45° [51, 52].

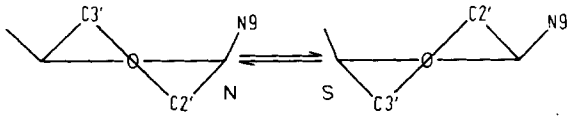

Fig. 2b. Pseudorotation (puckering) of the ribofuranose ring is described by the conformer equilibrium N(C2'-*exo*,C3'-*endo*)⇌S(C2'-*endo*,C3'-*exo*) [51, 53—56].

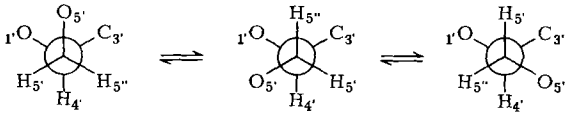

Fig. 2c. Newman projection along the exocyclic C5'—C4' bond shows the three rotamer positions *gauche,gauche (gg)*, *gauche,trans (gt)*, and *trans,-gauche (tg)* [51, 53—56].

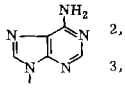
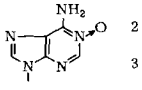
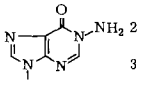
the transport process is shown by the investigation of base-modified adenine nucleotide analogs; a summary is given in Table 3.

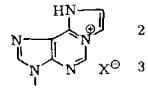
translocated by the adenine nucleotide carrier[45]. Structural changes in the phosphate chain that do not influence the number of charges are generally tolerated by the carrier molecule much better than are changes in the base (Table 4).

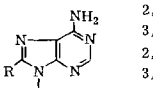
3.3 Substrate Analogs Containing Modified Sugar Moieties











The N⇄S equilibrium (pseudorotation, puckering; cf. Fig. 2) of the ribose ring[51, 53–56] has a considerable influence on the nucleotide conformation[51, 54–56]. For this reason the behavior of adenine nucleotide analogs with modified sugar moieties (Table 5) points to the importance of the nucleotide conformation for the interactions of ATP and ADP with the mitochondrial adenine nucleotide carrier.

4. Conclusions from the Studies with Substrate Analogs

Which conclusions can now be drawn from the findings presented in Tables 3 to 5 concerning the molecular require-
