Chemical Oscillations

By Ulrich F. Franck[*]

Under constant external conditions, chemical reactions may also proceed in a rhythmic manner. The kinetic mechanisms responsible for such oscillations prove to be unexpectedly complicated. It can nevertheless be demonstrated that chemical periodicity is caused by certain kinds of coupling between simultaneous reactions or transport processes. A general survey of the chemistry and phenomenology of the principal chemical oscillations is followed by a discussion of the situations leading to periodic reactions on the basis of the multivariable kinetics of feedback systems. Autocatalysis and autoinhibition play an important role, as also do kinetic instability and spatial propagation.

1. Introduction

Left to themselves under constant external conditions, normal chemical reaction systems equilibrate provided they are not completely inhibited. Thermodynamically open systems approach a likewise thermodynamically defined steady state, as shown schematically in a plot of concentration *versus* time (Fig. 1a).

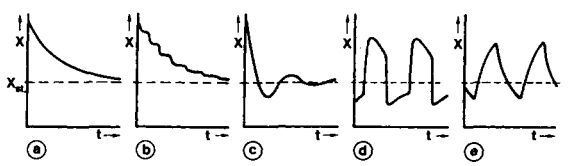

Fig. 1. Temporal behavior of thermodynamically open systems. X = concentration of starting compound. a) Normal non-periodic attainment of steady state; b) attainment of steady state at rhythmically changing rate; c) attainment of steady state *via* attenuated oscillation; d) flip-flop oscillation; e) sawtooth oscillation.

However, in their experimental work chemists, chemical engineers, and biologists are also acquainted with numerous examples of chemical systems deviating considerably from this pattern in their temporal behavior (cf. also Fig. 1b and 1c). One of the most interesting deviations is the ability of some chemical and physicochemical systems to undergo spontaneous oscillatory reaction (Fig. 1d and 1e).

Although this phenomenon of rhythmic chemical, and especially electrochemical, reactions has long been known, thorough experimental and theoretical studies have only been performed in the past 20 years. Several competent reviews of this field have recently been published (see *e.g.* [1–4]). In the present article, recent discoveries and viewpoints will be

evaluated to show that, in spite of the unexpected complexity of their mechanisms, the kinetics of oscillatory chemical reactions can probably be reduced to a limited number of kinetic principles, and is largely analogous to the kinetics of known mechanical and electrical systems.

Closely connected with chemical periodicity are other "anomalous" non-periodic modes of behavior, some of which are illustrated in Figure 2. They generally occur on slight modification of systems capable of oscillation. Systems no longer able to oscillate generally still possess bistability, *i.e.* they can exist in two stable reaction states whose interconversion can be triggered by external perturbations ("stimuli"). The study of non-periodic behavior is of great value for the assessment of oscillatory kinetics. It also underlines the close relationship with the excitation processes of nerve and muscle cells, which are themselves known to be capable of oscillatory behavior.

The phenomena mentioned have their origin in kinetic processes which are not observed in "normal" systems. A detailed account presented in Section 3.3 shows that mainly kinetic coupling exists between the effective reactions of the oscillatory system and gives rise to various forms of chemical feedback. As in mechanical and electrical systems, the generation of oscillations in chemical systems is also a consequence of feedback processes. Studies should therefore concentrate on the question how chemical feedback can come about, and what form it must take for oscillations to occur.

Chemical oscillations in homogeneous systems are currently under investigation in numerous laboratories. And yet, despite the overwhelming body of detailed factual material and great effort expended, not a single chemical oscillation has so far be completely elucidated beyond all doubt. The reasons are listed below:

Periodic chemical reactions occur only in extensively coupled multivariable systems. Such systems are extremely non-linear with respect to driving forces and the driven fluxes and reactions.

Oscillations affect changes of states far removed from equilibrium, to which the classical theories of the thermodynamics of equilibrium states and non-equilibrium states close to equilibrium are no longer directly applicable.

Oscillatory chemical systems contain unstable states which cause spontaneous rhythmically occurring spatial propagation of changes of state. Hence homogeneous systems in a thermodynamic sense are no longer present.

Section 3 is devoted to these kinetic features and difficulties. Before proceeding further, however, the principal chemical and physicochemical oscillations and their specific phenomenology will first be considered.

2. Phenomenology of Chemical and Physicochemical Oscillations

The external appearance of the oscillations observed in a large variety of systems is surprisingly uniform. The oscillograms either consist of periodic transitions of various degrees of sharpness between two quasi-steady states, or they have a sawtooth shape (Figs. 1d and 1e). Chemical oscillations therefore resemble non-linear flip-flop oscillations more closely than harmonic vibrations. The sinusoidal oscillograms occasionally recorded are by no means due to particularly simple linear processes.

In an open system with a regular flux of reactants the oscillations can be maintained indefinitely. In closed systems, where they were generally first observed, they are of limited duration sufficiently distant from equilibration.

2.1. Chemical Oscillations in Homogeneous Systems

2.1.1. Purely Chemical Oscillations in Homogeneous Solutions

This class of chemical oscillatory reactions presently attracts the greatest interest among both experimentalists and theorists. Oscillations were previously thought to be impossible in homogeneous solutions. The unfounded assumption that periodic behavior always requires the presence of a heterogeneous structure was apparently based on the view that control of the periodic change in the reaction can only be the result of the action of fluctuating interfacial states as known from heterogeneous catalysis.

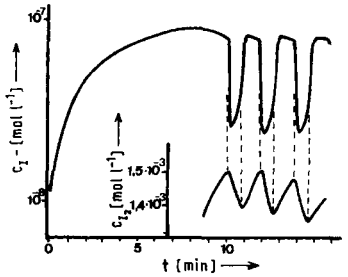

Fig. 3. Bray oscillation: decomposition of hydrogen peroxide in the presence of iodate and iodine. Upper curve, iodide concentration; lower curve, iodine concentration (according to [11]).

When *Bray* observed[5, 6] in 1920 that the decomposition of hydrogen peroxide in the presence of iodic acid and iodine follows a periodic course (Fig. 3), much effort was devoted to the search for the interfacial structures responsible for the oscillations—they were suspected to lie in microscopic oxygen bubbles[7, 8] and also in dust particles[9]. Meanwhile, after the discovery of further "homogeneous" periodically reacting chemical systems, it is known that structural heterogeneity is not necessary for the occurrence of oscillations.

The Bray reaction proceeds according to the simple equation

$$2H_2O_2 \xrightarrow{HIO_3/I_2} 2H_2O + O_2$$

Thus iodic acid and iodine are true catalysts. The usual formulation as two partial equations

$$\begin{array}{lrcl} 1) & 2HIO_3 + 5H_2O_2 & \rightarrow & I_2 + 5O_2 + 6H_2O \\ 2) & I_2 + 5H_2O_2 & \rightarrow & 2HIO_3 + 4H_2O \\ \hline & 10H_2O_2 & \rightarrow & 10H_2O + 5O_2 \end{array}$$

with H_2O_2 reducing the iodic acid and oxidizing the iodine describes the actual reactions occurring only incompletely or even incorrectly. Experimental results show that oxygen evolution is not stoichiometric with the optically observable conversion of iodine, and that the oxygen appears as product of the iodine reaction (2) and not of the iodic acid reaction (1) during the oscillation[2].

Degn[10] interprets these experimental observations in terms of an intermediate higher order branching reaction of a transient radical species. This would explain the non-stoichiometric relationship between the liberation of iodine and O_2 and also the suspected autocatalytic nature of a partial reaction.

Another mechanism has been proposed by *Matsuzaki, Nakajima*, and *Liebhafsky*[11], which comprises four essential reaction steps:

1)	$HIO_3 + H_2O_2$	$\rightarrow HIO_2 + H_2O + O_2$
2)	$HIO_2 + H_2O_2$	$\rightarrow HIO + H_2O + O_2$
3)	$2HIO_2 + HIO + H_2O_2$	$\rightarrow 3HIO_2 + H_2O$
4)	$HIO_2 + H_2O_2$	$\rightarrow HIO_3 + H_2O$
	$4H_2O_2$	$\rightarrow 4H_2O + 2O_2$

The third step is autocatalytic.

This reaction sequence corresponds to a mathematical model of systems capable of oscillation which has been put forward by *Prigogine, Nicolis*, and *Lefever*[12,13]—it has been designated as "Brusselator". The model (cf. Section 3.2) consists of the following four sub-steps:

1)	A	$\rightarrow$ X
2)	B + X	$\rightarrow$ D + X′
3)	2X + X′	$\rightarrow$ 3X
4)	X	$\rightarrow$ E
	A + B	$\rightarrow$ D + E

In the case of the Bray reaction, A and E would correspond to HIO_3, X to HIO_2, X′ to HIO, B to H_2O_2, and D to O_2, the overall balance being:

$$B \rightarrow D$$

because A = E.

The autocatalytic step (3) of the Brusselator and of the reaction model of the Bray reaction is trimolecular. This is the most problematic step of these models because trimolecular reactions are extremely improbable, especially in a reaction mixture like that of the Bray reaction for which 16 possible reactions of 11 reactants have to be considered[11] and in which two bimolecular reactions (2 and 4) are in competition.

In 1951, *Lynn*[14,15] found another homogeneous system exhibiting concentration oscillations: the thermal decomposition of sodium dithionite.

In buffered (pH $\approx$ 4) aqueous solution, sodium dithionite decomposes above 50 °C according to the reaction:

$$2Na_2S_2O_4 + H_2O \rightarrow 2NaHSO_3 + Na_2S_2O_3$$

Experimental findings indicate an autocatalytic reaction step suspected by *Mason* and *Depoy*[16] to lie in the following two-step radical reaction:

$HSO_2^{\bullet}$	$+HSO_3^-$	$\rightarrow H_2S_2O_5$
$H_2S_2O_5$	$+HS_2O_4^-$	$\rightarrow 2HSO_3^{\bullet} + HS_2O_3^-$
$HSO_2^{\bullet} + HSO_3^{\bullet} + HS_2O_4^-$		$\rightarrow HS_2O_3^- + 2HSO_3^{\bullet}$

According to *Wayman* and *Lem*[17], $HSO_3^{\bullet}$ takes up an electron to form the reaction product HSO_3^-.

Interest in chemical oscillations was awoken primarily by the discovery of a highly impressive reproducible periodic reaction by *Belousov*[18] (1958). On attempting to oxidize citric acid by bromate in the presence of Ce^{4+}, he noticed that the yellow color of the Ce^{4+} ion in the homogeneous reaction mixture vanished and reappeared in a constant rhythm.

Credit goes mainly to *Zhabotinskii*[19,20] for recognizing the importance of this reaction for the understanding of periodic chemical and biological processes. In particular, he showed that the reactants could be modified and their oscillatory ability thereby considerably improved. Thus the citric acid can be replaced to advantage by other brominatable organic compounds, especially by malonic acid. *Zhabotinskii* also recognized that the Ce^{4+} ion serves as electron transfer agent and can be replaced by redox systems having a correspondingly high positive redox potential. The reactants of the "Belousov-Zhabotinskii reaction", currently the most thoroughly studied process of its kind, are a solution of malonic acid, potassium bromate, and cerium(IV) sulfate in 3 N sulfuric acid. After an induction period of about 10 min, extremely regular oscillation sets in at a frequency of about two periods per minute (at room temperature). They persist for about 15 to 30 min in a closed system, and can be maintained indefinitely in an open system with a constant reactant flux.

Table 1 lists the components of the Belousov-Zhabotinskii reaction. Potential organic brominatable components are compounds bearing a hydrogen readily substituted by bromine in the proximity of a carbonyl group. The redox potential of the electron transfer agent must exceed 0.9 V[21], and the

Table 1. Modifications of the Belousov-Zhabotinskii reaction. Overall process for the most thoroughly investigated variant:

$$2BrO_3^- + 3CH_2(COOH)_2 + 2H^+ \rightarrow 2BrCH(COOH)_2 + 3CO_2 + 4H_2O$$

Reducing agent	Oxidizing agent	Electron transfer agent	Acidic medium
Malonic acid	$KBrO_3$	Ce^{3+}/Ce^{4+}	H_2SO_4
Bromomalonic acid	KIO_3/H_2O_2	Mn^{2+}/Mn^{3+}	$HClO_4$
Citric acid		Ferroin/Ferriin [a]	
Malic acid		$Ru(bpy)_3^{2+}/Ru(bpy)_3^{3+}$ [a]	
Gallic acid		$Ru(phen)_3^{2+}/Ru(phen)_3^{3+}$ [a]	
Acetone			
Acetonedicarboxylic acid			
2,4-Pentanedione			
2,5-Hexanedione			

[a] Ferroin = $Fe(phen)_3^{2+}$; ferriin = $Fe(phen)_3^{3+}$; bpy = 2,2′-bipyridine; phen = 1,10-phenanthroline.

reaction medium must contain a strong acid. Moreover, bromination can be replaced by iodination with iodate/hydrogen peroxide[22]. The Belousov-Zhabotinskii reaction has not yet been completely elucidated[19-21,23-29].

At present some ten reactions of twelve reactants are under discussion. Six of the ten reaction steps are regarded as essential partial reactions, two of them being considered as constituting an autocatalytic process. There remain the following five reactions viewed as responsible for the oscillations in a narrower sense:

1) $BrO_3^- + Br^- + 2H^+ \rightarrow HBrO_2 + HOBr$
2) $HBrO_2 + Br^- + H^+ \rightarrow 2HOBr$
3) $BrO_3^- + HBrO_2 + 2Ce^{3+} + 3H^+ \rightarrow 2HBrO_2 + 2Ce^{4+} + H_2O$
4) $2HBrO_2 \rightarrow BrO_3^- + HOBr + H^+$
5) $nCe^{4+} + BrCH(COOH)_2 \rightarrow nCe^{3+} + Br^- +$ oxidation products

Reaction (3) is a stoichiometric autocatalytic reaction with respect to $HBrO_2$. It is assumed to proceed in two steps *via* the $BrO_2^{\bullet}$ radical.

$$BrO_3^- + HBrO_2 + H^+ \rightarrow 2BrO_2^{\bullet} + H_2O$$
$$2BrO_2^{\bullet} + 2Ce^{3+} + 2H^+ \rightarrow 2HBrO_2 + 2Ce^{4+}$$
$$\overline{BrO_3^- + HBrO_2 + 2Ce^{3+} + 3H^+ \rightarrow 2HBrO_2 + 2Ce^{4+} + H_2O}$$

Assuming the protonations to be very fast, all the steps of the reactions given are of 2nd order.

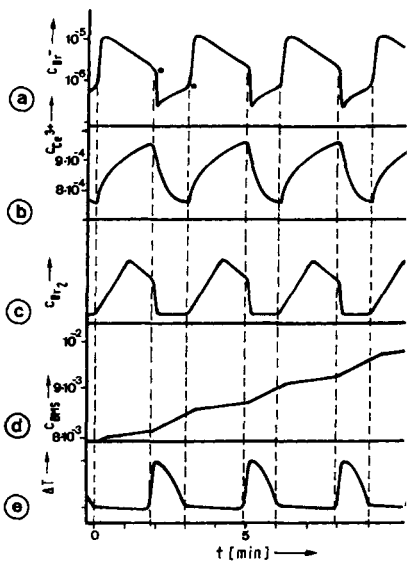

Fig. 4. Belousov-Zhabotinskii oscillation: bromination of malonic acid with bromate in the presence of Ce^{4+}. a) Br^- concentration [24]; b) Ce^{3+} concentration [79]; c) bromine concentration (spectroscopic measurement by *W. Geiseler* [79, 81]; d) concentration of bromomalonic acid (BMA) in a closed system (according to [80]); e) temperature oscillation in a heat-flow calorimeter (measurements by *W. Geiseler*) [79, 81]. The synchronization lines refer to the instability points of bromide concentration. Concentrations are given in mol l^{-1}.

The oscillation process is presented in synoptic manner with regard to the most important analytically accessible variables (Br^-, Ce^{3+}/Ce^{4+}, Br_2, bromomalonic acid, and temperature) in Figure 4.

The oscillations consist in a kind of flip-flop alternation between two reaction states: one in which Ce^{4+} is reduced and another in which Ce^{3+} is oxidized. The bromide concentration is relatively high in the reducing phase, and extremely low in the oxidizing phase. Formation of bromomalonic acid is more pronounced in the reducing phase than in the oxidizing phase. The same applies to the evolution of heat. Bromine appears briefly during the transition from the oxidizing to the reducing phase.

Noyes et al.[30,31] formulate the reaction sequence as follows: In the Belousov-Zhabotinskii reaction, bromination of malonic acid can, in principle, proceed *via* two mutually exclusive pathways.

a) Pathway involving reduction of Ce^{4+} to Ce^{3+} in the presence of bromide ion:

$$BrO_3^- + 2Br^- + 3H^+ \rightarrow 3HOBr$$
$$HOBr + CH_2(COOH)_2 \rightarrow BrCH(COOH)_2 + H_2O$$

Bromomalonic acid subsequently reduces the Ce^{4+} present to Ce^{3+}, thereby decomposing to CO_2 and bromide:

$$BrCH(COOH)_2 + 4Ce^{4+} + 2H_2O \rightarrow Br^- + 4Ce^{3+} + HCOOH + 2CO_2 + 5H^+$$
$$HCOOH + HOBr \rightarrow Br^- + CO_2 + H^+ + H_2O$$

The overall process in the reducing phase is:

$$BrO_3^- + 2CH_2(COOH)_2 + 4Ce^{4+} \rightarrow BrCH(COOH)_2 + 4Ce^{3+} + 3CO_2 + 3H^+ + H_2O$$

b) Pathway involving oxidation of Ce^{3+} to Ce^{4+} in the absence of bromide ion:

The oxidizing species is now bromate, which oxidizes Ce^{3+} and is itself reduced to HOBr. The latter then brominates malonic acid:

$$BrO_3^- + 4Ce^{3+} + CH_2(COOH)_2 + 5H^+ \rightarrow BrCH(COOH)_2 + 4Ce^{4+} + 3H_2O$$

Together, pathways a) and b) comprise the overall oscillation reaction:

$$2BrO_3^- + 3CH_2(COOH)_2 + 2H^+ \rightarrow 2BrCH(COOH)_2 + 3CO_2 + 4H_2O$$

The presence of Br^- thus determines which of the two bromination pathways is feasible. Each individual reaction pathway is assumed to proceed *via* intermediates not included in the above partial equations. Bromous acid ($HBrO_2$) is accordingly assigned a crucial role.

In the reducing phase (pathway a) the following intermediate steps are assumed to occur in the first equation:

$$BrO_3^- + Br^- + 2H^+ \rightarrow HBrO_2 + HOBr$$
$$HBrO_2 + Br^- + H^+ \rightarrow 2HOBr$$
$$\overline{BrO_3 + 2Br^- + 3H^+ \rightarrow 3HOBr}$$

In the oxidizing phase (pathway b), the reaction proceeds *via* the above mentioned and formulated autocatalytic step involving $HBrO_2$ (reaction 3). This species disproportionates to bromate and HOBr, which subsequently brominates malonic acid:

$$2BrO_3^- + 2HBrO_2 + 4Ce^{3+} + 6H^+ \rightarrow 4HBrO_2 + 4Ce^{4+} + 2H_2O$$
$$2HBrO_2 \rightarrow BrO_3^- + HOBr + H^+$$

$$BrO_3^- + 4Ce^{3+} + 5H^+ \rightarrow HOBr + 4Ce^{4+} + 2H_2O$$
$$HOBr + CH_2(COOH)_2 \rightarrow BrCH(COOH)_2 + H_2O$$

$$BrO_3^- + 4Ce^{3+} + CH_2(COOH)_2 + 5H^+ \rightarrow BrCH(COOH)_2 + 4Ce^{4+} + 3H_2O$$

This is the equation of pathway b).

Numerous experimental results suggest that the formulations presented here provide an essentially correct description of the individual reaction steps. However, various questions remain open, particularly in connection with the actual origin of the oscillations. A system of four simultaneous differential equations derived from the above formulations, called the "Oregonator"[25] by analogy with the "Brusselator" and which also has oscillatory solutions, takes the following form:

$$A + Y \rightarrow X + P$$
$$X + Y \rightarrow 2P$$
$$A + X \rightarrow 2X + Z$$
$$2X \rightarrow P + A$$
$$Z \rightarrow \frac{PY}{a+P} - \frac{P^2}{a+P}$$

$A = BrO_3^-$; $X = HBrO_2$; $Y = Br^-$; $Z = 2Ce^{4+}$; P = bromomalonic acid. A detailed discussion of the resulting differential equations will be found in the specialist literature[18-33].

2.1.2. Thermochemical Oscillations in Gas Reactions

Periodic reaction courses are also observed in a number of gas reactions. A typical example is shown in Figure 5. As with the periodic reactions occurring in solution, interfacial structures play no part.

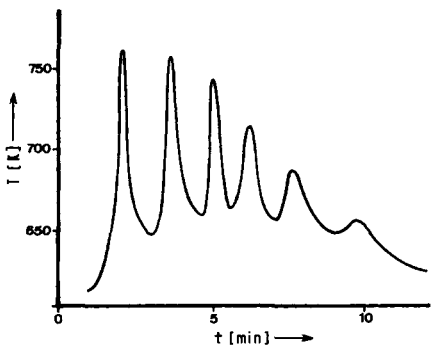

Fig. 5. Temperature oscillation in the thermochemical oxidation of propane in oxygen (C_3H_8: 50 mol %. P: 75 kNm^{-2}) (according to [37]).

On oxidation of hydrocarbons in mixtures with oxygen, "cold flames" occur at relatively low temperatures ($\approx$400 °C)[34-38]. This kind of combustion frequently proceeds with rhythmic emission of pale blue light and periodic evolution of heat.

Oscillations are also observed on combustion of hydrogen sulfide[39] and of carbon monoxide[40-42] in oxygen. The oscillations of phosphorus vapor in contact with oxygen described by *Rayleigh*[43, 44] may also belong to this class of periodic chemical reactions.

The kinetics of thermochemical oscillations is still poorly understood. Once again, however, autocatalytic processes and chemical feedback are known to play an important part. In gas phase reactions, autocatalysis frequently involves branched chain reactions which can occur both in the formation and in the decomposition of intermediates. Gas reactions generally span wide ranges of temperature. Under these conditions, the temperature dependence of the rate constants leads to marked non-linearity and non-stoichiometric coupling between all the participating reactions.

Two oscillating thermochemical reactions have recently been studied in particular detail, *viz.* the oscillations of cold flames of propane at about 330 °C (Fig. 5)[37] and the thermochemical oscillations of carbon monoxide in oxygen at 600 °C[41, 42]. The kinetics of these reactions is apparently very complicated. The most important reactions involve short-lived radicals which are very difficult or impossible to detect analytically. In the oscillatory combustion of CO[42], 18 reactions of 12 reactants are under consideration—eight simultaneous kinetic differential equations are obtained. An incomprehensible variety of material and thermal coupling modes results.

2.2. Oscillations in Heterogeneous Systems

This Section is concerned with systems whose oscillatory behavior is strictly linked with interfacial structures. Such is the case when one of the oscillatory variables is electrical in nature.

Oscillations in electrochemical systems concern changes of state involving local currents between regions in different electrochemical states. Such local currents can occur in closed circuits only at interfaces present at electrodes and ion membranes.

The treatment of heterogeneous catalytic reactions requires a knowledge of the structure of the interface because reaction-dependent interfacial states are crucial to the occurrence of periodicity.

2.2.1. Electrochemical Oscillations

Periodic electrode processes are the longest known of all chemical oscillations. As long ago as 1828, such reactions were reported by *Fechner*[45]. Around the turn of the century, *Ostwald*[46, 47] engaged in a thorough study of the oscillations of potential and corrosion of chromium in hydrochloric acid and of iron in nitric acid. He was the first to recognize a surprisingly complete kinetic analogy between electrochemical and electrophysiological oscillations[48] which is not limited merely to the actual oscillations but extends over the entire phenomenology of nervous stimulation. This was demonstrated by very impressive analogy experiments performed in the 1920's and 1930's by *Lillie*[49, 50].

Systematic physicochemical research into chemical oscillations did not begin until about 1940 with *Bonhoeffer*'s fundamental studies[51-53] on the "Ostwald-Lillie nerve model" and "Periodic chemical reactions".

We are now familiar with a large number of electrochemical oscillations. Most of them are observed at electrodes on which

anodic or cathodic surface layers can form. Such electrodes generally possess non-monotonic current-voltage curves, which arise because surface layer formation or removal sets in at a particular electrode voltage.

The current usually changes abruptly and the current-voltage curve shows the N-shaped course characteristic of surface layer electrodes[54, 55]. With suitable external circuitry, *i.e.* with a suitable position of the load line, the possibility of bistability arises which is one of the prerequisites for the occurrence of oscillations.

sponds to positive feedback and the coupled regeneration process to negative feedback.

There is also another kind of electrode oscillation[56] which differs in its temporal course and frequency from passivation-activation oscillation, and occurs only under potentiostatic conditions.

These oscillations are usually associated with electropolishing effects. Their frequency is relatively high, lying between 80 and 4000 Hz (Fig. 7). They give rise to a flickering effect which can readily be observed under a microscope. At certain

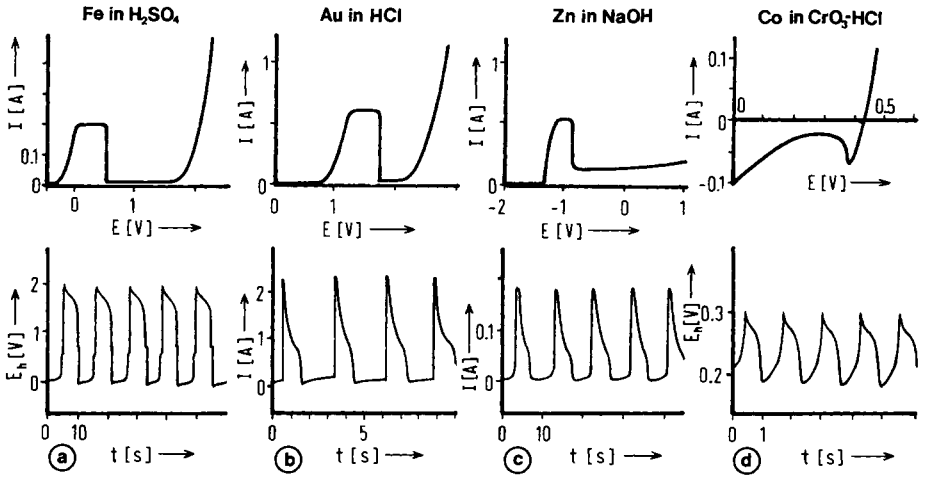

Fig. 6. Examples of electrochemical oscillations. Upper row, non-monotonic current-voltage curves; lower row, galvanostatic (I = const.) or potentiostatic (E = const.) oscillations. a) Galvanostatic voltage oscillation at iron in 3.16 N H_2SO_4 + 0.04 N HCl [56, 59]; b) potentiostatic current oscillation at gold in 4 N HCl at $E_h = +1.75$ V [82, 54]; c) potentiostatic current oscillation at zinc in 4 N NaOH at $E_h = -1.1$ V [82, 83]; d) spontaneous ($I = 0$) voltage oscillation at cobalt in 0.4 M CrO_3 + 1 N HCl [82, 84, 85].

Some typical examples of non-monotonic current-voltage curves and oscillograms recorded for surface layer electrodes are presented in Figure 6.

Periodicity at these electrodes arises because the voltage-independent passivation-activation process is coupled with a further process which, after a brief lapse of time, reverses the change of state resulting from passivation or activation. This mechanism will be examined more thoroughly in Section 3.3. It will also be shown that passivation-activation corre-

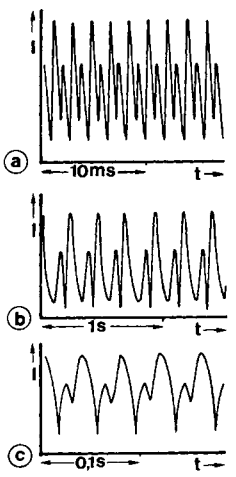

Fig. 7. Fast potentiostatic "flicker" oscillations [56, 83] a) at zinc in 1 N H_2SO_4 at $E_h = -0.29$ V; b) at iron in 1 N H_2SO_4 at $E_h = +0.3$ V; c) at silver in 0.7 N KCN at $E_h = +0.53$ V.

electrode potentials the flickering shows some degree of synchronization and interference colors appear, *e.g.* on zinc in sulfuric acid. The mechanism of these oscillations is not yet completely understood. It seems reasonable to invoke dynamic dissipative structures which synchronize at certain potentials and then become recognizable in the external current.

2.2.2. Oscillations in Membrane Systems

Electrochemical oscillations can occur at ion-conducting membranes in the same way as at electron-conducting electrodes. The electrophysiological oscillations of nerve, muscle, and sensory organ cells of living organisms are known to take place at such membranes. *Teorell*'s observation[57, 58] that even very simple porous ion exchange membranes exhibit oscillatory behavior under constant external conditions attracted considerable interest in this context.

The "Teorell membrane oscillator" has since been studied in great detail with respect to its ion-transport kinetics. It consists of a highly porous membrane of ion exchange material separating two compartments, which contain sodium chloride solutions of different concentrations, and carrying a constant electrical current (Fig. 8a). The essential oscillatory variables are the membrane potential E, determined by the membrane resistance, and the hydrostatic pressure P which is set up as a consequence of the hydrodynamic and electroosmotic volume flow V between the compartments on the two sides of the membrane.

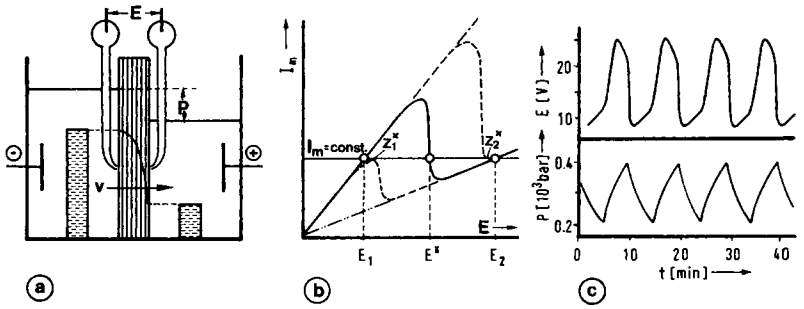

Fig. 8. The Teorell membrane oscillator. a) Experimental set-up; b) current-voltage curve [59]; c) oscillations of voltage and pressure [58, 59].

The voltage and pressure oscillations occurring in the Teorell oscillator are shown in Figure 8c. The membrane may consist of unglazed porcelain, porous sintered glass, porous plastic, or pressed powders of quartz, metal oxides, or organic ion-exchanger material.

Oscillations occur when the sign of the fixed ion charge, the direction of the electric current, and the concentration gradient of the salt solutions can be suitably combined[59, 60]. Under such conditions the membrane has a non-monotonic current-voltage curve (Fig. 8b) as a result of reversal of the direction of flux of the salt solution at a particular membrane potential and the membrane resistance jumps to the value corresponding to the modified influx of salt solution.

In Figure 8b the load line I_m=const. intersects the non-monotonic membrane characteristic at three positions: hence three steady states occur, of which the middle one is unstable and the two outside ones are stable. The volume flux, which is driven antagonistically by the pressure (P) and potential (E), shifts the critical flux reversal potential E^x in the same way as the hydrostatic pressure changes with the volume flux. The system becomes unstable at the limits shown in Figure 8b, the volume flux reverses, and the potential jumps onto the other branch of the membrane characteristic. In this way the state of the system alternates periodically between the two points of instability (Z_1^x and Z_2^x). The oscillations thus represent spontaneous alternating initiation of changes of state of the membrane which are triggered by the hydrostatic pressure, which itself depends upon the particular membrane state. The Teorell membrane oscillator convincingly shows how instability and kinetic coupling lead to oscillation. The existence of the non-monotonic characteristic is a consequence of positive feedback whereas the hydrostatic pressure effects a negative feedback.

From a chemical and structural standpoint, two other artificial excitable membranes resemble the oscillatory nerve membrane even more closely. These are the bimolecular lipid membranes containing antibiotics, which were developed by *Müller* and *Rudin*[61] (Fig. 9a), and the polyelectrolyte membranes produced and studied by *Shashoua*[62, 63] (Fig. 9b).

Both kinds of membranes are capable of oscillation and exhibit electrophysiological excitation phenomena. Like the Teorell membrane, they possess non-monotonic current-voltage curves. They are therefore bistable and have unstable states. In the case of the lipid membranes this behavior is caused by a pore-formation mechanism of the incorporated antibiotic (*e.g.* alamethicin). *Shashoua*[62] assumes that a mechanism of cation-anion contact analogous to the p-n junction in semiconductors operates in the polyelectrolyte membrane.

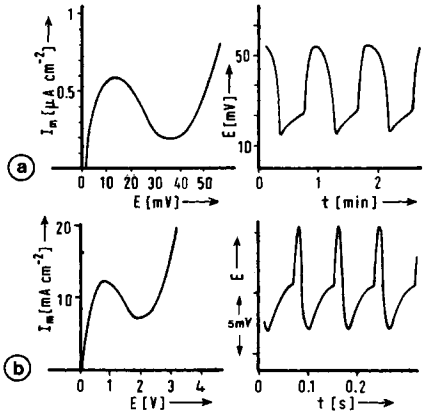

Fig. 9. Oscillations at biochemical membranes. a) Müller-Rudin oscillator [61]; left, current-voltage curve; right, galvanostatic voltage oscillation at a phosphatidylcholine double-layer membrane containing 10^{-7} g ml^{-1} of alamethicin and 10^{-5} g ml^{-1} of salmin. I = 3.2 μA cm^{-2} (according to experiments by *G. Boheim* [86]). b) Shashoua oscillator [62]; left, current-voltage curve of a polyglutamate-Ca^{2+} ion exchange membrane; right, voltage oscillation at a methacrylate-acrylic acid-Ca^{2+} membrane.

2.2.3. Chemical Oscillations in Systems with Heterogeneous Catalysts

Oscillations in heterogeneous systems include the periodic reactions observed in contact catalytic reactors. That unstable reaction states occur in exothermic reactions of gases at heterogeneous catalysts follows from theoretical studies by *Wagner*[64], *van Heerden*[65], and *Frank-Kamenetzkii*[66].

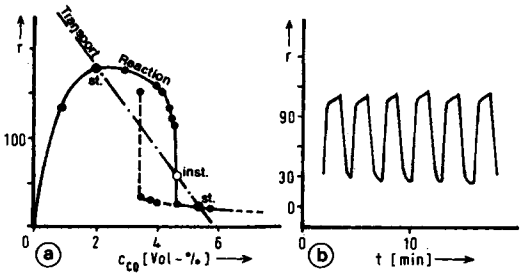

Fig. 10. Oscillation in the oxidation of CO by air at a platinum-Al_2O_3 contact catalyst. a) Reaction-transport characteristic; r is the relative rate constant in ppm CO_2 in exhaust gas; the broken curve indicates hysteresis on reverse order of measurement; b) oscillation at a single grain of catalyst; r refers to the CO_2 concentration in ppm (according to [67]).

The most exhaustive experimental studies have been performed on the oscillatory behavior of the oxidation of carbon

monoxide and of hydrogen by atmospheric oxygen over platinum-alumina catalysts[67]. Figure 10 shows an example of such an oscillation in a heterogeneous reaction taken from the work of *Wicke et al.*[67]. As in electrochemical oscillatory systems, non-monotonic reaction characteristics are found once again. There exist an unstable reaction state and two stable steady states.

Reactors of this kind are thus also bistable in the non-oscillatory state[67, 68], and the oscillations are periodic alternations between two quasi-stable reaction states. Two possible feedback modes exist in heterogeneously catalyzed reactions: 1) by the non-linear temperature dependence of catalyzed exothermic reactions and 2) by kinetic action of the reaction products on the effectiveness of the catalyst, for example by changing the surface coverage. The first case is an example of positive feedback and the second case one of negative feedback. Both kinds of feedback can lead to oscillations.

2.3. Oscillations in Biological Systems

Rhythmic processes are characteristic of living organisms. Elementary oscillatory phenomena were recognized and studied very early in electrophysiology, and hence much of the terminology of oscillation and excitation kinetics comes from neurophysiology.

2.3.1. Electrophysiological Oscillations

Oscillations of cells of nerve and muscle tissue and of sensory organs are periodic excitation processes at ionic membranes (Fig. 11) which possess a specific, potential-dependent selectivity for sodium and potassium ions. As a result, the nerve membrane exhibits a non-monotonic current-voltage curve like that of non-living ion membranes capable of oscillation and therefore possesses bistability and instability. The nature of the second or further kinetic variables has not yet been

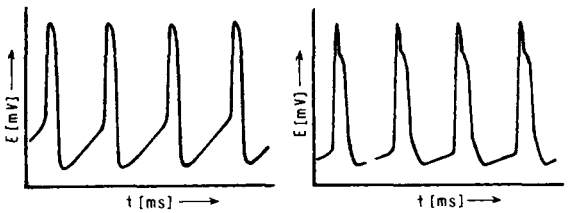

Fig. 11. Oscillations at biological membranes. a) At an octopus nerve fiber [87]; b) at a single heart muscle fiber [88].

unequivocally established for biological membranes capable of oscillation. Divalent ions such as the calcium ion might play an essential role.

2.3.2. Enzymatic Oscillations

Purely chemical oscillations have been known to occur in living organisms since 1955, when *Wilson* and *Calvin*[69] first observed such processes in the dark reaction of photosynthesis. Meanwhile, oscillatory reaction courses have been detected in numerous areas of biochemistry, in cell respiration, in carbohydrate metabolism, in enzyme synthesis, mitosis, morphogenesis, regeneration of damaged cells, and other essential life processes. The common feature of all these oscillations is their enzymatic nature.

Enzymatic reactions are known to be catalytic processes in which the enzyme is regenerated in a cyclic manner. It would appear that these reaction cycles do not always occur at a steady rate but rather in rhythmic waves. The reason is clearly seen to lie in the frequent substrate- or product-dependence of the enzyme effectiveness. Chemical feedback is then possible and the condition for an oscillatory reaction course is thus fulfilled.

In 1957, *Duysens* and *Amesz*[70] observed that glycolysis, *i.e.* the anaerobic degradation of glucose in living cells to pyruvate, follows a periodic course. The oscillatory glycolysis system can be isolated from cellular material by extraction and studied *in vitro*[71, 72]. In homogeneous phase this oscillation has the advantage that it can be relatively easily monitored by observing the fluorescence of the NADH participating in the reaction (Fig. 12).

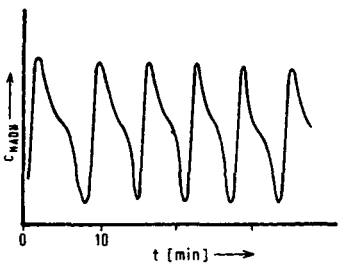

Fig. 12. Oscillation in glycolysis. The reduced form of nicotinamide dinucleotide (NADH) participating in glycolysis exhibits readily measurable fluorescence permitting fluorimetric monitoring of the oscillation (according to [89]).

Although the mechanism of oscillation of glycolysis has not yet been fully elucidated, a number of important chemical and kinetic aspects of this interesting process are known.

Phosphofructokinase, an allosteric enzyme, seems to play a critical role. This enzyme is inhibited by one of its substrates, ATP, and activated by its products, ADP and fructose 1,6-diphosphate. The chemical feedback necessary for oscillation is thus ensured[73].

Yamazaki, *Yokota*, and *Nakajima*[74, 75] found the peroxidase oxidation of NADH by atmospheric oxygen to be the first periodic enzyme reaction which can be maintained indefinitely in a thermodynamically open system.

2.4. Non-oscillatory Phenomena of Systems Capable of Oscillation

The special kinetic situation existing in oscillatory systems, due primarily to non-linear relationships, to kinetic coupling, and to instability, leads to typical temporal behavior when oscillations no longer occur under modified conditions. Non-oscillatory phenomena of this kind can provide valuable clues as to the nature of individual processes involved in the origin of oscillations.

The surprising degree of similarity in the behavior of systems capable of oscillation is apparent from the survey of their phenomenology presented in Figure 13[76, 77]; this survey could be readily extended. It also includes a very simple electronic semiconductor system (neurodyn model) which was developed on the basis of common kinetic features. It consists of a tunnel diode (TD) with a non-monotonic current-voltage curve and a NTC thermistor with the properties of coupled

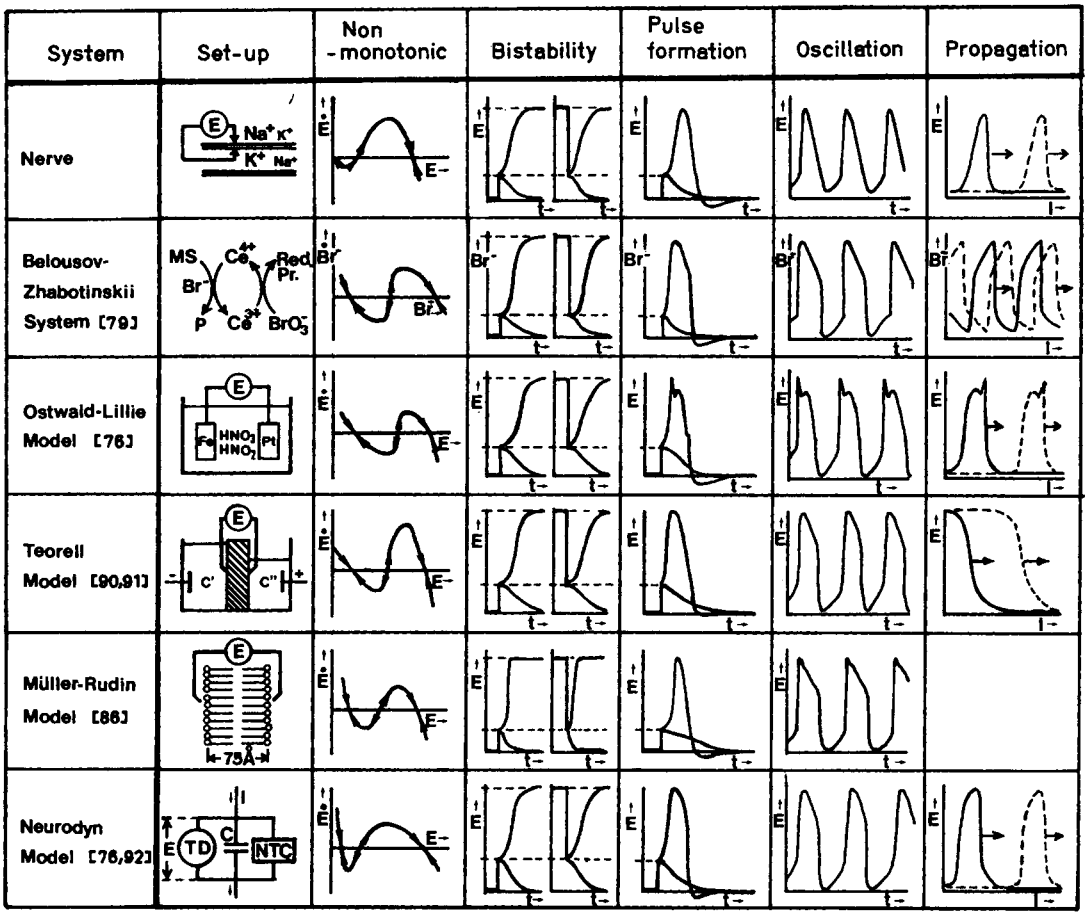

Fig. 13. Phenomenological analogy between chemical and physicochemical oscillatory systems. MA, malonic acid; P, product; Red. Pr., reduced products; $\dot{E}=dE/dt$; $\dot{B}r^-=dBr^-/dt$. The right- and left-hand curves in the column headed "Bistability" refer, respectively, to excitation from the lower to the upper and from the upper to the lower stable steady state; the broken lines indicate the position of the steady states.

regeneration. The entire phenomenology of excitable and oscillatory systems can be simulated with this model[76,92].

Systems no longer in oscillation usually still possess bistability (see Fig. 2a). Interconversion of the two stable reaction states, which can be triggered by external perturbation, obeys the so-called "all-or-none law" and therefore has threshold character. Typically, such transitions between states propagate spontaneously throughout the system once induced at a point by local transport processes ("local fluxes") set up at the boundaries between regions in different reaction states resulting from the bistability of the system (cf. Fig. 15).

In some cases, the triggered system may return to the original state in a spontaneous regeneration process coupled with the triggering reaction. We then have the phenomenon of triggered reaction pulses (for example, action potentials of nerves), which likewise propagate spontaneously.

The ubiquitous phenomena of overshoot (Fig. 2b), refractarity, and accommodation, which are all consequences of coupled regeneration, will not be considered in this article. The individual terms mean threshold alteration under superthreshold conditions (refractarity) or subthreshold conditions (accommodation).

3. Theory of Chemical Oscillations

The phenomenology of the oscillatory systems shows that certain thermodynamic and kinetic conditions must be fulfilled for periodic behavior to occur. The most important conditions will now be briefly summarized:

a) Oscillatory processes concern temporal changes of state which take place remote from thermodynamic equilibrium. They occur as temporally unlimited phenomena only in thermodynamically open systems, *i.e.* systems with a material flux.

b) Several kinetic variables participate in the periodic process. It follows from the phase shifts recognizable in the oscillograms that the variables are not directly interdependent but merely coupled with one another kinetically, *i.e.* they can be set independently but nevertheless mutually affect each other's rates of change. Hence no direct functions exist of the kind $y=f(x,...)$ but only a set of simultaneous differential equations of the kind:

$$\frac{dx}{dt}=f_x(x,y,...)$$

$$\frac{dy}{dt}=f_y(x,y,...)$$

. . .
. . .
. . .

c) Oscillatory systems are non-linear in their kinetic relationships, and they contain autocatalytic or autoinhibitory processes.

3.1. Multivariable Kinetics of Chemical Oscillations

Periodic chemical reactions are thus seen to be understandable only on the basis of multivariable kinetics, describable only in terms of sets of simultaneous differential equations.

Since two variables already suffice for a description of oscillations we shall limit the following brief treatment of multivariable kinetics to cases involving two variables:

The system under consideration will be described by two simultaneous differential equations in the kinetic variables x and y:

$$\frac{dx}{dt} = f_x(x,y);$$

$$\frac{dy}{dt} = f_y(x,y)$$

Elimination of the common term t gives:

$$\frac{\frac{dy}{dt}}{\frac{dx}{dt}} = \frac{dy}{dx} = \frac{f_y(x,y)}{f_x(x,y)}$$

i.e. an expression describing the direction in which the state of the system changes at each point x, y in an x/y coordinate system. A time-free "state portrait" (phase plane) of the system described by the kinetic differential equations is obtained. The reaction vectors thus given for each point form continuous trajectories which can be shown to intersect only at discrete points. The intersections of the trajectories shown are the steady states of the system. They may be stable or unstable, depending upon whether the temporal changes along the trajectories are directed into or out of the singular point. Figure 14 shows the portraits of the surroundings of various kinds of singular points occurring in kinetic systems. They may be "nodes", "foci", or "saddle points". The lines which

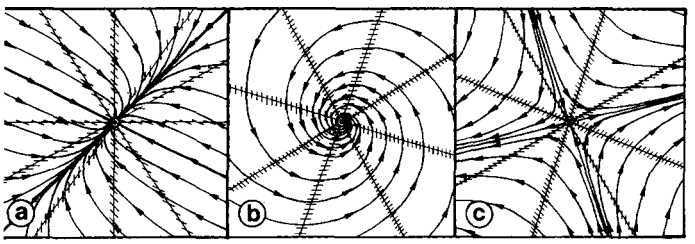

Fig. 14. Trajectories and isoclines surrounding singular points (=steady states) in the two-dimensional portrait of state. a) Stable nodes; b) stable foci; c) saddle point.

join states having the same direction of their trajectories in the state portrait are called isoclines.

The portraits of non-linear coupled systems of particular interest in the present article are shown in Figure 15. The cases shown are those of bistability, pulse formation, and oscillation, which are readily interconvertible by variation of the coefficients in the two kinetic differential equations.

Systems exhibiting bistability (Fig. 15a) possess three singular points, of which the middle one is a saddle point and the other two nodes or foci.

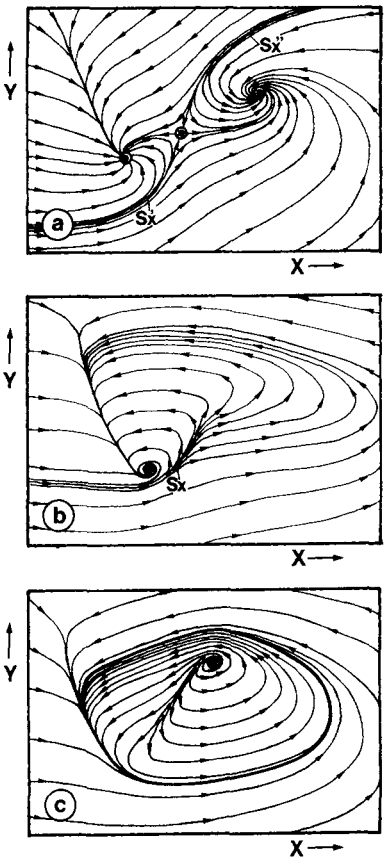

Fig. 15. State portraits of coupled systems. a) Bistability; b) excitable pulse formation (monostability); c) oscillation (astability). S_x = separatrix. The portraits correspond to the behavior of the neurodyn oscillator shown in the bottom row of Fig. 13 (experiments by *E. Lammel* [93]).

In the case of pulse formation ("monostability") (Fig. 15b) there exists only one stable node or focus and a "separatrix" (S_x), which determines whether the system returns directly (subthreshold stimulus) or *via* an extended route to the stable singular state (superthreshold stimulus).

In the oscillatory case (Fig. 15c) there arises a boundary cycle into which all the trajectories approach, whether they come from without or within. The system moves indefinitely on this closed loop, and its projections onto the x axis and the y axis show the oscillations of these two variables. They are seen have a phase lag of about one quarter of the entire cycle. In simultaneously recorded oscillograms one variable is seen to undergo maximum change when the other exhibits minimum change at its point of inversion. The kinetic situation in chemical oscillations is thus completely analogous to those known in mechanical and electrical oscillatory systems.

It is seen in Figure 15c that oscillatory systems in the interior of the boundary cycle contain a singular state which is an unstable focus.

In order to assess the behavior of systems including two kinetic variables, great importance attaches to the analysis of the isoclines (Fig. 14). Like the trajectories they intersect only at singular points; unlike the trajectories, however, which are generally no longer calculable in elementary form by integration, the isoclines are usually obtainable as relatively simple functions of x and y from the relation

$$f_y(x,y) - \sigma f_x(x,y) = 0$$

where $\sigma = dy/dx = \text{const.}$ refers to the trajectory slope characterizing the relevant isocline.

By means of the isoclines, the trajectories or paths of state can be approximately shown in the portrait of state and the properties of the singular states determined; in particular, it can be deduced from the position and shape of the isoclines whether a given system of simultaneous differential equations possesses oscillatory solutions or not.

3.2. The Problem of Stoichiometric Chemical Oscillations

The facts that chemical oscillations have hitherto always been discovered merely by chance and that no oscillatory system has yet been "synthesized" from known reactions, together with the failure to completely elucidate even one of the known oscillations, underline the difficulties besetting the formulation of periodic reactions with stoichiometric reaction equations.

The question then arises as to the possibility of realistic stoichiometric reactions being able to meet the known requirements for oscillation.

Only systems of two kinetic variables will be considered, and the following limitations apply:

a) The realistic range of existence lies in the first quadrant of the x/y coordinate system since x and y are concentrations and cannot assume negative values.

b) The isoclines must intersect at least once in the first quadrant in order that at least one steady state exists there.

c) The chemical reaction must be of second order or lower since reactions of higher order are unlikely or unrealistic.

Bearing these limitations in mind, there remain surprisingly few kinds of reactions which can be considered in setting up stoichiometric reaction mechanisms. Only five normal non-catalytic and two autocatalytic reactions are left in the discussion:

a) Uncoupled reactions (containing only one variable):

$A + X \rightarrow P$
$X + X \rightarrow P$
$A + X \rightarrow 2X$ (autocatalytic)

b) Coupled reactions (containing both variables):

$A + X \rightarrow Y$
$X + X \rightarrow Y$
$X + Y \rightarrow P$
$X + Y \rightarrow 2X$ (autocatalytic with respect to X)

These seven kinds of equations yield seven types of kinetic terms which can occur in the kinetic equations; it should be remembered that X and Y are interchangeable.

$$\frac{dx}{dt} = -kx \qquad \frac{dy}{dt} = +kx$$

$$\frac{dx}{dt} = -2kx^2 \qquad \frac{dy}{dt} = +kx^2$$

$$\frac{dx}{dt} = +kx \text{ (autocatalytic)} \qquad \frac{dx}{dt} = -kxy$$

$$\frac{dx}{dt} = +kxy \text{ (autocatalytic)}$$

Thus only linear and quadratic terms (x^2, y^2, xy) appear. Under these conditions the isoclines are always second order curves, *i.e.* conic sections; for the above terms they are hyperbolae, parabolae, and straight lines.

Taking into account the permissible kinetic terms, isocline analysis provides valuable information about the behavior of stoichiometric systems.

a) If the kinetic equations are linear and do not include an autocatalytic process, only one singular state occurs which is always a stable node in the first quadrant.

b) If the xy term is also present, the singular state can also be a focus, *i.e.* attenuated oscillations become possible.

c) If one of the linear terms is autocatalytic ($dx/dt = +kx$), then two singular states can occur in the first quadrant, of which one is a stable node and the other a saddle point, *i.e.* the system is excitable.

d) If quadratic terms are also present, three singular states can form in the first quadrant; the middle one is a saddle point and the others stable nodes. Bistability thus becomes possible[94].

e) Indefinite oscillations are *not* possible with the linear and quadratic terms given above.

If the choice of reactions is limited to stoichiometric ones, oscillations only become possible if terms of higher order (>2) are present in the kinetic equations.

In this context, the reader is reminded that, of the mathematical models of stoichiometric oscillations mentioned in Section 2.1.1, the Brusselator[12,13] includes a trimolecular reaction and the Oregonator[31] more than two kinetic variables and a non-stoichiometric coefficient ($P/(a+P)$).

A further realistic possibility for the generation of oscillations is provided by the presence of non-stoichiometric coupling processes, such as occur in chain branching and enzymatic reactions.

3.3. The Feedback Concept of Chemical Oscillations

The occurrence of unattenuated oscillations in electrical circuits and control loops as a consequence of feedback effects is a well known fact. Application of this concept to chemical reactions is unfamiliar since circuits and loops are not so immediately obvious. However, on closer study of chemical and physicochemical oscillation a very close analogy is seen to exist.

Feedback occurs when a process acts kinetically upon itself. It therefore consists basically in a closed chain of action. Such a cycle can arise in two ways:

a) If the output of a transmission system acts upon the input of the same system then we have a situation in which an "effect" is influencing its own "cause". Depending upon whether self-enhancement or self-inhibition occurs the phenomenons is described as positive or negative feedback, respective-

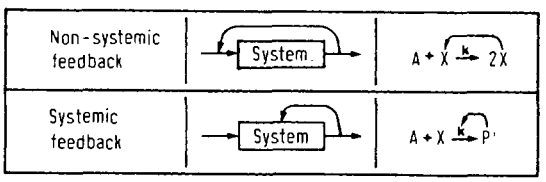

Fig. 16. "Non-systemic" and "systemic" feedback in chemical systems.

ly. The chemical analogy is stoichiometric autocatalysis (Fig. 16, top) in which the reaction product is also a reactant. This form of feedback has no effect upon the properties of the transmission system or upon the rate constant of the reaction. It is therefore designated "non-systemic" feedback.

b) Many feedback mechanisms act not upon the input but instead upon the transmission system itself. The kinetic analog is a reaction in which the reaction product influences the rate constant (Fig. 16, bottom). Owing to its action upon the properties of the system, this kind of feedback will be termed "systemic" feedback. It is the commonest kind of kinetic coupling in heterogeneous systems, *e.g.* at electrodes, contact catalysts, and membranes. It can arise in homogeneous systems, *e.g.* as a result of the markedly non-linear temperature dependence of the rate constants in thermochemical reactions, and in enzymatic systems, *e.g.* owing to the dependence of the catalytic activity of allosteric enzymes upon their products or substrates.

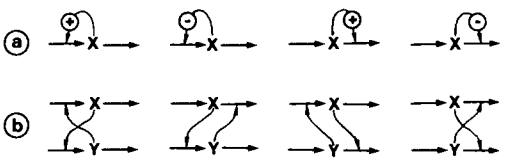

Fig. 17. Possible coupling modes in simply coupled chemical systems. a) Intrinsic coupling (autocatalysis ⊕, autoinhibition ⊖); b) cross-coupling (cross-catalysis, cross-inhibition).

Systemic feedback is usually non-stoichiometric (non-linear) and thus much more favorable to oscillations than stoichiometric non-systemic feedback which is linear, being restricted to bimolecular reactions.

In open systems, autocatalytic and autoinhibitory reactions can produce positive or negative feedback, depending upon whether the self-coupling affects the formation or consumption reaction of the coupled component. Four cases can occur (Fig. 17a), of which the first and last lead to positive feedback and the two middle ones to negative feedback.

Non-systemic or systemic coupling can also occur in kinetic interactions between simultaneous reactions. Feedback then occurs by "cross-catalysis", a concept introduced into the kinetics of chemical oscillations as long ago as 1948 by *Bonhoeffer*[52].

Once again there are four possible coupling modes which can lead to positive or negative feedback depending upon the direction of action of the individual couplings (Fig. 17b).

With regard to the occurrence of oscillation, interest is focused mainly on the kinetic behavior of chemical systems with positive and negative feedback. This will be considered with the aid of Fig. 18:

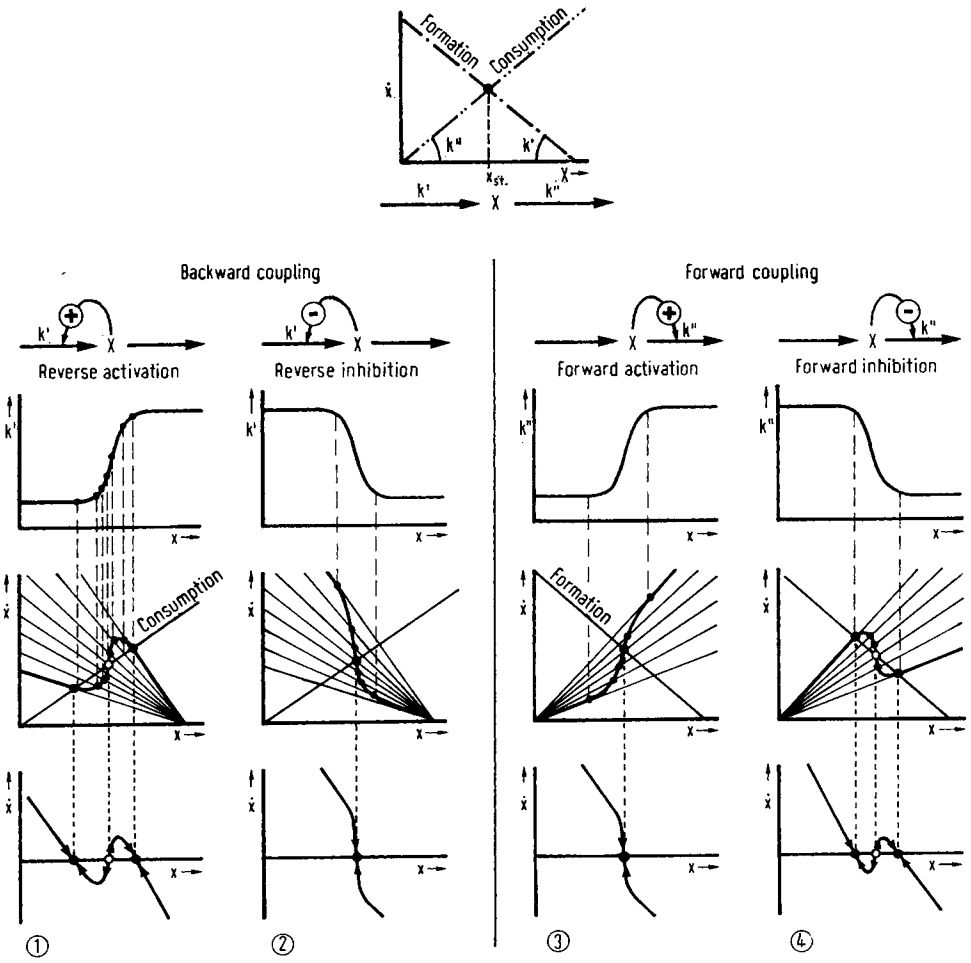

Fig. 18. Occurrence of typical kinetic characteristics by positive and negative feedback. Reverse activation (1) and forward inhibition (4) correspond to positive feedback effects, and reverse inhibition (2) and forward activation to negative feedback effects. $\dot{X} \equiv dX/dt$.

Assuming for the sake of simplicity that the formation and consumption reaction are of first order, a plot of dX/dt *versus* X for these reactions gives two straight lines which intersect at the steady state. Their slopes correspond to the relevant rate constants. Self-coupling alters the slope of one of the two lines according to the value of X: the formation reaction in the case of backward coupling, and the consumption reaction in the case of forward coupling. It can be seen in Figure 18 that non-monotonic characteristics result from positive feedback and monotonic characteristics from negative feedback. Thus, given sufficiently strong positive feedback, bistability and instability arise. Positive feedback therefore labilizes the system and is the actual cause of the propagation phenomenon occurring on adequate ("superthreshold") stimulation.

In contrast, negative feedback has a stabilizing effect and always generates only one stable steady state. The bottom row of Figure 18 shows the "dynamic" diagrams which describe the overall behavior of the feedback systems with respect to the formation and consumption of component X and which illustrate the stability situation by means of the inserted arrows.

Characteristic temporal behavior patterns result for positive and negative feedback, and can be used for experimental determination of the kind of feedback operating in a particular system (Fig. 19)[78]. In the case of positive feedback the system behaves in the manner of a capacitor. If the corresponding characteristic is non-monotonic then the threshold character of the triggering process is apparent.

In contrast, systems with negative feedback behave like an inductance and exhibit characteristic "overshoot" phenomena (see Fig. 2b).

always observed[78]. The oscillations arise from the antagonistic interaction of a relatively fast acting labilizing positive feedback and a slower acting stabilizing (regenerative) negative feedback. This situation can be represented in a simple feedback action scheme (Fig. 20). Hence the occurrence of oscillations depends not only upon the presence of both kinds of feedback but also upon the correct ratio of the action times.

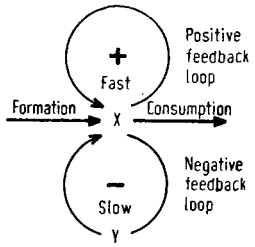

Fig. 20. Principle of antagonistic feedback in oscillatory systems.

As a supplement to Figure 13, the phenomenology of feedback systems and their causes are surveyed in Figure 21.

Each feedback loop can contain several variables in consecutive reactions. All these variables participate in the oscillatory process. In most cases it is possible to decide experimentally to which class of feedback a recorded oscillating variable belongs[78]. As shown by the examples in Figure 22, variables of the positive feedback loop are generally recognizable by pronounced discontinuities or resting points in their oscillograms which are due to the unstable states through which

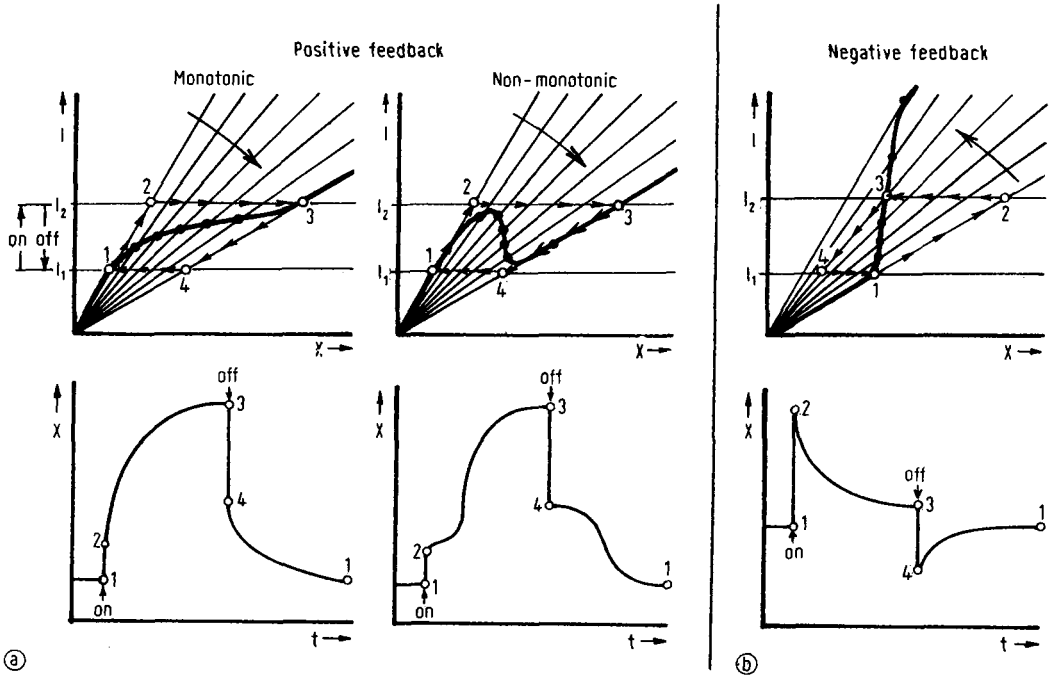

Fig. 19. Temporal behavior of electrochemical feedback systems [78] on sudden change of current. Systems with positive feedback have "pseudo-capacitive" properties, and systems with negative feedback "pseudo-inductive" properties.

On studying chemical oscillations with regard to their temporal behavior, characteristics of both kinds of feedback are

the systems pass. Variables of the negative feedback loop never exhibit such features owing to the absence of instabilities;

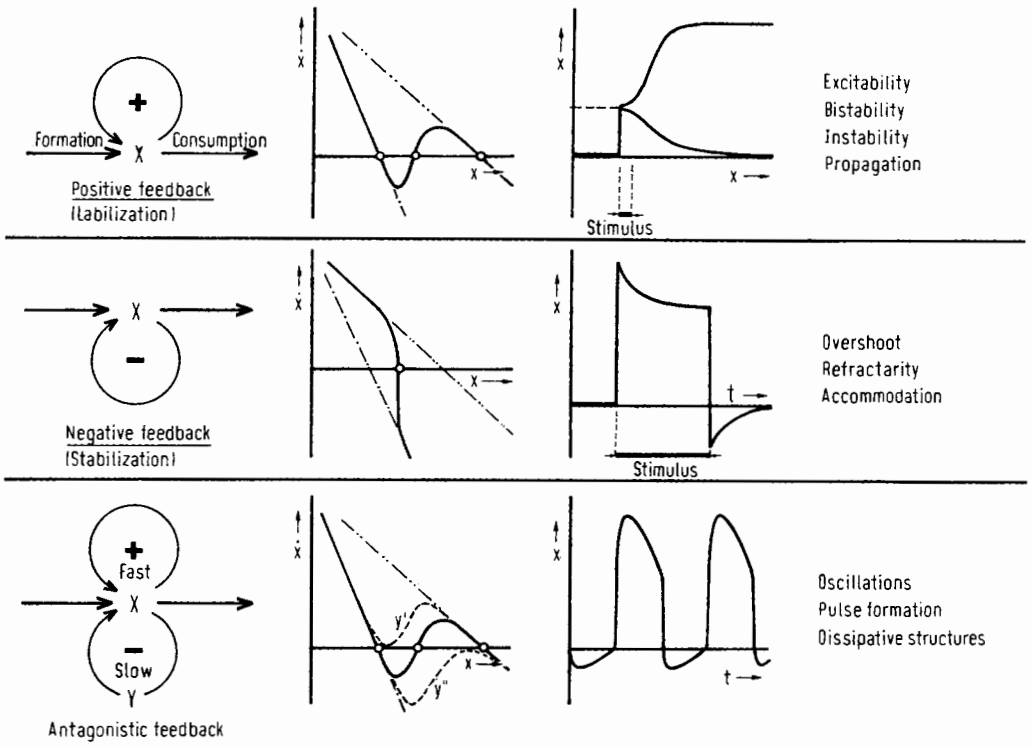

Fig. 21. Phenomenology of coupled systems and assignment to the various kinds of feedback.

their oscillograms therefore usually have a relatively simple sawtooth shape.

Chemical and electrochemical oscillations occasionally occur in chemical engineering, *e.g.* in heterogeneously catalyzed oscillations (Section 2.2.3). However, they have little engineering significance as far as improvement of overall processes is concerned. Instead, they represent an undesirable complication.

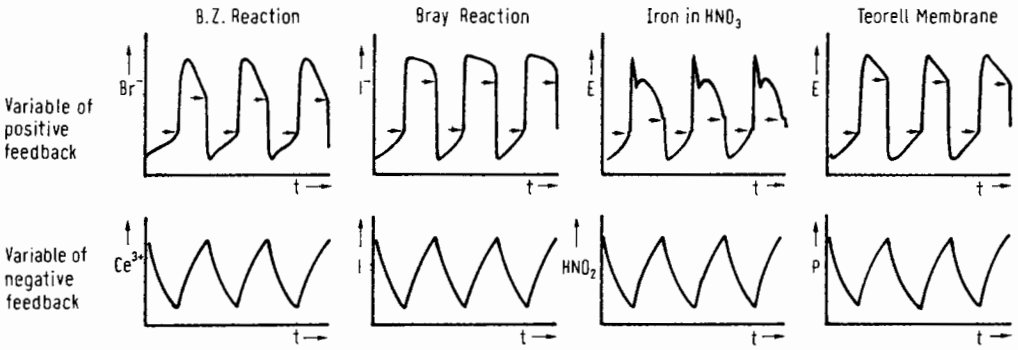

Fig. 22. Simultaneous oscillograms of variables of oscillatory systems [78]. Variables belonging to positive feedback loops generally exhibit flip-flop type oscillograms with characteristic instability features (→). Oscillograms of variables of negative feedback usually have a simple sawtooth shape without instability features (cf. Figs. 1d and 1e). B.-Z. reaction = Belousov-Zhabortinskii reaction.

4. Conclusion

At the close of an article about chemical oscillations it is logical to ask what significance such reactions possess in the various disciplines of science, and especially in chemistry. Are they merely a fortuitous kinetic curiosity whose occurrence is of more academic than practical interest, or are they of fundamental importance in certain scientific, biological, or technical processes.

In the theory of the thermodynamics of non-linear non-equilibrium processes oscillatory reaction courses are particularly striking and interesting phenomena which can only be treated by this theory, still very much in its infancy. It is mainly here that theoretical physics[95] is concerned with chemical oscillations.

Electropolishing processes exist which involve oscillatory activity of the electrode materials to be polished, *e.g.* in the electropolishing of steel in oxalic acid/hydrogen peroxide[96]. However, these are only exceptions in which oscillation kinetics is of engineering utility.

The significance of chemical oscillations in biology presents a completely different picture. The rhythmic nature of processes in bionics, *i.e.* "the chemical engineering of living organisms", has considerable advantages over non-periodic processes. Thus the oscillatory course of enzymatic reactions on a boundary cycle around an unstable steady state leads

to stabilization of the overall process, resulting in enhanced dynamic adaptability to changing external conditions and the possibility of synchronization with simultaneous processes. A rhythmic reaction course is of particular advantage if it leads *via* reaction steps which are mutually exclusive for kinetic reasons.

The orientation of living organisms according to time, *i.e.* the explicit recognition of temporal variables detectable even in single cell organisms such as *Euglena*, *Acetabularia*[97], can be accomplished only by rhythmic processes. In other words, "the biological clock" most probably has to be viewed as an oscillatory chemical mechanism. In the field of enzymatic processes such mechanisms are readily feasible owing to the manifold possibilities of systemic coupling in the metabolism of the living cell.

The ability of the excitable membranes of the nervous system to undergo oscillations permit, as already mentioned, propagation and processing of information.

In the evolutionary process chemical periodicity is also assumed[98] to be operative in spatial differentiation—the formation of defined structures. The activity of such structure-forming oscillatory mechanisms can be directly observed under the microscope, *e.g.* in cell division and in the regeneration of damaged cells.

The elucidation of the diverse manifestations and effects of chemical periodicity, which is clearly essential in living organisms, will only become possible once the kinetics of chemical oscillations can be understood in their elementary form. And this is probably the true reason for the avid interest recently shown in this area.

Industrial Applications of Photochemical Syntheses

By Martin Fischer[*]

The principal industrial applications of photochemistry have so far been in the fields of free-radical chlorination, sulfochlorination, sulfoxidation, and nitrosation. In addition, however, photochemical reactions are being utilized on an increasing scale for the synthesis of vitamins, drugs, and fragrances. The present article surveys the various kinds of light-induced reactions exploited industrially, the equipment developed, and uses of the photochemical products. Furthermore, the problems encountered in designing a photochemical production plant are discussed for the example of photonitrosation of cyclohexane.

1. Introduction

Most practical applications of photochemistry nowadays lie in areas in which the effect of a photochemical primary process is amplified by a large number of thermal consecutive reactions[1]. This is particularly true of photography, but also applies to photopolymerizations and radical chain syntheses. Use is made of advantageous features of photochemical reaction steps, precise energetic and spatial dosage of light, the high selectivity of individual light reactions, and independence of temperature, consumption of large amounts of light energy being avoided.

So far, there are only few examples of industrial photochemical syntheses with stoichiometric light requirements[2]. The ice was broken by the photonitrosation of cyclohexane (cf. Sections 2.4 and 7).

2. Free-Radical Reactions

The most important applications of photochemical syntheses still lie in the area of radical chain reactions. The 1940's saw the first industrial scale photochlorinations[3]. Since the light output of the mercury vapor lamps then available was but a few hundred watts, the use of light for industrial syntheses apart from vitamin D production was initially restricted to reactions with high quantum yields, *i.e.* to radical chain reactions.

Photochemical initiation of radical chains generally permits relatively low working temperatures, an essential condition for numerous syntheses involving free radicals. Compared with radical chain initiation by thermal decomposition of initiators such as peroxides and azo compounds, light-induced radical generation is of particular advantage in cases where the radical chains are very short and very many initiating radicals are accordingly required.

In the following survey of photochemical chlorination, sulfochlorination, sulfoxidation, and nitrosation the main emphasis is placed on the description of representative industrial equipment[4] rather than the extremely facile chemistry involved. Some details concerning the use of the photochemical products will also be presented.

2.1. Chlorination

Two different geometrical arrangements of light source and reaction space are employed in industrial photochlorination:

1) The lamp, which is generally shaped as a long cylinder, is fitted with a cooling jacket and immersed in the reaction solution.

2) The reaction solution is contained in a quartz or glass tube which is irradiated externally with one or more lamps.

The immersion well apparatus has the advantage that no light is lost to the surroundings. However, as a drawback, the light intensity falls off very rapidly with increasing distance from the lamp due to absorption by the reactants and to divergence of the light rays (Fig. 1).

Fig. 1. Light intensity distribution in an annular reaction space; L, cylindrical lamp; R, reaction space. Diminution of intensity from the inside to the outside because of a) divergence and b) absorption.

The inhomogeneous distribution of light and the consequent spatial variations in the generation of initiating radicals raises the danger of local overheating because most chlorinations are highly exothermic. Attempts are made to counteract this by thorough mixing of the reaction mixture.

If an empty cylindrical tube is irradiated by a radially symmetric external arrangement of light sources then the radiation density increases towards the axis of the tube owing to convergence of the light rays (Fig. 2a). If the tube is filled with absorbing compounds such as a chlorination mixture, how-

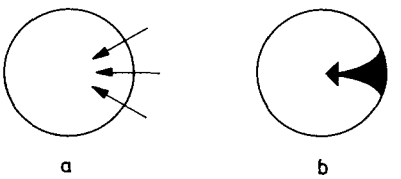

Fig. 2. Light intensity distribution in a cylindrical reaction space radially irradiated from an external source. a) Convergence of the light rays and b) absorption have opposing effects on the light intensity.

ever, the light intensity decreases from the outside to the inside owing to absorption (Fig. 2b).

In this case convergence of the light rays and absorption act in opposite directions and can partly balance each other; on suitable choice of tube diameter and absorption characteristics of the reaction medium a relatively uniform light distribution can be achieved. (For calculations of photoreactions in various irradiation apparatus, see [5].)

Light losses on external irradiation can be minimized by arranging the lamp and reactor tube along the focal lines of an elliptical reflector; an internal cooling tube can be fitted to remove excess heat from the reactor tube (Fig. 3)[6].

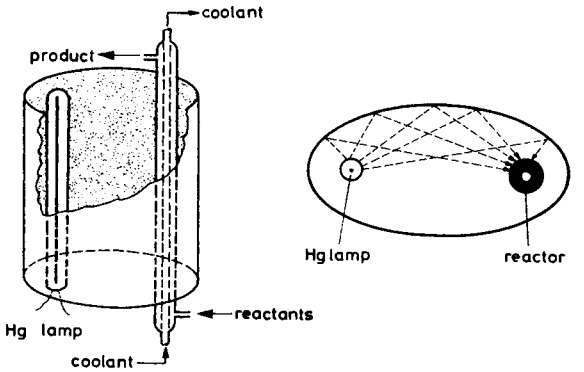

Fig. 3. External irradiation of a tube reactor; the lamp and reactor tube are located in the focal lines of an elliptic reflector. A cooling tube is located in the center of the reactor tube.

In practice, radical chain reactions with high quantum yields are frequently conducted without any great attempt being made to optimize utilization of the light. An example of industrial chlorination in externally irradiated glass tubes was described several years ago by scientists working at Phillips Petroleum[7], *viz.* the production of monochloroalkanes from a C_{11-14} *n*-paraffin cut.

$$RH + Cl_2 \xrightarrow{h\nu} RCl + HCl$$

RH = mixture of *n*-alkanes

The production apparatus essentially consists of two pairs of Vycor tubes (7.5 × 150 cm) and a water-cooled 7.5 kW mercury lamp. A cylindrical reflecting shield of polished aluminum reduces dissipation of light to the surroundings.

Removal of the considerable heat of reaction creates problems in photochlorination in externally irradiated glass tubes. To ensure that the temperature does not rise above 40 °C—uncontrolled decomposition has been observed at higher temperatures—only 15 mol% of chlorine is introduced. Prior to entering the second pair of reactor tubes the reaction mixture is first cooled to *ca.* 5 °C.

Further chlorination to form the undesired dichloro compounds is avoided by stopping the reaction at an overall conversion of 30 %. Owing to the high rate of photochlorination—the residence time of the solution in the irradiated

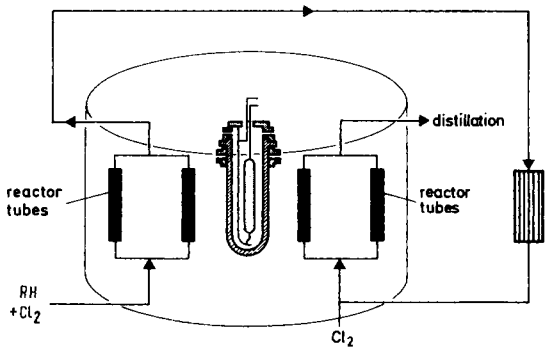

Fig. 4. Industrial photochlorination unit for the production of monochloroalkanes. Two pairs of Vycor tubes are irradiated with a 7.5 kW mercury lamp. RH = mixture of *n*-alkanes.

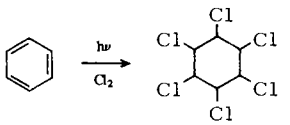


section is only about 20 s—a relatively small production unit of the kind shown in Figure 4 has a production capacity of some 27 t of chloroparaffin per day, corresponding to about 10000 t/a.

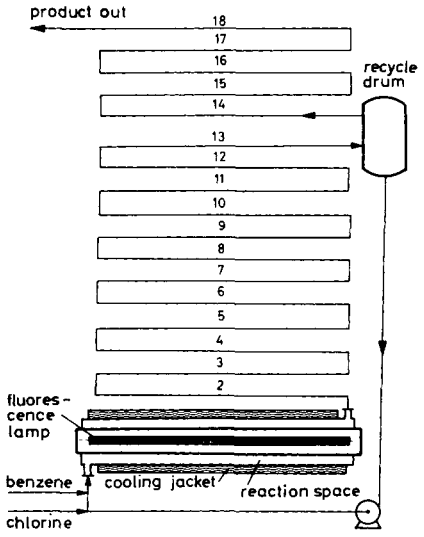
Compared to the thermal process, however, the photochemical monochlorination of paraffins is only of minor significance[8, 9].

The chloroalkanes are used for alkylation of benzene to give alkylbenzenes, which serve as starting materials for alkylbenzenesulfonates, an important class of detergents[9].

A chlorination apparatus in which the lamps are surrounded by the reaction solution, *i.e.* in which an annular reaction space is irradiated from its center, has been developed by Ethyl Corporation for the photochlorination of benzene to produce hexachlorocyclohexane[10].

The reactor shown schematically in Figure 5 comprises 18 tube segments, of which 17 are represented by lines. Two 40 W fluorescent lamps are located at the center of each segment. The pump at bottom right rapidly recycles the bulk of the reaction solution in the first 13 segments so that the heat of reaction is efficiently removed by the cooling jacket. A side stream passes through segments 14 to 18 (where residual chlorine reacts) at the same rate as fresh benzene and chlorine are fed in at bottom left.

Plugging of the tubes by crystalline product is avoided by maintaining the concentration of hexachlorocyclohexane in the reaction solution below 15 %. This means that only 4 % of the benzene feed can be converted on passage through the reactor. The chlorine consumption[10] of 270 kg/h in the unit indicates that nearly 3 m^3 of benzene feed is required per hour. The quantum yield of this industrial chlorination amounts to *ca.* 2500.



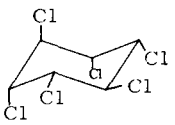


Fig. 5. Reactor for photochlorination of benzene to form hexachlorocyclohexane.

The photoaddition of chlorine to benzene serves for production of the γ-isomer of hexachlorocyclohexane, a versatile insecticide marketed as Lindane or Gammexane (γ-BHC). Unlike other chlorinated hydrocarbons, this plant protection agent still commands considerable interest because it is degraded biologically with comparative ease. The very modest yield of *ca.* 15 % is unsatisfactory, however.

The photochlorination of toluene to benzyl chloride, benzylidene dichloride, and benzotrichloride[11], known to every chemist from his practical course work, should not go without mention. Mixtures of the first two compounds are produced in a series of four lead-lined photoreactors at 80—110 °C[12].

$$C_6H_5CH_3 \xrightarrow[Cl_2]{h\nu} C_6H_5CH_2Cl \xrightarrow[Cl_2]{h\nu} C_6H_5CHCl_2 \xrightarrow[Cl_2]{h\nu} C_6H_5CCl_3$$

Benzyl chloride, also obtained by purely thermal chlorination of toluene, is converted mainly into benzyl alcohol, a well-known fragrance. It is also used in the synthesis of drugs, disinfectants, and emulsifiers[12]. On hydrolysis, or preferably on reaction with benzoic acid, benzylidene dichloride affords benzaldehyde; in the latter case a further valuable intermediate, benzoyl chloride, is also obtained.

$$C_6H_5CHCl_2 + C_6H_5CO_2H \rightarrow C_6H_5CHO + C_6H_5COCl + HCl$$

Benzotrichloride is a valuable intermediate for dyes of the triphenylmethane, xanthene, and anthraquinone series and for plant protection agents.

2.2. Sulfochlorination

Another well known reaction, photochemical sulfochlorination of paraffins, is of great industrial importance[9, 13]. In sulfochlorination the action of light is again limited to the formation of chlorine atoms from chlorine. The sulfonyl chloride group is distributed almost randomly over all C atoms of the hydrocarbon chain[14].

$$RH + SO_2 + Cl_2 \xrightarrow{h\nu} RSO_2Cl + HCl$$

RH = mixture of *n*-alkanes

Clean photochemical sulfochlorination requires the use of unbranched alkanes. Side chains favor competing chlorination. Normal alkanes of high purity are nowadays available in industrial quantities by means of molecular sieve processes.

Sulfochlorination does not stop at the stage of the monosulfonyl chlorides. Since di- and polysulfonyl chlorides have undesirable technical properties the reaction must be stopped at conversions of 30 to 50 %. Yields of 80 to 90 % are then obtained.

Under industrial conditions the quantum yield is about 2000. This means an energy consumption of *ca.* 30 Wh for 1 kg of sulfonyl chloride on use of fluorescent lamps.

Industrial sulfochlorination has been reviewed by *Lindner*[15].

Most of the alkanesulfonyl chlorides produced industrially are hydrolyzed by caustic soda to give water-soluble alkanesulfonates which are used mainly as emulsifiers for polymerizations[9].

$$RSO_2Cl + 2\,NaOH \rightarrow RSO_3Na + NaCl + H_2O$$

Owing to contamination with di- and polysulfonates, which cannot be removed under industrial conditions, the stringent demands nowadays placed on detergents can no longer be fulfilled by this type of alkanesulfonates and they are now hardly used in detergent manufacture[16, 17].

Reaction of alkanesulfonyl chlorides with ammonia leads to sulfonamides, which are used as textile auxiliaries[16] and also reacted further with chloroacetic acid to form a mixture of sulfonylaminoacetic acids. Compounds of this type serve as emulsifiers and as anticorrosion agents for mineral oils[16, 18].

$$RSO_2Cl \xrightarrow{NH_3} RSO_2NH_2 \xrightarrow[NaOH]{ClCH_2CO_2H} RSO_2NHCH_2CO_2H$$

2.3. Sulfoxidation

All the chlorine used in sulfochlorination is eventually recovered as hydrogen chloride or sodium chloride. A far more elegant synthesis of alkanesulfonates has been found in sulfoxidation, in which oxygen serves as oxidizing agent instead of chlorine.

$$RH + SO_2 + {}^1/_2O_2 \xrightarrow{h\nu} RSO_3H$$

$$RSO_3H + NaOH \rightarrow RSO_3Na + H_2O$$

$RH = C_{14-18}$-*n*-alkanes

Photochemical sulfoxidation has been developed as an industrial process at Hoechst[9, 19, 20]. The best one of several variants seems to be the so-called light-water process. The primary sulfoxidation product, peroxysulfonic acid, is trapped by water before it can undergo radical decomposition.

$$RSO_2OOH + H_2O + SO_2 \rightarrow RSO_3H + H_2SO_4$$

An equimolar amount of sulfuric acid is formed as coproduct and has to be removed on work-up.

Figure 6 shows a flowsheet of the industrial sulfoxidation process[20]. The photoreaction occurs in an immersed lamp reactor. A mercury lamp serves as light source. The photoreactor containing paraffin is gassed from below with sulfur dioxide and oxygen (molar ratio 2:1). Thorough mixing is accomplished by circulating the gaseous reactants by means of an external pump. Water is fed in together with paraffin at the top of the reactor. Sulfonic acid and sulfuric acid are continuously extracted into the water, thus largely precluding further reaction of the mono- to di- and polysulfonic acids.

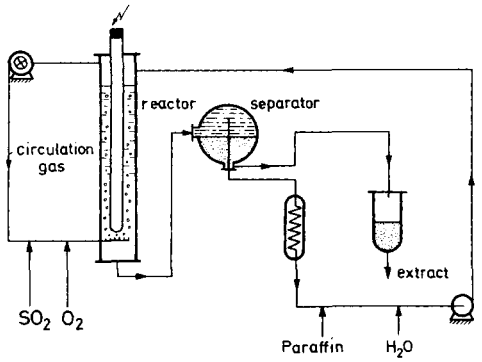

Fig. 6. Simplified flowsheet of the light-water process for sulfoxidation.

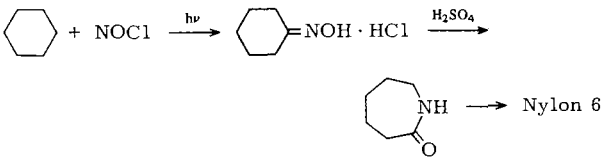


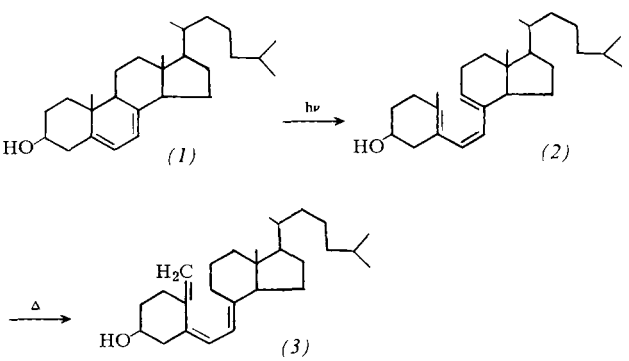
The mixture of aqueous acids is continuously removed in a separator and the unreacted paraffin returned to the photoreactor (Fig. 6). The rather involved isolation of the sulfonic acid[21] will not be considered here.

Compared to conventional photochlorinations or sulfochlorinations the light consumption of sulfoxidation is very high. About 0.2 kWh of electrical energy is required for lamp operation in the production of 1 kg of alkanesulfonate[20]. This means that only *ca.* 1600 t/a can be produced with one 40 kW mercury lamp.

Hoechst presently operates production plants having a total capacity of *ca.* 50000 t/a in the Federal Republic of Germany and France[22].

2.4. Photonitrosation

The light energy costs do not usually play a decisive role in industrial radical chain reactions because the light quanta supplied act with a high multiplication factor. In contrast, photochemical syntheses with quantum yields of about one could only be implemented on an industrial scale once powerful and efficient mercury lamps became available. The development of industrially utilizable lamps was prompted by the photonitrosation of cyclohexane, *i. e.* the light induced reaction of nitrosyl chloride with cyclohexane to form cyclohexanone oxime.



In the 1950's, with the common aim of developing a more economic synthesis of caprolactam, the monomer of nylon 6, several industrial companies and university departments in France, Germany, Japan, the USSR, and the USA started studies on the industrial feasibility of the photonitrosation of cyclohexane. The Japanese chemical company Toray finally decided to conduct the photochemical synthesis in a large production plant[23]. Details are given in Section 7.

3. Photochemical Synthesis of Vitamin D and Related Compounds

3.1. Vitamin D_3

In all the syntheses so far described, radicals, mainly chlorine atoms, are generated in the primary photochemical process. One of the oldest non-radical industrial photoreactions is the synthesis of vitamin D. Whereas vitamin D_2, produced from ergosterol, formerly took pride of place, interest is nowadays focused mainly on vitamin D_3: the latter compound, unlike the former, is also active in poultry. Most of the vitamin D_3 now produced is not used to prevent or cure rickets in children but instead as an additive in animal nutrition.

The starting material for the photochemical synthesis of vitamin D_3 is 7-dehydrocholesterol *(1)*, accessible in four steps from cholesterol[24]. Photochemical ring opening leads initially to previtamin D_3 *(2)*. On heating to 50—80 °C a hydrogen shift occurs to give the thermodynamically more stable vitamin D_3 *(3)*.

Because of the high absorbance of 7-dehydrocholesterol (Fig. 7) photolysis must be performed in relatively dilute solution (*ca.* 1 %). Ethanol or ether serves as solvent[24, 25].

The absorption spectrum of *(2)* completely overlaps that of *(1)*; thus a steadily increasing proportion of the incident

light is absorbed by *(2)* as conversion increases. Unfortunately, the quantum yield of the consecutive photoreaction of *(2)*

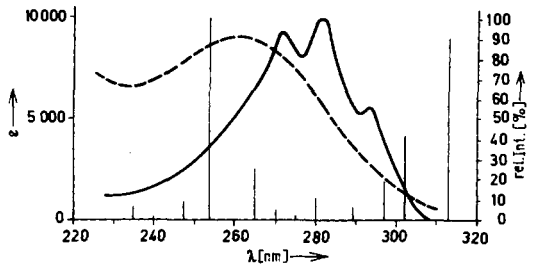


Fig. 7. UV spectra of 7-dehydrocholesterol *(1)* (——) and previtamin D_3 *(2)* (------). Emission lines of the medium pressure mercury lamp.

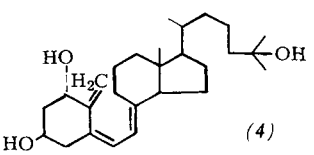
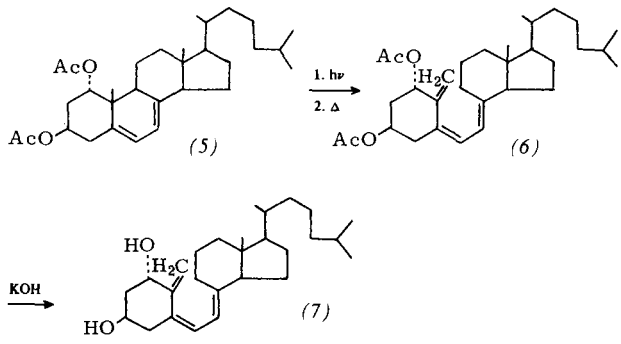


to give tachysterol, the *trans* isomeric triene, is greater than that of its formation[26]. It is therefore essential to stop irradiation of *(1)* once 30—50 % conversion has been reached and to isolate previtamin *(2)*.

The emission of a mercury lamp is regrettably very poorly adapted to the spectrum of 7-dehydrocholesterol *(1)* (Fig. 7): only the relatively weak emission lines at 280, 289, and 297 nm can be exploited, which together amount to only 8.5 mol quanta/h for a 40 kW lamp (total emission over all wavelengths: 174 mol quanta/h)[*].

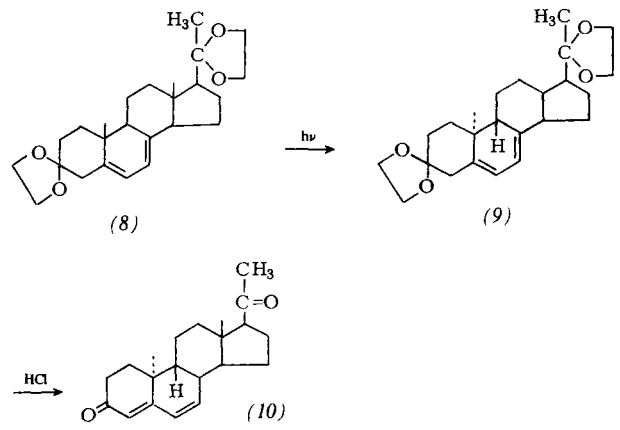
Given a quantum yield of 0.31 for transformation of *(1)* into *(2)*[26], then $8.5 \times 0.31 = 2.64$ mol of *(2)*/h should be obtainable with a 40 kW lamp. This means that the synthesis of 1 kg of vitamin D_3 requires an irradiation time of 1 h, and thus an energy consumption of 40 kWh. The actual energy required is twice as high: *ca.* 80 kWh/kg vitamin D_3.

3.2. Hydroxy Derivatives of Vitamin D_3



Some years ago it was established[27] that not vitamin D_3 itself but a metabolite formed in liver and kidney, 1α,25-dihydroxyvitamin D_3 *(4)*, is the actual active form responsible for regulating calcium metabolism. Compound *(3)* exhibits very high vitamin D_3 activity in patients having impaired kidney function.

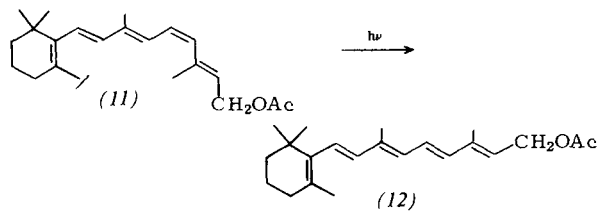
(4)



1α-Hydroxy-vitamin D_3 *(7)* proves just as active as *(4)*, but is much easier to produce. The intermediate *(5)* is accessible from cholesterol in six steps[28,29].

The same reaction conditions as established for the parent compound are employed for photochemical ring opening of *(5)* to the previtamin D_3 derivative and subsequent thermal hydrogen shift to give the diacetate *(6)*[28,29]. Alkaline hydrolysis ultimately yields 1α-hydroxy-vitamin D_3 *(7)*. A hydroxylated vitamin D_3 will probably be marketed before long[30].

3.3. Dydrogesterone

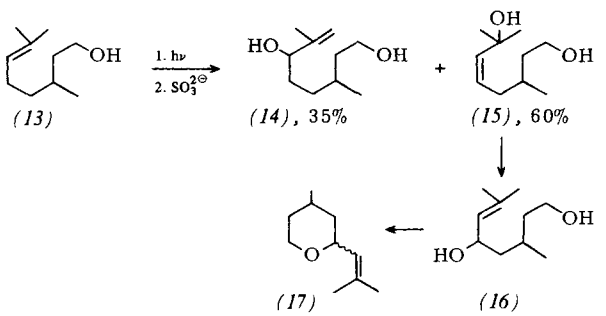


The synthesis of the sexual hormone dydrogesterone *(10)* developed by Philips-Duphar can be regarded as "spin-off" from intensive research work in the vitamin D area[31]. In analogy to the known photochemical transformation of 7-dehydrocholesterol *(1)* into the 10α-methyl isomer lumisterol$_3$, irradiation of the pregnadiene derivative *(8)* gives the retrosteroid *(9)* which is cleaved to form *(10)* by HCl in alcohol.

4. Photoisomerization of Vitamin A Acetate

The Wittig synthesis of vitamin A acetate, performed on an industrial scale at BASF[32], affords a mixture of two stereoisomers, the all-*trans* *(12)* and the 11-*cis* form *(11)*. Only the all-*trans* isomer *(12)* is suitable for use in pharmaceuticals and animal feeds.

A very mild photochemical method has therefore been developed at BASF[33] for converting 11-*cis*- into all-*trans*-vitamin A acetate: it consists in irradiating the stereoisomeric mixture

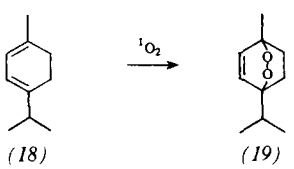


[*] A mol quantum is equal to 6.023×10^{23} photons.

with visible light in the presence of a colored sensitizer such as tetraphenylporphinatozinc or chlorophyll. A photochemical isomerization process which can also be used for transforming the 9-*cis* isomer into the all-*trans* form was recently described in a patent application by Hoffmann-La Roche[34].

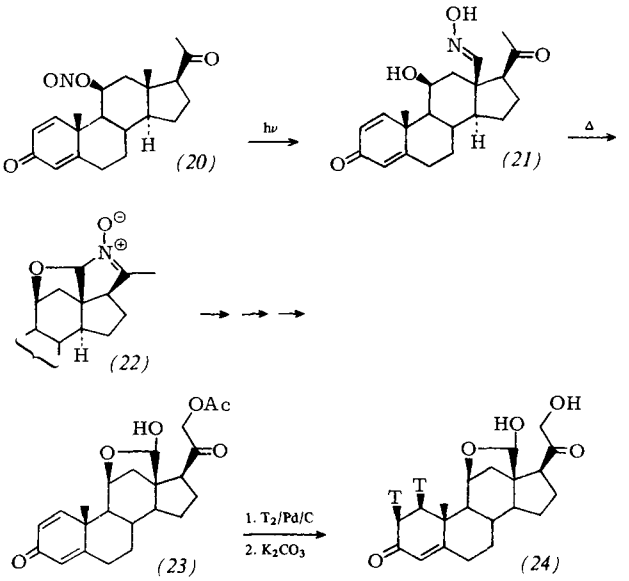
5. Photooxygenation

5.1. Rose Oxide



A further highly promising field for industrial photochemistry is the synthesis of fragrances. Small scale production of rose oxide *(17)* is already being conducted at the Firmenich and Dragoco companies.

Photooxygenation of citronellol *(13)* with rose bengal as sensitizer gives a mixture of two isomeric hydroperoxides[35] which can be reduced by sulfite to the alcohols *(14)* and *(15)*. The main product *(15)* undergoes allylic rearrangement to *(16)* in acid solution; *(16)* cyclizes with elimination of water to rose oxide *(17)*.



5.2. Ascaridole

Another sensitized photooxidation, *i.e.* reaction of α-terpinene *(18)* with singlet oxygen to give ascaridole *(19)*, acquired some importance after World War II[36]. It is no longer performed owing to the toxicity of this anthelmintic.

6. The Barton Reaction

The functionalization of saturated carbon atoms by photolysis of nitrites, discovered by *D. H. R. Barton*[37], is used in the production of tritium-labeled aldosterone *(24)*. The photochemical step of the multi-step synthesis consists in the transformation of the pregnane derivative *(20)* into the C-18-oxime *(21)* which gives the nitrone *(22)* on heating[38].

Compound *(22)* can be converted in a series of conventional steps into 1,2-didehydroaldosterone acetate *(23)* which yields the radioactively labeled aldosterone *(24)* by catalytic tritiation and subsequent hydrolysis[39]. The American company New England Nuclear produces *(24)* on a small scale for use as a medical diagnostic aid.

7. Scale-up of Laboratory Photoreactions to Industrial Processes: Photonitrosation of Cyclohexane

Further development of the technology of photochemical processes is of crucial significance for the future of industrial photochemistry. The present state of the art can best be described with the aid of an example, the photonitrosation of cyclohexane already mentioned above.

7.1. The Problem

In the interest of a readily comprehensible presentation of technical aspects, let us consider the decision processes that an industrial chemist faces and the data he works with when scaling-up a photochemical reaction from the laboratory

to a production plant for the case of the photochemical synthesis of cyclohexanone oxime. Assuming that a photochemical plant for producing 10000 t/a of cyclohexanone oxime were to be developed: What typically photochemical questions arise? What parameters play an essential role on scale-up? And finally: What kind of photoreactor design is particularly suitable for large-scale manufacture of oxime?

7.2. Laboratory Results as the Basis of Planning

The starting point for the design of an industrial plant is the results of laboratory experiments on photonitrosation.

The various process steps are simulated on a small scale under conditions corresponding as closely as possible to those met in practice to permit early detection and mastering of fundamental technical problems.

Photochemical synthesis of cyclohexanone oxime can be performed in the usual immersion well apparatus fitted with a medium pressure mercury vapor lamp (Fig. 8)[41].

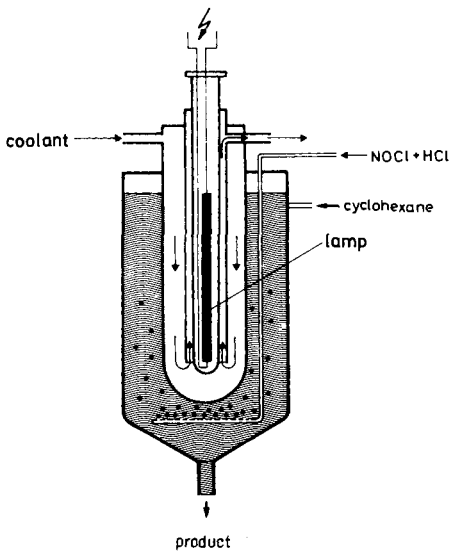


Fig. 8. Immersion well apparatus for photonitrosation on a laboratory scale. The mercury lamp is located at the center of a cold finger, NOCl and HCl are blown in through a glass frit. The oily bis(hydrochloride) of the oxime can be withdrawn from the bottom.

With a view to the design of large-scale industrial plant, continuous operation should already be aimed at in the laboratory. Cyclohexanone oxime can readily be removed from the irradiation apparatus as the bis(hydrochloride) which has a greater specific gravity and is insoluble in cyclohexane if hydrogen chloride is fed into the reactor together with nitrosyl chloride[40].

Continuous long-term experiments required for ascertaining optimum reaction conditions and determining the capacity of the laboratory apparatus are precluded by formation of a light-absorbing tarry deposit on the surface of the lamp cooler[23,40,44]. The short-wavelength emission of the mercury lamp is mainly responsible for formation of this coating[44,45]: If the emission between 248 and 366 nm is filtered out by addition of sodium nitrite to the cooling water of the lamp then photonitrosation can be performed for several days without significant coating[46].

Under optimum conditions the yield of oxime is 89 %[41]. The most important by-product is chlorocyclohexane, which has to be removed by distillation to prevent its accumulation.

Owing to the low absorbance of nitrosyl chloride in the long-wave region (Fig. 11) and to the limited layer thickness in laboratory apparatus, the light is not completely absorbed. It is therefore impossible to determine the maximum product output for a lamp of given wattage in the laboratory.

When beginning to design a production plant on the basis of the above laboratory results very many questions have to be answered, for example: Are the starting materials, especially nitrosyl chloride, available in industrial quantities? What materials of construction apart from glass are sufficiently resistant to the exceptionally corrosive reaction mixture? What measures can be adopted to ensure optimum temperature control and mixing in the photoreactor? How is the oxime best isolated? How can the accumulation of by-products be avoided?

These questions, which occur in modified form in the design of very many chemical production plants, are not necessarily typical of a photochemical process. They will therefore be put aside in favor of specifically photochemical problems.

7.3. Choice of Lamp

A very important condition for the design of a photoprocess is a knowledge of commercially available lamps[4]. The most powerful present-day lamps are medium pressure mercury vapor lamps with a power consumption of 60 kW. A schematic diagram of such a lamp fitted with cooling jacket is shown in Figure 9. The lamp is *ca.* 2 m long and 6 cm in diameter, and can be cooled with water or a filter solution.

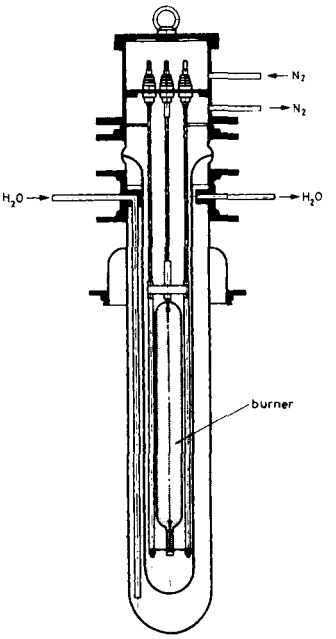

Fig. 9. 60 kW mercury lamp with cooling jacket.

Figure 10 shows a 60 kW lamp shortly after ignition. A 60 kW mercury lamp costing about $ 1500.—[*] without cooling jacket can be run for up to a year without significant loss of output provided that it is not switched off and on too frequently[23].

[*] Mercury lamps for industrial processes are available from Quarzlampen GmbH, Hanau, and Comp. Electromécanique Etabl. SCAM, Paris.

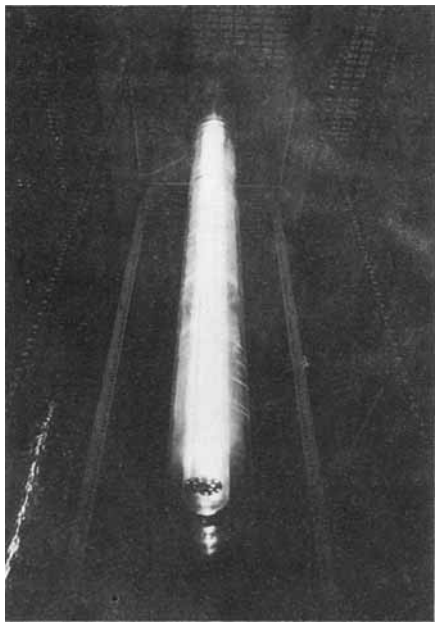

Fig. 10. 60 kW mercury lamp with cooling jacket. The lamp was photographed shortly after being switched on before it was burning brightly.

It is important that all the emission lines of the mercury lamp in the ultraviolet and visible region of the spectrum be absorbed to a greater or lesser extent by nitrosyl chloride in order to ensure a good utilization of the light energy (Fig. 11). Overlap is seen to be considerably better than in the synthesis of vitamin D because of the broad absorption bands of nitrosyl chloride.

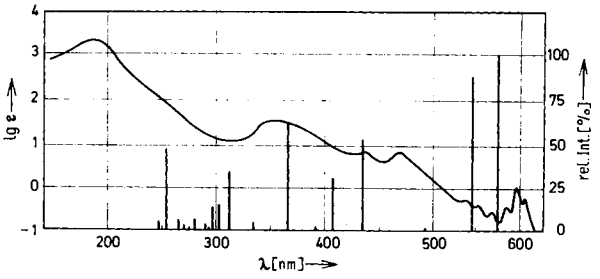

Fig. 11. Absorption spectrum of nitrosyl chloride and emission lines of an undoped mercury lamp. The relative intensity of the emission lines (right-hand scale) refers to mol quanta/h and not to the wattage.

Unfortunately, however, deposit formation on the immersion well precludes use of the emission lines between 248 and 366 nm for photonitrosation. Thus *ca.* 43 % of the overall light emission of the lamp cannot be used. A shift to the desired spectral region of 400—600 nm can be induced by addition of small amounts of thallium iodide to the mercury discharge. This doping causes a very intense emission at 535 nm at the expense of all mercury lines (Fig. 12).

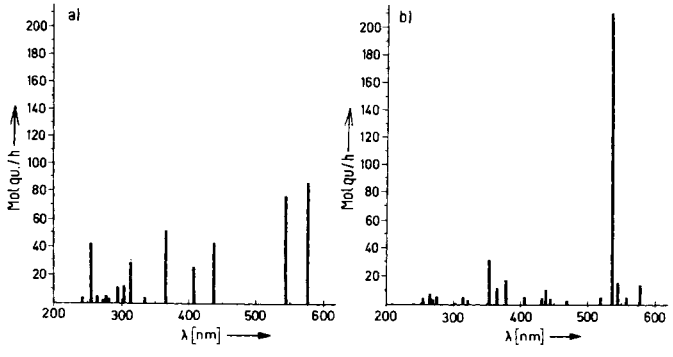

Fig. 12. a) Emission spectrum of an undoped mercury lamp; b) emission spectrum of a mercury lamp doped with TlI.

7.4. Number of Lamps Required

Once the type of lamp required for the production plant—a Tl-doped mercury lamp—has been established[47], it is logical to ask how many lamps will be required for the projected capacity of 10000 t/a of oxime, or how much product can be expected per year from a single 60 kW lamp.

The most reliable method of determining this quantity is undoubtedly to build a pilot reactor with a 60 kW lamp and to test it. However, it is relatively easy to estimate the amount of product expected from the light emission of the doped mercury lamp and the quantum yield of oxime formation. The output of a Tl-doped 60 kW mercury lamp at 535 nm is 13.1 kW or 210 mol quanta/h. Assuming a quantum yield of 0.8 under industrial conditions[42,43], 168 mol or 19 kg of oxime can be expected per hour.

Formation of up to 0.4 kg oxime/kWh power consumption of the lamp was determined by experiment; this corresponds to 24 kg/h for a doped 60 kW lamp. The discrepancy between this figure and the above estimate comes about because the weaker lines (Fig. 12b) also contribute to oxime formation in addition to the emission at 535 nm.

24 kg of oxime per hour corresponds to a capacity of 200 t/a for one 60 kW lamp. Hence it follows that the projected 10000 t/a plant will require 50 lamps.

7.5. Arrangement of Lamps in an Industrial Photoreactor

It would be quite feasible to install 50 photoreactors in parallel. However, in view of the fact that each reactor would have to be fitted with numerous supply lines for starting materials and products, for electrical energy and the filter solution for cooling the lamps, the construction of 50 individual reactors appears a very complicated and expensive task. It is much more reasonable to develop photoreactors containing say 50 lamps instead of just one.

A photoreactor fitted with 50 industrial mercury lamps will have to be designed in a completely different way from the laboratory immersion well apparatus with only one light source. A question of paramount importance in the construction of a multi-lamp reactor will concern the geometrical arrangement of the individual 60 kW lamps, which in turn determines the light distribution.

The mechanical sensitivity of the lamp cooling wells, which are at least 2.5 m long, immediately suggests that the lamps

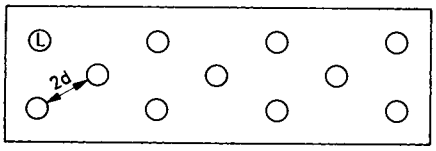

Fig. 13. Arrangement of several lamps L (shown in section) in a rectangular reaction vessel.

should be suspended in the reaction solution from above. What is the optimum distance of the lamps from one another and from the walls of the reactor (Fig. 13)?

Asked in another way: How far does the light emitted from a lamp penetrate the reaction solution before it is largely absorbed?

The thickness of the layer of solution which absorbs 99% of the light of wavelength 535 nm can be approximately calculated with the aid of equations (a) and (b) (see Fig. 14). In

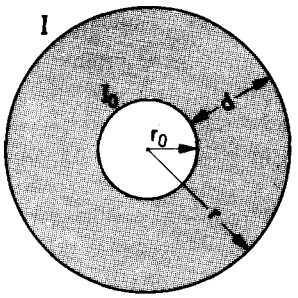

Fig. 14. Layer of liquid reached by the light from a lamp. r_0 = radius of the lamp cooling jacket; d = thickness of layer of solution absorbing 99% of the light; I, I_0 = intensity of light.

a first approximation the light is assumed to be emitted radially and light scattering by the heterogeneous reaction mixture is considered insignificant.

$$\log\frac{I_0}{I} = \log\frac{r}{r_0} + 2.3\cdot\varepsilon_c(r-r_0) \qquad \text{(a)}$$

$$d = r - r_0 \qquad \text{(b)}$$

If I_0 is the intensity of light at the surface of the lamp cooler, $I = 10^{-2} I_0$ = intensity of light at a distance d from the lamp, $\varepsilon = 0.9$, $c = 0.037$ mol NOCl/l, and $r_0 = 10$ cm, the value of r is calculated as 30 cm, and the thickness d of the layer in which the light is almost completely absorbed is 20 cm.

The distance between two lamps should accordingly not exceed 40 cm if dark zones are to be avoided. Experiments confirmed the suitability of this distance[23].

The region still reached by the light from a given lamp will of course depend upon the wavelength. Light of shorter wavelength such as the intense 366-nm mercury line is absorbed in a much thinner layer of only 0.4 cm, corresponding to the higher absorbance of NOCl at this wavelength.

Thus the oxime due to short wave light is formed in the immediate vicinity of the lamp. It is therefore hardly surprising that the hydrophilic oxime bis(hydrochloride) which is insoluble in cyclohexane is deposited on the likewise hydrophilic glass of the cooling well where it resinifies under the action of light and nitrosyl chloride to form a tarry deposit. As already mentioned, however, formation of this coating can be largely suppressed by use of a filter solution for elimination of UV light.

7.6. Example of an Industrial Multi-lamp Reactor

A rectangular plan appears to be the most suitable for an industrial multi-lamp reactor. The individual lamps could then be arranged as shown in Figure 13. Figure 15 shows a section through a multi-lamp reactor proposed by the Toray company[48].

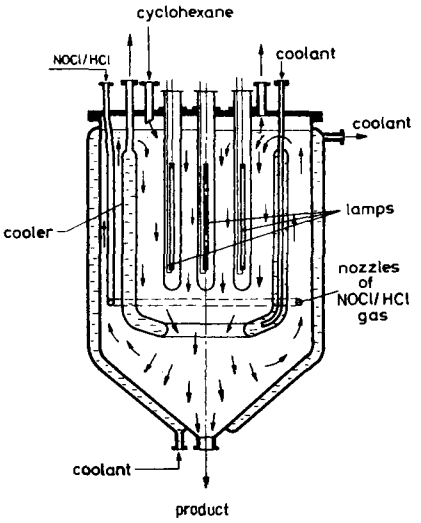

Fig. 15. Section through a photonitrosation reactor (after [48]).

Apart from the lamps, an opaque wall carrying coolant is also incorporated in the tapered trough. The reaction gases NOCl and HCl are introduced into the outer compartment of the reactor. The cyclohexane in this space is carried along by the rising gases and simultaneously saturated with NOCl and HCl. The liquid phase flows in direction indicated by arrows past the lamps, whereupon the oxime bis(hydrochloride) is formed and sinks to the bottom as fine oil droplets. The droplets coalesce during their downward passage to give a high density oily liquid which travels down the inclined floor of the vessel and can be withdrawn from the bottom. The insolubility of the oxime bis(hydrochloride) thus permits facile product removal and hence continuous operation so important for an industrial synthesis.

Figure 16 shows a view of the upper part of the Toray industrial photoreactor. The tops of the lamps housing the electrical supply lines can be recognized.

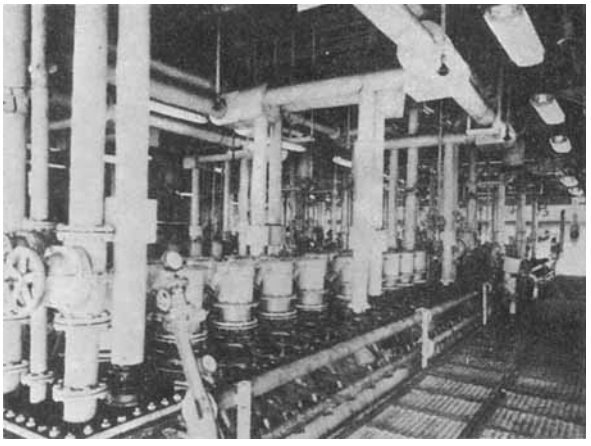

Fig. 16. Photograph of an industrial photoreactor operated by the Toray company [23].

The photochemical aspects emphasized in this account represent but a small part of the enormous task of developing

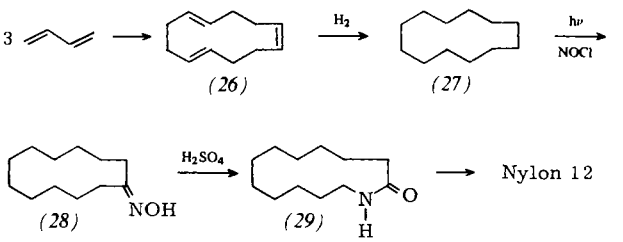
a plant for the photochemical production of cyclohexanone oxime. The choice of materials of construction was particularly difficult because the reaction mixture is highly corrosive towards all the usual materials. The only material sufficiently resistant for use as reactor lining is the very expensive titanium[44].

Problems of cooling, mixing, replacement of burnt-out lamps, and removal of deposits which cannot be avoided in long-term operation, can only be mentioned in passing.

A vital question for all commercial scale photochemical syntheses is that of safety, arising from the close proximity of the lamp—an 800 °C hot source of ignition—and flammable liquids. In order to control these hazards the lamps are run in a nitrogen atmosphere and an automatic shut down device switches them off automatically in the event of a breakdown, *e.g.* failure of the cooling water supply or a temperature rise in the reactor.

Development of a photochemical process for the synthesis of caprolactam is not restricted to the design of a photoreactor. Economical production processes are also required for nitrosyl chloride and for the Beckmann rearrangement of the oxime to the lactam[23,44]. We shall not consider these processes here.

7.7. Economics of Photonitrosation



Questions of economics are of supreme importance for the industrial realization of a large-scale photochemical process[49]. For the photochemical synthesis of cyclohexanone this means that the production costs should not be higher than those of conventional processes based on phenol or toluene. The photochemical synthesis has the advantage of fewer steps and higher overall yields than competing processes. However, the fact that only one company has decided to employ the photonitrosation process suggests that the photochemical lactam synthesis does not have any cost advantages over conventional syntheses. Some 160000 t/a of caprolactam are now produced by the photonitrosation process at Toray[49].

In this connection, the cost of energy and lamps incurred by the photochemical synthesis step is very important: it has already been mentioned that the production of 1 kg of cyclohexanone oxime requires 2.5 kWh of electrical energy for operating the lamps. At a price of 5 cents/kWh, the energy costs amount to 12.5 cents/kg of oxime. The cost of the lamps calculated from the capacity, lifetime, and initial purchase price is 1 cent/kg, which is a relatively low value.

These data clearly show that a photochemical synthesis step does not have to be expensive, provided that the quantum yield is not much lower than unity and the photoreactive starting material also absorbs in the long-wavelength region of the spectrum. Long-wavelength light is less expensive than short-wavelength light because the individual quanta contain less energy, and high-performance sources are available for visible light.

8. Lauryllactam by Photonitrosation

Apart from the synthesis of caprolactam, photonitrosation has meanwhile found a second industrial application: the production of lauryllactam, the monomer of nylon 12[50]. In place of cyclohexane, cyclododecane *(27)*, accessible from butadiene *(25)* in two steps, is converted into the oxime *(28)* by nitrosyl chloride and light.

On account of its low density and low absorption of water, lauryllactam *(29)* is used for a number of special purposes, in particular for the production of dimensionally stable plastic components (automobile construction) and for plastic coating of metals[51].

The photochemical lauryllactam process was developed by ATO in France. The photochemical plant having a present capacity of 8000 t/a comprises several photoreactors, each containing 27 lamps of 60 kW power consumption[52].

9. The Importance of Industrial Photochemistry

In his comprehensive monograph "Allgemeine Photochemie" written some 40 years ago, *Plotnikow* predicted that photochemical syntheses on an industrial sclae would be limited to a few special cases, *i.e.* to the production of particularly expensive specialties[53]. He justified this statement by pointing out that light reactions generally require irradiation of large surface areas which would incur very high costs. In *Plotnikow*'s opinion, a tree is an ideal photochemical factory; its leaves present a maximum absorption area for a minimum volume. He urgently warned against any, necessarily imperfect, imitation of Nature.

Nowadays, light reactions have acquired a firm place in the armamentarium of industrial methods. The foundations of photochemical technology have been laid, for it is now possible to scale-up photoreactions from the laboratory to production units employing 40- or 60 kW lamps.

The space-time yields of non-radical photochemical syntheses, which are still frequently unsatisfactory, should be improved by the development of even more powerful lamps; prototypes of 100 kW mercury lamps have already been constructed.

Numerous patent applications indicate that although light will continue to be used predominantly for initiating radical chain reactions, its use in the production of synthetically demanding products for drugs, plant protection, and fragrances will steadily increase. Thus our extensive knowledge about the manifold possibilities of photochemical syntheses[54] will find more and more practical application.

Organomercury Compounds in Organic Synthesis

By Richard C. Larock[*]

Organomercurials have been known since 1850 and many synthetic routes to these compounds presently exist. The ability of these compounds to accommodate a wide variety of functional groups and to tolerate quite diverse reaction conditions makes them attractive as synthetic intermediates. While the solvomercuration-demercuration and divalent carbon transfer reactions remain the most widely used of the organomercurial reactions, a number of new synthetic procedures employing organomercurials have been developed in recent years. Many of these involve transmetallation reactions with palladium salts.

1. Introduction

Organomercurials were among the first organometallic compounds to have been prepared over 125 years ago. Early interest in their medicinal use encouraged chemists to synthesize many organomercurials. Although these compounds found increasing utility in the synthesis of other organometallic compounds, their low chemical reactivity towards organic substrates limited their early use in organic synthesis. With the development of the more reactive Grignard and organolithium reagents, interest in the synthetic applications of these compounds waned. However, with the increasing interest in recent years in the development of organometallic reagents which will undergo mild carbon-carbon bond formation and yet tolerate a variety of functionality, the organomercurials have seen a rebirth of interest. The ready availability of these compounds, their ability to accommodate essentially all important organic functional groups, and their remarkable chemical and thermal stability have made them attractive as synthetic intermediates. These factors plus the ease with which these compounds undergo transmetallation reactions with a number of transition metals, most notably palladium, have provided a large number of new procedures which should prove of interest to the synthetic organic chemist.

This review will only very briefly outline some of the methods of synthesis of organomercurials which have proven useful in the development of these compounds as reagents and intermediates in organic synthesis. The major portion of the review will then cover a number of new synthetic applications of these compounds. Only those reactions whose generality has been established will be covered. No attempt will be made to cover any of the uses of mercury salts as oxidizing agents in organic chemistry. The use of mercury(II) oxide in this respect has already been extensively reviewed[1].

2. Synthesis of Organomercury Compounds

Today a wide variety of synthetic procedures exist for the preparation of organomercurials. These methods have been reviewed in two recent books[2, 3]. Only those reactions which lead to synthetically valuable organomercury reagents or intermediates will be mentioned here.

[*] Prof. Richard C. Larock
Department of Chemistry
Iowa State University
Ames, Iowa 50011 (USA)

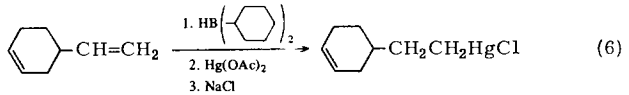
The direct synthesis of organomercurials from organic halides and metallic mercury or mercury amalgams is rather limited [eq. (1)][4]. However, methyl, methylene, benzyl, propargyl and several allylic and β-acylvinyl iodides undergo a facile reaction in the presence of light. Alkyl bromides will react when activated by electron withdrawing groups, but alkyl chlorides are generally unreactive. Utilization of mercury amalgams usually results in formation of the corresponding diorganomercury compounds of type HgR_2, but the yields are generally low.

$$R{-}X + Hg \rightarrow R{-}Hg{-}X \quad (1)$$

Organomercurials are most commonly prepared from the corresponding organolithium or -magnesium compounds [eqs. (2) and (3)][5]. However, the severe limitations on functionality and the already numerous synthetic applications of these highly reactive organometallics severely restrict the synthetic utility of the resulting organomercury compounds.

$$RLi + HgX_2 \rightarrow RHgX + LiX \quad (2)$$

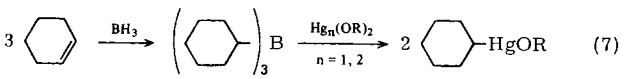
$$RMgX + HgX_2 \rightarrow RHgX + MgX_2 \quad (3)$$



Halomethylmercury compounds have proven very valuable as carbene transfer reagents. They are most readily obtained by carbanion displacement reactions on organomercury halides [eq. (4)][6]. A large number of these reagents have been prepared and many are now commercially available. Their utility as transfer reagents will be discussed in Section 4.

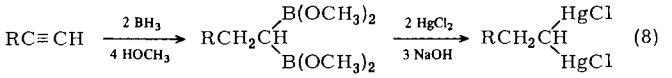
$$RHgX + HCX_3 + KOC(CH_3)_3 \xrightarrow[THF]{} RHgCX_3 + HOC(CH_3)_3 + KX \quad (4)$$

The mercuration of organoboranes offers a very valuable method for the synthesis of organomercurials containing a variety of functional groups[7]. Primary trialkylboranes, readily available *via* hydroboration of terminal olefins, undergo a rapid quantitative reaction with mercury(II) acetate at room temperature to give the corresponding alkylmercury acetates [eq. (5)][8]. Treatment with aqueous sodium chloride provides excellent yields of the alkylmercury chlorides. Secondary alkyl groups do not react under these mild conditions allowing



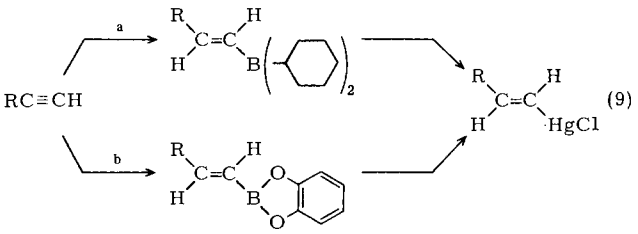
$$3RCH{=}CH_2 \xrightarrow{BH_3} (RCH_2CH_2)_3B \xrightarrow{3Hg(OAc)_2} 3RCH_2CH_2HgOAc \quad (5)$$

the use of dicyclohexylborane for selective hydroboration-mercuration [eq. (6)]. Dialkylmercury compounds can be prepared



(6)

in a similar manner[9]. Secondary alkylmercury compounds are readily obtained from internal olefins *via* hydroboration-mercuration using mercury alkoxides [eq. (7)][10,11].



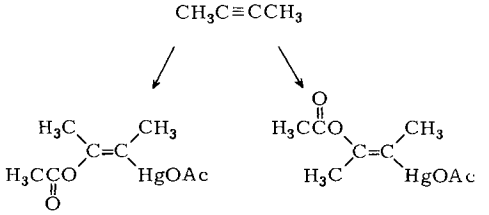
(7)

The hydroboration-mercuration of alkynes can be controlled to give either alkylidenebis(mercury(II) chlorides) [eq. (8)][12] or vinylmercury(II) chlorides [eq. (9)][13,14]. The dicy-

(8)

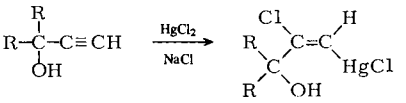
(9)

clohexylborane route (Route a) to vinylmercurials gives excellent yields from terminal alkynes and has been shown to tolerate functional groups[13]. The "pyrocatecholborane" procedure (Route b) is superior for the conversion of internal alkynes to vinylmercurials[14].



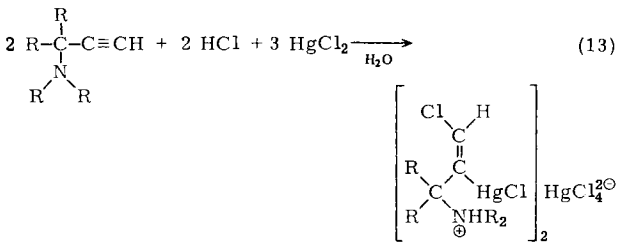
In a protic solvent mercury salts react directly with alkenes to form a wide variety of very valuable β-substituted organomercurials [eq. (10)][15]. These reactions have proven exceed-

(10)



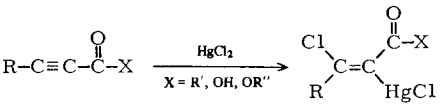
ingly useful for the Markownikoff functionalization of alkenes when employed in conjunction with a demercuration step, and will be discussed in detail in Section 3.

At this time we will discuss only the analogous alkyne addition reactions which lead to organomercurials useful in other synthetic transformations. Mercury(II) acetate readily reacts with internal alkynes in acetic acid to give β-(acetoxy)-vinylmercurials. Depending upon reaction conditions, 2-butyne gives either the *trans* or the *cis* addition product [eq. (11)][16]. Certain propargylic alcohols and diols react readily



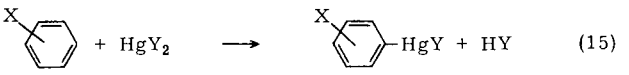
(11)

with saturated aqueous solutions of mercury(II) chloride and sodium chloride to give the corresponding *trans*-β-chlorovinylmercury(II) chlorides [eq. (12)][17]. We have also recently



(12)

observed analogous addition reactions with alkynylamines in dilute hydrochloric acid [(eq. (13)][18]. Ketones, carboxylic



(13)

acids and esters containing a CC triple bond also undergo similar addition reactions [eq. (14)][19,20].

(14)

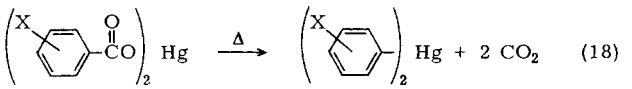
The most important route to arylmercurials is undoubtedly the direct mercuration of aromatic compounds [eq. (15)][21,22].

(15)

This reaction has been extensively studied from both a mechanistic and synthetic standpoint. It generally exhibits the characteristics of a typical electrophilic aromatic substitution reaction and is facilitated by highly ionic mercury salts and by electron donating groups on the aromatic ring. Arylmercurials containing a large variety of organic functional groups have been prepared in this manner.

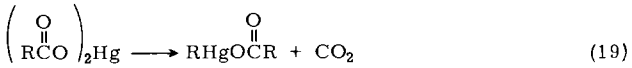
The direct mercuration of aromatic compounds has one major drawback. It often results in mixtures of *o*, *m*, and *p* isomers. This complication can be easily avoided by employing diazonium salts[23]. Copper promotes the facile displacement of nitrogen from the double salts of aryldiazonium halides and mercury(II) halides [eq. (16)]. With excess copper and

(16)



aqueous ammonia diarylmercury compounds are produced. These reactions also proceed in high yield when copper(I) chloride is employed.

Arylhydrazines can also be directly converted into arylmercurials upon treatment with mercury(II) acetate and copper(II) acetate [eq. (17)][24].

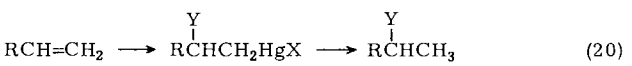


(17)

The thermal decarboxylation of the mercury(II) salts of arenecarboxylates provides an alternate method for the synthesis of arylmercurials, but appears limited to aryl groups containing strong electron withdrawing groups [eq. (18)][25].

(18)

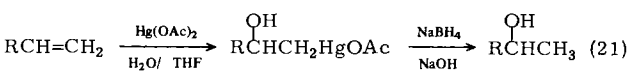
The photochemical or peroxide initiated decomposition of aliphatic or aromatic mercury carboxylates proceeds under much milder conditions and often provides excellent yields of the corresponding organomercury carboxylates [eq. (19)][26].



(19)

Although this discussion of the preparation of organomercurials has been kept purposely short, it is obvious that a wide variety of methods for their synthesis exist and that a substantial number of these methods are quite general and accommodate considerable organic functionality. With this in mind we are ready to explore some of the synthetic applications of these compounds.

3. Solvomercuration-Demercuration Reactions

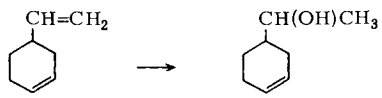


The solvomercuration-demercuration of alkenes is probably the most important synthetic method employing intermediate organomercurials [eq. (20)]. This sequence has provided a

(20)

very general method for the Markownikoff functionalization of alkenes. Its advantages over other procedures are: (1) extremely mild reaction conditions are involved, (2) considerable functionality is accommodated, (3) carbon skeletal rearrangements are rare, and (4) numerous nucleophiles, Y, can be employed. We shall only very briefly cover each of the different types of solvomercuration adducts which can be formed and the major methods by which they can be demercurated. Primary emphasis will be on those procedures which accomplish the above transformation *in situ*, without isolation of the intermediate organomercurial, as these are clearly the synthetically more appealing procedures.

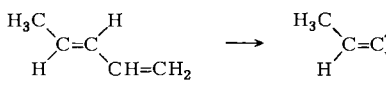
The oxymercuration-demercuration reaction is the most widely used synthetic procedure [eq. (21)]. It provides



(21)

a very convenient procedure for the Markownikoff hydration of alkenes, nicely complementing hydroboration-oxidation. Although many β-hydroxyalkylmercurials have been isolated from this reaction[27], and a few subsequently reduced with various reducing agents, the recent work of *H. C. Brown et al.* on the *in situ* oxymercuration-demercuration of alkenes using sodium tetrahydridoborate as the reducing agent provides the most convenient procedure[28]. This procedure is applicable to mono-, di-, tri- and tetraalkyl, as well as phenyl substituted alkenes. The relative rates of hydroxymercuration have also been determined[29]:

$$R_2C{=}CH_2 > RCH{=}CH_2 > \textit{cis}\text{-}RCH{=}CHR > \textit{trans}\text{-}RCH{=}CHR > R_2C{=}CHR > R_2C{=}CR_2$$

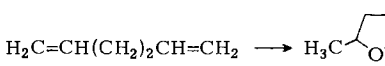


The regio- and stereochemistry of this reaction have been thoroughly examined[28, 30–34]. The reaction generally involves a *trans*-Markownikoff addition. However, with certain strained alkenes such as norbornene[32] and *trans*-cyclooctene and -nonene[35] *cis*-addition occurs. Substituted cyclohexenes give almost exclusively the axial alcohol[33, 34]. Optically active alcohols can also be obtained by employing chiral mercury(II) carboxylates[36, 37].

The oxymercuration-demercuration of dienes has proven quite interesting. The monohydration of unsymmetrical dienes can be accomplished using one equivalent of mercury(II) tri-

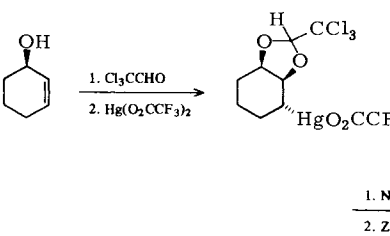
(22)

fluoroacetate [eq. (22)][38]. Fair yields of unsaturated alcohols can also be obtained from conjugated dienes [eq. (23)]. When



(23)

two equivalents of mercury(II) salt are employed, diols are obtained in high yields [eq. (24)], except in those cases where



(24)

hydroxyl participation can result in the formation of tetrahydrofurans or tetrahydropyrans [eq. (25)][39]. These results are

(25)

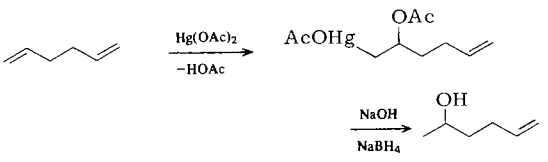
best explained by two consecutive Markownikoff additions. Cyclic ether formation from dienes and unsaturated alcohols has been reported by a number of workers and can often proceed in high yield[40]. A number of interesting cyclic and polycyclic ethers have been prepared in this manner. One can take advantage of these reactions to convert cyclohexenols into *cis*-1,2-diols [eq. (26)][41].

(26)

Alkenes and dienes readily undergo alkoxymercuration-demercuration when an alcohol is used as the solvent [eq. (27)]. Although numerous β-alkoxymercurials have been pre-

pared using mercury(II) acetate[27], and some of these subsequently demercurated, mercury(II) trifluoroacetate appears to

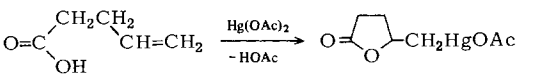
$$RCH{=}CH_2 \xrightarrow[R'OH]{Hg(O_2CCF_3)_2} RCH(OR')CH_2HgO_2CCF_3 \xrightarrow[NaOH]{NaBH_4} RCH(OR')CH_3 \quad (27)$$



be a far superior reagent and, when employed in conjunction with an *in situ* alkaline $NaBH_4$ reduction, provides a very convenient route to highly branched ethers[42].

Peroxymercuration has also been achieved using mercury(II) carboxylates and both hydrogen peroxide and *tert*-butyl hydroperoxide [eq. (28)][43]. The alkyl *tert*-butyl peroxides can

$$RCH{=}CH_2 \xrightarrow[Hg(O_2CR')_2]{tBuOOH} RCH(OOtBu)CH_2HgO_2CR' \xrightarrow[NaOH]{NaBH_4} RCH(OOtBu)CH_3 \quad (28)$$

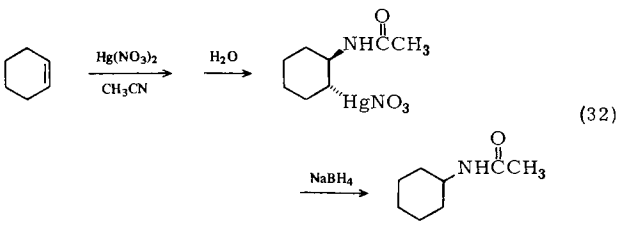


be demercurated with $NaBH_4$[44]. Cyclic peroxides can also be prepared from dienes by this approach[45].

Solvomercuration reactions can also prove useful for the synthesis of esters and lactones. In the absence of a protic solvent mercuric acetate will add directly to alkenes[46]. The monoaddition of mercury(II) acetate to dienes provides an improved method for the monohydration of symmetrical dienes [eq. (29)][47]. Both acyclic[48] and bicyclic[49] γ,δ-un-

(29)

saturated carboxylic acids form γ-lactones when treated with mercury(II) acetate [eq. (30)].



(30)

The aminomercuration of alkenes has been reported by a number of workers [eq. (31)][47, 50–52]. Both mercury(II)

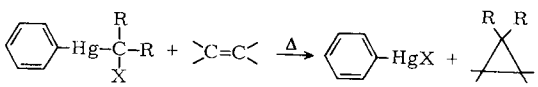
$$RCH{=}CH_2 + 2\ HNR'_2 + HgX_2 \longrightarrow RCH(NR'_2)CH_2HgX \quad (31)$$

chloride and acetate, as well as primary and secondary alkyl and aryl amines, have been allowed to react with a wide variety of alkenes. The reaction has also been extended to the synthesis of heterocyclic amines by employing unsaturated amines and dienes[53, 54]. A variety of reducing agents have been used to reduce the mercurials[47, 51, 54, 55].

The amidomercuration of alkenes can readily be accomplished using mercury(II) nitrate and nitriles followed by hydrolysis[56, 57]. Reduction with sodium amalgam or $NaBH_4$ gives high yields of the corresponding amide [eq. (32)]. $LiAlH_4$ reduction gives the corresponding secondary amine[57].

(32)

A number of other mercury salts will also add across the double bonds of alkenes. In this manner β-azido[58], β-nitro[59], β-fluoro[60] and β-(trinitromethyl)[60] mercurials have been prepared.



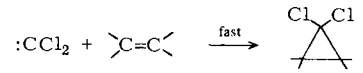
There are only a few examples of carbon-carbon bond formation *via* solvomercuration reactions[61]. Certain aromatic compounds react with alkenes in the presence of mercury(II) salts to give β-aryl alcohols or carboxylates, as well as 1,2-diarylalkanes. 1,3-Dicarbonyl compounds also undergo coupling with ethylene and mercury(II) salts.

The mercuration of alkynes has been much less thoroughly studied and appears rather limited in its synthetic utility[62]. Hydroxymercuration conditions provide a convenient method for the catalytic hydrolysis of alkynes to ketones. Alkoxymercuration generally produces ketals directly, although enol ethers have been obtained. Enol acetates can also be obtained if acetic anhydride is used as the solvent.

A few comments on the methods of demercuration should be made before concluding this section[63]. Although hydrazine has been employed as a reducing agent, it generally gives poor yields. $LiAlH_4$ has also been used, but offers no advantages over the widely used $NaBH_4$ procedure. This latter procedure usually proceeds in very high yield, although free radicals are involved and rearrangement products are sometimes observed[64]. On the other hand, sodium amalgam provides a valuable method for the stereospecific replacement of mercury by deuterium[65].

4. Carbene Transfer

α-Halomethylmercury compounds have found extensive use in organic synthesis as carbene transfer reagents. They have proven particularly useful for the synthesis of cyclopropanes from alkenes [eq. (33)]. The utility of these compounds has



(33)

been extensively studied by *Seyferth et al.* and several reviews have appeared recently[66–68]. Rather than repeat those reviews, we shall primarily concentrate on the synthetic utility of these reagents, pointing out the advantages and disadvantages.

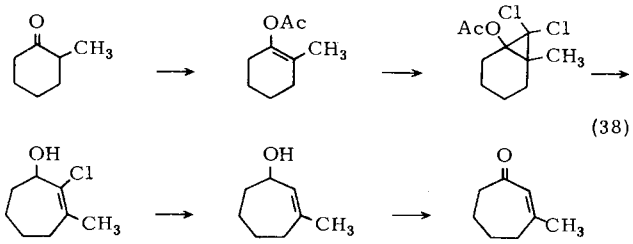
The majority of these carbene transfer reactions have employed phenyl(trihalomethyl)mercury compounds. In general, these reagents appear to reversibly dissociate "free"

(34)

(35)

carbenes which then rapidly react with the alkene to generate cyclopropanes [eqs. (34) and (35)][69, 70]. Clean transfer of the more nucleophilic halide (I > Br > Cl) from carbon to mercury is observed in these reactions, apparently by a concerted intramolecular rearrangement[71]. The relative rates of reaction of various halomethylmercurials follow the same order (I > Br > Cl). Replacement of the phenyl group by a cyclohexyl group has also been observed to facilitate reaction[72].

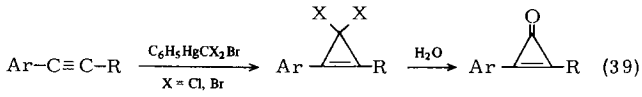
Apparently, not all transfer reactions of this type proceed *via* a carbene intermediate however. For example, $(BrCH_2)_2Hg$ appears to involve a direct transfer of the CH_2 moiety from the mercurial to the alkene[73]. Under certain circumstances trihalomethyl carbanions can also be involved in these reactions. In those cases where the carbene is not readily thermally released by the mercurial, iodide ion can be employed to displace the trihalomethyl anion which subsequently decomposes to a carbene [eqs. (36) and (37)][74–76].



(36)

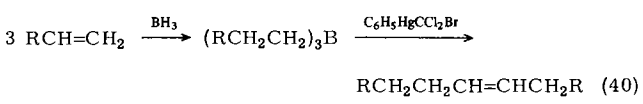
$$^{\ominus}CF_3 \longrightarrow :CF_2 + F^{\ominus} \qquad (37)$$

The α-halomethylmercurials have proven very valuable for the synthesis of cyclopropanes for a number of reasons. They proceed at reasonable temperatures under neutral reaction conditions, avoiding the introduction of strong bases or other potentially reactive reagents which are generally necessary for the formation of other transfer reagents. Thus, potentially serious side reactions between the actual carbene transfer reagent and reagents used to generate this species are avoided. Furthermore, the organomercurial reagent itself is generally inert to most substrates with which one desires to carry out a reaction. The phenylmercury(II) halide by-product in these reactions is also inert and usually precipitates from solution during reaction. It can also be easily reused in the preparation of additional transfer reagents. The insolubility of the resultant mercurial allows it to be removed from the cyclopropane product by simple filtration. These reactions can also generally be run in a variety of solvents. In general, one can employ an equimolar ratio of alkene and organomercurial and temperatures of 50—100 °C. Under these conditions simple alkenes give essentially quantitative yields. Those alkenes, such as ethylene, *trans*-stilbene, tetrachloroethylene, trimethyl(vinyl)silane and 3,3-dimethyl-1-pentene, which are generally unreactive towards other carbene reagents give satisfactory yields with the mercurial reagents. Alkenes, such as acrylonitrile, methyl acrylate and vinyl acetate which readily polymerize in the presence of base or reagents which generate the trihalomethyl carbanion, also give good yields with these reagents. A large number of functional groups are apparently accommodated by this reaction.



There are, however, several limitations to the use of these reagents. The most obvious one is the need to prepare and isolate the intermediate organomercurial. However, a number of literature procedures presently exist for the preparation of these compounds. The presence of certain functional groups in the alkene can also create problems. Carboxylic acids, alcohols and amines all react with these reagents. Reactions with a number of other functional groups can occur in the absence of carbon-carbon double bonds and a number of unusual heterocyclic compounds can be prepared in this manner.

These reagents have found other uses in organic synthesis as well. *Stork* has utilized dichlorocarbene additions to enol acetates as a means of ring expanding cyclic ketones to enones [eq. (38)][77].



(38)

The addition of dihalocarbenes to arylacetylenes has provided a convenient route to aryl substituted cyclopropenones [eq. (39)][78, 79]. This reaction fails with dialkylacetylenes.

(39)

Organoboranes, derived from terminal alkenes *via* hydroboration, are readily coupled in good yield upon treatment with bromodichloromethyl(phenyl)mercury [eq. (40)][80].

(40)

Treatment of aldehydes and ketones with these same mercurials and triphenylphosphane provides an interesting route to a variety of vinyl halides [eq. (41)][81, 82]. This Wittig-like

$$R_2C{=}O + C_6H_5HgCHBr_2 + (C_6H_5)_3P \rightarrow R_2C{=}CHBr \qquad (41)$$

reaction quite likely proceeds through an intermediate phosphorus ylide.

All told, the halomethyl(phenyl)mercury reagents have proven extremely valuable for the synthesis of halocyclopropanes and exhibit a number of other interesting reactions which appear to possess considerable synthetic potential.

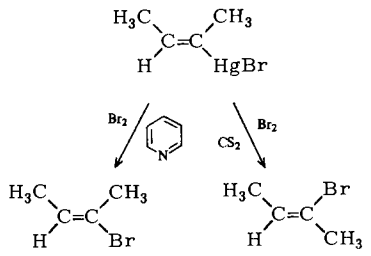
5. Halogenation of Organomercury Compounds

Organomercurials generally react quite readily with chlorine, bromine and iodine to give the corresponding organic halides [eqs. (42) and (43)]. This reaction has been widely

$$R_2Hg + X_2 \rightarrow RHgX + RX \qquad (42)$$

$$RHgX + X_2 \rightarrow HgX_2 + RX \qquad (43)$$

X = Cl, Br, I



used to determine the position of the mercury atom in organomercurials. Synthetically, however, it is of rather limited importance since the usual starting materials for the preparation of organomercurials are either (1) organic halides themselves, (2) compounds derived from organic halides (organomagnesium or -lithium compounds), or (3) compounds readily halogenated directly (organoboranes, arenes, diazonium salts).

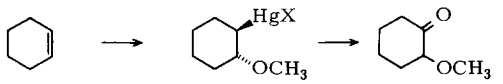
There are perhaps several noteworthy exceptions however. Several reports indicate that the halogenation of organomercurials prepared by solvomercuration reactions provides a convenient method for the synthesis of β-substituted organic halides [eq. (44)][83-87]. Equally valuable is the bromination

$$RCH{=}CH_2 \longrightarrow \underset{\displaystyle HgX}{\overset{\displaystyle Y}{RCH{-}CH_2}} \xrightarrow{X_2} \underset{\displaystyle X}{\overset{\displaystyle Y}{RCH{-}CH_2}} \qquad (44)$$

Y = –OH, –OR'; X = Br, I

of vinylmercury bromides which can apparently be controlled to give either the retained or inverted vinyl bromide simply by changing the solvent [eq. (45)][88]. The iodination of

(45)



alkenyl-[89], alkynyl-[90,91] and arylmercurials[92] also appears to be of preparative utility.

It is interesting to note that the *in situ* iodination of *n*-alkylmercuric acetates derived from the mercuration of tri-*n*-alkylboranes gives the corresponding acetates and *not* the iodides, although the iodides are apparently intermediates in this reaction [eq. (46)][93]. *In situ* bromination provides the corresponding alkyl bromides[94].

$$3\ RCH{=}CH_2 \xrightarrow{BH_3} (RCH_2CH_2)_3B \xrightarrow[2.\ 3\ I_2]{1.\ 3\ Hg(OAc)_2} 3\ RCH_2CH_2OAc \qquad (46)$$

6. Oxidation and Sulfur Displacement Reactions

The large majority of organomercurials are very stable towards oxygen. On the other hand, organomercurials are readily oxidized by ozone[95]. Primary alkylmercurials give the corresponding carboxylic acid, plus all carboxylic acids possible from stepwise loss of carbon. Secondary organomercurials give good yields of ketones. This reaction would appear to be of value for the synthesis of α-substituted ketones from alkenes *via* solvomercuration-oxidation [eq. (47)]. Although

(47)

tertiary alkylmercurials yield the corresponding tertiary alcohols upon ozonolysis, this reaction is of little value due to the limited availability of these organomercurials.

The oxidation of either hydroxy- or methoxymercuration products with catalytic amounts of palladium(II) chloride and copper(II) chloride provides a very convenient method for

$$RCH{=}CH_2 \longrightarrow \underset{\displaystyle HgOAc}{\overset{\displaystyle OR'}{RCHCH_2}} \xrightarrow[3\ CuCl_2]{cat.\ PdCl_2} RCCH_3 \qquad (48)$$

the conversion of alkenes directly to ketones [eq. (48)][96]. If ethylene glycol is employed as the solvent the 1,3-dioxolane can be obtained directly [eq. (49)][97].

$$RCH{=}CH_2 \longrightarrow \underset{\displaystyle HgOAc}{\overset{\displaystyle OCH_2CH_2OH}{RCHCH_2}} \xrightarrow[3\ CuCl_2]{cat.\ PdCl_2} \underset{\displaystyle R}{\overset{\displaystyle O}{\overset{\displaystyle O}{\diagup\!\diagdown}}}\!\!CH_3 \qquad (49)$$

An analogous ketone preparation can be achieved by employing chromium trioxide and only a catalytic amount of mercury(II) acetate [eq. (50)][98]. This reaction presumably

$$RCH{=}CH_2 \xrightarrow[\substack{CrO_3/H_2SO_4\\ H_2O}]{cat.\ Hg(OAc)_2} RCCH_3 \qquad (50)$$

proceeds through intermediate β-hydroxy and β-keto mercurials. While the palladium reaction apparently gives good yields of ketones from internal olefins, the chromium trioxide procedure gives only 20—56% yields.

Arylmercurials have been oxidized in high yield to phenols by first treating with borane and then oxidizing the resulting arylborane [eq. (51)][99].

$$ArHgCl \xrightarrow{BH_3} [Ar{-}B\lessgtr] \xrightarrow[NaOH]{H_2O_2} ArOH \qquad (51)$$

Thermolysis of a large number of vinylmercury salts leads, often in high yields, to the corresponding vinyl oxygen and sulfur derivatives and metallic mercury [eq. (52)][100-106].

$$CH_2{=}CHHgX \xrightarrow{\Delta} CH_2{=}CHX + Hg \qquad (52)$$

X = $-\overset{O}{\overset{\|}{O}}CR$, –OAr, –SAr, –SR, –OTs, –SCN, $-S\overset{O}{\overset{\|}{C}}OR$,

$-OS(=O)_2-C_6H_4-CH_3$, $-ON{=}C(CF_3)_2$, $-OP(=O)(OR)_2$, $-OP(=O)(CH_3)OR$,

$-SP(=S)(OR)_2$, $-OSO_2F$

This reaction seems to be quite general and would appear to have some synthetic utility.

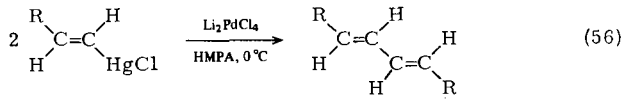
Diaryl sulfides can be prepared by heating diarylmercurials and sulfur to 190—250°C [eq. (53)][107-110]. At 140—180°C

$$Ar{-}Hg{-}Ar \xrightarrow[190-250\,^\circ C]{S_8} Ar{-}S{-}Ar \qquad (53)$$

using either alkyl or arylmercury chlorides in sulfolane, good yields of the corresponding disulfides can be obtained instead [eq. (54)][111].

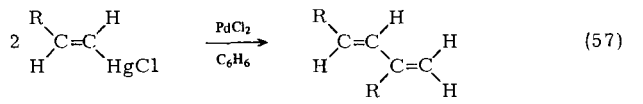
$$2\ RHgCl \xrightarrow[140-180\,^\circ C]{S_8} R{-}S{-}S{-}R \qquad (54)$$

7. Dimerization of the Organic Moiety of Organomercury Compounds



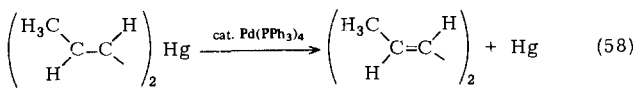
Transition metals have proven useful for the dimerization of a number of organomercurials. Dibenzylmercury and a number of diarylmercurials can be dimerized by heating with finely divided nickel, palladium, platinum, copper, gold or silver metals [eq. (55)][112]. Silver powder has been used to synthesize biferrocenyl[113], as well as biphenylene[114,115],

(55)



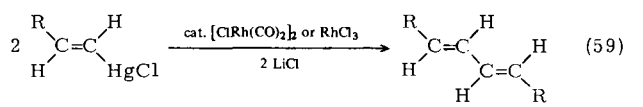
octafluorobiphenylene[116], benzo[*a*]biphenylene[117] and triphenylene[118] from cyclic arylmercurials.

Under certain conditions transition metal salts have also proven highly efficient for the dimerization of both aryl and vinylmercurials. Recently, several new procedures have been developed for the dimerization of vinylmercurials. We have observed that symmetrical 1,3-dienes and polyenes can be obtained in excellent yields by treating vinylmercury chlorides with lithium chloride and stoichiometric amounts of palladium chloride in hexamethylphosphoramide (HMPA) at 0°C [eq. (56)][119]. When benzene is used as the solvent an unusual



(56)

"head-to-tail" dimerization occurs instead [eq. (57)][120]. Catalytic procedures also exist for the symmetrical dimerization.



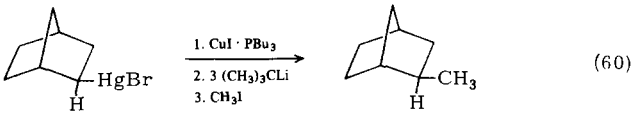
(57)

Thus, *Vedejs* and *Weeks* have reported that *cis*- and *trans*-dipropenylmercury are catalytically dimerized by *tetrakis*(triphenylphosphane)palladium(0) [eq. (58)][121]. More recently, we have

(58)

observed that rhodium(I) and rhodium(III) salts very efficiently catalyze the dimerization of both aryl and vinyl groups of organomercury chlorides [eq. (59)][122]. Palladium chloride

(59)

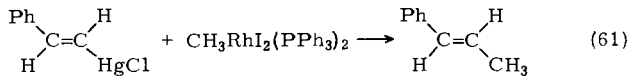


plus copper(II) chloride[123] or copper metal[124], or palladium acetate alone[125], have also been reported to dimerize arylmercurials. Surprisingly little use seems to have been made of any of these reactions for the synthesis of biaryls.

To date, alkylmercurials other than allylmercury iodide[119] and benzylmercurials[112, 119] have not been dimerized in good yield.

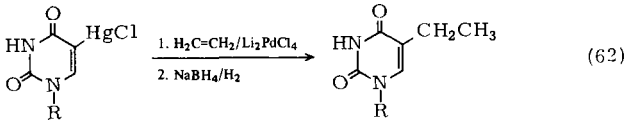
8. Reactions of Organomercury Compounds with Alkylating Reagents

In general, organomercurials are quite inert towards alkyl halides. Only under forcing conditions will arylmethyl halides alkylate dibutylmercury and arylmercurials[126–129]. The yields in these reactions are generally quite low. However, these reactions can be carried out at −15 to −20°C if aluminum bromide is added[130]. Diphenyl- and dibenzylmercury react with methyl iodide, ethyl bromide, chloromethyl methyl ether, benzyl bromide, *p*-nitrobenzyl bromide, and benzhydryl bromide to give low to modest yields of coupled products under these conditions. The highly reactive α-mercurated carbonyl compounds are readily alkylated at room temperature even in the absence of catalysts[131, 132].



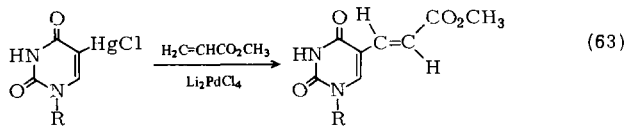
Transition metal reagents can also be used to promote alkylation. *Whitesides* has reported an interesting copper reaction which results in overall alkylation of an organomercurial [eq. (60)][133]. Unfortunately, this procedure appears to have

(60)



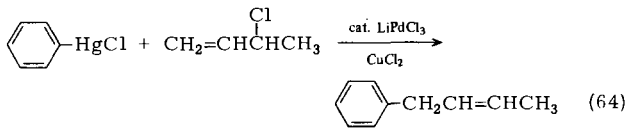
no advantages over the direct use of organocuprates since alkyl lithium reagents are required in both procedures.

Recently, we have observed that organorhodium(III) compounds will couple with both aryl- and vinylmercurials and we are presently studying the generality and synthetic utility of this reaction [eq. (61)][134].



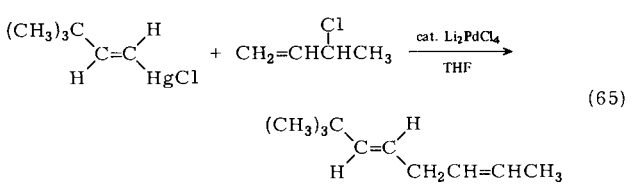
(61)

Bergstrom and *Ruth* have been able to alkylate, allylate and alkenylate 5-(chloromercury)nucleosides by taking advantage of previously reported organopalladium reactions [eq. (62)][135]. Use of allyl chloride gives the 5-allyl derivative



(62)

directly without reduction and methyl acrylate gives the 3-*trans* substituted propenoate [eq. (63)] (see Section 9).



(63)

Both aryl- and vinylmercurials also undergo a smooth coupling with allylic halides when palladium chloride plus lithium chloride is employed as a catalyst. *Heck* reports that arylmercuric halides give 31—87% yields of allylaromatics [eq. (64)][136]. We have found that vinylmercurials give similar

(64)

yields of 1,4-dienes [eq. (65)][137]. It is especially noteworthy that both these reactions tolerate a number of functional

(65)

groups, occur at or below room temperature, and result in transposition of the double bond of the allylic halide. These reactions apparently proceed as indicated below [eqs. (66) to (68)].

$$RHgCl + PdCl_4^{2\ominus} \longrightarrow RPdCl_3^{2\ominus} + HgCl_2 \quad (66)$$

$$RPdCl_3^{2\ominus} + CH_2{=}CHCHCH_3 \longrightarrow \left[\begin{matrix} Cl_3Pd & Cl \\ RCH_2CH & CHCH_3 \end{matrix}\right]^{2\ominus} \quad (67)$$

$$\left[\begin{matrix} Cl_3Pd & Cl \\ RCH_2CH & CHCH_3 \end{matrix}\right]^{2\ominus} \longrightarrow RCH_2CH{=}CHCH_3 + PdCl_4^{2\ominus} \quad (68)$$

9. Alkene Substitution and Addition Reactions

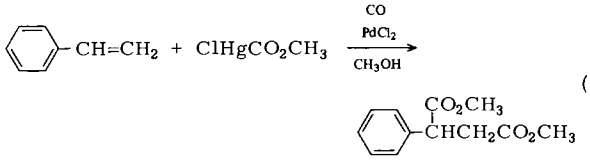
In 1968 *Heck* reported a number of interesting reactions of organomercurials and alkenes promoted by palladium salts. Simple alkenes undergo vinylic hydrogen substitution reactions [eq. (69)][138]. In the reactions of alkenes containing

$$RHgX + PdX_2 + CH_2{=}CHY \rightarrow RCH{=}CHY \quad (69)$$

allylic hydrogens a mixture of isomeric substituted alkenes is obtained. These reactions are apparently limited to arylmercurials, alkoxycarbonylmercurials, and alkylmercurials which do not contain β-hydrogen atoms[138, 139]. A large number of functional groups are apparently accommodated by this reaction.

The reaction apparently involves the following sequence of reactions [eqs. (70) to (73)][140, 141]. When the original

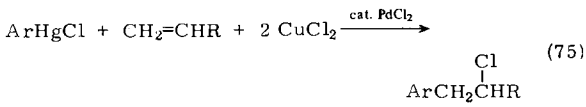
$$RHgX + PdX_2 \longrightarrow RPdX + HgX_2 \quad (70)$$



$$RPdX + CH_2{=}CHY \longrightarrow RCH_2\underset{\displaystyle PdX}{\underset{|}{C}}HY \quad (71)$$

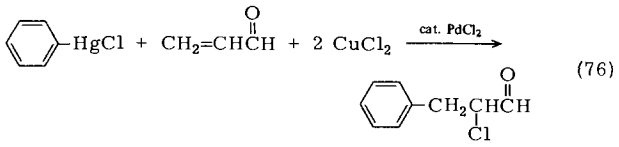
$$RCH_2\underset{\displaystyle PdX}{\underset{|}{C}}HY \longrightarrow RCH{=}CHY + HPdX \quad (72)$$

$$HPdX \longrightarrow HX + Pd \quad (73)$$



alkene contains allylic hydrogens, palladium hydride elimination can occur in more than one direction leading to an isomeric mixture. These reactions can be made catalytic in palladium if a reoxidant such as copper(II) chloride is employed to oxidize the palladium metal back to palladium(II).

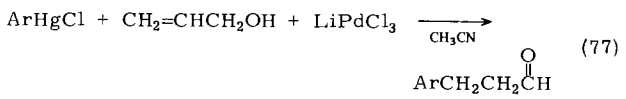
The intermediate organopalladium addition compounds from the alkoxycarbonylmercurial addition reactions can be trapped by carbonylation, providing a novel synthesis of substituted succinic esters [eq. (74)][142].



(74)

If the reaction of arylmercurials and alkenes is run in the presence of catalytic amounts of palladium chloride and

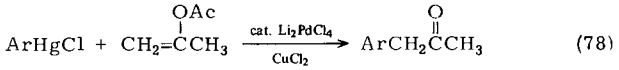
(75)



approximately 2 M copper(II) chloride, β-arylalkyl chlorides are produced instead [eq. (75)][143]. This reaction appears

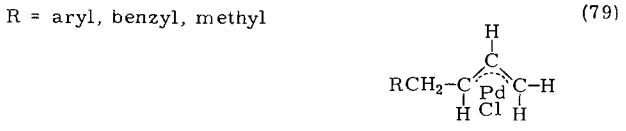
(76)

valuable for the synthesis of α-halocarbonyl compounds [eq. (76)].



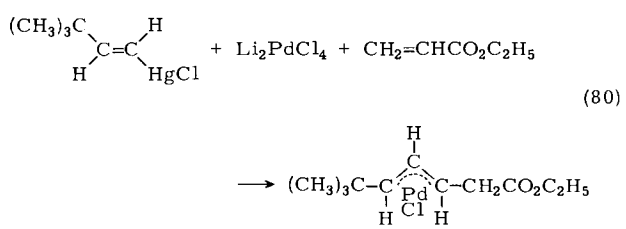
The reaction of primary and secondary allylic alcohols takes an entirely different course and produces 3-arylaldehydes and ketones respectively, although in low yield [eq. (77)][144].

(77)



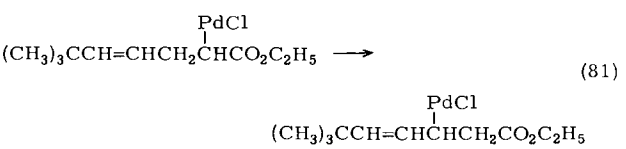
Apparently, the initial alkylpalladium compound obtained upon addition of the aryl palladium species to the carbon-carbon double bond preferentially eliminates a hydride from the carbon containing the hydroxyl group, producing an enol of the eventual carbonyl compound.

The reaction of enol esters provides 2-arylaldehydes and ketones, albeit generally in quite low yield [eq. (78)][145].



(78)

The reaction of organomercurials, palladium salts and conjugated dienes gives low to moderate yields of π-allylpalladium compounds [eq. (79)][146]. Quite surprisingly, the reaction



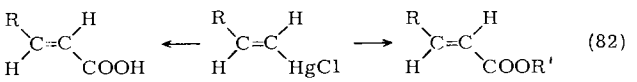
(79)

of vinylmercurials, palladium chloride and simple alkenes produces quite high yields of π-allylpalladium compounds also

(80)

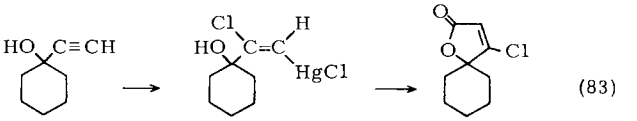
[eq. (80)][147]. The π-allylpalladium compounds are apparently produced by a palladium hydride rearrangement [eq. (81)].

(81)



The palladium promoted addition of organic groups from organomercurials to carbon-carbon double bonds appears to be a very general reaction. The reactions also accommodate

a large number of functional groups. Unfortunately, however, they cannot be employed with organomercurials possessing β-hydrogens and many reactions give rather low yields. Nevertheless, the ease with which carbon-carbon bond formation occurs suggests considerable synthetic utility.



10. Carbonylation Reactions

The direct carbonylation of organomercurials by carbon monoxide is of limited synthetic utility[148-151]. It requires high temperatures and pressures and generally gives only very poor yields. However, palladium salts readily promote the carbonylation of organomercurials. For example, *Henry* has reported that ethylmercury(II) chloride reacts with palladium chloride and carbon monoxide at atmospheric pressure to give propionic acid upon aqueous workup[152]. Similarly, arylmercurials give acid chlorides in acetonitrile, esters in alcohol solvents, and anhydrides when palladium acetate is employed. Unfortunately, the yields are generally low.

On the other hand, vinylmercurials are readily carbonylated at low temperatures and one atmosphere carbon monoxide if lithium chloride and palladium chloride are used[153]. Depending on the solvent used, one obtains excellent yields of either α,β-unsaturated carboxylic acids or esters [eq. (82)].

(82)

These reactions can be accomplished with only catalytic amounts of palladium chloride or palladium on carbon, if copper(II) chloride is added as a reoxidant. These reactions have recently provided a novel new route to butenolides *via* carbonylation of the vinylmercurials derived from the addition of mercury(II) chloride to alkynyl alcohols [eq. (83)][17].

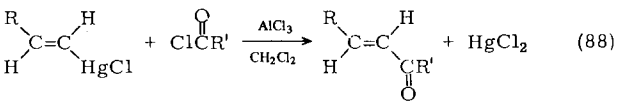
(83)

Diarylketones have also been obtained upon carbonylation of arylmercurials. Arylmercuric chlorides react with palladium chloride salts under 50 psig of carbon monoxide to give low yields of diaryl ketones[154]. Rhodium(I) and (III) complexes give somewhat better yields and can be run at atmospheric pressure. These reactions can be accomplished in considerably higher yield by using either tetracarbonylnickel[155] or octacarbonyldicobalt[156, 157]. The latter procedure can also be employed using only catalytic amounts of the carbonylmetal if the reaction is photolyzed [eq. (84)][158].

$$Ar_2Hg + CO \xrightarrow[h\nu]{\text{cat. } Co_2(CO)_8} Ar_2C{=}O + Hg \qquad (84)$$

11. Acylation of Organomercury Compounds

Most organomercurials are unreactive towards acid halides. However, a few arylmercury chlorides have been acylated to give the corresponding ketones [eq. (85)][128, 129]. α-Mercurated carbonyl compounds react readily with acid halides to produce the corresponding enol esters [eq. (86)][132].



$$ArHgCl + ClCR \longrightarrow ArCR + HgCl_2 \qquad (85)$$

$$RCCl + ClHgCH_2CR' \longrightarrow CH_2{=}CR' + HgCl_2 \qquad (86)$$

Both $Pd[P(C_6H_5)_3]_4$[159] and aluminum halides[160, 161] promote rapid acylation of dialkyl- and diarylmercurials [eq. (87)], but it appears that only one of the two organic groups

$$R_2Hg + ClCR' \longrightarrow RCR' + RHgCl \qquad (87)$$

of the organomercurial reacts under these conditions. However, vinylmercury chlorides and aluminum trichloride react readily with acid chlorides to give excellent yields of α,β-unsaturated ketones with retention of configuration [eq. (88)][162].

(88)

12. Conclusion

Organomercurials have been known since 1850. They are now readily available by a number of routes and possess a number of characteristics which make them attractive as synthetic intermediates. Until lately, however, their low chemical reactivity has limited their use in organic synthesis. Recently, transition metal exchange reactions have been employed to promote a number of synthetically interesting reactions. These reactions appear to accommodate a large number of organic functional groups. However, the two most widely used reactions of organomercurials remain the carbene transfer reactions and solvomercuration-demercuration reactions.

Solid Ionic Conductors: Principles and Applications

By Hans Rickert[*]

Solid ionic conductors, also called solid electrolytes, transport electric current by means of ions. The best known examples of these usually crystalline compounds include doped ZrO_2, as well as AgI, β-Al_2O_3, and CaF_2. Ionic conduction in solid electrolytes reaches its maximum value if a partial lattice of a solid compound undergoes transition at elevated temperature to a quasimolten state. The ionic conductivity in such solid compounds is then as high as in molten salts. Solid electrolytes have found many scientific and technological applications; thus, they can be used to study thermodynamic and kinetic problems, and to build fuel cells, batteries, sensors, and chemotronic components.

1. Principles

Solid ionic conductors are solid, generally crystalline, compounds in which electric current is carried by charged atoms, *i.e.* by ions. The passage of current is thus associated with mass transfer. Such ionic conductors are called "solid electrolytes", by analogy to liquid electrolyte solutions, and have permitted development of a new scientific discipline, *viz.* solid-state electrochemistry. The associated technology is termed solid-state ionics, in contrast to solid-state electronics.

The fact of ionic conduction in solids presents two sets of questions. First, how can ionic conduction arise microscopically at the atomic level, and how large can this ionic conduction become? Secondly, what applications are open to solid conductors in science and technology?

The first set of questions leads us to discuss disorder in solids. One limiting case is structural disorder—the quasimolten state—of a partial lattice of crystalline compound. This explains how the ionic conduction in certain solid electrolytes can become as high as that in concentrated electrolyte solutions or molten salts. However, unlike the liquid electrolytes, solid ionic conductors require no vessel to contain them, since they are still solid in spite of their quasimolten partial lattice. A solid ionic conductor can itself act as container or as the partition between electrode compartments; this leads to interesting constructional possibilities in the design of galvanic cells not provided by liquid electrolyte solutions or molten salts.

We thus come to the second set of questions, those concerning scientific and technological applications. The potential uses are largely based on the fact that solid electrolytes can be used to construct galvanic cells (also called elements) suitable for many different purposes; for example, not only for batteries or fuel cells but also for measurement or control engineering purposes, for display units, and for the developing field of chemotronic components. In the scientific area, galvanic cells containing solid electrolytes can be used in both thermodynamic and kinetic investigations. The importance of galvanic solid-state cells for thermodynamic investigations lies in the fact that their EMF provides information about chemical potentials or thermodynamic activities, partial pressures, and free energies. In kinetic investigations it is also important that reaction rates can be measured *via* the electric current in suitably constructed galvanic cells. The combination of rate measurement *via* an electric current with measurement of thermodynamic quantities *via* the EMF often permits analysis of kinetic processes. Both engineering applications and thermodynamic and kinetic studies will be illustrated in this

Otto-Hahn-Strasse, D-4600 Dortmund 50 (Germany)

review by typical examples. However, the theoretical principles underlying solid electrolytes will be considered first, and important solid ionic conductors surveyed. For further study the reader is referred to an introductory textbook[1] and to various reviews and conference proceedings[2-13].

1.1. Solid Electrolytes

The fact that solid substances, and in particular crystalline compounds, can act as ionic conductors has been known since the end of the last century. The atomistic interpretation of the possibility of ionic conduction in solids is also not new—it goes back to the twenties, to *Joffé*[14], to *Frenkel*[15], and to *Schottky* and *Wagner*[16]. Ionic conduction in solids is made possible by disorder in a crystal lattice, *i.e.* deviation from ideal order. At finite temperatures, unoccupied sites (vacancies) may occur in the crystal lattice, and/or additional particles may be present interstitially (interstitial atoms or ions) between the regular positions of the host lattice. Further defect centers may be due to foreign ions occupying interstitial sites.

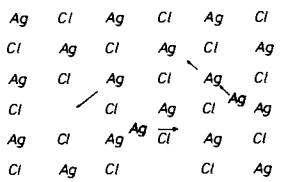

Fig. 1. Two-dimensional section through an AgCl crystal with lattice defects (schematic).

A possible defect is illustrated schematically in Figure 1 for silver chloride. The two-dimensional section through the silver chloride lattice shows silver and chlorine particles mainly in their normal positions. These particles have not been assigned any electric charge, because it is only meaningful to express charge relative to the unperturbed lattice, and silver and chloride ions in their normal sites are electrically neutral relative to the unperturbed lattice. The figure also shows two silver ions at interstitial sites; these ions bear an excess of positive charge. Two unoccupied sites can be seen, and these vacancies are charged negatively relative to the unperturbed lattice.

Possible transport mechanisms are also indicated in Figure 1 by arrows: a silver particle lying close to a vacancy may move into it. Moreover, the interstitial particles can change sites and thus bring about mass transfer. The concentrations of imperfection centers are subject to the laws of thermodynamic equilibrium, as demonstrated by *Frenkel*[15] and especially by *Wagner* and *Schottky*[16]. The concentrations of the various defects are related to one another by laws of mass action, just like the concentrations of ions on electrolytic dissociation in liquid electrolyte solutions. Thus, the treatment of imperfections can justifiably be compared with that of electrolytic dissociation. Disordered particles, and also vacancies, can be regarded as quasichemical species and have led to their own chemistry, called imperfection chemistry. Unfortunately, in the older and in the more recent literature different symbols are used for the imperfection centers, and the meanings attached to them are also different[17-20].

The concentrations of imperfection centers increase with rising temperature. The limiting case are crystals in which the concentrations of vacancies and interstitial particles become comparable; there then occurs a statistical distribution of particles in normal lattice positions and in interstitial positions. In this state it is no longer reasonable to distinguish between regular and interstitial lattice positions. The total number of possible positions for a single type of particle may be several times higher than the number of such particles in the crystal. This state is known as structural disorder (a partial lattice of the crystal is now quasimolten) and can be reached by a continuous process (CaF_2, see below) or by a discontinuous one (AgI). At 149 °C AgI passes from the β- into the α-phase, the iodide lattice changing into a cubic body-centered structure while the silver ions are distributed randomly between the iodide ions.

On the basis of X-ray structure analyses carried out by *Strock*[21,22], the silver ions in α-AgI were formerly assigned fixed positions over which they were distributed statistically (Fig. 2). Although there are 42 point positions for two silver

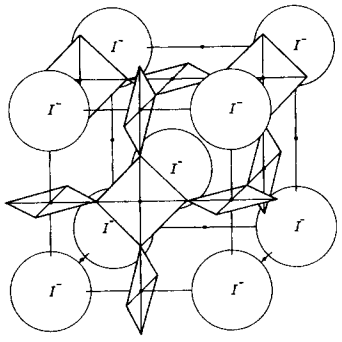

Fig. 2. Silver iodide lattice with the assumption of point sites for the silver ions (for two silver ions there are 42 point sites).

ions, the very size of these ions precludes independent occupation of all these positions. Discussion of the correlation factor for tracer diffusion in Ag_2S[23], which has a disorder analogous to that in AgI, as well as investigations by microwave techniques and by neutron scattering[24-27], have shown that it is more reasonable to speak of regions in which the silver ions engage in essentially random motion (Fig. 3).

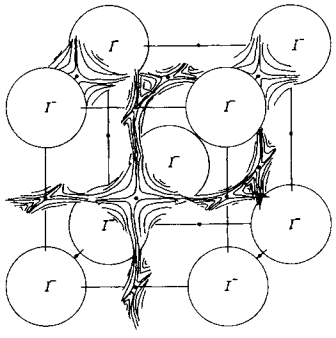

Fig. 3. Silver iodide lattice with the assumption of regions in which the silver ions can move.

The idea that the silver ions in α-AgI are already in a quasimolten state is supported by the diffusion coefficients, which are of the order $10^{-5}\,cm^2\,s^{-1}$ for a liquid, and by

thermodynamic values. The entropy for the transition from β-AgI to α-AgI amounts to $14.5\,JK^{-1}\,mol^{-1}$, the entropy of fusion to $11.3\,JK^{-1}\,mol^{-1}$. It is assumed that silver iodide melts in two stages. In the β→α transition the silver partial lattice passes into the quasimolten state (structural disorder), whereas the iodide partial lattice does not become liquid below the actual melting point. Comparable crystals that nevertheless do not show the special behavior of structural disorder before they actually melt have an entropy of fusion about as large as the sum of the transition entropy and entropy of fusion in AgI, *i.e.* about twice as large as the residual entropy of fusion in AgI. An analogous situation is found in some other crystalline compounds that contain a quasimolten partial lattice after passing through a transition point. This has been pointed out especially by *O'Keefe* and *Hyde*[28]. However, it should be mentioned that in all cases where an ordered state of one partial lattice is transformed into a disordered state, structural changes will also occur in the other partial lattice. It must remain an open question how the silver ions would behave if the iodide partial lattice of α-AgI remained unchanged at lower temperatures, *i.e.* if it were possible to supercool the α-AgI. It is conceivable that in this case the silver ions would become continuously more ordered as the temperature were lowered.

Compounds of another group (example CaF_2) undergo a continuous transition from the ordered to the strongly disordered state on heating. This continuous transition of a partial lattice into the quasimolten state without a change in the partial lattice of the other type of ion is also accompanied by characteristic thermodynamic properties: in the temperature region in which strong disorder develops, an abnormally high specific heat becomes evident[28]; thus, an increase in disorder requires the supply of additional energy.

In solid electrolytes with structural disorder not only are all the particles of one kind of ion mobile, so that they can all contribute simultaneously to current transport, but also their diffusion coefficient and thus their mobility attain values such as are found otherwise only in liquids or in gases compressed to the density of liquids. The ions thereby attain maximum limiting values not only for concentration but also for mobility, as determined by the nature of condensed systems. Thus, ionic conductors are optimized with respect to the partial conductivity of one type of ion, because the partial conductivity is governed by the relation:

$$\sigma_i = |z_i| F u_i c_i \qquad (1)$$

where z_i is the ionic valence, F Faraday's constant, u_i the electric mobility, and c_i the concentration of the mobile ions. If the concentration of the mobile particles c_i and their mobility u_i have reached their maximal values, then according to eq. (1) the partial conductivity σ_i also attains its maximal value. The high mobility and thus the high diffusion constant become intelligible within the atomistic picture if it is assumed that the ions hardly vibrate at all about their rest positions but instead move irregularly within the lattice with thermal velocities. Solid electrolytes containing structural disorder are often called "superionic conductors" or "optimized electrolytes".

Summarizing, it can be said that the possibility of ionic conduction in solids is due to disorder in the latter, and especially to the interstitial ions and vacancies. The disorder can become so great that the particles assume a random distribution and therefore behave like liquids, swimming in the space between the lattice sites of the other type of ion. Table 1 lists some solid electrolytes, but makes no claim to completeness if only because new electrolytes are currently being reported monthly and sometimes weekly. Figure 4 shows the conductivities of some important solid electrolytes as a function of the reciprocal temperature; the conductivity of concentrated sulfuric acid is included for comparison. It can be seen that the conductivity of solid electrolytes can lie in the same range as that of concentrated liquid electrolytes. For silver iodide, a solid electrolyte in which structural disorder sets in at a transition point, the conductivity jumps by about four orders of magnitude on transformation of the β- into the α-phase. In calcium fluoride, however, the conductivity rises continuously up to the melting point, but here undergoes no further change due to the melting process, *i.e.* at the melting point solid and liquid calcium fluoride have almost the same conductivity. In silver iodide the conductivity of the melt is actually slightly lower than the conductivity of the solid material shortly before the melting point.

Doped zirconium dioxide and thorium dioxide are important solid electrolytes which owe their conductivity to trans-

Table 1. Solid electrolytes. The ion named in the first column is that mainly responsible for the conductivity.

Conducting ion	Compound	Temperature range [°C]	Ref.
Oxide (O^{2-})	$ZrO_2(Y_2O_3)$	600–1600	[29]
	$ThO_2(Y_2O_3)$	600–1100	[30]
	$CeO_2(Gd_2O_3)$	500–1500	[65, 66]

port of oxygen ions. Recently, doped cerium dioxide has also been discussed for particular applications. Zirconium dioxide can be used between 600 and 1600 °C. It is also an interesting example of how high ionic conductivity can arise by processes other than those discussed above. The disorder centers responsible for the ionic conductivity of zirconium dioxide are charged oxygen ion vacancies. These are produced by dissolution of CaO, MgO, or Y_2O_3 in the zirconium dioxide. The calcium is incorporated at zirconium positions; since, however, only one oxygen ion is introduced with each calcium ion, one oxygen position remains unoccupied for each calcium atom introduced. The amount of doping is of the order of 10 mol-%; in this way it can be seen why doping produces a very large number of vacancies in the zirconium dioxide.

An important Na^+ ionic conductor is $Na_2O \cdot 11\,Al_2O_3$, so-called β-Al_2O_3. The mobile sodium ions are incorporated into the plane of the lattice and can therefore move only in two dimensions; polycrystalline material is used to obtain three-dimensional conductivity. $RbAg_4I_5$ and related compounds are interesting ionic conductors that display high ionic conductivity even at room temperature; in these materials the silver ions are mobile. They show structural disorder similar to that in AgI. $RbAg_4I_5$ has gained importance for manufacture of chemotronic components (see Section 2.4).

1.2. Galvanic Cells Embodying Solid Electrolytes

Galvanic cells can be set up with solid electrolytes just as with liquid ones, and therein lies their great importance. Their manifold applications will be discussed below with the aid of examples, but we shall first describe their most important properties. For this purpose we shall consider the galvanic cell represented schematically in Figure 5: it consists of doped

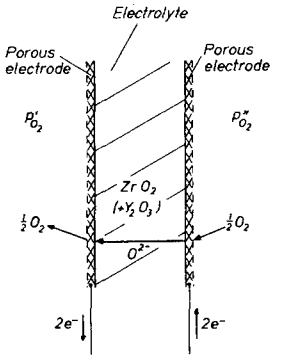

Fig. 5. Galvanic solid-state cell with zirconium dioxide as solid electrolyte and two oxygen electrodes with different oxygen partial pressures (schematic).

zirconium dioxide as the solid electrolyte with almost pure ionic conduction for oxygen ions. On the two sides there are porous, electronically conducting electrodes bathed in gaseous oxygen at different partial pressures. The zirconium dioxide must separate the electrode spaces from one another in gas-tight manner. For example, a tube of zirconium dioxide can be used that carries an electrode on the inner and another on the outer side, the outside and the inside being surrounded by gaseous oxygen at different partial pressures. If in the galvanic cell illustrated a positive electric current flows from the left to the right electrode, 1 mol of O_2 is transported from the right to the left electrode space by the passage of 4 faradays (4 F). The following cell reaction occurs:

$$O_2 \text{ (right electrode)} \rightarrow O_2 \text{ (left electrode)} \qquad (2)$$

The galvanic cell can thus be used as an oxygen pump if an external power source causes electric current to pass through the cell. It can, however, also act as a source of current, if different partial pressures of oxygen are maintained on the left and right. The electric work that in the reversible case of the galvanic element can be performed with the passage of 4 faradays amounts to $4EF$, where E is the EMF of the galvanic cell, defined as the electric potential of the right minus that of the left electrode. This work is equal to the negative free energy ΔG of cell reaction (2). We thus have:

$$\Delta G \text{ (cell reaction)} = -4\,EF \qquad (3)$$

ΔG can be expressed by the chemical potentials μ_{O_2} of oxygen, and we then have, for eq. (3), the following expression:

$$\mu_{O_2} \text{ (left electrode)} - \mu_{O_2} \text{ (right electrode)} = -4\,EF \qquad (4)$$

The chemical potential μ_{O_2} is connected with the oxygen partial pressure p_{O_2} by the following equation:

$$\mu_{O_2} = \mu^{\ominus}_{O_2} + R\,T \ln \frac{p_{O_2}}{p^{\ominus}_{O_2}} \qquad (5)$$

Here $\mu^{\ominus}_{O_2}$ denotes the standard chemical potential of oxygen, corresponding to a partial pressure $p^{\ominus}_{O_2}$ of 1 atm. R is the gas constant and T the absolute temperature. Substitution of eq. (5) into eq. (4) gives:

$$E = \frac{RT}{4F} \ln \frac{p_{O_2}\text{ (right electrode)}}{p_{O_2}\text{ (left electrode)}} \tag{6}$$

This shows a relation to exist between E, the EMF of the galvanic cell, and the ratio of oxygen partial pressures at the two electrodes. According to equations (4) to (6), the EMF of a galvanic cell thus contains valuable thermodynamic information. The EMF makes it possible to deduce the free energy of the cell reaction and the chemical potentials of the electrode components or the partial pressures of gases. For Figure 5, a particularly easily understood galvanic cell was chosen, with a very simple cell reaction. Cell reactions can, however, be of very varied types, according to the electrodes and the electrolytes used, and thus free energies could be and have been determined for many chemical reactions. This is illustrated in Section 3.2.2 by the formation of silver sulfide from silver and sulfur. Reaction enthalpies and reaction entropies can also be deduced from the temperature-dependence of the EMF.

However, galvanic cells are important not only for thermodynamic but also for kinetic studies. An electric current I passing through the cell shown in Figure 5 is a measure of the rate J at which oxygen is transported from right to left. The relation is:

$$J = I/(4F)\ [\text{mol/s}] \tag{7}$$

The transport of mass—in the form of ions through the electrolyte or of electrons through the external current circuit—can often be assigned to a chemical reaction or a transport process at an electrode. In this way reaction rates can be measured electrically (for examples see Section 3.2). It is often possible to analyze a reaction mechanism in detail by a combination of rate measurement by means of the electric current with measurement of thermodynamic quantities—in particular of chemical potentials—*via* the EMF of the galvanic cell.

2. Technological Applications of Solid Electrolytes

Solid electrolytes have recently required major technological importance. Four typical groups of application are discussed below as examples.

2.1. Sensors

Galvanic cells embodying solid electrolytes can be used for rapid, direct measurement of partial pressures in gases or of concentrations in liquids and melts. An especially important typical example is the cell, represented schematically in Figure 5, containing doped zirconium dioxide as the solid electrolyte. By using cells of this type a wide range of oxygen partial pressures in gases can be determined. The zirconium dioxide probe for such work is used at temperatures between about 500 and 1000 °C. In this temperature range zirconium dioxide becomes markedly electron-conducting only when the partial pressure of oxygen falls to about 10^{-16} atm, *i.e.* oxygen partial pressure can be measured with this probe down to such very low values. Such low partial pressures are of practical importance if, for example, mixtures of H_2/H_2O and CO/CO_2 or equilibria between metals and metal oxides are concerned. This wide range of oxygen partial pressures makes the zirconium oxide probe an excellent analytical instrument for measurements in gases. It should also be mentioned that the measured value is obtained very fast, indeed almost instantaneously. In such measurements a reference atmosphere, *e.g.* air or a metal/metal oxide mixture, is located on one side of the zirconium dioxide, so that the oxygen partial pressure is already known at one electrode; the oxygen partial pressure at the other electrode is then measured *via* the EMF in accordance with eq. (6). In the measurement the gas can be passed to the sensor. Commercial apparatus[67, 68] is available for measuring the oxygen content of *e.g.* highly purified inert gases.

Interesting applications lie in the field of medicine for studying the oxygen consumption in exhaled air, and in industry in the analysis of exhaust gases from furnaces or combustion engines. In such work it is often advisable to arrange the zirconium dioxide probe in the exhaust gas stream near the reaction space. Figure 6 shows such a probe that can be used for the control and regulation of the combustion process in Otto engines of motor vehicles[69]. This possibility of very exact control of gasoline/air mixtures is of particular interest in connection with the avoidance of air pollution.

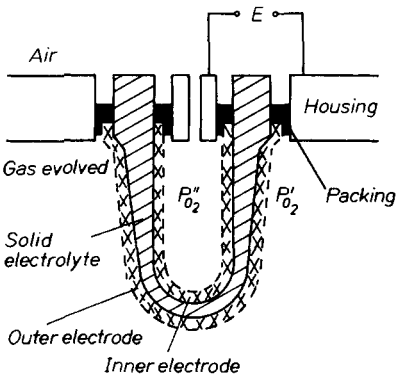

Fig. 6. Zirconium dioxide probe for the measurement of partial pressures of oxygen. The housing and packing are electrically conducting.

A similar probe can be used to measure the concentration or thermodynamic activity of oxygen in liquid metals. For example, the probe may be dipped in the melt during steel production; the direct display of the oxygen activity can be of appreciable advantage. If the range of oxygen pressure which can be measured is insufficient because of incipient electron conduction in zirconium dioxide, doped thorium dioxide can be used, which permits very much lower oxygen activities to be measured. By means of ThO_2 $(+Y_2O_3)$ the content of oxygen can be measured in, *e.g.* liquid sodium. The partial pressures of other gases, *e.g.* sulfur, can also be measured by sensors[70].

2.2. Fuel Cells and Electrolyzers

Figure 7 shows schematically the mode of operation of a high-temperature fuel cell incorporating zirconium dioxide

as the solid electrolyte. The zirconium dioxide in, *e.g.* tube or disk form, separates two electrode compartments, one containing air or pure oxygen and the other a fuel gas, *e.g.* hydrogen and carbon monoxide. The zirconium oxide carries two porous electrodes: nickel can be used on the fuel side, and on the oxygen side lanthanum-nickel oxide or some other electron-conducting oxide compatible with zirconium dioxide. The zirconium dioxide must be about 1 mm thick so that it can carry the electrodes. Other developments are in progress, to construct the zirconium dioxide as a thin-layer electrolyte, *i.e.* considerably thinner than 1 mm; mechanical strength of the cell must then be achieved in some other way, *e.g.* by strengthening the electrode.

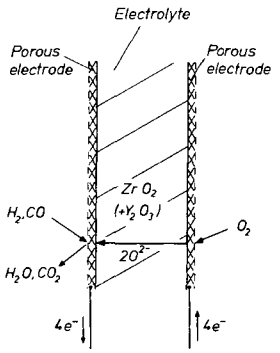

Fig. 7. High-temperature fuel cell (schematic).

In a high-temperature fuel cell the oxygen takes up electrons at one electrode, then migrates through the electrolyte as ions and combines at the other electrode with H_2 or CO to give H_2O or CO_2, respectively, whereby the electrons are given up and flow again to the other electrode in the external current circuit. In this way the desired energy is made available to the user. The advantages of the high-temperature fuel cell are that little or no polarization occurs at the electrodes and that high current densities can be achieved, *e.g.* 600 mA/cm^2 with a power density of 400 mW/cm^2. Difficulties arise with choice of the constructional material, and one disadvantage is that the cell can be heated only slowly to the working temperature. Further descriptions of high-temperature fuel cells, whose development is still in progress, are to be found in the literature[71-74].

By reversing the direction of the current flow in a high-temperature fuel cell, *i.e.* by supplying electrical energy in rather than removing it, steam can be decomposed and the cell can thus be used as an electrolyzer. The hydrogen produced can be stored or conducted by pipelines to remote sites where it can in turn serve for the production of energy on demand in a high-temperature fuel cell. This principle is being discussed in connection with large-scale energy storage and with the transport of energy. Other studies aim at decomposing steam and carbon dioxide in an electrolysis cell embodying zirconium dioxide so as to recover the oxygen from exhaled breath; this could be useful *e.g.* in manned spaceflight. The principle of the electrolysis cell can also serve for the purification of gases if it is desired to remove residual traces of oxygen, or for the deoxidation of liquid metals.

2.3. Solid-Electrolyte Batteries. Example: The Sodium-Sulfur Cell

The principle of a sodium-sulfur cell is shown in Figure 8. The solid electrolyte, an Na^+-ion conductor, consists of β-Al_2O_3 with the molecular formula $NaAl_{11}O_{17}$. It is generally used in the form of a tube closed at one end and filled with liquid sodium as the anode. An iron sponge, which absorbs

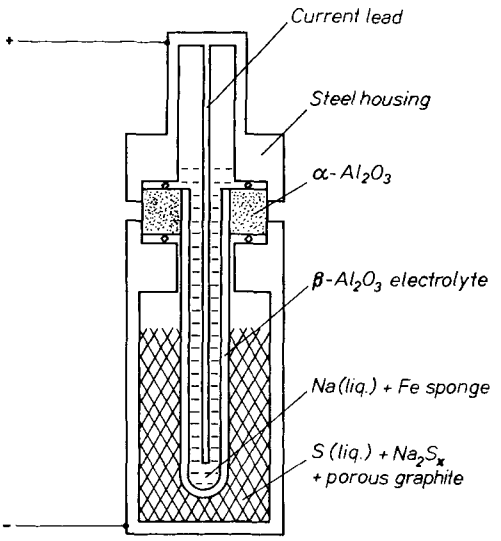

Fig. 8. Sodium-sulfur cell (schematic).

the liquid sodium, serves to improve the wetting of the electrolyte and at the same time to improve safety. A metal wire leads out of the cathode to carry the current. The cathode consists of liquid sodium polysulfide and sulfur in porous graphite. The working temperature of the sodium-sulfur cell is usually around 300 °C. In the cell reaction sodium ions pass through the electrolyte and electrons through the external circuit, so that sodium is dissolved in sodium polysulfide. In this way electrical energy can be liberated. The energy density of the sodium-sulfur cell is many times greater than that of the customary lead accumulators, and moreover, the materials needed for the electrolytes and electrodes are available in large quantities. The cell can be recharged by reversing the direction of the current. For all these reasons there is at present great interest in the sodium-sulfur cell. It is being discussed for large-scale energy storage and for electrotraction (for electric motor vehicles), and prototypes have already been built. Further details can be found in [75-77].

As well as the sodium-sulfur cell, cell systems have been developed with other solid electrolytes, some of these being characterized by very long lifetimes. Possible storage times of ten years and more have been reported; such lifetimes cannot be even approached with conventional batteries.

2.4. Chemotronic Components

Solid electrolytes or galvanic cells containing solid electrolytes, which find use in electrical circuits, are often called chemotronic components. Below we shall describe coulometers and time switches, analog memories, and capacitors containing solid electrolytes.

2.4.1. Coulometers and Time Switches

The galvanic cell

$Ag|RbAg_4I_5|Au$

can serve as a coulometer or time switch. The electrolyte $RbAg_4I_5$ is a good Ag^+-ion conductor even at room temperature. On passage of a current through this cell, silver is deposited in the gold electrode. The time switch is then in the loaded state. The silver can be transported back to the original silver electrode by a current flowing in the reverse direction. In this stripping process the cell potential is determined mainly by ohmic losses in the solid electrolyte. These losses depend on the current strength chosen and lie in the millivolt range. When all the silver has been stripped from the gold electrode the cell shows a sudden rise of potential, which can be used as a signal. Such electrochemical switches are suitable for times in the region of seconds to months. The $Ag|RbAg_4I_5|Au$ cell can also be used as a coulometer: the amount of current flowing during charging is then determined by the discharge process (for details see[78, 79]).

2.4.2. Analog Memories

The arrangement shown in Figure 9 has been proposed by *Takahashi* and *Yamamoto*[80] for use as an analog memory. The arrangement is symmetrical; on the outside there are two silver electrodes with a layer of the solid electrolyte $RbAg_4I_5$ on the inside of each; between these electrolyte layers is interposed a central electrode of silver selenide in which a small amount of silver phosphate has been dissolved. At

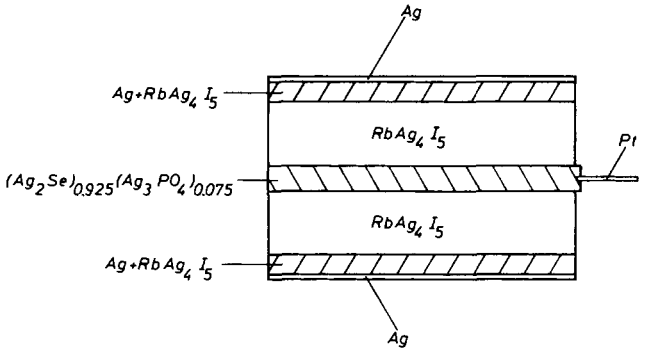

Fig. 9. Analog memory (schematic).

room temperature this solid selenide shows a remarkably high ionic conduction as well as a high electronic conduction. Current flowing over one-half of the arrangement can remove silver from this mixed-conductivity compound. The chemical potential of the silver in this selenide is thereby reduced and an EMF appears between the central electrode and the two outer electrodes. To avoid polarization effects, the EMF is measured against the silver electrode through which no current is flowing. The EMF changes continuously with the amount of charge that has passed, so that naturally more information can be stored than in the coulometers or time switches described above. Moreover, the reproducibility and accuracy of such devices are appreciably greater.

2.4.3. Capacitors Containing Solid Electrolytes

Capacitors can be built with $RbAg_4I_5$ as the electrolyte, one silver electrode, and an electrode of graphite and $RbAg_4I_5$; their capacities are of the order of 10 Faraday/cm^3, which is a thousand times larger than those of conventional capacitors, since here the capacity of the electrochemical double layer is utilized directly at the graphite/electrolyte interface. This interface can be made very large by intimate mixing of the substances concerned. However, the potential of a single cell is limited to 0.6 V, because the electrolyte begins to decompose at higher potentials. Possible applications of capacitors of this type are similar to those of the components described above, but in addition the capacitors have been discussed for energy storage because of their very high capacities.

3. Scientific Applications of Solid Ionic Conductors

Solid electrolytes can be utilized for both thermodynamic and kinetic investigations. This is illustrated below, again by means of selected examples.

3.1. Thermodynamic Applications

As discussed above, the EMF of galvanic cells containing solid electrolytes can be used for the determination of free energies, chemical potentials, partial pressures, or thermodynamic activities. By using the temperature-dependence of the EMF, information can also be obtained on the enthalpies and the entropies of the cell reactions. Consider, for example, the galvanic cell represented in Figure 10; it has been used by *Kiukkula* and *Wagner*[81] to determined the ΔG^0 for the

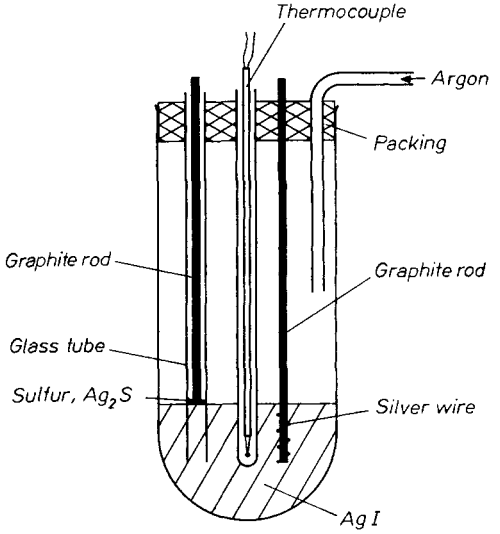

Fig. 10. Galvanic cell, C,Ag(solid)|AgI(solid)|Ag_2S(solid)S(liq.),C.

formation of Ag_2S. In these investigations AgI is first introduced into the apparatus in the form of a melt; after solidification, it serves as a solid electrolyte with almost pure Ag^+ ionic conduction. One electrode consists of a silver wire on a graphite shank, and the other electrode is a mixture of Ag_2S and sulfur, also on a graphite shank. On the passage of 2 faraday through the circuit from the silver electrode to the Ag_2S/sulfur electrode, the following reaction occurs:

$$2Ag + S = Ag_2S \quad (8)$$

Since all the reactants are present in their standard states, the cell EMF gives directly the standard Gibbs energy ΔG^0 (Ag_2S) for the formation of Ag_2S from silver and sulfur:

$$\Delta G^0(Ag_2S) = -2EF \quad (9)$$

In recent years a large number of other thermodynamic investigations have been carried out with solid ionic conductors. The reader is referred to the specialist literature[1, 11, 82] for further information.

3.2. Kinetic Investigations with Solid Ionic Conductors

In kinetic studies the measurement of the EMF of a suitably constructed galvanic cell is supplemented by measurement of the electrical current. How kinetic processes can be studied in this way will be discussed in the following Sections devoted to four selected examples.

3.2.1. Electrochemical Measurement of Oxygen Diffusion in Metals

The first kinetic investigation[83] with zirconium dioxide as the solid electrolyte was the determination of the diffusion coefficient D_O of oxygen in solid metals. The experimental arrangement is shown schematically in Figure 11. A silver

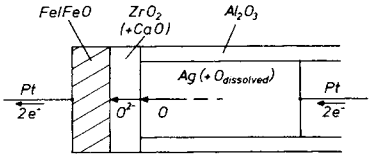

Fig. 11. Experimental arrangement for the electrochemical measurement of the diffusion of oxygen in solid silver (schematic).

cylinder was fused onto a zirconium dioxide tablet and surrounded on the outside by an Al_2O_3 tube to prevent radial diffusion of oxygen from the silver. Before the experiment the silver was saturated with oxygen and then formed an electrode in the galvanic circuit. The other electrode was a mixture of iron and ferrous oxide. As the current flows, oxygen ions move in the direction indicated by the arrows through the zirconium dioxide to the Fe/FeO electrode, where they are consumed by reaction with the iron. This consumption is compensated by oxygen which diffuses from the silver to the silver/zirconium dioxide phase boundary. The diffusion stream is thus converted into an electric current and so becomes accessible to measurement. Evaluation depends on the choice of the boundary and the initial conditions. Since the initial study, other diffusion measurements have been carried out, not only on metals but also on compounds[84–86].

3.2.2. Electrochemical Investigations of the Penetration of Silver through the Solid Silver/Solid Silver Sulfide Interface

The basic component of the experimental arrangement shown in Figure 12 is the solid-state cell

Pt,Ag(solid)|AgI|Ag_2S(solid),Pt

with AgI as an almost pure Ag^+ conductor. The difference from the arrangement in Figure 10 is that the Ag_2S is here not in equilibrium with the sulfur. The stoichiometry of the Ag_2S can thus be varied even if only within narrow limits, and so can the chemical potential of the silver in the Ag_2S. This cell exhibits two properties that are very important for

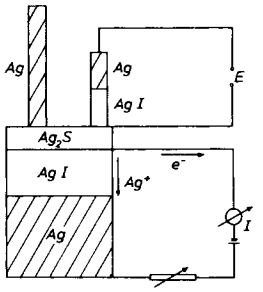

Fig. 12. Measurement arrangement for the electrochemical investigation of the passage of silver through the Ag/Ag_2S phase boundary.

the investigations concerned: first, a current passing through the cell, whose right-hand side is connected to the positive pole of an external power source, is a measure of the rate at which silver is removed from the Ag_2S, the silver ions dispersing through the AgI and the electrons through the platinum. Secondly, E, the EMF of the cell, depends on the chemical potential μ_{Ag} of the silver in the Ag_2S. When no current is flowing, we have:

$$\mu^0_{Ag} - \mu_{Ag} = EF \quad (10)$$

where μ^0_{Ag} denotes the chemical potential of pure silver and F is the Faraday constant.

Both possibilities were utilized in the experimental arrangement shown in Figure 12. The experiments were conducted in the temperature range of 200 to 400 °C[87, 88].

An Ag_2S tablet a few tenths of a millimeter thick rests on an AgI cylinder and this on a cylinder made of silver. The Ag_2S and the Ag are connected with platinum leads, so that a circuit is formed. The current in this circuit can be controlled by a resistor and measured by an ammeter. When a current flows, silver is removed from the Ag_2S and the chemical potential of the silver in Ag_2S falls continuously until finally sulfur is liberated (as sulfur vapor) from the Ag_2S unless further silver is added at the other side—which is accomplished through a silver rod standing on the Ag_2S tablet. In the steady state as much silver passes from the silver rod into the Ag_2S as is transported away through the AgI or the platinum in the form of silver ions and electrons. The steady state can be recognized by the fact that the chemical potential of the silver in the Ag_2S becomes constant. This potential can be measured by the Ag/AgI probe included in Figure 12. This probe produces a galvanic cell of the form Pt,Ag(solid)|AgI|Ag_2S(solid),Pt, whose EMF E according to eq. (10) is a measure of the difference between the chemical potentials of the silver in pure silver and in silver sulfide. In this way the measurements of current and potential are separated, and the potential measurements cannot be distorted by polarization phenomena. The probe thus corresponds to a Luggin capillary such as has long been used for studies on the electrochemistry of liquid phases. By using other special

probes it is also possible to measure electrochemical potential differences of silver ions and electrons and allow silver ions and electrons to pass separately through the phase boundary[89]. The results are important for understanding the reaction between silver and sulfur[88].

3.2.3. Electrochemical Investigation of Formation of Surface Layers on Metals; Example: Formation of Nickel Sulfide on Nickel at High Temperatures

The formation of nickel sulfide on nickel was investigated[90] with the aid of the experimental arrangement shown in Figure 13. Silver iodide was used as the solid electrolyte, being a

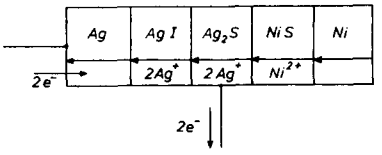

Fig. 13. Galvanic cell for the electrochemical investigation of the formation of NiS on nickel.

pure Ag^+ ionic conductor under the experimental conditions. The negative pole of a power source was connected to the left side of the arrangement and the positive pole to the right side. The galvanic cell itself consisted of tablets pressed together in a glass tube furnace flushed with nitrogen. As in the preceding example, an electric current passing through the cell is first of all a measure of the rate at which silver is removed from the silver sulfide, since silver ions migrate through the AgI and electrons through the external circuit. In this case, however, the rate of loss of the silver corresponds to the rate of the formation of nickel sulfide on nickel, since in this reaction nickel displaces the silver from the Ag_2S. The experiments were carried out in the galvanostatic and potentiostatic modes. The important quantities were again (a) the current, which is a measure of the reaction rate, here the formation of nickel sulfide, and (b) the cell EMF, which is not only a measure of the chemical potential of the silver in silver sulfide, but, in view of the Gibbs-Duhem equation, also a measure of the chemical potential of the sulfur in this compound and thus, because of the high mobility of the silver in Ag_2S, also a measure of the chemical potential of the sulfur at the Ag_2S/NiS phase boundary. In this way the parabolic constant k for the rate of formation of NiS on nickel at 400°C could be measured as a function of the chemical potential of the sulfur on the outside of NiS. The results provided information about the disorder in NiS.

3.2.4. Electrochemical Investigation of Evaporation Processes

We shall next consider, as an example, the evaporation of sulfur molecules from an Ag_2S surface into vacuum between 200 and 400°C[91].

The experimental arrangement shown in Figure 14 contains two cells of the type discussed in Section 3.2.2. A current flows through one of these cells. In the steady state the amount of sulfur evaporated from the silver sulfide surface and the amount of silver removed in the form of ions and electrons are equivalent. Once again, the steady state is recognizable by the fact that the chemical potential of the silver in the

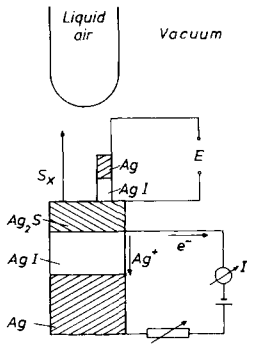

Fig. 14. Arrangement for the electrochemical investigation of the evaporation of sulfur from an Ag_2S surface into vacuum (schematic).

silver sulfide undergoes no further change and that E, the EMF of the second galvanic cell, remains constant. As was discussed in Section 3.2.3, this EMF provides a measure of the chemical potential of the silver and also of the sulfur in silver sulfide. In this way the rate of evaporation of sulfur can be measured as a function of the chemical potential of the sulfur in silver sulfide. The experimental arrangements are such that the evaporating sulfur, which is in vacuum, can be precipitated on a cold finger cooled with liquid air. Recent investigations[92] have shown that the evaporation coefficient for the evaporation of S_2 molecules from a sulfur surface is 0.5.

I am indebted to Dr. Holzäpfel and Dr. Contreras for their help in the preparation of this article, and in particular for compiling references.

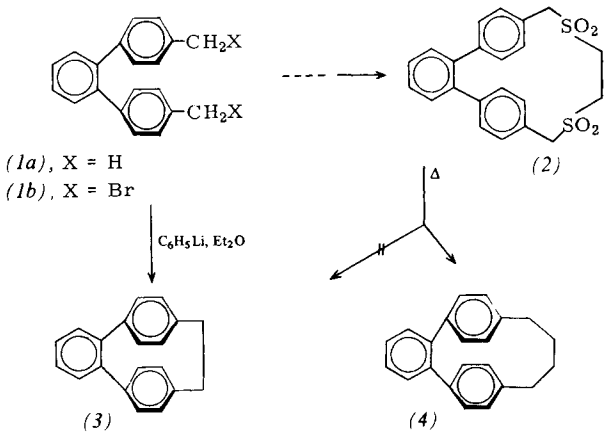
COMMUNICATIONS

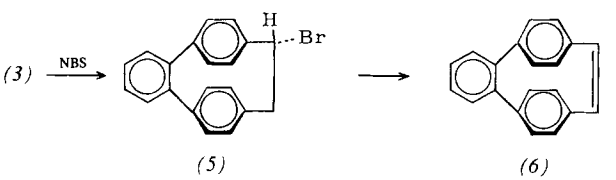
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.



Cyclophanes Having Orthogonal Benzene Rings[**]

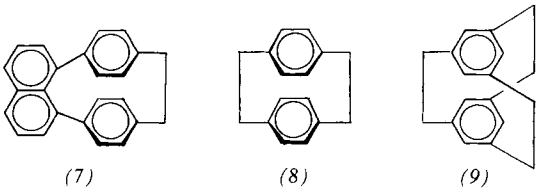
By *Neil Jacobson* and *Virgil Boekelheide*[*]

One of the attractions of cyclophane chemistry is that it provides compounds for which the spatial relationships are clearly defined by the rigid geometry of the molecule. Of particular interest are examples where benzene rings are held orthogonal to each other. In 1975, *Vögtle* and *Grütze*[1] reported that attempts to prepare [2](4',4'')orthoterphenylophane *(3)*, by the conversion of 4',4''-bis(bromomethyl)orthoterphenyl *(1b)* into the corresponding cyclic disulfone *(2)* followed by pyrolysis, did not give the desired *(3)*, but only [4](4',4'')orthoterphenylophane *(4)*.



[*] N. Jacobson and Prof. Dr. V. Boekelheide
Department of Chemistry, University of Oregon
Eugene, Oregon 97403 (USA)

[**] This work was supported by the National Science Foundation.



We now report that treatment of *(1b)* with phenyllithium in ether leads directly to the desired [2](4′,4″)orthoterphenylophane *(3)* in 22% yield, isolated after recrystallization from heptane as long white needles [m.p. 217—219 °C; NMR ($CDCl_3$): an AA′BB′ pattern centered at $\tau = 2.49$ (4H, *o*-ArH), a singlet at $\tau = 3.44$ (8H, *p*-ArH), and a singlet at $\tau = 6.89$ (4H, $ArCH_2$—)[2]].

Treatment of *(3)* with *N*-bromosuccinimide gives the corresponding monobromo derivate *(5)*, after preparative thin-layer chromatography over silica gel using a 1 : 9 mixture of benzene and petroleum ether (30—60 °C) for elution, as white crystals [m.p. 190—193 °C; NMR ($CDCl_3$): a multiplet at $\tau = 2.3$—2.8 (4H, *o*-ArH), a multiplet at $\tau = 3.2$—3.7 (8H, *p*-ArH), a multiplet at $\tau = 4.78$ (1H, $J = 7$ Hz, $J' = 9$ Hz, >CHBr), a multiplet at $\tau = 5.94$ (1H, $J' = 9$ Hz, $J'' = 14$ Hz, —CH_2CHBr), and a multiplet at $\tau = 6.68$ (1H, $J = 7$ Hz, $J'' = 14$ Hz, —CH_2CHBr)].

When *(5)* was warmed with potassium *tert*-butoxide in *tert*-butanol, it was readily converted in 75% yield into the corresponding olefin *(6)*, isolated after recrystallization from heptane as white platelets [m.p. 227—229 °C; NMR ($CDCl_3$): an AA′BB′ pattern centered at $\tau = 2.47$ (4H, *o*-ArH), a singlet at $\tau = 2.71$ (2H, —CH=CH—), and an AA′BB′ centered at $\tau = 3.40$ (8H, *p*-ArH).

In Table 1 the ^{1}H-NMR values for the bridging and *p*-phenylene protons of *(3)* and *(6)* are compared with those of some closely related cyclophanes *(7)*—*(9)*. As a general rule, the shorter the distance between decks in layered cyclophanes the higher the upfield chemical shift values for the attached aromatic protons. The upfield shift in going from the orthoterphenyl precursor *(1a)* to *(3)* and to *(6)* is relatively small. Presumably, this is due to the fact that the two *p*-phenylene rings of *(1a)* are forced to be parallel by steric constraints and, though still free to rotate, must rotate in a concerted fashion. Thus, fashioning a bridge across the C-4- and C-4″-positions of *(1a)*, as in *(3)* and *(6)*, does not markedly alter the geometry of these molecules from that of *(1a)* itself. The distance between decks in layered cyclophanes is affected both by the bond lengths in the bridges and the bond angles, with the latter usually being the most important. This is borne out in the comparison in Table 1 of *(6)* with *(3)* and with the naphthalene analog *(7)*[3]. However, the chemical shift values for the *p*-phenylene protons of *(6)*, *(3)*, and *(7)* show only small differences and are distinctly lower than for [2.2]paracyclophane *(8)*, where the distance between decks is known to be 3.14 Å[4], and very much lower than for the extreme example of [2.2.2](1,3,5)cyclophane *(9)*, where the average distance between decks is only 2.80 Å[5].

Table 1. Comparative ^{1}H-NMR data (τ values) of the compounds *(1a)*, *(3)*, *(6)*—*(9)*.

Cpd.	C—H (*p*-phenylene)	C—H (bridge)	Ref.
(1a)	3.28		
(6)	3.40	2.71	
(3)	3.44	6.89	
(7)	3.49	6.93	[3]
(8)	3.63	6.95	[6]
(9)	4.27	7.25	[7]

The ultraviolet absorption spectra of *(3)* and *(6)* show long wavelength absorption bands at 308 nm ($\varepsilon = 128$) and 307.5 nm ($\varepsilon = 134$), respectively. This is about the same as that observed for *(7)* and at slightly longer wavelength than that of [2.2]paracyclophane (302 nm, $\varepsilon = 96$). Thus, the experimental data for *(3)* and *(6)* suggest that there is very little, if any, interaction between the π-electron clouds of the orthogonal benzene rings.

Synthesis of Disparlure by Kolbe Electrolysis[1]

By *Helmut Klünenberg* and *Hans J. Schäfer*[*]

Disparlure [(*Z*)-7,8-epoxy-2-methyloctadecane] *(1)*, the sex attractant of the gypsy moth *Lymantria dispar*[2], has been obtained stereoselectively containing various amounts of the (*E*) isomer by several synthetic pathways[2a, 3]. Since the attractant properties of synthetic pheromones may be greatly diminished by "contamination" with geometric isomers[4] we

[*] Prof. Dr. H. J. Schäfer, Dipl.-Chem. H. Klünenberg
Organisch-chemisches Institut der Universität
Orléans-Ring 23, D-4400 Münster (Germany)

attempted to prepare configurationally pure *(1)*. Our aim was achieved by double Kolbe electrolysis starting from (*Z*,*Z*)-1,5-cyclooctadiene *(2)* (cf. Scheme 1).

Scheme 1. a) O_3; Jones reagent; b) MeOH, H^+; c) MeOH, KOH; H^+; d) $CH_3(CH_2)_7CO_2H$, Pt anode, MeOH; MeOH, KOH; H^+; e) $(CH_3)_2CH(CH_2)_2CO_2H$, Pt anode, MeOH; f) *m*-Cl—$C_6H_4CO_3H$.

Ozonolysis of *(2)*[5] and oxidative work-up with Jones reagent[6] afforded *(3a)* which was esterified to *(3b)* with methanol/sulfuric acid (cat.); *(3b)* was then partially hydrolyzed to *(4)* with methanolic potassium hydroxide. Separation of *(3b)* from *(4)* is possible by digesting the potassium salt of *(4)* with pentane, and that of *(4)* from *(3a)* by dissolution in carbon tetrachloride. A 1 : 10 mixture of *(4)* and pelargonic acid is 1 % neutralized and co-electrolyzed at 240 mA/cm^2. The symmetrical dimer of *(4)* is not formed; the Kolbe dimer of pelargonic acid is extracted from the potassium salt of *(5)* with light petroleum. Under the same conditions as *(4)*, but with 4-methylvaleric acid as co-reactant, compound *(5)* gives *(6)*, which can be separated from the symmetrical dimers by distillation. Compound *(6)* is epoxidized to *(1)*, whose structural data are in full agreement with those described in the literature[2, 3].

The monoester *(4)* is a suitable starting compound for the synthesis of other *Z*-configurated pheromones.

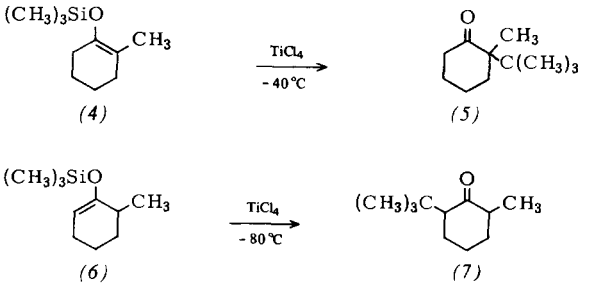
tert-Alkylation of Ketones and Aldehydes[**]

By *Manfred T. Reetz* and *Wilhelm F. Maier*[*]

Although the α-alkylation of carbonyl compounds *via* their corresponding bases is one of the most important C—C coupling reactions, it fails in the case of *tert*-alkyl groups. Thus on treatment with *tert*-alkyl halides, enolates or enamines yield practically only elimination or substitution products[1, 2]. We now present a simple solution to this problem[3] involving the use of Lewis acids:



If the silylenol ethers *(2)*[4], which are easily obtained from ketones or aldehydes, are allowed to react with *tert*-butyl chloride in the presence of $TiCl_4$, $FeCl_3$, or $ZnCl_2$, the desired *tert*-butyl derivatives *(3)* are produced in good yields (Table 1). In the case of $TiCl_4$, optimum yields are obtained by using equimolar quantities of the Lewis acid in the temperature range −40 to −78 °C. Catalytic quantities of $FeCl_3$ or $ZnCl_2$ induce equally smooth conversions at room temperature.

Table 1. *tert*-Butylation of ketones and aldehydes.

Silylenol ether	Lewis acid	Product	Yield [%]
1-Trimethylsiloxy-cyclohexene	$TiCl_4$	2-*tert*-Butyl-cyclohexanone	85
	$FeCl_3$		70
1-Trimethylsiloxy-cyclopentene	$TiCl_4$	2-*tert*-Butyl pentanone	78
1-Trimethylsiloxy-6-methylcyclohexene	$TiCl_4$	2-*tert*-Butyl-6-methyl-cyclohexanone	67
1-Trimethylsiloxy-2-methylcyclohexene	$TiCl_4$	2-*tert*-Butyl-2-methyl-cyclohexanone	86
2-Trimethylsiloxy-3-methyl-2-butene	$TiCl_4$	3,3,4,4-Tetramethyl-2-pentanone	95
2-Trimethylsiloxy-propene	$ZnCl_2$ [a]	4,4-Dimethyl-2-pentanone	40
1-Trimethylsiloxy-1-butene	$ZnCl_2$ [a]	2-Ethyl-3,3-dimethylbutanal	30

[a] In these cases $TiCl_4$ is not very effective.

The alkylations proceed with a high degree of regiospecifity, *e.g.* the reactions of *(4)* and *(6)* give less than 5 % of the wrong isomer. The smooth conversion of *(4)* into *(5)* also underlines a further unusual feature of this procedure—namely the ready accessibility of compounds with two neighboring quaternary carbon atoms. The few methods so far known

[**] This work was supported by the Fonds der Chemischen Industrie.

for the synthesis of hexasubstituted ethanes involve several steps and usually give low yields due to steric factors[5].

The alkylation of *(8)* by *(9)* affording *(10)* (yield 45%) demonstrates that other *tert*-alkyl chlorides can also be used[6].

(8) *(9)* *(10)*

Synthesis of 2-tert-butylcyclopentanone

Titanium tetrachloride (20 g) in dichloromethane (30 ml) cooled to −45 °C is added under nitrogen within a period of 2 min to a mixture of 1-trimethylsiloxycyclopentene (15.6 g) and *tert*-butyl chloride (10.0 g) in dichloromethane (50 ml) at −45 °C. After stirring for 30 min, the mixture is diluted with CH_2Cl_2 (100 ml) and extracted with ice/water (500 ml). The aqueous phase is then washed with CH_2Cl_2 (2 × 100 ml). The organic phases are dried over magnesium chloride and the solvent evaporated off. 78% of the crude product (15 g) can be identified by gas chromatography as 2-*tert*-butylcyclopentanone. Fractional distillation affords 9.2 g (66%) of the pure compound, b.p. 95 °C/45 torr [^{1}H-NMR (CCl_4): τ = 9.0 (s, 9H), 8.4—7.5 (m, 7H)].

Effect of Shift Reagents on NMR Coupling Constants

By *Geoffrey Brian Porter* and *Jon Simpson*[*]

Lanthanide shift reagents (LSR) are accepted as a standard aid in the interpretation of complex NMR spectra, but recent reviews[1] show that little has been reported on the variation of coupling constants as a result of the addition of such reagents. These reviews reveal that some workers have tried to relate a change in coupling constant to the inductive effect of the metal atom or conformational changes in cyclic systems. In the structural elucidation of flexible molecules the possible change in conformer populations must also be considered. This is particularly true when comparisons are made with X-ray diffraction results.

We wish to report a significant change in vicinal coupling constants observed during a study of the diastereomeric esters *(1)* derived from 2,3-diphenyl-3-hydroxypropionic acid. These esters have been characterized both chemically and by comparison of NMR spectra[2]. During the course of further ^{1}H-NMR measurements on these compounds, using [D_{27}]-Eu(fod)$_3$ and [D_{27}]-La(fod)$_3$, the values of J_{23} were found to vary as shown in Figure 1.

(1)

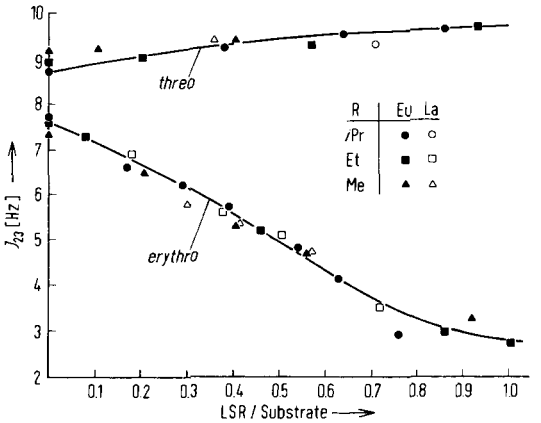

Fig. 1. Vicinal coupling constants (J_{23}) as a function of LSR/substrate ratio.

The initial values for J (no shift reagent present) correspond to a predominance of the rotamers T_A and E_A (cf. Figure 2, which shows the theoretical coupling constant for each rotamer calculated by the method of *Bothner-By*[3], using the appropriate electronegativities).

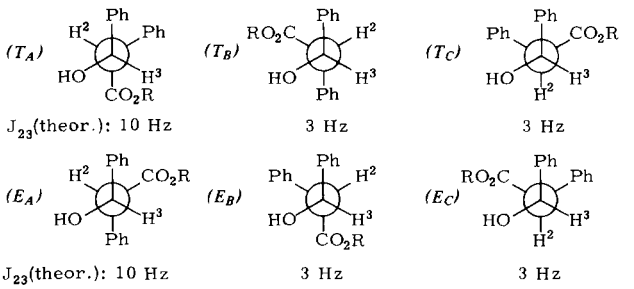

Fig. 2. *Threo* and *erythro* rotamers (*T*) and (*E*) of the diastereomeric esters *(1)*, and calculated J_{23} values.

When shift reagent is added, the chemical shift behavior is consistent with a 1:1 complex[4]. The most probable explanation for this and the results in Figure 1 is bidentate coordination of the shift reagent by both functional groups in the substrate. This can take place only if the groups are *gauche* to each other. Thus, in the *threo* series the shift reagent increases the population of (T_A) even further, so that J_{23} tends to the theoretical value for this rotamer alone. (T_B) is presumably excluded because of the presence of four adjacent

[*] Dr. G. B. Porter, J. Simpson
Chemistry Branch, Royal Military College of Science
Shrivenham, Swindon SN6 8LA (England)

bulky groups. In the *erythro* series, on the other hand, chelation requires an increase in the proportion of (E_B) or (E_C), and J_{23} progressively decreases to a limiting value which agrees closely with the calculated figure. Although both of these rotamers have four adjacent bulky groups, chelation with a lanthanide ion must be sufficient to overcome steric repulsion when there is no alternative.

Confirmation of this interpretation, based on chemical shift data, is available in work on other bifunctional systems[5]. However, direct evidence of bidentate coordination from suitable coupling constants has not hitherto been reported.

Stretching Frequency and Force Constant of the Tungsten-Carbon Triple Bond[1]

By *Ernst Otto Fischer, Nguyen Quy Dao*, and *Wolfgang Rainer Wagner*[*]

In order to gain a further insight into the nature of the metal-carbon bond in carbyne complexes of transition metals[2] we have analyzed the IR and Raman spectra of *trans*-X(CO)$_4$W≡CCH$_3$ (X = Cl, Br, I) and *trans*-Br(CO)$_4$W≡CCD$_3$.

Figure 1 shows the Raman spectrum of the undeuterated bromo complex in the crystalline state; the spectra of the homologous chloro and iodo complexes exhibit the same characteristics.

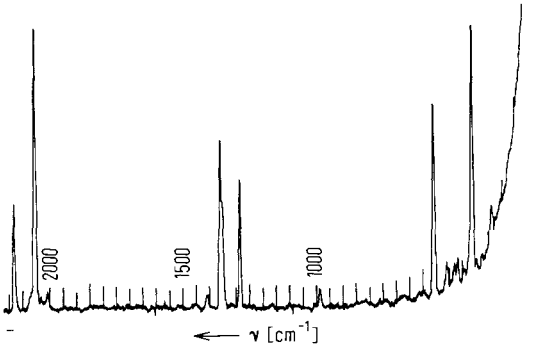

Fig. 1. Raman spectrum of crystalline *trans*-Br(CO)$_4$W≡CCH$_3$.

Only two relatively intense bands appear at 1355 and 1282 cm^{-1} and a weaker one at 1409 cm^{-1} in the region expected for ν(W≡C) frequencies (800—1500 cm^{-1}). Since the weaker band is shifted to lower frequencies by deuteration it can be unequivocally assigned to the deformation mode $\delta_d(CH_3)$. The more problematic assignment of the two strong bands ν(W≡C) *versus* $\delta_s(CH_3)$ was accomplished by comparison with the spectrum of the analogous trideuteriomethylcarbyne complex. In this range, *trans*-Br(CO)$_4$W≡CCD$_3$ shows only one intense absorption in its solid-state Raman spectrum. The solution spectrum shows this band to be polarized and thus due to a totally symmetric vibration. We assign it to the stretching vibration of the tungsten-carbon triple bond.

In the undeuterated compound this vibration couples with the symmetric deformation vibration of the methyl group, occurring in the same region and belonging to the same symmetry class. As a result of Fermi resonance[3] two bands of similar intensity appear above and below (1355 and 1282 cm^{-1}) the frequency of 1315 cm^{-1} observed for the deuterated complex; they are both polarized in the same way and therefore are indeed a mixture of the normal modes δ_s(W≡C) and $\delta_s(CH_3)$.

The IR spectra (KBr) also show a strong band arising from a W≡C stretching mode (cf. Table 1).

Table 1. W≡C stretching vibration in X(CO)$_4$W≡CCR$_3$; limits of error: IR ±5 cm^{-1}; Raman (RA) ±2 cm^{-1}.

X	Cl		Br		I		Br	
R	H		H		H		D	
	RA	IR	RA	IR	RA	IR	RA	IR
	1361 1353 [a]	1355	1355 1347 [a]	1352	1358	1353		
							1315	1312
	1283	1272	1282	1274	1280	1276		

[a] These bands occur as double bands.

On comparison with the W≡N stretching vibration in the complexes $Cl_4WNC_2Cl_5$ and $Cl_3CCN(Cl_4)WNC_2Cl_5$[4] (intense band at 1286 cm^{-1}) the ratio of the frequencies ν(W≡C) : ν(W≡N) = 1.02 is of the same order as the theoretical frequency ratio of 1.074 calculated for a diatomic harmonic oscillator. According to our results based on a complete normal coordinate calculation, the value of 7.4 mdyn Å^{-1} is determined for the force constant of the W≡C bond.

Our results constitute independent proof of the metal-carbon triple bond in carbyne complexes deduced from previous X-ray studies.

Experimental

trans-Br(CO)$_4$W≡CCD$_3$: A sample of (CO)$_5$W=C(OCH$_3$)(CD$_3$)[5] (3.85 g, 10 mmol) is treated in the same way as the nondeuterated compound[6] with BBr_3 in pentane, and the product is purified by chromatography with CH_2Cl_2 on silica gel at −35 °C. After recrystallization and drying *in vacuo* at −10 °C the bromocarbyne complex is obtained as colorless crystals. Yield 2.6 g (65 %).

The Raman spectra (Coderg PH 1 with He-Ne laser, Spectra Physics Model 125) were recorded in the solid state at −196 °C or in solution (CH_2Cl_2) at −25 °C.—The IR spectra were recorded at room temperature (Beckman IR 10).

Copolymerization of Tetrameric Thioformaldehyde with Oligomeric Thioformaldehydes, Substituted Analogs, or Sulfur

By *Max Schmidt* and *Eckhard Weissflog*[*]

In acid solution, hydrogen sulfide and formalin afford trimeric thioformaldehyde $(CH_2S)_3$ [1,3,5-trithiane *(1)*] as well as polymethylene sulfides $(CH_2S)_n$. The latter products are not thermoplastic; their melting or decomposition temperatures depend upon the conditions of their preparation and vary between 160 and 220 °C[1]. The trithiane *(1)*, the oligomeric thioformaldehyde having the highest melting point (*ca.* 215 °C), can be polymerized only under relatively drastic conditions[2]. This also applies to the substituted trithianes we have prepared so far and to some substituted tetrathiocanes[3].

In contrast, it proves much easier to convert tetrameric thioformaldehyde $(CH_2S)_4$ [1,3,5,7-tetrathiocane *(2)*] and the next higher homolog $(CH_2S)_5$ into polymethylene sulfide, which is highly crystalline up to its relatively sharp melting point (without decomposition) of *ca.* 240 °C, by treatment with boron trifluoride-diethyl ether[4].

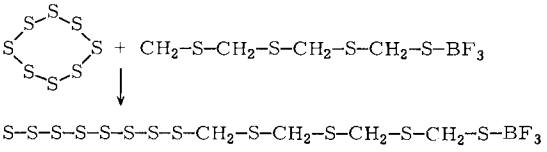
We have now found that the highly reactive intermediate *(3)* (diradical or zwitterion?) presumably formed from boron trifluoride-diethyl ether and the tetrathiocane *(2)* according to

(2)

$$CH_2\text{–}S\text{–}CH_2\text{–}S\text{–}CH_2\text{–}S\text{–}CH_2\text{–}S\text{–}BF_3$$

(3)

is able to attack trithianes including *(1)*, substituted tetrathiocanes, and elemental sulfur (as well as elemental selenium, albeit less effectively) in such a way that copolymers with interesting properties are formed under mild conditions. For instance, an equimolar mixture of *(1)* and *(2)* reacts with $BF_3 \cdot Et_2O$ at *ca.* 100 °C to give a practically quantitative yield of a polymethylene sulfide mixture which melts without decomposition between 245 and 265 °C. Even at a molar ratio of *(1)* to *(2)* of 4:1 the polymeric product $(CH_2S)_n$ is still formed in 87 % yield (although only at *ca.* 150 °C owing to the higher melting point of the starting mixture).



The oligomeric thioformaldehydes form silver complexes which can be utilized for their separation[5]. The granular polymer from the above reaction complexes Ag^+ ions from aqueous solution. These ions can be eluted with aqueous NH_3 to regenerate the pure polymer.

[*] Prof. Dr. M. Schmidt, Dr. E. Weissflog
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

We have already substituted the carbon atom of *(1)* and *(2)* to varying degrees on a previous occasion (R = CH_3, $Si(CH_3)_3$, $Ge(CH_3)_3$, $Sn(CH_3)_3$, or COOH instead of H)[3]. Like pure *(1)*, these derivatives also undergo BF_3-catalyzed copolymerization with *(2)*. The original substitution pattern is rediscovered at the carbon atoms of the C—S—C chains, modified according to the ratio of the reactants.

The properties of the new polymers are expectedly influenced by the substituents. They usually have wide melting ranges and some of them are thermoplastic. Those containing carboxyl groups are suitable for use as ion exchangers (the ion selectivity has yet to be investigated).

Oligomeric thioformaldehydes and elemental sulfur form homogeneous melts whose physical properties deviate considerably from those of pure sulfur. Treatment of a molten mixture of *(2)* and S_8 with $BF_3 \cdot Et_2O$ results in extensive incorporation of sulfur into the insoluble polymeric product. Once again the reactive intermediate *(3)* will first be formed and open the sulfur rings in a subsequent step:

Procedures (typical examples)

a) Compounds *(1)* (1.38 g, 0.01 mol) and *(2)* (1.84 g, 0.01 mol) are mixed together and melted. The clear homogeneous melt solidifies within seconds on addition of a small drop of $BF_3 \cdot Et_2O$ at *ca.* 100 °C. The brittle polymer is ground mechanically and extracted for 8 h with benzene, whereupon 0.13 g of *(1)* dissolves. Yield of $(CH_2S)_n$: 3.09 g (96 %). The almost colorless product forms a clear melt between 260 and 265 °C; at slightly higher temperature it decomposes slowly with evolution of gas.

b) Compound *(2)* (1.84 g, 0.01 mol) and 1,3,5,7-tetrathiocane-2-carboxylic acid[3b] (2.28 g, 0.01 mol) are suspended in xylene (10 ml) and heated to boiling. After addition of a drop of $BF_3 \cdot Et_2O$ the mixture is filtered. The solid residue is washed several times with hot benzene, then with concentrated NH_3 solution, and finally with dilute hydrochloric acid. The dried colorless finely crystalline product melts between 160 and 200 °C, decomposition with evolution of gas being observed at 180 °C. Yield of $[-(CH_2S)_7-CH(COOH)-S-]_n$: 1.73 g (42 %). One carbon atom in eight in the C—S—C chain bears a carboxyl group.

c) Compound *(2)* (0.92 g, 5 mmol) and S_8 (0.64 g, 2.5 mmol) are melted together (*ca.* 95 °C) to form a pale yellow mobile liquid. At 110 °C a drop of $BF_3 \cdot Et_2O$ is added and the mixture stirred mechanically. Polymerization is complete within about 15 s. The cooled brittle mixture is ground and extracted with benzene for 48 h. Mainly cyclooctasulfur crystallizes from the extract. The almost colorless polymer melts with partial decomposition at 146—149 °C. Yield: 1.22 g (78.2 % for $(CH_2S_2)_n$). Thus about half of the sulfur is incorporated into the insoluble polymer.

$[Au_2(WS_4)_2]^{2-}$, A Novel Inorganic Ring System

By *Achim Müller, Horst Dornfeld, Gerald Henkel, Bernt Krebs*, and *M. P. A. Viegers*[*]

Whereas thioheteroanions, containing a transition element with an open d shell as central atom can be classified from the structural point of view according to the rules of classical complex chemistry[1], unexpected and interesting coordination is found in those thioheteroanions which contain only metal atoms with closed d shells, such as $[Sn_2(WS_4)_2]^{4-}$[2].

We have now isolated a cyclic thioheteroanion as the salt $[(C_6H_5)_4P]_2[Au_2(WS_4)_2]$ *(1)* in the form of dark red crystals by reaction of $[Au(S_2O_3)_2]^{3-}$ with WS_4^{2-}. Compound *(1)* could be characterized by elemental analysis and X-ray structure analysis, as well as by ^{197}Au Mössbauer and vibrational spectroscopy.

The structure of the new gold(I) compound was determined from single crystal diffractometer data ($R = 6.9$ %). *(1)* crystallizes in the triclinic space group $P\bar{1}$ with the unit cell constants $a = 12.871(3)$, $b = 11.197(3)$, $c = 11.011(3)$ Å, $\alpha = 119.03(3)$, $\beta = 91.64(3)$, $\gamma = 108.85(3)°$. The dimeric, centrosymmetrical complex anion $[Au_2(WS_4)_2]^{2-}$ contains bidentate, nearly regular tetrahedral WS_4^{2-} ligands [average WS bond length: 2.136 Å (terminal), 2.243 Å (bridge); SWS bond angles: 105.6–112.9(2)°]. The SAuS linkage is approximately linear [SAuS angle: 167.2(2); AuS bond length: between 2.292(6) and 2.414(6) Å].

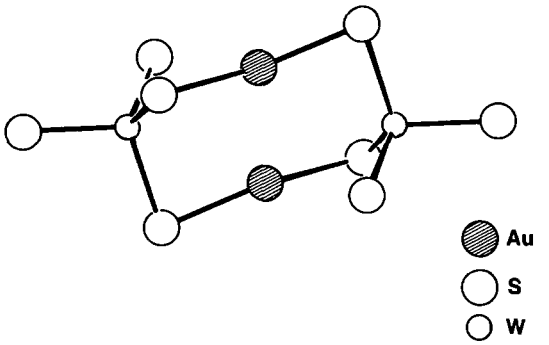

Fig. 1. Structure of the cyclic thioheteroanion $[Au_2(WS_4)_2]^{2-}$.

The heteroanion is disordered in the crystal structure, the Au atoms being distributed over three positions. Therefore, three orientations of identical rings (twisted by nearly 120° with respect to each other) can be distinguished.

[+] Author to whom correspondence should be addressed.

Though the IR spectrum of *(1)* [ν(WS) at 494 (m), 489 (m) and ν(AuS) at 329 (w) cm^{-1}] shows the coordination of WS_4^{2-} as a ligand (with significant differences in comparison to the spectra of transition metal coordination compounds where the metal acts as central atom), the molecular structure cannot be deduced from those data. Useful information has been obtained from the 77 keV ^{197}Au Mössbauer spectrum[3]: the quadrupole splitting and the chemical shift ($QS = 5.58$ mm/s, $IS = 0.86$ mm/s) constitute proof of an almost linear SAuS linkage[4], where the bonding involves only 6s and 6p orbitals of gold(I) and the π-acceptor strength of the ligand WS_4^{2-} from Au is negligible (in contrast to transition metal systems with open d shells).

Experimental

To an aqueous solution (600 ml) of $Na_3[Au(S_2O_3)_2]\cdot 2H_2O$ (0.1 g) and $[(C_6H_5)_4P]Br$ (0.24 g) is quickly added a freshly prepared solution (20 ml H_2O) of $(NH_4)_2WS_4$ (0.1 g). After immediate filtration the precipitate is briefly digested in nitromethane (0.7 ml). The residue is dissolved in dimethylformamide (4 ml). After addition of ethanol (4 ml) dark red crystals of *(1)* slowly precipitate (about 15 h); yield 0.04 g (27%).

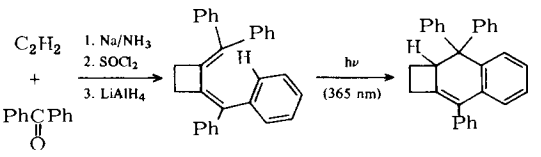
Novel Method for the Detection of Indirectly Identifiable Photochemical Intermediates[**]

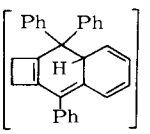
By *Gerd Kaupp* and *Heinz-Willi Grüter*[*]

Kinetic, flash spectroscopic, and magnetic (ESR, CIDNP) methods have been used for the detection of short-lived photointermediates[1], but none of these techniques is universally applicable.

In *thermally supported photoreactions* a comparison of the temperature dependence of luminescence and photochemical quantum yield provides mechanistic data. For example, if a singlet photoreaction A→P proceeds in two steps *via* an intermediate Z, its quantum yield can decrease or increase



[*] Univ.-Doz. Dr. G. Kaupp, H.-W. Grüter
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

with decreasing temperature[2], so long as the formation of Z remains unhindered. The temperature dependence of the fluorescence yield, on the other hand, is independent of the ratio *a/b*. In contrast, direct transitions from A* to P (concerted reactions without Z) necessitate an inverse relationship between quantum yield and fluorescence rate.

The application of these principles can be illustrated quite clearly by the productive intramolecular photoaddition of an aromatic C—H bond to an exocyclic double bond in *(1)*.

(1) *(2)*

(3)

Compound *(1)*[3], which is readily accessible from acetylene and benzophenone, largely avoids α- and β-cleavages[4] after absorption of light. The photolysis leads to 95 % *(2)*, whose structure has been confirmed by ^{1}H-NMR, ^{13}C-NMR, UV, IR, and mass spectra and by elemental analysis[5]. In contrast to the related photoreactions of fulgides[6] no absorption spectrum of a colored intermediate having structure *(3)* can be recorded at temperatures down to −80 °C, and there is still no experimental evidence for corresponding formulations in the isomerizations of overcrowded indan derivatives[7]. Evidence for (or against) an intermediate is therefore urgently required:

Compound *(1)* does not fluoresce at 25 and −80 °C but does so very intensely at −190 and −196 °C [ether/ethanol = 1:2; λ_{max}^{corr} = 460 (sh), 482, 494 (sh), 512 (sh), 527 nm (sh)]. This is fundamentally different from the temperature dependence of the photochemical formation of *(2)*, which proceeds seven times more slowly at −80 °C than at 25 °C (365 nm) and not at all at −190 °C [here also no colored product, but now stability of *(1)*]. Obviously the formation of an intermediate product [presumably *(3)*] from electronically excited *(1)* is unhindered down to −80 °C, but at −190 °C is no longer possible because of a slight energy barrier. The *a/b* ratio [here the ratio of the formation of *(1)* and of *(2)* from *(3)*] is in principle temperature dependent, since it is based on competing thermally activated processes.

The observed kinetic effect is independent of whether the intermediate product does or does not enrich to the UV detection limit under the irradiation conditions (I_0 *ca.* 4×10^{-8} E/s). As a further consequence of the mechanism *via* an intermediate, an influence of the solvent on the *a/b* ratio, *i.e.* on the photochemical quantum yield (cyclohexane: 0.0049, ethyl bromide: 0.0039, benzene: 0.0038, dichloromethane: 0.0027, methanol: 0.0026, acetonitrile: 0.0026), must be expected. The measured (N_2 or O_2, 25 °C, λ = 365 nm)[1a] values, which are very reliable because of the disappearing steady state concentration of *(3)* (in the transparent solvents three isosbestic points between 220 and 300 nm) confirm this prediction and at the same time also the singlet mechanism.

This method of detection of short-lived photointermediates should also be applicable to reactions which can be frozen-in only below 77 K, and still other deactivation processes might be useful instead of fluorescence.

3,3,8-Triphenyl-1,2,2a,3-tetrahydrocyclobuta[b]naphthalene (2):

A solution of 1,2-bis(diphenylmethylene)cyclobutane *(1)* (1.0 g) in benzene (300 ml) is irradiated at 20—25 °C with a mercury high-pressure lamp (Hanau, Q-81) through a glass filter (Wertheimer UVW-55) or a 0.5 M $Cu(NO_3)_2$ solution (1 cm) while being mixed by passage of a stream of N_2. After *ca.* 16 h the UV spectrum of *(1)* (λ_{max} = 357 nm) has all but disappeared. The solvent is removed and the residue crystallized by addition of 50 ml boiling methanol: 950 mg *(2)*, m.p. 180—181 °C.

Selenium Dioxide Insertion into the Iron-Methyl Bond of η^5-$C_5H_5Fe(CO)_2CH_3$[1]

By *Ingo-Peter Lorenz*[*]

SO_2 insertions into transition metal-carbon bonds have long been used for the synthesis of sulfinato complexes[2]. Corresponding insertion reactions of the homologous SeO_2 have so far not been described.

We report here on the first synthesis of a novel seleninato complex[3] by SeO_2 insertion into the iron-methyl bond of η^5-$C_5H_5Fe(CO)_2CH_3$ *(1)*: freshly sublimed SeO_2 completely dissolves in a well stirred solution of *(1)* in benzene, and a precipitate of *(2)* is immediately formed according to

$$\underset{(1)}{\eta^5\text{-}C_5H_5Fe(CO)_2CH_3} + SeO_2 \rightarrow \underset{(2)}{\eta^5\text{-}C_5H_5Fe(CO)_2Se(O)_2CH_3}$$

Some by-products are formed at the same time, including a little $[\eta^5\text{-}C_5H_5Fe(CO)_2]_2$ and large amounts of tris(methaneseleninato-*O,O'*)iron(III), $Fe(O_2SeCH_3)_3$[3b]. *(2)* is a brown,

[*] Dr. I.-P. Lorenz
Institut für Anorganische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen 1 (Germany)

finely crystalline solid which is stable in air for a few days, is not sublimable *in vacuo* below 130°C, and in the freshly prepared state is only moderately soluble in CH_2Cl_2 and CH_3OH; it is insoluble in other solvents. The composition and structure of the compound has been confirmed by elemental analysis and mass, ^1H-NMR, and IR spectroscopy.

The monomolecular structure of *(2)* in the dissolved and in the gaseous states follows from the molecular weight (obs. 300, osmometric in CH_2Cl_2) and the mass spectrum, which shows, besides the molecular ion ($m/e = 302$ and 304 in the natural isotopic ratio, 70 eV, 120°C), the successive elimination of the two CO ligands and the CH_3SeO_2 group (with fragmentation) as well as the recombination product $[\eta^5\text{-}C_5H_5Fe(CO)_2]_2$ as the ion of greatest mass. The 60-MHz ^1H-NMR spectrum (CD_3OD) shows two singlets at $\delta = 3.02$ (CH_3) and 5.05 (C_5H_5) in the expected intensity ratio. The chemical shift of the methyl protons excludes an Fe—C bond; the shift of the cyclopentadienyl protons of *(2)* downfield compared to those of the starting compound *(1)* can be explained by the electronegative character of the seleninate group.

In the IR spectrum of *(2)* the two $\nu(C{\equiv}O)$ frequencies (C_s symmetry, A′ + A″) appear as singlets at 2056 and 2009 cm^{-1} (in CH_2Cl_2) and thus—as in the case of the corresponding sulfinato complex[4] (as doublets)—lie about 50 cm^{-1} higher than in the spectrum of *(1)*; they indicate substantial π-acceptor ability of the seleninate ligands. Since no absorption occurs in the acyl-CO region (1700—1580 cm^{-1}) a reaction analogous to "CO-insertion"[5] can be ruled out. This is confirmed by $\nu(SeC)$ and $\nu(SeO_2)$ vibrations: As in the case of other alkaneseleninates $\nu(SeC)$ is observed at 570 cm^{-1} (in KBr); the position and frequency of $\nu_{as}(SeO_2)$ and $\nu_s(SeO_2)$ of compound *(2)* [859 (s) and 728 (s) cm^{-1}, respectively; solid/KBr] are consistent with coordination of the $RSeO_2^-$ group *via* selenium (seleninato-*Se* type)[3]. Hence, *(2)* can be regarded as a stable organometallic derivative of the highly reactive selenones. The reverse reaction, *i.e.* cleavage of SeO_2 from *(2)*, has not been observed.

(2) can be synthesized in the form of red-brown finely crystalline needles (m.p. 140°C) also by reaction of $\eta^5\text{-}C_5H_5Fe(CO)_2Cl$ with sodium methaneseleninate in dichloromethane or methanol[3b]:

$$\eta^5\text{-}C_5H_5Fe(CO)_2Cl + CH_3SeO_2Na \rightarrow (2) + NaCl$$

Experimental[6]

A suspension of freshly sublimed SeO_2 (2.22 g, 20 mmol) in a solution of *(1)* (3.88 g, 20 mmol) in benzene (50 ml) is stirred for 5 h at 50°C, filtered, and the unreacted *(1)* and $[\eta^5\text{-}C_5H_5Fe(CO)_2]_2$ washed with benzene. After brief drying the residue is extracted for *ca.* 6 h with 70 ml boiling dichloromethane using an extraction frit. The resulting solution is concentrated by evaporation and cooled, whereupon a brown crystalline product separates out. Filtration, washing with petroleum ether, and vacuum drying affords 720 mg (12%) *(2)*, m.p. 138—139°C. The residue from the extraction contains exclusively $Fe(O_2SeCH_3)_3$[3b].

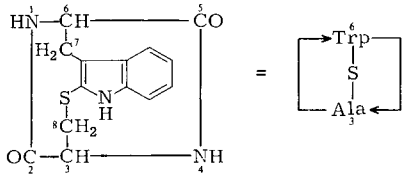
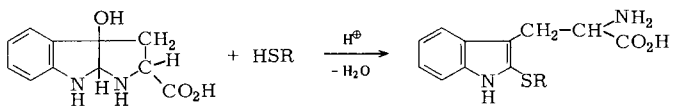
L,L-3,6-[Methanothio(2,3-indolo)methano]piperazine-2,5-dione, the Smallest Phallotoxin Model

By *Theodor Wieland, Christian Birr*, and *Giancarlo Zanotti*[*]

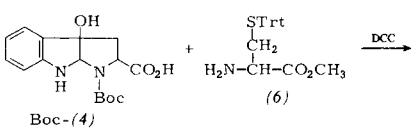


The phallotoxins [*e.g.* phalloin *(1)*], bicyclic heptapeptides from the green deathcap toadstool *(Amanita phalloides)*[1], contain a thioether bridge linking the mercapto group of a former cysteine with position 2 of a tryptophan side chain as a characteristic structural unit. The double amino acid *S*-(2-tryptophanyl)cysteine *(2)* was called tryptathionine[2].

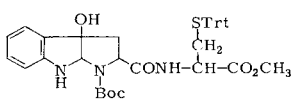


(1)

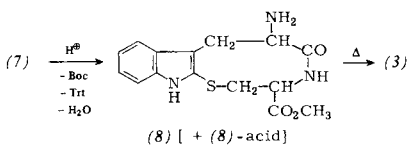
(2)



(3)



(4) *(5)*



The intramolecular double cyclic peptide of *(2)*, a piperazinedione *(3)*, is the first member of an interesting series

Boc-*(4)* *(6)*

(7)

(8) [+ *(8)*-acid]

[*] Prof. Dr. Th. Wieland, Priv.-Doz. Dr. Ch. Birr, Dr. G. Zanotti
Max-Planck-Institut für medizinische Forschung, Abteilung Naturstoff-Chemie
Jahnstrasse 29, D-6900 Heidelberg 1 (Germany)

of phallotoxins. Our synthesis of this "miniphallotoxin" made use of a publication by *Savige* and *Fontana*[3], according to which 3a-hydroxy-1,2,3,3a,8,8a-hexahydropyrrolo[2,3-*b*]indole-2-carboxylic acid *(4)* (designated here as Hpi), obtained from L-tryptophan by oxidation with peracetic acid[4], reacts with thiols in the presence of acids including cysteine[3] to give good yields of 2^{ind}-thioethers *(5)* of tryptophan. Since we wished to use this approach for synthesizing bicyclic peptides of type *(1)* it was be to examined whether with the smallest peptide model *(7)* the thioether formation induced by protonation also leads to the cyclic product *(8)*.

In order to use the diastereomeric "proline derivative" *(4)*[4] as the acyl component of a dipeptide synthesis with L(*S*-trityl)-cysteine methyl ester *(6)* it was protected at the pyrrolidine nitrogen by *tert*-butoxycarbonylation and coupled in this form (as Boc-*(4)*) to *(6)* with the aid of dicyclohexylcarbodiimide (DCC). The *S*- and *N*-protecting groups were removed from the dipeptide ester *(7)* by 50% trifluoroacetic acid, which led to simultaneous formation of cyclic thioether *(8)*. However, since the methyl ester *(8)* is partly hydrolyzed (to the *(8)*-acid), this component must subsequently be transformed back into *(8)* (with intermediate Boc protection of the primary amino function). On heating in *sec*-butyl alcohol/toluene the nine-membered monocyclic compound *(8)* gives the bicyclic piperazinedione *(3)*. This, the simplest phallotoxin analog was identified by elemental analysis and UV and mass spectrometry; it is nontoxic and shows no affinity for F-actin[5].

Experimental

N^{pyr}-Boc-Hpi [Boc-*(4)*]: A suspension of crystalline Hpi[4] (11.5 g, 0.053 mol) in dioxane/water (1:1, 50 ml) is stirred with Boc-azide (21.45 g, 0.15 mol) at room temperature for 3 h at pH 9.5 to 10 (0.5 N NaOH, pH stat). After removal of dioxane, the aqueous solution is washed once with ether and, after acidification to pH 3 with citric acid, several times with ethyl acetate. After washing twice with water and drying over Na_2SO_4 the solution is evaporated down *in vacuo* and the residue recrystallized from ethyl acetate: yield 14.0 g (81%); m.p. 180°C, $[\alpha]_D = +170°$ ($c = 1$, methanol).

Boc-Hpi-Cys(Trt)OMe *(7)*: A solution of Boc-*(4)* (5.8 g, 19.1 mmol) in ethyl acetate (120 ml) is stirred for 1 h with a solution of *(6)*[6] (7.2 g, 19.1 mmol) in dichloromethane (400 ml) at 0°C with admixture of dicyclohexylcarbodiimide (3.93 g, 19.1 mmol) in dioxane (50 ml), and then for 4 h at 20°C. The dicyclohexylurea is filtered off and the filtrate washed with 50% citric acid (2×), 0.5 N hydrogencarbonate (2×), and water (2×), and then dried over Na_2SO_4. The noncrystalline evaporation residue amounts to 13.4 g (≈100%). A sample purified by preparative thin layer chromatography (ether/light petroleum (65°C), 8:2) shows $[\alpha]_D = +71°$ ($c = 0.6$, methanol).

Cyclosulfide *(8)* and *(8)*-acid: A solution of *(7)* (13 g, 19 mmol) in 50% trifluoroacetic acid (260 ml) is maintained at 20°C for 48 h, filtered, and evaporated *in vacuo*. The residue is digested several times with ether and chromatographed with methanol on Sephadex LH-20. The first UV absorbing substance to appear is *(8)* (260 mg), followed directly by *(8)*-acid (760 mg), $\varepsilon_{290} = 10370$ (in methanol). In order to esterify the acid a 500-mg sample (1.63 mmol) in dioxane/water (1:1) is converted, in an autotitrator at pH 10 as described above, into the Boc derivative of the primary amino group with Boc-azide (466 mg, 3.26 mmol); it precipitates on acidification during work-up in the same way as for *(4)*. The precipitate is filtered off, washed with water, and dried in a desiccator. A 330-mg sample of Boc-*(8)*-acid is methylated with diazomethane in ether, and the methyl ester obtained on evaporation is transformed into *(8)* on standing in trifluoroacetic acid for 20 min. 250 mg is isolated (100%).

Piperazinedione *(3)*: A solution of *(8)* (250 mg) in a 2:1 mixture of *sec*-butyl alcohol and toluene is heated under reflux for 3 h. The crystals precipitated on cooling (84 mg) are filtered off under suction, washed with methanol, and recrystallized from the 2:1 solvent mixture: 36 mg of *(3)*, dec. >290°C. $[\alpha]_D = +429°$ ($c = 0.1$, methanol). MS (Dr. *H. J. Förster*, Ingelheim): $m/e = 287$. $\varepsilon_{290} = 10470$ (methanol). The ^{1}H-NMR spectrum shows all the expected proton signals; in the ^{13}C-NMR spectrum the signals (TMS as standard) of C-3 or C-6 appear at 53.38 or 54.07, of C-2 or C-5 at 166.85 or 170.91, of C-7 at 44.39, and of C-8 at 28.11 (Dr. *K. H. Pook*, *W. Pryss*, Ingelheim).

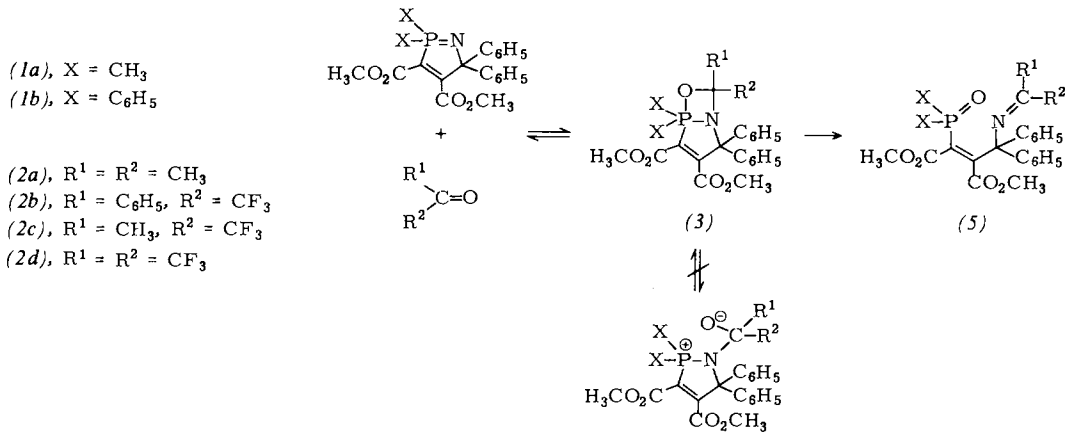
Stable [2+2]-Cycloadducts of Ketones with Phosphazenes Having Five-Membered Rings[1]

By *Alfred Schmidpeter* and *Thomas von Criegern*[*]



On the basis of kinetic studies a betaine intermediate has recently been proposed to occur in the reaction of λ^5-phosphazenes (phosphane imides) with aldehydes or ketones discovered by *Staudinger et al.*[2]; the reaction products are assumed to form from it *via* a four-membered ring containing pentacovalent phosphorus[3]:

However, it was pointed out that, in contrast to the situation in the Wittig reaction, there is still no direct experimental evidence for an intermediate and that mechanistic alternatives therefore cannot be unequivocally ruled out[3].

In the reaction of five-membered ring phosphazenes such as 1,2λ^5-azaphospholes *(1)*[4] with ketones *(2)* we have now isolated the crystalline [2+2]-cycloadducts *(3)*[5]. Their bicyclic structure follows from the characteristic upfield shift of pentacoordinated phosphorus observed in the ^{31}P-NMR spectrum (Table 1) and from the diastereotopism of X = CH_3

[*] Prof. Dr. A. Schmidpeter, Dipl.-Chem. T. v. Criegern
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

observed for *(3b)* and *(3c)* ($R^1 \neq R^2$) in the ^{1}H-NMR spectrum. $\delta(^{31}P)$ shows a clear-cut and regular progression to lower field with each CF_3 group, indicating increasing polarity of the PO bond on going from *(3a)* to *(3d)* and from *(3e)* to *(3h)*. However, an equilibrium contribution of the betaine form *(4)* [$\delta(^{31}P)$ value predicted $\approx +70$] can be ruled out since the ^{31}P shift of the adduct hardly changes with solvent polarity (Table 1).

Table 1. ^{31}P-NMR shift in $CDCl_3$ (or Me_2SO) and proportion Q of the cycloadducts *(3)* dissociated (0.7 M $CDCl_3$ solution).

	X	R^1	R^2	$\delta(^{31}P)$	Q [%] at T [°C] = −20	0	20	40	60
(3a)	CH_3	CH_3	CH_3	−55.4		34	53	65	80
(3b)	CH_3	C_6H_5	CF_3	−46.6				10	18
(3c)	CH_3	CH_3	CF_3	−46.6 (−44.6)				—	
(3d)	CH_3	CF_3	CF_3	−35.1 (−34.0)				—	
(3e)	C_6H_5	CH_3	CH_3	−49.3	76	92			
(3f)	C_6H_5	C_6H_5	CF_3	−43.2	42	59	67	74	
(3g)	C_6H_5	CH_3	CF_3	−41.2				11	19
(3h)	C_6H_5	CF_3	CF_3	−34.9				—	

Some of the cycloadducts decompose to their components in solution; their ^{1}H-, ^{19}F-, and ^{31}P-NMR spectra show signals of *(1)* and *(2)* in addition to those of *(3)*. Dissociation is promoted by dilution and by higher temperatures (Table 1). The positions of the equilibria reveal that the stability of the cycloadducts towards reversion *(3)* is determined mainly by the acceptor strength of the ketone *(2a)* < *(2b)* < *(2c)* < *(2d)* and by the donor strength of the phosphazene *(1a)* > *(1b)*. The adduct of lowest stability *(3e)* dissociates completely at room temperature in 0.7 M $CDCl_3$ solution. It also quantitatively regenerates *(1b)* on dry warming *in vacuo*, in the same way as *(3a)* regenerates *(1a)*.

On heating solutions of the other cycloadducts *(3)* to >60 °C, reversible dissociation is accompanied by slow irreversible decomposition. The alternative [2+2]-cleavage of the oxazaphosphete ring gives the ketimine-phosphane oxides *(5)*, in keeping with *Staudinger*'s results[2]. Unlike ketones, aldehydes such as *(2)*, $R^1 = H$, $R^2 = CCl_3$, p-$C_6H_4NO_2$, C_6F_5 immediately react with *(1)* to give the ring-opened product *(5)*; no intermediate *(3)* can be detected.

From our results a four-membered ring intermediate rather than a betaine intermediate appears likely in general for the carbonyl/iminophosphorane reaction, as in the Wittig reaction[6]. It can be isolated in the exceptional case of *(3)* owing to the stabilizing effect of incorporation of σ^5-phosphorus as bridgehead[7].

7-Oxa-5-aza-1-phosphabicyclo[3.2.0]hept-2-enes (3)

An excess of the ketone *(2)* is added to the yellow concentrated solution of *(1)* in $CHCl_3$, which is usually decolorized. On addition of *n*-pentane the colorless cycloadduct *(3)* is precipitated and can be recrystallized from $CHCl_3$/*n*-pentane.

Synthesis of *cyclo*-Heptasulfur, S_7, from S_8[1]

By *Ralf Steudel* and *Hans-Joachim Mäusle*[*]

On melting, *cyclo*-octasulfur is transformed into a mixture of S_8, S_7, S_6, and S_μ (polymeric sulfur insoluble in CS_2)[2];

[*] Prof. Dr. R. Steudel, Dipl.-Chem. H.-J. Mäusle
Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

at the equilibrium melting point (115.2 °C) the concentration of S_7 is *ca.* 4 % w/w and at the polymerization temperature (159 °C) *ca.* 8 %[3]. The formation of S_7 and S_6 most likely proceeds *via* S_μ, which arises from S_8 by homolytic ring-opening and copolymerization of the chain with *cyclo*-S_8[4] and from which, conversely, small cyclic molecules can be split off. We have now found that S_7 can be isolated in pure form with little effort from quenched sulfur melts by fractional extraction and crystallization exploiting the tendency of S_7 to form supersaturated solutions in CS_2. Precipitation can be achieved by inoculation with S_7 or addition of finely ground glass. The S_7 thus obtained shows no contamination by S_8 or S_6 in the Raman spectrum and is identical with that obtained as condensation product from $(C_5H_5)_2TiS_5$ and S_2Cl_2[5]. The yield is *ca.* 10 % of the S_7 present in equilibrium in liquid sulfur at 159 °C; most of the unconverted sulfur can be processed again for the synthesis of S_7. No exacting measures are required regarding the purity of the sulfur or the solvent.

At an annual world production of *ca.* 30×10^6 t of liquid sulfur, containing *ca.* 2×10^6 t S_7 in equilibrium, these results would justify a more detailed investigation of the chemical properties of *cyclo*-heptasulfur.

Experimental

100 g sulfur is heated in a 250 ml round-bottom flask at 200 °C for 30 min and then *slowly* cooled to 159 °C. As soon as the melt has become less viscous it is allowed to flow in as thin a stream as possible into liquid nitrogen. The liquid nitrogen is removed very carefully by decantation from the bright yellow powder, which is then extracted at room temperature with purified CS_2 (70 ml) for 1 h with vigorous stirring. The intensely yellow solution is filtered and stored for 20 h at −78 °C, whereupon S_8 crystallizes out. The solution is then decanted, which must be carried out as quickly as possible so as to prevent any S_8 being redissolved on warming. The solution is stirred for 2 h in a 100-ml round-bottom flask at −78 °C together with finely-ground glass (3 spatulasful) until precipitation of finely crystalline sulfur. After settling the precipitate is sucked as dry as possible using an immersion filter frit (D3 or D4), and then rapidly extracted (3 × 10 ml) with analytically pure toluene at 25 °C, the solution being decanted off each time from the orange red residue. On cooling the combined extracts, finely crystalline S_7 precipitates out. The mother liquor is carefully decanted off or sucked off as above; the product is dissolved in CS_2 (5 ml), crystallized out again at −78 °C, and isolated by rapid suction at a glass-frit. Depending on the melting point the product is again recrystallized once or twice from CS_2. Yield: 0.6–0.8 g needle-shaped or lance-shaped, intensely yellow crystals (m.p. 38–39 °C); solubility at −78 °C: 1.7 g/100 g CS_2.

X-Ray Structure Analysis of *cyclo*-Decasulfur, S_{10}[1]

By *Richard Reinhardt, Ralf Steudel*, and *Fritz Schuster*[*]

cyclo-Decasulfur is obtainable in the form of thermally unstable, light-sensitive, yellow crystals as product of the reaction of $(C_5H_5)_2TiS_5$ with SO_2Cl_2, and has been characterized by molecular weight determination[2], mass spectra[3], and vibrational spectra[4]. Controlled decomposition of *cyclo*-polysulfur oxides such as S_6O_2 and S_7O also leads to pure crystalline S_{10}[5]; to elucidate the mechanism of formation of S_{10} we have carried out a single-crystal X-ray structural analysis.

The space group and approximate lattice constants were determined from deJong-Bouman and precession photographs at *ca.* −110 °C. The results showed the monoclinic space group C2/c with an unusually small angle of 37° for the normal setting, but with an angle of 110° after transformation into I2/n. Refinement of 24 Bragg angles according to the method of least squares afforded the cell constants in I2/n: $a = 824.0(4)$, $b = 1027.5(9)$, $c = 1277.6(9)$ pm, $\beta = 110.59(2)°$, $Z = 4$, $d_{calc} = 2.103\ g \cdot cm^{-3}$ (−110 °C). 961 independent reflections up to $\theta = 25°$ were measured on an automatic single-crystal diffractometer using $Mo_{K\alpha}$ radiation and corrected in the usual way; 19 reflections were classified as unobserved ($I \leq 2\sigma$). A meaningful prediction of the structure was not achievable with direct methods and the interpretation of a Patterson synthesis did not appear promising. However, on the basis of spectroscopic measurements and symmetry considerations[4] the possible arrangements of the atoms were so limited that the phase problem could be solved by trial and error methods and the structure refined with anisotropic temperature factors to $R = 0.039$. An absorption correction ($\mu = 20.07\ cm^{-1}$) was not carried out.

The four S_{10} molecules in the unit cell occupy C_2 symmetry positions, but to a good approximation have the very rare point group symmetry D_2 (three orthogonal twofold axes of rotation as the only symmetry elements). Six atoms lie in a plane (maximum deviation from the least squares plane 1.5 pm) and two atoms are situated above and two below the plane (see Fig. 1). This conformation, which hitherto has not been observed in sulfur chemistry, does not correspond to the predicted D_{5d} symmetry[6]. The arithmetical mean bond lengths (205.6 pm) and valence angles (106.2°) closely correspond to the values observed in S_{12} (205.3 pm, 106.6°[7]); formally, S_{10} can be composed of two identical S_5 units, obtain-

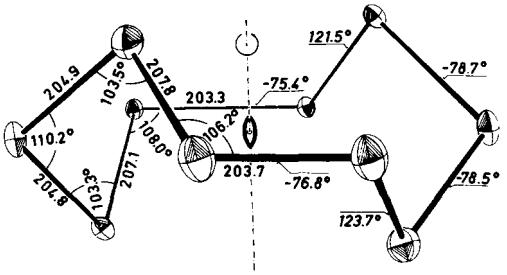

Fig. 1. Molecular structure, bond lengths [pm], valence angles, and torsion angles of S_{10}. The maximum standard deviation of the bond lengths is 0.4 pm, that of the angles 0.2°. The crystallographic two-fold symmetry axis is shown. The distance between the two horizontal bonds is 541 pm.

able from the S_{12} molecule (left and right halves of the molecule in Fig. 1).

Although no unusually long or short bonds are present, an alternation of bond lengths symmetric to one of the C_2 axes is clearly recognizable. This can be interpreted in terms of the alternating torsion angles which have the value 123 ± 2 or $-77\pm2°$, the greater value leading to a weakening of the SS bonds which then gives rise to a slight shortening of the neighboring bonds owing to strong bond-bond interaction[7]. The lower thermal stability of S_{10} compared to that of S_8 and S_{12} can be attributed to the four large torsion angles of *ca.* 123°, which exceed the previously observed values in sulfur rings by more than 20°. This results in a stronger electron pair repulsion between neighboring atoms and thus a decrease in bond energy[7]. The smallest intermolecular distance between nuclei is 323 pm.

Hence the structures of the sulfur homocycles S_n with $n=6$, 7, 8, 10, 12, 18, and 20 are now known.

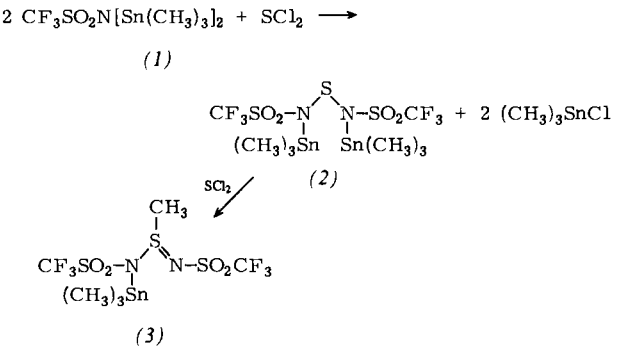
An Alkylsulfur Imide Amide (Methanesulfinamidine)—Relation between Coordination Number and Bond Length[**]



By *Herbert W. Roesky, Manfred Diehl, Hartmut Fuess*, and *Jan Willem Bats*[*]

Reaction of sulfur dichloride with nitrogen-containing organometallic compounds is a known method for the synthesis of sulfur diamides *(A)* and sulfur diimides *(B)*[1]. To our knowledge, however, no sulfur derivatives of type *(C)* have yet been prepared in this way[1b].

(A) *(B)* *(C)*

We have now found that *N,N*-bis(trimethylstannyl)trifluoromethanesulfonamide[2] *(1)* reacts with sulfur dichloride in the molar ratio 2:1 to give the sulfur diamide *(2)*. On treatment with an additional amount of SCl_2 compound *(2)* affords the methylsulfur imide amide *(3)*. Alkylation of sulfur with cleavage of a R_3Sn group was observed for the first time in this reaction.

(1) *(2)* *(3)*

The white crystalline product *(3)* could not be unequivocally characterized by elemental analysis, mass spectrum, ^1H- and ^{19}F-NMR spectra (the structure of a *N*-methyl derivative of type *(A)* could not be ruled out).

In addition to proving the structure, X-ray analysis provided further information. On the one hand, conventional formulation with alternate single and double bonds, as shown for *(3)*, is unsuitable for describing the actual bonding. A correlation apparently exists between the bond lengths and the coordination numbers (CN) of the participating atoms (cf. Fig. 1).

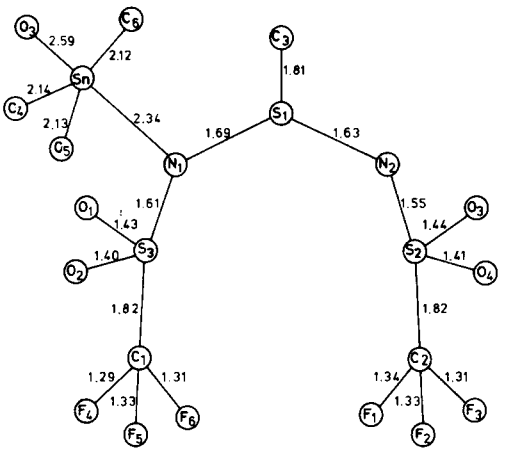


Fig. 1. Molecular structure and numbering of the atoms of *(3)*; bond lengths in Å.

In the case of the shortest SN bond (S2—N2: 155 pm) sulfur has coordination 4 and nitrogen coordination 2. An increase in CN of the atom N1 leads to a lengthening of the S3—N1 distance to 161 pm. A similar effect is observed for the sulfur atom S1 having CN 3. S1—N2 is shorter than S1—N1. According to structural studies performed so far on sulfilimines and sulfamates[3] this observation could be of general validity for sulfur having coordination numbers 4 and 3, leading to the following series of increasing bond lengths:

$$S(CN=4)—N(CN=2) < S(CN=4)—N(CN=3) \approx S(CN=3)—N(CN=2) < S(CN=3)—N(CN=3)$$

On the other hand, the tin atom is in a trigonal-bipyramidal configuration[4] in the crystal, with the three methyl groups,

the N1 atom, and the O3 atom of an adjacent molecule as nearest neighbors[5].

Experimental

A solution of SCl_2 (1.03 g, 0.01 mol) in CH_2Cl_2 (20 ml) is slowly added dropwise to a stirred suspension of *(1)* (4.77 g, 0.01 mol) in CH_2Cl_2 (30 ml). The red color of SCl_2 disappears, and a clear solution is formed. Compound *(2)* is precipitated as intermediate, and is consumed on further addition of SCl_2. A clear solution is formed once again. On completion of the reaction (*ca.* 3 h) compound *(3)* precipitates; recrystallization from CH_2Cl_2 gives colorless needles, m.p. 132—134 °C. After removal of solvent and sublimation of $(CH_3)_3SnCl$ and $(CH_3)_2SnCl_2$ in an oil-pump vacuum at 40 °C most of the product is obtained as residue; yield 0.5 g.—IR (Nujol, cm^{-1}): 1380 s, 1340 s, 1335 m, 1242 s, 1235 s, 1225 s, 1216 s, 1205 s, 1194 s, 1152 s, 1038 m, 1005 w, 981 m, 917 s, 795 m, 770 m, 767 w, 738 w.—MS (70 eV): *m/e* (rel. int.) = 506 M^+ (1), 491 $M^+ - CH_3$ (59), 165 $(CH_3)_3Sn$ (100).—^{19}F-NMR: $\delta = -77.8$ (s).—^{1}H-NMR: $\delta(CH_3)_3Sn = -0.96$ (s), $\delta(CH_3) = -2.9$ (s).

The First Reversible Thermal Dissociation of Distannanes, $R_3Sn—SnR_3$

By *Hans U. Buschhaus* and *Wilhelm P. Neumann*[*]

Hexaalkyldistannanes have hitherto been considered as thermally stable up to at least 170 °C[1] or even 235 °C[2]. At higher temperatures irreversible formation of alkyl radicals and polymers, and deposition of tin were observed. As with highly substituted ethanes and their reversible dissociation to alkyl[3] or ketyl radicals[4], the frontstrain or backstrain of bulky residues should also weaken the Sn—Sn bond to such an extent that reversible thermal dissociation may occur. We have now been able to observe this effect in the case of the aryl derivatives *(1)*:

$$\underset{(1)}{R_3Sn—SnR_3} \overset{\Delta}{\rightleftharpoons} \underset{(2)}{2\,R_3Sn\cdot}$$

(a): R = 2,4,6-trimethylphenyl
(b): R = 2,4,6-triethylphenyl

Equal ESR singlets begin to appear in solutions of *(1a)* at 180 °C, and even at 100 °C in solutions of *(1b)*. They disappear instantaneously upon cooling ($g = 2.0075$, line width 5 G). The more bulky ethyl group in *(1b)* is seen to have a considerable influence. ESR intensity measurements gave the dissociation energies $D_{Sn—Sn} = 190 \pm 8$ kJ/mol for *(1a)*, and only 125 ± 5 kJ/mol for *(1b)*, which is considerably less than for $Me_3Sn—SnMe_3$ (210—240 kJ/mol)[5]:

We have prepared the previously unknown distannanes *(1)* by a novel procedure:

$$2\,R_3SnH + NC—CMe_2—N{=}N—CMe_2—CN \overset{\Delta}{\rightleftharpoons} \underset{(3)}{} N_2 + 2\,HCMe_2—CN + \underset{}{(1)}$$

During this reaction, carried out in nonane at 100 °C, the ESR signals of the stannyl radicals *(2)* appear.

Thus, two further transient radicals $R_3Sn\cdot$ have become accessible to measurement in solution, in addition to the tris-(2-phenyl-2-methylpropyl)stannyl radical which was recently subjected to detailed study as an example of this species[6].

Procedure

Preparation of *(1a)*: *(3a)*[7] (1.5 g, 3.1 mmol) is dissolved in anhydrous toluene (50 ml) in an argon atmosphere. Azoisobutyronitrile (0.37 g, 2.2 mmol) is then added, and the mixture is stirred for 8 h at 60 °C. A colorless solid is deposited, which is filtered off with exclusion of air, washed twice with hot toluene, and dried *in vacuo*. Yield: 1.3 g (87 %) of *(1a)*, colorless crystals, dec. > 300 °C, identified by CH analysis, IR, mass spectrometry, very sparingly soluble in the usual solvents, sparingly soluble in phenanthrene or 1-methylnaphthalene.

(1b) is prepared similarly from *(3b)* (5.0 g, 8.3 mmol), obtained by a procedure resembling that for *(3a)*, in nonane (50 ml) and azoisobutyronitrile (1.40 g, 8.3 mmol). After centrifugation and recrystallization from nonane, colorless needles are isolated, dec. > 300 °C, soluble in hot nonane and 1-methylnaphthalene, identified by CH analysis, IR, and mass spectrometry.

Dissociation experiments: In an ESR tube, *(1a)* (about 50 mg) is suspended in 1-methylnaphthalene (1 ml) or melted in phenanthrene (3 g) under argon, or *(1b)* (50 mg) is suspended in 1-methylnaphthalene (1 ml) or nonane (1 ml), and heated to the desired temperature in a Varian E6 X-band ESR spectrometer. Intensity measurements are performed on *(2a)* in the 180—230 °C range (at higher temperatures *(1a)* becomes red and decomposes irreversibly), and on *(2b)* in the 100—160 °C range. The intensities of the signals depend on the applied microwave energy. UV irradiation of *(1a)* and *(1b)* yields *(2a)* and *(2b)*, respectively, even at lower temperatures.

Bombykal, a Second Pheromone Component of the Silkworm Moth *Bombyx mori L.*

By *Gerhard Kasang, Karl Ernst Kaissling, Otto Vostrowsky,* and *Hans Jürgen Bestmann*[*]

Dedicated to Professor Adolf Butenandt on the occasion of his 75th birthday

In 1959 *Butenandt et al.* reported the isolation and elucidation of the structure of the first insect sex attractant[1]. The compound concerned was (*E*)-10,(*Z*)-12-hexadecadien-1-ol (bombykol), which is secreted from the abdominal glands (sacculi laterales) of the female silkworm moth *Bombyx mori L.* and serves as an attractant only to the male members of the same species. It has hitherto been assumed that bombykol was the only pheromone that played a role in the chemical communication system between the different sexes of the species *Bombyx mori*[2].

Electrophysiological assay of single cells of the olfactory hairs of the male animals showed, however, that only one of the two morphologically different receptor cells[3] was responsive to bombykol, whereas the female's scent excited both cells[4]. This pointed to the presence of a second pheromone component. It was then found that the cell type not excited by bombykol was responsive[4] to (*E*)-10,(*Z*)-12-hexadecadien-1-al (bombykal)[5], a compound recently synthesized in our laboratories. This finding prompted us to search for signs of the presence of bombykal in the glands of the female animal of *Bombyx mori*[6]. We have now succeeded in demonstrating the presence of bombykal in extracts from the abdominal glands of female silk worm moths which were bred in Taiwan and Italy.

The abdominal tips excised from 460 freshly emerged female silkworm moths were together extracted with benzene. The concentrated extract was purified and separated by preparative thin-layer chromatography on silica gel. The zones corresponding to bombykal and bombykol ($R_f = 0.53$ and 0.29, hexane/ethyl methyl ketone = 80:20) were removed[7] and eluted with chloroform/ethanol (99:1). The fractions thus obtained were evaporated to dryness, dissolved in heptane (30 µl), and gas chromatographically analyzed (4 m stainless steel column $^1/_8''$ ID, 3% SE-30 on chromosorb W-AW-DMCS 80/100 mesh, 200°C, isothermal). The results are shown in Table 1.

Table 1. Content of bombykal and bombykol[8] in the extract from 460 abdominal tips excised from female silkworm moths[9].

Compound	Retention time [min]	Total amount [µg]	Content per gland [ng]	Proportion [%]
Bombykal	5.6	7	15.2	7.2
Bombykol	6.8	90	195.7	92.8

The retention times of the natural bombykal and bombykol were identical with those of the synthetic compounds[5]. The GC analyses of the two fractions were repeated on a 50 m thin-film glass capillary (0.32 mm ID, OV 101) coupled to a mass spectrometer[10] (70 eV, EI spectrum, 2.5 s/scan). The retention times of natural and synthetic bombykal and bombykol were once again identical (co-chromatography), being 19.90 and 22.30 min, respectively (splitless injection, 5 min 25°C, 80 to 220°C, 8°/min). The mass spectrum of the fraction with $t_R = 19.90$ min was identical with the spectrum of synthetic bombykal [*m/e* = 236 (M^+, 6%), 235 ($M^+ - H$, 2%), 192 ($M^+ - CH_3CHO$, 0.9%), 67 (100%) and 44 (CH_3CHO^+, 30%)].

The fact that bombykal is present in the abdominal glands of the female *Bombyx mori* and that the antennae of the male have specific and highly-sensitive receptor cells for this compound proves that bombykal is a second pheromone component of the silkworm moth. At the same time it shows that also *Bombyx mori*, the classical "pet" of pheromone research[1, 11], uses a multicomponent system for communication between the sexes, as has been found to be the case for numerous other species of Lepidoptera[12]. The ratio of the components of such a pheromone complex is decisive for its mode of action and species specificity[13].

Triptycenophanes—Synthesis *via* "Double Nonbenzylic Sulfone Pyrolysis"[1]

By *Fritz Vögtle* and *Philippe Koo Tze Mew*[*]

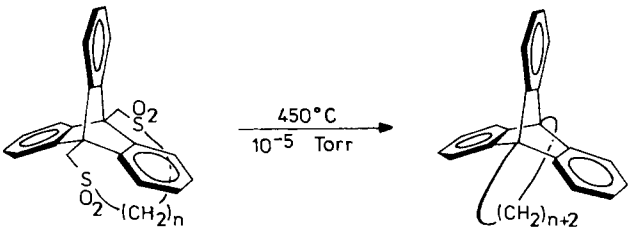
The tricyclic molecular skeleton *(1)*, called "paddlane"[2], has been the object of numerous synthetic studies which have been partly successful in only isolated cases *(2)*, *(3)*, *(4)*[2a–c].

[*] Prof. Dr. F. Vögtle, Dipl.-Chem. P. Koo Tze Mew
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn (Germany)

(1) (2) (3) (4)

We now describe novel synthetic pathways leading to previously unknown triptycene hydrocarbons *(9)* bearing a 9,10 alkano bridge, related Diels-Alder adducts *(10)*, and their stereochemistry.

Syntheses:



Starting from dithia(9,10)anthracenophanes *(5)* obtainable by methods utilizing the dilution principle, and the bissulfones *(6)* prepared therefrom by oxidation with *m*-chloroperbenzoic acid, Diels-Alder addition with benzyne leads to the triptycenophane derivatives *(8)* in 5% yield (cf. Table 1).

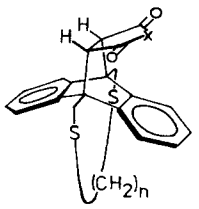
(5), X = S *(a)*: n = 8 *(7)*

(6), X = SO_2 *(b)*: n = 12

Surprisingly, "double nonbenzylic sulfone pyrolysis"[3] proceeds *via* recombination of the aliphatic bridge with the methylene groups located at the bridgehead to give the hydrocarbon *(9b)* of [(*n*+2).2.2]paddlane type, albeit in only low yield[4] (cf. Table 1).

(8) *(a)*: n = 8 *(9)*

(b): n = 12



The alternative approach—synthesis of [*n*+2](9,10)triptycenophane *(9)* *via* pyrolysis of the bissulfone *(6)*—proceeded only as far as *(7)* whose reaction with benzyne failed to give *(9)*, probably owing to excessively high ring strain.

Attempted cycloaddition of benzyne to the bissulfides *(5)* was also unsuccessful since the C—S bond was broken. In contrast, the analogous Diels-Alder addition of dienophiles such as maleic anhydride or *N*-phenylmaleimide to the anthracenophanes *(5)* to *(10)* proved possible.

Table 1. Melting points and ^{1}H-NMR data of the compounds synthesized.

	M.p. [°C]	Yield [%]	^{1}H-NMR (90 MHz, δ values in $CDCl_3$/TMS int.) CH (Phenylene)	CH_2 (Bridgehead)

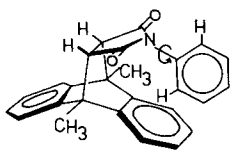
(10a), X = O

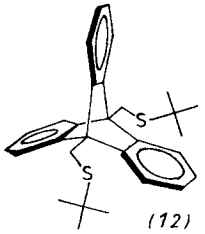
(10b), X = NC_6H_5



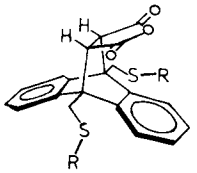
n = 8, 12

Stereochemistry and steric interactions: In the triptycenophanes *(8a)* and *(8b)* the triptycene system cannot rotate under the $(CH_2)_8$ or $(CH_2)_{12}$ bridge. This follows both from the ^{1}H-NMR spectrum, which exhibits two groups of signals in the intensity ratio 2:1 for the aromatic protons, and from consideration of space-filling models which show the bridge to be clamped between two of the three benzene rings[5]. The same applies to the hydrocarbon *(9b)*, whose UV absorption (λ_{max} = 280, 274, and 265 nm) shows a bathochromic shift relative to that of 9,10-dimethyltriptycene (276, 267, 258 nm; in isooctane); furthermore the longest wavelength maximum shows a significantly lower extinction.

As in *(8)* and *(9)*, the chain is fixed in the Diels-Alder adduct *(10)*, on the side opposite the former dienophile. This backside attack in Diels-Alder cycloaddition seems reasonable on steric grounds. The bridge CH_2 protons are diastereotopic and appear as an AB system, as is clear from the Newman projection *A* of *(10)*:



(10A)



(11)

Once again the triptycene-type structural unit of *(10)* is unable to pass under the—too short—bridge, not even on warming to 120 °C (slow decomposition starts at higher temperature). The upfield shift of the phenyl protons *ortho* to nitrogen in the *N*-phenylmaleimide adduct *(10b)* is remarkable. Space-filling models show that these protons should come into the region of the shielding anisotropic effect of the benzene ring lying below them by rotation of the phenyl group about the C—N bond. A similar situation is expectedly observed in the open-chain compound *(11)* obtainable analogously by Diels-Alder reaction of 9,10-dimethylanthracene with *N*-phenylmaleimide.

A further insight into the stereochemistry of the bridged triptycene system is provided by comparisons with the open-chain analogs *(12)* and *(13)*.

(12)

(13a), R = $C(CH_3)_3$

(13b), R = $CH_2C_6H_5$

In the *tert*-butyl compound *(12)* rotation about the triptycenyl—CH_2S bond is sterically hindered: the resonance signals of the H_α,H_β protons of the aromatic rings show broadening, the effect being more pronounced for the α part than for the β part. On cooling, the α part is observed to split into two signals in the intensity ratio 2:1 since rotation of the CH_2StBu group is frozen in [rotational barrier $\Delta G_{Tr}^{\neq} \approx 15.7$ kcal/mol (65.7 kJ/mol)]. These results are in accord with those obtained for 9,10-bis(chloromethyl)triptycene[6]. The corresponding rotation is less hindered in the benzyl compound *(13b)* [$\Delta G_c^{\neq} < 10$ kcal/mol (42 kJ/mol)]. The NMR signals of the aromatic protons are not broadened; the diastereotopic bridgehead CH_2 protons absorb as an AB system.

Quaternary Ammonium Salts as Catalysts of Nucleophilic Substitution Reactions in a Solid-Liquid Two-Phase System

By *Andrzej Jończyk, Maria Ludwikow*, and *Mieczyslaw Mąkosza*[*]

Macrocyclic polyethers (crown ethers) form stable complexes with alkali metal cations, and are able to solubilize many inorganic salts in moderately polar solvents[1,2]. The anions of such solubilized salts are poorly solvated and exhibit high activity, hence the name "naked anions"[3]. For practical purposes the use of 5—10 mol-% of crown ethers suffices for complete conversion of substrates[1-3]. Thus, crown ethers evidently effect continuous transfer of the anions from the solid phase into solution. This process is similar to a "phase-transfer" catalyzed[4] liquid-liquid reaction, and it might therefore be expected that in the liquid-solid system the reactions should also be catalyzed by the much less expensive tetraalkylammonium (TAA) salts.

In contrast to previous studies[2,4b] we have now found that lipophilic TAA salts do indeed catalyze the reactions of inorganic salts in a solid-liquid system[5]:

[*] Prof. Dr. M. Mąkosza, Dr. A. Jończyk, Dipl.-Chem. M. Ludwikow
Institute of Organic Chemistry and Technology, Technical University (Politechnika)
Koszykowa 75, 00-662 Warsaw (Poland)

$$R{-}X_{liquid} + MY_{solid} \xrightarrow[CH_3CN \text{ or } CH_2Cl_2]{\text{Aliquat 336}} R{-}Y_{liquid} + MX_{solid}$$

RX	MY	Solvent	t [a] [h]	Conversion [%] [b]
$C_6H_5CH_2Cl$	NaOAc	CH_3CN	4.5 [c]	100 [d]
$C_4H_9OSO_2CH_3$	NaOAc	CH_3CN	5.0	61
$C_6H_5CH_2Cl$	KSCN	CH_3CN	1.5	100 [e]
C_4H_9Br	KSCN	CH_3CN	2.0	98 [e]
$C_6H_5CH_2Cl$	KF	CH_3CN	25.0	30
$C_6H_5CH_2Cl$	KBr	CH_3CN	5.0	39
$C_4H_9OSO_2CH_3$	KNO_2	CH_2Cl_2	30.0	32
$C_6H_5CH_2Cl$	NaCN	CH_3CN	10.0	88

[a] We have not optimized the reaction time. [b] Determined by GLC. [c] After 1 h, conversion 81 %. [d] Without catalyst, conversion ≈10 %. [e] The same results with and without catalyst.

If a solution of alkyl halide or methanesulfonate in acetonitrile or dichloromethane with an excess of a dried and ground sodium or potassium salt (Table) and 1—3 % of Aliquat 336 (trade name for technical grade methyltrioctylammonium chloride) then a nucleophilic substitution takes place. The tabulated data evidence a strong catalytic effect of the quaternary ammonium compounds. The fact that they are somewhat less effective catalysts than crown ethers is, in our opinion, due to different structures of solubilized ion pairs (cation-anion interactions).

In the case of specific examples suitable choice of catalyst and optimization of the reaction conditions may greatly improve the yields.

Reactive Derivatives of Aliphatic *N*-Sulfinylamines—Alkylation of *N*-Sulfinylalkylamines and Bis(*tert*-butyl)-sulfur Diimide

By *Günter Kresze* and *Michael Rössert*[*]

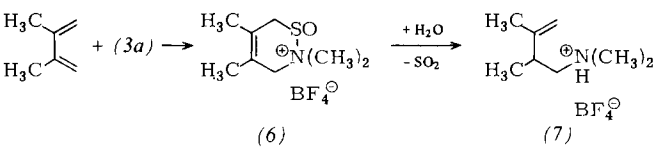
N-Sulfinyldimethylimmonium hexachloroantimonate is a known compound[1]. We have now found that compounds of this type are readily accessible by alkylation of aliphatic *N*-sulfinylamines *(1)* with trialkyloxonium tetrafluoroborates *(2)*:

$$R^1NSO + R^2_3O^{\oplus}BF_4^{\ominus} \longrightarrow \begin{matrix} & & R^1 \\ & & \diagdown \\ & & N^{\oplus}{=}SO \\ & & \diagup \\ & & R^2 \end{matrix} BF_4^{\ominus} + R^2_2O$$

(1) *(2)*

(3a), $R^1 = R^2 = CH_3$
(3b), $R^1 = C_2H_5$, $R^2 = CH_3$

Thus the immonium salt *(3a)* is obtained in 97 % yield by direct reaction of the amine without solvent at 15 °C [m.p. 72—75 °C; ^{1}H-NMR (in CD_3NO_2): $\delta = 4.02$ (6H) s]. The ethyl derivative can be prepared analogously [oil; ^{1}H-NMR (in CD_3CN): $\delta = 1.52$ (3H) t, 3.82 (3H) s, 4.35 (2H) q, $J = 7$ Hz].



N,N'-Bis(*tert*-butyl)sulfur diimide *(4)* can also be monoalkylated by the same procedure:

$$t\text{BuN=S=N}t\text{Bu} \xrightarrow{[R_3O]BF_4} t\text{BuN}^{\oplus}{=}\text{S=N}t\text{Bu}\ BF_4^{\ominus}$$
$$\quad\quad R$$

(4) *(5a)*, R = CH_3
(5b), R = C_2H_5

The salts *(5a)* [m.p. 124 °C (dec.); ^{1}H-NMR (in CD_3NO_2): $\delta = 1.64$ (9H) s, 1.73 (9H) s, 3.71 (3H) s] and *(5b)* [m.p. 108 °C (dec.); ^{1}H-NMR (in CD_3NO_2): $\delta = 1.37$ (3H) t, 1.66 (9H) s, 1.73 (9H) s, 4.35 (2H) q, $J = 7$ Hz] were synthesized in 91 and 92 % yield, respectively.

As electron-deficient *N*-sulfinyl compounds[2], the immonium tetrafluoroborates *(3)* are very suitable for cycloaddition reactions. For example, *(3a)* reacts cleanly with 2,3-dimethylbutadiene in acetonitrile to form the adduct *(6)* [m.p. 86—88 °C; ^{1}H-NMR (in CD_3NO_2): $\delta = 1.83$ (6H) s (br) ($CH_3C{=}$), 3.16 and 3.27 (6H) s (CH_3N), 3.60—4.60 (4H) m (CH_2S and CH_2N)].

(6) *(7)*

Hydrolysis of *(6)* leads to the (1-buten-4-yl)ammonium salt *(7)*, m.p. 90—92 °C.

General procedure

N-Sulfinylalkylamine (13 mmol) is added to trialkyloxonium tetrafluoroborate (10 mmol) at 15 °C and the mixture is allowed to react at this temperature for 10 h. The crude product is washed [*(3a)*] or extracted [*(3b)*] with a large amount of dichloromethane and dried *in vacuo*.

The preparation of *(5a)* and *(5b)* can be performed in analogous manner except that dichloromethane is used as solvent. The crude product can be recrystallized from dichloromethane/ether.

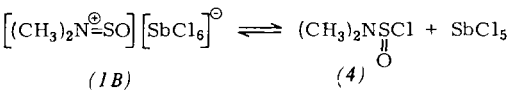
A New Synthetic Entry to Mono-, Bis-, and Tris-(amino)sulfonium Salts

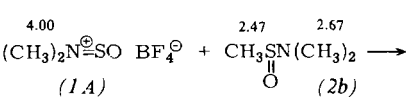
By *Günter Kresze* and *Michael Rössert*[*]



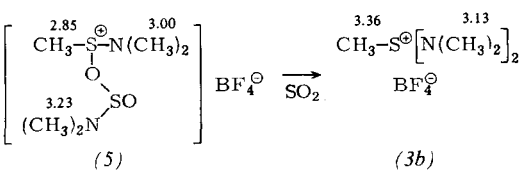
Reactive *N*-sulfinylamine derivatives are transformed into sulfimides on reaction with sulfoxides. *N*-Sulfinyldimethylimmonium tetrafluoroborate *(1A)* synthesized by us on a previous occasion[1] gives monoaminosulfonium tetrafluoroborates such as *(3a)*; it can react analogously with *N,N*-dimethylmethanesulfinamide *(2b)* to give the bis(amino)sulfonium salt *(3b)* or with *N,N'*-sulfinylbis(dimethylamine) to form the tris(amino)sulfonium salt *(3c)*.

(2) *(1A)* *(3)*

(a): $R^1 = R^2 = CH_3$
(b): $R^1 = CH_3$, $R^2 = N(CH_3)_2$
(c): $R^1 = R^2 = N(CH_3)_2$



The hexachloroantimonate *(3d)* corresponding to *(3c)* can be prepared analogously; however, in the case of the $SbCl_6$ salt *(1B)* corresponding to *(1A)* it would appear that retrocleavage can have an interfering effect. Whereas *(1A)* fails to react with diphenyl sulfoxide, fast reaction to form dimethylaminosulfinyl chloride *(4)* and an addition compound of diphenyl sulfoxide and antimony pentachloride is observed with *(1B)*.



(1B) *(4)*

The adduct assumed to occur as intermediate in the reactions of *(1A)*, for instance *(5)*, appears to be relatively stable: the ^{1}H-NMR spectra of a solution of *(1A)* and *(2b)* in CD_3NO_2 show a distinct shift of the signals of the reactants immediately upon mixing, while the signals of the product *(3b)* appear only slowly (cf. δ values in reaction scheme).

Reaction to form *(3b)* is complete within 1 h at room temperature.

(1A) *(2b)*

(5) *(3b)*

The hexachloroantimonates corresponding to tetrafluoroborates *(3)* have already been prepared by another method[2]. The alternative method which we now propose provides a facile entry to the aminosulfonium salts which are resistant to ethanol [*(3a)*, *(3b)*] and to water [*(3b)*].

[*] Prof. Dr. G. Kresze, Dipl.-Chem. M. Rössert
Organisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

Procedure

An equivalent amount of the sulfinyl compound *(2)* is added to a 2 M solution of *(1A)* or *(1B)* in acetonitrile at −25 °C; the mixture is allowed to warm over a period of 1 h and then stirred for 2 h at room temperature. The solvent is drawn off in a water-pump vacuum and the residue dissolved in CH_2Cl_2. Insoluble material is filtered off and product *(3)* precipitated with ether.

In the case of *(3a)* the precipitate is washed with warm ethanol, yield 46 %, m.p. 150—155 °C; ^{1}H-NMR (in CD_3NO_2): $\delta = 2.98$ (6H) s, 3.08 (6H) s.—*(3b)* is recrystallized from ethanol, yield 67 %, dec. 185—190 °C after yellow coloration above 160 °C; ^{1}H-NMR (in CD_3NO_2); $\delta = 3.13$ (12H) s, 3.36 (3H) s.—*(3d)* is recrystallized from acetonitrile/ether, yield 20 %, dec. 160 °C after yellow coloration above 120 °C; ^{1}H-NMR (in CD_3CN): $\delta = 2.89$ (18H) s.

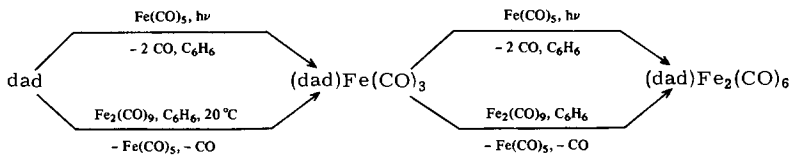
New Compounds from 1,4-Diaza-1,3-dienes and Iron Carbonyls: Hexacarbonyl(1,4-diazadiene)diiron and Substituted 2(3*H*)-Imidazolones[**]

By *Hans-Werner Frühauf, Armin Landers, Richard Goddard,* and *Carl Krüger*[*]



In the presence of 1,4-diaza-1,3-dienes *(1)*, "dad", the tricarbonyliron complexes *(2)*, (dad)$Fe(CO)_3$, are formed photochemically from $Fe(CO)_5$ and thermally from $Fe_2(CO)_9$[1, 2]. Adopting this approach, we attempted to prepare a series of partly known complexes *(2)* in order to obtain the corresponding (dad)(diene)Fe(CO) complexes[3] by photochemical reaction with dienes[4]. In most cases, however, we did not only isolate *(2)* but in addition the novel dinuclear complexes *(3)*, (dad)$Fe_2(CO)_6$, formed in a secondary reaction.

For instance, photolysis of $Fe(CO)_5$ with *(1b)* (molar ratio 2:1) in *n*-hexane gives the diiron complex *(3b)* in over 90 % yield after a single recrystallization from *n*-hexane.

As a result of unsymmetrical coordination to the $Fe_2(CO)_6$ unit, the signals of the symmetrical dad ligands appear double in the ^{1}H-NMR spectra of complexes *(3)*: *e.g. (3a)* in C_6D_6: 1 H (d) at $\delta = 6.87$ and 2.87 with $J = 1.9$ Hz and 9 H (s) at

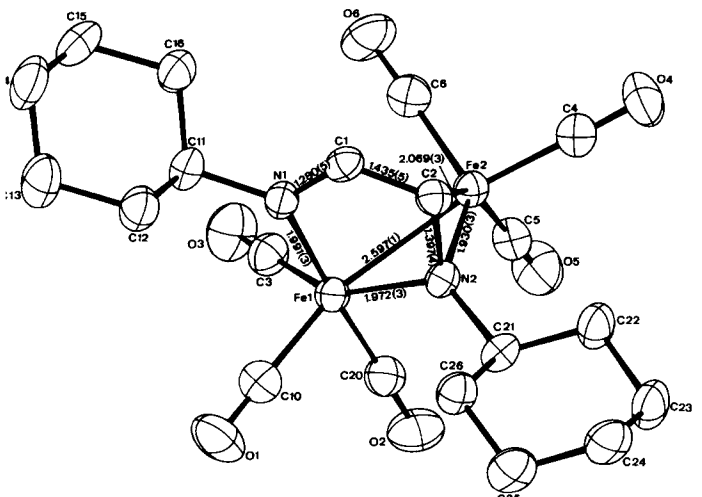
$\delta = 1.25$ and 0.82. The IR spectra show five or six CO stretching bands between *ca.* 2060 and 1940 cm^{-1} (Table 1) with an intensity distribution resembling that for other unsymmetrical $Fe_2(CO)_6$ complexes[5].

Table 1. IR data of some compounds *(3)* and *(4)*, ν_{CO} [cm^{-1}].

dad *(1)*		R^1/R^2	*(3)* [a]	*(4)* [b]
	*(a)*	H /*t*-C_4H_9	2057, 2007, 1984, 1970, 1946	1664
	(b)	H /C_6H_{11}	2059, 2007, 1987, 1973, 1948 (sh), 1945	—
	(c)	CH_3/C_6H_4-*p*-OCH_3	2062, 2007, 1195, 1979, 1945, 1941	1675, 1640

[a] In *n*-hexane. [b] ν_{CO} and $\nu_{C=C}$ in KBr; *(4a)* in *n*-hexane: 1689, 1687 (sh) cm^{-1}.

The structure of *(3b)* could be elucidated by X-ray structure analysis [cell data: $a = 14.724(3)$, $b = 10.576(2)$, $c = 15.686(5)$ Å, $\beta = 112.63(2)°$, space group $P2_1/c$, $Z = 4$; 4874 reflections of which 1913 were considered unobserved (2σ); $R = 0.036$ ($R_w = 0.040$)]. While nitrogen atom N1 of the dad ligand occupies an axial position at Fe1 by means of its lone pair and is doubly bonded to C1 with a remarkably short bond length, N2 forms an unsymmetrical bridge between the Fe—Fe system displaying a characteristic metal-metal internuclear distance (Fig. 1). The N2C2 group is therefore to be regarded as a three-electron donor to Fe2 and a one-electron donor to Fe1. This situation is not reflected in different N—C bond lengths to the cyclohexyl groups (1.492(4) and 1.488(4) Å). The coplanarity of the conjugated system N1—C1—C2—N2 (±0.05 Å) is only negligibly perturbed by the unsymmetrical complexation (dihedral angle N1—C1—C2—N2 = 12.2°).



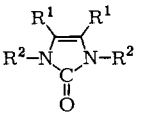


Fig. 1. Molecular structure of hexacarbonyl(1,4-dicyclohexyl-1,4-diazabutadiene)diiron *(3b)* and numbering of the atoms.

The formation of *(2)* competes with transformation of some dad ligands of the open-chain 1,4-diazabutadiene type into *N,N'*-disubstituted 2(3*H*)-imidazolones *(4)* by CO insertion; compounds *(4)* can easily be separated from the mixture of *(2)* and *(3)* by chromatography. Imines of 2-acylpyridines do not undergo this competing reaction.

(4a), R^1 = H, R^2 = *t*-C_4H_9
(4c), R^1 = CH_3, R^2 = C_6H_4-*p*-OCH_3

Compound *(4a)* is formed particularly readily during the preparation of *(2a)*, and like the latter it sublimes well *in vacuo*. In *n*-hexane its CO stretching vibration appears at 1689 cm^{-1}. In the case of *(2a)*, we were unable to observe this IR band [2] or signal doubling in the ^{1}H-NMR spectrum of the coordinated ligand, from which an unsymmetrical n,π coordination was previously inferred.

Procedure

(1c) (1.0 g, 3.37 mmol) and $Fe(CO)_5$ (0.91 ml, 1.33 g, 6.76 mmol) in degassed benzene (100 ml) are irradiated under argon in an immersion well apparatus (glass or quartz) with a Hg high-pressure lamp for 30 h. Alternatively, *(1c)* (1.0 g) and $Fe_2(CO)_9$ (2.44 g, 6.7 mmol) in benzene (100 ml) can be stirred at room temperature for 48 h. The filtered reaction solution is evaporated down (about 1.6 g of residue) and chromatographed under argon on de-aerated silica gel. A mixture of *(2c)* and *(3c)* is eluted with benzene, and then *ca.* 450 mg of *(4c)* (m.p. from ethyl acetate 168—169 °C) with ethyl acetate. The fraction containing *(2c)* and *(3c)* can either be transformed into pure *(2c)* in an autoclave at 50 °C under 50 bar of CO (700—750 mg from *n*-hexane) or evaporated down in order to wash out the *(2c)*, which is highly soluble in *n*-hexane. Yield of *(3c)* *ca.* 600 mg.

In the corresponding reaction of *(1a)* the mixture of *(2a)* and *(3a)* obtained by chromatography can be separated by sublimation of *(2a)*. *(4a)* is recrystallized from *n*-hexane, m.p. 113 °C (in sealed tube)[6].

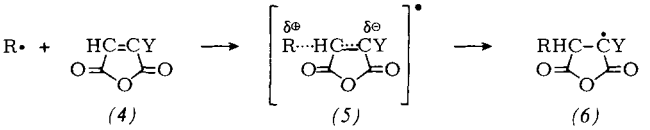
Reactivity of Alkenes in Free-Radical Additions[**]

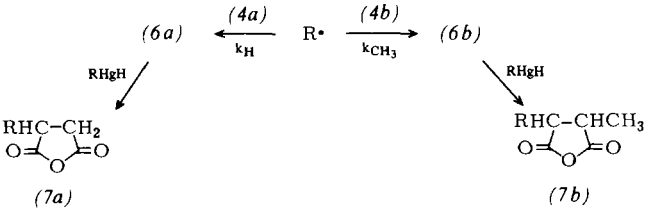
By *Bernd Giese* and *Wolfgang Zwick*[*]



The preferred attack of radicals at the lower alkylated carbon atoms of alkenes is usually explained in terms of a stabilizing influence of alkyl groups on radicals[1]. If the stability of the radicals increases with increasing degree of alkylation on the radical carbon atom and this effect becomes significant in the transition state, then the reactivity of the alkene in radical additions ought to increase with its degree of alkylation. Indeed, propene is more rapidly attacked than ethylene by electron deficient radicals such as $Cl^{\bullet}$[2a], $Br^{\bullet}$[2b], $HO^{\bullet}$[2c], $F_2N^{\bullet}$[2d] or $(CF_3)_2FC^{\bullet}$[2e]. The gradation of reactivity of the olefins *(1)*, however, is no unequivocal proof of the greater stability of the secondary radical *(3b)* compared to the primary radical *(3a)*, because the difference in rate of addition of electron deficient, electrophilic radicals X• can also be due to the polar effect[1,4] of the methyl substituents (Y = CH_3) in the transition state *(2)*.

(1) *(2)* *(3)*

(a): Y = H
(b): Y = CH_3



In order to differentiate between the polar effect and radical stabilization, the relative reactivities of maleic anhydride *(4a)* and methylmaleic anhydride *(4b)* towards electron rich, nucleophilic[5] alkyl radicals R• was determined. In these additions the electron-donating methyl group (Y = CH_3) exerts a counteracting influence on the polar effect in the transition state *(5)* on the one hand, and on the stability of the adduct radical *(6)* on the other.

(4) *(5)* *(6)*

(a): Y = H
(b): Y = CH_3

For measurement of the relative reactivities the organomercury salts RHgX were allowed to react with $NaBH_4$ in chloroform in the presence of at least a 20-fold excess of the olefin mixture *(4a)*/*(4b)*. Under these conditions alkyl radicals are formed which add in high yields to the olefins *(4a)* and *(4b)*[6]. The H-capturing products *(7a)* and *(7b)* are formed quantitatively from the adduct radicals *(6a)* and *(6b)*[6],

(7a) *(7b)*

$$\frac{k_H}{k_{CH_3}} = \frac{[(7a)]\,[(4b)]}{[(7b)]\,[(4a)]} \qquad (I)$$

so that the ratio of the rate constants k_H/k_{CH_3} for the individual radicals can be determined according to Eq. (I)[5].

The difference in the activation parameters for the reactions with olefins *(4a)* and *(4b)* were determined from measurements carried out between 246 and 298 K. These data, together with the competition constants k_H/k_{CH_3} at 263 K, are listed in Table 1.

Table 1. Competition constants at 263 K (mean error ±10%), differences in activation enthalpies [kJ mol^{-1}] (mean error ±2 kJ mol^{-1}) and differences in activation entropies [JK^{-1} mol^{-1}] (mean error ±6 JK^{-1} mol^{-1}) for the competing addition of alkyl radicals R• to maleic anhydride *(4a)* and methylmaleic anhydride *(4b)* in $CHCl_3$.

Radical R•	k_H/k_{CH_3}	$\Delta H^{\ddagger}_{CH_3} - \Delta H^{\ddagger}_{H}$	$\Delta S^{\ddagger}_{CH_3} - \Delta S^{\ddagger}_{H}$
$(CH_3)_3C^{\bullet}$	13.6	0.0	−21
$c\text{-}C_6H_{11}^{\bullet}$	9.8	1.2	−15
$n\text{-}C_5H_{11}CH_2^{\bullet}$	6.5 [a]		

[a] The mean error here is ±20%. Because of this large error and simultaneously small competition constants, determination of the activation parameters was dispensed with.

The competition constants k_H/k_{CH_3} (Table 1) show that maleic anhydride reacts distinctly more rapidly with alkyl radicals than the higher alkylated methylmaleic anhydride[7]. Formation of the secondary radical *(6a)* is thus energetically more favorable than that of the tertiary radical *(6b)*. Hence, the radical stabilization effect of a methyl group on the rate of radical addition is so slight that the polar effects, and in the case of bulky groups also the steric effects, of the alkyl substituents predominate.

The gradation of reactivity in the case of electrophilic radicals[2] and the increase in selectivity on going from primary *n*-hexyl through the secondary cyclohexyl to the *tert*-butyl radical shows (Table 1) that the reactivity of differently alkylated alkenes largely depends upon the nucleophilicity of the radicals. Whereas electron deficient radicals react more rapidly with higher alkylated alkenes[2] electron rich alkyl radicals react more rapidly with lower alkylated alkenes (Table 1). It is therefore also understandable that the only slightly nucleophilic methyl radical adds to ethylene, propene and 2-methylpropene almost equally rapidly[8].

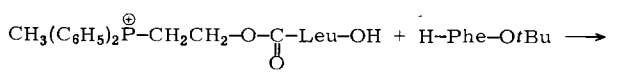
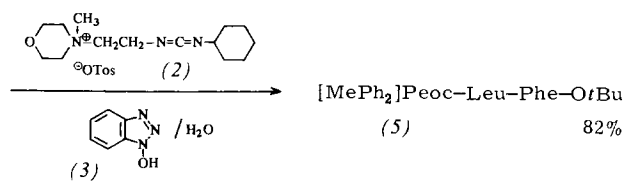
Syntheses with 2-Phosphonioethoxycarbonyl Protecting Groups: Peptide Synthesis in Water[**]

By *Horst Kunz*[*]



Peptide synthesis in aqueous solution has long been a principal aim of peptide chemistry[1]. Using water-soluble carbodiimides containing quaternary ammonium groups, *Sheehan et al.* succeeded in linking *N*-phthaloylglycine and glycine ethyl ester to form the dipeptide[2a] and in coupling a linear tripeptide to give the cyclohexapeptide[2b] in aqueous medium. Generalization of this synthetic pathway has hitherto been precluded by the insufficient solubility of the components undergoing coupling, especially the *N*-protected amino acids and peptides. Conventional protecting groups for the amino function, such as the Z and Boc groups, have hydrophobic character. *Pfaender et al.* recently reported the stepwise heterogeneous reaction of amino acid *N*-carboxylic anhydrides (NCA) with amino acids and peptides bound to polyethyleneimine in weakly alkaline aqueous phase[3]. This process, requiring no amino-protecting group, has no relevance to fragment condensation; moreover, the ready decomposition of NCAs in water would probably also interfere with reactions in homogeneous phase.

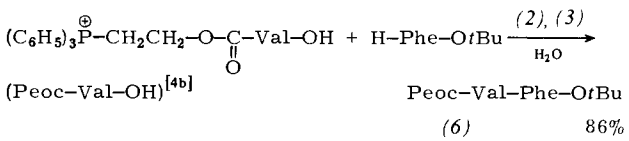
Peptide synthesis in homogeneous aqueous solution requires protecting groups which promote the water-solubility of the protected amino acids and peptides. 2-Phosphonioethoxycarbonyl (Peoc) groups[4] *(1)* have this property.



(1), R^1,R^2,R^3 = Alkyl, Aryl

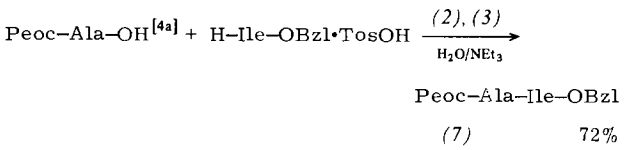
The Peoc protecting groups can be removed from the protected amino functions under mildly basic conditions. This base lability is due to the CH acidity of the methylene group located in α-position to the phosphorus. Furthermore, in order to avoid even a weakly alkaline milieu for condensation, a modified Geiger-König technique[5] was employed in the experiments on peptide synthesis in aqueous solution: using the water soluble carbodiimide *(2)* in the presence of 1-hydroxybenzotriazole *(3)*, 2-(methyldiphenylphosphonio)ethoxycar-

(4) (= [$MePh_2$]Peoc-Leu-OH)



(2) *(3)*

[$MePh_2$]Peoc-Leu-Phe-O*t*Bu *(5)* 82%

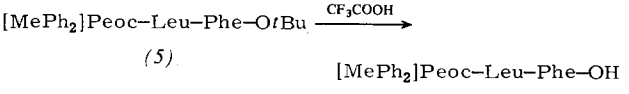


bonylleucine[4b] *(4)* can be linked with phenylalanine *tert*-butyl ester to give the Peoc-dipeptide ester *(5)* in good yield.

The low pH value of the reaction solution (*ca.* 4.5 initially and *ca.* 3.5 at conclusion of reaction) should also permit use of the more sensitive triphenylphosphonioethoxycarbonyl group. The synthesis of the two Peoc dipeptide esters *(6)* and *(7)* confirms this assumption.

(Peoc-Val-OH)[4b]

Peoc-Val-Phe-O*t*Bu *(6)* 86%



Peoc-Ala-Ile-OBzl *(7)* 72%

As demonstrated by compound *(7)*, the amino acid hydrosalts and triethylamine can be used instead of the free amino esters.

The Peoc-dipeptide esters *(5)*, *(6)*, and *(7)* precipitate as oils from the aqueous solutions. They were extracted with dichloromethane and transformed into the iodides by treatment with NaI in acetone prior to structural elucidation and calculation of yields because the Peoc-amino acids were used as bromides or chlorides and the carbodiimide *(2)* as *p*-toluenesulfonate.

In addition to the ester and urethane carbonyl bands (1715—1730 cm^{-1}) the IR spectra also contain the amide I band of the newly formed peptide bond at 1650—1670 cm^{-1}; the amide II band is observed at 1500—1550 cm^{-1} and a sharp band characteristic for phosphonium salts with aromatic ligands attached to phosphorus at 1435 cm^{-1}. In the ^{1}H-NMR spectra (in $CDCl_3$ rel. to TMS) the phenyl protons of the Peoc protecting group absorb at $\delta = 7.8$, and thus at significantly lower field than the aromatic protons of the phenylalanine in *(5)* and *(6)* ($\delta = 7.2$) and the benzyl ester in *(7)* ($\delta = 7.3$). Furthermore, the IR and ^{1}H-NMR spectra of *(5)* are identical in all essential details with those of the compound already prepared in dichloromethane[4b].

After transformation into its iodide, [$MePh_2$]Peoc-Leu-Phe-O*t*Bu prepared in CH_2Cl_2 by the Wünsch-Weygand procedure[6] exhibits a rotation of $[\alpha]_D^{22} = -16.5°$ ($c = 2$, methanol). Using the same starting materials, synthesis in water led to product *(5)* having $[\alpha]_D^{22} = -16.9°$ ($c = 2$, methanol). The coupling process in aqueous solution accordingly appears to be just as effective as proven techniques in organic phase. The pronounced acid-stability of the Peoc protecting groups[4a] permits simple deprotection of the Peoc-dipeptide esters. Thus the Peoc-dipeptide *(8)* could be obtained quantitatively from *(5)* by treatment with trifluoroacetic acid at room temperature for 2 h.

(5)

[$MePh_2$]Peoc-Leu-Phe-OH *(8)*

This *N*-protected peptide of two hydrophobic amino acids is adequately soluble in water containing 5% of methanol for further reactions, *e.g.*

$$(8) + \text{H–Phe–O}t\text{Bu} \xrightarrow[H_2O]{(2),\,(3)} [\text{MePh}_2]\text{Peoc–Leu–Phe–Phe–O}t\text{Bu}$$

(9) 92%

In keeping with its phosphonium salt character, the Peoc-tripeptide ester *(9)* can be recrystallized like *(5)*, *(6)*, and *(7)* from dichloromethane/ether.

Procedure

To a stirred sample of the amino ester (2.5 mmol, or equivalent amounts of its toluenesulfonate and triethylamine) in water (10 ml) are added 1-hydroxybenzotriazole (0.34 g, 2.5 mmol) and, at 0°C, *N*-cyclohexyl-*N'*-β-(*N*-methylmorpholino)ethylcarbodiimide *p*-toluenesulfonate (1.2 g, 2.8 mmol; *ex* Merck) and Peoc-amino acid (2.5 mmol)[4]. After addition of water (10 ml) and cessation of cooling the suspension gradually clears and the Peoc-dipeptide ester precipitates as oil which is extracted after 48 h with CH_2Cl_2. The solution is washed with 1 N hydrochloric acid and water and dried over sodium sulfate. The foamy amorphous Peoc-dipeptide ester remaining on evaporation of the solvent is shown by its IR and ^{1}H-NMR spectra to contain tosylate ions. It is stirred with a solution of NaI in acetone, the precipitated sodium salts are filtered off, the filtrate is evaporated to dryness and digested with CH_2Cl_2. After renewed filtration the Peoc-dipeptide ester is obtained as the amorphous iodide by evaporation (traces of *(3)* cannot be removed by recrystallization from chloroform/ether or acetone/ethyl acetate/ether).

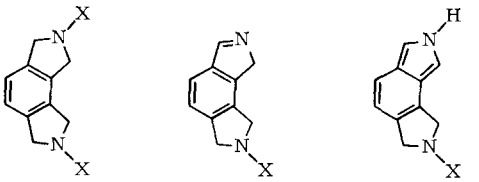
Tricyclic Isoindoles[1]

By *Richard Kreher* and *Karl Josef Herd*[*]

The synthesis of the tricyclic hetarenes *(1)* was attempted in order to study the influence of annelation on the thermal stability and chemical reactivity of 1*H*- and 2*H*-isoindoles[3].

(1a) *(1b)* *(1c)*



[*] Prof. Dr. R. Kreher, Dipl.-Ing. K. J. Herd
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

We intended to establish, in the case of angular annelation, which of the tautomeric forms *(1a)*, *(1b)*, and *(1c)* with benzenoid or quinonoid structure is thermally more stable[4].

The synthetic goal was preparation of the benzenoid hetarene *(1a)* having two CN double bonds. With this aim 1,2,3,4-tetrakis(bromomethyl)benzene[5] was allowed to react with methanesulfonamide. The twofold cyclization was achieved in a one-step homogeneous reaction under basic conditions[2] (acetone/ethanol/water; 5 h/reflux), affording the desired product in 30% yield.

Introduction of the CN double bond[6] is accomplished by reaction of the tricyclic intermediate *(2)*, $X = SO_2CH_3$, m.p. >260°C, with potassium *tert*-butoxide in anhydrous dimethyl sulfoxide (2.5 h/65°C). 1,2-Elimination of methanesulfinic acid should then lead directly to the 1*H*-isoindole *(3a)*, which appears to rearrange into the tautomeric 2*H*-isoindole *(3c)* under basic reaction conditions. The NH group is established by an intense IR absorption band ($\nu = 3395\ cm^{-1}$) and by a broad ^{1}H-NMR signal ($\tau = -0.5$ to -2.5), which disappears by H/D exchange on addition of deuterium oxide. It follows from the NMR spectrum, as well as from the mass spectrum, that only one methylsulfonyl group is eliminated.

According to spectroscopic data the angular annelation of a heterocyclic five-membered ring does not lead to any change in stability[3]. The *o*-quinonoid structure *(3c)* is confirmed by chemical reaction with dienophiles (*N*-phenylmaleimide, dimethylacetylenedicarboxylate, and dimethyl azodicarboxylate)[7].

(2) *(3a)* *(3c)*

Table 1. 2-Methylsulfonyl-7*H*-1,3-dihydropyrrolo[3,4-*e*]isoindole *(3c)*.

$C_{10}H_9N_2X$, $X = SO_2CH_3$, yield 45—52%, m.p. 145—146°C (dec.) (ethyl acetate/*n*-heptane); ^{1}H-NMR (D_6-acetone + D_2O): $\tau = 2.46$ (dd, $J_{45} = 9$ Hz, $J_{56} = 0.5$ Hz, 1 H, CH-5), 2.64 (d, $J_{68} = 1.5$ Hz, 1 H, CH-8), 2.79 (mc, 1 H, CH-6), 3.24 (d, $J_{45} = 9$ Hz, 1 H, CH-4), 5.28 (s, broad, 2 H, CH_2), 5.33 (s, broad, 2 H, CH_2), 7.07 (s, 3 H, SO_2CH_3); UV (CH_2Cl_2, −20°C): λ_{max} ($\log\varepsilon$) = 265 (3.11), 281 (3.08), 291 (3.21), 313 (sh, 3.63), 325 (3.72), 337 (sh, 3.60) nm; MS (70 eV/160°C): *m/e* = 236 (16%, M^+), 157 (28%, $M^+ - SO_2CH_3$), 156 (100%, $M^+ - HO_2SCH_3$).

Table 2. 7*H*-Pyrrolo[3,4-*e*]isoindole *(1c)*.

$C_{10}H_8N_2$, yield 34%, m.p. >120°C (dec.), sublimation at 112—117°C/0.01 torr; ^{1}H-NMR (D_6-acetone + D_2O): $\tau = 2.80$ (d, $J_{13} = 2$ Hz, 2 H, CH-1 and CH-8), 2.95 (d, $J_{13} = 2$ Hz, 2 H, CH-3 and CH-6), 3.07 (s, 2 H, CH-4 and CH-5); ^{13}C-NMR (D_6-DMSO): $\delta = 120.0$ (int. 79, q), 115.7 (54, q), 115.1 (204), 110.6 (144), 107.2 (168); UV (CH_2Cl_2): λ_{max} ($\log\varepsilon$) = 257 (4.17), 261 (4.18), 273 (4.10), 290 (4.07), 300 (4.03), 327 (sh, 2.67) nm; MS (70 eV/110°C): *m/e* = 156 (100%, M^+), 152 (3%, $M^+ - 2H_2$).

The introduction of two CN double bonds in the same manner is possible in a one-step procedure under drastic conditions (3 h/110°C) starting from *(2)*. The twofold elimination of methanesulfinic acid can proceed in different directions leading to tautomeric 1*H*-isoindole *(1a)* or 2*H*-isoindole *(1b)* with the CN double bond in the 2,3- and/or 6,7-position, respectively. This phenomenon does not need further investigation, since the 1,2-elimination is accompanied by a spon-

taneous tautomeric rearrangement to the 7*H*-pyrrolo[3,4-*e*]-isoindole *(1c)*. The symmetrical molecular structure follows, mainly from the ^{1}H-NMR spectrum, which provides no evidence for tautomeric forms having a cyclic methylene group. The intense band at 3380 cm^{-1} in the IR spectrum is typical for the NH group, which gives rise to a broad signal ($\tau = -0.5$ to -1.5) in the ^{1}H-NMR spectrum. On addition of deuterium oxide in acetone or dimethyl sulfoxide a regiospecific H/D exchange takes place at the heteroatom.

The synthesis of the tricyclic hetarene *(1c)* provides evidence for the thermal stabilization of the 2*H*-isoindole by annelation of a pyrroloid ring system[8]. The chemical reactivity resembles that of 2*H*-isoindole, as exemplified by the sensitivity towards oxygen and the formation of a 1:2 adduct with *N*-phenylmaleimide. The structurally isomeric tricyclic hetarene with linear annelation might also be accessible by the same synthetic principle.

Molecular Structure of F_5SOSF_5, $F_5SeOSeF_5$, and $F_5TeOTeF_5$: d-Orbital Participation in Bonds between Main Group Elements[**]

By *Heinz Oberhammer* and *Konrad Seppelt*[*]

Do the bonding molecular orbitals in compounds of main group elements contain significant contributions from d atomic orbitals? Such d-orbital participation should be especially favored in SF_6, SeF_6, and TeF_6, owing to the number and the electronegativity of the fluorine atoms[1]. Recent SCF calculations (Xα-SW method) suggest a modest bonding contribution from chalcogen d orbitals[2], mainly as (pd)σ-bond ($2e_g$ orbital in SF_6) and more weakly as (pd)π bond ($1t_{2g}$ orbital). The older concept of "back donation" adequately describes the situation since the use of sulfur d orbitals does lead to a calculable drop in polarity of the bond.

In order to obtain experimental evidence for d-orbital participation, we have prepared the homologous chalcogen oxyfluorides F_5SOSeF_5, $F_5SeOSeF_5$, and $F_5TeOTeF_5$ by modified existing methods or by new ones, subjected them to rigorous purification, and investigated their structure by electron diffraction.

$$2SF_4 + OF_2 \xrightarrow{h\nu,\ -78\,^\circ C} F_5S{-}O{-}SF_5;\ \text{yield of pure cpd } 20\%$$

$$Xe(OSeF_5)_2 \xrightarrow{130\,^\circ C} F_5Se{-}O{-}SeF_5{}^{[3]};\ \text{yield of pure cpd } 18\%$$

$$TeO_2 + F_2/N_2 \longrightarrow F_5Te{-}O{-}TeF_5{}^{[4]};\ \text{yield of pure cpd } 12\%$$

All three compounds are exceptionally stable and have a relatively high vapor pressure at room temperature. The results

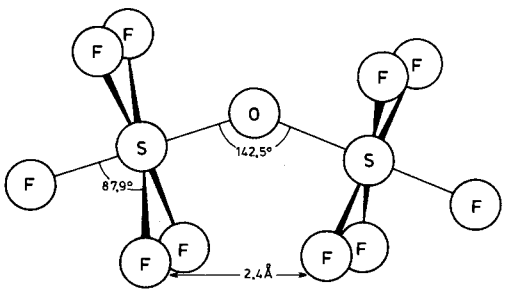

Fig. 1. Molecular structure of F_5SOSF_5.

Table 1. Bond lengths [Å] and bond angles [°] in the compounds $F_5X{-}O{-}XF_5$ [a].

[a] m, average; e, equatorial; a, axial.

The molecular structures show two unexpected features: a) the bond angle of the oxygen bridge is remarkably constant and large (142.5, 142.4, 145.5°). Purely steric considerations would suggest the angle to be largest in the sulfur compound because of the hindrance of four equatorial fluorine atoms. And in the tellurium compound, where the angle could be the smallest, it even increases slightly.—b) The two mutually hindering pairs of fluorine atoms are in an eclipsed arrangement although just a slight twisting of the XF_5 groups would considerably reduce the strain. (Due to the significance of this argument all three molecules were closely scrutinized for possible dihedral angles.) The deviation of the fluorine atoms by 2.1° from perfect octahedral geometry in the case of the sulfur

compound (by only 1.1° in $F_5SeOSeF_5$, and by 0.2° in $F_5TeOTeF_5$) points to the steric strain arising from this conformation.

The large and nearly constant bond angle and the eclipsed geometry suggest π-double bond contributions between the oxygen and the higher chalcogens. The X—O bonds are shorter than known single bond lengths and in the case of $F_5TeOTeF_5$ are equal to the formal double bond in gaseous TeO_2 (1.83 Å)[5]. This double bond is best characterized as an additional (pd)π bond to which d orbitals of d_{xy} type, *etc.*, contribute for reasons of symmetry—as described for SF_6 by the $1t_{2g}$ orbital. It may also be assumed that a (pd)π component of this kind is present in the chalcogen-fluorine bond of F_5XOXF_5 and XF_6 but is not experimentally detectable.

As indicated by the slightly increased bond angle and most drastically shortened bond, the (pd)π bonding contribution seems to be greatest in the tellurium compound.

The explanation using some (pd)π bonding can only be avoided by suggesting partial chalcogen-oxygen double bonds at the expense of chalcogen-fluorine bonds, in the manner of a hyperconjugation:

However, since the chalcogen-fluorine bonds are the same as those of the corresponding hexafluorides (cf. Table 1), this alternative can be ruled out. Ionic bonding contributions of the $^{\ominus}O—S^{\oplus}$ type (Schomaker-Stevenson relation) also fail to provide a satisfactory explanation because the difference in electronegativity is small.

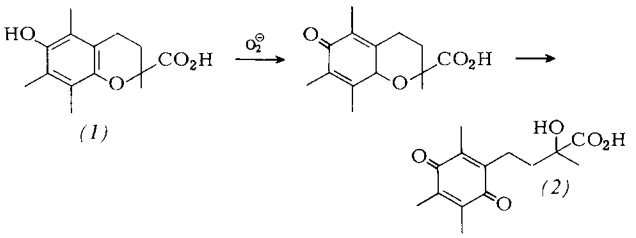
A mechanism for the transport and reduction of nitrate is proposed by *R. G. Butz* and *W. A. Jackson*. A tetrahedral aggregate of four nitrate reductase molecules is anchored in the membrane in such a way that one monomer faces outwards and the other three face inwards towards the cytoplasm. As a result, the transport and reduction of a nitrate ion is accompanied by the transport of two additional nitrate ions. The nitrate reductase is closely coupled to an ATPase which can be activated by nitrate; ADP can thus inhibit nitrate reduction by occupying the adenylate binding site of the ATPase. An analogous system, consisting of nitrate reductase dimers with associated ATPase, is proposed for nitrate transport and reduction in some algae and chloroplasts. [A Mechanism for Nitrate Transport and Reduction. Phytochemistry *16*, 409—417 (1977); 119 references]

[Rd 978 IE]

The hormone-dependent lipase of adipose tissue is the subject of an article by *D. Steinberg* and *J. C. Khoo*. Recent studies have shown that this enzyme is functionally and immunochemically different from the lipoprotein lipase which is responsible for the uptake of plasma triglycerides. Furthermore, the latter enzyme is not influenced by the cyclic AMP dependent protein kinase, which does however activate the hydrolases of adipose tissue which degrade tri-, di-, and monoglycerides as well as cholesterol esters. This activation is reversible; it is abolished by a protein phosphatase from heart and liver. [Hormone-Sensitive Lipase of Adipose Tissue. Federation Proc. *36*, 1986—1990 (1977); 44 references]

[Rd 979 IE]



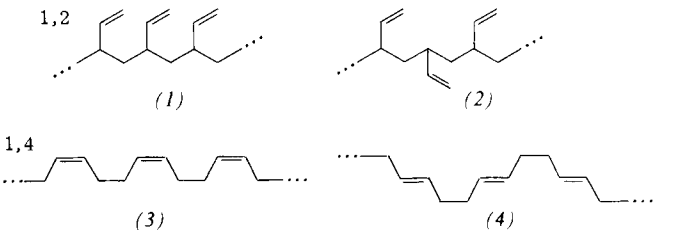
Uses of the trifluoromethanesulfonyl group in organic synthesis are outlined in an article by *J. B. Hendrickson, D. D. Sternbach*, and *K. K. Bair*. CF_3SO_2 ("trifyl") is reported to be one of the strongest electron-withdrawing groups known. All the properties (except nucleophilicity) which make the methanesulfonyl group especially valuable in synthetic organic chemistry are enhanced in CF_3SO_2. The primary electrophilic reagent is the anhydride, obtained from the acid by dehydration with P_2O_5. The most important nucleophilic form is the anion $CF_3SO_2^-$, obtained by reduction of the acid chloride with iodide. Both reagents are stable. In general, the CF_3SO_2 group is employed in the sense of a protecting group. It is inert to a wide variety of reaction conditions, but can be readily removed in various ways. [Trifyl Activation in Organic Synthesis. Acc. Chem. Res. *10*, 306—312 (1977); 44 references]

[Rd 989 IE]

Sulfilimines (sulfimides) are compounds of trivalent sulfur possessing a polar sulfur-nitrogen bond. Compared with the analogous sulfoxides they have been rather neglected, although they should be of similar chemical utility. A survey of the formation, stereochemistry, and reactions of sulfoxides and sulfilimines has been written by *S. Oae*. [Sulfoxides and Sulfilimines in *S. Oae*: Organic Chemistry of Sulfur. Plenum Press, New York 1977, pp. 383—471; 486 references]

[Rd 968 IE]

The organic chemistry of the hyperoxide ion (O_2^-) forms the theme of a progress report by *E. Lee-Ruff*. The hyperoxide ion is present in all aerobic organisms; its participation in biological oxidations has been investigated with the aid of simple model organic compounds. Thus, *e.g.*, the hydroxychroman *(1)* (vitamin E model) is transformed by O_2^- into the quinone *(2)*, which functions as a free radical scavenger;

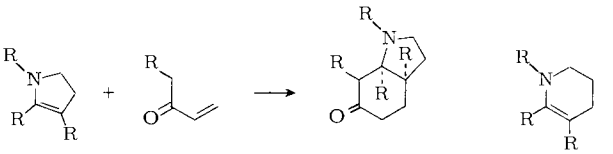


(1) *(2)*

similarly, vitamin E acts as an antioxidant for lipids. The reducing action of O_2^- was observed in its reaction with *o*- and *p*-benzoquinone, which are converted into the radical anions, while conversely the radical anion of 2,3-dimethylnaphthoquinone reduces O_2 to O_2^-. [The Organic Chemistry of Superoxides. Chem. Soc. Rev. *6*, 195—214 (1977); 145 references]

[Rd 986 IE]

The polymerization of butadiene is reviewed in an article by *D. H. Richards*. In principle the reaction can lead to four "homopolymers", all of which have been synthesized [*(1)* isotactic, *(2)* syndiotactic, *(3) cis*, and *(4) trans*]. Polybutadienes having a mixed structure (atactic) can be regarded as "copolymers". The structures have been investigated spectroscopically. The composition of the polymers largely depends upon the catalyst and the reaction conditions. Thus, radical-initiated emulsion polymerization leads to formation of a polymer containing 16—22% *(1)*+*(2)*, 3—20% *(3)* and 60—74% *(4)*; with titanium halogenides + AlR_3 or AlR_2X



(1) *(2)* *(3)* *(4)*

up to 94% *(3)* is formed, with vanadium halogenides + AlR_3 or AlR_2X > 95% *(4)*. [The Polymerization and Copolymerization of Butadiene. Chem. Soc. Rev. *6*, 235—260 (1977); 114 references]

[Rd 987 IE]

General methods for the synthesis of alkaloids are reviewed by *R. V. Stevens*. In spite of the numerous different structures involved, it should be possible to generate a large number of the alkaloids from only two relatively simple synthons [*(1)* and *(4)*]. Reaction of *(1)* and *(4)*, respectively, with vinyl ketones such as *(2)* should afford hydrogenated indo-

(1) *(2)* *(3)* *(4)*

lones *(2)* and hydrogenated quinolones. The concept, which was put to the test using *(1)* as example, did in fact prove true and has permitted the synthesis of many alkaloids. [General Methods of Alkaloid Synthesis. Acc. Chem. Res. *10*, 193—198 (1977); 35 references]

BOOK REVIEWS

Die toxikologisch-chemische Analyse (Toxicological-Chemical Analysis). By *R. K. Müller*. Verlag Chemie GmbH, Weinheim—New York 1977. 1st edit., xvi, 604 pp., 40 figs., 29 tables, bound, DM 138.—.

The field of toxicological-chemical analysis has long suffered from the lack of a concise and systematic laboratory handbook. This gap has now been successfully filled by the editor and 20 coauthors, whose work has made concise information with reference to more detailed literature available to a wide circle of interested readers.

Besides the principles of toxicology and pathological anatomy of intoxications, the authors treat the organization aspects: preservation, packaging, registration, and protocol, which provide the beginner in particular with a good introduction into this field of work.

The chapter on "Methods of Toxicological-Chemical Analysis" deserves special attention. It gives not only the methods of isolation, extraction, and separation, but also indications that enable the applicability of the relevant methods to be assessed. All the modern methods, such as UV, visible, IR, MS, and NMR spectroscopy are discussed.

What makes this book particularly valuable in practice is the alphabetically arranged monograph section giving currently interesting compounds divided into medicinal preparations, addictive drugs, and plant-protection agents; each entry is provided with brief information on use, constitution, melting point, molecular weight, solubility, behavior in TLC and the LD_{50}.

These data are collected in the concluding tables that systematize detection of the poison and are supplemented by information about TLC systems and color reactions from chromatographic detection, and by numerical characteristics such as λ_{max}, $E^{1\%}_{1cm}$, main and subsidiary bands (IR), and the principal peak (MS) of the substances dealt with. This work ends with an extensive subject index.

Lj. Kraus [NB 394 IE]

Block Copolymers—Overview and Critical Survey. By *A. Noshay* and *J. E. McGrath*. Academic Press, Inc., New York 1977. 1st edit., xvi, 516 pp., bound, $ 45.00.

This book is a successful attempt to systematize and to review critically the literature on block copolymers, which

has grown so enormously particularly in the last decade. Even though the authors place more emphasis on academic publications than on patent literature, this appears justified by the generally more informative content of the scientific papers.

The first part of the book treats the following problems, generally in qualitative but didactically very apt manner: definition of block copolymers, syntheses, possibilities of structure elucidation, properties, and applications. Above all, it is made clear that the structures reproduced mainly require demanding syntheses and that it is difficult to correlate structure and properties without a knowledge of chemical history. In some cases one can only resort to speculation. Particular attention is of course paid to the occurrence of both elastic and thermoplastic properties in one polymer, and the interesting possible applications of block polymers are discussed (membranes, protection of surfaces, biomedical applications). It is clearly indicated that valuable progress in this area can be expected if the synthetic processes can be made economical (continuous, without a solvent) and, in particular, if the methods of characterization can be improved.

In Part 2 block copolymers are systematically classified by the structure of the compounds into AB (two-block), ABA (three-block), and $(AB)_n$ (multiblock copolymers). Here the treatment follows established practice, but in this case specially adapted to the components, dealing with problems of synthesis, methods for the elucidation of structure, morphology of the products, relations between structure and properties, and comparison of properties with those of statistical copolymers having the same molecular composition. Clear reaction schemes, comparative tables, and diagrams facilitate an approach to the problems. This book is excellently suited not only for the expert but also for the reader hoping for an introduction into the field of block copolymers, not least because the cited literature (*ca.* 2000 references) was collected from a very wide field.

Restriction Endonucleases

By Werner Arber[*]

Restriction endonucleases are enzymes commonly found in bacteria which can fragment DNA. Cleavage of the DNA molecule takes place after recognition of a nucleotide sequence which is specific for each restriction endonuclease. Some of the enzymes split the DNA within the recognition sequence. This property allows these enzymes to be used for the systematic fragmentation of DNA molecules in structural and functional analyses of genetic material. The biological function of restriction endonucleases could be to provide a sort of primitive immune system which enables the cells to destroy foreign genetic material. Methylation of nucleotides lying within the recognition sequence serves to protect the cell's own DNA from being degraded by its restriction endonucleases. Restriction endonucleases were discovered during the investigation of the restriction of viral growth observed on changing hosts.

1. Introduction

Endonucleases are enzymes which can split nucleic acid chain molecules into fragments. Depending on the enzyme under consideration, the nucleic acid is cleaved more or less randomly or at specific sites which are determined, for example, by the nucleotide sequence of the nucleic acid. In principle, the prolonged action of an enzyme of the former type results in extensive degradation of the nucleic acid to give relatively small oligonucleotides. In contrast, the endonucleases which act at specific sites on deoxyribonucleic acid (DNA) produce reproducible populations of fragments of specific lengths; the ends of each fragment are determined by the specific cleavage sites of the enzyme.

This rough classification is not sufficient for many of the endonucleases studied in the past few years. It has namely been shown that some enzymes cannot carry out their endonucleolytic functions in the native state; they require a preliminary activation in which interaction with a specific recognition sequence of the nucleic acid plays an important role. The recognition sequence generally seems to be defined by a sequence of four to perhaps twenty nucleotides in the nucleic acid. The nucleotides critical for recognition need not necessarily follow one another but may be separated by nucleotides which are not important for recognition.

The term "restriction endonucleases" groups together a large number of microbial enzymes which cleave DNA in a specific manner. The fact that the cleavage reaction depends upon the interaction of the enzyme with a specific recognition sequence is an important common feature of all restriction endonucleases so far studied. According to the enzyme under consideration, the cleavage of the nucleic acid following this activation occurs either at the recognition site itself, at a defined distance away from the recognition site or, finally, at a position relatively far away from the recognition site and which varies from case to case. However, before we discuss the characterization of these reactions in more detail, the following biological considerations should help to account for the name given to this family of enzymes.

2. Discovery of the Restriction and Modification Systems

Whilst investigating the host specificity of bacterial viruses at the beginning of the 1950's, several research workers observed that on changing hosts these viruses often did not multiply very well at first, but then adapted to the new host and as a result then grew uninhibited[1–4]. This adaptation—so-called host-controlled modification—is not, however, genet-

[*] Prof. Dr. W. Arber

Klingelbergstrasse 70, CH-4056 Basel (Switzerland)

ically stable, *i.e.* it does not involve selection of a mutant capable of reproduction. The specific modification of the virus for a given host is, on the contrary, lost on growth in another host so that on reinfection of the first host only a small fraction of the virus particles can continue to multiply. This phenomenon of strong retardation of viral growth by the host was called restriction. Figure 1 illustrates, by way of example, host-controlled restriction and modification of bacterial viruses.

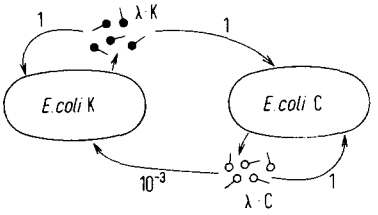

Fig. 1. Example of a restriction and modification system. The two *Escherichia coli* strains K and C are natural hosts for bacteriophage λ. As long as phage λ is grown on the same host, under optimal conditions each virus particle produces progeny viruses on infection (plating probability 1). On changing the host the following is observed: phage λ·C, which has grown on strain C, grows on strain K with a probability of only 10^{-3}. The few progeny particles are, however, now λ·K and thus grow well on strain K. On the other hand, λ·K also grows well on strain C but the newly produced viral progeny have now become λ·C and are no longer capable of infecting strain K. In this example strain K, but not strain C, possesses a restriction and modification system. C accepts all viruses, regardless of which host they have grown on. K only completely accepts those viruses which have previously grown on K and have thus been specifically modified for K. K modifies merely 1‰ of the viruses grown on C.

The molecular processes responsible for restriction and modification were largely elucidated at the beginning of the 1960's: both restriction and modification act directly on DNA, *i.e.* on the genetic material[5,6]. This was surprising, as it was known that the modification could not be further inherited in a genetically stable form. The following observations were crucial for the new findings: in the restriction situation (*e.g.* infection of strain K with phage λ·C, Fig. 1) the phage DNA was quickly degraded by the host cells which survived the infection. This meant that the genetic material foreign to the host cell was destroyed during restriction. If, on the other hand, the phage λ·K was allowed to multiply for a single growth cycle on a non-restrictive strain, then the only progeny to show K-specific modification (*i.e.* were capable of uninhibited infection of strain K) were those in which at least one of the two DNA strands consisted of parental material (semiconservative replication). This showed that the modification in strain K acted directly on the DNA and did not impede its further correct replication, and furthermore that the modifying principle remained associated with the parental DNA strand during replication.

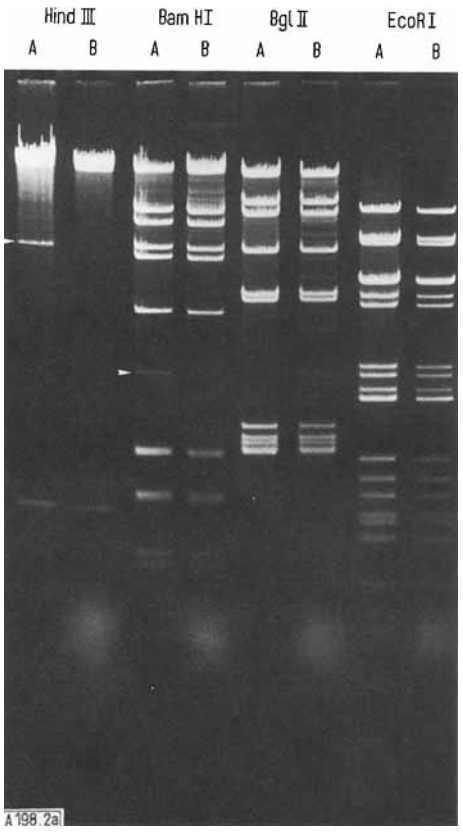
It was then shown that the modification was due to the methylation of nucleotides[7-10]. In the example of strain K discussed here, certain adenine residues in specific nucleotide sequences are methylated to give N^6-methyladenine. This methylation does not change the genetic content of the nucleic acid in any way and seems to have the sole purpose of protecting the DNA against the action of the K-specific restriction endonuclease, the term now used for the DNA-degrading enzyme. This enzyme can, however, split all DNA molecules in which this specific methylation is lacking.

On the basis of these findings it is probable that restriction and modification systems are designed to defend their carrier cells against infection by foreign genetic material. The cell's own DNA is protected from the action of the restriction endonuclease by the modifying methylation. It soon became apparent that this phenomenon is not limited to viral DNA but also affects cellular DNA in the same way so that restriction is also effective, for example, in conjugation-mediated genetic exchange between two strains of bacteria[11-14].

Other biological functions than those discussed here, which are equivalent to those of a primitive immune system, have not so far been identified but discussions on this point have still not been concluded[15].

Restriction and modification systems have as yet only been detected unequivocally in bacteria. It seems that they are widely distributed in the large variety of bacterial species that exists. Systematic studies have so far been limited to a relatively small number of strains, above all to *Escherichia coli* and related enterobacteria, to *Bacillus subtilis* and various types of *Pseudomonas* and *Haemophilus*[16,17]. The genetic information for restriction and modification systems is often located in the bacterial chromosomes but occasionally also in plasmids or the genomes of bacteriophages. Natural strains of bacteria are found which have a single restriction and modification system, others have several, often unrelated systems and, finally, there are also strains in which restriction and modification systems have not as yet been detected. Mutants which no longer exhibit restriction and modification can also be isolated from strains with a restriction and modification system[18,19]. Under laboratory conditions these mutant strains do not seem to be at a disadvantage when compared with their unmutated parents, but this may not be the case in the ecological equilibrium of nature.

The effectiveness of a restriction and modification system with respect to a foreign genome depends, of course, on whether this genome is sensitive to the restriction and modification system under consideration. As has already been indicated, this requires the presence of specific recognition sites on the DNA molecule for the restriction and modification system. With very small DNA molecules (*e.g.* the genome of a small virus), it may be that no recognition site is to be found along the whole of the genome. If the genome contains, for example, a single recognition site, the sensitivity to the restriction is often lost due to mutation of a nucleotide at this specificity site[20]. In this way the recognition site can be genetically mapped. Historically speaking, this type of experiment led to appreciation of the fact that recognition sites play a key role in enzyme reactions[21].



3. Enzymology of Restriction and Modification

After prolonged efforts, the restriction endonucleases from *E. coli* K and related strains were isolated towards the end of the 1960's[22-24]. It soon became clear that these rather large enzymes with molecular weights of approximately 450000 not only cleaved unmodified DNA *in vitro* but, under slightly modified reaction conditions, could also catalyze the specific methylation of the relevant restriction and modification system[25]. Each DNA strand received a methyl group

for each of its recognition sites[10]. It may be noted that, by definition, the methyl-accepting nucleotide is part of the recognition sequence, as completely methylated (*i. e.* modified) DNA is not attacked by the enzyme nor is the activity of the enzyme affected.

It was generally expected that the cleavage reaction would also occur at the recognition sites but this was not found to be the case. Rather, the cleavage products of the *in vitro* splitting of small DNA substrates having only a few recognition sites were shown to be of very variable sizes[26]. Thus, restriction cleavage brought about by restriction endonucleases from *E. coli* did not take place at the recognition site but at other positions on the DNA molecule and then not always at the same site. After cleavage of DNA with these enzymes, a given section (*e. g.* a specific gene) is not to be found in a uniform population of equally long fragments but, almost as is the case in random fragmentation, in fragments of very different lengths.

In 1970 it became clear that in this field nature also allows itself a variety of possibilities. Site-specific endonucleases were isolated from a strain of *Haemophilus influenzae*, and these enzymes were indeed able to split a given DNA substrate into a population of specific fragments[27]. Analysis of the nucleotide sequences at the ends of the cleavage products confirmed the specificity of the cleavage[28]. The present simplest test for demonstration of site-specific cleavage of a DNA molecule is the electrophoretic separation of the fragments in agarose gel[29]. The migration of the fragments in this medium is approximately inversely proportional to the logarithms of their molecular weights; the fragment bands are readily visible under UV light on addition of ethidium bromide (Fig. 2).

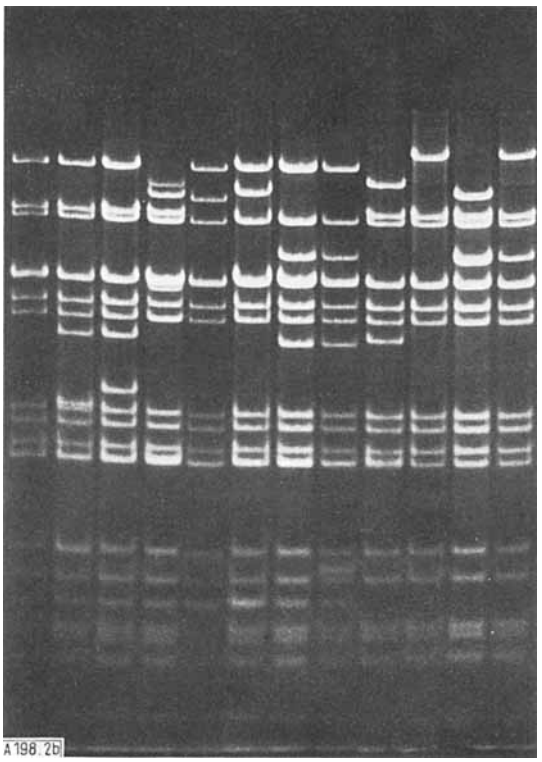


Fig. 2. Gel electrophoresis of restriction cleavage fragments of the bacteriophage P1 genome. a) Restriction cleavage of P1 DNA (A: isolated from phage particles; b: isolated as the prophage genome from P1 lysogenic bacteria) with the restriction endonucleases *Hind*III, *Bam*HI, *Bgl*II and *Eco*RI. The electrophoretic migration of the fragments in the agarose gel proceeds in the downward direction and is inversely proportional to the logarithm of the molecular weight. Large fragments are therefore at the top and small ones at the bottom. The fragments were visualized by addition of ethidium bromide and exposure to UV light. The bands marked with an arrowhead were only found in DNA extracted from phage particles; this indicates the specificity of the packaging of the DNA into phage particles (*Hind*III and *Bam*HI). All clearly visible bands are a result of complete digestion whereas weak bands originate from partial digestion (photograph: Dr. *Brigitte Bächi*). b) Comparison of the *Eco*RI fragmentation of P1 DNA (left slot) with that of eleven, independently isolated, deletion and insertion derivatives of bacteriophage P1. If the restriction cleavage map is known, the site of the deletion and insertion can be established from the missing bands. New bands originate from the region in which deletion has occurred, as well as from inserted material and its immediate vicinity. The six smallest *Eco*RI fragments of the P1 DNA have already moved out of the bottom of the gel (photograph: Dr. *Shigeru Iida*).

A few years ago a systematic search was begun for other such enzymes capable of site-specific cleavage of DNA molecules. Extracts from a large number of bacterial strains were intentionally purified crudely and examined, under relatively simply conceived, standard conditions, for their ability to specifically fragment several, selected DNA molecules. As expected, this procedure lead to the discovery of predominantly site-specific endonucleases whose isolation and detection was relatively unproblematic. The tests were probably unable to detect a series of similar enzymes which are less stable and are also dependent on cofactors. In spite of this, the investigations were surprisingly fruitful—to-date approximately 100 bacterial, site-specific endonucleases have already been described[17].

Only a few of these enzymes have so far been shown to belong to biologically characterized restriction and modification systems. It soon became customary, however, to refer to the whole group of described enzymes as "restriction endonucleases".

As has already been discussed, two vital components always belong to a restriction and modification system—namely the cleavage and the modification activities. It can well be assumed that modification is often brought about by means of methylation but other mechanisms for protecting the cell's own DNA from the restriction endonucleases can be envisaged.

4. Specific Recognition and Cleavage

As has already been described, relatively large enzyme complexes are found in *E. coli* bacteria which can either cleave or methylate DNA. It may be asked how these enzymes decide which function they should carry out. This decision seems to depend strongly on the primary structure of the DNA at the recognition sites. We now know that the restriction endonucleases from *E. coli* K can only recognize K-specific recognition sites effectively after activation with *S*-adenosylmethionine (Fig. 3). In double-stranded DNA such a site may be in one of the three following states: 1. It does not yet possess any methyl groups introduced by K-specific modification. This is normally the state of infective, foreign DNA. 2. One strand of the DNA is already methylated but not the other. This state is produced routinely after each replication cycle of previously completely modified DNA. 3. Both strands have a methyl group at the recognition site. This state is established shortly after DNA replication by the action of the modification activity on the second state.

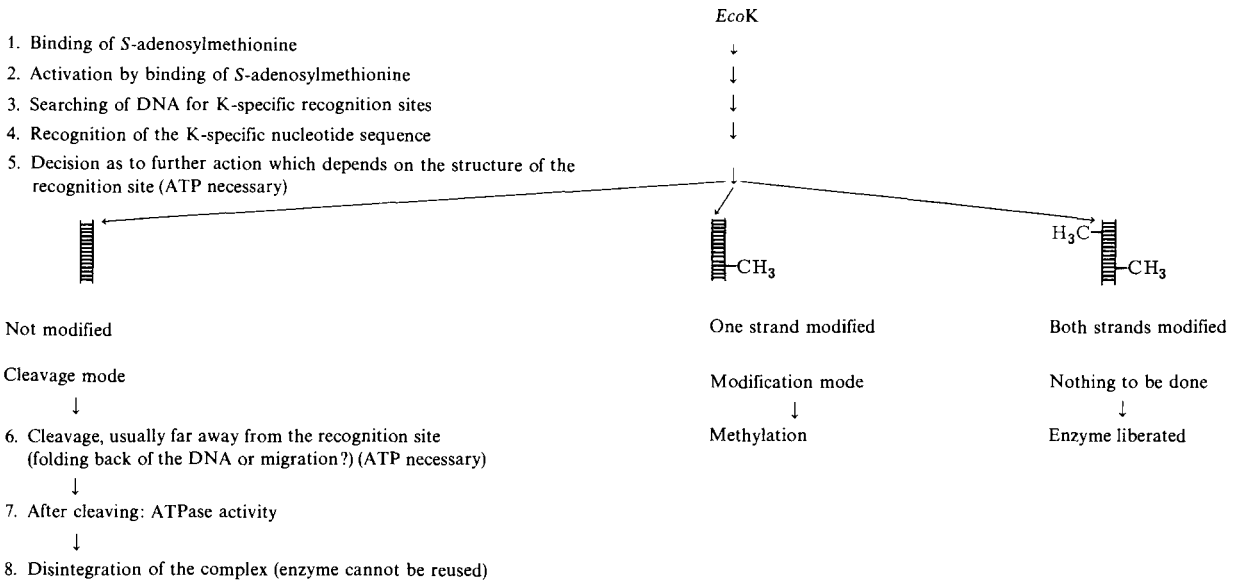

Fig. 3. Mode of action of the restriction endonuclease *Eco*K (schematic) [30, 31].

From the above it follows that it is to the cell's advantage if, in the case of unmodified (unmethylated) recognition sites, the enzyme complex decides in favor of cleaving the DNA which leads to the destruction of invading, foreign DNA; in the case of DNA modified (methylated) in one strand, it is better if the complex decides to methylate the second strand as well. Completely methylated recognition sites are also recognized by the enzyme, however these sites do not activate the enzyme but liberate it. This mode of action, which is logical for the cell, seems indeed to be the basis for the further behavior of the enzyme towards the DNA[32]. It is assumed that specific conformational changes occur as a physical manifestation of the decision taken in the recognition process; these changes direct the enzyme into either the cleavage or the methylation mode. It should be remembered that these complex *E. coli* enzymes cleave the DNA at a position far beyond the recognition site which could be achieved, for example, by folding back of the DNA molecule. At all events, ATP is required for cleavage as well as for active recognition.

One of the three gene products which constitute the enzyme complex seems to be primarily responsible for the actual recognition process of these enzymes[21]. Mutants of the gene responsible lose their capacity for specific recognition. The product of this gene couples the recognition specificity of the methylation reaction with that of the cleavage reaction. This situation points out the biological reason for the coupling of modification with restriction—the cell's own DNA has to be optimally protected.

The following picture can be drawn for at least some of the enzymes belonging to the large group of restriction endonucleases showing site-specific cleavage, but this should not however be generalized before more experimental data are available. The restriction endonuclease *Eco*RI coded for by an *E. coli* plasmid, is a dimer or tetramer of a polypeptide with a molecular weight of 28 500[33]. It is therefore the product of a single gene. This enzyme can only split DNA endonucleolytically but cannot protect against this cleavage. The same *E. coli* plasmid also codes, however, for a DNA methylase with a molecular weight of 40000[34, 35]. The methylation catalyzed by this enzyme occurs in the recognition sequence specific for the endonuclease *Eco*RI (Table 1). The two enzymes are thus the two parts of the *Eco*RI-specific restriction and modification system. In this case it should be noted that two, perhaps independent, gene products are involved which, under certain circumstances, could have been formed independently during evolution. This hypothesis has not however been proved experimentally; an initial gene duplication can also be envisaged which is followed by divergence of the two genes with retention of the part of the gene product necessary for specific recognition of a nucleotide sequence.

In some cases the endonucleolytic cleavage reaction has been studied more closely[22, 27, 33]. It was found that one of the strands of the double-stranded DNA is first split; under favorable conditions it is possible to isolate the resulting intermediate. The second DNA strand is also broken in a second step. A few restriction endonucleases also seem to be able to cleave single-stranded DNA specifically[36–38].

Analysis of the ends of the DNA fragments is of interest. The ends of the cleavage products of many restriction endonucleases cleaving at specific sites are very well characterized. Some of the enzymes split the two strands at the same level, others at positions some distance away from each other; in the latter case double-stranded DNA fragments are formed which have short, single-stranded ends. Table 1 contains some examples of both of these types. Where known, the position of the nucleotides which can be methylated in the modification reaction are also included in Table 1. Comparison of the examples shows the variety of possibilities which exist.

Table 1. Examples of recognition sequences of restriction endonucleases. Most of the data are taken from the publication of *Roberts* [17] which also contains the original references; the remaing data are the unpublished work of *R. J. Roberts* and *T. A. Bickle*. The recognition sequences are so arranged that their 5′ terminal ends are at the upper left and lower right hand sides. The cleavage sites are indicated by arrows. The nucleotides which are so far known to be methylated in the modification reaction are marked with an asterisk. Nucleotide bases: C = cytosine, G = guanine, A = adenine, T = thymine, Py = cytosine or thymine, Pu = guanine or adenine. The symbols for the restriction endonucleases were derived as follows: The first 3 letters give an abbreviation for the microorganism producing the enzyme, *e.g. Bam* for *Bacillus amyloliquefaciens*, the fourth letter (if any) designates the particular bacterial strain, the roman number given at the end identifies a particular enzyme isolated from the strain in question [47].

Recognition sequence	Specific for following restriction endonucleases
$G^{\downarrow}GATCC$ $CCTAG_{\uparrow}G$	*Bam*HI
$A^{\downarrow}GATCT$ $TCTAG_{\uparrow}A$	*Bgl*II
$^{\downarrow}G\overset{*}{A}TC$ $CTA\overset{*}{}G_{\uparrow}$	*Mbo*I
$\overset{*}{A}^{\downarrow}AGCTT$ $TTCGA_{\uparrow}\overset{*}{A}$	*Hin*dIII
$CTGCA^{\downarrow}G$ $G_{\uparrow}ACGTC$	*Pst*I
$G^{\downarrow}A\overset{*}{A}TTC$ $CTTA\overset{*}{}A_{\uparrow}G$	*Eco*RI
$GTPy^{\downarrow}Pu\overset{*}{A}C$ $CA\overset{*}{}Pu_{\uparrow}PyTG$	*Hin*dII
$^{\downarrow}C\overset{*}{C}AGG$ $GGTC\overset{*}{}C_{\uparrow}$	*Eco*RII
$C^{\downarrow}CCGGG$ $GGGCC_{\uparrow}C$	*Xma*I
$CCC^{\downarrow}GGG$ $GGG_{\uparrow}CCC$	*Sma*I
$C^{\downarrow}CGG$ $GGC_{\uparrow}C$	*Hpa*II, *Hap*II, *Mno*I
$TGG^{\downarrow}CCA$ $ACC_{\uparrow}GGT$	*Bal*I
$G G^{\downarrow} C C$ $C C_{\uparrow} G G$	*Bsu*I, *Hae*III

Almost all recognition sequences studied (see Table 1) exhibit twofold rotational symmetry. This may be connected with the specific interaction between the enzyme and double-stranded DNA. Knowledge of the number of nucleotide pairs comprising a recognition site, together with the fact that DNA is composed of only four nucleotides, allows prediction of the average frequency of a specific recognition sequence in the DNA. Similarly, the maximum possible number of recognition sequences of a given length can be calculated[21]. Seven of the 16 possible rotationally symmetrical tetranucleotide pairs have so far been demonstrated to be recognition sequences of one or more restriction endonucleases[17].

In this context it should be mentioned that two independent restriction endonucleases sometimes recognize the same nucleotide sequence but they then cleave in different ways. On the other hand, independent enzymes exist which produce the same cleavage products but which show marked differences in their enzyme kinetics[17].

5. Restriction Endonucleases in Biological Research

With the site-specifically cleaving restriction endonucleases nature has provided the research worker with a supply of long desired tools which allow genetic material to be systematically investigated. As long as the research worker had to rely on the occurrence of random breaks during the fragmentation of large DNA molecules, he could not expect to obtain uniform material for structural and functional analyses. This objective has meanwhile been attained with the restriction endonucleases.

One of the goals of the molecular geneticist is to identify the exact nucleotide sequence of a genome. As most gene carriers are very long DNA molecular chains, this problem must be approached systematically. Small genomes (*e.g.* the DNA molecules of small viruses) can be most easily analyzed. The first step of their analysis consists in drawing up a restriction cleavage map, *i.e.* one attempts to map all the cleavage sites of the genome which are specific for one or more restriction endonucleases (cf. Fig. 4). This can be achieved, for example, by a stepwise procedure involving isolation of partially cleaved intermediates or by double digestion experiments in which the cleavage products of one restriction endonuclease are isolated and then treated with a second restriction endonuclease. These, together with a series of supplementary techniques involving specific, radioactive-labeling of fragment ends, usually allow unequivocal physical genome maps to be constructed. An example is given in Figure 4.

The actual physical distances can be checked and uncertainties resolved by electron-microscopical studies involving hybridization between denatured restriction fragments themselves and between these fragments and the whole genome.

A further step consists in identifying the genetic information on sections of the genome. Here purified restriction fragments also play an important role, several routes may be tried to express the genetic information.

A series of very good methods is now available for determining the nucleotide sequence of DNA[41–43]. The ideal starting material is still however a preparation of the material to be analyzed which is as pure as possible. Fragments containing

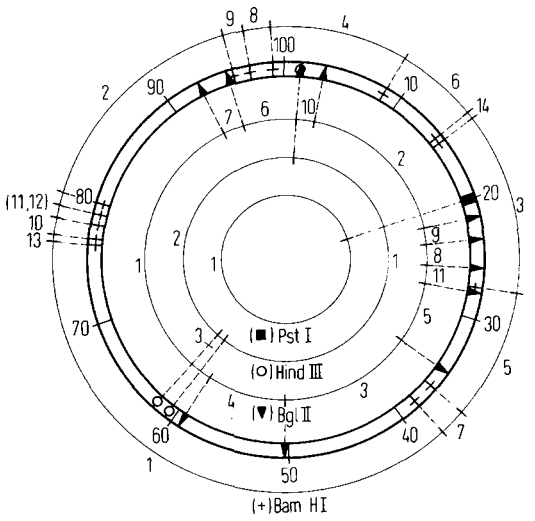

Fig. 4. Restriction cleavage map of the bacteriophage P1 genome [39]. The genome of bacteriophage P1 occurs as an autonomic plasmid in P1 lysogenic bacteria in the form of a circular DNA molecule with approximately 90000 base pairs (molecular weight approximately 59×10^6). For the physical genetic map the genome is subdivided into 100 units which are drawn to scale on the thickened circle. The cleavage sites of the four restriction endonucleases—*Pst*I (■), *Hind*III (○), *Bgl*II (▼) and *Bam*HI (+)—are also shown on this circle. The cleavage sites of each enzyme have been transferred to a separate, finely drawn ring; the DNA fragments are numbered according to their size (1 = longest fragment etc.). (The sequence of the neighboring fragments 11 and 12 arising from cleavage with *Bam*HI is not yet known.) As is shown in Table 1, each of the four restriction endonucleases utilized recognizes a specific sequence of six nucleotide pairs. In DNA which is statistically built up from the four natural deoxyribonucleotides (P1 DNA contains however approximately 23% guanine, 23% cytosine, 27% adenine and 27% thymine nucleotides [40]), one specific hexanucleotide can be statistically predicted for every 4096 nucleotides. For a DNA molecule the size of the P1 genome there would then be 22 recognition sites in each of the restriction endonucleases under consideration. Experimentally, eleven cleavage sites were found for *Bgl*II, 14 for *Bam*HI, three for *Hind*III and one for *Pst*I. On the other hand, the P1 genome has 26 cleavage sites for the enzyme *Eco*RI which also recognizes a specific hexanucleotide (Table 1). These data reflect the fact that the sequential arrangement of the nucleotide building blocks of the genetic material deviates from a purely statistical distribution.

approximately 100 nucleotides can be directly analyzed. With the help of detailed restriction cleavage maps, restriction endonucleases can be selected which permit a region of the genome to be cleaved into such fragments. It should perhaps be added that nowadays the primary interest of the molecular geneticist are the "punctuation marks" contained within a genome rather than the complete sequence of a gene coding for a specific polypeptide. Punctuation marks are sites on the nucleic acid at which, for example, mRNA replication or synthesis of a polypeptide begins and ends and also the sites which are important for the replication of the DNA itself. Further interest is centered on the sites which have specific affinities for functionally important gene products (*e.g.* repressor molecules). Finally, a great deal of attention has also been given to the study of those sites within a genome which are responsible for a considerably enhanced probability of recombination. It is hoped that more exact statements can be made about the mechanisms for the regulation of gene expression and the level of stability of the genetic material when the structure of all these sites is known. This research cannot of course be restricted solely to biochemical-physical investigations but must be supplemented by systematic genetic studies—the characterization of specific mutants and the investigation of their effects. Such investigations are therefore a very extensive undertaking and can only be directly applied to a few, selected, intensively studied systems.

It is however also desirable to analyze certain sections of more complex genomes (*e.g.* eukaryotic chromosomes) in detail. Here the use of restriction endonucleases has also been of considerable help. With the aid of the enzyme DNA ligase, single restriction cleavage fragments can be covalently incorporated into small DNA molecules (plasmids or bacteriophage genomes) which are capable of self-replication and in this case are called vectors[44, 45]. This incorporation is particularly easy if both the vector DNA and the DNA fragment to be inserted have short, complementary single-stranded ends, as is the case with the products of many of the restriction endonucleases (Table 1). Such ends hybridize spontaneously

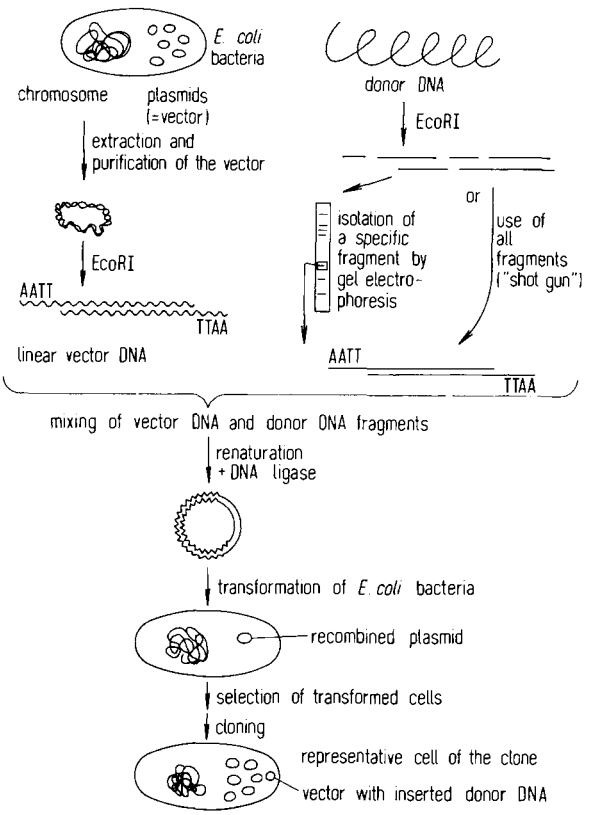

Fig. 5. Scheme for a simple *in vitro* recombination experiment. In the example illustrated here a small (molecular weight approximately 5×10^6), autonomically replicating plasmid serves as a vector; it only has a few well characterized genes and one cleavage site for *Eco*RI. On cleavage with *Eco*RI a linear DNA molecule with single-stranded ends is formed from the circular plasmid, these ends can easily recombine under renaturation conditions. If however donor DNA, which has likewise been cleaved with *Eco*RI, is added, one or more donor DNA fragments are then often incorporated into the ring which is formed. Cyclization to a covalently bound ring can be achieved by using the enzyme DNA ligase. In the transformation step the plasmid DNA penetrates an *E. coli* cell with a low but reproducible probability. The cells transformed with recombined plasmids can be selected from the large number of non-transformed *E. coli* cells by skilled choice of the vector based on the consideration of specific vector functions. The transformed bacteria are then purified by "cloning", *i.e.* by growing a culture from a single cell. All cells of a clone are therefore genetically and functionally identical. In the example given, each bacterial cell has several plasmids. Their numbers can be drastically increased by a special experimental procedure. The recombined donor DNA fragment can be obtained in its purified form and in the desired quantities by isolation of the recombined plasmids from the transformed clone and recleavage of the plasmid with *Eco*RI. The "clonable" donor DNA fragment may be several times larger than the plasmid. In principle no lower limit is set for this size. Before recombination a specific donor DNA fragment size can be selected by gel electrophoresis, alternatively all DNA fragments can be put into the renaturation mixture ("shot gun" experiment).

so that the DNA fragments brought together can be easily linked. This technique has become known as *in vitro* recombination of DNA (Fig. 5). It enables genetic material to combine whatever its origin. The aim of such experiments is to multiply the fragment inserted into the vector ("cloning") until there is sufficient material for structural and functional analyses. Such analyses could not of course be contemplated without thorough purification of the DNA segment of interest from the total gene carrier.

A further application of this technique consists in trying to express the known genetic information of a cloned DNA fragment under especially favorable conditions so that large quantities of this specific gene product are produced which can then be purified with relatively little difficulty. Possible applications of this method are, for example, the production of medically important antisera or other bioorganic gene products which are of ecological importance. In all these cases knowledge of the "punctuation marks" for optimal expression of the gene in question can play a significant role. There are still however many problems to be solved in this respect.

The possibility of *in vitro* combination of genetic material from different origins has confronted science with the question of the potential, scarcely predictable, undesirable effects of recombined gene material. Safety precautions for the prevention of possible risks have been proposed amazingly quickly[46]. How real the much discussed risks are can only be assessed when the gene flow within the total genetic potential is known. The question still to be answered is whether a certain amount of exchange of genetic information between unrelated living organisms is or was admissible during evolution and in daily biological events, or whether the barriers between species are very strict. There are indeed indications that a so-called, illegitimate exchange takes place repeatedly in nature, but concrete statistical data about this phenomenon are largely lacking and are also not easy to obtain. It can be asked whether the much discussed universality of the genetic code would also have come about if living organisms were forbidden to exchange sections of their genomes with unrelated species from time to time. With strict isolation one could imagine that more than one genetic code would have been formed.

As regards the world-wide discussion of the prohibition of certain lines of research which has been raised by the possibility of *in vitro* recombination of DNA, it may be apt to point out that, in every type of basic research, the long term effect of a result cannot be predicted. This makes control of research and the erection of barriers difficult. In about 1960 the investigation of the events in host-controlled restriction and modification of viruses was a purely microbiological problem with medical interest. One wanted to know how cells managed to ward off all viruses except those which had previously grown in their own sister cells. The finding that this repulsion took place at the level of the viral DNA and led to its degradation then opened up the way for the isolation of the restriction endonucleases and their further applications in the study of the structure and function of DNA.

Use of Electron-Density Plots in Applied Quantum Chemistry

By Ilyas Absar and John R. Van Wazer[*]

The uses in applied quantum chemistry of computer-produced three-dimensional diagrams of electron-density distributions are discussed. The two major catagories of such diagrams are contrasted; and advantages are described for plots showing as the third dimension the point-by-point electron density in a cross-sectional cut (corresponding to the other two dimensions) through a molecule. Examples are presented to show how these plots may be used (1) to assess the adequacies of a given mathematical representation employed in the calculation of a wavefunction, (2) to clarify the interrelationship between an individual molecular orbital and the atomic orbitals of the constituent atoms, as well as (3) to explain the canonical set of molecular orbitals of any selected molecule. Furthermore these plots serve (4) to demonstrate clearly a replication of key characteristics between certain molecular orbitals in different molecules. These examples are accompanied by others which indicate how the electron-density plots may be used (5) to understand and clarify accepted chemical dogma. Finally, the possibility is discussed of employing quantum calculations on a wider scale so as to be of value in the more practical aspects of chemistry.

1. Introduction

Although electron-density diagrams have been used for many years in quantum chemistry, several kinds of three-dimensional plots accurately produced from wavefunctions by computer-controlled graphic systems have been introduced[1-4] since 1970. It has turned out that such plots are useful aids in interpreting[5] the results obtained from quantum calculations. Several books[5-7] treating this matter present many examples of such plots for various atoms and molecules; and it is our purpose here to survey these plots and to review some of their uses other than the obvious one of just depicting data.

2. Choice of Plots

Since a wavefunction, ψ, or its corresponding electron density, $\psi\psi^*$, must be described in four dimensions (three for the spatial geometry and one for the point-by-point value of the function), any three-dimensional plot must leave out some information; but yet no more than three dimensions may be depicted clearly in a spatial model or in its corresponding perspective diagram plotted on a sheet of paper. Two ways of handling this problem are commonly employed. One is to show the variation of the function across a chosen plane (or other surface) passing through the subject array of atoms, *e.g.* a molecule or crystal. In a linear or planar molecule, the chosen plane is generally selected to be that of the atoms; but, even for planar molecules, it is also often informative to plot one or more additional planes perpendicular to the plane of the molecule. For more complex molecular geometries, judicious selection of the planes to be studied must be made in order to depict clearly the spatial variation of the wavefunction or electron density. These cross-sectional plots have been prepared[6] using a linear or logarithmic scale for the electron density. Although the logarithmic scale (or a square-root or cube-root scale) has the advantage of encompassing the highest density values while simultaneously emphasizing the lower values appearing in the bonding and intermolecular regions, it does give a distorted density presentation. We prefer[5] to use a linear scale for the electron density and to truncate the sharp density peaks that appear close to the nuclei of atoms having core electrons.

The other way is to show only the surface(s) corresponding to some chosen value of the function in space so as to obtain what we usually call shape plots. The difficulties here are that the detailed spatial distribution of the function is thereby virtually ignored, while the selection of the chosen value of the function is extremely arbitrary. This latter problem is illustrated in Figure 1, in which a cross-sectional electron-density distribution (using a linear scale) for water sits on top of a series of shape plots corresponding to various chosen values of the electron density in this molecule. It is clear from these shape plots (a through e) that the choice of a relatively high electron density for this molecule will give only a tiny, nearly perfect sphere closely surrounding the oxygen nucleus; whereas a very low value will lead to a large, nearly spherical contour centered on the molecule. Thus, details of molecular structure will show up in shape plots only within a restricted intermediate range of the adjustable parameter (the chosen electron density). On those few occasions in which we find it valuable to calculate shape plots, we commonly employ a value for this parameter of $0.6\,e/Å^3$ for depicting the whole atom or molecule and $0.14\,e/Å^3$ for the constituent valence orbitals, since these choices were found[5] to correspond rather well to the van der Waals radii of common atoms from the second and third period of the Periodic Table. This choice of $0.14\,e/Å^3$ was employed in the shape plots describing the molecular orbitals of water[5] in Figure 2.

Because of the detailed point-by-point information presented in cross-sectional electron-density distributions, this

kind of linearly scaled plot will be shown in most of the examples presented below to illustrate advantageous uses of the computer-produced three-dimensional graphs. Although it is possible to produce similar cross-sectional plots of wavefunctions ψ, we have decided not to include this approach among the following examples, since electron density $\psi\psi^*$ is a physically meaningful quantity while the wavefunction is not.

3. Adequacy of Various Mathematical Shortcuts

The usual off-hand criterion for the adequacy of a basis set employed in a self-consistent-field (SCF) calculation is the calculated total energy, with wavefunctions of higher quality giving lower (*i.e.* more negative) energies. This approach however may sometimes be misleading, so that a low-energy result can be of much poorer quality than one of appreciably higher energy. For example, we have intercompared[5] cross-sectional electron-density plots of the canonical molecular orbitals[*] of the water molecule calculated in a variety of basis sets. These plots showed, as expected, that an extended Slater[8] and a large Gaussian basis set[9] (both with polarizing functions) gave electronic distributions that were essentially identical and that the quality of much smaller Slater and Gaussian descriptions was quite good, except for a readily noted rounding of the top of the sharp humps corresponding to the hydrogen atoms in the Gaussian basis set. Indeed, even a CNDO semiempirical calculation[10, 11] gave quite well-shaped electronic distributions for each of the valence-shell molecular orbitals. However, as exemplified for orbital $1b_2$ in Figure 3, a one-center calculation[12] employing an extended-Slater basis set centered solely on the oxygen atom did very poorly in that there was no evidence whatsoever of the expected humps at the site of each hydrogen atom. This behavior was observed for all of the valence orbitals ($2a_1$, $1b_2$, and $3a_1$) that ought to show clumping of electronic charge around each hydrogen. It was also seen for the total electronic density.

The total energy was calculated to be -75.922 a.u. for this one-center representation as compared to -76.005 a.u. for the extended-Slater and only -75.703 a.u. for the minimum-Slater basis set[10] (which gave properly shaped electronic distributions). About 15 years ago, one-center calculations were very popular because (1) they were less costly than the usual calculation in which appropriate atomic orbitals were assigned to all of the atoms in the molecule and (2) the resulting total energies for a given level of adequacy of the basis set were very good for the molecules being studied at that time. On the basis of this one example, it would seem that the reason the one-center representation worked so well was that binary hydrides (such as methane, ammonia, and water) were emphasized in theoretical studies at that time. Because of the small energy contribution to a molecule from a hydrogen atom as compared to a second-period atom, a good basis set so improved the contribution of the latter to the total energy that neglect of the hydrogens was more than offset. Incidentally, most of the total energy of water is attributable to the presence of the oxygen core electrons. We suggest that anyone investigating an alternative method for calculating wavefunctions would be well advised to employ plots of the type described herein to see if the spatial distribution of the electron density (or the wavefunction) exhibits at least the proper gross shape.

During the last few years, one of us *(J. V. W.)* and his associates have been devoting considerable effort[13–15] to making the pseudopotential technique for solving the Schroedinger equation into a practical method (NOCOR) for use in everyday quantum chemistry. Therefore, quite early in this endeavor we compared cross-sectional electron-density plots of the valence shell for the NOCOR wavefunctions against those from an equivalent full-SCF calculation, as shown in

[*] The canonical molecular orbitals are understood to be that set among the infinite range of possible MOs which represents the solution of the Hartree-Fock SCF matrix and is adapted to the symmetry of the molecule. Fig. 2. Shape (left) and cross-sectional electron-density diagrams (right) for the valence-shell molecular orbitals of water.

Figure 4. In the usual NOCOR procedure, the valence electrons are handled by the standard SCF procedure while the set of core electrons of each atom are simulated by a potential function and the core-valence interactions are treated by the pseudopotential function V^{PP} [eq. 1], in which ε_c and ϕ_c represent the core eigenvalues and eigenfunctions, while the subscript v refers to a valence orbital and $\chi_v^{(i)}$ is a pseudo-wavefunction representing this valence orbital.

$$V^{PP}\chi_v^{(i)} = \sum_c |\phi_c\rangle (\varepsilon_v^{(i)} - \varepsilon_c) \langle \phi_c | \chi_v^{(i)} \rangle \qquad (1)$$

In view of the fact that in this approach there are no orthogonality restraints between the individual core electrons and a valence electron, the wavefunction of the latter has no need to exhibit a nodal structure in the core region. Therefore the electron densities corresponding to the valence molecular orbitals shown for the I_2 molecule[16] in Figure 4 smoothly die out in the core region in such a way that the integrated electronic density of each orbital in this region equals that corresponding to the summation of the antinodes occurring in the same region in the case of the same orbital obtained from a full-SCF calculation. The point of Figure 4 (and of similar intercomparisons of electron-density distribution plots from pseudopotential and full-SCF calculations) is that in the valence region the wavefunction of the total molecule or of each individual orbital is essentially indistinguishable from one obtained from an equivalent SCF calculation that includes all of the core electrons.

4. Interrelationships between Orbitals

Since atoms have only one nucleus, the symmetry of individual orbitals (*e.g.* s, p, d, *etc.*) must be discussed in terms of these orbitals and cannot be treated with respect to the nuclear geometry. On the other hand, it is standard practice in the case of molecular orbitals to employ appropriate group-theory designations derived from the symmetry of the nuclear arrangement (*e.g.* a_1, a_2, and e for a molecule of C_{3v} symmetry). As a result, this scheme of notation for describing molecular

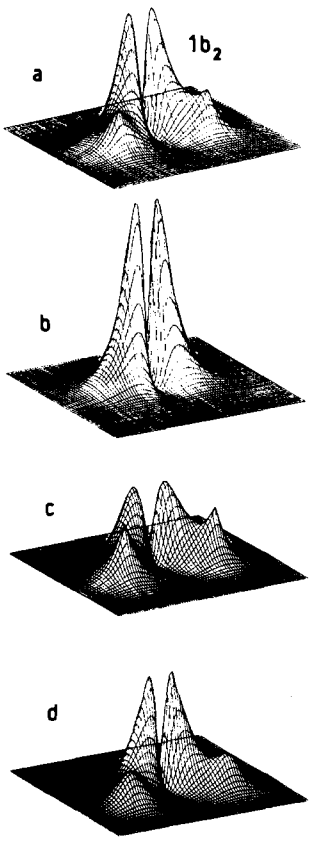

Fig. 3. Cross-sectional electron-density plots of the $1b_2$ orbital of water: a) with an extended-Slater basis set; b) in a one-center representation; c) in a minimum Slater presentation; d) with a moderately-sized Gaussian basis set employing seven s- and three p-type exponents for the oxygen and three s-type for each hydrogen.

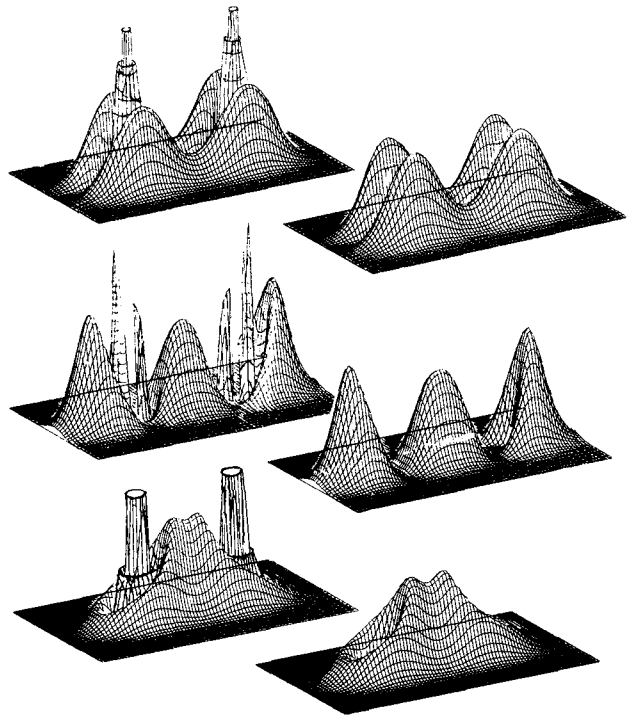

Fig. 4. Comparison of the electron-density plots of three valence orbitals (starting at the bottom, 19 σ_g, 21 σ_g, and 11 π_u) of the I_2 molecule as determined in a full-SCF calculation (left column) and by the NOCOR pseudopotential method (right column) in the same basis set. Note that the antinodes of the 5s and 5p contributing atomic orbitals appearing in the core region do not show up in the NOCOR calculation which, however, beautifully reproduces the valence-bonding structure.

orbitals does not make clear their constitution in terms of the atomic orbitals of the contributing atoms. However, the relationship between a molecular orbital and its contributing atomic orbitals may be seen at a glance from an electron-density distribution plot. The connection is clearly seen in either of the two kinds of plots shown in Figure 2, where the most stable of the H_2O valence orbitals, $2a_1$, is seen to be based on the 2s atomic orbital of oxygen. Each of the three remaining filled valence molecular orbitals of water is based on one of a set of three orthogonal oxygen p orbitals. The most stable of these three p-dominated orbitals is $1b_2$ in which the C_{2v} axis of the molecule passes through the nodal plane. This is followed by orbital $3a_1$ in which the nodal plane of the oxygen p orbital lies parallel to the line connecting the pair of hydrogen atoms. In the least stable of the filled orbitals, $1b_1$, the nodal plane passes through the two hydrogen atoms so that there can be no H—O bonding. As a result, when going from the most to the least stable of the valence orbitals, one proceeds from a nodeless molecular orbital through a set of three orbitals exhibiting orthogonal nodal planes—a molecular sequence that is reminiscent of the stability sequence found for a second-period isolated atom, *e.g.* 2s and the three 2p's. Moreover, atomic orbitals are utilized in building molecular orbitals in such a way that the more stable atomic orbitals appear in the more stable molecular orbitals as long as the nodal requirements of the orbitals are met. In other words, one can consider molecular orbitals in terms of a modified aufbau principle, that is analogous to the one concerned with atomic orbitals. This aufbau approach holds for the molecular orbitals of highly complicated molecules of varying symmetries, and this is readily seen[5] from the electron-density plots.

In working with electron-density plots of molecular orbitals, we noticed[17,18] that each molecular orbital of a given molecule bore striking resemblances (with respect to the magnitude and geometry of the individual atomic contributions) to molecular orbitals of other molecules. Even though this close correspondence between certain molecular orbitals in different molecules was sometimes seen in quite unrelated chemical structures, the effect was first noticed and is particularly pronounced in the case of a series of related molecules. This has been demonstrated in our orbital book[5] for a number of molecular sequences such as methanethiol, methanol, and dimethyl ether; methylamine, methylphosphane, and methylphosphorane; cyclopropane, phosphirane, and thiirane; or water, formaldehyde, and ketene. Most of the time, orbitals shown to be interrelated by inspection of the electron-density plots follow the standard orbital-correlation rules of quantum chemistry. However there are occasional exceptions, each of which may be explained logically.

As an example of these intermolecular relationships, consider the valence-shell molecular orbitals of H_2S, H_2SO, and H_2SO_2, the latter two molecules being analogs of sulfoxides and sulfones. The underlying computations on the progressive introduction of one and then two S—O bonds to H_2S have been reported[18]. Figure 5 shows the intermolecular relationships (dotted lines) between the molecular orbitals of H_2S, H_2SO, and H_2SO_2. Although most of these relationships can be established unambiguously from symmetry considerations, orbital-density plots not only give a clear-cut demonstration of which orbitals across a series of molecules are interrelated

but also delineate the details of how this occurs, thus leading to the resolution of any ambiguities.

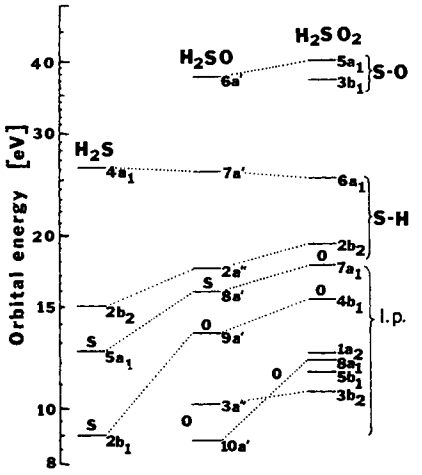

Fig. 5. A correlation plot for the valence orbitals of H_2S, H_2SO, and H_2SO_2, showing the most stable orbitals at the top. The orbitals involved in S—O and S—H bonding are so indicated; while l.p. stands for the lone-pair orbitals, with their assignment to either sulfur or oxygen being denoted above the line corresponding to each orbital.

Two orbital sequences involving shifts from sulfur lone-pair to oxygen lone-pair character are depicted in Figure 6. The sequence of Figure 6a ($5a_1$ of H_2S, 8a' of H_2SO, and $7a_1$ of H_2SO_2) shows a persistence of charge attributable to the sulfur lone pairs in H_2S, not only in H_2SO but also in H_2SO_2! It should be observed that the oxygen lone-pair charge in H_2SO reappears practically unchanged for each oxygen of H_2SO_2; also the small charge concentration lying on the axis between the two hydrogen atoms persists throughout the entire sequence. In Figure 6b are shown orbitals $2b_1$ of H_2S, 9a' of H_2SO, and $4b_1$ of H_2SO_2. The transition from sulfur to oxygen lone-pair character occurs through conversion of sulfur lone-pair charge into S—O bonding; however the character of the charge distribution about the sulfur nucleus again persists, the similarity being strikingly apparent in comparing the two more symmetric molecules H_2S and H_2SO_2.

5. Electron-Density Difference Plots

Variations in electron densities can be studied by the use of cross-sectional electron-density-difference plots, which are perhaps an even more powerful tool than the density plots themselves. Although the commonly used difference plots are those showing the electron density of the molecule minus the overlapping electron densities of the unbonded atoms positioned as in the molecule, difference plots may be used in many other ways, some quite novel.

An example of the common type of difference plot is shown according to our approach in Figure 7 for the ethane molecule, with the plane of observation passing through the two carbon atoms and a pair of *(anti)* hydrogen atoms[5]. Figure 7a depicts the electron density of the C_2H_6 molecule minus that due to superpositions of the two carbon atoms in their usual s^2p^2 ground state and the six hydrogen atoms, with these atoms centered at the proper positions corresponding to the ethane molecule and being described in the same basis set as the molecule. Figure 7b is a similar plot, except that in this case the carbon atoms have been hydridized to the sp^3 configuration. Both of these difference plots show an accumulation in the C—H and C—C bonding regions due to molecule formation. In Figure 7a the negative cones at the positions of the atomic nuclei clearly demonstrate that much of the change in charge between the atoms within and without the molecule involves the s orbitals of the carbon atoms. The major difference between the two plots is the sharp downward pointing peaks (Fig. 7a) and upward pointing peaks (Fig. 7b) at the carbon nuclei. This is due to the fact that, in the sp^3 hybridization of the carbon atoms, one of the 2s electrons of the s^2p^2 ground state was transferred to a 2p

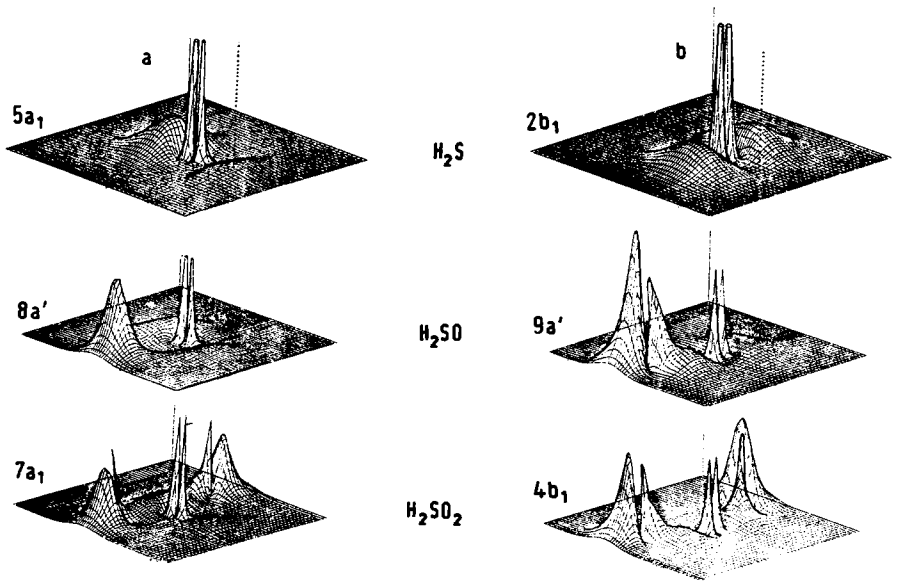

Fig. 6. Electron-density diagrams for two selected sets of correlated orbitals in the series of molecules: H_2S, H_2SO, and H_2SO_2. a) orbitals $5a_1$, 8a', $7a_1$; b) $2b_1$, 9a', $4b_1$.

orbital. The plots show that in the ground state there is too much whereas in the sp^3 hybrid there is not enough charge of the 2s type. Obviously, proper hybridization must lie somewhere in between.

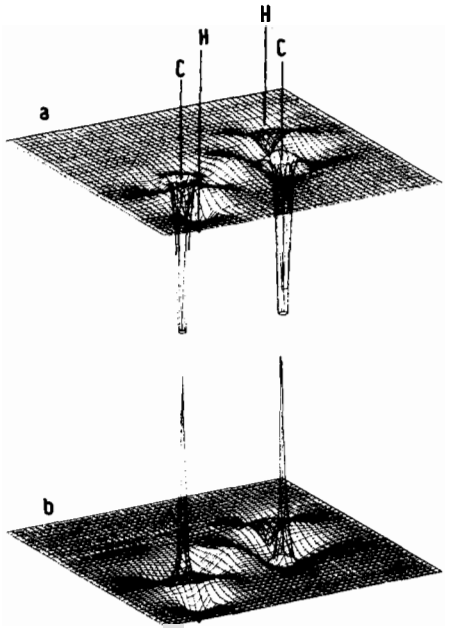

Fig. 7. Electron-density-difference plots for a plane passing through the two carbon atoms and a pair of *(anti)* hydrogen atoms in the ethane molecule. a) molecular electron density minus that obtained by summing over the ground-state constituent atoms placed in the same positions in which they appear in the molecule. b) as in a) except that the carbon atoms of the summation have been hybridized to the sp^3 configuration. These diagrams are plotted to show both plus and minus differences, so that they appear to be transparent. Note that the electron-density differences in these plots are magnified to show up details.

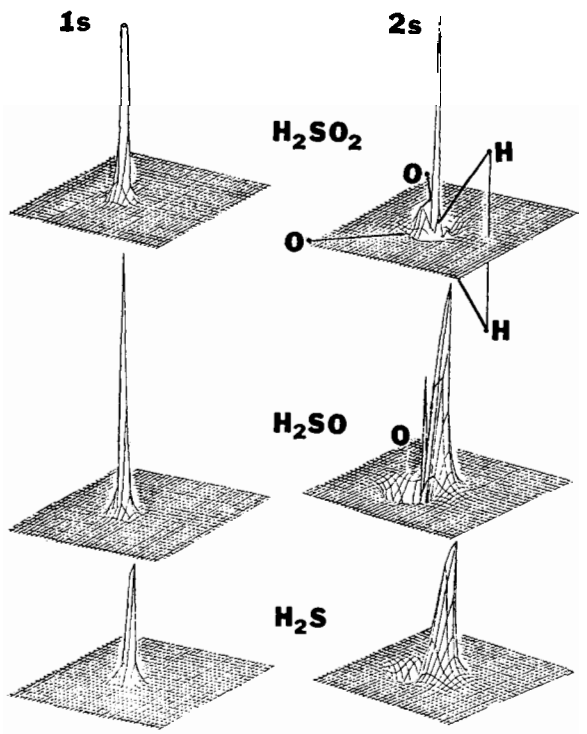

Fig. 8. Cross-sectional electron-density plots of the sulfur core orbitals of s symmetry in the series of molecules H_2S, H_2SO, and H_2SO_2. Note that the 2s orbital exhibits appreciable deformation from its spherical shape in the isolated sulfur atom; whereas this is not true for the 1s orbital. The positions of the hydrogen and oxygen atoms are indicated on one of these plots.

An example of the novel usage of electron-density-difference maps is to elucidate very small changes in electronic structure, as was found in a study[19] of the relationship between the inner-shell molecular orbitals of a series of structurally related molecules. Figure 8 shows electron-density-difference maps for the sulfur "1s" and "2s" molecular orbitals minus the respective atomic orbitals for H_2S, H_2SO, and H_2SO_2. Note that the charge distribution of the sulfur "2s" core electron in any of these molecules no longer exhibits spherical symmetry. This effect is most pronounced in the "2s" orbitals of H_2S and H_2SO, the two cases where sulfur lone pairs are present. Figure 8 demonstrates that the core electrons are not as insensitive to changes in the valence structure as was supposed for so many years. Inner-orbital photoelectron spectroscopy (ESCA) has experimentally demonstrated this fact with respect to the core binding energies[20–22]. The matter of small geometrical deformations in core orbitals (as indicated in Fig. 8) is worthy of further consideration in more precise calculations than the moderately sized basis sets we employed. Other interesting phenomena (such as the electronic effects of internal rotation about a particular bond, ring-closure reactions, and the significance of discussing particular bonds with respect to their covalent or ionic character) are fruitfully studied[5] using electron-density-difference plots. A set of difference plots showing the effect of allowing d character to third-period atoms in a molecule is presented in Figure 10 (see below).

6. Clarification of Chemical Dogma

There is a common misconception that SCF wavefunctions are too delocalized for direct interpretation. As a result, considerable effort has been put into schemes[23–26] for the localization of the canonical molecular orbitals resulting from single-determinant SCF calculations. However, one of the important contributions to the understanding of molecular orbitals made by electron-density plots is a clear demonstration of the fact that canonical molecular orbitals are readily understood in terms of the constituent atomic orbitals and that their interpretation in terms of standard chemical theory is easy and straightforward. This has been demonstrated by our book[5] and numerous papers from our group[2,17,18,27–31]. Although the numerical array of a wavefunction (or many of the various other mathematical arrays which can be used to represent it) may be utilized to characterize a molecular orbital with respect to the details of its atomic makeup, this approach is somewhat cumbersome and often not fully informative, even for those experienced in the mathematics of quantum chemistry. On the other hand, a quick visual inspection of a properly chosen three-dimensional cross-sectional electron-density plot shows up the details with great clarity.

The fact that a single-determinant wavefunction can be decomposed into an infinite number of different sets of "orbitals" has led some people to feel that molecular orbitals are highly arbitrary constructs. This is untrue however, since the molecular orbitals obtained from a standard SCF calculation (the canonical set) are just as meaningful as is the use of s, p, d, *etc.* orbitals for describing isolated atoms, and in the same sense. This means that anyone who uses the standard s-p-d nomenclature for describing the symmetry of atomic

orbitals must, for exactly the same reasons that these atomic orbitals were chosen over other alternatives (hybrids), put equal faith in the canonical molecular orbitals. Inspection of cross-sectional electron-density plots (*e.g.* see Figs. 2—9) shows how the canonical molecular orbitals retain much of the form of the constituent atomic orbitals.

The σ, π, and δ notation used in discussing chemical bonding properly applies only to linear molecules. However, for many years chemists have applied this notation to molecules having other than linear symmetry, sometimes quite inappropriately. Another aspect of three-dimension cross-sectional electron-density plots is that they show graphically how appropriate is the use of this notation for discussing chemical bonding in a given molecule and demonstrate the complications involved. For example, examination of a series of electron-density diagrams corresponding to varying amounts of internal rotation of a molecule which does not exhibit a high degree of symmetry with respect to the bond axis of rotation has shown that in such cases one can indeed speak of twisting of the electronic distributions making up the bond. This behavior is demonstrated by the valence orbitals of diphosphane. As shown in Figure 9, an H_2PPH_2 orbital[30] which is π-like with respect to the P—P bond in the eclipsed and staggered forms of diphosphane, may be considered as being a twisted π bond in the intermediate rotameric forms in which the pair of hydrogen atoms on each phosphorus are no longer present in relative positions which would allow "normal" π-bonding[5].

In discussing the contribution of d orbitals to the chemistry of atoms of the Third Period, chemists have customarily differentiated sharply between $p_\pi \rightarrow d_\pi$ charge transfer and the polarization of d orbitals. When electron-density plots are made for most molecules (even those in which $p_\pi \rightarrow d_\pi$ charge transfer is to be expected), it turns out that electron-density plots of the entire molecule, the valence shell, or, to a lesser extent, the various individual orbitals as calculated with d character being allowed or disallowed to the charge-accepting atom differ only slightly. However, by subtracting the point-by-point electron density in, say, the no-d plot from that in the plot where d character was incorporated, one obtains an electron-density-difference plot in which the only features are the small changes from the one to the other of the electron-density distributions being compared.

For example, in the case of the chlorosilane molecule, *Howell* and *Van Wazer* carried out four SCF calculations[31]: One corresponding to d orbitals being disallowed, another with appropriate d functions being incorporated into the mathematical description of the silicon atom, and a third with the d functions being alloted to the chlorine. The fourth case corresponded to d character being allowed to both the silicon and the chlorine atoms. The usual kind of numerical data reported from SCF calculations are presented for this molecule in Table 1, from which it should be noted that the greatest stabilization upon adding d character to the molecule results from placing the d function on the silicon rather than on the chlorine. This stabilization is reflected in both the Si—Cl and Si—H overlap charges. The Mulliken charge on the silicon atom is particularly affected by putting the d orbital on the silicon, going from the no-d value of +0.3 to −0.3 upon adding d character to the silicon in this basis set. These findings would customarily be interpreted to show that, upon allowing d character to the silicon, there is a large transfer of charge to that atom; whereas, when it is allowed to the

Charge on H	− 0.06	+ 0.09	− 0.08	+ 0.08
S-Cl overlap	0.61	0.86	0.65	0.89
S-H overlap	0.69	0.81	0.70	0.81

[a] The binding energy is the difference between the sum of the total energies of the constituent atoms and the total molecular energy, with 1 a.u. = 27.21 eV and no correction for electron correlation.

chlorine, the charge is transferred away from that atom. The casual interpretation is that the d orbitals on silicon are splendidly adapted to collecting charge; whereas d character on the chlorine leads to a small amount of charge loss, primarily to the hydrogen atoms. The standard code words for these observations are p→d transfer involving the silicon d orbitals and a simple polarizing effect (accompanied by little charge transfer) due to the chlorine d orbitals.

antibonding. Orbitals 3e and 4e are characterized by Si—Cl π bonding and antibonding, respectively. The data of this table also give support to the accepted picture of the effect of adding d character to either the silicon or the chlorine atom.

Figures 10a and 10b show electron-density-difference plots for the total molecule and for orbitals 9a and 4e. These orbitals were chosen because they exhibit a particularly large

Table 2. Interatomic charge transfer in each molecular orbital of chlorosilane (H_3SiCl) from adding d character.

Orbital	Predominant character	Charge transfer upon adding d to Si atom	Charge transfer upon adding d to Cl atom
4e	Cl $n_{\perp}$ + (Si—Cl)π^*	Cl $\xrightarrow{0.211}$ Si $\xrightarrow{0.116}$ 3H	3H $\xrightarrow{0.015}$ Si $\xrightarrow{0.014}$ Cl
9a	(Si—Cl)σ + Cl $n_{\parallel}$	Cl $\xrightarrow{0.033}$ Si $\xleftarrow{0.026}$ 3H	Cl $\xleftarrow{0.011}$ Si $\xrightarrow{0.007}$ 3H
3e	(Si—H)σ + (Si—Cl)π	3H $\xrightarrow{0.292}$ Si $\xrightarrow{0.084}$ Cl	Cl $\xrightarrow{0.005}$ Si $\xrightarrow{0.052}$ 3H
8a	(Si—H)σ + (Si—Cl)σ^*	Si $\xrightarrow{0.006}$ 3H	Cl $\xleftarrow{0.012}$ Si $\xrightarrow{0.003}$ 3H
7a	(Si—Cl)σ + Cl $n_{\parallel}$	Cl $\xrightarrow{0.006}$ Si $\xrightarrow{0.002}$ 3H	Si $\xrightarrow{0.022}$ Cl

In Table 2, the calculated interatomic charge transfer is shown for the individual H_3SiCl valence orbitals due to adding d character to either the silicon or the chlorine atom. Note that the second column of this table indicates the predominate character of each orbital with respect to the Si—Cl and Si—H bonds, as well as to the chlorine lone pairs. The lone pairs are indicated by the letter n followed by either a $\parallel$ or a $\perp$ sign to indicate that the lone-pair charge being discussed is disposed along the C_{3v} axis of the molecule or on either side of this axis respectively. The bonding character of each molecular orbital is readily seen in its electron-density plot, although some additional information can be obtained from the numerical data. Note in Table 2 that orbital 7a exhibits appreciable Si—Cl σ bonding, whereas 8a shows Si—Cl σ amount of charge transfer, according to either the full set of difference plots or the charge-transfer data of Table 2. In order to orient the reader, regular electron-density-distribution plots are presented in Figure 10c. These plots for the two selected molecular orbitals clearly demonstrate the π anti- or nonbonding character of orbital 4e with respect to the Si—Cl bond and the σ character of orbital 9a with respect to this bond.

It seems apparent from inspection of Figure 10 that allowing d character to either the chlorine or the silicon gives rather similar charge rearrangements; except for the fact that, when the d orbitals are on the silicon, the interaction between this atom and its neighboring hydrogens is also considerably modified. The net effect of adding d character to either the

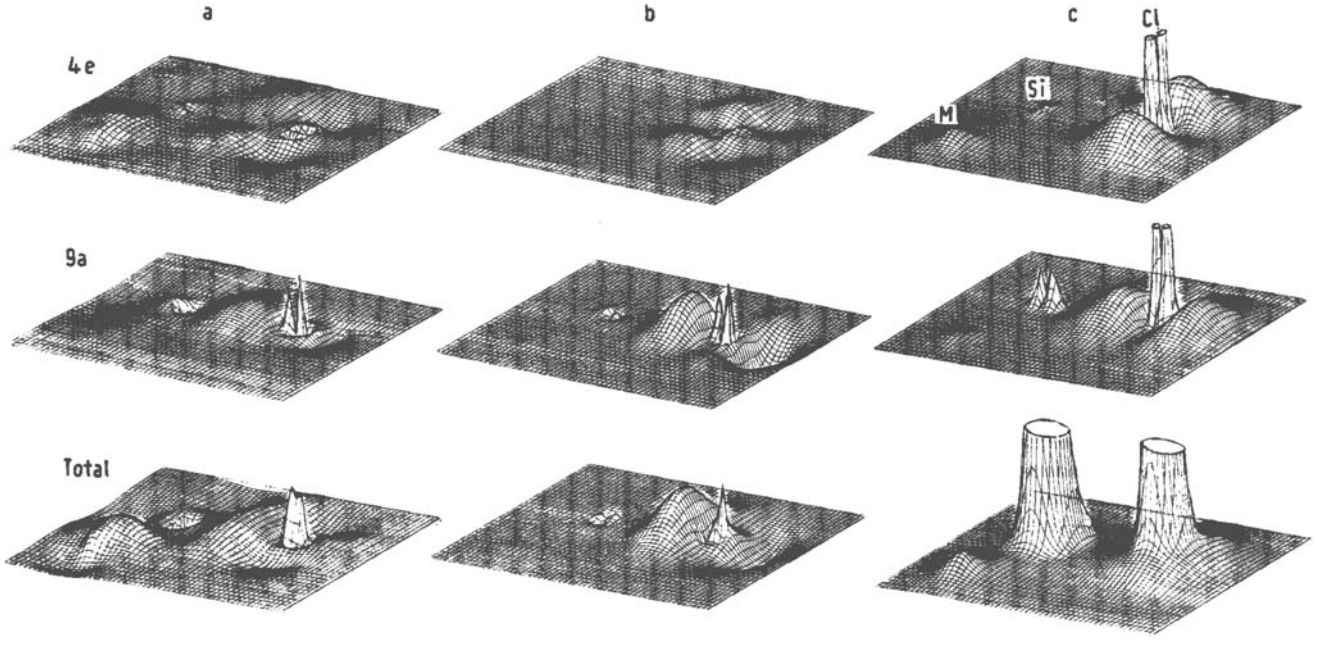

Fig. 10. Difference plots showing the effect of allowing d character to a) the silicon and b) the chlorine atoms in chlorosilane for two selected valence-shell orbitals and the total molecule. c) Cross-sectional electron-density plots at a fifth of the magnification employed in the difference plots (not including d orbitals). The molecule is so arranged that the reference plane passes through the silicon and chlorine atoms as well as one of the hydrogen atoms.

silicon or the chlorine is to move charge from the lone-pair region of the chlorine atom to the Si—Cl bonding region, and thereby to reduce the polarity of the molecule, as indicated by the respective calculated dipole moments. Therefore, it seems clear that the mathematical description of the H_3SiCl molecule in the limited (sp) basis set employed is constrained so that there is too much charge in the chlorine lone-pair region unless d functions are employed somewhere. The real purpose of supplementing a basis set with orbitals exhibiting more angular degrees of freedom is simply to lessen the constraints placed on the mathematical description so that shape of the electronic distribution will approach its optimum value. It is clear from the chlorosilane example discussed here that the language used to describe the charge shifts is in many respects inconsequential, being based on arbitrary constructs having only tenuous connection with what appears to be physical reality.

7. Quantum Calculations for Everyone

Rightfully or wrongfully, chemists have directed considerable attention to relating their experimental findings to electronic structure, even though most of the concepts of electronic structure thus employed have been qualitative and often quite speculative. Even today, much of the chemical jargon and published remarks dealing with electronic explanations of chemical effects are sufficiently vague to be rather meaningless. As computers become more efficient and more readily available, there will probably be an increasingly general use of quantum-chemical calculations. Another advance that will make such calculations cheaper and much more readily available lies in the use of trustworthy mathematical approximations in addition to those approximations presently employed in the standard calculations. We feel that the pseudopotential method is particularly advantageous in this respect. Already by this method a vast group of inorganic structures based on atoms from all over the Periodic Table have now become accessible to quantum calculations—calculations which had previously been pretty well restricted to molecules based on atoms from the first to the third period.

We believe that the chemists carrying out quantum calculations, in cases where the calculational details are of peripheral interest, would be well advised to utilize electron-density plots to aid in understanding the calculated results. Our book[5] on this subject should be a guide in this respect. In any event, only time will tell as to whether a more general use of quantum calculations across the broad spectrum of pure and applied chemistry will result in useful advances in either practical work or conceptual organization. There is a significant probability that more general use of these calculations will result in widespread disillusionment, a situation which will be of social value if this attitude extends to the present emphasis on relating physical events to mere speculations concerning electronic structure. On the other hand, an increase in the availability and reliability of quantum calculations may turn out to be really useful and to have a meaningful impact on the future development of chemistry. We hope the latter alternative will come true.

Solid-State Photochemistry—A Method of Generating Unusual Valence States

By Gerhard Lehmann[*]

High-energy radiation can give rise to pairs of complementary defects in nonmetallic solids by the transfer of electrons between various types of atoms. These "color centers" which are generally paramagnetic, can usually be described as unusual valence states of an element. They are destroyed by heating and in most cases regenerated by renewed irradiation. In a heteropolar solid the formation of color centers usually leads to cancellation of point charges due to foreign ions of other valence or to vacancies. This is shown by the examples of kunzite, brazilianite, smoky quartz, and citrine; the most important methods for the structural elucidation of color centers are also described. Application of the principle of charge balance opens up possibilities for the production of unusual valence states, *e.g.* Al^{2+}, F^{2-}, Fe^{4+}, and O^{-}. Moreover, the type of the color center often permits far-reaching conclusions to be drawn about the defect structure of real crystals, which could hardly be clarified in other ways.

1. Basic Features of the Method

Ionizing radiation can cause three types of permanent changes in a solid.

a) The most drastic change is of course photolysis or radiolysis, and thus complete and irreversible decomposition. It is characteristic of certain compound classes, in particular of many organic compounds, which sometimes undergo characteristic changes utilized for preparative purposes[1].

b) Another possibility is a displacement of individual atoms from their equilibrium positions, *e.g.* with the formation of vacancies and interstitial atoms. Except for the alkali-metal halides, in which this takes place even with ultraviolet radiation[2], particle irradiation of higher energy is necessary in other classes of compounds.

c) Finally an electron can be transferred from a donor $D^{(-)}$ to an acceptor $A^{(+)}$. In accordance with the formal equation (1)[**]:

$$D^{(-)} + A^{(+)} \xrightarrow{h\nu} D + A \qquad (1)$$

this process usually leads to the formation of two paramagnetic defects, of which D is described as a hole center and A as an electron center. Whereas b) is a mainly physicomechanical process, which to a large extent obeys the laws of classical mechanics, c) comprises a photochemical redox process in which $D^{(-)}$ is oxidized and $A^{(+)}$ is reduced. The pioneering work of *Pohl* and his associates led to these color centers' being regarded in Germany as the domain of the physicist, and it has often been assumed that their formation is restricted to the alkali-metal halides, the classical representatives of ionic crystals. In reality, color centers can be produced in practically all crystalline or amorphous insulators. The color of many minerals is due to color centers. Among the quartzes alone we find three examples: the violet color of amethyst, the dark brown of smoky quartz, and the greenish yellow of natural citrine. The brown color of fired amethyst[3,4] is of different origin.

The basis of the photochemical redox reaction (1) is kinetic in nature: electromagnetic radiation of sufficiently high energy liberates electrons from all types of atoms. These electrons can leave the solid if they are produced sufficiently close to the surface. Photoelectron spectroscopy (XPS or ESCA = Electron Spectroscopy for Chemical Analysis)[5-8] provides a means of determining the binding energies of the electrons and their changes dependent upon valence and chemical environment. If an electron is produced in the interior of the solid, it can only migrate over a short distance before being captured by an atom—sometimes one of a different kind. As soon as $D^{(-)}$ has released its electron, it must thus compete for it with $A^{(+)}$. The situation can be visualized by considering a board with two types of depressions, some deep and narrow, some shallow and wide. If ball bearings are dropped on this board, their diameter being smaller than that of the narrow depressions, then more of them will be found in the wide than in the narrow depressions. This relationship will only be reversed if the board is shaken so vigorously that the ball bearings are repeatedly forced out of the shallow depressions. Translating these concepts into photoelectrons in a solid substance, we can therefore say that $A^{(+)}$ must have a potential well broader than that of D (*i.e.* a higher electron capture cross-section). Since, however, $A^{(+)}$ binds the captured electrons only loosely, the potential well of $A^{(+)}$ is always flatter than that of D. Therefore, reaction (1) can in most cases be reversed by heat (which corresponds to shaking of the board), and often also regenerated selectively by light:

$$D + A \xrightarrow{\text{Activation}} D^{(-)} + A^{(+)} \qquad (1a)$$

Subsequent irreversible reactions may occur particularly if neutral atoms are formed by the electron transfer (by loss of electrons from anions X^- or by electron capture by univalent cations M^+). The colloidal sodium in blue rock salt is a known example of such subsequent reactions: the primary products are electrons in anionic vacancies, the known F centers, and neutral Cl atoms (which attach themselves to the Cl^- in

[*] Prof. Dr. G. Lehmann
Institut für Physikalische Chemie der Universität
Schlossplatz 4, D-4400 Münster (Germany)

[**] The charges in parentheses on the left-hand side of equation (1) symbolize effective charges with respect to the lattice considered as neutral. Their significance will become apparent in what follows.

the lattice). Over geological periods the chlorine is lost as molecular Cl_2 and the electrons unite with the Na^+ ions to give colloidal metal particles:

$$V_{Cl} + Cl^- \xrightarrow{h\nu} e^-(Cl) + Cl^0 \qquad (2)$$
$$\downarrow Na^+ \qquad \downarrow$$
$$Na \qquad \tfrac{1}{2}Cl_2$$

(V_{Cl} = anionic vacancy; $e^-(Cl)$ = F center)

The governing principle in the formation of color centers by ionizing radiation in heteropolar solids is the balancing of point charges; this is why effective charges are given on the left in eq. (1). The formation of the F centers in NaCl is an example of this charge equalization, since a vacant anionic site is a positive point charge (and the Cl atoms are formed next to negatively charged vacant cationic sites). In oxides there are foreign atoms of different valence that are more important than the intrinsic vacancies as carriers of these point charges.

The great majority of color centers metastable at room temperature are formed according to this principle, as is found from countless examples. Thus, beryllium oxide doped with trivalent aluminum forms bivalent aluminum on irradiation[9], and on doping with fluoride the otherwise unstable fluorine dianion F^{2-} is obtained[10]:

$$Al^{3+}(\underline{Be}O) \xrightarrow{h\nu} Al^{2+} \qquad (3a)$$

$$F^-(Be\underline{O}) \xrightarrow{h\nu} F^{2-} \qquad (3b)$$

(It should be remembered that gaseous O^{2-} is also unstable and loses an electron spontaneously.) The foreign atom must be situated at a lattice site of the (underlined) host ion and not at an interstitial site if it is to be photochemically active in this way. Charge composition for incorporation of impurities with valence states different from the host ions can occur in several ways, *e.g.* in the case of incorporation of lower valence cations or higher valence anions through anion vacancies, through hydrogen in the form of OH^- groups in place of O^{2-}, or through simultaneous incorporation of a higher valence cation and a high valence anion and *vice versa*. In natural crystals a combination of these possibilities is likely to prevail, but in many instances the mechanism of charge compensation is still unknown.

It is not possible to produce bivalent lithium by doping of BeO with this metal; instead, a univalent negative oxygen is formed next to the Li^+ ion (in the language of physics, a defect electron is placed on an oxygen ion)[11,12].

$$Li^+(\underline{Be}O) \xrightarrow{h\nu} (Li^{2+}—O^{2-}) \longrightarrow Li^+—O^- \qquad (3c)$$

It can be assumed that bivalent lithium is in fact first formed, but changes to Li^+ by a very rapid electron transfer from oxygen to lithium, in which about 50 eV of energy[*] is liberated. The bracketed intermediate is thus regarded as a very highly excited state of the hole center D. Such subsequent relaxation processes can throw an obscuring cloud over much charge compensation.

Ions with empty d or f shells, such as Ti^{4+}[13], V^{5+}[14], and La^{3+}, apparently always have a large electron capture cross-section (*i.e.* they are good photochemical oxidizing agents) independently of their environment. Thus, their introduction often produces color centers whose formation contradicts the charge equalization principle, as the following examples show:

$$Ti^{4+}(\underline{Si}O_2) \xrightarrow{h\nu} Ti^{3+} \qquad (4a)$$

$$V^{5+}(NaAl_3(\underline{P}O_4)_2(OH)_4) \xrightarrow{h\nu} V^{4+} \qquad (4b)$$

Knowledge and planned application of these principles makes it possible to generate unusual valence states that are often unobtainable in any other way. These reactions have so far been hardly utilized; apart from preparative applications, conclusions about disorder in real crystals can be drawn from the structure of the color centers.

2. Limitations of the Method

Although the examples given above are most impressive, there are limitations to the method apart from the relaxation to an energetically more favorable state as shown in reaction (3c). To be certain of a sufficiently long life of the color center, the potential well of A must be deep enough in comparison with the thermal energy kT and similarly the bottom of the potential well of D must be sufficiently separated from the valence band. If these conditions are not fulfilled, the color centers will be destroyed by recombination of the electrons with defect electrons. This recombination can occur by excitation of an electron from the electron center A into the conduction band or excitation of an electron from the valence band into the hole center D and subsequent migration of the electron (or the hole in the valence band) to the complementary center. The energy relationships are illustrated schematically in Figure 1. The principle of charge compensation is barely perceptible in the structure of color centers stable

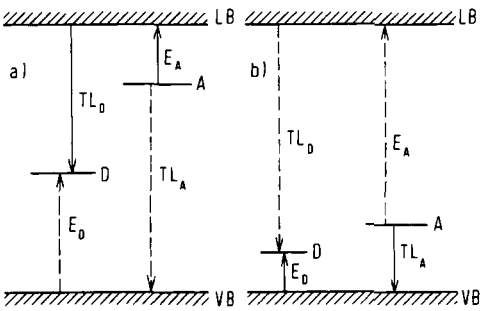

Fig. 1. Schematic representation of the position of defect electron centers D and electron centers A between the valence band VB and the conduction band LB. a) On thermal destruction of the color centers (recombination), electrons are excited from A into the conduction band, since the activation energy $E_A < E_D$. Thermoluminescence TL_D is then possible. b) On recombination electrons are excited out of the valence band, since $E_D < E_A$. The thermoluminescence corresponds to TL_A. Case b) occurs with the color centers in smoky quartz and citrine (see Section 5).

[*] 1 eV ≙ 23 kcal/mol or about 100 kJ/mol.

only at very low temperatures, because here very shallow potential wells are already effective.

Since foreign ions of different valence cannot be included in any desired concentration, the color centers are always produced in a dilute state. The attainable concentrations of such foreign ions are usually around 0.1 mol-% or below, and often much lower still on crystallization from solutions. Only rarely, as in the case of ammonium halides, can concentrations in the percent region be attained. In the modifications of ammonium halides of CsCl structure, ions such as Mn^{2+} and Cu^{2+} occupy an interstitial position between two NH_4^+ sites, so that they are surrounded by four halide ions in square-planar configuration. Neutral water molecules can be included in place of the missing ammonium ions, so that the transition-metal ions have a compressed octahedral coordination, as investigations of the electron spin resonance[15-17] and optical absorption[18-20] have shown.

Electron and defect electron centers must be separated from one another by at least about 50 Å, for otherwise spontaneous recombination, in some circumstances very slow, may occur by the quantum-mechanical tunneling process. In contrast to the migration of electrons by way of the conduction or valence bands, the tunneling process is not thermally activated and thus cannot be prevented by cooling.

An example of tunnel recombination is provided by the semiprecious stone kunzite, a lithium aluminum silicate of composition $LiAlSi_2O_6$ (spodumene) containing at the most 1 % of manganese (see Section 3). Part of the initially bivalent built-in manganese obviously passes on irradiation through a trivalent state (rose-violet), which occurs in most of the natural crystals, into the tetravalent state (green)[21] that is rarely observed in nature. Part of the tetravalent manganese (5 % was measured in one crystal)[22] decomposes over a period of a few days to the trivalent state with the emission of an intense yellowish luminescence characteristic of Mn^{2+} in sixfold coordination. The intensity of this emission decreases only slowly with time (in inverse proportion to the square root of the time), and is barely changed when the crystal is cooled to liquid-nitrogen temperature[21]. As shown in Figure 2, there is no systematic temperature variation of the decomposition rate between 16 and 86 °C.

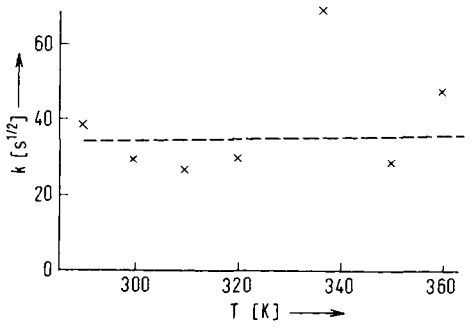

Fig. 2. Rate constants k for spontaneous decomposition of the green color centers (Mn^{4+}) in kunzite. The decomposition follows the rate equation

$$I = I_0 \cdot k/(k^2 + t)^{1/2}$$

where I = luminescence intensity is a measure of the rate. Within the limits of experimental error it was not possible to establish any temperature dependence of the rate constants.

Even if, as in this example, foreign ions can be included in higher concentrations, because of the necessary spatial separation between the electron and defect-electron centers their concentrations are limited to relatively small values, typically about 100 ppm. With foreign ions of different valence the preservation of neutrality requires further defects, and these are normally also point charges in the lattice. Thus, centers complementary to each other can be formed, as for example in the case of the alkali-metal halides: anionic vacancies take up electrons and form F centers as electron centers, and defect-electron centers (Cl^0) are formed directly next to the cationic vacancies. A condition for this is again the minimal spatial separation. Either the charge equalization must take place at some position further removed and not next to the foreign ion, or the defect must be able to migrate out of the neighborhood of the foreign ion immediately after the electron transfer, the absence of electrostatic attraction thus being a favorable prerequisite for charge compensation. Thus, alkali-metal ions present in quartz next to aluminum can diffuse away at room temperature in the formation of smoky quartz centers on the aluminum[23]. Hydrogen in the form of OH groups cannot do this in the neighborhood of aluminum, and this is probably why Al—H defects cannot be changed into smoky quartz centers[24]. The minimal spatial separation is one reason why introduction of foreign ions of different valence does not always lead to the formation of color centers at or next to these foreign ions.

In Sections 3 to 5 it will be shown in greater detail on selected examples how solid-state photochemistry can be used to produce unusual valence states and how conclusions about the defect structures of real crystals can be drawn from the structure of color centers formed. Since little is generally known about these possibilities, so that they have not been widely utilized, the examples must be drawn from nature, and they are chosen so that emphasis of each brings out the advantages and the limitations of a particular method of investigation.

3. Color Centers in Kunzite

The rose-violet or green color centers in kunzite (spodumene $LiAlSi_2O_6$) are obtained only in the presence of manganese (present in the bivalent state), so that manganese must be involved in the formation of the color centers. The depth of color and the contents of trace elements were correlated with one another some time ago for the allochromatic minerals, *i.e.* minerals variously colored by foreign atoms, but often and particularly where the measurements had been most exact, the proportionality between the content of foreign atoms and the depth of color is not very good. Today we can easily account for the failure of this correlation. On the one hand complementary defects $D^{(-)}$ and $A^{(+)}$ are needed for the formation of color centers, and it is possible that only one kind of defect-electron centers but several kinds of electron centers (or *vice versa*) may be present in conditions that change from crystal to crystal. On the other hand the foreign atoms are often present in various arrangements, only one of which is capable of forming color centers.

In kunzite a stepwise transfer of a total of two electrons takes place[21], whence it seems reasonable to assume the

formation of higher valence states of the manganese. This assumption can be tested by means of the optical spectra of the rose-violet and the green color centers. Since the ligand field theory predicts within narrow limits the number and the position of the bands for these valence states as a function of the geometry of the surrounding anions, and since we can also estimate the intensities from the wealth of experience, we can therefore decide which positions in the lattice can be occupied by the color-center-forming manganese. The manganese can occupy the lattice sites of the lithium, the aluminum, or the silicon. In spodumene lithium and aluminum are sixfold coordinated in distorted octahedral symmetry, whereas the silicons are surrounded by oxygens in distorted tetrahedra. Absorption spectra of the green color centers are shown in Figure 3. These spectra were recorded in linear polarized light. The pronounced anisotropy of the intensity proves that we are dealing with oriented and thus atomically distributed absorption centers of low symmetry.

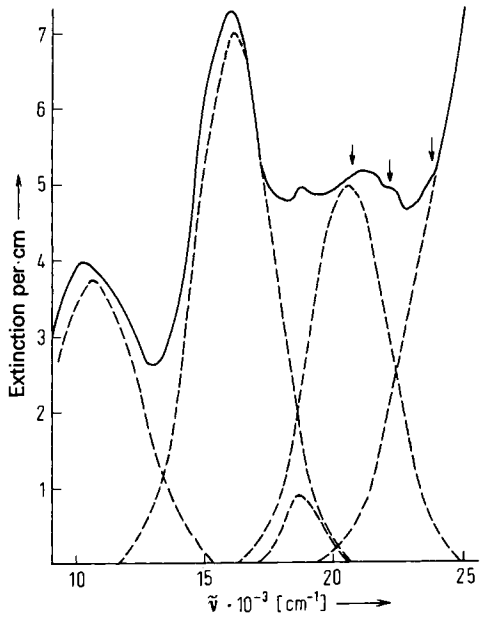

Fig. 3. Optical absorption of the green color centers (Mn^{4+}) in kunzite, measured at 78 K with linearly polarized light, whose electrical vector is oriented parallel to the crystal *a*-axis. Other orientations give the same bands in other intensity ratios. The arrows indicate Mn^{2+} absorptions.

The spectrum in Figure 3 cannot be explained on the basis of tetravalent manganese in approximately octahedral coordination because, since Mn^{4+} is isoelectronic with Cr^{3+}, the Mn^{4+} spectrum should be analogous to the Cr^{3+} spectrum, except that due to the greater ligand field strength parameter of manganese(IV) the bands should be at higher wave numbers compared with chromium(III). Thus, with octahedral coordination the first moderately intense (spin-allowed) band should occur at about 23000 cm^{-1}[25]. The spectrum can, however, be explained very well by a distorted tetrahedral coordination of Mn^{IV}[21]. This would then indicate that at least part of the bivalent manganese is present at the lattice sites of the silicon. Because of the differences in ionic radii and valence states this at first appears surprising, but it has been demonstrated in garnets by Mössbauer investigations that bivalent iron to some extent occupies the tetrahedral sites of the silicon[26]. The trivalent manganese (rose-violet) must then also be present in distorted tetrahedral coordination. The spectrum shown in Figure 4 can be explained on the basis of an approxi-

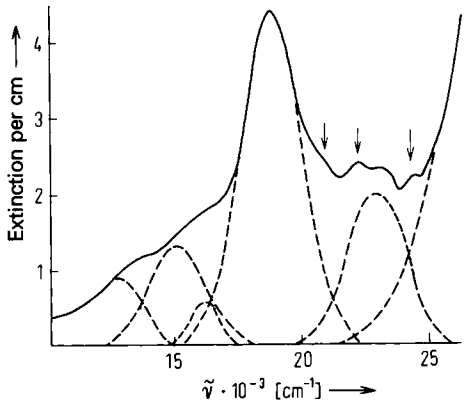

Fig. 4. Optical absorption of the rose-violet color centers (Mn^{3+}) in kunzite. Measurement conditions as in Fig. 3. The arrows indicate Mn^{2+} absorptions.

mately octahedral or a distorted tetrahedral arrangement of Mn^{III}, and was evaluated by *Recker et al.*[27] as an indication of Mn^{III} at the lattice sites of the aluminum. This ambiguity has its origin in the properties of the d^4 configuration, which (like the d^9 configuration of bivalent copper) leads to an orbit-degenerate ground state in octahedral or tetrahedral coordination. Deviations from the cubic symmetry remove this degeneracy, at least partially; the associated energy gain should cause spontaneous distortion. This Jahn-Teller effect[28, 29] has been demonstrated in a considerable number of compounds[30]. It also stops compounds such as $Cu^{II}M_2{}^{III}O_4$ and $M^{II}Mn_2{}^{III}O_4$ from crystallizing in the cubic spinel structure, at least at low temperatures.

Figure 5 shows that splitting of the ground state leads to an average transition energy, which is higher than can be expected from the magnitude of the ligand field strength parameter *Dq*. The ratio of the excitation energies of distorted tetrahedral and of octahedral complexes of these ions is thus distinctly greater than the ratio (about 0.6) of *Dq* values that can be obtained from electrostatic calculations with consideration of the approximately 6% shorter bond length in the tetrahedral case.

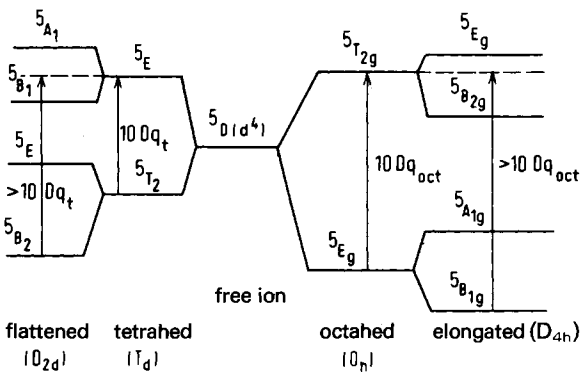

Fig. 5. Energy levels of Mn^{3+} in octahedral and tetrahedral symmetry and with additional (tetragonal) distortion.

The position of the more intense electron-transfer bands at higher energies can also be estimated within narrow limits by means of the concept of optical electronegativities[31]. The position of the absorption edges for the rose-violet and green color centers agrees well with the values calculated for Mn^{III} and Mn^{IV}[21].

On grounds of intensity the ligand field spectra of lower-valence transition metal ions are generally unobtainable as color centers. The optical spectra can never be regarded as proof of a specific structure of the color centers, although some structures can be excluded and others made probable.

Electron paramagnetic resonance is extremely important for the structural elucidation of color centers. The deviation of the g factors from the value for the free electron can be used to yield information on the position of the excited state by means of eq. (5) (where n is a small integer):

$$\Delta g = n \cdot \lambda / \Delta E \qquad (5)$$

This information can then be compared with the optical spectrum. The spin-orbit coupling parameter λ is known within narrow limits. Since according to Hund's third rule it changes its sign with a half-filled shell, the direction of the deviation shows whether an electron center with $g < g_{free}$ or a defect-electron center with $g > g_{free}$ is present. Further information can be provided by hyperfine or superhyperfine[*] splitting of the signal; this splitting arises by interaction of the electron spin with the nuclear angular momentum I on the paramagnetic atom or in its environment. The number m of lines gives the magnitude of the nuclear angular momentum from $m = 2I + 1$; if there are several equivalent nuclei, one obtains the number of lines corresponding to the total angular momentum, in intensity ratios given by binomial coefficients, as is known for organic radicals[32]. Finally, the magnitude of the splitting is determined by the electron distribution; for example, the isotropic fraction is proportional to the s-electron density on the nucleus with angular momentum I. In a single crystal these quantities are in general anisotropic, so that information is also obtained about the orientation of the centers in the lattice. A very good review of color centers in inorganic substances, with findings up to about 1966, has been given by *Atkins* and *Symons*[33], who also treat the principles of EPR spectroscopy more rigorously.

Neither trivalent nor tetravalent manganese could yet be detected in spodumene by EPR, but it was possible to show the participation of Mn^{II} in the formation of the green color centers. Thus, on the conversion of the green into the rose-violet color centers the intensities of the EPR spectra of Mn^{II} increase by a few percent, while for Fe^{III} even an increase of about 20 % was observed[22]. This is explained most simply by assuming that both bivalent manganese and trivalent iron can act as acceptors $A^{(-)}$, *i.e.* are partially converted into univalent manganese or bivalent iron (though the EPR spectra of these species could only be observed at low temperatures).

In the case of iron in amethyst it was concluded some years ago from the optical spectra and the changes in the EPR spectra of trivalent iron that the cause of the coloration was tetravalent iron at the sites of the silicon (and bivalent iron in interstitial positions)[3]. Recently an EPR signal was observed from a center with total spin $S = 2$[34], which could arise from either bivalent or tetravalent iron; the small line width at room temperature makes it extremely improbable that bivalent iron is the cause.

A direct proof of the presence of tetravalent manganese in kunzite would be very interesting, because here there appears to be a tetrahedral low-spin complex with $S = 1/2$[21] and because Mn^{IV} has not yet been proved with certainty to exist in tetrahedral coordination[35]. Because of the large parameter Dq, the ligand field stabilization energy (greater even than for Cr^{III}) favors octahedral over tetrahedral coordination by about 50 kcal/mol. If Mn^{II} is present and is photochemically converted into Mn^{IV}, there is no point in asking which coordination is favored by Mn^{IV} during the growth of the crystal; it remains to be discovered whether nature selects the route *via* Mn^{II} outlined above.

4. Color Centers in Brazilianite

Brazilianite is a sodium aluminum hydroxyphosphate of composition $NaAl_3(OH)_4(PO_4)_2$, which crystallizes in the monoclinic space group $P2_1/c$[36]. It occurs in nature in well-formed green to brown crystals, the color being due at least indirectly to color centers. Brazilianite is composed of elements which, except for oxygen, consist of only one isotope with nonzero nuclear angular momentum I: ^1H and ^{31}P with $I = 1/2$, ^{23}Na with $I = 3/2$, and ^{27}Al with $I = 5/2$. Thus, in every case the EPR signals should exhibit superhyperfine splitting, which facilitates elucidation of the structure.

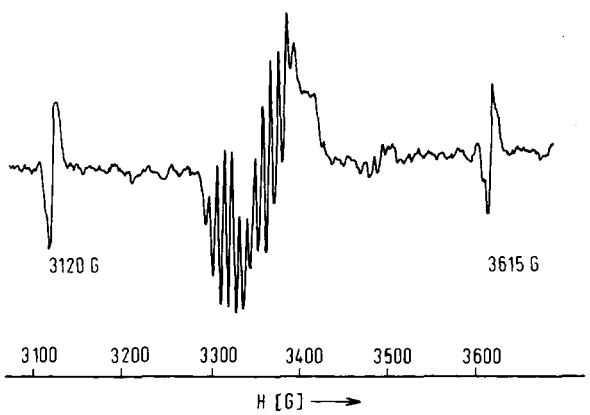

Fig. 6. Section of the EPR spectrum of irradiated brazilianite. The multiplet in the middle is derived from hole centers $Al^{3+}—O^-—P^{5+}$ and the two outer signals are due to atomic hydrogen. Microwave frequency 9.6 GHz, c- and b-axes of the crystal perpendicular to the magnetic field.

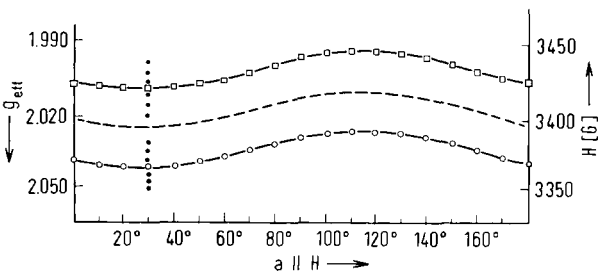

Fig. 7. EPR spectra of the defect electron centers in brazilianite on rotation around the b-axis. All the shf lines are indicated (●) only for one orientation, for other orientations only the center-point of the sextets (□ and ○). The broken line shows the center-points of doublet splitting.

[*] Known as the hf or shf structure.

A section of an overall spectrum is given in Fig. 6; a signal with a total of twelve lines can be seen in the middle. Figure 7 shows how the position of this signal changes with rotation around the twofold axis of the crystal. It consists of two sextets separated by about 50 gauss, the midpoint being at g factors above the value for a free electron (2.0023). Since the sextet splitting can arise only from the aluminum (no other nuclei with $I = {}^5/_2$ are present, according to trace analysis, in sufficient amounts), we must have here an O^-—Al^{3+} center in which the unpaired electron has a small electron density at the aluminum nucleus. The additional doublet splitting can originate from a phosphorus atom or a proton. A proton can almost certainly be ruled out, for two reasons: In the first place, because the electronegativity of OH is greater than that of O^-, a defect electron on an OH group would not be stable; secondly, the splitting may amount only to about 20 gauss. Then an Al^{3+}—O^-—P^{5+} center must be present. Remaining doubt could be removed by replacement of the hydrogen by deuterium, which with its $I = 1$ should give triplet splitting.

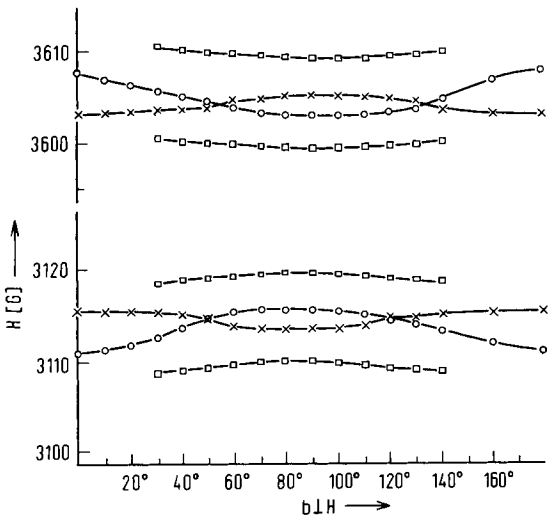

Fig. 8. EPR spectra of the hydrogen atoms in brazilianite on rotation around the c-axis. The atomic hydrogen is present in three arrangements; the additional doublet splitting in one arrangement (□) indicates the proton of an OH group.

In Figure 6 two other signals can be recognized, with a separation of about 500 gauss. Figure 8 shows that these must originate from atomic hydrogen (for which the hfs splitting of about 500 gauss is characteristic) at three lattice positions.

The structure of these color centers is thus in principle clarified, as is that of the previously mentioned V^{4+}, which gives an octet as a result of splitting due to ^{51}V with $I = {}^7/_2$. It is more difficult to say from which defects the color centers are formed. Atomic hydrogen is not found in native crystals; it is formed by artificial irradiation and is destroyed already at 160 °C, whereas the defect electron center Al^{3+}—O^-—P^{5+} is stable up to 190 °C. Atomic hydrogen cannot be formed from the stoichiometric OH groups of the mineral; this is shown by experiments in which the hydrogen was repeatedly removed by heating and regenerated by irradiation. It was then found that one of the hydrogen spectra appeared increasingly weakly, which can only be explained by an impoverishment of the crystal in this hydrogen. Here then is a case where electron centers and defect electron centers are destroyed separately and, at least in part, irreversibly.

The twelve oxygen atoms of the empirical formula have three different coordinations: 2 Al and 1 H (4 O), 2 Al and 1 P (2 O), and one each of Al, P, and Na (6)[36]. Only the last two coordinations come into question as carriers of defect electrons. Thus, in the second, one Al could be replaced by Mg or Zn (other bivalent ions are excluded by trace analyses, except for Fe^{2+} which, however, passes into Fe^{3+}). An additional shf splitting by ^{25}Mg or ^{67}Zn with $I = {}^5/_2$ and 10 % abundance (4.1 % for ^{67}Zn) would then be observed, which is not the case. Furthermore, the defect electron spectrum can also be produced in (polycrystalline) synthetic brazilianite not doped with magnesium or zinc. This possibility therefore appears unlikely and we must consider a partial replacement of sodium by hydrogen in the form of OH groups and formation of the color centers by:

$$Al^{3+}—\overset{\overset{H}{|}}{O}^-—P^{5+} \xrightarrow{h\nu} H + Al^{3+}—O^-—P^{5+} \qquad (6)$$

The formation of atomic hydrogen in a number of other phosphates[33] makes this kind of disorder plausible—it corresponds to partial formation of an acid phosphate. Its extent should increase with decreasing pH of the solution from which the crystals are grown. Tests should be carried out on model substances to see whether the amount of atomic hydrogen produced depends on pH.

5. Color Centers in Smoky Quartz and in Citrine[37]

In spite of the different colors of smoky quartz (brown-black) and citrine (yellow) their color centers are closely related; the cause of the difference is unknown. Comparative experiments on their decomposition kinetics have, however, contributed considerably to solution of this problem.

In smoky quartz defect electrons are present on oxygen next to a substitutional aluminum[23]; the principle of charge equalization is thus also recognizable here. The defect electrons can be exchanged at relatively low temperature between the oxygen ions of the AlO_4 tetrahedra[*][38]. It is thus understandable why the line width of the EPR signals increases above 20 K; they are therefore not observable at room temperature. Only one of the absorption bands in the visible region ("A_3 band" at 23800 cm^{-1}) originates from the smoky quartz centers[39]; the origin of the longer-wave A_1 and A_2 bands at 14900 and 20600 cm^{-1}, respectively, is still unknown. According to *Schirmer*[40], the light-induced transfer of the defect electron between two equivalent oxygen ions is the cause of the A_3 band. This model is in agreement with all previous experience. If, as in the case of the hole center in brazilianite, the defect electron is localized on one particular oxygen (as indicated by the sharpness of the EPR spectra at room temperature), then there will be no absorption bands in the visible region, because excitation within the 2p level of oxygen is Laporte forbidden; thus, only weak absorption can be obtained there, and other excitations

[*] In fact the point symmetry of the silicon in α-quartz is only C_2, so that there are two pairs of oxygens with slightly different bond lengths.

occur with much higher energies. If, however, the defect electron can be exchanged between oxygen ions of the same valence, as in the O^-—Li^+ center in BeO[11,12] and probably also in the felspar sanidine[41], then we find broad and intense absorption bands in the visible region of the spectrum.

In the color centers of natural citrines defect electrons are also adjacent to an aluminum[42]. This is shown, *inter alia*, by the EPR spectra in Figure 9. One can recognize a sextet very well resolved at room temperature, together with less well resolved lines at somewhat lower magnetic fields. At

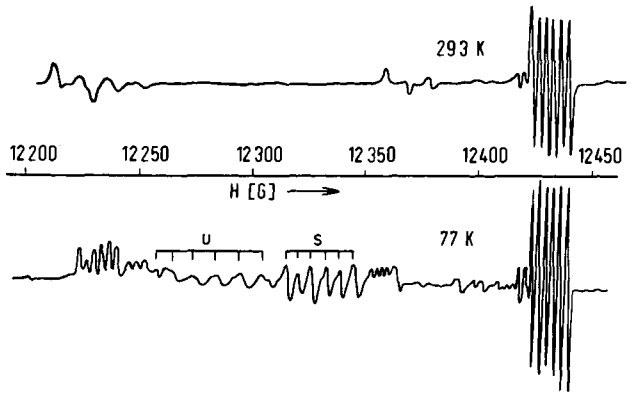

Fig. 9. EPR spectra of natural citrine at 34.8 GHz, magnetic field approximately parallel to the threefold axis of the crystal. At 77 K there appear additional sextets from smoky quartz centers (S) and from centers of unknown structure (U). In the selected orientation only one sextet from smoky quartz centers is present, but several from the citrine centers, which must thus be present in various orientations.

77 K the latter's resolution is somewhat better and there is a sextet of smoky quartz centers (S) present in a lower concentration together with the signal of another center of unknown structure (U). The citrine centers produce an uncharacteristic slightly anisotropic increase in optical absorption up to the UV, but no band in the visible region. In contrast to the situation at the smoky quartz center, the defect electron at the citrine center is thus localized on one oxygen atom. One of the four possible oxygens must be so energetically favored as a carrier of the defect electron that the latter's exchange is no longer recognizable at room temperature. Greater bond lengths lead to a gain in energy. For the difference in Si—O separations of the oxygen pairs in α-quartz, of the order of 0.01 Å[43], an energy difference of 0.7 kcal/mol has been measured for smoky quartz centers, in good agreement with the value calculated on the basis of electrostatic concepts[38].

Only in favorable cases can decomposition kinetics yield information about the stability of a color center. If electron and defect electron centers are destroyed at the same time, we must know whether recombination occurs *via* excitation of the electron into the conduction band or by excitation of the defect electron into the valence band (see Figure 1). Destruction of the smoky quartz or citrine centers is accompanied by thermoluminescence, *i. e.* an emission of light. Their spectral distributions are shown in Figure 10.

In both cases, therefore, the energy stored on irradiation is, with a high probability[*] emitted as light. The emission

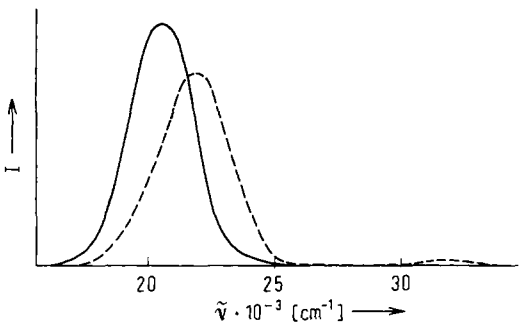

Fig. 10. Thermoluminescence of smoky quartz centers (——) and of citrine centers (----). The intensities I are not normalized to the same center concentrations.

maxima give the distance of the electron center from the valence band in cases of defect electron excitation. If the electron is excited, the distance of the defect electron center from the conduction band is involved. The main band in citrine is displaced to higher energies than that in smoky quartz. Since, however, a greater stability of defect electron centers means a larger distance from the valence band and therefore a smaller one from the conduction band, the emission can only represent the separation of the electron centers from the valence band; it must therefore be the defect electron that is excited. If this excitation is the rate-determining step in the destruction of the color centers, the activation energy for the reaction can be determined from the separation of the defect electron centers from the valence band. The difference between activation energies gives the energy difference between the smoky quartz and the citrine centers. As isothermal measurements of the destruction of optical absorption of the two centers have shown, the reaction orders are close to unity; consequently, excitation of the defect electron is indeed rate-determining. The activation energies are about 36 kcal/mol for citrine and about 30 kcal/mol for smoky quartz. These values were checked by measuring the temperature maxima of the emission intensities during rapid linear heating of the samples. Figure 11 shows the glow curves obtained, from whose maxima the activation energies can be calculated[44]. They are in good agreement with the values measured isothermally (the smoky quartz centers gave, because of the two maxima, two values close together). This good agreement is proof that the same process lies at the basis of thermoluminescence and the destruction of absorption bands.

The additional stabilization of the citrine centers amounts to about 6 kcal/mol. The cause of this stabilization is still unclear; it seems reasonable to assume an extension of one

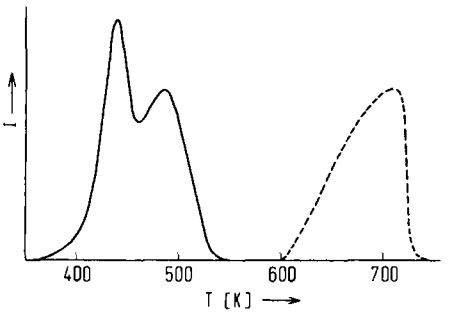

Fig. 11. Glow curves for smoky quartz centers (——) and citrine centers (intense emission bands) (----). Heating rates 3.5 and 6 K/min.

[*] This can be expressed quantitatively as the quantum yield (number of light quanta emitted per center decomposed).

aluminum-oxygen distance to a value close to the normal Al—O bond length (1.74 Å[45]). (The normal Si—O bond is only 1.61 Å[43].) Only the absence of a neighboring silicon or oxygen atom could cause an increase of this magnitude. Since these vacancies are not thermodynamically stable, they perhaps could be formed by high-energy particle irradiation. At the moment it is only certain that smoky quartz centers consist of a defect electron on an undisturbed AlO_4 tetrahedron, while there is an additional fairly large disturbance at the citrine centers[*].

6. Prospects

All the examples in this review have been taken from the realm of naturally occurring minerals. It seems pertinent to imitate nature and to draw conclusions from the results, *e.g.* about the growth conditions of natural crystals. In some cases this has already been done as for smoky quartz and amethyst, but in others (citrine) the attempts so far have been unsuccessful. Knowledge of the principles of formation enables plans to be drawn up for a systematic synthesis of unusual valence states or for unfavorable coordination of specific ions, and then to select the most favorable plan for the experimental synthesis. Since the incorporation of charged point defects is nearly always a prerequisite for success, it is in general more promising to grow the crystals from the melt rather than from solution, because then the crystal can much more easily be forced to pick up foreign atoms. Undesirable thermal reductions, such as that of Cu^{II} to Cu^{I} in the growth of doped cadmium halide crystals from melts, can be reversed by subsequent irradiation. In the case of $CdBr_2$ defects are formed during crystal growth, with a still unknown structure[47]:

$$Cu^{2+}(CdBr_2) + Br^- \xrightarrow{kT} Cu^+ + Br \longrightarrow A^{(+)} \qquad (7)$$

The energy of ultraviolet radiation suffices for re-formation of bivalent copper[46]:

$$Cu^+(CdBr_2) + A^{(+)} \xrightarrow{h\nu\,(UV)} Cu^{2+} + A \qquad (8)$$

It must also be possible in this way to prepare Cu^{2+} in CdI_2, *i.e.* a diluted CuI_2, and to investigate it.

There are many possible applications to structural problems. Here let us consider only the question of the blue coloration of corundum by bivalent iron. In crystal growth by the Verneuil process or from melts bivalent iron is obtained in place of trivalent on simultaneous doping with titanium. The blue color of such crystals has been explained[48,49] by an intervalence transition between Fe^{II} and Ti^{IV}, which is possible only if Fe^{2+}—O^{2-}—Ti^{4+} complexes are present, *i.e.* if charge compensation occurs in the immediate neighborhood of the Fe^{II}. Against this interpretation is, among other things, the fact that natural blue sapphires contain hardly any titanium[50]. Here, because of the different conditions of growth, the charge is equalized in a different way, probably through OH groups. The blue color of natural sapphire is readily explained by ligand field transitions of Fe^{II}[51]. The blue color of the synthetic crystals is destroyed by X-ray irradiation, apparently because of the reaction:

$$Fe^{2+}(\underline{Al_2O_3}) + Ti^{4+}(\underline{Al_2O_3}) \xrightarrow{h\nu} Fe^{3+} + Ti^{3+} \qquad (9)$$

which, however, is possible only if the two ions are not next to each other. Although direct proof of eq. (9) has not yet been provided, the sapphire question indicates well the variety of problems to whose solution solid-state photochemistry can contribute.

I am indebted to Dr. A. Räuber, Institut für Angewandte Festkörperphysik der Fraunhofer-Gesellschaft, Freiburg, for the Q-band EPR spectrum of citrine. The examples were largely taken from our own work which was supported partly by the Deutsche Forschungsgemeinschaft and partly by the Ministerium für Wissenschaft and Forschung des Landes Nordrhein-Westfalen.

Interpenetrating Polymer Networks

By Daniel Klempner[*]

Besides mechanical blending and copolymerization there is a third possible way in which two polymers can be combined. Each polymer forms its own network, while both networks interpenetrate each other. There are no covalent bonds between the polymers. Such interpenetrating networks have been synthesized sequentially (from polymer A and monomer B) and simultaneously (from monomer A and monomer B). It is preferable that the polymers be of different chemical type; usually, an elastomer and a glass are combined, *e.g.* a polyurethane and a polyacrylate. Depending upon the ratio of component polymers either a strengthened elastomer or a glass having impact strength is formed. So far, there are no direct methods for establishing the degree of interpenetration.

1. Introduction

The chemical and physical combination of two or more structurally dissimilar polymers has been of commercial and academic interest for a number of years, since it provides a convenient route for the modification of properties to meet specific needs. It has been used to facilitate processing and to impart flexibility, tensile and impact strength, chemical resistance, weatherability, flammability resistance, and a variety of other properties[1-4]. The physical properties of the combined polymers depend not only on the properties of the constituent polymers but also on the way they are combined.

Mechanical blending is the oldest way of physically combining two or more linear polymers and is accomplished by mixing the polymers in a liquid state, *e.g.* melt, solution or dispersion.

Chemical combinations of polymers can be defined as the combination of two or more types of polymers (or corresponding monomers) generally *via* covalent bonds and can be achieved by random, alternate, block, or graft copolymerization.

Interpenetrating polymer networks (IPN's) are a novel type of polymer blend composed of crosslinked polymers. They are more or less intimate mixtures of two or more distinct crosslinked polymer networks with no covalent bonds between the polymers, *i.e.* polymer A crosslinks only with other molecules of polymer A, as does polymer B. A schematic representation of an ideal IPN is shown in Figure 1.

Thus, IPN's may be described as combinations of chemically dissimilar polymers in which the chains of one are completely entangled with those of the other. The entanglements must

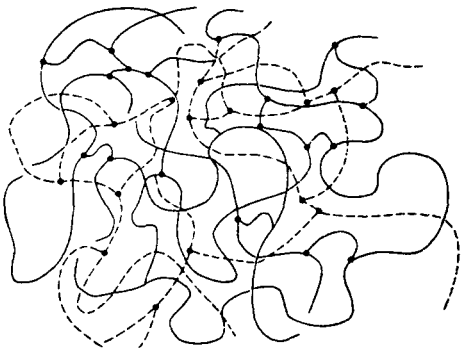

Fig. 1. Ideal Interpenetrating Polymer Network (IPN). —— Polymer A, ... Polymer B.

be of a permanent nature and are made so by this homocrosslinking of the two polymers. IPN's can be of various chemical types and can be synthesized in a variety of ways. There are two basic techniques for producing IPN's. In the first, a crosslinked polymer of type A is swollen with a second monomer of type B, plus crosslinking agents. This is followed by the polymerization and crosslinking of polymer B *in situ*. The second consists of combining the linear polymers, prepolymers, or monomers of the two polymer types, together with their respective crosslinking agents, in some liquid form, *e.g.* bulk (melt), solution, or dispersion. This is followed by the simultaneous polymerization and crosslinking of the two polymers. Care must of course be taken in the selection of

the polymers to prevent reaction occurring between them. It is also preferable that the polymers be of different chemical types so that the resulting material will be more than just a copolymer. Interest centers in these materials for a variety of reasons. Some of the more important ones are discussed below:

1. IPN's represent a mode of blending two or more polymers to produce a mixture in which phase separation is not as extensive as would be otherwise. In fact, it is the only way of combining crosslinked polymers. Normal blending or mixing of polymers results in a multi-phase morphology due to the well known thermodynamic incompatibility of polymers. This incompatibility is due to the relatively small gain in entropy upon mixing the polymers due to contiguity restrictions imposed by their large chain length[5]. However, if mixing is accomplished on a lower molecular weight level, and then polymerization accomplished simultaneously with crosslinking, phase separation may be kinetically controlled since the entanglements will have been made permanent by the crosslinking. In other words, phase separation cannot occur without breaking covalent bonds.

IPN's synthesized to date exhibit varying degrees of phase separation, dependent principally on the compatibility of the polymers. With highly incompatible polymers, the thermodynamics of phase separation are so powerful that it occurs substantially before the kinetic ramifications (*i.e.* crosslinking) can prevent it. In these cases, only small gains in phase mixing occur. In cases where the polymers are more compatible, phase separation can be almost completely circumvented. Note that complete compatibility (an almost impossible situation) is not necessary to achieve complete phase mixing, *i.e.* interpenetration, since the "permanent" entanglements produced by interpenetration prevent phase separation. With intermediate situations of compatibility, intermediate and complex phase behavior (morphology) results. Thus, IPN's with dispersed phase domains ranging from a few microns (the largest)[6], to a few hundred ångströms (intermediate)[7], finally to those with no resolvable domain structure (complete mixing)[8] have been reported.

2. IPN's represent a special example of topological isomerism[9] in macromolecules[10]. Some permanent entanglements between the different crosslinked networks are inevitable in any sufficiently intimate mixture of the crosslinked networks. These represent examples of catenation in polymer systems, *i.e.* different ways of imbedding these molecules in three dimensional space. Permanent entanglements are hindering constraints on the motion of segments and ought to simulate covalently bound chemical crosslinks[11]. Simplified theoretical models of such permanent entanglements[12] exhibit a surprisingly large non-linear elastic restoring force unlike that expected with chemical crosslinks from ideal rubber elasticity theory.

3. The combining of varied chemical types of polymeric networks in different compositions, often resulting in controlled different morphologies, has produced IPN's with synergistic behavior. For example, if one polymer is a glass (glass transition, T_g, above room temperature) and the other is elastomeric (T_g below room temperature), one obtains a reinforced rubber, if the elastomer phase is the continuous, predominant one, or a high impact plastic if the glassy phase is continuous[13]. In the case of more complete phase mixing, enhancement in numerous mechanical properties is due to the increased physical crosslink density due to this interpenetration. IPN's have been synthesized with intermediate maxima *versus* network composition in bulk properties such as tensile strength[14–22], impact strength[16,17], and thermal resistance[16–18,20], and minima in surface properties such as critical surface tension. Certain of these synergistic properties of IPN's such as the mechanical properties reflect their special architecture. Others such as thermal resistance, may simply be consequences of the fact that IPN's are usually blends of different chemical types of networks and may have little to do with their special structure[23].

In this paper, we shall present a brief historical review of IPN's since their inception, including their synthesis, morphology, and classification. We shall then discuss some of the most important developments in recent years and present some of the prominent unsolved problems.

2. Synthesis, Classification, and Morphology

In an excellent review of IPN's, *Sperling*[24] points out that ... "the IPN topology was long known and apparently 'rediscovered' several times." He cites patents dating from the forties in Great Britain and the fifties in the United States. Thus, *e.g. Staudinger* and *Hutchinson*[25] describe the use of IPN's to produce smooth sheets of bulk polymerized homopolymers while *Solt*[26] somewhat later described the use of anionic and cationic IPN's as ion exchange resins. The term IPN was first introduced by *Millar*[27], who studied "homo-IPN's" in which both polymer networks were composed of polystyrene crosslinked with divinylbenzene. He prepared a series of these IPN's by allowing the first crosslinked polystyrene network to imbibe a calculated amount of a suitable mixture of styrene and a 50% divinylbenzene-toluene solution, containing catalyst, and then polymerizing the imbibed monomers within the original polymer network. *Millar* found a small increase in density of the resultant network which he ascribed to interpenetration.

Shibayama and *Suzuki*[28,29] studied the viscoelastic properties of such polystyrene homo-IPN's prepared in a manner similar to those prepared by *Millar*. But they found practically no difference in density between a control polystyrene network and the IPN. They did find, however, much larger crosslink densities in the IPN's. Besides additional crosslink formation by chain transfer and extension of the original network, these authors ascribed the increase in crosslink density to the increase in entanglements caused by the superposition of the networks. They found as expected an increase in rubber modulus, a decrease in swelling tendency (in agreement with *Millar*), while the glass transition temperature and the viscoelastic properties in the glass-to-rubber transition region were not much altered. Other such homo-IPN's were synthesized by *Shibayama et al.*[29,30] and more recently by *Clark*[31].

A number of different IPN nomenclature schemes have been introduced. A very simple scheme[32] is based on morphology, topology and method of synthesis. According to this scheme essentially all of the above examples of IPN's are sequential interpenetrating polymer networks (SIPN). SIPN's are formed by the swelling method outlined above; they are

termed sequential since one material is completely polymerized and crosslinked while the other is still a monomer. In this scheme *Millar*'s homo-IPN's are called interpenetrating homopolymer networks (IHPN). A much more extensive classification scheme has been recently developed[33] which considers the nature of the reactive unit (*e.g.* monomer, crosslinker, *etc.*) the operation involved (*e.g.* polymerization of monomer, grafting, *etc.*) and most importantly the sequence of operations.

Since 1969, two groups independently developed systematically the concept of IPN's composed of two or more chemically different polymers. Initially *Frisch et al.*[14,34] produced a latex interpenetrating polymer network (LIPN) by mixing dispersions, for example, of a polyurethane-urea (U) and a polyacrylate[14]. This was followed by casting a film and crosslinking. The polyacrylate was essentially crosslinked through sulfur and double bonds by a free radical process. The urethane polymer was crosslinked thermally by reaction with triols.

This system was particularly chosen for two reasons: (1) the difference in crosslinking mechanism of the two polymers and (2) the ability of the urethane network to be selectively hydrolyzed at its ether linkages. Thus, films of the IPN were hydrolyzed with dilute hydrochloric acid, leaving still an integral polymer film. Weight loss and infrared spectroscopy showed that almost all of the urethane component was hydrolyzed and separated. This chemical proof suggested strongly that a considerable part of the individual networks were not chemically bound to each other, but indeed topologically interlocked. Subsequent work[6,35] showed that these materials appear to exhibit two distinct T_g's when studied by a Vibron viscoelastometer, but only one T_g could be resolved by differential scanning calorimetry (DSC) measurements[*] (cf. also Fig. 2).

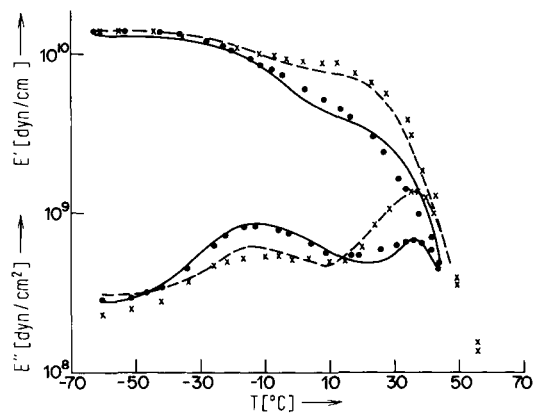

Fig. 2. Real (E') and loss (E'') moduli *vs.* temperature (T) for IPN of poly(urethane-urea) (U) and polyacrylate (H). ●●● U/H = 50/50, × × × U/H = 30/70, solid lines represent predictions based on theoretical models.

[*] A brief comment concerning the glass transition behavior of blends of polymers is warranted at this point. If two polymers combine to form a single phase mixture, one fairly sharp T_g, intermediate in temperature to the T_g's of the component polymers, would be expected. If separate, distinct phases occur, each phase should exhibit its own independent thermal response. Thus, two T_g's corresponding to the T_g's of the component polymers should occur. Any phase mixing which could occur at the phase boundaries would be expected to shift the component polymer T_g's inwards, *i.e.* towards each other until, if the domain size becomes small enough, one broad T_g would occur. Complete phase mixing would be indicated by one sharp T_g.

Electron microscopy of these IPN's (Fig. 3) also indicates their two-phase nature, with the polyacrylate as the continuous phase and the polyurethane the dispersed phase at concentrations as high as 70 % U, where a phase inversion apparently occurs.

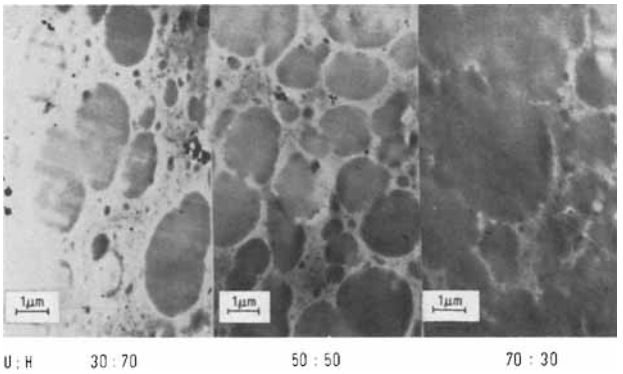

Fig. 3. Electron micrographs of IPN's of a poly(urethane-urea) (dark phase) (U) and a polyacrylate (H).

The domain sizes are of the order of magnitude of a micron to 1000 Å, *i.e.* about a factor of ten smaller than the latex particles in the original latices. These are the earliest examples of *Kato*'s osmium tetroxide staining technique[36] being used on IPN's. In this technique, osmium tetroxide preferentially stains one of the polymers (in this case the polyurethane), causing it to appear as the darker phase in the electron micrograph, due to the presence of the heavy metal atoms. The mechanical behavior of these IPN's substantiates this phase inversion. The fact that only one broad T_g was observed calorimetrically suggests that phase separation was not complete and that some interpenetration must take place at the phase boundaries.

Other examples of such LIPN's have been prepared[14]; since most of these consist of two different elastomeric networks, they have also been referred to as interpenetrating elastomeric networks (IEN).

Sperling et al.[37–40] prepared, as early as 1969, a series of SIPN's. While the SIPN made from poly(ethyl acrylate) and polystyrene[37] exhibited two distinct T_g's somewhat shifted towards one another, the SIPN, made from the polymers with zero heat of mixing, poly(ethyl acrylate) and poly(methyl methacrylate), exhibited only one broadened T_g[38]. In view of the further mechanical, solubility and thermal studies there is little doubt that these results can only be satisfactorily explained on the basis of interpenetration and not simply chain transfer crosslinking. These materials were synthesized to provide rather more or less compatible polymer blends, whose phases would remain finely divided without the need for further mechanical mixing.

Electron microscopic studies of the SIPN morphology[41] substantiated this behavior. For the 50 : 50 poly(ethyl acrylate) polystyrene IPN, the poly(ethyl acrylate) component contained *ca.* 1 % butadiene as a comonomer to facilitate osmium tetroxide staining. Figure 4 exhibits the complex morphology of this system. The cell walls are mainly poly(ethyl acrylate), the inner cell domains being mainly polystyrene. A fine structure is observed mainly within the cell walls. Sometimes, but not as frequently, the fine structure is observed inside the cells.

In the first case polystyrene domains are pervading the poly(ethyl acrylate) walls, whereas in the latter, poly(ethyl acrylate) particles are pervading the polystyrene cells. The sizes of the cells are approximately 1000 Å. The poly(ethyl acrylate) and the polystyrene microstructures are of the order of 100 Å. Although the cells are irregularly shaped, they exhibit a certain orientation which coincides with the radiation direction of polymerization.

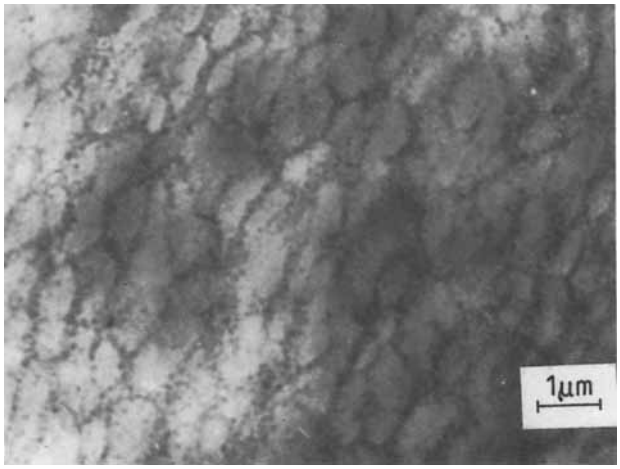

Fig. 4. Electron micrograph of a 50:50 poly(ethyl acrylate)/polystyrene IPN. Note appearance of a cellular structure and a fine structure within the cell walls.

The electron micrograph of the more compatible system, poly(ethyl acrylate) and poly(methyl methacrylate) 75:25 is shown in Figure 5. It can be seen that this material, while still exhibiting two phases, has only the fine structure, of the order of magnitude of 100 Å.

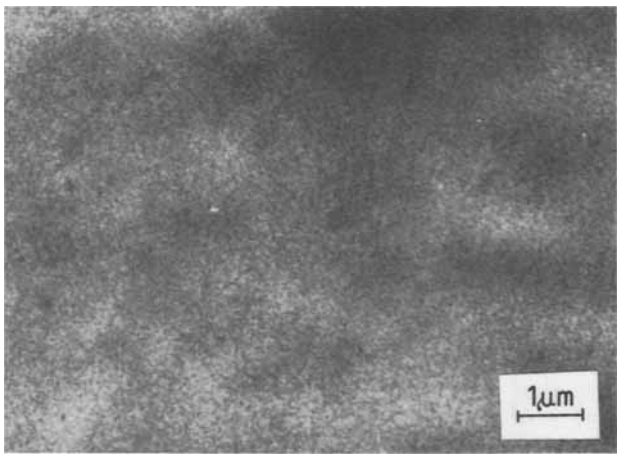

Fig. 5. Electron micrograph of a 75:25 poly(ethyl acrylate)/poly(methyl methacrylate) IPN. No cellular structure was detected for this composition; only the fine structure is present.

Presumably, the sequential mode of synthesis of these SIPN's provides the electron microscopic "cellular" and "fine" structures. Similarly, the underlying size of the latices in our IPN's and the difficulty of overcoming both the surface and bulk forces keeping the particles apart prevent a uniform morphology with very small domain sizes up to submolecular dimensions. To overcome this, both *Sperling* and his coworkers and our group developed the simultaneous interpenetrating networks (SIN). This technique, along with some other new developments, shall be discussed in the following sections.

3. Simultaneous Interpenetrating Networks

The method employed by us[16–23,42–45] involves mixing the linear prepolymers, together with crosslinking agents and catalysts (with or without solvent) casting films and/or sheets, and subsequently thermally curing them *in situ*. Care was taken to employ a step reaction with a chain reaction, or two step reactions which did not interfere with each other. In this fashion, binary SIN's composed of polyurethane-epoxy[18,42], polyurethane-unsaturated polyester[42], and polyurethane-polyacrylate[16,17,19,43] were formed. In all cases, one component was a rubbery polymer and the other a glassy one. This not only provided for the mutual reinforcement described earlier (*i. e.* either a high impact plastic or a reinforced elastomer), but also facilitated a phase analysis by glass transition measurements since this depends on the component polymers having widely separated T_g's.

The rubbery polymer was, in all cases, a polyurethane. It was made by the two-step prepolymer technique in which an isocyanate-terminated urethane prepolymer was first synthesized by reacting a hydroxyl-terminated low molecular weight polyether or polyester (polyol), usually difunctional, but in some cases multi-functional with a diisocyanate. This low molecular weight prepolymer (usually $\bar{M} \approx 500$—2000) was then chain extended and crosslinked simultaneously by reacting with short chain diols and triols, catalyzed by organotin compounds. Thus, a wide variety of polyurethanes were employed by varying the nature of the polyols, isocyanates, and chain extenders. This allowed determination of structure-property relationships.

The epoxy was also a liquid prepolymer or monomer and was cured with 2,4,6-tris(dimethylaminomethyl)phenol (DMP-30), a tertiary amine which would be non-reactive with the isocyanate.

The unsaturated polyester was a low molecular weight ($\bar{M}$ *ca.* 2000) polyester containing some unsaturation which was crosslinked with styrene *via* a free radical process, again non-reactive with the urethane component. The polyacrylate was also a fairly low molecular weight polymer ($\approx$ 10000) which was crosslinked with a butylated melamine-formaldehyde resin *via* pendant hydroxyls (it was a copolymer of butyl methacrylate, methacrylic acid, styrene, and hydroxyethyl methacrylate). In this case the isocyanate-terminated prepolymer had to be blocked by reacting with 2-butanoneoxime, in order to render it non-reactive with the pendant hydroxyls on the polyacrylate, and thus prevent grafting between the component polymers. Deblocking occurred only slowly at the curing temperatures, so that the pendant hydroxyls all reacted before the isocyanate deblocked.

IPN's were formed by mixing the urethane prepolymer (either in solution or in bulk), together with its chain extenders and crosslinking agents, with either the epoxy, polyacrylate, or polyester together with their respective crosslinking agents, casting films or molding sheets, and thermally curing them at *ca.* 100 °C overnight. All the IPN's exhibited single phase

morphologies, as evidenced by the presence of one intermediate T_g measured calorimetrically. Electron microscopic studies of the polyurethane-polyacrylate IPN's (Fig. 6 to 8) substantiate these results. No microstructure at all can be seen. Some granularity may be noted in the high polyurethane IPN (Fig. 8), but this is not evidence of phase separation since it occurs in the greatest amount in the 100 % polyurethane so is probably not a characteristic of the IPN's themselves.

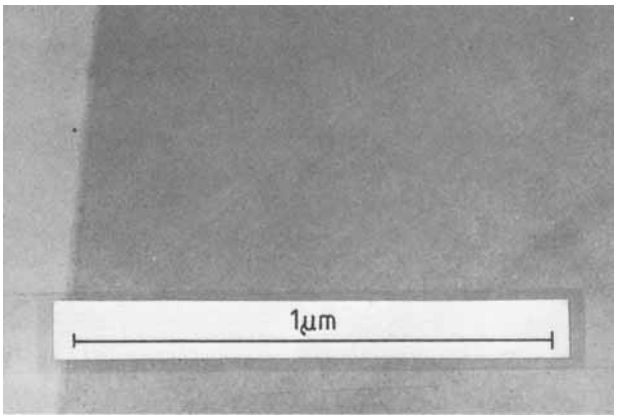

Fig. 6. Electron micrograph of a single-phase polyurethane (PU)/-polyacrylate (PA) IPN. PU/PA = 25/75.

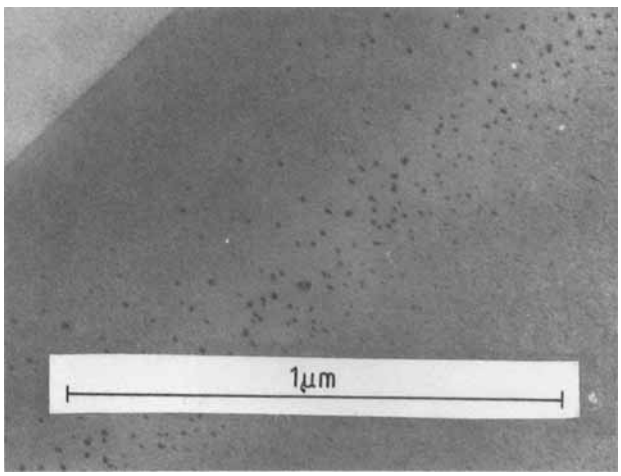

Fig. 7. Electron micrograph of a 50:50 PU/PA single-phase IPN.

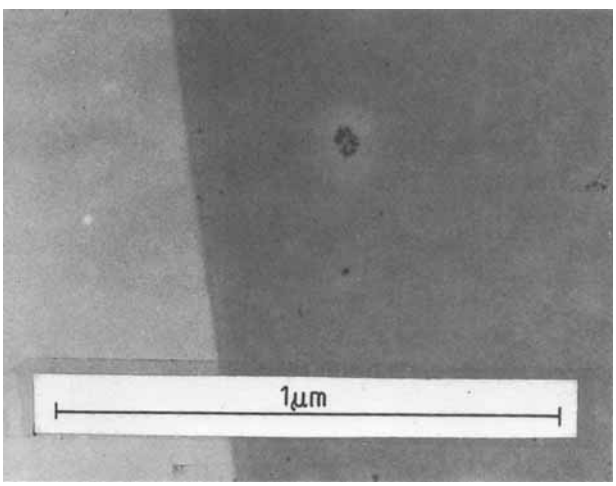

Fig. 8. Electron micrograph of a 75/25 PU/PA single-phase IPN.

The physical and mechanical properties of these IPN's showed interesting and remarkable trends. Maxima in tensile strengths *vs.* IPN composition which were significantly higher than the tensile strengths of the component polymers occurred for most of the above SIN's. Typical results for the polyurethane-epoxy IPN are shown in Figure 9.

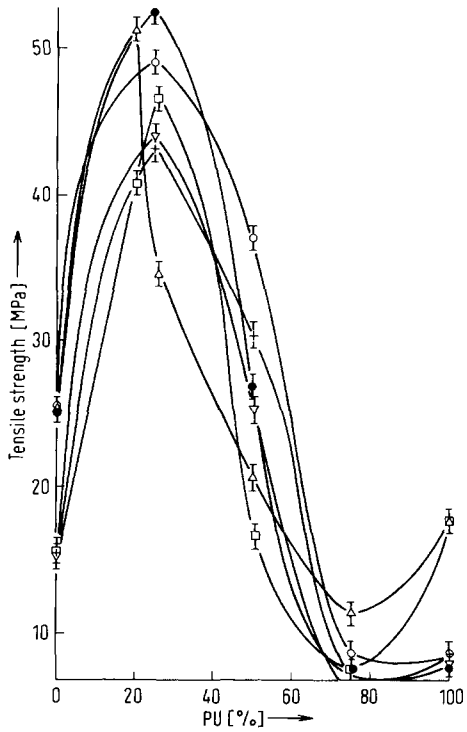

Fig. 9. Tensile strengths *vs.* composition for polyurethane/-epoxy IPN's. The several curves represent IPN's composed of varying polyurethanes and epoxies. Note the behavior is the same in all cases.

In many cases, minima also occurred. The maxima were attributed to an increase in crosslink density due to interpenetration, since it is well known that the tensile strength of a crosslinked rubber goes through a maximum as the crosslink density increases. The minima were attributed to initial weakening of the strong hydrogen bonding present in the polyurethanes by the interpenetrating chains of the second polymer. Crosslinking between the two polymers was postulated to be another possibility for maxima in the strength properties, since this possibility did exist with these IPN's. The melamine-formaldehyde resin could conceivably react with the hydroxyl-terminated chain extenders of the polyurethane, in the case of the polyacrylate IPN's. For the unsaturated polyester IPN's, reaction between the isocyanate-terminated prepolymer and the terminal hydroxyl and/or carboxyl groups of the polyester is certainly possible. Some of the epoxide polymers studied contained some pendant hydroxyls which could react with the isocyanate. In addition, the epoxide itself could react with the isocyanate. However, under the curing conditions employed (catalyst, temperature, *etc.*) the authors speculated that this "inter-reaction" would be minimal. Infrared studies seem to support this view[16, 17]. Other properties which showed enhancement were the thermal resistance (as evidenced by thermogravimetric analysis) and the impact strength.

The method employed by *Sperling et al.*[46] to form the SIN's involved simultaneously synthesizing crosslinked epox-

ide polymers and *n*-butyl acrylate polymers. A two-phase morphology resulted, with the dispersed rubber (poly(*n*-butyl acrylate)) domains being of the order of 0.1—0.2 μ in size. The actual dimensions of the dispersed phase, and the extent of molecular mixing (interpenetration) between the two networks was found to depend on the relative rates of polymerization, or the gelation time. The minimum domain size and therefore greatest amount of interpenetration occurred when the closest approach to simultaneity was attained. Spherical, rather than elongated rubber domains yielded the greatest toughening of the epoxy when the domains were smaller than optimum.

4. Interpenetrating Latex Polymer Networks

Another type of latex IPN, different in nature from those we synthesized[6,17,15,37,35] and discussed in Section 3, are those of *Sperling et al.*[47–50], which resulted in semicompatible IPN's. This synthesis consisted of making a seed latex of crosslinked polymer A, and then introducing monomer B (containing crosslinking agent), followed by a second emulsion polymerization. Films were formed either by coagulating or drying the IPN latex. Numerous polymer combinations were studied, including poly(vinyl chloride)/poly(butadiene-acrylonitrile)[49], and a variety of methacrylic/acrylic combinations, such as poly(ethyl methacrylate)/poly(*n*-butyl acrylate)[50]. The interesting characteristic of these IPN's is that they display glass transitions that are broadened and, in some cases, span the entire temperature range between the two component polymer transitions. As mentioned earlier, this type of behavior suggests semi-compatibility, *i.e.* much less phase separation between the polymers. It does not imply complete phase mixing, as only one sharp T_g would then be observed. The morphology suggested was a core-shell structure[51], where the polymer A core gradually becomes enriched in polymer B on going from the center of the latex particle to the surface.

The broadened glass transition behavior of these IPN's has led to their study as noise and vibration damping coatings. When a material is in its glass transition region, the mechanical damping factor, or dissipation factor, tan δ, (as obtained from a dynamic mechanical relaxation measurement) goes through a maximum. The interest in these IPN's is due to the fact that their glass transition extends over a wide temperature range, which means that they would be useful damping materials not just over a short temperature span (the usual transition of polymers), but over a wide range of temperatures.

5. Incompatible Polyurethane Simultaneous Interpenetrating Networks

We recently synthesized a series of SIN's[20,22,44,45,52,53], with a polyurethane as the rubber component, which are characterized by a heterophase morphology similar to the LIPN's[6,17,15,34,35], as opposed to the single phase nature of the previously described SIN's[8,16–19,43]. The factors which distinguish these SIN's from the previous single phase ones are the nature and the crosslinking mechanism of the glassy polymer. Two polymers were selected as the glassy ones: polystyrene (crosslinked with divinylbenzene), and poly(methylmethacrylate) crosslinked with trimethylolpropane trimethacrylate. The solubility parameters of these polymers (which reflects their compatibilities) were farther from the polyurethane than those of the previously discussed glassy polymers used in the compatible SIN's. In addition, practically no chance for reaction between the polymers in these SIN's existed, as they did in the case of the earlier ones. Any interreacting, or grafting, between the component polymers would help to compatibilize them.

The polyurethane—poly(methyl methacrylate) SIN's exhibited less phase separation than did the polystyrene SIN's (as would be expected from a solubility parameter study) as evidenced by the relative shifts in T_g's (measured by dynamic mechanical spectroscopy and calorimetry) as well as electron microscopy (Fig. 10 and 11). The size of the dispersed domains is much smaller for the poly(methylmethacrylate) IPN's than the polystyrene. Interpenetration was postulated to occur at the phase boundaries.

The effect of interpenetration on the morphology, as well as properties, was deduced in this study. Pseudo-IPN's (in which only one component was crosslinked) and linear blends were formed by omitting the appropriate crosslinking agent.

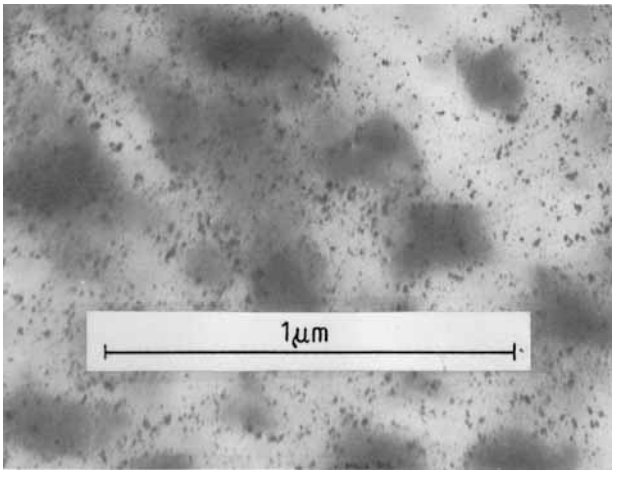

Fig. 10. Electron micrograph of polyurethane/-polystyrene Simultaneous Interpenetrating Networks: Polyurethane/polystyrene in the ratio 75:25.

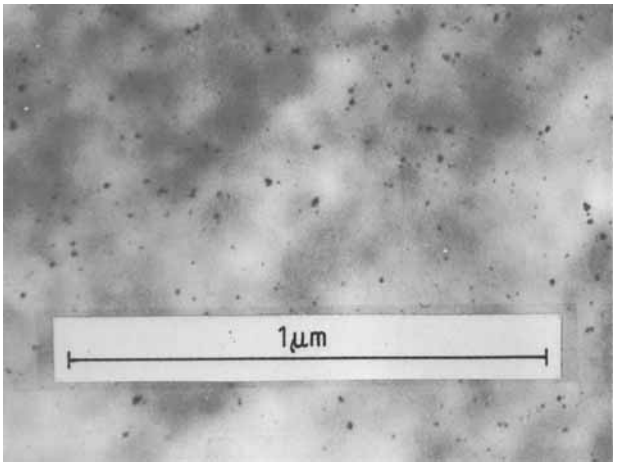

Fig. 11. Electron micrograph of polyurethane/poly(methyl methacrylate) simultaneous interpenetrating networks: polyurethane/poly(methylmethacrylate) in the ratio 75:25.

Both electron microscopy and glass transition behavior showed that the extent of phase separation was greater in the case of the pseudo-IPN's and linear blends. This indicated the role of permanent interpenetration on reducing phase separation by reducing the domain size of the dispersed phase. Pseudo-IPN's and linear blends could not limit phase separation since no topological constraints exist. The polymers can simply "unthread" and phase separate without breaking covalent bonds. The ultimate properties also reflect this behavior. Significant enhancement in tensile strength occurred with these IPN's, much greater than that for the pseudo-IPN's or linear blends. In this case, it is not the increased crosslink density which can explain this phenomenon, but the mutual glassy-rubbery reinforcement effect. Interpenetration serves to decrease the domain size and provide adhesion between the phases, thereby increasing the enhancement effect.

The densities of these IPN's[45], as measured hydrostatically, were increased, due presumably to the partial mixing of the component networks. This density increase agreed well with the specific volume hypothesis of *Kwei*[54] for a compatible polymer pair.

6. Current Studies

Sperling et al. are presently actively pursuing IPN's based on castor oil[55, 56] and those consisting of poly(styrene-butadiene)/polystyrene[57, 58].

The latter IPN's were prepared by the sequential technique. The polymer synthesized first was varied as well as the level of crosslinking. Pseudo-IPS's were also made. Electron microscopic investigations showed that the polymer synthesized first formed the more continuous phase and tended to control the morphology. The second polymer formed a cellular structure whose size was determined principally by the degree of crosslinking of polymer A, with an increase in crosslinking producing a finer structure. The coarsest structure was with the pseudo-IPN's, in agreement with our observations[44]. Thus, the two principal groups studying IPN's both agree on this very important concept, *i. e.* that interpenetration does affect the morphology and can somewhat "compatibilize" incompatible polymers. The mechanical behavior of these polymers was also studied[58]. Dynamic mechanical behavior showed two distinct T_g's in agreement with the electron microscopic data. These IPN's produced toughened materials, similar to our SIN's[20, 22], as evidenced by tensile and impact tests. Crazing appeared to be the principal toughening mechanism, and an optimum degree of toughness was obtained at an intermediate level of crosslinking of the polymer A component.

The castor oil based IPN's consisted of a polyurethane and either polystyrene or poly(methylmethacrylate). They were made again by the sequential technique, in which polyurethanes based on castor oil were swollen with the vinyl monomer. These IPN's were produced in order to develop a high impact material in which the rigid vinyl polymers were toughened by the rubbery polyurethane, in a fashion similar to our heterophase SIN's (see Section 3). The unique feature of these IPN's is that the elastomeric phase was based on a non-petroleum product, a facet of obvious importance in the light of today's energy shortage. The castor oil was polymerized both by sulfur, through the unsaturation on the molecule, or with diisocyanates, to form a polyurethane. This polymer was then swollen with the vinyl monomer, plus crosslinker and catalyst, and polymerized. One problem with this IPN is that undoubtedly much grafting occurs between the component polymers, since castor oil is an unsaturated material and subject to attack by the free radicals from the vinyl polymerization. The authors contend, however, that the amount of interpenetration is greater than the amount of grafting. Electron microscopy revealed a two phase morphology. The domain size ranged from 300 to 500 Å. Either increasing the castor oil content or decreasing its crosslink density caused the domain size of the dispersed polystyrene to increase. Measurements with a torsional pendulum gave separate, distinct T_g's for the component polymers. The IPN's were all clear and tough. Depending on compositions, either reinforced elastomers or impact resistant plastics resulted.

Our group is presently pursuing several avenues. In order to determine the mechanism behind the single phase morphology of the previously described polyurethane/polyacrylate SIN's, pseudo-IPN's and linear blends were prepared[59]. In addition, a polyacrylate very similar to the one discussed earlier, was prepared which crosslinked by a free radical process. In this manner, the possibilities of grafting which existed with the earlier SIN's were removed. The morphologies in all cases, as determined by differential scanning calorimetry, were heterophase. In all cases, two T_g's corresponding to the T_g's of the component polymers, resulted. They were shifted inwards, indicating some interpenetration, most likely at the phase boundaries. This suggests that grafting did occur in the earlier IPN's and that it played an important role in compatibilizing the polymers. The effect of polymerization kinetics on the morphology was determined. It was found that interpenetration increased as the reaction rates increased, and reached a maximum when the gel time of both polymers was the same, in agreement with *Sperling*'s results[57]. It was postulated that this was most likely due to the fact that increasing the reaction rate lowers the diffusion time allowed for phase separation. The initial prepolymer mixture is single phase, since the molecular weights are low enough to allow complete mixing. As the polymers are chain extended and crosslinked, they phase separate due to their thermodynamic incompatibility. This phase separation is naturally diffusion controlled and thus requires time. If the curing reactions are accelerated, less time will be available for diffusion and subsequent phase separation. When fully crosslinked, further phase separation cannot take place due to topological restraints imposed by the crosslinking of the component polymers, *i. e.* "disentangling" of the chains cannot occur without rupturing covalent bonds. Thus, further crosslinking would be expected to yield less phase separation. Significant enhancements in the tensile strengths resulted for the IPN's, but not for the pseudo-IPN's or linear blends. This reflects the higher level of mixing most likely present in the full IPN's (both polymers crosslinked).

Our team is also studying the surface, adhesive and barrier properties of polyurethane-epoxy SIN's[60]. Single phase morphologies were again found by glass transition analysis for these SIN's. They exhibited significantly enhanced adhesive properties, such as lap shear strength and peel strength (Fig. 12 and 13).

Maxima in these properties as a function of composition occurred at the same place as the maximum in tensile strength (Fig. 14).

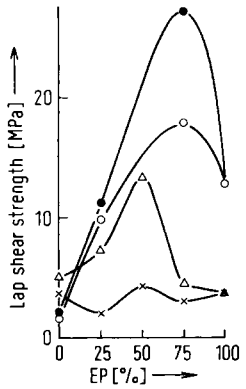

Fig. 12. Lap shear strength *vs.* composition for a polyurethane/epoxy IPN.

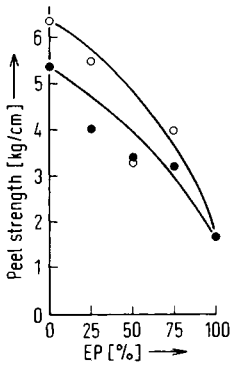

Fig. 13. Peel strength *vs.* composition for a polyurethane/epoxy IPN.

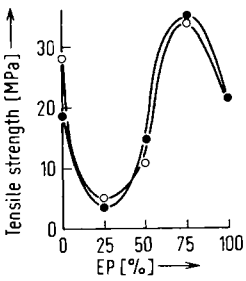

Fig. 14. Tensile strength *vs.* composition for a polyurethane/epoxy IPN.

Likewise, minima in critical surface tension, as determined by measuring the contact angles of a series of liquids, occurred at the same composition (Fig. 15).

This is consistent with the adhesive results since low critical surface tensions indicate higher wettability of these materials. This, together with the tensile properties, suggests that the failure in the peel and lap shear tests was both adhesive and cohesive. The barrier properties were investigated by determination of the water vapor permeabilities of SIN coatings (Fig. 16).

These results were indicative of a single phase morphology, in agreement with the glass transition results.

Finally, we have discovered an acrylic polymer that is extremely compatible with polyurethanes. A series of IPN's, pseudo-IPN's, and linear blends is being prepared.

A new group has recently started investigations on IPN systems[61]. They have produced SIPN's of a polyurethane and polystyrene similar in chemistry to our SIN's[20]. They found, for the first time, a third T_g, (as measured by gas chromatography) between the component T_g's, suggesting a three phase morphology, the two component polymers plus

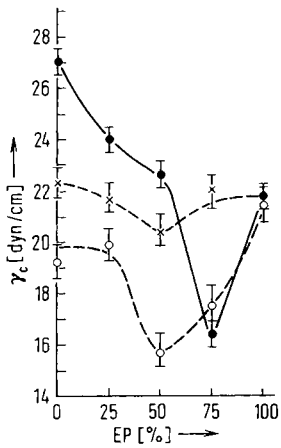

Fig. 15. Critical surface tension *vs.* composition for a polyurethane/epoxy IPN.

an interpenetrating region substantial enough to possess its own T_g. They also developed a thermodynamic method of obtaining the crosslink density (an indication of interpenetration) of this IPN from the measured retention volume in gas chromatography with the IPN as the column packing material. For the first time, theoretical calculations regarding the compatibilities of the component polymers were made.

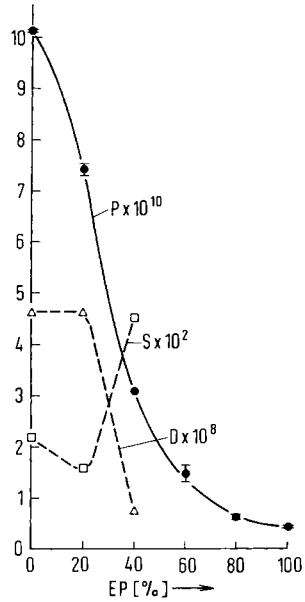

Fig. 16. Water-vapor permeabilities of a polyurethane/epoxy IPN. P[g·cm/cm^2·s·(cm Hg)] is the permeability coefficient; S[g/cm^3·(cm Hg)] is the solubility coefficient; D[cm^2/s] is the diffusion coefficient.

7. Unsolved Problems and Future Studies

How much interpenetration is really occurring? All investigations to date assume that single phase morphologies imply

interpenetration, *i.e.* entanglement of the chains of both polymers, similar to that which occurs in homopolymers. But this is not necessarily the case. A technique must be devised to "see" the chains. Electron microscopy is not yet a sensitive enough probe for polymers. Catenanes, or threaded macrocycles naturally occurring in cyclic DNA, have been "seen" electron microscopically[62], since DNA is a thick enough molecule to be resolved by the electron microscope. No such evidence has been presented for IPN's.

Another problem is the extent of grafting occurring between the polymers. Only one attempt has been made to demonstrate the absence of covalent bonds between the polymers[14]. For true topological interpenetration to occur, there must be no covalent bonds between the polymers. Most of the investigations to-date have tried to minimize grafting by the appropriate selection of polymers and crosslinking mechanisms. However, positive proof of the absence of grafting has not been given.

All IPN's to-date have been two-component. Multi-component IPN's would be expected to exhibit highly complex morphologies and should present a very interesting study. Fascinating physical properties should be expected from such complex networks.

One technique for the formation of IPN's which has not been attempted is the growing of both polymers from a single substrate, followed by cleavage of the bonds between them. This would insure that the chains of both polymers would be in close proximity during polymerization and increase the chance of interpenetration. Such a technique has been used successfully for the synthesis of threaded macrocycles, or catenanes[63, 64].

Polymers are useful as materials in forms other than plastics, rubbers, and coatings, *e.g.* as foams. Preliminary interpenetrating foams made by *Frisch* (unpublished) have shown excellent properties[65]. One interesting application of this could be in reducing the flammability of rigid polyurethane foams, the biggest hindrance to the widespread use of these materials in insulation. Most of the techniques for reducing flammability severely reduce the physical and mechanical properties of these foams. IPN foams could conceivably be made in which one polymer is the base network, and the other contains fire and smoke reducing elements, such as phosphorus and halogens. This could conceivably result in less of a sacrifice in properties.

Further studies of the barrier properties of IPN's are necessary. This could be an extremely useful probe in determining the topology of these networks. Very little work on permeabilities of composite structures has been performed.

Lastly, and undoubtedly the most difficult task, are the theoretical considerations. Statistical mechanical calculations to predict the topology could prove quite useful. Such calculations have been made for catenanes[9]. An extension of these calculations for the polymer situation should be possible. They must, of course, take into account the compatibility problem, as well as the statistical problem. The former problem has not been solved satisfactorily for simple polymer blends, and should thus prove all the more complex for IPN's. If this problem is solved, the morphologies and properties of IPN's of any polymer pairs could be predicted.

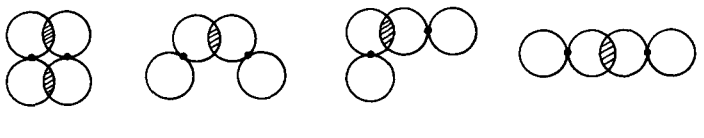
The Realities of Extended Homoaromaticity

By Leo A. Paquette[*]

Homoaromaticity has been the subject of many investigations and continues to remain an extraordinarily rich area of chemistry. Quantitative experimental evaluation of the level of long range delocalization and assessment of interactions in molecules having two or more insulating atoms, together with various theoretical estimates of energies and geometries, are areas currently being examined. The primary intention of this review is to provide a critical up-to-date survey of relevant spectral and structural data, as well as an analysis of the many reactions believed to involve generation of homoaromatic ions. Extensively discussed are mono-, bis-, and trishomoaromatic systems arranged on the basis of their cationic, anionic, or uncharged nature. Presentation of these individualized segments is preceded by a brief analysis of homoaromatic overlap.

1. Introduction



The concept of homoaromaticity was advanced by *Saul Winstein* almost 20 years ago to account for the unusual solvolytic behavior of the bicyclo[3.1.0]hex-3-yl cation[1]. The hypothesis has proven inspirational to many chemists and has had the undeniable effect of directing much experimental and theoretical attention to this field[2]. Major advances continue to be made, chiefly because of the extraordinary richness of the molecular architecture to which the theory may in principle be applied. Extensive discussion and debate have accompanied these developments. In part this has been due to an increasing sophistication in our theoretical understanding of the subject. But the varied success encountered in the observation of homoconjugative delocalization within certain ions and molecules of predesigned structure has also generated some consternation. At issue is the rather qualitative question: how extensively can π-electron delocalization in $(4n+2)$ conjugated polyenes be interrupted by one or more saturated atoms (sp^3 centers) with continued maintenance of some form of ring current? The primary intention of this review is to survey somewhat critically the major new developments in homoaromaticity with particular emphasis on higher order (bis, tris, *etc.*) phenomena and to address the above question in the light of current thinking.

2. Homoaromatic Orbital Overlap

We herein refer to the all too familiar parallel alignment of π orbitals so characteristic of aromatic systems (cf. *A*) as pp-π overlap. This combination possesses a node in the plane of the bond axis, has angular momentum about this axis, and is doubly degenerate. When a $(4n+2)$ cyclic array of these orbitals is fractured to accommodate an sp^3-hybridized center, electron delocalization can only be maintained if the two flanking π-atomic orbitals become canted more or less as in *B*. For obvious reasons, overlap becomes restricted to single lobes, the boundaries of which are limited to that surface of the molecule opposite to the bridging atom. The extent of interpenetration of the opposed p_z orbitals in *B* can be expected to depend heavily upon their mutual orientation and the internuclear distance separating the trigonal atoms. The net level of homoaromatic delocalization will be linked directly to the resultant overlap integral and the degree to which these atomic orbitals contribute to the molecular wave

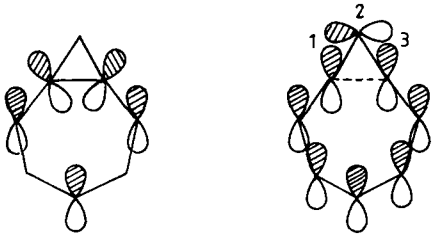
functions comprising the ground state configuration of the molecule. The situation prevailing for a specific compound where known will be discussed in the individual sections which follow.

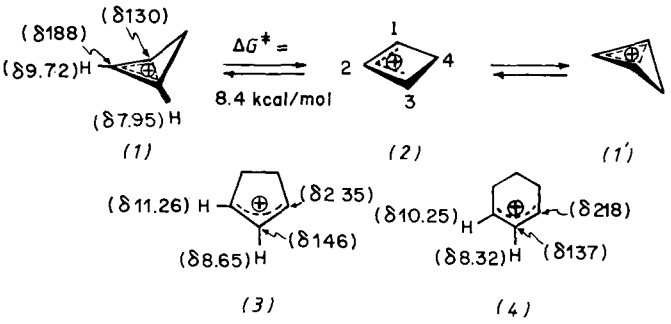


A B C D

Increasing σ Contribution →

The orbital overlap in *B* lies intermediate between pp-π and pp-σ. Further progressive alteration of this spatial orientation can lead to *C* and *D*. Anticipated by such changes is a further diminution in the level of π interaction and a concomitant increase in σ contributions to the bond energy (a fixed separation of atom pairs is assumed). The consequences of perpendicular pπ orbital arrangement as given by *C* has been examined in very few situations[3–5]. At the far extreme, the combination of parallel colinear atomic pπ orbitals depicted in *D* is seen to be cylindrically symmetrical about the bond axis, to lack angular momentum, and to be nondegenerate. The commonly prevailing π contributions to p orbital interaction are completely factored out in *D* and examination of pure pp-σ interactive behavior should be possible. However, molecules having this interesting feature are currently unknown (with the possible exception of diazabicyclo-[2.2.2]octane[6])[7], although the transition states of many reactions (Diels-Alder, *etc.*) are believed to encompass approach of a pair of pπ reactants in such sigmoid fashion. While *C* and *D* do not fall strictly within the confines established for homoaromatic interaction, they are briefly mentioned here for completeness.

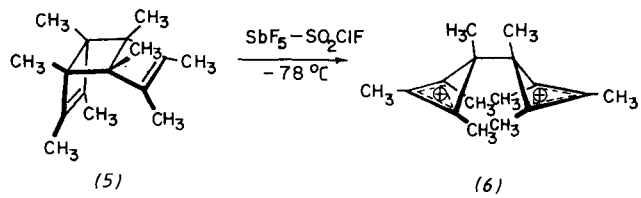
Considerable theoretical effort has been expended in attempts to assess the energetics of homoaromatic interaction. Both *Hehre*[8] and *Haddon*[9] have opted not to view the external methylene carbon as an isolated entity, but to consider it instead as part of a cyclopropane ring to which a linear segment is attached. In these terms, the monohomotropylium cation can be considered stabilized by appropriate interaction of the HOMO Walsh cyclopropane orbital and the LUMO



E *F*

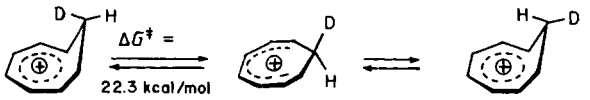
of pentadienyl as in *E*. However, this type of interaction is seemingly valid only if the cyclopropane ring is closed (the allowable bond length has never been specified) and such is unlikely to be the case. For this reason, the Möbius representation *F* which utilizes the outer electrons of the C-2 methylene for back-donation to the pentadienyl moiety in order to lengthen the C-1—C-3 distance was in vogue briefly, although later discarded[10]. *Jorgensen* has utilized extended Hückel, MINDO/3, and perturbation theory calculations to arrive at rather quantitative estimates of the energetic importance of homoaromatic overlap in certain select systems[11].

3. Monohomoaromatic Systems



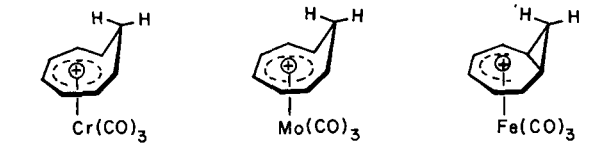
3.1. Cations

Monohomocyclopropenium cations are the simplest possible homoaromatic systems. Experimental support for the existence of 1,3 overlap as in *(1)* has been derived exclusively from ^{1}H- and ^{13}C-NMR data[12,13]. In particular, the pronounced upfield shifting of C-1 and C-3 as well as H-1 and H-3 (relative to that in *(3)* and *(4)* where the ordering is actually reversed) has been interpreted as indicative of homoconjugative interaction which shifts greater positive charge to C-2. Also, the methylene protons exhibit a temperature dependence consistent with a nonplanar conformation, although the small Δδ which separates them would seem to indicate that the extent of ring puckering is small[13]. This conclusion is supported by the experimentally determined

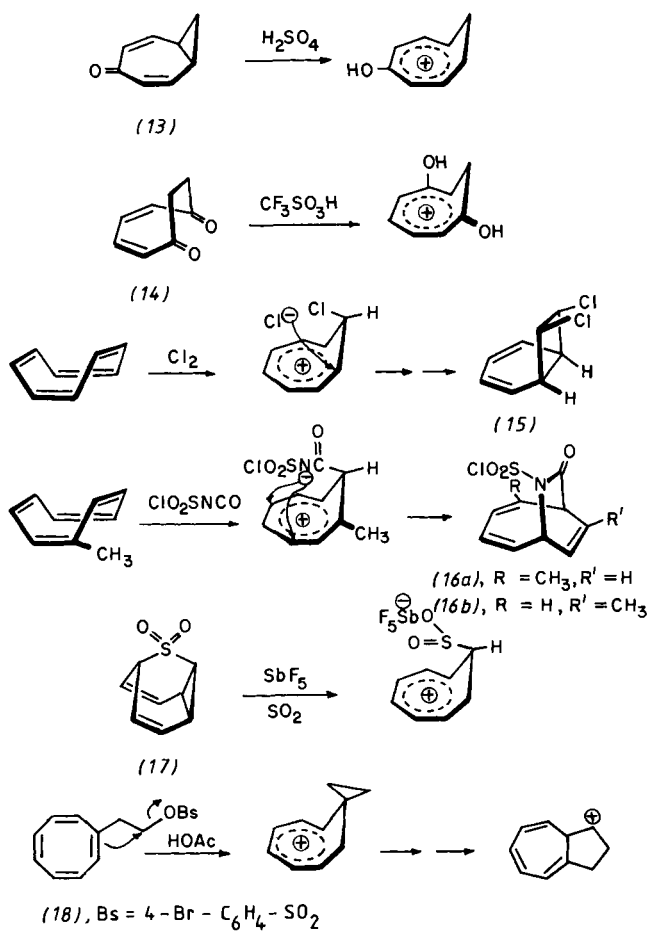


8.4 kcal/mol barrier to ring flipping, the level of which compares closely with theoretical estimates[11]. Despite this convincing evidence for electronic delocalization, it is unfortunate that no structural (*e.g.* X-ray) data are available to provide irrefutable information concerning the C-1—C-3 distance (calcd 1.739 Å)[11], the C-2—C-1—C-4 angle (calcd 148.3°)[11], and other important molecular dimensions.

Some measure of the driving force underlying the generation of these cations is provided by the overwhelming tendency of *(5)* to undergo clean two-electron oxidative ring opening in SbF_5-SO_2ClF with generation of *(6)*[14].

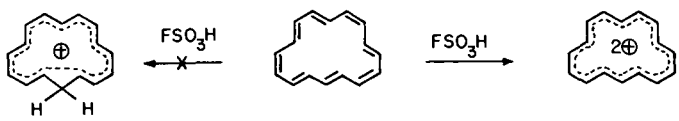


Developments in homotropylium ion chemistry began with *Pettit*'s early observation that treatment of cyclooctatetraene with concentrated H_2SO_4 or with $SbCl_5$ and HCl in nitromethane generated a cation with an unusual ^{1}H-NMR spectrum[15]. Subsequent work in *Winstein*'s laboratory showed the available



(7) (8) (9)

data to be best accommodated by a delocalized six electron structure where the prevailing ring current deshields the *exo* proton and shields the *endo* one ($\Delta\delta = 5.8$ ppm)[16]. Through use of D_2SO_4 below -15 °C, it could be demonstrated that D^+ attacks predominantly (80 %) from a position within the interior of the cyclooctatetraene tub conformation to give *(7)*, which on warming suffers *exo/endo* equilibration presumably *via* the planar cation *(8)* ($\Delta G^{\neq} = 22.3$ kcal/mol)[17]. The suggestion that a ring current was present in *(7)* received further support from ^{13}C-NMR analysis[18] and demonstration that the *hexahapto*-carbonylmetal complexes *(10)* and *(11)* have similar $\Delta\delta$'s, but that the value for the η^4-tricarbonyliron complex *(12)* is significantly attenuated[16,19].

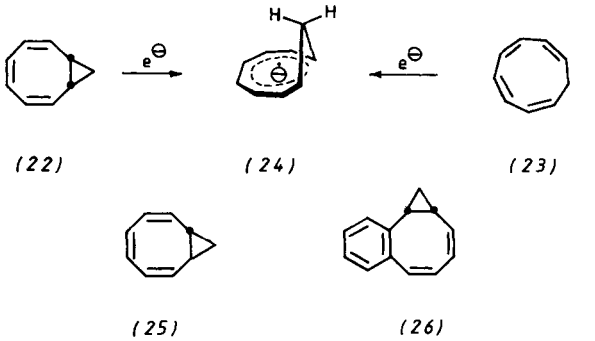


(10) (Δδ = 4.5) (11) (Δδ = 3.6) (12) (Δδ = 0.2)

The generation of homotropylium cations is an entirely general phenomenon which can arise upon (a) simple protonation of suitable acceptor molecules such as *(13)*[20] and

(13) (14) (15) (16a), R = CH3, R' = H (16b), R = H, R' = CH3 (17) (18), Bs = 4-Br-C6H4-SO2

(14)[21], (b) bonding of a biparticulate (*e.g.* Cl_2)[22] or uniparticulate electrophile (*e.g.* $ClSO_2NCO$) to cyclooctatetraene and its derivatives[23], (c) electrophilic attack upon a cyclic precursor such as *(17)*[24], and (d) solvolysis of an appropriate substrate such as *(18)*[25]. It is particularly ironic, therefore, that not one of the many known derivatives has been subjected to crystal structure analysis. Highly relevant questions concerning the internuclear distance separating C-1 from C-7, the angle of tilt of C-8 from the basal plane defined by the other seven carbon atoms, the bond lengths separating these centers, and the like, still remain unanswered. Until one or more definitive studies of this type are completed, we are forced to rely heavily upon the several theoretical estimates of π-electron distribution and homoconjugative interaction[8-11].

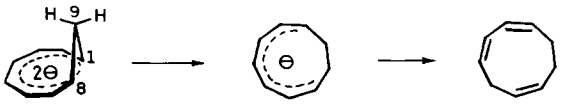


(20) (19) (21)

As one progressively increases the size of the homoaromatic ring, the level of resonance stabilization can be expected to decrease regularly to the point where it will eventually be offset by the strain energy caused by introduction of the homoconjugate bridge[8]. The upper limit in the maximum size of the ring may therefore be quite low. In the only experimental work to date which bears on this question, *Oth, Schröder*, and their coworkers have observed that dissolution of [16]annulene *(19)* in FSO_3H does not result in conventional protonation with the formation of *(20)*, but rather constitutes an oxidative method for generating the [16]annulenium dication *(21)*[26].

3.2. Anions

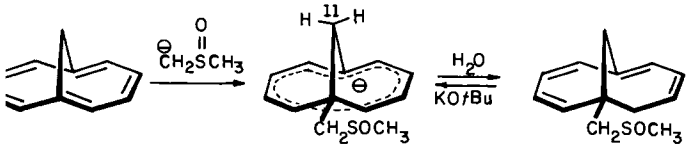
Because homocyclopentadienide anions are as yet unknown[27], the level of possible 6π6C delocalization attainable, if any, cannot be appreciated.



Upon reduction of *cis*-bicyclo[6.1.0]nonatriene *(22)*[28,29] or *cis*-cyclononatriene *(23)*[4,28], there is generated the radical anion *(24)* whose homoaromatic character has been inferred from ESR data and the contrasting behavior of the *trans* fused bicyclic *(25)*. The latter triene cannot undergo symmetry allowed disrotatory cyclopropane ring fission without engendering prohibitive strain energy. Electrochemical studies[30] on *(22)*, *(25)*, *(26)*, and structurally related molecules in

(22) (24) (23) (25) (26)

tetrahydrofuran and acetonitrile solution showed these hydrocarbons to deviate widely in their behavior from that exhibited by such 4*n* cyclic polyolefins as cyclooctatetraene[31] and [16]annulene[32] which are recognized to give rise to resonance stabilized reduction products. Both *(22)* and *(25)*, for example, undergo reduction with considerable difficulty, their respective waves appearing in the region characteristic of ordinary medium-ring trienes. Furthermore, none of the electron transfer processes are nernstian and cyclic voltammetry has revealed no reoxidizable product for any of the waves. It would appear therefore that at least in this instance electrochemistry does not serve as a suitable criterion for the assessment of developing homoaromatic character.

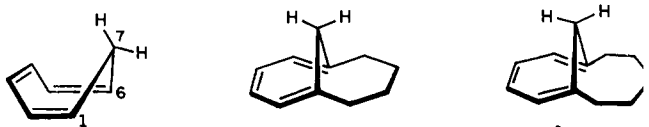


An early report by *Winstein* had indicated that further reduction of the radical anion *(24)* had provided the monohomocyclooctatetraene dianion *(27)*[28]. However, the original

(27) ($\Delta\delta = 2.6$) *(28)* *(29)*

spectral data given for *(27)* and the chemical reactivity ascribed to it are incongruous with more recent findings and must be questioned. The combined efforts of *Bates*[33] and *Paquette*[34] have generated convincing spectral evidence showing that *(27)* adopts the illustrated conformation where each of the original double bonds experiences some twisting to accommodate the homoconjugate bridge while maintaining maximum conjugative overlap. These dianions are much more basic than cyclooctatetraene dianions, being subject to ready protonation by ammonia at C-1 or C-8 with formation of cyclononatrienide anions *(28)*[34]. Subsequent quenching with a more electrophilic reagent permits isolation of 1,3,6-cyclononatriene derivatives [cf. *(29)*][34,35].

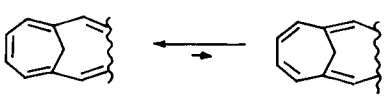
The only example of a possible monohomocyclononatetraenide anion *(31)* has been discovered by *Böll* while examining the nucleophilic addition of dimsyl anion to 1,6-meth-



(30) *(31)* *(32)*

ano[10]annulene *(30)*[36]. As is often customary, the ^{1}H-NMR spectrum of *(31)* [which shows the C-11 protons to resonate at high field ($\delta = 0.18$)] was used as the sole indicator of extended cyclic delocalization.

3.3. Neutral Systems

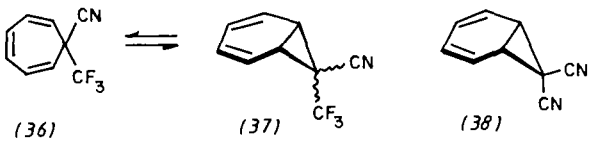


The question of whether cycloheptatriene and its derivatives are neutral homoaromatic molecules is one of long standing[37]. From electron diffraction studies[38], it is clear that the parent hydrocarbon adopts a boat conformation *(33)* in which the methylene group and the —CH=CH— structural element situated opposite to it are bent out of the basal plane (C-1, C-2, C-5, C-6). A cross section of *(33)* when viewed from this plane shows the C-1, C-6 p_z lobes to be geometrically related as in *B*. Since the internuclear distance and the mutual orientation of these two p orbitals relative to each other have been accurately determined, it is possible through use of vector analysis and Slater orbitals to calculate the extent of interpenetration as given by the overlap integral *S*[39]. These computations, which are facilitated by the C_s symmetry inherent in *(33)*, obviously require the two p_z orbi-

(33) ($\Delta\delta = 1.4$) *(34)* ($\Delta\delta = 2.22$) *(35)* ($\Delta\delta = 1.34$)

tals to possess the same phase in the overlap region (*i.e.*, a positive interaction) and the atomic orbital in question to be a dominant contributor to the molecular wave function. For *(33)*, the high degree of π bond localization supports the full occupancy, while its photoelectron spectrum[40] provides suitable evidence for the proper symmetry of these orbitals. The resultant magnitude of *S* (0.042) reveals that some overlap does occur at the periphery of those p_z lobes which are canted inward and that a finite level of homoaromatic interaction probably does exist. This level is obviously of low order (compare later) since the barrier to ring inversion, during which C-1 and C-6 overlap must suffer temporary disruption, is only *ca.* 6 kcal/mol[41,42].

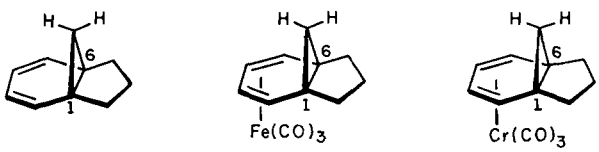
Evidence that cycloheptatriene can support an induced diamagnetic ring current (at least when in a magnetic field) comes from direct analysis of its ^{1}H-NMR spectrum[41-43] and diamagnetic susceptibility data (the exaltation is 59% that of benzene)[44]. As *Childs* and *Pikulic* have noted[45], the entirely comparable differences in susceptibility exaltation between benzene (13.7) and the tropylium cation (17) *versus* 7-*tert*-butylcycloheptatriene (14.8) and the monohomotropylium cation (21) suggests that there is equal right on this basis to refer to the triene as a homobenzene. In bridged cycloheptatrienes such as *(34)* and *(35)*[46] the *syn* methylene bridge proton lies over the π electron cloud and is again subject to ring current shielding (the *anti* proton lies in the deshielding zone). The difference between the $\Delta\delta$ values of *(34)* and *(35)* may be related to the degree of "pinching" by the polymethylene bracket and the resultant alteration in the C-1—C-6 internuclear vector. In this connection, much experimental data have now been amassed showing that the cycloheptatriene part structure *G* is thermodynamically preferred over the 1,6-dimethylenecycloheptatriene part structure *H* in a rather diversified array of annulated molecules[47-51]. Although strain



G *H*

effects may contribute in part to this phenomenon, one cannot avoid the conclusion that electronic factors exert a major impact upon the ground state stabilities.

The existence of *(33)* in equilibrium with an extremely small quantity of norcaradiene cannot be detected experimen-



tally[52] but can be indirectly deduced from several of its chemical reactions[37]. Particularly dramatic is the shift in this equilibrium with C-7 substitution. For example, *(36)* and *(37)* have been isolated as separate entities (thereby eliminating these structures as possible resonance forms of a single homobenzene) and *(38)* is the preferred form of the 7,7-dicyano derivative[53]. *Hoffman*[54] and *Günther*[55] were the first to treat this question from the theoretical viewpoint by considering the interaction of the orbitals of the electron-withdrawing C-7 substituent with the cyclopropane Walsh orbitals in *(37)* and *(38)*. More recently, a direct relationship

(36) *(37)* *(38)*

between the stereochemistry (*syn vs anti*) and electronic character of the substituent and the position of equilibrium in monofunctionalized systems has been implicated[56]. Further experimental work is necessary before this issue is fully clarified.

One must be careful not to equate homoconjugative overlap in *(33)* with "norcaradiene-like character." Strictly speaking, homoconjugative interaction in the triene involves pπ orbitals (possibly admixed with low levels of s character) which are geometrically prohibited from entering into overlap as in *A* and which therefore can partake of interaction only on one surface as in *B*. In any norcaradiene tautomer, key atoms C-1 and C-6 have experienced extensive formal rehybridization, the internal bond is probably as sigmoid as cyclopropyl character allows, and the relative geometry of the carbon frame has undergone substantial alteration. This does not mean that norcaradienes cannot display ring current effects in their own right. Compound *(39)*[46–57], for example, exhibits widely divergent cyclopropyl hydrogen shifts and vinyl protons approximately 0.45 ppm downfield from their expected position[58]. Because steric effects and anisotropic contributions from the conjugated diene unit seemingly cannot account for an overall Δδ of this magnitude[58], this evidence has been construed as indicative of homobenzenoid character. However, no structural data is available. In the tricarbonyliron complex *(40)*[59] (C-1—C-6 = 1.52 Å) where the diene segment

(39) (Δδ = 1.66) *(40)* (Δδ = 0.2) *(41)* (Δδ = 1.6)

is now entirely localized, the cyclopropyl protons differ minimally in their shifts. An electronic structure comparable to the uncomplexed system *(39)* is regained upon η^6 bonding as in the chromium complex *(41)*[59] (C-1—C-6 = 1.65 Å)[60]. Given the weight of this evidence and the shortcomings of nomenclature, it would seem most appropriate to distinguish between *(33)*, *(39)*, and their homologs in terms of π- and σ-homoaromatic systems, respectively.

The extent to which the electronic nature of 1,6-methano[10]annulene *(30)* is modified by π-homoaromatic interaction superimposed upon the dominant peripheral 10π electron delocalization remains unclear. The existence of non-negligible 1,6 overlap as suggested by theory[9,61] is seemingly manifested in its photoelectron[62], ultraviolet[63], and ^{13}C-NMR spectra[64]. X-ray crystal structure data for several of its derivatives are available, but like the cycloheptatrienes the C-1—C-6 distances vary widely (1.780—2.257 Å)[65–67] with simple substitution; in fact, the 11,11-dimethyl derivative is a tricyclic bisnorcaradiene[65].

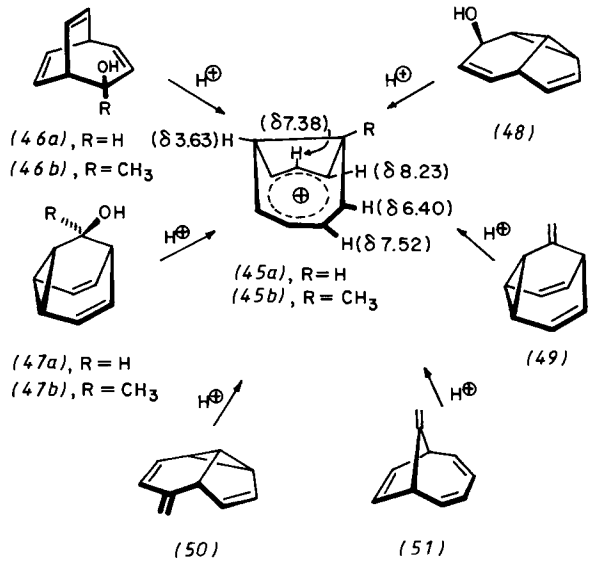
4. Bishomoaromatic Systems

4.1. Cations

The magnitude of homoaromatic stabilization is certain to diminish with increasing interruption by methylene groups of the otherwise conjugated π framework. Under these circumstances, neutral molecules cannot be expected to exhibit homoaromatic character to the same extent as ionic species which continue to possess a reasonable driving force for charge delocalization. A case in point is the 7-norbornenyl cation *(42)*[68], now recognized on the basis of cumulative rate effect

(42)

studies[69], direct NMR spectral examination[70], and responsiveness to varied electron demand[71,72] to be a symmetrical π-bishomocyclopropenium cation and not a rapidly equilibrating pair of classical ions[76]. As expected, the extent of delocalization is critically dependent upon structural geometry. Thus, 4-bromocyclopentene shows no anchimeric assistance to ionization[77], while the annulated homologs *(43)* undergo solvolyses at rates in direct proportion to the level of puckering of the one-carbon bridge (Table 1).



(43) *(44)*

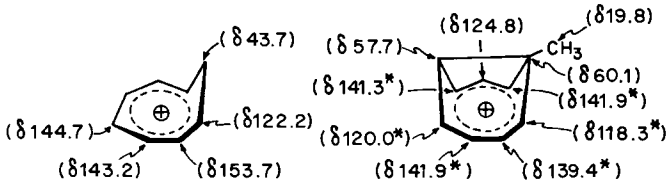


Table 1. Solvolysis constants (k_{rel}) of compounds of type *(43)* and *(44)*, X = OTs.

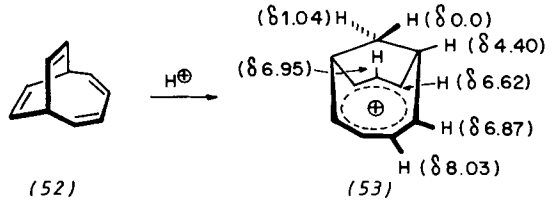
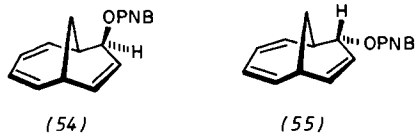
	n	k_{rel} *(43)*	k_{rel} *(44)*	Ref.
a	1	$10^{14.7}$	10^5	[73]
b	2	10^{11}	1	[2]
c	3	$10^{8.3}$	10^3	[74]
d	4	$10^{4.5}$	$10^{3.5}$	[75]

At the present time, no unbridged 1,4-bishomotropylium cation is known. The bridged system *(45a)* has, however, been generated in superacidic media from a variety of alcohol precursors such as *(46a)*, *(47a)*, and *(48)*[78–80]. Its monomethyl derivative *(45b)* has been comparably prepared from *(46b)* and *(47b)*[80], as well as by protonation of *(49)*—*(51)*[81].

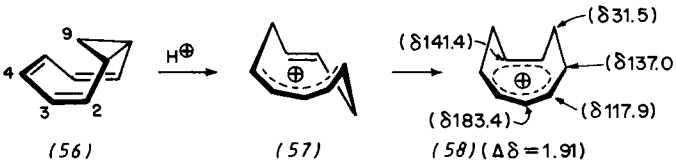


Higher derivatives of *(45)* have been implicated in other electrophilic additions to these methylene hydrocarbons[82]. Evidence for the homoaromatic character of *(45a)* (which is unstable and decomposes above −90°C) and *(45b)* has been deduced largely from spectral observations made under long life conditions. When comparison is made between the ^{13}C-NMR spectra of the monohomotropylium cation and the cation *(45b)*, it is readily seen that, although extensive

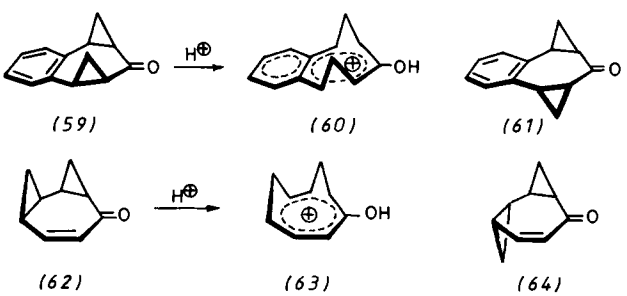


charge delocalization is present in the latter, the level of charge dispersal is reduced relative to the former which exhibits more equitable deshielding of its seven basal carbon atoms. In striking contrast, solvolytic studies provide no apparent indication of rate enhancement consistent with the intermediacy of *(45)*, although 1,4-bishomotropylium ion intervention after the rate-determining step cannot be ruled out[79,80,83].

A second bridged 1,4-bishomotropylium cation *(53)*, so constructed that two methylene hydrogens reside over the



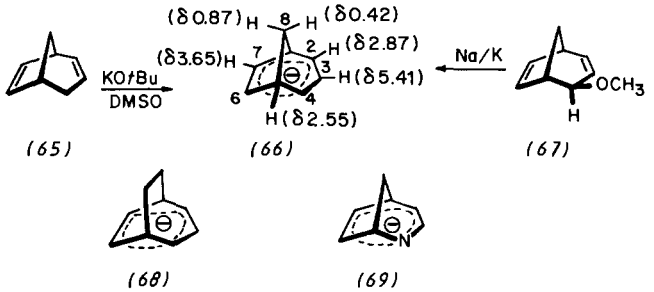
face of the homoaromatic ring system, can be conveniently prepared by dissolution of bicyclo[4.2.2]deca-2,4,7,9-tetraene *(52)* in a superacid medium below −100°C[80,84,85]. The assigned structure with its implied ring current is entirely consistent with the observed coupling constants and the sizable shielding effects (*ca.* 1 ppm) operating on the methylene protons. Other electrophilic additions to *(52)* and its derivatives agree with the mechanistic premise that attack occurs at C-2 with participation by a pair of electrons from one of the ethylene bridges[86–88]. Ion *(53)* appears to have a stronger ring current and to be more delocalized than *(45)*. Also, the substantial *(54)*/*(55)* rate ratio ($10^{4.5}$) signals that anchimeric acceleration can operate in precursors to *(53)*[80].



Attempts to generate yet other bridged 1,4-bishomotropylium ions from various precursors have provided some quite unexpected and interesting results[89,90].

Comparable protonation of *cis*-bicyclo[6.1.0]nonatriene is recognized to occur at C-3 in its thermodynamically less stable folded conformation *(56)* with initial generation of transoid cation *(57)* (not observable), the latter experiencing rapid bridge flipping to give the unbridged 1,3-bishomotropylium cation *(58)*[18,91]. The ring current effect in *(58)* is again clearly weaker than in the monohomotropylium derivative.

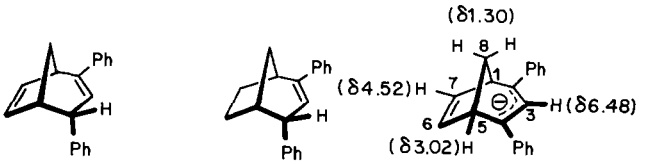
The requirement that electrophilic attack occur stereoselectively from the *exo* side of *(56)* was tested by examining the reactivity of the *syn*- and the *anti*-9-methyl derivatives. The former cannot attain a folded conformation for obvious steric reasons and in fact proved unreactive under conditions where the *anti* isomer was rapidly transformed into its bishomotropylium counterpart.



Upon protonation of *(49)*—*(52)* and *(56)*, there is seen to occur electronic and conformational realignments adequate to achieve effective π-bishomoaromatic delocalization. Preformed cyclopropane systems, however, frequently do not possess a comparable capability for structural readjustment. Assessment of the stereochemical requirements for σ-bishomoaromaticity is thereby made possible. In the two pairs of isomers studied so far[92,93], it has been found that *cisoid* bishomotropones *(59)* and *(62)* have internal cyclopropane orbitals properly aligned to enable the attainment of bishomoaromatic character in their conjugate acids *(60)* and *(63)*, respectively. In contrast, *trans* fused arrangements of the bridging groups as in *(61)* and *(64)* are not conducive to such

cyclic delocalization [compare *(57)*] if the chemical shifts of their methylene protons in acidic solution are again suitably diagnostic of the presence of a ring current.

4.2. Anions



Our present appreciation of 1,3-bishomocyclopentadienide character rests upon several experimental findings. These include the exceptional facility with which bicyclo[3.2.1]octa-2,6-diene *(65)* undergoes proton-deuterium exchange at C-4 to give *(66)*[94], a property shared by its 6,7-benzolog[95] and related molecules[96], and the ^{1}H-NMR spectrum of *(66)*, the direct observation of which was made possible by Na—K reduction of *(67)* (the *endo* isomer reacts much more slowly)[94,97]. Carbanion *(68)*[98] and the hetero system *(69)*[99] exhibit entirely comparable spectral properties suggestive of a sustained ring current. In *(66)*, for example, the upfield chemical shift of H-6 and H-7 and the downfield shift of H-3 compared to those in *(65)* has been construed as indicative of the delocalization of the negative charge over C-6 and C-7. Although the topologies of *(66)*, *(68)*, and *(69)* as enforced by the rather rigid framework geometries are conducive to orbital interaction, and HMO calculations do indicate that this interaction will be bonding[2], a number of findings are not in necessary agreement with the above view. Firstly, one sees that all of the proton shifts in *(66)* appear at high field for a homoaromatic system, thereby indicating that the prevailing diamagnetic ring current, if any, must be small. Secondly, the measurements of deprotonation rates provide information on kinetic properties and need not reflect thermodynamic differences; therefore, the extent to which the anticipated inductive and strain contributions of the second (C-6=C-7) double bond in *(65)* might facilitate carbanion formation is difficult to quantify in absolute terms[100].

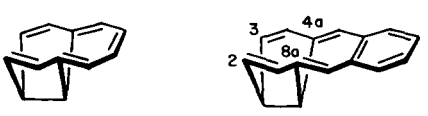
(65) *(66)* *(67)*

(68) *(69)*

In this connection, *Trimitsis* and *Tuncay* have recently compared the rate of base-catalyzed hydrogen-deuterium exchange at C-4 in diene *(70)* with that of its dihydro derivative *(71)*[101]. The kinetic imbalance was observed to be only 3.3 (compare $k(65)/k$(dihydro-*(65)*)$=10^{4.5}$)[94] and both rate constants were closely related to that of the acyclic analog 1,3-diphenylpropene where no bishomoaromatic delocalization can develop. Accordingly, it may be argued that the added stabilization provided by the phenyl groups to the developing allylic carbanion moiety eliminates the need for involvement of the 6,7-double bond in charge delocalization. However, the ^{1}H-NMR spectrum of *(72)* bears strikingly close similarity to that of *(66)*[102]. For example, H-6 and H-7 have experienced a substantial upfield shift (1.04 ppm) relative to *(70)* (this is 45% as large as that observed in *(66)*). The bridge protons at C-8 likewise appear upfield [60% as large as that in *(66)*] while H-3 has moved downfield by 1.10 ppm. If *(72)* truly does not display charge delocalization to C-6 and C-7, then it must be concluded that anisotropic effects due to the allyl anion play a more important role in influencing proton shifts than heretofore realized. At best,

(70) *(71)* *(72)*

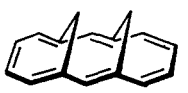
we see that quantitative dissection of the properties of these anions into σ and π contributions remains incompletely resolved. The desirability of obtaining reliable X-ray structural data wherever this may be possible is again very apparent.



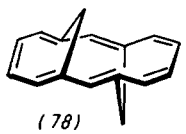
A single attempt to generate a bishomocyclooctatetraenyl dianion has been reported. Reduction to tetraene *(73)* did not however give rise to *(74)* but to a highly basic species where the charge was localized in the triene segment of the molecule[103].

(73) *(74)*

4.3. Neutral Systems



The transition state for degenerate Cope rearrangement in bridged homotropilidenes is bishomobenzenoid in character. The energy gap separating ground state and activated complex is smallest for semibullvalene ($\Delta H^{\neq}=4.8$ kcal/mol)[104]. Prompted by the theoretical conclusions of *Hoffmann*[105] and *Dewar*[106], considerable attention has been paid to the possible creation of a transition state so stabilized that it becomes a neutral homoaromatic ground state. The placement of substituents upon[107], and bracketing of[51,108], the semibullvalene nucleus have so far not led to observation of the desired phenomenon. Extrapolations based upon a recent crystal structure analysis of several 1,5-disubstituted 9-thiabarbaralane 9,9-dioxides[109] suggest that 1,5-difluorosemibullvalene might exhibit this most intriguing property. But the preparation of this fluorocarbon remains to be realized.

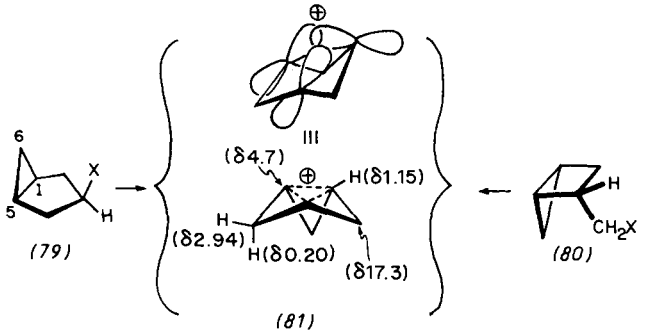


(75) *(76)*

Both *Paquette*[51,110] and *Vogel*[111] have prepared hydrocarbon *(75)* (called elassovalene[110]) and examined its ability to support homoconjugation. The combined weight of spectral evidence[51,110-112] and diamagnetic exaltation criteria[110]

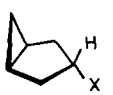
reveal this molecule to possess at a minimum some degree of homoaromatic character in the bridged cycloheptatriene portion of the structure. A more definite assessment of π-electron distribution and structural dimension in this ring system has been realized by synthesis of the 6,7-benzo derivative *(76)* and X-ray structure analysis of this crystalline substance[39]. With precise knowledge of key distances C-4a—C-8a = 2.44 and C-2—C-3 = 2.54 Å and the relative orientations of the p orbitals at these four sites, the respective overlap integrals were determined to be 0.061 and 0.050, respectively. The difference between these values is revealingly sizable and quantitatively indicative of better overlap in the central portion of the molecule. Interestingly, the overlap integral between C-2 and C-3 (see Section 3.3, $S = 0.042$) is somewhat larger than that determined for cycloheptatetriene. It follows from these findings that mutually canted homoconjugated carbon atoms can still interact when separated by internuclear distances as large as 2.54 Å.

(77)



(78)

Although *Vogel* has demonstrated that geometric factors exert important consequences on the electronic properties of higher bridged annulenes such as *(77)* (aromatic)[113] and *(78)* (nonaromatic)[114], it remains unclear in these examples (as in 1,6-methano[10]annulene) if any transannular interaction is at play.



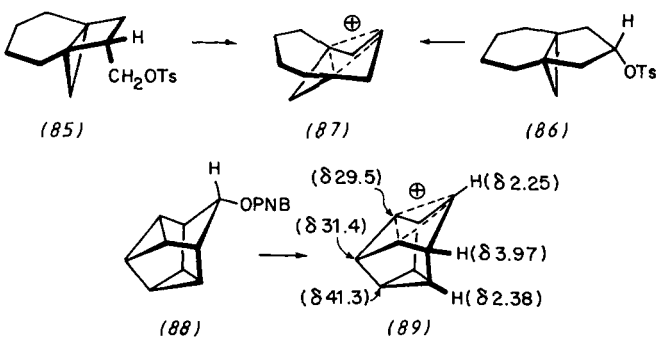
5. Trishomoaromatic Systems

5.1. Cations

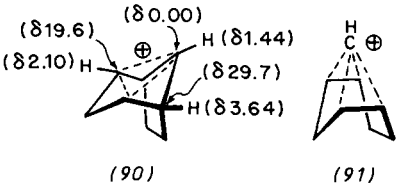
On the basis of the solvolytic behavior of *cis* tosylates *(79)*-OTs[115] and *(80)*-OTs[116] which are converted to *(79)*-OAc and *(79)*-OH, respectively, in greater than 90% yield, it has been argued that trishomocyclopropenium cation *(81)* intervenes. This conclusion is supported by the formation from [6,6-D_2]-*(79)*-OTs of *(79)*-OAc having 1.35 methylene protons per cyclopropane ring[117], the direct NMR spectroscopic observation of *(81)* upon ionization of *(79)*-Cl superacid solution at −120 °C[118], and theoretical calculations[119,120]. The spectral data in particular agree with the conclusion that *(81)* is extensively charge-delocalized, possesses C_{3v} symmetry, and gains substantial energetic benefit from homoconjugation.

Despite such evidence, a number of notable failures to generate *(81)* have been reported[121–124]. These include the deamination of *(79)*-NH_2 and *(82)*-NH_2[121] and the solvolysis of *(82)*-OTs[117] which lead to complex product distributions rationalizable in terms of classical cation *(83)*. This led *Winstein* to postulate that leakage from *(83)* to *(81)* is relatively inefficient[117]. In addition, the protonation of bicyclo[3.1.0]hex-2-ene furnishes *(84)* rather than *(81)*[122].

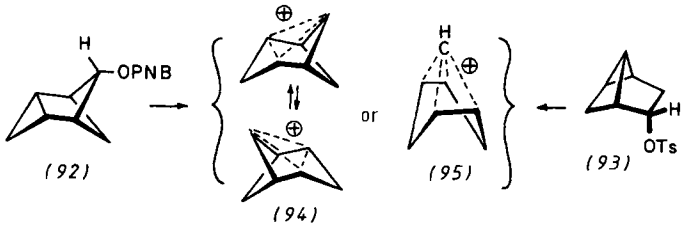
(82)



(83)



(84)



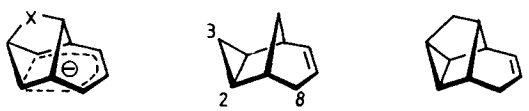
This particular reaction course is now recognized to be thermodynamically justified since the cyclopropylmethyl cation *(83)* is apparently more stable than *(81)*[120].

In recent years, interest in trishomocyclopropenium cations and their precursors has greatly intensified[125–136]. Thus, in addition to the closely related systems *(85)*[125] and *(86)*[58], detailed attention has been paid to *Coates'* cation *(89)*, the highly delocalized nature of which has been uncovered by kinetic studies on *(88)* (rate enhancement of 10^{10} to 10^{12}; strain relief not an issue since rearrangement is degenerate)[126], analysis of remote and proximate substituent effects upon ionization[127], application of the tool of increasing electron demand[128], direct detection by NMR spectroscopy[129], and theoretical analysis[130]. *Masamune* has generated the simpler ethano-bridged cation *(90)* under long-life conditions and has suggested on the basis of the spectral evidence that the square pyramidal species *(91)* may contribute significantly[131]. Whatever the true structure, this trishomoaromatic system does respond to leveling effects[132]. Solvolysis of *(92)*[133] and *(93)*[134] gives a common cation, direct NMR observation of which at −110 °C reveals it to be rapidly equilibrating under these conditions [*i.e. (94)*] or fully delocalized as in *(95)*[135].

Previously, two-fold interruptions of 6π7C tropylium topology were shown not to seriously disrupt charge delocalization

(92) (94) (95) (93)

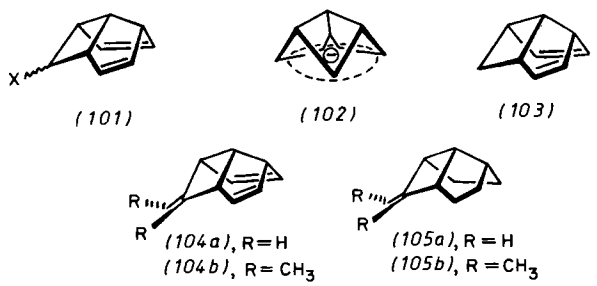
as long as the methylene carbons were maintained in a *syn* disposition. Simple extrapolation of this reasoning would argue that the tricyclo[5.3.1.$0^{4,11}$]undeca-2,5,8-trienyl cation might well exhibit trishomoaromatic character as depicted in *(96)*. However, neither the solvolysis of *(97)*-OPNB (short-lived conditions)[137] nor exposure of *(97)*-OH, *(97)*-Cl, or



(96) (97)

(97)-OCH_3 to superacidic conditions[137,138] has provided evidence for extended charge delocalization beyond simple allylic character.

5.2. Anions



Evidence for extended electronic interaction between an allyl anion and a proximate cyclopropane ring or olefinic bond in potential trishomocyclopentadienide anions has also been sought, but without success. Thus, in *Freeman* and *Hardy*'s attempts to introduce delocalization such as *(98)*

(98) (99) (100)

by deprotonation of *(99)* and *(100)*, no enhancement in the rates of H/D exchange was observed for either hydrocarbon in KO*t*Bu/[D_6]-DMSO[139]. Experiments involving Na/K cleavage of the *exo*-8-methoxy derivative of *(99)* also proved unrewarding[140].

Various reactions of *(101)*-I and *(101)*-Cl (both epimers) have provided no evidence for trishomoaromatic stabilization of the related anion as in *(102)*[141]. Nortriquinacene *(103)* does not experience ready deprotonation at its methylene carbon and in fact MINDO/3 calculations predict this carbanion not only to be classical in structure, but to have a pyramidal anionic carbon as well[141,142]. Furthermore,

(101) (102) (103)

(104a), R=H
(104b), R=CH_3
(105a), R=H
(105b), R=CH_3

photoelectron spectroscopic studies involving *(103)*, *(104)*, and *(105)* indicate the absence of through-space interactions in the alkylidenenortriquinacenes[143].

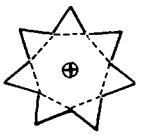
The presence of a driving force for trishomoaromatic charge delocalization has also not been found in the trishomocyclooctatetraenide dianion *(106)*[103]. Experimentally, reduction of *(107)* gives a highly basic dianion (not observed spectroscopically) which, on the basis of its ensuing reactions, is believed to have the charge concentrated on its diene segment [compare *(27)* and *(74)*][103].

(106) (107)

5.3. Neutral Systems

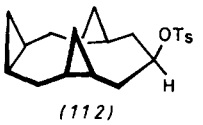
Three possible uncharged six-electron trishomoaromatic analogs of benzene have been synthesized. They are 1,4,7-cyclononatriene *(108)*[144], triquinacene *(109)*[145], and diademane *(110)*[146]. In the case of *(108)*, it has been concluded from ^{1}H-NMR spectroscopy, heats of hydrogenation studies,

(108) (109) (110)



X-ray crystallographic data[147], and theoretical assessments[148] that the triene is not homoaromatic. More recently, however, photoelectron spectroscopy has revealed an appreciable interaction of its π bonds, the 0.9 eV split between the degenerate HOMO's indicating a resonance integral of 0.3 eV[149]. Also, from the distance separating the sp^2-hybridized carbons (distance between bridged π centers 2.46 Å)[147] and the mutual orientation of their inner p lobes, the extent of interaction as measured by the overlap integral is seen to be significant ($S=0.066$)[39]. In *(109)*, the lessened split (0.35—0.4 eV)[150] reveals the lower limit of the resonance integral between its π orbitals (distance = 2.553 Å)[151] to be 0.1 eV. This value is lowered somewhat from its true level because hyperconjugative interactions seemingly destabilize the lowest π orbital, causing the split to be smaller than it would if through-space interactions operated exclusively. Notwithstanding, the homoconjugation in *(109)*, as enforced by its unique topology, is measurably decreased ($S=0.054$)[39] relative to *(108)*. Diademane *(110)* lacks even this level of interaction[152].

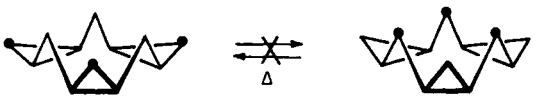
6. Higher Homoaromatic Systems



Winstein has attempted to gain access to the perhomotropylium cation *(111)* through solvolysis of *(112)* and its epimer[153]. But the homoaromatic species is not formed, the rates, products, and lack of deuterium scrambling suggesting that delocalized intermediates are unimportant.

Triscyclopropanation of *(108)* in all *cis* fashion leads to adoption by the resultant saturated hydrocarbon of a crown

conformation which so fixes the medium ring methylene groups that the inner protons experience strong shielding while the outer protons are deshielded[154]. Yet when the



(111)

(112)

two hexadeuterio isomers *(113)* and *(114)* were recently prepared and thermolyzed, no scrambling of the isotopic label was seen[155]. The lack of bond shifting, as well as the demonstrated noninterconvertibility of two trioxa analogs[156], signals the unresponsiveness of this class of compounds to the attainment of "hexahomobenzenoid" transition states.

(113) (114)

7. Summary

In light of the above findings, we see that proper structural modification of a variety of molecular systems possessing $(4n+2)$ π electrons or a suitable array of π and strained σ (cyclopropane) electrons can indeed remain conducive to maintenance of a ring current. But through-space interaction between the composite segments is acutely sensitive to geometry, mutual proximity, and energy levels of the relevant orbitals. Such effects are not unique to homoaromatic molecules. For bridged bicyclic dienes of the Dewar benzene, norbornadiene, bicyclo[2.2.2]octadiene, *etc.*, type, the same is true. In this series, through-space interaction becomes greatly attenuated with incremental lengthening of the oligomethylene bridge (from 0 to 4 carbon atoms)[157].

As the number of insulating atoms is increased, the ability to satisfy these major requirements becomes more and more taxed. This is particularly noticeable for neutral molecules which lack the driving force for charge dispersal embodied in ions. For such substances, crystal structure data are necessary to give quantitative meaning to the extent of orbital overlap. This refined treatment is, of course, equally valuable for ions, but the experimental task in these cases is understandably more complicated.

Although the future will undoubtedly bring refinements and expanded dimension to this field of study, a certain number of concepts dealing with novel forms of conjugation extended over three dimensional space have already gained attention in recent years. And beyond bicycloaromaticity[5], ribbon topology[142], spiroconjugation[158], and subjacent orbital control[159] lie new frontiers of understanding which will continue to challenge practicing chemists.

COMMUNICATIONS

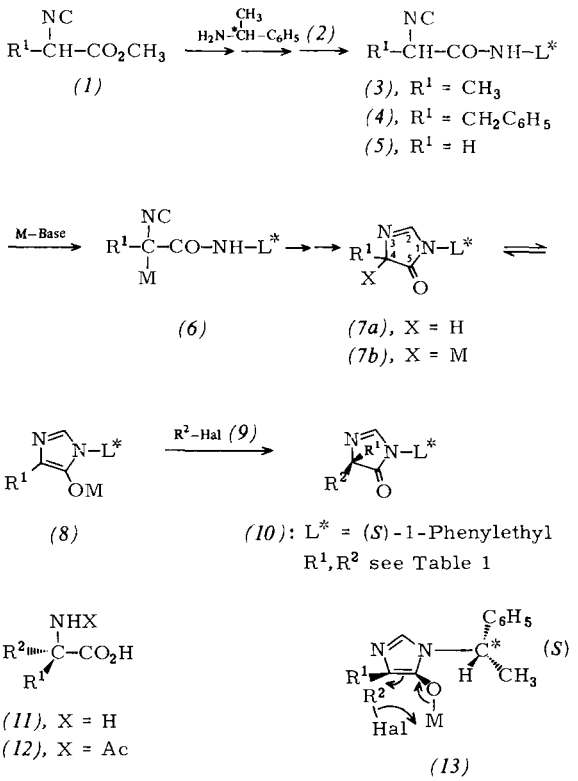
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Asymmetric Synthesis of α-Alkyl-α-aminocarboxylic Acids by Alkylation of 1-*chiral*-Substituted 2-Imidazolin-5-ones[1]

By *Ulrich Schöllkopf, Hans Heinrich Hausberg, Inga Hoppe, Marcos Segal*, and *Udo Reiter*[*]

Owing to the immensely important role played by optically active amino acids in pure and applied chemistry, asymmetric amino acid synthesis has attracted especial interest. Of preparative importance, however, are only those methods which a) are relatively easy to carry out with good chemical yields, b) give high optical yields, and c) enable recovery of the chiral auxiliary agent[2].

We wish to report an asymmetric synthesis of α-alkyl-α-amino acids *(11)*, which in many cases satisfies these requirements[3]. The 4-metalated 4-alkyl-1-[(*S*)-1-phenylethyl]-2-imidazolin-5-ones *(7b)* or their tautomers *(8)* are alkylated with R^2-Hal *(9)* and the resulting 4,4-disubstituted imidazolinones *(10)* hydrolyzed to the amino acids *(11)*. After the hydrolysis the (*S*)-1-phenylethylamine *(2)* used for the synthesis of *(7)*, can be recovered. In the case of alkylating agents *(9)* with large R^2 groups, *e.g.* benzyl halides, the asymmetric induction at C-4 of *(10)* is almost 100%; it decreases with decreasing size of R^2 (cf. Table 1). The stereoselectivity of the reaction can be determined ^{1}H-NMR spectroscopically at the stage of the imidazolinone *(10)* (usually at 60 MHz and without shift reagents), preferably by observing the doublet of the methyl protons of the phenylethyl moiety, which shows different chemical shifts in the two diastereomers. An induction of >95% (cf. Table 1) is assumed if only one diastereomer is recognizable in the NMR spectrum.



The 2-imidazolin-5-ones *(7a)* are obtained either from the (*S*)-α-amino *N*-phenylethylcarboxamides with orthoformates[4] or, better, by base-induced cyclization of the (*S*)-*N*-phenylethyl-2-isocyanoalkanamides *(3)*—*(4)*. Isolation of the imidazolinone *(7a)* is, however, unnecessary. Reaction of the amides *(3)* to *(4)*—prepared from methyl 2-isocyanoalkanoate *(1)* and (*S*)-1-phenylethylamine *(2)*—with one equivalent of a metalating agent (M-base such as butyllithium, potassium *tert*-butoxide, sodium hydroxide *etc.*) leads to the 4-metalated imidazolinones *(7b) in situ*. The cyclization *(6)* →→ *(7b)* proceeds apparently rapidly, so that the same results can be achieved with this (more convenient) *in situ* method [Method A, cf. Table 1] as when starting from *(7a)*. In some experiments we used (*S*)-*N*-phenylethylisocyanoacetamide *(5)* as starting compound. Twofold metalation

[*] Prof. Dr. U. Schöllkopf, Dr. H.-H. Hausberg, Dr. I. Hoppe, Dipl.-Chem. M. Segal, Dipl.-Chem. U. Reiter

Tammannstr. 2, D-3400 Göttingen (Germany)

of *(5)* with two equivalents of butyllithium and subsequent reaction with R^1-Hal afforded the intermediate *(6)*, M = Li, which cyclized to *(7b)*⇌*(8)*, from which *(10)* was finally obtained by reaction with R^2-Hal [Method B, cf. Table 1]. In order to achieve the highest possible optical yield *via* this route it would seem advisable to first incorporate the smaller substituents as R^1-Hal [cf. in Table 1 *e.g. (10a)* with *(10o)*, *(10j)* with *(10p)*]. As expected the preferred configuration at C-4 of *(10)* changes if the sequence of incorporation of R^1 and R^2 is changed [cf. in Table 1 *e.g. (10a)* with *(10o)*, *(10n)* with *(10t)*, *(10l)* with *(10q)*].

Hydrolysis of the 4,4-disubstituted imidazolinones *(10)* necessitates more or less drastic conditions, depending on the nature of R^1 and R^2. In principle, the hydrolysis can be carried out under acid or alkaline conditions. Thus, *e.g.*, we obtained (*S*)-α-methylphenylalanine *(11a)* by acid hydrolysis [from *(10a)*][5], but later found out that alkaline hydrolysis (with KOH in ethanol/water, glycol/water *etc.*) was more suitable[6]. The amino acids *(11)* have been characterized by way of their (readily crystallizing) *N*-acetyl derivatives *(12)*[6].

With (*S*)-configuration of the 1-phenylethyl group (L*)—as revealed by the synthesis of the configuratively known (*S*)-α-methylphenylalanine[3] *(11a)* and (*S*)-α-methyl-DOPA[6]—the configuration shown in formulas *(10)* and *(11)* is induced [*S* when R^2 has priority over R^1, otherwise *R*]. The following model concept explains this finding: in the most favorable conformation for *(8)* the hydrogen atom in the ring plane of the heterocycle is oriented towards the oxygen atom[7], which—complexed with metal atom and solvent—is the "largest" neighbor. Methyl and phenyl groups lie below and above the diastereotopic heterocyclic plane [cf. *(13)*]; for steric reasons R^2 preferably enters at that side which bears the smaller methyl group. Accordingly, the degree of induction depends on the size of the entering group R^2 [cf. in Table 1 *e.g.*

(10o) with *(10n)*], and not on that of the stationary substituents R^1 [cf. in Table 1 *(10a)*, *(10i)*—*(10n)*][8].

Experimental

(*S*)-*N*-phenylethyl-2-isocyanoalkanamides *(3)*—*(5)*: (*S*)-1-phenylethylamine *(2)* (12.1 g, 0.1 mol) and *(1)* (0.1 mol) are

[f] After *Mąkosza*, with veratryl chloride, 50%. NaOH, TEBA, CH_2Cl_2, 25—40°C.
[g] 55% ee; optically pure *(12b)*: −52° (2.0, CH_3OH) [6].
[h] For *(11c)*.
[i] With iodide.

mixed together with 0.1 g *p*-toluenesulfonic acid with stirring. *(3)*: 11.3 g (0.1 mol) *(1a)*, 12 h at room temperature, 30 min at 100 °C; crystallization from methanol or chromatography on alumina with ether; 16.4 g (81 %) *(3)*, m.p. 89 °C. *(4)*: 18.9 g (0.1 mol) *(1b)*, 12 h at 60 °C, then methanol removed *in vacuo*; 26.5 g (95 %) *(4)*, m.p. 135—136 °C (from isopropanol). *(5)*: 9.9 g (0.1 mol) *(1c)*, 12 h at 30—35 °C without catalyst, otherwise as in the case of *(4)*; 15 g (80 %) *(5)*, m.p. 122—123 °C (from ethyl acetate).

2-Imidazolin-5-ones *(7a)*: To a solution of *(3)* or *(4)* in tetrahydrofuran at −60 °C is added 1 equivalent of butyllithium or potassium *tert*-butoxide and the stirred mixture warmed to −20 °C, neutralized with glacial acetic acid, and worked up in the usual way. *(7a)*, $R^1 = CH_3$: b.p. 105 °C/10^{-3} torr (with enol form). *(7a)*, $R^1 = CH_2C_6H_5$: used as crude product (no enol form detectable). *(7a)*, $R^1 = H$: not preparable, unstable.

2-Imidazolin-5-ones *(10)*: Method A: To a solution of *(3)* (3.03 g, 15 mmol) in 20 ml dry tetrahydrofuran at −60 °C is added 15 mmol butyllithium (dropwise) (9.4 ml of a 1.6 M solution in hexane) or 15 mmol potassium *tert*-butoxide. A solution of 15 mmol R^2-Hal *(9)* in *ca.* 10 ml tetrahydrofuran is added dropwise at −60 °C to the solution of *(7b)*⇌*(8)*. The mixture is allowed to warm to room temperature, the solvent removed *in vacuo*, and the residue taken up in 20 ml CH_2Cl_2. The solution is washed with 2 × 20 ml water, dried over magnesium sulfate, and worked up in the usual way (cf. Table 1).—In the case of *(4)*, 0.84 g (3 mmol) in 15 ml THF is metalated with 3 mmol BuLi at −78 °C. For the cyclization *(6)* → *(7)* the solution is allowed to warm to room temperature. It is then cooled to −70 °C and treated with 3 mmol *(9)*. After 3 h at room temperature the solution is neutralized with glacial acetic acid, the solvent removed, and the residue worked up in the usual way.—Method B: 20 mmol butyllithium (13 ml of a 1.5 M solution in hexane) is added dropwise at −78 °C to a solution of *(5)* (1.9 g, 10 mmol) in 25 ml THF. The mixture is stirred for 10 min, treated with a solution of 10 mmol R^1-Hal in 10 ml THF, and then allowed to warm to +10 °C. Finally, 10 mmol *(9)* in 10 ml THF is added and the whole stirred for *ca.* 2 h. Work-up as in Method A.

Amino acids *(11)* and *(12)*: A mixture of 2 g of *(10)*, 20 ml ethanol, 10 ml water and 2 g KOH (if need be, glycol or triglycol instead of ethanol) is boiled under reflux until completion of hydrolysis (up to 20 h). Water is then added, if necessary after removal of the ethanol, and the solution extracted twice with CH_2Cl_2 [separation of *(2)*]. Further work-up depends upon the properties of *(11)*. On acidification of the aqueous phase with 6 N HCl, *(11)* often precipitates. In other cases the aqueous phase is neutralized and evaporated down *in vacuo*. The crude product (contaminated with KCl) can be used for the acylation: A solution of *(11)* (1 g) in dimethylformamide (10 ml) is treated with 2-equivalents of acetic anhydride and the mixture heated for 1 h at 90 °C. The solution is then evaporated down at 10^{-2} torr and *(12)* isolated by recrystallization from ethanol or ethanol/water.

[7] According to an X-ray structure analysis the hydrogen atom of the 1-phenylethyl group in *(10a)* lies in the plane of the heterocycle and points towards the oxygen; moreover, the benzyl group inserted at C-4 is located on the same side as the methyl group of the phenylethyl moiety, its phenyl ring is located near the carbonyl group: *W. Saenger*, Max-Planck-Institut für Experimentelle Medizin, Göttingen, private communication.
[8] If a methyl group is inserted at C-2 in *(7b)*⇌*(8)*, the extent of induction is drastically reduced.

The $Co_2(CO)_8/Ph_3P$-Catalyzed Reaction of Aldehydes with Hydrosilane and Carbon Monoxide[1]

By *Yoshio Seki, Shinji Murai*, and *Noboru Sonoda*[*]

We recently reported that olefins[2] and cyclic ethers[3] give enol silyl ethers and silyl-protected hydroxyaldehydes, respectively, when allowed to react with a hydrosilane and carbon monoxide in the presence of $Co_2(CO)_8$.

We now wish to report the new catalyzed reaction of aldehydes with $HSiR_3$ and CO to give 1,2-bis(siloxy)olefins *(1)*.

(1)

Table 1. Physical properties of some silyl-protected 1,2-enediols *(1)*.

	R	B.p. [°C/torr]	IR [a] ν (C=C) [cm^{-1}]	^{1}H-NMR [b] δ (HC=C, s)

[a] Without solvent.
[b] In CCl_4. The signals at higher fields correspond to (*Z*) isomers and those at lower field to (*E*) isomers.

Reaction of *n*-heptanal with diethyl(methyl)silane (threefold excess w.r.t. aldehyde) and carbon monoxide in the presence of $Co_2(CO)_8$ and triphenylphosphane gave a mixture of (*E*)- and (*Z*)-1,2-bis[diethyl(methyl)siloxy]-1-octenes *(1a)* in 66 % yield (cf. Table 1). The use of Ph_3P as a cocatalyst is necessary

Suita, Osaka 565 (Japan)
[+] Author to whom correspondence should be addressed.

to prevent undesired hydrosilylation of the aldehyde. Analogously, reaction of *n*-butanal and cyclohexanecarboxaldehyde gave *(1b)* and *(1c)* in 67 % and 37 % yields, respectively. In the case of cyclohexanecarboxaldehyde, the yield of *(1c)* was low because of the formation of diethyl(methyl)siloxymethylenecyclohexane (61 %) by dehydrogenative silylation. Interestingly, a similar reaction (using a fivefold excess of the hydrosilane, but in this case without Ph_3P) of tetrahydrofuran was found to give the same type of compound *(1d)* in 89 % yield—probably *via* the intermediate 5-diethyl(methyl)siloxy-*n*-pentanal, which was the product when the reaction was carried out using a fivefold excess of tetrahydrofuran over the silane and without Ph_3P[3].

It has been reported that formates can be produced from aldehydes (*via* O—C bond formation) under hydroformylation (oxo synthesis) conditions[4]. In contrast, by using a hydrosilane instead of hydrogen, bis-siloxyalkenes *(1)* instead of esters were obtained (*via* C—C bond formation).

Experimental:

Synthesis of *(1a)*: A solution of 1.14 g (10 mmol) of *n*-heptanal, 4.4 ml (30 mmol) of diethyl(methyl)silane, 0.068 g (0.2 mmol) of $Co_2(CO)_8$, and 0.052 g (0.2 mmol) of triphenylphosphane in 20 ml of benzene was placed in a 100 ml stainless steel autoclave. The autoclave was flushed with N_2 (50 kp/cm^2) and CO (50 kp/cm^2), then charged with CO (50 kp/cm^2) and heated at 140 °C with stirring. After 20 h, the autoclave was cooled and depressurized. Analysis of the reaction mixture by GLC [Silicon OV-1, 5 %, on Uniport KS, 3 m, 170 °C, internal standard *n*-hexadecane] showed it to contain *(1a)* in 66 % yield; at longer retention times there were at least two further unidentified products (total *ca.* 14 %). An analytical sample of *(1a)* was obtained by fractional distillation (b.p. 120–123 °C/0.5 torr) and preparative gas chromatography (190 °C).

Binuclear Iron Complexes Containing Unsymmetrically Substituted Silanediyl Bridges[1]

By *Wolfgang Malisch* and *Wolfgang Ries*[*]

The ability of 4B elements germanium, tin, and lead to function as bridges between transition metal atoms has been demonstrated by numerous examples[2], whereas only few corresponding examples of complexes with silicon bridges have so far been described[3]. We have now found that nucleophilic metalation of chlorosilyliron complexes of type *(1)*[4] with the extremely reactive anion $[Cp(CO)_2Fe]^{\ominus}$[5] affords easy access to binuclear complexes containing a silicon bridge if the chlorosilyl group still bears at least one hydrogen atom and the reaction is carried out heterogeneously in methylcyclohexane.

Diferriosilane *(2)*, which is isolable as orange-yellow crystals, m.p. 89—90 °C, exhibits increasing solubility in the series pentane cyclohexane, benzene, toluene, and, according to the IR spectrum, has C_1 symmetry[6] in the dissolved state (cyclohexane). The prochiral character of the $Cp(CO)_2Fe$ group is demonstrated by ^{13}C-NMR spectroscopy[1]. The unusual position of the νSiH vibrational band at 2025 cm^{-1} characterizes the metal group as a strong donor. This "transition metal effect" also gives rise to the pronounced tendency of the strongly hydridic *Si*—H function to undergo exchange reactions, as exemplified by the halogenation of the latter on reaction with CCl_4 or $PhC^{\oplus}BF_4^{\ominus}$ under very mild conditions (in benzene, 25 °C)[1].

(3a), m.p. 163–165 °C

When *(2)*, either in the solid state or in solution, is exposed to daylight it is slowly transformed with loss of CO into the bicyclic species *(3a)*, in which the two iron atoms are now coupled both directly and by a CO bridge. This conversion can be considerably accelerated photochemically[7].

The ^{1}H-NMR spectrum of *(3a)* in benzene contains, besides four signals for the cyclopentadienyl groups, three signals each for the HSi and the CH_3 groups (as quartet and doublet, respectively) and thus proves that the ring system is present

in solution as a mixture of all three theoretically conceivable stereoisomers[8]. An unequivocal assignment of signals (cf. Table 1) is possible only in the case of the *trans* form (two C_5H_5 signals of equal intensity). Assuming steric preference for the *cis*(H) form an isomeric ratio of 56/*cis*(H): 26/*cis*(CH_3): 18/*trans* would result. Spectra recorded immediately after dissolution of crystalline *(3a)* show only the two *cis* isomers [86/*cis*(H): 14/*cis*(CH_3)], while the equilibrium concentration of the *trans* form is reached only after 20 minutes. Hence, a *cis*/*trans* isomerization already takes place at room temperature, and, in principle, is possible both from the *cis*(H) as well as from the *cis*(CH_3) form[9].

(3b): ^{1}H-NMR (C_6D_6): *trans*: $\delta C_5H_5 = 4.42$, 4.28 (s, 5H); $\delta CH_3 = 1.62$ (s, 3H) / *cis*(Cl): $\delta C_5H_5 = 4.23$ (s, 10H); $\delta CH_3 = 1.71$ (s, 3H)) / *cis*(CH_3): $\delta C_5H_5 = 4.03$ (s, 10H); $\delta CH_3 = 1.59$ (s, 3H).—IR (cyclohexane): νCO = 2000 (w), 1980 (vs), 1968 (sh), 1946 (s), 1791 (vs) cm^{-1}.

[a] Chemical shifts downfield rel. to TMS int.; coupling constants in Hz. Analytical data consistent with the given formulas.

In accord with the even smaller magnitude of the Si—H valence vibration (νSiH = 2015 cm^{-1}), hydrogen exchange at the silanediyl bridge of *(3a)* proceeds more rapidly than in the open-chain species *(2)*.

Reaction of *(3a)* with CCl_4 smoothly affords the chloro-substituted cyclic compound *(3b)*, m.p. 183—185 °C, which is distinctly more stable than the hydrosilane *(3a)* (both thermally and solvolytically), and in which the isomeric equilibrium is shifted further in favor of the *cis*(X) form [83/*cis*(Cl): 5/*cis*(CH_3): 12/*trans*]. The derivative *(3b)* can also be generated photolytically from *(4)*[11].

Experimental:

(2): A solution of $Cp(CO)_3FeSiHCH_3Cl$[4] (1.57 g, 6.12 mmol) in 50 ml methylcyclohexane is treated with 1.58 g (7.88 mmol) of dry $Na[Fe(CO)_2Cp]$[5]. The mixture is stirred in the absence of light for 6d at 25 °C, filtered, the filtrate evaporated *in vacuo*, and the resulting residue extracted several times with pentane. Freezing out at −78 °C affords 1.43 g (59 %) *(2)*.

(3a): A solution of *(2)* (492 mg, 1.24 mmol) in 60 ml benzene is irradiated for *ca.* 6 h with UV light (quartz lamp Q150 Hanau), the carbon monoxide that is formed being removed from the reaction vessel with a stream of N_2. The filtered solution is concentrated to 7 ml and *(3a)* precipitated with 5 ml pentane at room temperature. The deep-red crystals are washed twice with 5 ml cold pentane and dried *in vacuo*; yield 271 mg (59 %).

(3b): A suspension of *(3a)* (270 mg, 0.73 mmol) in 5 ml CCl_4 is allowed to stand for 30 min at 25 °C. After removal of volatile components, multiple extraction of the solid residue with 10 ml toluene/methylcyclohexane (1 : 1) and freezing out at −78 °C affords 242 mg (82 %) *(3b)*.

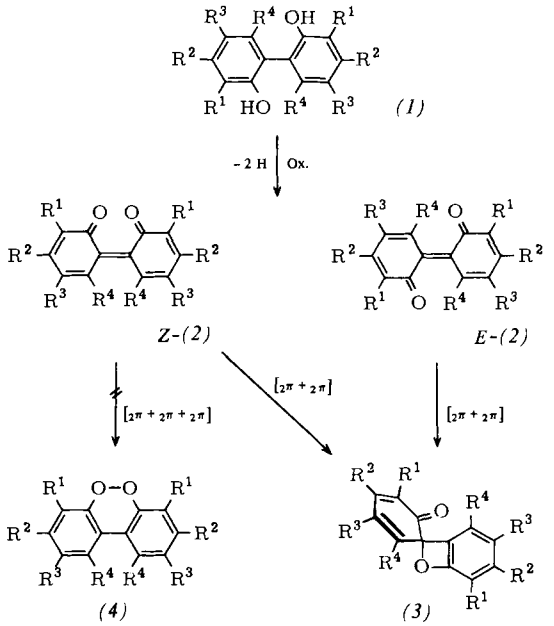
[7] An analogous cyclization reaction has already been observed with $(CH_3)_2Ge$-bridged complexes: *R. C. Job, M. D. Curtis*, Inorg. Chem. *12*, 2514 (1973).
[8] This finding is confirmed by the $^{13}C\{^1H\}$-NMR spectrum (in C_6D_6). $\delta C_5H_5 = 83.83$, 84.27, 84.86, 85.30; $\delta CH_3 = 7.89$, 8.97, 10.09; $\delta CO_{term} = 212.57$.
[9] Investigations presently being carried out on the activation parameters of this process should clarify whether the *cis*/*cis* and *cis*/*trans* isomerizations are independent processes.

Oxepinobenzofurans—The True Nature of Sterically Hindered "Benzoxetes"



By *Herbert Meier, Hans-Peter Schneider, Anton Rieker*, and *Peter B. Hitchcock*[*]

In 1961 *E. Müller et al.* observed that dehydrogenation of 2,4-di-*tert*-butylphenol, 2,4-di-*tert*-butyl-6-iodophenol, or biphenol *(1a)* in benzene yields a deep violet solution suspected to contain the corresponding *o,o'*-diphenoquinone *(2a)* (*Z*- and/or *E*-configuration). A pale yellow compound, assigned the structure of a benzoxete *(3a)*, could be isolated in good yield[1].

Structural proof was based on the formal analogy to the formation of homologous spiroquinol ethers, reduction to the biphenol *(1a)*, and the ^{1}H-NMR spectrum[1]. Later on, compound *(4a)* first isolated by *Baltes* and *Volbert* in 1955, which exists in equilibrium with the diphenoquinone *(2b)*[2a], was ascribed the same kind of structure *(3b)*[2b,c]. The oxidation products of the biphenols *(1c—g)* were also regarded

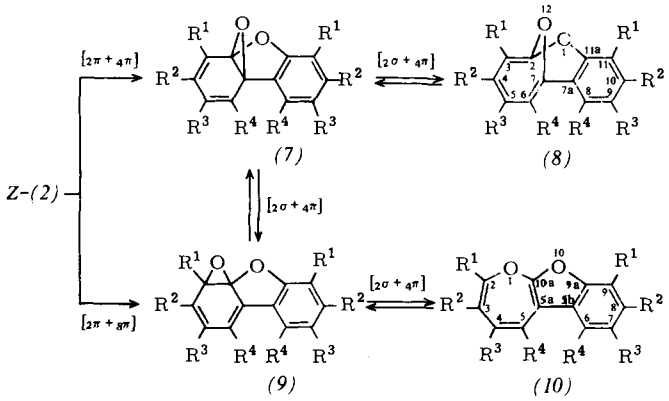
as benzoxetes *(3c—g)*[3]. Further synthetic pathways leading to these "benzoxetes" and numerous reactions have been reported up to the present[4].

	R^1	R^2	R^3	R^4
(a)	*t*Bu	H	*t*Bu	H
(b)	*t*Bu	H	OMe	H
(c)	*t*Pent	H	*t*Pent	H
(d)	*t*Bu	H	Trityl	H
(e)	*t*Bu	H	*t*Bu	Me
(f)	*t*Bu	H	*t*Bu	Cl
(g)	*t*Bu	Cl	OMe	Cl

According to an EHT calculation[5], valence isomerization of *o*-methylenecyclohexadienone to benzoxete should be a strongly endothermic process. This is incompatible with the low activation barrier of isomerization of compound *(2)*, which proceeds spontaneously at room temperature. Moreover, the thermal and chemical behavior of the products contradict observations made on benzoxete systems formed *in situ*[6]. We have therefore re-examined the valence isomers of the diphenoquinones *(2a)*, *(2b)*, *(2f)*, and *(2g)* and found that the IR absorption observed in the region of 1645 cm^{-1} cannot be assigned to the C=O stretching absorption of a *o*-quinol ether on account of its wave number and intensity. In the ^{13}C-NMR spectra the presence of a carbonyl carbon atom of a quinol ether structure can likewise be strictly ruled out. Compounds *(5)*[1] and *(6)*[7] served as reference substances. Hence the benzoxete structure *(3)* can be discounted.

(5)



δ(CO) = 199.7 ppm

(6)

δ(CO) = 194.2 ppm

o,o'-Diphenoquinones are theoretically capable of undergoing a variety of valence isomerizations starting from either the *Z* or the *E* configuration. It follows from the ^{1}H- and ^{13}C-NMR spectra of the valence isomers that only those processes take place which involve *both CO groups* and lead to *asymmetric structures*. Thus, the only remaining possible intramolecular cycloadditions of these 14π electron systems are *Z-(2)*→*(7)*→*(8)* and *Z-(2)*→*(9)*→*(10)*:

This situation is reminiscent of oxygen-bridged [10]annulene[8]. Spectroscopic data oppose a benzene oxide structure and favor an oxepin structure *(8/10)*[9]: IR (KBr): resolved bands of medium intensity at 1600—1660 cm^{-1}.—^{1}H-NMR ($CDCl_3$): AB system of aromatic ring protons in *(8/10a)* at δ = 7.2 and 7.1 with $J_{1,3}$ = 2 Hz and AB system of the non-aromatic ring protons at δ = 6.4 and 5.5 with $J_{1,3} \leq 1$ Hz.—^{13}C-NMR ($CDCl_3$): 12 signals of expected multiplicity each for the sp^2 carbon atoms in the range $170.8 \geq \delta \geq 90.6$, which are not compatible with an epoxide structure but rather with the oxepin (ketene acetal) structures [C-3/C-5a: $100 \geq \delta \geq 96$; C-2/C-10a: $161 \geq \delta \geq 153$].

Thermal equilibria *(8)*⇌*(7)* and *(10)*⇌*(9)* can be ruled out on the basis of NMR measurements. However, the deoxygenation of *(8)* and *(10)* with triphenylphosphane or hydrogen iodide to the symmetrical dibenzofuran system[11] suggests a certain degree of reversibility. Differentiation between the two oxepin systems *(8)* and *(10)* is impossible by means of spectroscopic criteria alone. A decision in favor of the linearly annelated oxepino[2,3-*b*]benzofuran system *(10)* was provided by the X-ray analysis of *(8/10g)*. Whether the oxygen-bridged 2,7-epoxy-1-benzoxonins *(8)* can be formed on suitable substitution and under favorable reaction conditions and what mechanistic possibilities exist for the process *(1)*→*(10)* remain open questions.

Redetermination of the structure of the dehydrogenation products of *(1)* leads to the following conclusions:

1) To our knowledge, compounds *(8/10)* are the first oxepinobenzofurans to have been reported and belong to the very first oxepins ever isolated—*(8/10b)* in 1955[10].

2) The *o*-methylenecyclohexadienone partial structure in the *o,o'*-diphenoquinones does not tend to cyclize to benzoxete systems. This also indicates the possibility of reversion of a 2,4-cyclohexadienone to an oxepin ("reversal" of the NIH effect)[9a].

3) The mechanistic conclusions drawn from the benzoxete formulation and the structures of the formulated reaction products must be re-examined.

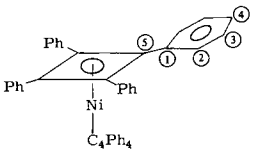
Bis(tetraphenylcyclobutadiene)nickel

By *Heinz Hoberg, Reinhild Krause-Göing*, and *Richard Mynott*[*]

The possibility of stabilizing cyclobutadiene by coordination to a transition metal was already pointed out as long ago as 1956[1], and soon afterwards *Criegee et al.* described the synthesis of the first monocyclobutadiene complex[2]. The isolation of bis(cyclobutadiene) complexes of the sandwich type, however, has so far not been reported in the literature[3].

We are able to show, on the basis of spectroscopic data and chemical behavior, that the compound of composition $C_8(C_6H_5)_8Ni$[4], obtained in *ca.* 5 % yield on reaction of (pentaphenyl)aluminacyclopentadiene *(1)* with Li metal and $NiBr_2$, is the octaphenyl derivative of bis(cyclobutadiene)nickel *(2)*.

(1) *(2)*



+ $C_{12}(C_6H_5)_{12}Ni_2$ + $C_8(C_6H_5)_8$ + ...

(2) crystallizes as well-formed small blue needles[5], m.p. 404 °C (dec).—The mass spectrum shows the molecular ion at $m/e = 770$ as well as characteristic fragments at $m/e = 414$ $[C_4(C_6H_5)_4Ni]$, 236 $[C_2(C_6H_5)_2Ni]$, and 178 $[C_2(C_6H_5)_2]$. The molecular weight of 765 (determined vaporimetrically in benzene) confirms the monomeric structure of the complex.

Only phenyl groups are detectable in the IR and ^{1}H-NMR spectra. In the UV spectrum (toluene) three bands are observed outside the phenyl absorption region (above 280 nm) at 295 ($\log\varepsilon = 4.8$), 370 (4.4), and 450 (4.7) nm. The band at 295 nm is of special significance regarding the assignment of structure for *(2)*, since an absorption maximum in the neighborhood of 300 nm is characteristic for cyclobutadiene-transition metal complexes[6]; the maximum at 450 nm corresponds to a d→d transition in the Ni complex.

The ^{13}C-NMR spectrum (Table 1) contains only five signals, thus indicating a high symmetry of the compound and ruling out a (tetraphenyl)nickelacyclopentadiene system[7].

Table 1. ^{13}C-NMR spectrum (25.2 MHz, Varian XL-100A-15) of complex *(2)* in [D$_8$]-tetrahydrofuran at 34 °C, reference signal β-CD$_2$ ($\delta_{TMS} = 25.3$).

	Signal	δ	Intensity
	1	133.8	small
	2, 3	128.9	2
		128.4	2
	4	127.0	1
	5	114.5	small

The signals at δ = 128.9, 128.4, and 127.0 in the ratio 2:2:1 lie in the region of protonated phenyl C atoms. With a small flip angle (α = 18°, pulse frequency 1.0 s) resonances are observed at δ = 133.8 and 114.5 which are to be assigned to the "quaternary" phenyl and cyclobutadiene C atoms (cf. Table 2).

Table 2. Chemical shifts of the four-membered ring C atoms in cyclobutadienenickel complexes.

Compound	Solvent	δ
$[C_4(C_6H_5)_4NiBr_2]_2$ [a]	$CDCl_3$	100.1
$[C_4(CH_3)_4NiCl_2]_2$ [b]	$CDCl_3$	108.0
(2)	[D$_8$]-THF	114.5

[a] *H. H. Freedman*, J. Am. Chem. Soc. *83*, 2194 (1961). [b] See [2a].

The low chemical reactivity of *(2)* is consistent with complete enclosure of the central Ni atom by the two tetraphenylcyclobutadiene ligands. Thus, the ligands cannot be replaced by CO, even at 110 °C and 1 atm. *(2)* is not attacked by boiling water within 24 h and is stable towards air over prolonged periods. In concentrated HNO_3 *(2)* is slowly oxidized, yielding mainly 1,2,3,4-tetraphenyl-2-butene-1,4-dione[8]. Mass spectrometric investigation reveals a further product with the molecular ion at $m/e = 372$ $[C_4(C_6H_5)_4O]$.

The cyclobutadiene system in *(2)* can be reduced or hydrogenated only with difficulty. No change is observed on treatment with $LiAlH_4$ in diethyl ether (35 °C, 48 h), Et_2AlH in toluene (110 °C, 48 h), H_2/Raney-Ni in hexane, or H_2/PtO_2 in ethanol (20 °C, 72 h). Metallic potassium, however, attacks *(2)* in liquid ammonia; hydrolysis affords predominantly 1,2,3,4-tetraphenylbutane and small amounts of 1,2,3,4-tetraphenylbutene.

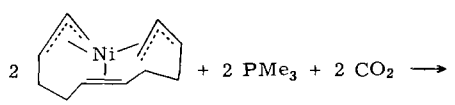
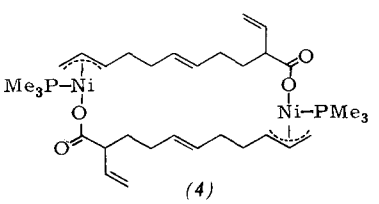
Reactions of Carbon Dioxide with Allylnickel Compounds[**].

By *P. W. Jolly, Stefan Stobbe, Günther Wilke, Richard Goddard, Carl Krüger, Janine C. Sekutowski,* and *Yi-Hung Tsay*[*]



The fixation of carbon dioxide to transition metals has attracted considerable interest in recent years[1]. However, attempts to incorporate carbon dioxide in cooligomerization reactions have so far met with little success[2].

Although nickel(0) forms stable CO_2-complexes[3] and catalyzes the cyclo-cooligomerization of CO_2 with alkynes to substituted pyrones[2b], stoichiometric reactions of CO_2 with organonickel compounds have not yet been described. We have investigated the reaction of carbon dioxide with π-allylnickel complexes in order to gain an insight into possible catalytic reactions. Bis(η^3-methylallyl)nickel *(1)* reacts quantitatively with CO_2 in the presence of basic phosphanes to give carboxylates of type *(2)*:



(1) *(2)*, R = CH_3, C_6H_{11}

The alkene-α,ω-bis(η^3-allyl)nickel complex *(3)*, which is formed as an intermediate in the cyclotrimerization of butadiene[4], reacts analogously with CO_2 in the presence of trimethylphosphane to give the dimer *(4)* (cryoscopic molecular weight determination).

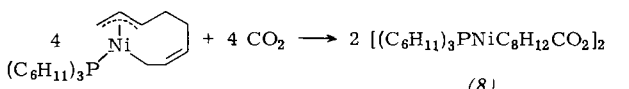
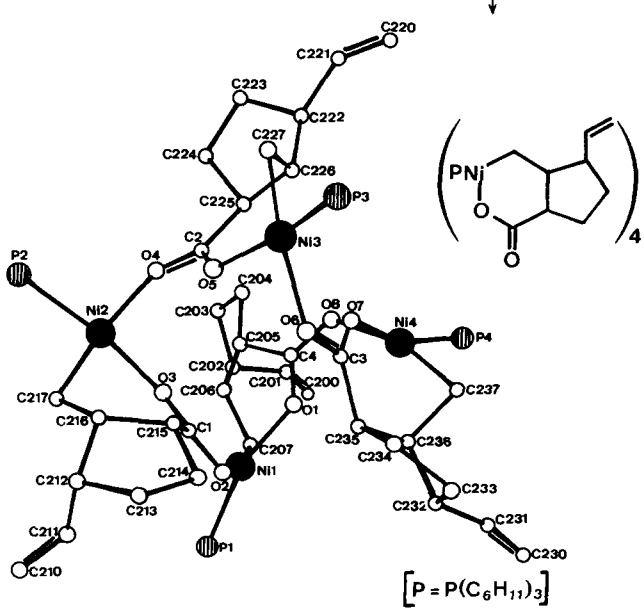
Max-Planck-Institut für Kohlenforschung
Lembkestr. 5, D-4330 Mülheim-Ruhr 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.—Atomic parameters and Fo/Fc lists of the X-ray structure analyses are obtainable on request from the authors *(Goddard, Krüger, Sekutowski, Tsay)*.

The alkenyl-η^3-allyl(phosphane)nickel complexes, formed as intermediates in the Ni-catalyzed cyclodimerization of 1,3-dienes[5], also react smoothly with CO_2; the skeletal structure of the products, however, depends upon the diene employed.



(5)



Treatment of *(5)* with CO_2 leads to *(6)*, which is structurally analogous to *(4)*. (*(5)* is prepared by reaction of isoprene with tricyclohexylphosphanenickel(0) and exists in two isomeric forms.) The structure of the dimer *(6)* was elucidated X-ray crystallographically[6].

The compound *(7)* from butadiene, corresponding to *(5)*, reacts with CO_2 to give the dimer *(8)*, which on heating in a toluene-acetone mixture rearranges into the tetrameric nickelalactone *(9)*. Complex *(9)* can also be prepared from $[(C_6H_{11})_3P]_2NiCO_2$ and butadiene. Its structure has been confirmed by X-ray structure analysis[7].

(7) *(8)*

These results are best explained as CO_2 insertion into an allylnickel σ-bond formed under the influence of the phosphane. Similar behavior is observed in the reaction of π-allylnickel complexes with isocyanates or SO_2[8].

Experimental

Synthesis of *(2)* ($R=C_6H_{11}$): Tricyclohexylphosphane (3.43 g, 12.3 mmol) is added at −30°C to a solution of *(1)*[9] (2.10 g, 12.4 mmol) in 10 ml toluene. After 2—3 h a stream of CO_2 is fed into the reaction vessel and the mixture stirred for 24 h. The yellow precipitate which separates after a short while is isolated at −30°C, washed twice with 10 ml ether, and dried under high vacuum at −10°C. Yield 4.25 (70%).—^{13}C-NMR (−50°C, D_8-toluene): δ = 40.5 (CH_2), 123.37 (CMe), 71.15 (d, J_{PC} = 19 Hz, CH_2) [η^3-Allyl]; 23.08, 23.56 (CH_3); 175.09 (C=O), 47.83 (CH_2), 143.69 (C=), 112.19 (=CH_2); 32.73, 29.83, 27.89, 26.76 (C_6H_{11}). IR (KBr): $\nu_{C=O}$ 1610 cm^{-1}.

Synthesis of *(6)*: Passage of CO_2 through a solution of *(5)* (4.75 g, 10 mmol) in ether or toluene leads to precipitation of *(6)* as a yellow solid. Yield 3.63 g (70%). IR (KBr): $\nu_{C=O}$ 1615 cm^{-1}.

Synthesis of *(9)*: A suspension of *(8)* in acetone heated to 60°C is diluted with toluene until complete dissolution. On cooling *(9)* precipitates as red crystals in almost quantitative yield.—IR (KBr): $\nu_{C=O}$ 1540 cm^{-1}.

Synthesis and Crystal Structure of a Methylenebis(diphenylphosphane) Complex of Silver Bromide Containing a Trigonal Bipyramidal Ag_3Br_2 Central Unit

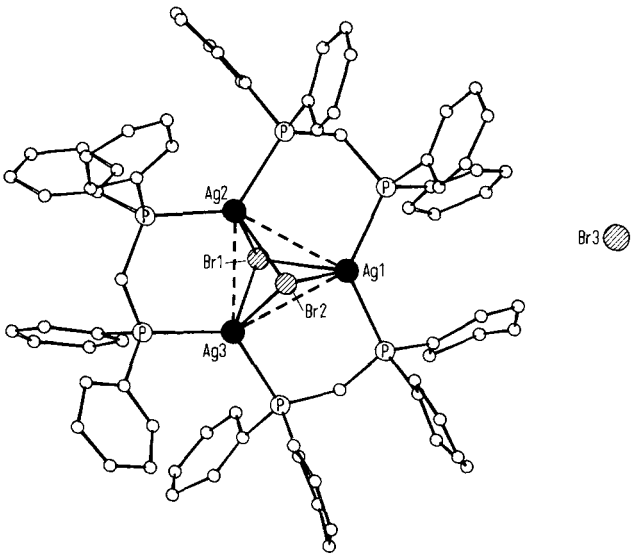
By *Aref A. M. Aly, Dietmar Neugebauer, Olli Orama, Ulrich Schubert*, and *Hubert Schmidbaur*[*]

We recently reported a 2:1 complex of gold(I) chloride with methylenebis(diphenylphosphane)[1]. The ligand $CH_2(PPh_2)_2$ ("dpm") is characterized, like 1,8-naphthyridines[2] and some phosphorus ylides[3], by the fact that the metal atoms in its dinuclear coordination compounds lie in very close proximity to one another, thus favoring a transition to metal-metal bonding[4]. In dpm complexes of copper, aggregated groups are found to be present whose metal centers have a high tendency to fourfold coordination[5].

In the hitherto uninvestigated system silver(I) halide/dpm we have now discovered that specifically AgBr forms a 1:1 complex *(1)* in which formally three monomer units unite with dissociation of a $Br^{\ominus}$ ion to give a novel $Ag_3Br_2^{\oplus}$ structural moiety:

$$3\ AgBr + 3\ dpm \longrightarrow (dpm)_3Ag_3Br_2^{\oplus}Br^{\ominus} \qquad (1)$$

The product obtained on reaction of equimolar amounts of the reactants at 20°C in toluene crystallizes from CH_2Cl_2/pentane and shows the conductivity of a 1:1 electrolyte in CH_2Cl_2 ($17.2\,\Omega^{-1}\,cm^2\,mol^{-1}$ at 20°C, w.r.t. the trimer). The ^{1}H-NMR spectrum contains, besides the phenyl multiplet, only one complex signal for the CH_2 groups, indicating structural equivalence of all the dpm units. The structure and dimensions of the complex as deduced from an X-ray diffraction analysis[6] are depicted in Figure 1.



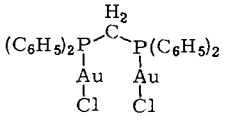


Fig. 1. Structure of crystalline complex *(1)*. Important bond lengths [pm] and angles [°]:

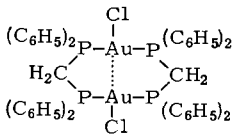
Ag1—Ag2	336.2(3)	Ag1—Br1	294.2(4)
Ag2—Ag3	319.2(3)	Ag1—Br2	278.4(4)
Ag1—Ag3	335.6(3)	Ag2—Br1	280.8(4)
		Ag2—Br2	283.8(4)
Ag—P	242(1) to 247(1)	Ag3—Br1	284.6(4)
		Ag3—Br2	279.0(4)
Ag1—Ag2—Ag3	61.5(1)	Ag1—Br1—Ag2	71.5(1)
Ag1—Ag3—Ag2	61.7(1)	Ag2—Br1—Ag3	68.7(1)
Ag2—Ag1—Ag3	56.7(1)	Ag1—Br1—Ag3	70.9(1)
		Ag1—Br2—Ag2	73.5(1)
		Ag2—Br2—Ag3	69.1(1)
		Ag1—Br2—Ag3	70.9(1)



The silver atoms in *(1)* form an almost equilateral triangle; together with two approximately equidistant bromine atoms there arises a trigonal bipyramidal central unit. The sides of the Ag_3 triangle are singly bridged by a dpm ligand whose phenyl groups are twisted to avoid steric hinderance. In such an arrangement the silver atoms have coordination number

[*] Prof. Dr. H. Schmidbaur, A. A. M. Aly (M.A.), D. Neugebauer, Dr. O. Orama [**], Dr. U. Schubert

[**] Alexander-von-Humboldt Fellow.

four, but the valence angles deviate somewhat from tetrahedral geometry. The two bromine atoms of the Ag_3Br_2 cage are each bound to all three silver atoms (sharp trigonal pyramids with small AgBrAg angles), while the third bromine atom is present as an isolated $Br^{\ominus}$ ion. All in all, the structure contains six $BrAg_2P_2C$ six-membered rings which are "condensed" *via* the Ag_3Br_2 skeleton in a chair or tub conformation. The metal-metal contacts of 319—336 ppm may still be regarded as non-bonding.

(2)

(3)

By way of comparison the Au—Au bond length in the gold complex *(2)*[1] is 335.1(2) pm, while the numerous analogous copper compounds so far described[5] have Cu—Cu distances of 2.546 to 3.281 pm; the cyclic derivative *(2)* has the shortest Au—Au contact of 296.2(1) pm[7].

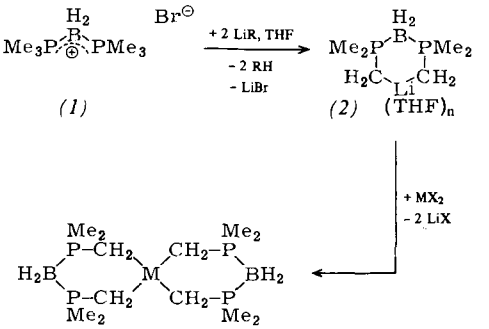
The Boratobis(dimethylphosphiniomethylide) Anion, a Novel Ligand System for Organometallic Compounds

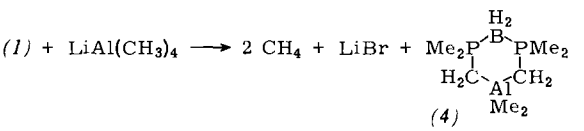
By *Hubert Schmidbaur, Gerhard Müller, Ulrich Schubert*, and *Olli Orama*[*]

Despite their unusually interesting properties, phosphaneboranes *(A)* have hitherto hardly been investigated[1]. Especially remarkable is the thermal and chemical stability of the boratobis(trialkylphosphonium) salts *(B)*, which are soluble without decomposition in water and even stable toward mineral acids as well as alkalis[2].



$R_3P{\rightarrow}BH_3$ *(A)* $[R_3P{\rightarrow}BH_2{\leftarrow}PR_3]^{\oplus}X^{\ominus}$ *(B)*

We have succeeded in functionalizing the alkyl groups of this cationic species such that the corresponding ylide anions *(C)* can be incorporated in organometallic compounds as novel ligands. The products closely resemble the isoelectronic methanido- and nitridobis(dialkylphosphiniomethylide) derivatives *(D)* and *(E)*, respectively[3].



(C) *(D)* *(E)*

Boratobis(trimethylphosphonium) bromide *(1)*, which is readily accessible by a new one-pot method[4], rapidly reacts with two equivalents of *tert*- or *n*-butyllithium in tetrahydrofuran at -25 °C with loss of alkane to give the lithium complex of the ylide anion *(2)*, detectable in solution by NMR spectroscopy. Further reaction with metal halides leads to the chelate complexes *(3)* in good yields.

(1) *(2)* *(3a)*, M = Zn; *(3b)*, M = Cd; *(3c)*, M = Ni

Such metal boratobis(dimethylphosphiniomethylides) *(3)* are also obtainable by direct reaction of *(1)* with metal hydrides or alkyl derivatives, *e.g.* according to:

(4)

Composition and structure of the complexes were confirmed by elemental analysis, IR and NMR spectra, and by an X-ray structure analysis of *(3c)*[5]. Both the ^{1}H- as well as ^{11}B-, ^{13}C-, and ^{31}P-NMR spectra show equivalence of all Me_2PCH_2 groups in the molecules, and thus symmetrical bonding of the ligands to the metal. ^{1}H-, ^{13}C-, ^{111,113}Cd satellites confirm *e.g.* strong M-CH_2 interactions in *(3b)*. The only slightly altered BH_2 vibrations (IR) and BH-/BP coupling constants (NMR) compared to those observed in *(1)* indicate that the geometry of the CPBPC skeleton changes very little during formation of the complex so that the products can be assumed to contain largely strain-free six-membered rings, presumably in the chair conformation.

The properties of the new organometallic compounds *(3)* and *(4)* resemble those of the analogous derivatives of *(D)* and *(E)*. They are, however, thermally less stable if they contain readily reducible metals [*e.g. (3b)* and *(3c)*, but not *(4)*]. Here, the reducing effect of the borane function is still in evidence.

Procedure

A solution of butyllithium (20 mmol) in pentane or hexane is added dropwise with stirring at -25 °C to a suspension of *(1)* (2.45 g, 10 mmol) in tetrahydrofuran (50 ml). After 30 min, 5 mmol of metal halide (X = Cl, Br) is added and the reaction mixture stirred for a further 12 h at 20 °C. The

Molecular Structure of a Benzocyclobutadiene

By *Werner Winter* and *Henner Straub*[*]

In connection with the cyclobutadiene problem[1], cyclobutadienoid compounds such as the monobenzo-annelated derivative of [4]annulene are also of theoretical and preparative interest[2]. Besides the matrix isolation of the benzocyclobutadiene *(1)*, $R^1 = R^2 = H$, at 8 K[3], substituted benzocyclobutadienes isolable at room temperature have recently also been synthesized[4]. Such kinetically stabilized derivatives should permit the first experimental determination of the molecular geometry of a free benzocyclobutadiene. The derivative *(1)*[4b] was used for an X-ray structure analysis, since this yellow crystalline hydrocarbon is storable under nitrogen for months and the electronic system of such a derivative substituted only with alkyl groups can hardly be falsified compared to that of the parent compound ($R^1 = R^2 = H$). The bicyclic 8π system can be described by the three Kekulé structures *A*, *B*, and *C* (Kekulé indices: *A* 0.905, *B* 0.941, *C* 0.832)[5].

$R^1 = C(CH_3)_3$, $R^2 = CH_3$

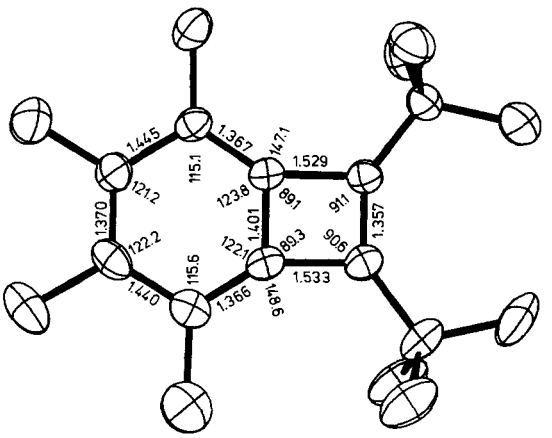

Fig. 1. ORTEP plot of *(1)*. The mean standard deviation for the bond lengths is 0.006 Å, for the bond angles 0.4°.

The crystal structure analysis[6] of *(1)* shows, within the limit of experimental error, that the benzocyclobutadiene moiety is planar. Further, since the C atoms bound directly to the bicycle deviate maximally by only about ±0.04 Å from this plane the whole system may be regarded as nearly planar.

The shortest C—C bond (1.36 Å) in the four-membered ring of *(1)* is to be interpreted as an isolated double bond;

[*] Dr. W. Winter, Dr. H. Straub
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

it is hardly influenced by the other 6π electrons of the six-membered ring. The longest bonds of the four-membered ring (1.53 Å) are somewhat longer than the usual single bonds of sp^2-hybridized C atoms. Both bond lengths are in good agreement with those of other cyclobutadiene systems[7] where, as also in *(1)*, the steric interaction of the bulky substituents could be responsible for stretching of the corresponding bonds of the four-membered ring. The shortest distance of only 2.11 Å between an H atom of a methyl group in the 3,6 position and the H atom of a methyl group of the *tert*-butyl moiety clearly shows that the substituents R^1 and R^2 in *(1)* approach each other to within the van der Waals distance.

The measured bond lengths in *(1)* rule out any noticeable participation of the resonance structure *(1C)*. The benzocyclobutadiene ground state is accordingly best described in terms of the two resonance structures *(1A)* and *(1B)*, the bond lengths in the six-membered ring suggesting greater participation of structure *(1B)*. Comparison of the experimentally determined bond lengths and angles of *(1)* with the calculated values of benzocyclobutadiene ($R^1=R^2=H$)[5,8] shows surprisingly good agreement. A large deviation is found only in the lengths of four-membered ring single bonds (calculated 1.49 Å), which can be attributed to the repulsive effect of the bulky substituents.

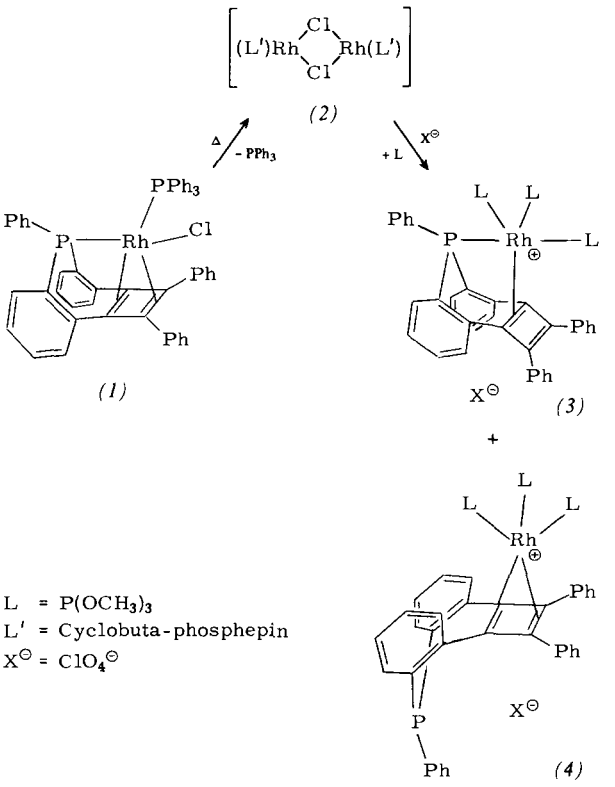
Valence Isomeric η^2- and η^4-Cyclobutadiene-Rh^I Complexes



By *Werner Winter* and *Joachim Strähle*[*]

Transition metal complexes with η^4-cyclobutadiene ligands are well known. The isolation of iron complexes with η^2-coordinated cyclobutadiene was first described in 1974[1]; these unusual coordination compounds were characterized on the basis of spectroscopic data and their reaction products.

We now report the first synthesis of isomeric rhodium(I) complexes bearing variously coordinated cyclobutadiene.

[*] Dr. W. Winter [+]
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)
Prof. Dr. J. Strähle
Institut für Anorganische Chemie der Universität Tübingen
[+] To whom correspondence should be addressed.

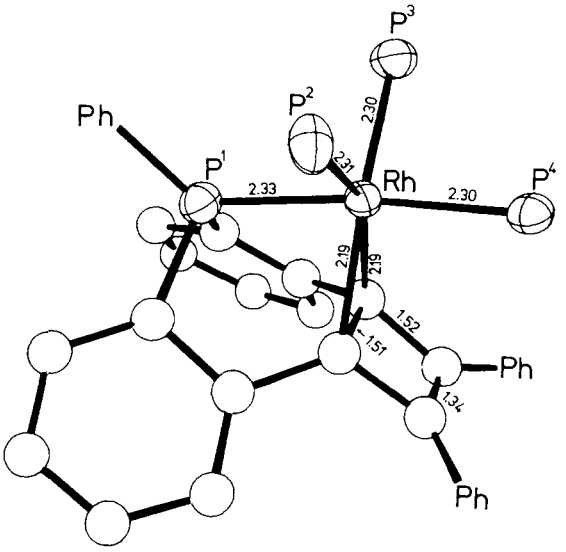
Heating of the violet Rh^I cyclobutadiene chelate complex *(1)*[2] in inert organic solvents (*e.g.* boiling xylene) leads, *via* cleavage of PPh_3, to an ocher-colored complex *(2)* which is insoluble in all the usual solvents:

L = $P(OCH_3)_3$
L' = Cyclobuta-phosphepin
$X^{\ominus}$ = $ClO_4^{\ominus}$

Apart from an elemental analysis, the insolubility of *(2)* precluded investigation of the complete structure or possible structural changes of the cyclobutadiene ligands. An attempt was therefore made to transform this product into a "soluble form" by cleavage of the Rh—Cl bridges. Treatment of *(2)* with an excess of trimethyl phosphite[3] in ethanol in the presence of $ClO_4^{\ominus}$ led within a few minutes to complete dissolution of the solid. Crystallization with CH_2Cl_2/ether gives mixture of red *(3)* and bright-yellow crystalls *(4)* (total yield >80%). Apart from differences in the usual analytical data (conductivity, IR, UV, NMR)[4], *(3)* and *(4)* differ characteristically in the $^{31}P\{^1H\}$-NMR spectrum: while *(3)* shows only signals of the Rh-coordinated P atoms, the spectrum of *(4)* also displays a singlet at $\delta=-0.7$ (H_3PO_4 ext; 36.43 MHz). This signal can be unequivocally assigned to a non-coordinated phosphepin P atom. The "inert gas rule" thus leads to formulation of a η^2- [for *(3)*] and a η^4-cyclobutadiene complex for *(4)*.

For confirmation of the structure we have carried out an X-ray structure analysis on *(3)*[5].

Figure 1 shows the essential structural features of *(3)*: the ligand arrangement at the rhodium approximately corresponds to a trigonal bipyramid, in which the phosphepin P atom occupies an apical position and the cyclobutadiene bond an equatorial position in the seven-membered ring. Strong back-bonding into π* orbitals of the seven-membered ring cyclobutadiene double bond leads to elongation of the C=C bond to 1.51 Å and pronounced angulation of the four-membered ring at the coordinated C atoms. The non-coordinated double bond of the four-membered ring, with a length of 1.34 Å, retains its double bond character.



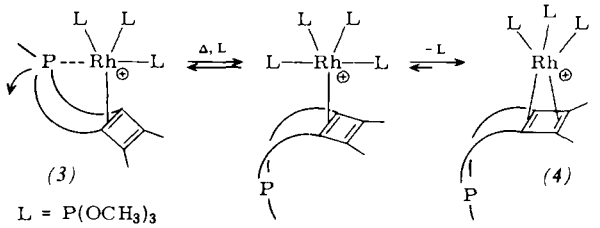


Fig. 1. Structure of the cationic complex *(3)* [phenyl- and (phosphite)OCH_3 substituents omitted for clarity]. The standard deviations for the Rh—P, Rh—C, and C—C bond lengths are 0.01, 0.02, and 0.03 Å, respectively.

The course of the reaction *(1)* → *(4)* reveals still further interesting points:

1) When the reaction of *(2)* with trimethyl phosphite is carried out at room temperature, *(3)* and *(4)* are formed in a ratio of about 1:1, while on prolonged heating under reflux (1 h) essentially only *(4)* is formed. However, since *(3)* is completely stable in boiling ethanol and is converted into *(4)* only in the presence of excess trimethyl phosphite, the transformation *(3)* → *(4)* most likely proceeds *via* a dissociative mechanism:

2) If, instead of *(2)*, the violet complex *(1)* is allowed to react with $P(OCH_3)_3$ at room temperature, only complexes of type *(3)* [L = PPh_3 and $P(OCH_3)_3$] are formed, and *no* complexes of type *(4)*. On the other hand, like *(2)*, *(1)* affords exclusively the complex *(4)* on prolonged refluxing.

The above findings lead to the following conclusions: on the one hand, the ring inversion of the dibenzo[*b*,*f*]-η-cyclobuta[*d*]phosphepin ligands in the transition *(3)* → *(4)* requires a surprisingly low free activation enthalpy [$\Delta G^{\neq}_{78\,°C}$ *ca.* 25—26 kcal·mol^{-1} with an estimated half-life of 15 min for *(3)*] in comparison to other non-complexed benzoannelated phosphepins (ΔG^{+}: 30–34 kcal·mol^{-1})[6]; on the other, either both conformers of this ligand must already be present in the insoluble complex *(2)*, or *(2)* forms a transition state in which the activation threshold for inversion is "undermined" by an intermediary phosphepin ring-opening.

The overall reaction sequence *(1)* → *(4)* has also been confirmed by X-ray structure analyses[4] of *(1)* and *(4)*.

N-Fluorosulfonylsulfimide (*N*-(Fluorosulfonyl)sulfur Imide Dioxide)[**]

By *Herbert W. Roesky* and *Minoru Aramaki*[*]

N-Fluorosulfonylsulfimide could previously only be isolated as the cyclic dimer *(1)*[1]. Organic derivatives of sulfimide were postulated as intermediates in the dehydrohalogenation of the corresponding sulfamoyl chlorides[2]. We have now found that 1:1 adducts of *N*-fluorosulfonylsulfimide are readily accessible by reaction of *(1)* with tetrasulfur tetranitride or pyridine.

Lewis bases stabilize the monomeric *N*-fluorosulfonylsulfimide. The adducts *(2)* are interesting examples for the study of SN bond lengths as a function of coordination number. *(2a)* is a brick red crystalline solid, *(2b)* a white crystalline solid; they can be recrystallized from CH_2Cl_2 and stored without decomposition in dry air. Surprisingly, in the reaction of the dimeric sulfimide with benzonitrile

not the 1:1 adduct but the 1:2 adduct *(4)* is isolated. Presumably, the initially formed, strained three-membered ring *(3)* reacts further with benzonitrile to give *(4)*, a 1λ⁶,2,4,6-thiatriazine. Analogous reactions of *(1)* should lead to a wide variety of interesting new compounds.

Procedure

(1)[1] (3.7 g, 11.6 mmol), diluted with CH_2Cl_2 (20 ml), is added dropwise to a solution of N_4S_4 (4.3 g, 23.4 mmol) in CH_2Cl_2 (450 ml). Dark-red *(2a)* immediately precipitates. The adduct is recrystallized from CH_3CN; yield 4.45 g (56 %), dec. pt. 105—110 °C; MS: $m/e = 283$ ($M^+ - NSO$); ^{19}F-NMR (in CH_3CN): $\delta = -55.8$ (s), rel. $CFCl_3$ ext.

For *(2b)*, prepared in an analogous way: M.p. 100 °C; MS: $m/e = 240$ (M^+); ^{19}F-NMR (in CH_3CN): $\delta = -53.5$ (s).

(1) (40 g, 12.4 mmol), diluted with CH_2Cl_2 (10 ml), is added dropwise to a solution of benzonitrile (5.1 g, 49.6 mmol) in CH_2Cl_2 (20 ml). The white crystalline reaction product *(4)* can be recrystallized from CH_3CN or C_6H_6; yield 5.5 g (60 %), m.p. 145 °C. MS: $m/e = 367$ (M^+, 100 %), 348 ($M^+ - F$, 2 %); ^{19}F-NMR (in C_6H_6): $\delta = -59.9$ (s).

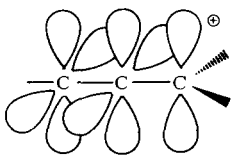
[4+3]-Cycloadditions of Allenyl Cations[**]

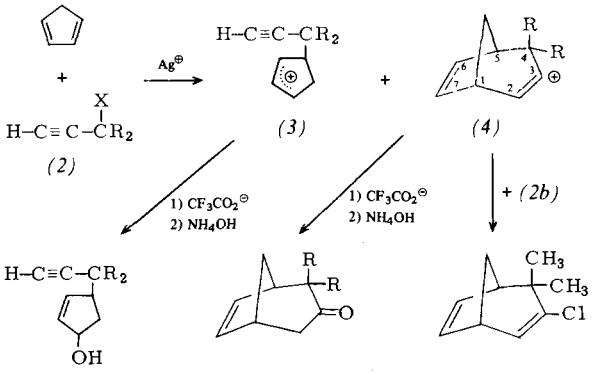
By *Herbert Mayr* and *Bärbel Grubmüller*[*]

Cycloadditions of allyl cations with dienes (Eq. A) have been studied in detail by *H. M. R. Hoffmann*[1].



(A)

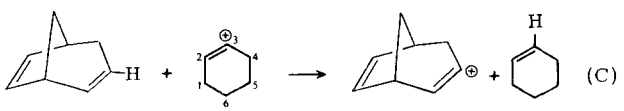
(B)



We now wish to report the first corresponding reactions of allenyl cations *(1)*, which proceed *via* formation of vinyl cations (Eq. B).

(1)

Treatment of a solution of propargyl bromide *(2a)*, X = Br, and cyclopentadiene in pentane with silver trifluoroacetate[2] and subsequent hydrolysis with aqueous ammonia affords a mixture of 85 % 4-(2-propynyl)cyclopent-2-en-1-ol *(5a)* and 15 % bicyclo[3.2.1]oct-6-en-3-one *(6a)* in 46 % yield. In a similar way reaction of 3-chloro-3-methyl-1-butyne *(2b)*, X = Cl, affords 28 % *(5b)*, 35 % *(6b)* and 37 % 3-chloro-4,4-dimethylbicyclo[3.2.1]octa-2,6-diene *(7b)* in a total yield of 50 %. Apart from insignificant amounts of high-molecular compounds, only the alcohols *(2)*, X = OH, were formed as by-products.



The cyclopentenols *(5)*, which occur as a mixture of diastereomers, can be identified by CrO_3-oxidation to the corresponding cyclopentenones. The spectroscopic data of the ketones *(6)* are in accord with data given in the literature[3]. The structure of *(7b)* was confirmed by ^{13}C-NMR and mass spectroscopy. The ^{1}H-NMR spectrum of this compound shows three olefinic protons [quartets at $\delta = 5.82$ and 6.30 (H^6 and H^7; $J_{67} = 6$, $J_{56} = J_{17} = 3$ Hz) as well as a doublet at $\delta = 6.03$ (H^2; $J_{12} = 7$ Hz)]; as expected on decoupling of the bridgehead protons H^1 and H^5 two doublets and a singlet are observed in the vinylic region. Similar ^{1}H-NMR spectra have been reported for other 3-halobicyclo[3.2.1]octa-2,6-dienes[4].

(a): R = H; *(b)*: R = CH_3

Formation of the products *(5)* to *(7)* can be explained in terms of intermediate allenyl cations *(1)* which are formed on reaction of $Ag^{\oplus}$ with *(2)*. Cyclopentadiene can attack *(1)* at the sp^2 carbon atom and thus give the alkynylcyclopentenyl cation *(3)*, which is intercepted by $CF_3CO_2^{\ominus}$. Hydrolysis of the resulting trifluoroacetate finally affords the alcohol *(5)*. A further possible explanation for the formation of *(3)* is that cyclopentadiene already attacks the alkynyl halide before the CX bond is completely cleaved.

The bicyclic products *(6)* and *(7b)* are derived from the vinyl cation *(4)*, which can be formed by concerted or stepwise cycloaddition of allenyl cation to cyclopentadiene. Reaction of *(4)* with $CF_3CO_2^{\ominus}$ affords a vinyl ester, whose hydrolysis leads to the ketone *(6)*. Alternatively, *(4)* can react with *(2b)* with formation of *(7b)* and liberation of a 1,1-dimethylallenyl cation. The corresponding reaction with *(2a)* is not observed, probably because the unsubstituted allenyl cation is insufficiently stabilized. Consistent with the proposed mechanism, *(7b)* is not formed if the concentration of *(2b)* is kept small by slow dropwise addition.

(8) *(4a)*, $\Delta H = 5.2$ kcal/mol (C)

According to MINDO/3 calculations[5] the vinyl cation *(4a)* is less stabilized than the monocyclic vinyl cation *(8)* by about 5 kcal/mol (Eq. C)—presumably because the optimized $C^2C^3C^4$ angle (146°) in *(4a)* deviates further from linear geometry than the corresponding angle (153°) in *(8)*[6]. For both vinyl cations *(4a)* and *(8)*, MINDO/3 calculations

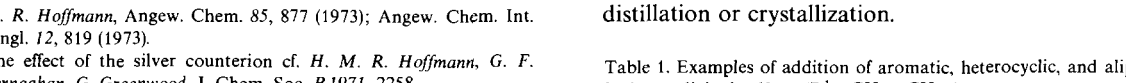
A New Preparation of Symmetrical γ-Diketones[1]

By *Hermann Stetter* and *Hans-Jürgen Bender*[*]

The thiazolium salt-catalyzed addition of aliphatic, aromatic, and heterocyclic aldehydes[2] to activated double bonds can also be extended to α,β-unsaturated sulfones.

Surprisingly, however, the product is not the expected γ-keto sulfone but a 1:1 mixture of γ-diketone and γ-disulfone. We explain this result as a consequence of cleavage of the γ-keto sulfone *(3)* into sulfinate *(4)* and vinyl ketone *(5)*. A further molecule of aldehyde *(1)* adds to the vinyl ketone to form the symmetrical γ-diketone *(7)*, which is actually isolated. The sulfinate ion reacts with unconsumed vinyl sulfone *(2)*, giving the γ-disulfone *(6)* which can likewise be isolated.



The reaction has been observed for several aryl vinyl sulfones and can be exploited preparatively when divinyl sulfone (R^1 = CH=CH_2) is used as double bond component since separation of γ-disulfone and γ-diketone is then a simple operation. Moreover, the ratio of aldehyde to vinyl sulfone can then be limited to 2:1.

[*] Prof. Dr. H. Stetter, Dipl.-Chem. H.-J. Bender
Institut für Organische Chemie der Technischen Hochschule
Professor-Pirlet-Strasse 1, D-5100 Aachen (Germany)

The reactions compiled in Table 1 were performed under the following reaction conditions:

In the case of aliphatic aldehydes, the aldehyde (0.2 mol) and divinyl sulfone (0.1 mol) are jointly added dropwise to a hot stirred solution of thiazolium salt[2] (0.02 mol) and sodium acetate (0.04 mol) in ethanol (200 ml); aromatic and heterocyclic aldehydes can be immediately added to the reaction solution so that only the double bond component has to be added dropwise. The mixture is stirred for 12 h under reflux, poured into water, and then extracted with chloroform to give the corresponding γ-diketone which is purified by distillation or crystallization.

Table 1. Examples of addition of aromatic, heterocyclic, and aliphatic aldehydes to divinyl sulfone (R^1 = CH_2=CH–).

R^2	Yield [%] [a]	B.p. [°C/torr] M.p. [°C]	Ref. (m.p., b.p.)

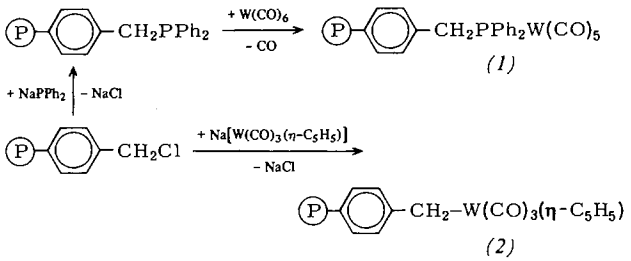
Olefin Metathesis with Polymer-Bound Tungsten Complexes[1]

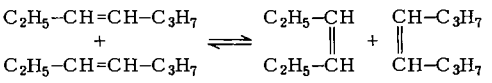


By *Siegfried Warwel* and *Peter Buschmeyer*[*]

Ready separation of homogeneous transition metal catalysts from the substrate and catalyst recycling processes are of decisive importance in industrial applications. A possible solution of such problems is proved by the so-called heterogeniza-

[*] Priv.-Doz. Dr. S. Warwel, Dipl.-Chem. P. Buschmeyer
Institut für Technische Chemie und Petrolchemie der Technischen Hochschule
Alte Maastrichter Strasse 2, D-5100 Aachen (Germany)

tion of transition metal complexes, *i.e.* their linkage to insoluble inorganic or organic carriers.



We now describe the first use of polymer-bound carbonyltungsten complexes for the metathesis of open-chain monoolefins. The tungsten-polymer complexes *(1)* and *(2)*

(1)

(2)

prepared according to *Pittman et al.*[2] from a commercially available *Merrifield* resin[3] effect, after activation with iBuAlCl$_2$/O$_2$, selective metathesis of *trans*-3-heptene to give an equilibrium mixture.

Compound *(1)* or *(2)* was then separated from cocatalyst and the olefins by filtration. After washing with methanol and drying at 25 °C *in vacuo* the complex catalysts could be re-used.

The tungsten complex *(1)* coordinated to the polymeric matrix proved to be a storage catalyst: the polymeric phosphane ligand serves as reservoir for a coordinatively unsaturated tungsten species which is displaced by the alkylaluminum compound and then forms a homogeneous catalyst for the metathesis reaction. Compound *(1)* can therefore be re-used only in a limited number of runs (Figure 1).

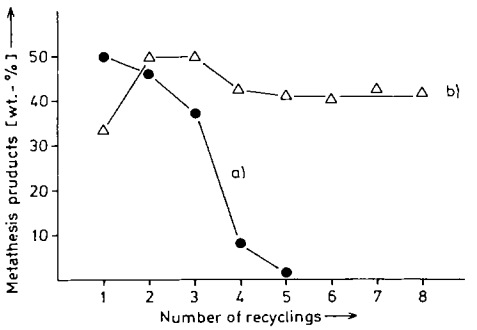


Fig. 1. Metathesis of *trans*-3-heptene with polymer-bound tungsten complex catalysts—conversion as a function of the number of recyclings on use of a) *(1)*/iBuAlCl$_2$/O$_2$ and b) *(2)*/iBuAlCl$_2$/O$_2$ in the ratio W:Al:O$_2$:olefin = 1:4:2:700 (22—24 °C; 60 min per metathesis reaction).

In contrast, the tungsten complex *(2)* covalently bonded to the polymer combined the advantages of homogeneous and heterogeneous metathesis catalysts, *i.e.* activity and selectivity under mild conditions on the one hand, and ready removal from the reaction solution, regeneratability, and especially the possibility of frequent re-use, on the other hand. On repeated recycling the activity profile of *(2)* corresponds to that of heterogeneous catalysts; low initial activity (experiment 1) is followed by a maximum (experiments 2 and 3) which then adjusts to a constant value (experiments 4 to 8).

The scope of the catalysts was examined with other open-chain olefins having an internal double bond (*cis*- and *trans*-hexene, mixture of *n*-octene isomers) and confirmed; co-metathesis of these olefins with vinylcyclohexene was also possible. The development of further complex catalysts with polymeric ligands could prove of value in elucidating the mechanism of olefin metathesis.

Metathesis of trans-3-heptene with (2)/iBuAlCl$_2$/O$_2$

Compound *(2)* (60 mg, containing 9.3 % W) is placed in a dry *ca.* 10 ml-capacity Schlenk tube. After repeated evacuation and flushing with argon, *trans*-3-heptene (2.06 g, 21 mmol) containing 15 wt% of methylcyclohexane as GC standard as well as isobutylaluminum dichloride (0.12 mmol; 0.24 ml of a 0.5 M solution in chlorobenzene) and O$_2$ (1.4 ml, 0.06 mmol) are added from syringes; the contents of the vessel are mixed with a magnetic stirrer. After 60 min a sample of the reaction solution is treated with small amount of CH$_3$OH and analyzed by gas chromatography (3-heptene 67.0, 3-hexene 14.6, 4-octene 18.4 wt %). Compound *(2)* is separated from the other compounds by filtration, washed with *ca.* 20 ml of CH$_3$OH, dried at 25 °C *in vacuo*, and re-used for metathesis.

Quantitative Resolution of Enantiomers of *trans*-2,3-Epoxybutane by Complexation Chromatography on an Optically Active Nickel(II) Complex[**]

By *Volker Schurig* and *Waldemar Bürkle*[*]

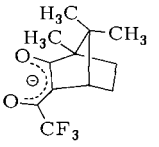
Enantiomers often differ characteristically in their pharmacological and physiological properties (substrate-receptor interaction). It is therefore advantageous to be able to directly determine the enantiomer composition of chiral substrates rapidly and quantitatively, without having to resort to derivatization and measurement of optical rotation, and to gain information about the kinetic and thermodynamic factors of chiral differentiation.

The method of choice for this purpose is the gas chromatographic resolution of enantiomers on optically active stationary phases by selective interactions between hydrogen bonds, as introduced by *Gil-Av* and *Feibush*[1].

We recently reported the first chromatographic resolution of a chiral olefin by enantiospecific π-complexation on a rhodium(I) compound *(1)*[2] and thus showed that the rapid and reversible ligand-metal coordination interaction can have the necessary thermodynamic parameters for "chiral recognition" in GC systems.

[*] Univ.-Doz. Dr. V. Schurig, W. Bürkle
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



We have now demonstrated the previously postulated[3] resolution of enantiomers of chiral σ-donor substrates containing elements of groups 5 and 6 on optically active dimeric nickel(II) bis(3-trifluoroacetyl-1*R*-camphorate) *(2)*, with the quantitative separation of dissymmetric (C_2) *E*-dimethyloxirane (*trans*-2,3-epoxybutane) *(4a)* as example. While we were

$Rh(CO)_2$(tfac-1*R*-Cam) *(1)*

$Eu(tfac\text{-}1R\text{-}Cam)_3$ *(3)*

tfac-1*R*-Cam =

carrying out our investigations *Golding et al.* reported the (incomplete) resolution of the enantiomers of methyloxirane (epoxypropane) *(5)* on the europium(III) complex *(3)*; separation of *(4a)*, however, was not observed[4].

trans (*threo*)
racemic
"homochiral"

(4a)

cis (*erythro*)
meso
"heterochiral"

(4b)

On chromatography of *(4a)* on a 200-m capillary column loaded with 1*R*-*(2)* in squalane, the mirror image isomers appear as two sharply separated peaks (Fig. 1). Racemic *(5)* is resolved into its antipodes by 1*R*-*(2)* as well. The surprisingly high resolution of *(4a)* ($\alpha = 1.27$, 50 °C) permits its separation also in shorter time with shorter length columns[5]. Successful resolution was demonstrated by use of the racemic nickel complex 1*S*,1*R*-*(2)*, where peak coalescence occurs in the case of *(4a)* and *(5)*. Separation of the diastereomers *(4a)* and *(4b)* (Fig. 1) could also be achieved with the highly selective complex *(2)*. In accordance with the greater tendency of *cis*- over *trans*-2-butene to undergo π-complexation with *(1)*[6] the *cis* compound *(4b)* also exhibits a much stronger coordination with *(2)* than does the *trans*-diastereomer. It is noteworthy that the observed enantiomer differentiation, whose Gibbs-Helmholtz parameters[3] are still being investigated, is already achieved by enantiospecific "one-point" coordination interaction[7].

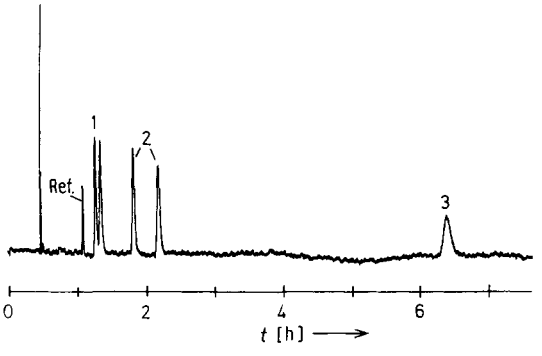

Fig. 1. Resolution of enantiomers and diastereomers of *(4)* and *(5)* by complexation chromatography on 1*R*-*(2)* (0.15 *m* in squalane) at 50 °C.
1, Peak splitting (1:1) for *(5)*; 2, peak splitting (1:1) for *(4a)*; 3, *(4b)*; reference standard: cyclohexane. Column: 200 m × 0.5 mm nickel capillary, carrier gas: 2.1 ml/min N_2, split 1:50.

The method described here, which does not necessitate the preparation of derivatives or purification of substances, is suitable for the determination of enantiomer composition in the study of racemization, retention, or inversion, as well as asymmetric induction in the formation or ring-opening of chiral substrates such as *(4a)* and *(5)*. The GC method thus surpasses the NMR method (use of chiral "shift" reagents, *e.g. (3)*) in simplicity, accuracy, and sensitivity (amount of substance required 10^{-9} g!). The nickel complex 1*R*-*(2)* is readily accessible[8].

Substituted Bicyclohexyls—A New Class of Nematic Liquid Crystals[**]

By *Rudolf Eidenschink, Dietrich Erdmann, Joachim Krause*, and *Ludwig Pohl*[*]

We have found that *trans,trans*-4'-alkylbicyclohexyl-4-carbonitriles *(3)* exhibit nematic phases (Table 1) whose transition temperatures to the isotropic phase are considerably higher than those of the recently described 4-(*trans*-4-alkylcyclohexyl)benzonitriles[1].

This result does not conform to the molecular-statistical theory of *Maier* and *Saupe*[2], according to which the nematic-isotropic transition temperature should be essentially proportional to the molecular polarizability anisotropy. Rather it becomes clear that shape anisotropy can make a considerable—hitherto disregarded—contribution to the stability of nematic phases[3].

In order to prepare *(3)*, 4-(*trans*-4-alkylcyclohexyl)benzoic acids *(1)*, obtained by a known procedure[1], are hydrogenated over palladium/activated charcoal (10% Pd) in glacial acetic acid. The resulting mixture of saturated stereoisomeric carboxylic acids is treated with sulfinyl chloride by the same method as used in the preparation of *trans*-4-alkylcyclohexanecarboxylic acids[4]. After hydrolysis of the acid chlorides, the pure *trans,trans*-4'-alkylbicyclohexyl-4-carboxylic acids *(2)* (Table 1) were obtained by repeated recrystallization from light petroleum (boiling range 50 to 70 °C). These acids could be converted, in the usual way, into the corresponding nitriles by brief action of sulfinyl chloride, reaction with ammonia solution, and dehydration of the resulting amides with $POCl_3$. The structures of *(3a)* to *(3c)* have been confirmed by elemental analysis, and IR and mass spectrometry.

Table 1. Nematic ranges of compounds *(2)* and *(3)*.

	R	Yield [%]	M.p. [°C]	Clear point [°C]
(2a)	n-C_3H_7	34	197	246
(2b)	n-C_5H_{11}	39	224	243
(2c)	n-C_7H_{15}	45	230	238
(3a)	n-C_3H_7	56	58	80 [a]
(3b)	n-C_5H_{11}	60	62	85 [b]
(3c)	n-C_7H_{15}	67	71	83

[a] Monotropic transitions at 18, 44, 48 (smectic-smectic), and 57 °C (smectic-nematic).
[b] Monotropic transitions at 43 °C (smectic-smectic) and 52 °C (smectic-nematic).

The new compounds *(3)* are photochemically, electrochemically, and thermally stable. In keeping with their molecular structure, they fail to show any UV absorption above 200 nm. They have a positive dielectric anisotropy whose magnitude lies between 3 and 4, an optical anisotropy of <0.1, and, as the first monomeric thermotropic-nematic class of liquid crystals, a negative diamagnetic anisotropy[5]. As a result of these properties, they can serve as anisotropic solvents for the measurement of polarized absorption and fluorescence spectra in the entire UV range and also permit the recording of high-resolution NMR spectra with rotating samples, thus giving rise to resolutions comparable with those in isotropic solution (signal half-width <1 Hz)[6].

Preparation of *cyclo*-Hexasulfur Oxide, S_6O[1]

By *Ralf Steudel* and *Jürgen Steidel*[*]

Among the homocyclic sulfur oxides S_nO, S_8O[2] and S_7O[3] have so far been prepared pure while the extremely unstable species S_5O[4] has only been detected in solution. We have now succeeded in preparing the first derivative of *cyclo*-hexasulfur, *viz.* S_6O.

S_6O is formed on oxidation of S_6 by trifluoroperacetic acid at -10 to -20 °C in dichloromethane:

$$S_6 + CF_3CO_3H \rightarrow S_6O + CF_3CO_2H$$

Depending upon the reaction conditions, two different products of the same composition are formed. α-S_6O arises when S_6 reacts with the peroxy acid at -20 °C within 2 h in the molar ratio 1:1.2 and the oxidation product is precipitated after a further 5 h by addition of pentane and cooling. Recrystallization gives a 5 % yield of orange transparent spearhead-shaped crystals which undergo spontaneous decomposition to polymeric sulfur with evolution of SO_2 at 39 °C. At 25 °C decomposition is almost complete within 2 h; at -50 °C no decomposition can be detected even after several weeks. The composition corresponds exactly to the formula S_6O. In the mass spectrum the molecular ion appears with low intensity at $m/e = 208/210$[5]. Vacuum pyrolysis affords the product S_2O characteristic of polysulfur oxides.

According to the Raman spectrum[5] α-S_6O contains small amounts of S_6 in solid solution which cannot be removed by repeated recrystallization. Attempts to achieve complete oxidation of S_6 by working at a higher temperature (-10 °C) and with an excess of peroxy acid ($S_6 : CF_3CO_3H = 1:2.2$) led to isolation of β-S_6O which likewise still contained traces of S_6. β-S_6O forms dark orange, transparent prismatic or truncated pyramidal crystals which decompose at 34 °C. Its stability corresponds to that of α-S_6O. Both oxides are moderately soluble in CS_2, CH_2Cl_2, and $CHBr_3$.

The Raman spectra of α- and β-S_6O show characteristic differences in wave numbers and intensities; in particular a number of normal modes are split to doublets in the case of α-S_6O (Table 1). In solution in CS_2 or $CHBr_3$ both modifications give identical IR spectra (Table 1). Model calculations using the force constants[6] of S_6 and S_8O show that the spectra can be assigned on the basis of a structure analogous to that of S_8O with a chair-shaped S_6 ring and an exocyclic oxygen atom.

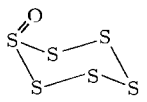

Table 1. Normal modes of S_6O in the solid and dissolved state (cm^{-1}; Raman intensities in parentheses).

Raman α-S_6O	Raman β-S_6O	IR (in $CHBr_3$)	Assignment

equatorial oxygen) but to different lattice symmetries, with S_6 occupying a small number of lattice sites in both cases.

The synthesis of S_6O raises the number of known nonpolymeric sulfur oxides to 11 (SO, SO_2, SO_3, SO_4, S_2O, S_2O_2, S_3O_9, S_5O, S_6O, S_7O, S_8O).

Procedure

CF_3CO_3H solution: $(CF_3CO)_2O$ (8.1 ml) is added at 0°C to a vigously stirred emulsion of H_2O_2 (1.67 g, 80 %) in CH_2Cl_2 (91 ml; purified by column chromatography on basic Al_2O_3). The mixture is warmed to 25°C and stirring is continued until no droplets of H_2O_2 can be seen.

S_6O: In order to prepare α-S_6O, S_6 (4.18 g; β-S_6O: 5.75 g S_6) is dissolved in highly pure CH_2Cl_2 (2.3 l) at 0°C and protected from the action of light. At −20°C (−10°C) 66.1 ml (167 ml) of the CF_3CO_3H solution is added dropwise with stirring over 2 h (15 min). The reaction solution is stirred for 5 h (3 h) and, after addition of *n*-pentane (1.5 l, −20°C), cooled to −78°C, whereupon 1.13 g of a crude product containing α-S_6O (0.64 g of crude product containing β-S_6O) crystallize. Recrystallization from 900 ml (350 ml) purified CH_2Cl_2 affords 241 mg of α-S_6O (78 mg of β-S_6O) with a slight residual trace of S_6 (solid solution).

Molecular and Crystal Structure of an Organocyclotriarsane[**]

By *Gerhard Thiele, Gerd Zoubek, Helmut A. Lindner*, and *Jochen Ellermann*[*]

Organocycloarsanes $(RAs)_n$ with $n=4$, 5 and 6 are well known[1], and their structure has been elucidated by X-ray structure analyses on some representative examples[2]. The first compound of this type to be synthesized containing a three-membered As ring—also known to be a structural unit in the As_4 molecule and its derivatives[3]—was 4-methyl-1,2,6-triarsatricyclo[2.2.1.$0^{2,6}$]heptane *(1)*[4]. We have now been able to synthesize *(1)* in good yields and to investigate its crystal and molecular structures.

The colorless, monoclinic crystals of *(1)* [space group C2/m; unit cell with $a=1101.5(6)$, $b=907.2(5)$, $c=829.6(5)$ pm, $\beta=104.9(6)°$, $Z=4$] show a distorted cubic close packing of $CH_3C(CH_2As)_3$ molecules. In the crystal these are situated in a plane of symmetry, but there is little deviation from the C_{3v} symmetry expected for the free molecule. In the As_3 ring the As—As bond lengths are almost equal (Fig. 1) and

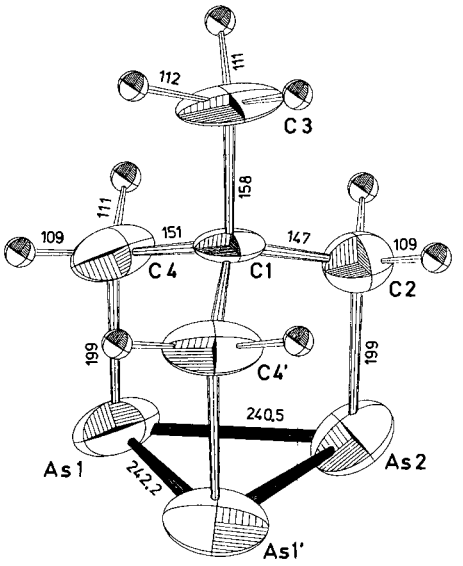

Fig. 1. Structure of the molecule *(1)*, with bond lengths in [pm]; standard deviation for *d*(As—As) 0.5, for *d*(As—C) 2, for *d*(C—C) 2.5, and for *d*(C—H) 4 pm. A plane of symmetry passes through the atoms C1, C2, C3 and As2. The angle at the C atoms deviate at most by about 1° from the tetrahedral angle; other angles: As1—As1'—As2 = 59.7(2), As1—As2—As1' = 60.5(2), As1—As1'—C4' = 90.2(6), As2—As1—C4 = 90.7(6), As1—As2—C2 = 90.1(6)°.

comparable to those found in As_4 (244 pm[3a]). Remarkably the organic moiety is oriented almost perpendicularly to the As_3 plane, the As—As—C angles being *ca.* 90°. The reasons for this observed contraction in comparison[8] to the similarly built As_4S_3 molecules of the two modifications of dimorphite, whose corresponding angles (about 101°)[5] approach the tetrahedral angle, might largely be geometric. The basal plane of the trigonal $CH_3C(CH_2)_3$ pyramid has edges of almost the same length as the As_3 triangle, while that of the AsS_3 pyramid in As_4S_3 is much larger (*ca.* 340 pm). The shortest intermolecular As—As distances (388 pm) deviate very little from the sum of the van der Waals radii, so that only slight interactions between the molecules are to be expected. In accordance with this are the color and thermal behavior of the crystals.

Experimental

$CH_3C(CH_2AsI_2)_3$[6] (1.5 g, 1.42 mmol) is dissolved in 20 ml dry peroxide-free tetrahydrofuran (THF) under nitrogen as protective gas. 2—3 ml of this solution is poured onto 1 g (40 mmol) of granulated sodium and the mixture carefully warmed with stirring until reduction with frothing sets in; the color of the mixture first turns dark-red and then changes to green-yellow. The rest of the THF solution is added dropwise within 15 min without further warming and then filtered free of excess Na, NaI and decomposition products. After removal of the THF at 20°C, *(1)* is separated from any

NaI present by sublimation (90°C/10^{-5} bar); yield 305 mg (73 %).

Crystals suitable for the X-ray structure analysis were grown by cooling a 0.03 M solution of *(1)* in THF to −30°C. After decanting off the mother liquor, the crystals were washed twice at room temperature with 2 ml petroleum ether. A crystal in the form of a monoclinic prism was measured on a four-circle diffractometer (Philips PW 1100, $Mo_{K\alpha}$ radiation; graphite monochromator) ($3° \leqq \theta \leqq 24°$). For the structure determination (program system SHELX[7]) 2656 measurements were available, giving a set of 671 independent data. Refinement (for all heavy atoms with an anisotropic temperature factor, for the H atoms with a common isotropic temperature factor) led to an R value of 0.088.

Structure of the 1:1 Adduct of Aminoiminophosphane and *tert*-Butyl Azide

By *Siegfried Pohl, Edgar Niecke*, and *Hans-Günther Schäfer*[*]

We recently reported the addition of *tert*-butyl azide to an aminoiminophosphane and suggested that the product obtained had the structure of an imino-bridged triaza-λ^5-phosphetine *(2a)*[1]. A crystal structure analysis of the analogously prepared 1:1 adduct of bis(trimethylsilyl)amino-*tert*-butyliminophosphane and *tert*-butyl azide, however, is not consistent with the structure *(2b)* but with that of a tetraaza-λ^3-phospholine *(3b)*. It would now seem that the compound previously characterized as *(2a)* should more correctly be described as having the structure *(3a)*.

[*] Prof. Dr. E. Niecke, Dr. S. Pohl, Dipl.-Chem. H.-G. Schäfer
Fakultät für Chemie der Universität
Universitätsstrasse, D-4800 Bielefeld 1 (Germany)

The cyclic silylaminophosphane *(3b)* is a colorless solid which can be isolated in pure form after removal of aminodiiminophosphorane, formed as liquid by-product in the reaction[2], and several recrystallizations from a little toluene. Its structure has been confirmed by a complete X-ray structure analysis[3] (cf. Fig. 1).

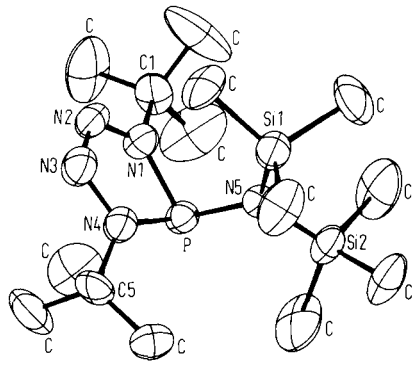

Fig. 1. Molecular structure of 1,4-di-*tert*-butyl-5-bis(trimethylsilyl)amino-Δ^2-tetraazaphospholine *(3b)* in the solid (without H atoms, 50 % probability vibration ellipsoids).

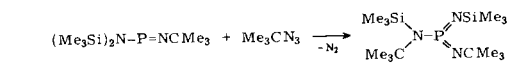

Coordination and bonding at the phosphorus are not unusual and thus provide no indicative evidence for the extreme high-field shift of the ^{31}P-NMR signal. The five-membered ring is almost planar (angle between the normals to the planes through N1, N2, N3, N4, and N1, P, N4: 7.8°). The considerable difference between the two P—N5—Si angles (*ca.* 15°) can be attributed to steric interaction between the bis(trimethylsilyl)amino group and the *tert*-butyl groups (cf. Ref.[4]).

The ^{1}H- and ^{13}C{^{1}H}-NMR spectra show the three and four groups of signals to be expected for the different stereochemistry of the two trimethylsilyl groups[5]. In temperature dependent ^{1}H-NMR measurements between 25 and 100°C there is no noticeable change in signal multiplicity—a finding which, in combination with the structural data, would indicate steric fixation of the $(Me_3Si)_2N$ groups. The different configurations of the two Me_3Si groups and the different P—N—Si bond angles account for the large difference in the P—C and P—H coupling constants. A surprising feature in comparison to the previously known phosphanes containing the PN_3 unit is the upfield shift of the ^{31}P-NMR signal ($\delta = 36.4$, H_3PO_4 ext.), which for *(3a)* ($\delta = 23.9$[1]) was erroneously regarded as indicating fourfold coordination of the phosphorus. The cause of this shielding of the ^{31}P nucleus in tetraaza-λ^3-phospholines is still unclear.

Crystal Structure of Sb_2O_5 [**]

By *Martin Jansen*[*]

Although the $Sb_2O_3/Sb_2O_5/H_2O$ system has been repeatedly studied by various methods[1], the nature of antimony(v) oxide has remained a matter of controversy because there is still a lack of sufficient knowledge about the phases occurring therein and their homogeneity ranges. In the course of new preparative and structural studies it has now been possible to determine the crystal structures of Sb_2O_5 and $Sb_2O_5 \cdot {}^3/_5 H_2O \equiv Sb_5O_{12}OH \cdot H_2O$[2].

The space group, lattice constants, and number of formula units per unit cell of Sb_2O_5 are: C2/c; $a = 1455$, $b = 478.2$, $c = 2289$ pm, $\beta = 90°$; $Z = 20$. Since reflections hkl with odd l can only be found for $l = 5$, and then only at low intensity, a subcell can be given with $a' = a$, $b' = b$, $c' = c/2$. It therefore follows that of the 3347 independent reflections measured (Philips PW 1100 automatic four-circle diffractometer, Mo-K_α, graphite monochromator, ω scan) only 1243 have net intensities greater than $1.5\,\sigma(I)$. All the crystals examined were microtwinned; structural elucidation was accomplished by Patterson and Fourier methods.

In contrast to As_2O_5[3] all the cations in Sb_2O_5 are in octahedral coordination ($d_{Sb-O} = 191$—208 pm), and the coordination numbers of oxygen towards antimony are 2 and 3. Figure 1 shows the crystal structure of Sb_2O_5, looking along [010]. "Layers" of rutile structure linked by common octahedral corners are seen. The relationship to the rutile type becomes all the clearer on imagining the rutile structure to be completely regenerated by a series of translations, as indicated by the arrows in Figure 1. The possibility of deriving crystal structures of oxides having the composition MO_{2+x} from the rutile type has already been discussed at length[4].

Sb_2O_5 is the first pentoxide of a main group element whose principles of coordination and connection correspond to those of an analogous oxide of a subgroup element, *viz.* B—Nb_2O_5[5].

Institut für Anorganische und Analytische Chemie der Universität
Heinrich-Buff-Ring 58, D-6300 Lahn-Giessen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

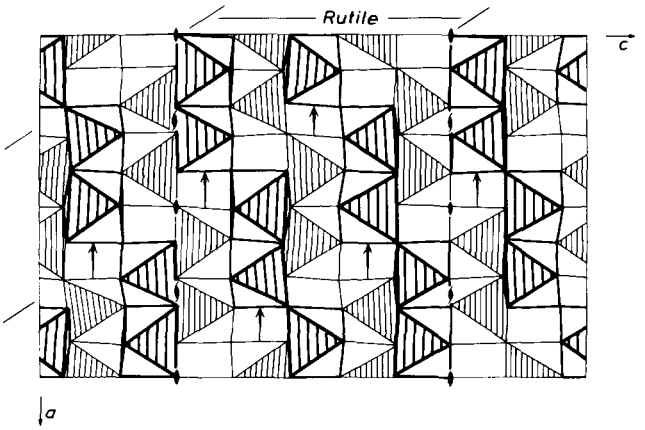

Fig. 1. Crystal structure of Sb_2O_5, as viewed along [010].

Experimental

Our results confirm earlier reports[1b] that Sb_2O_5 cannot be prepared under normal pressure.

In order to prepare Sb_2O_5, antimony(III) oxide (analytical grade, Merck) was heated in a steel autoclave (corundum finger crucible, closed with a corundum stopper but not gas tight); the autoclave (volume 20 ml, sample volume including corundum crucible 6 ml) was charged with liquid oxygen (9 ml). Reaction conditions: duration 3 weeks; temperature 700 °C.

Human chorionic gonadotropin, its receptor and mechanism of action, is the title of paper by *O. P. Bahl*. Chorionic gonadotropin consists of two non-covalently linked subunits which are only effective in complex form. The protein contains carbohydrate chains. These can be removed stepwise; however, the products so obtained are still capable of binding to the receptor. Although they inhibit the accumulation of *cyclo*-AMP effected by the native chorionic gonadotropin they promote production of steroid in the target cell. This finding would suggest the possible existence of other carriers of hormone action apart from *cyclo*-AMP. The receptor for the hormone could be isolated from radioactively labeled corpus luteum membranes, thus permitting investigation of the mode of action of the hormone on a molecular basis. [Human Chorionic Gonadotropin, its Receptor and Mechanism of Action. Fed. Proc. *36*, 2119—2127 (1977); 56 references]
[Rd 990 IE]

Reactions in which inorganic pyrophosphate replaces ATP as a source of energy are described by *H. G. Wood*. In biochemistry it is generally believed that pyrophosphate is an end product of metabolism serving at most to make preceding reactions

irreversible once it has been hydrolyzed. However, on the basis of recent knowledge this viewpoint is gradually losing favor. Although the energy of hydrolysis of pyrophosphates is less than that of ATP it is still sufficient to make synthesis reactions possible. In the organisms *Entamoeba hystolytica* and *Propionibacterium shermanii*, enzymic reactions have been discovered in which pyrophosphate plays a role. Examples

$$\text{Pyrophosphate} + \text{oxaloacetate} \rightleftharpoons \text{phosphoenol pyruvate} + \text{phosphate} + CO_2 \quad (1)$$

$$\text{Pyrophosphate} + \text{AMP} + \text{phosphoenol pyruvate} \rightleftharpoons \text{pyruvate} + \text{ATP} + \text{phosphate} \quad (2)$$

$$\text{Pyrophosphate} + \text{fructose-6-phosphate} \rightleftharpoons \text{phosphate} + \text{fructose-1,6-diphosphate} \quad (3)$$

are the reactions *(1)* to *(3)*, which are catalyzed by a carboxytransphosphorylase, a pyruvate-phosphate-dikinase and a pyrophosphate-phosphofructokinase, respectively. [Some Reactions in which Inorganic Pyrophosphate Replaces ATP and Serves as a Source of Energy. Fed. Proc. *36*, 2197—2205 (1977); 52 references]

The structure and function of *Escherichia coli* ribosomes are described in an article by *H. G. Wittmann*. The ribosome consists of a 30S subunit, composed of 21 proteins and a 16S RNA, and a 50S subunit made up of 34 proteins and 5S and 23S RNA. All components have been isolated and characterized, and in some cases the sequences are already known. The overall structure of the subunits is presently under investigation. The methods employed in these investigations include crosslinking of neighboring components, fragmentation of subunits, localization of binding sites of proteins to the RNA, neutron scattering, fluorescence spectroscopy and immuno-electron microscopy. The latter method affords the most useful information. Protein biosynthesis at the ribosomes consists in several steps; the participation of the individual components of the ribosomes is investigated with the aid of affinity-labeling and reconstitution. [Structure and Function of *Escherichia coli* Ribosomes. Fed. Proc. *36*, 2075—2080 (1977); 105 references]

[Rd 992 IE]

The structural basis for the variation in redox potentials of cytochromes is discussed by *G. R. Moore* and *R. J. P. Williams*. Structural studies on proteins are usually aimed at gaining knowledge of the biological properties of proteins on a molecular basis. In the case of redox potentials of cytochromes the determining factors are mainly the charges of the axial ligands and their donor and acceptor strengths for electrons. In contrast changes in the spin state of the central metal ion and steric factors are of secondary importance. [Structural Basis for the Variation in Redox Potential of Cytochromes. FEBS Lett. *79*, 229—232 (1977); 24 references]

The biosynthesis of melittin, the venom of the honey bee, is the subject of a report by *G. Kreil, G. Suchanek*, and *I. Kindås-Mügge*. According to feeding experiments with radioactive amino acids, bees produce in their venom glands promellitin, a precursor of the poison proper, which is about 8 or 9 amino acids longer at the N-terminus. The mRNA for mellitin has been isolated from the venom glands of young queen bees. After injection of this RNA into frog oocytes a polypeptide very similar to promellitin was synthesized; translation in cell-free mammals or plants on the other hand led to prepromellitin, which, in contrast to promellitin, contains further amino acid residues at the N and C terminus. [Biosynthesis of a Secretory Peptide in Honey Bee Venom Glands: Intermediates Detected *in vivo* and *in vitro*. Fed. Proc. *36*, 2081—2086 (1977); 45 references]

[Rd 994 IE]

Short-term effects of hormones on the carbohydrate and lipid metabolism of the liver are described in an article by *D. A. Hems*. A series of hormones, mostly peptides, influence the catabolism of liver glycogens and fats. Not all of them act *via* cyclic nucleoside phosphates; probably the Ca^{2+} level plays a role in some cases. Elucidation of the mode of action could contribute to a better understanding of the reaction of the cell membrane of the regulation processes, and perhaps also endocrine disturbances. [Short-term Hormonal Control of Hepatic Carbohydrate and Lipid Catabolism. FEBS Lett. *80*, 237—245 (1977); 60 references]

[Rd 995 IE]

N—C=C—C=O compounds ("enaminones") of type *(1)* are described in an article by *J. V. Greenhill*. These vinylogous amides or vinylogous urethanes are mainly used for the synthesis of heterocycles, *e.g. (2)* and *(3)*. Enaminones, which

can be regarded as protected amines, are possibly also potential precursors for drugs. [Enaminones. Chem. Soc. Rev. *6*, 277—294 (1977); 61 references]

[Rd 996 IE]

Reactions of organosulfur compounds promoted by metal ions are reviewed by *D. P. N. Satchell*. A typical example is the hydrolysis of thiol esters in aqueous solvents. This spontaneous reaction is catalyzed by H^+ (weakly) [eq. (1)], and by Hg^{2+} or Ag^+ (strongly) [eq. (2)]. The reactions of thiols, disulfides,

$$RCO{-}SR' + H_2O \xrightarrow{H_3O^+} RCO_2H + R'SH \quad (1)$$

$$RCO{-}SR' + 2H_2O + Ag^+ \rightarrow RCO_2H + R'SAg + H_3O^+ \quad (2)$$

thioethers, thioacetals, thioesters, thioacids, thioanhydrides, and thioamides are described. In these compounds sulfur is divalent and can interact directly with the metal. Apart from Hg and Ag, *inter alia*, Pb, Cd, Pt, Pd, Ni, Fe, Cu, Au, and Tl in the form of their ions are also suitable for these reactions. [Metal-ion-promoted Reactions of Organo-sulphur Compounds. Chem. Soc. Rev. *6*, 345—371 (1971); 65 references]

The Analytical Chemistry of Synthetic Dyes. Edited by *K. Venkataraman*. John Wiley & Sons, New York—London 1977. xxiv, 591 pp., numerous figs. and tables, bound, £ 31.90.

This book, a collaborative effort of 23 authors, presents in 20 chapters the method used in dyestuff analysis. The physicochemical methods customarily used in the analysis of dyestuffs are treated in the first ten chapters (thin-layer chromatography, paper chromatography, paper electrophoresis, high-pressure liquid chromatography, gas chromatography, colorimetry in dyestuff solutions, IR, NMR, and mass spectrometry, as well as X-ray diffraction), though in these descriptions fundamental theoretical and practical knowledge is assumed. The standpoint of methodical application to dyestuff analysis is given prominence, and the articles therefore correspond to the readers' expectations. Somewhat too little information is given in the chapter on mass spectrometry: having 13 pages, it is about the same length as the chapter on gas chromatography (11 pages), which is relatively unimportant for dyestuff analysis.

The chapter on methods of chemical degradation is too short, and in addition the references given are sometimes difficultly accessible. Some procedures, *e.g.* pyrolysis and dry distillation with alkali metal hydroxides, are described too briefly, although in difficult cases these can provide decisive evidence for the structure of a dye.

The identification of dyes and pigments on their substrates is treated well and extensively. A chapter on quantitative dyestuff analysis deals mainly with dyes fixed on textile fibers. Special themes, such as analysis of hair dyes and of dyes for foods, drugs, and cosmetics, are also treated. The conclusion of the book is an opportune contribution to ecological and toxicological problems.

By and large, *Venkataraman*'s new book provides a satisfactory presentation of the themes discussed. The 1200 references help in delving deeper into specific questions. The book closes a gap in the chemical literature; it will be welcomed not only by the dyestuff analyst but will also prove of value to the dyestuff chemist engaged in preparative work.

Energetic Materials. Vol. 1. Physics and Chemistry of the Inorganic Azides. Edited by *H. D. Fair* and *R. F. Walker*. Plenum Press, New York 1977. 1st edit., xv, 503 pp., numerous figs. and tables, bound, $ 59.40.

Although azides have been known since 1890 and a large number of ionic and covalent inorganic azides have been prepared, most of the detailed work on their physical properties in particular was done only in the last two decades.

The present book opens with a brief introduction followed by nine main chapters to which several authors contributed. These deal mainly with the physical properties of azides and with their decomposition reactions induced by physical means, the literature up to about 1975 being considered. The first chapter gives a review of the inorganic and organometallic azides and of the general and special methods used in their preparation. Next information is provided about crystal growth and crystal structures, very many data being presented in tables and important structures being illustrated. There is an excellent and very extensive review of molecular and lattice vibrations, of optical and electrical properties, and of electron structure calculations. The last four chapters deal very carefully with the stability of azides and with their slow or rapid decomposition induced by heat, friction, impact, electricity, or irradiation. The progressive development of explosions is demonstrated by many photographs.

For all who work with azides this book can be strongly recommended as a mine of information on the literature and data available on the physicochemical behavior of this class of compounds. The data are presented critically and from diverse points of view, and open questions are faced honestly and not simply buried.

Armin Schmidt [NB 388 IE]

Energetic Materials. Vol. 2. Technology of the Inorganic Azides. Edited by *H. D. Fair* and *R. F. Walker*, Plenum Press, New York 1977. 1st edit., xiv, 296 pp., numerous figs. and tables, bound, $ 47.40.

The information collected in the last twenty years on the technology of azides, in particular the technology of lead and silver azides, is reported in this book in a set of seven chapters.

The first chapter contains a really detailed account of the preparation, stabilization, and processing of lead and silver azides. The plant used for their manufacture and the products are illustrated by photographs. Many physical properties of the products stabilized in a variety of ways are tabulated. A further chapter deals with the analysis of, in particular, industrial products for their azide content and traces of metals. In line with the character of these compounds, the following four chapters are devoted in particular detail to the handling, storage, and destruction of these materials, to sensitivity tests, and to their reactions and to impact, friction, heat, radiation, and electricity. The physiological action of azides is also mentioned. The last chapter concerns the use of azides as detonators and as explosives.

The book as a whole contains an abundance of industrially important data, plant, and technical drawings. If we except the analytical chapter, the book will thus be of the greatest value to readers with industrial interests. On the other hand, it would be advantageous to all dealing with azides to learn the many tests that permit statements to be made about the behavior of this class of compounds toward external influences.

Armin Schmidt [NB 389 IE]

Grundlagen der enzymatischen Analyse (Principles of Enzymatic Analysis). Edited by *H. U. Bergmeyer* in collaboration with *K. Gawehn*. Verlag Chemie GmbH, Weinheim—New York 1977. 1st edit., xii, 267 pp., 99 figs., 30 tables, bound, DM 44.—.

The many new procedures of enzymatic analysis and the increasing mechanization of modern clinical and biochemical laboratories led to the decision to publish separately the chapter on "Principles of Enzymatic Analysis" from *Bergmeyer*'s valued major work[*].

The book is divided into the following main sections: 1. Introduction, 2. Theoretical Principles, 3. Handling of Biochemical Reagents and Sample Material, 4. Techniques of Measurement and Apparatus, and 5. Obtaining and Assessing Results of Measurements.

Naturally, for methods for the determination of individual enzymes, the reader must still turn to the larger work. The "Principles" rather explain the quantitative procedures customary today and the experimental details of biochemical analysis. The conclusion is a review of the numbering and

[*] Cf. Angew. Chem. Int. Ed. Engl. *14*, 268 (1975).

classification of enzymes, the new SI units, and a table of numerical values and their units. The book can thus be recommended not only as an aid to students but also as an introduction to all research groups and experimental workers in biochemistry and clinical chemistry.

Joachim Jentsch [NB 395 IE]

Gaschromatographie (taschentext 48) (Gas Chromatography) (Pocketbook 48). By *G. Schomburg*. Verlag Chemie GmbH, Weinheim—New York 1977. 1st edit., x, 188 pp., 62 figs., 7 tables, br., DM 22.—.

Although the importance of gas chromatography as a method of separation is increasing steadily in research and industrial applications, there is hardly any new introductory monograph that is in any way adequate for the present state of development in this field. The book now under review undoubtedly fills a gap in the market in that, being written for the newcomer to gas chromatography, it emphasizes above all the practical aspects and steers him away from typical mistakes. The chapter on modern GLC equipment is restricted to the essentials without forgetting important new techniques. It is useful to have the comparative description of the commercially available instruments from the experienced experimentalist's point of view. Particular care is given to working out the possibilities of systematizing the qualitative and quantitative results in respect of "reproducibility, comparability, and accuracy". This chapter is supplemented in the experimental part of the book by some fundamental exercises with exact experimental data. The theoretical principles of gas chromatography, the parameters important for the experimental worker, and the consequences of their variation in operation of a GLC system are presented clearly and intelligibly. Only the experts will note that *Schomburg* entirely avoids use of the customary term "Trennzahl" [separation number] and limits the somewhat controversial concept of separation performance to "Trennstufenzahl" [number of separation stages] and "Auflösung" [resolution].

The book is so very suitable for helping the beginner to gas chromatography over the initial difficulties that it should be highly welcome to Technical College teachers as a basis for tuition in this subject.

Nitrogen as Leaving Group: Dediazoniations of Aromatic Diazonium Ions

By Heinrich Zollinger[*]

On heating, aromatic diazonium salts eliminate nitrogen by two fundamentally different mechanistic pathways, *i.e.* heterolysis and homolysis. Among these pathways a series of variants are known, giving rise to a whole variety of mechanisms. This article considers the effect of specific solvation, apparently characteristic of diazonium ions, by various solvents (fluorinated alcohols, methanol, water, dimethyl sulfoxide, pyridine, and hexamethylphosphoric triamide) on the mechanism. Apart from the donor properties of the solvent, the oxidation potential and the presence of additives play a major role in determining what reaction type will predominate.

1. Introduction

Molecular nitrogen is one of the best nucleofugic leaving groups known: diazoalkanes afford carbenes *via* metastable diazonium ions; in aromatic diazonium ions nitrogen is readily replaced by nucleophiles, especially by solvent. A comprehensive account of nitrogen as leaving group in aliphatic diazonium ions has been written by *Kirmse*[1]. Several years ago we reported[2] the current state of knowledge about the mechanisms of aromatic dediazoniations and expressed the belief that a number of open questions would soon be answered. This has indeed come about: in this connection a reaction was discovered which would hardly have been deemed possible in 1973, *i.e.* the reaction of molecular nitrogen with intermediates of aromatic dediazoniation[3]. The time is therefore ripe for a survey of known mechanisms of decomposition of aromatic diazonium ions.

In the following we shall adopt the systematic nomenclature of substitution reactions proposed by *Bunnett*[4]: regardless of mechanism, all reactions in which both nitrogen atoms of an azo or diazo compound are replaced by another group are designated dediazoniations; this term is preceded by the name of the entering group. A Gomberg-Bachmann arylation is accordingly designated as aryl-dediazoniation, a hydrolysis as hydroxy-dediazoniation, and replacement of the diazo group by hydrogen as hydro-dediazoniation.

This article is not a comprehensive compilation and discussion of all recent publications about the dediazoniations of aromatic diazonium salts. Instead, the main emphasis is placed on recent mechanistic findings relating to the heterolytic and homolytic thermal dediazoniations which have been obtained in solvents exerting a characteristic influence on the mechanism. These are 2,2,2-trifluoroethanol (TFE) and 1,1,1,3,3,3-hexafluoroisopropanol (HFIP), dimethyl sulfoxide (DMSO), hexamethylphosphoric triamide (HMPA), methanol, pyridine, and weakly alkaline aqueous buffer solutions. We shall not consider photodediazoniations.

As will become evident in the following sections, a *variety* of mechanisms has been found in the dediazoniations of aromatic diazonium salts. This is surprising, since only an S_N1-type dissociation of the diazonium ion to an aryl cation and N_2 would be expected by analogy with the dediazoniation step of aliphatic diazonium ions and from the extremely high stability of the nitrogen molecule.

However, two characteristic examples should suffice to show that seemingly slight modifications in the reaction system can lead to entirely different reaction products; these suggest fundamentally different dediazoniation mechanisms:

1) As already observed by *Horner* and *Stöhr*[5] and by *DeTar et al.*[6], and thoroughly investigated by *Bunnett et al.*[7], numerous arene diazonium ions in methanol decompose in a nitrogen atmosphere with formation of the corresponding

[*] Prof. Dr. H. Zollinger
Technisch-Chemisches Laboratorium
Eidgenössische Technische Hochschule
CH-8092 Zürich (Switzerland)

hydrocarbon, *i.e.* a hydro-dediazoniation occurs (a); in the presence of oxygen, however, methoxy-dediazoniation (b) takes place.

$$Ar{-}N_2^{\oplus} + CH_3OH \begin{cases} \xrightarrow[N_2]{\text{under}} Ar{-}H + CH_2O + H^{\oplus} + N_2 & \text{(a)} \\ \xrightarrow[O_2]{\text{under}} Ar{-}OCH_3 + H^{\oplus} + N_2 & \text{(b)} \end{cases}$$

2) In DMSO as solvent, aryl-dediazoniation of the unsubstituted benzenediazonium ion with nitrobenzene leads mainly *via meta* substitution to 3-nitrobiphenyl, whereas in the case of the *p*-nitrobenzenediazonium ion the formation of *ortho*- and *para*-substituted products (2,4'- and 4,4'-dinitrobiphenyl) prevails[8]. This indicates an electrophilic aromatic substitution in the former case, and a radical mechanism in the latter case.

2. Dediazoniations in Trifluoroethanol and in Hexafluoroisopropanol

On the basis of the classical studies by *Crossley et al.*[9] dating from 1940, it was long accepted without question that the hydrolysis of arenediazonium salts in acid solution proceeds by an S_N1 mechanism, *i.e.* consists of a rate-determining irreversible dissociation of the diazonium ion into an aryl cation and nitrogen and fast subsequent reaction of the cation with water or other nucleophiles present in solution [eqs. (c) to (e)]. Apart from a somewhat neglected publication by *E. S. Lewis* and *Hinds*[10] in 1952, the first doubts regarding the correctness of this concept were voiced in 1964 when reactions were discovered whose kinetics could be influenced by the concentration of nucleophiles present in the system[11-13].

$$Ar{-}N_2^{\oplus} \xrightarrow{\text{slow}} Ar^{\oplus} + N_2 \qquad \text{(c)}$$

$$Ar^{\oplus} + H_2O \xrightarrow{\text{fast}} Ar{-}\overset{\oplus}{O}H_2 \xrightleftharpoons{\text{fast}} ArOH + H^{\oplus} \qquad \text{(d)}$$

$$Ar^{\oplus} + Nu^{n\ominus} \rightarrow Ar{-}Nu^{(n-1)\ominus} \qquad \text{(e)}$$

Nu = nucleophile, $n = 0, 1, 2$, *etc.*

The question whether aryl cations are indeed intermediates of heterolytic dediazoniations therefore still remained to be answered[2] in 1973.

Not long afterwards a solution to the problem came from two quarters: *Swain et al.*[14,15] investigated and interpreted the effects of substitutions on the kinetics of dediazoniation in water: the kinetic results were analyzed by use of dual parameter substituent constants $\mathcal{F}$ (=field effect) and $\mathcal{R}$ (resonance effect) and, according to *Swain* and *Lupton*[16], are compatible with the intermediacy of an aryl cation but not with an S_N2-type transition state. The same conclusion was reached by *Swain et al.*[14,17] from the primary kinetic isotope effects in the dediazoniation of ^{15}N-labeled arenediazonium ions and the secondary kinetic isotope effects in the dediazoniation of ring-deuterated salts.

The occasional influence of nucleophile concentration on the reaction rate could not be interpreted in this way; it can, however, be understood from the observation that the formation of aryl cation and N_2 is reservible: in our laboratory it was shown by ^{15}N-labeling experiments that aryl cations generated from ^{15}N-diazonium ions are able to form ^{14}N-diazonium ions with "external" $^{14}N_2$ molecules[3,18], *i.e.* that the reverse reaction of eq. (c) is possible [see eqs. (f) and (g)]. Hence the aryl cation is a steady-state intermediate which, according to classical Bodenstein kinetics [eq. (h)], must lead to a drop in the overall reaction rate on increasing the concentration of nitrogen and to a rise in the rate on increasing the concentration of the nucleophiles.

$$Ar{-}N_2^{\oplus} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ar^{\oplus} + N_2 \qquad \text{(f)}$$

$$Ar^{\oplus} + Nu^{n\ominus} \xrightarrow{k_2} Ar{-}Nu^{(n-1)\ominus} \qquad \text{(g)}$$

$$v = [Ar{-}N_2^{\oplus}] \frac{k_1 k_2 [Nu^{n\ominus}]}{k_{-1}[N_2] + k_2[Nu^{n\ominus}]} \qquad \text{(h)}$$

This could indeed be confirmed in 2,2,2-trifluoroethanol (TFE) and in 1,1,1,3,3,3-hexafluoroisopropanol (HFIP)[19]: radical side reactions are exceptional in these very weakly nucleophilic solvents, in contrast to the situation in water. The kinetic effects are larger owing to the greater solubility of nitrogen.

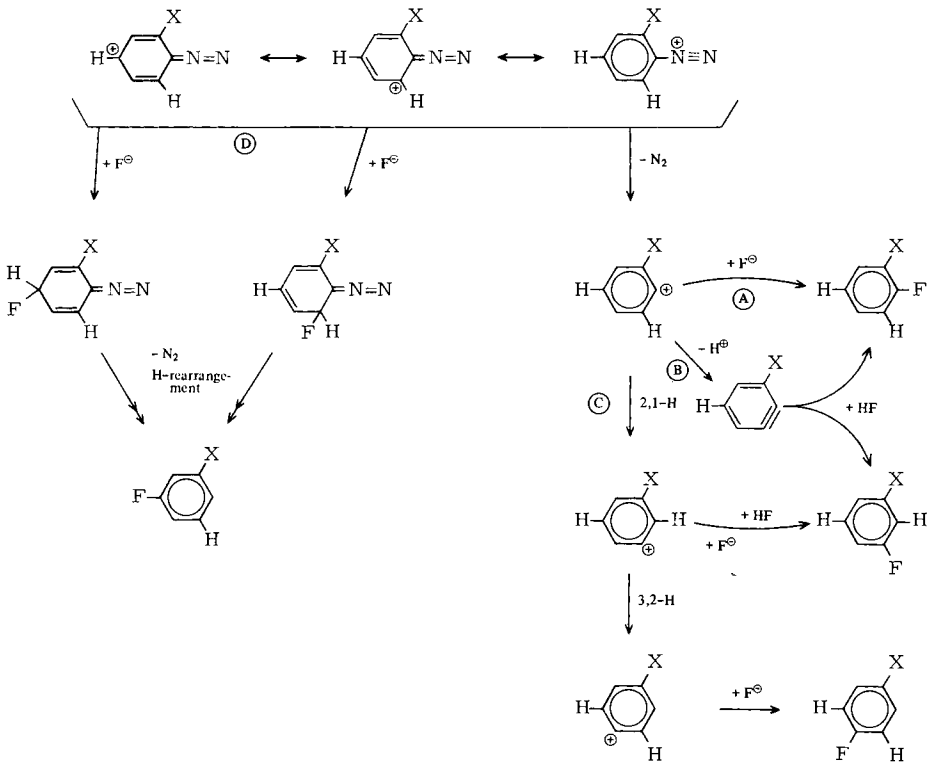
Furthermore, it was found that the N_α-N_β rearrangement, *i.e.* the reaction

$$Ar{-}\overset{\oplus}{N}_\alpha{\equiv}{}^{15}N_\beta \rightleftarrows Ar{-}{}^{15}\overset{\oplus}{N}_\alpha{\equiv}N_\beta$$

occurs to a greater extent in TFE and HFIP than in water. This rearrangement was first observed in water (1–2% after 70% dediazoniation) by *E. S. Lewis*[20], but was suspected to be a mere artifact[21]. With the 2,4,6-trimethylbenzenediazonium ion ($^{15}N_\beta$) the extent of N_α-N_β rearrangement after 70% dediazoniation reaches 20.9 and 37.0% in TFE and HFIP, respectively[19].

In TFE the aryl cation could also be trapped by carbon monoxide, which is isoelectronic with molecular nitrogen[18]

$$Ar^{\oplus} + CO \rightarrow Ar{-}\overset{\oplus}{C}{=}O \rightarrow \rightarrow Ar{-}CO{-}OCH_2CF_3$$



This reaction was unsuccessful when attempted in water by *Lewis et al.*[10].

Becker, Kuzmin, et al.[22] have interpreted the short-lived intermediates detected by flash photolysis of aqueous solutions of diazonium salts as aryl cations. Supporting evidence for this assignment comes from the substituent dependence of the rate of hydrolysis of these intermediates, which obeys the classical Hammett relation with a predictably small ϱ value (+0.36) owing to the high reactivity. In the light of a recent study[23], however, it appears doubtful that these intermediates are aryl cations.

Dediazoniation *via* aryne intermediates, known to be possible in some cases[24], could be ruled out experimentally by *Swain et al.*[15] and by our own group[13] for the reaction conditions under discussion.

The products of dediazoniation in pyridinium polyhydrogenfluoride investigated by *Olah et al.*[25] clearly demonstrate the versatility of heterolytic dediazoniations. The product ratio suggests that, apart from S_N1 substitutions and reactions *via* arynes, σ-substitutions of the type described by *Kovacic*[26]

and S_N1 substitutions with 2,1- and 3,2-hydrogen shifts may also occur (Scheme 1).

Scheme 1. Dediazoniation in pyridinium polyhydrogenfluoride solution. X = CH_3, path Ⓐ; X = NO_2, path Ⓓ; X = CF_3, paths Ⓑ + Ⓒ + Ⓓ.

Let us now concentrate on path Ⓐ, and particularly on the question whether the path (f)→(g), *i.e.* the mechanism involving *one* steady-state intermediate, the aryl cation, provides the only possible interpretation of the experimental data.

To this end it seems logical to examine whether the kinetic data for dediazoniation of 2,4,6-trimethylbenzenediazonium ion in TFE and HFIP are compatible with the dependence on nitrogen concentration $[N_2]$ expected from eq. (h). $[N_2]$ can be increased in this solvent by working at a higher nitrogen pressure. Figure 1 shows the results of kinetic measurements at 1–300 atm of argon or nitrogen: the drop in rate expected from eq. (h) at increased nitrogen pressure, *i.e.* increased nitrogen concentration, is clearly observed—however, it also occurs, although to a lesser extent, with argon! The reason for this effect of argon pressure on the rate (argon can be assumed not to react with aryl cations) is to be found in the known[27] activation volume of dediazoniation. The effect can be eliminated by performing kinetic experiments at constant total pressure (300 atm) with argon/nitrogen mixtures and determining the solubility of nitrogen in TFE under these conditions by a direct method[19]. The solubility of nitrogen in TFE is found to be about 23 times higher than in water. This is another reason why TFE is an ideal solvent for the study of heterolytic dediazoniations!

Kinetic measurements under pressures of 300 atm are not simple: statistical evaluation of 41 runs gave a standard deviation of $\pm 0.5\%$ to $\pm 2.8\%$ for the first order rate constant. The 41 experimental k_{exp} values measured at eight different nitrogen concentrations between 0 and 3.053 mol/l were shown by F tests to be compatible not only with the function (k), which corresponds to the kinetic equation (h) for the "simple" aryl cation mechanism, but also—although not so well—with a linear dependence of the rate constant k_{exp} on $[N_2]$; *i.e.* with function (i) or—more satisfactorily—with function (l)[28].

$$k_{exp} = a - b[N_2] \quad \text{(i)}$$

$$k_{exp} = \frac{a'}{b'[N_2] + c'} \quad \text{(k)}$$

$$k_{exp} = \frac{a''}{b''[N_2] + c''} + d'' \quad \text{(l)}$$

Eq. (i) can be ruled out mechanistically: this function would correspond (under certain boundary conditions) to a *com-*

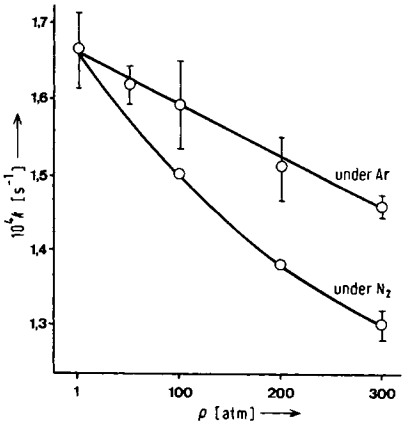


Fig. 1. Rate of dediazoniation of 2,4,6-trimethylbenzenediazonium tetrafluoroborate in TFE at increasing nitrogen and argon pressures [19].

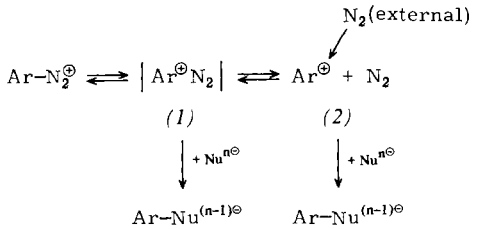
pletely reversible reaction. It is impossible, however, to regenerate the diazonium salt from the *final* products of dediazoniation and nitrogen.

The function (l) can be ascribed to several mechanistic variants with *two* steady-state intermediates. These intermediates may occur competitively or consecutively[28].

Let us note that it is concluded all too frequently and far too hastily from kinetic data that any mechanism compatible with experimental work is the right one. This conclusion is *fundamentally* false[29]. It is only correct to say that a mechanism which fits the data cannot be discounted; other mechanisms may also be compatible with the experimental data. Perhaps the first mechanism can be ruled out by *further* experiments.

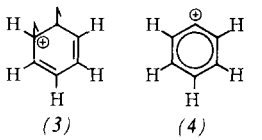


Dediazoniation mechanisms with two competitive or consecutive intermediates have already been proposed by *Lewis et al.*[11] for the reaction of diazonium salts with thiocyanate ions; a decision has yet to be made.

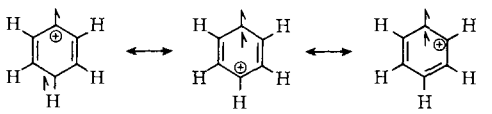
In our case, differentiation of the functions (k) and (l) became possible by use of special statistical methods. Function (k) can be ruled out within the probability limits set by the accuracy of the kinetic measurements.

Evidence supporting (l), *i.e. two* (or more) steady state intermediates, also comes from purely chemical criteria:

N_α-N_β rearrangement proceeds much faster than the reaction with external nitrogen. Thus after 70% conversion of 2,4,6-trimethylbenzenediazonium tetrafluoroborate (in HFIP, $[N_2]=4.94$ mol/l), N_α-N_β rearrangement could be detected, as already mentioned, in 37.0% of the remaining diazonium salt, whereas exchange with external nitrogen had occurred in only 16.5% of the salt. Moreover, steric substituent effects (comparison of benzene- with 2,4,6-trimethylbenzenediazonium salts) and solvent effects (comparison between HFIP and TFE) on the kinetics of exchange and N_α-N_β rearrangement can hardly be explained without assuming two or more intermediates.



These results are compatible with the conclusion that the N_α-N_β rearrangement takes place in an initial intermediate, possibly corresponding to the encounter complex[30] but that exchange with external nitrogen requires a "free" aryl cation.



The initial intermediate *(1)* corresponds to a contact ion pair, as first proposed by *Winstein et al.* for the generation of carbocations from molecules[31]. Species *(1)* should therefore be described as a contact ion-molecule pair[32]. In contrast to *Winstein*'s ion pairs, coulombic interaction does not contribute to the stability of the pair $|Ar^{\oplus}N_2|$. The relative stability of *(1)* can be understood *qualitatively* in terms of orbital interaction diagrams, as have been considered for addition of a proton to a C=C double bond[33], and with the aid of HOMO/LUMO concepts[34].

Distinction between the reactivity of encounter complex-type intermediates such as *(1)* and that of solvent-separated and "free" aryl cations (or ion pairs) such as *(2)* could be a problem of selectivity disguised by microdiffusion, as studied by *Rys*[35].

A further question still to be answered is the structure of the aryl cation: in 1961 *Taft*[36] postulated that the aryl cation exists as a biradical *(3)*. However, recent *ab initio* MO calculations[37] show the singlet structure *(4)* to be more stable than a biradical *(3)* or triplet structure *(5)* for the unsubstituted phenyl cation. This result confirms earlier semi-empirical calculations[38].

(3) *(4)*

(5)

The biradical hypothesis was based on the effect of substituents on the kinetics of dediazoniation, which were not understood at the time. As already mentioned, this problem has meanwhile been solved by *Swain*[15]: a biradical can be ruled out.

Evidence favoring a triplet (of the ground state) is provided, however, by ESR spectra recorded at 77 K on photolysis of arenediazonium salts bearing electron donor substituents in the *para* position[39], and also by the influence of diluent on the stereospecificity of addition of *cis*-2-butene to 2,6-di-*tert*-butyl-4-diazo-2,5-cyclohexadienone ("3,5-di-*tert*-butylbenzene 1,4-diazoxide")[40]. *Ab initio* calculations on the stability of arenediazonium ions with donors in the *para* position (NH_2, OH) are also compatible with a triplet[41].

Remarkably, with the exception of a conjecture concerning the intermediate in the case of the *p*-nitro compound[42], these demonstrations of triplet character are limited to aryl cations having electron donors in the *para* position. Generalization of this result seems unjustified for the following reasons: it is quite possible that singlet or triplet structures may be preferred depending upon the substitution of the benzene ring and there is consequently the possibility of two (competitive or consecutive) intermediates at some stage of the association process (such as ion-molecule pairs and ion pairs).

The significance of a detailed examination of aryl cation-type intermediates of heterolytic dediazoniation far exceeds this particular reaction because it has so far proved impossible to demonstrate the occurrence of aryl cations in other reactions. Only recently, four research teams jointly reported unsuccessful attempts to produce aryl cations from activated arenesulfonates (*e.g.* from trifluoromethanesulfonates) by analogy with the known vinyl cations[42a].

3. Dediazoniation in Dimethyl Sulfoxide

On account of the isomeric ratios already mentioned for arylation with *p*-nitrobenzenediazonium salts in dimethyl sulf-

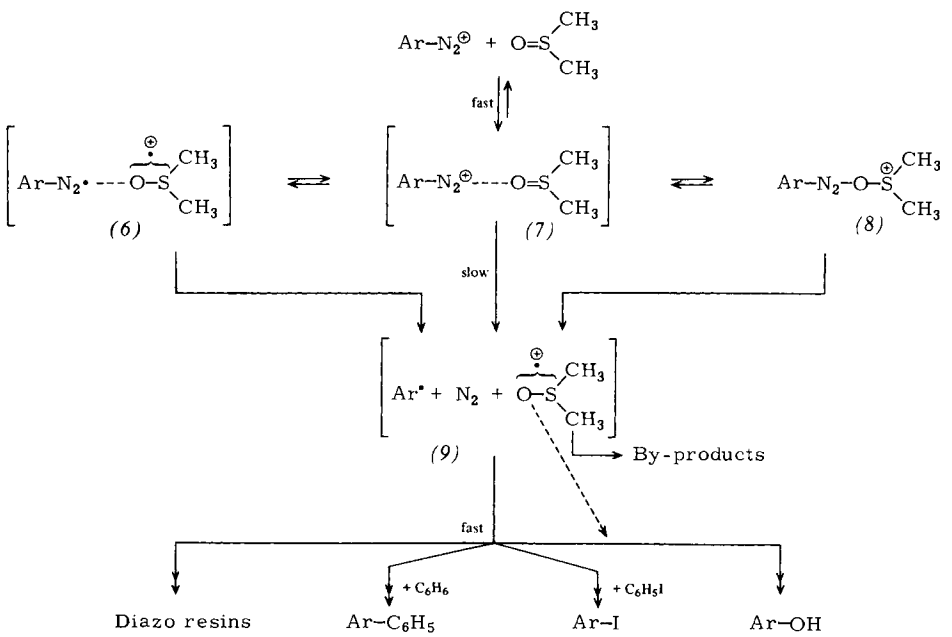
Table 1. Dediazoniation products of *p*-nitrobenzenediazonium tetrafluoroborate in DMSO at 50°C in the absence or presence of iodobenzene (Ar = *p*-O_2N—C_6H_4) [43].

Experimental group	ArN_2BF_4 [mol/l]	C_6H_5I [mol/l]	Yield [%] Ar—OH	Ar—H	Ar—F	Ar—$SOCH_3$	Ar—CH_2SOCH_3	Ar—SCH_3	Ar—I
1	2×10^{-2}	—	88–90	1–2	<0.1	<0.1	<0.1	trace	—
2	2×10^{-2}	2×10^{-2}	16–18	4–5	*	*	*	*	1–2
3	8×10^{-2}	8×10^{-2}	16–27	8	*	*	*	*	6–14

*: Not determined.

oxide (DMSO), it appeared of interest to study the decomposition of these salts in DMSO in the absence of aromatic substrates[43]. Group 1 in Table 1 shows that *p*-nitrophenol is formed in high yield. If the reaction is performed in ^{18}O-DMSO, the oxygen of the phenolic OH group is found to arise exclusively from DMSO. In the presence of iodobenzene (experimental groups 2 and 3) the yield of *p*-nitrophenol falls off sharply; nitrobenzene (from hydro-dediazoniation) is accompanied by 1-iodo-4-nitrobenzene and also by a large amount of unidentified polymeric material. All these products, and especially ArI formed by iodine transfer according to *Bunnett, Cadogan, et al.*[44], are unmistakable indications of a radical decomposition. Up to 90% conversion, the reaction strictly obeys 1st order kinetics. That is rather unusual for radical dediazoniation. The reaction rate is constant within the limits of experimental error, whether the reaction is performed under nitrogen, under air, in glass or Teflon vessels, or even in a mixture of DMSO and benzene (2:1) and in the presence of an equivalent of iodobenzene, although different products are formed under the two last-mentioned sets of conditions. The reaction proceeds about ten times faster than in acidic aqueous solution where it follows a heterolytic course.

It is also remarkable that the electronic spectrum of this diazonium salt in DMSO differs significantly from that recorded in water or TFE, and that admixture of benzene up to a ratio DMSO:benzene of 1:2 hardly alters the spectrum typical for pure DMSO solution.



All these results are compatible with the reaction mechanism shown in Scheme 2.

The UV spectra suggest that equilibrium between the diazonium ion and the solvent, on the one hand, and the electron donor-acceptor complex *(7)* (charge-transfer complex), on the other, lies on the side of the complex *(7)*. According to *Gutmann*[45], DMSO is a good electron donor solvent. This complex might possibly not exist in the form of *(7)* but as a radical pair *(6)* or covalent compound *(8)*. Dissociation of this complex in a cage *(9)* to form an aryl radical, a nitrogen molecule, and the radical cation corresponding to DMSO is slow and rate-determining. Fast subsequent steps lead to the products obtained.

The observation that addition of pyridine enhances the rate of decomposition, shifts the order of reaction from unity to zero, and considerably diminishes formation of *p*-nitrophenol also warrants attention. This is compatible with superior electron donor properties of pyridine as compared to DMSO[45]: generation of the corresponding diazopyridinium cation in one or several of the forms corresponding to *(7)*, *(6)*, and *(8)* competes with formation of *(7)*. This observation plays an important role in the discussion in Section 7.

4. Dediazoniation in Hexamethylphosphoric Triamide

Numerous methods have been reported for the reduction of diazonium salts, *i.e.* for replacement of the diazonio group by hydrogen (hydro-dediazoniation, eq. (a)). The most recent literature survey has been completed by *Tröndlin* and *Rüchardt*[46]. We shall consider just one system in detail

Scheme 2

because it is of importance for the solvation effects discussed in Section 7, *i.e.* hydro-dediazoniation in hexamethylphosphoric triamide (HMPA). This reaction was discovered by *Newman et al.*[47] and examined mechanistically by *Tröndlin* and *Rüchardt*[46].

This dediazoniation is significantly faster than the reaction in DMSO. Determination and evaluation of the order of reaction according to time and concentration (n_t and n_c, respectively) with respect to diazonium salt and HMPA (in HMPA/acetonitrile mixtures) and the effects of inhibitors and initiators are compatible with a chain mechanism. The IR spectrum strongly suggests occurrence of the immonium salt *(10)*.

$$Ar\bullet + H_3C{-}\underset{\displaystyle CH_3}{N}{-}PO[N(CH_3)_2]_2 \longrightarrow Ar{-}H + H_2\dot{C}{-}\underset{\displaystyle CH_3}{N}{-}PO[N(CH_3)_2]_2$$

$$Ar{-}N_2^{\oplus} + H_2\dot{C}{-}\underset{\displaystyle CH_3}{N}{-}PO[N(CH_3)_2]_2 \longrightarrow Ar{-}N_2\bullet + H_2C{=}\overset{\oplus}{\underset{\displaystyle CH_3}{N}}{-}PO[N(CH_3)_2]_2 \quad (10)$$

$$Ar{-}N_2\bullet \longrightarrow Ar\bullet + N_2$$

Measurements of redox potentials disfavor electron transfer from HMPA to the diazonium ion; a diazoanhydride intermediate (A—N_2—O—N_2—Ar) analogous to the Gomberg-Bachmann reaction in water/arene mixtures[48] can be ruled out

$$HMPA + Ar{-}N_2^{\oplus} \downarrow$$

$$[(CH_3)_2N]_3\overset{\oplus}{P}{-}O{-}N_2{-}Ar \longrightarrow Ar\bullet + [(CH_3)_2N]_3\overset{\oplus}{P}{-}O{-}N{=}N\bullet \quad (11)$$

$$H^{\oplus} + H_2\dot{C}{-}\underset{\displaystyle CH_3}{N}{-}PO[N(CH_3)_2]_2 \longleftarrow [(CH_3)_2N]_3P{-}O^{\oplus\bullet} + N_2$$

for kinetic reasons. The authors therefore suspect an initiation reaction *via* an adduct *(11)* to the nucleophilic center, *i.e.* the oxygen of HMPA.

5. Dediazoniations in Methanol

The behavior of diazonium salts dissolved in methanol is of particular interest owing to the influence of the atmosphere (containing or devoid of O_2). As mentioned in Section 1, methoxy-dediazoniation [eq. (b)] usually predominates in the presence of oxygen whereas hydro-dediazoniation generally predominates under nitrogen or argon [eq. (a)].

Two papers published by *Bunnett et al.*[51] in 1968 are of considerable importance, not only because of the mechanistic discussion but also for methodological reasons: they demonstrate how difficult it is to resolve the influences of the individual reactions when performing such competition studies under very similar conditions.

All experimental data (product analyses and kinetic results), obtained with rigorous exclusion of oxygen, are compatible with a radical chain mechanism [eqs. (m) to (o)] already postulated in principle by *DeTar*[6,49]. The aryldiazo radical (Ar—N=N•) was demonstrated to exist as an intermediate by *Closs et al.*[50]. The rate constant of its decomposition [eq. (o)] was estimated to be 10^7 to $10^9\ s^{-1}$[32].

$$Ar\bullet + CH_3OH \rightarrow Ar{-}H + \bullet CH_2OH \quad (m)$$

$$\bullet CH_2OH + Ar{-}N_2^{\oplus} \rightarrow Ar{-}N{=}N\bullet + CH_2\overset{\oplus}{O}H \quad (n)$$

$$Ar{-}N{=}N\bullet \rightarrow Ar\bullet + N_2 \quad (o)$$

This chain reaction appears reasonable since it would give $CH_2\overset{\oplus}{O}H$ from which two thermodynamically highly stable compounds, *i.e.* formaldehyde *(12)* and methoxymethanol *(13)*, can be formed by proton transfer to the solvent.

$$CH_2\overset{\oplus}{O}H + CH_3OH \rightarrow CH_2O + CH_3\overset{\oplus}{O}H_2 \quad (12)$$

$$CH_2O + CH_3OH \rightarrow CH_3OCH_2OH \quad (13)$$

A question remaining unanswered by *Bunnett*'s investigation is that of the chain-initiating reaction. It could be homolysis of the addition product *(14)* of the diazonium ion and the solvent or electron transfer from methanol to the diazonium ion [eq. (p)].

$$Ar{-}N_2^{\oplus} + CH_3OH \rightleftharpoons Ar{-}N_2{-}\overset{\oplus}{\underset{\displaystyle H}{O}}\!\!\diagup^{CH_3} \quad (14)$$

$$Ar{-}N_2{-}\overset{\oplus}{\underset{\displaystyle H}{O}}\!\!\diagup^{CH_3} \longrightarrow Ar{-}N_2\bullet + H\dot{\overset{\oplus}{O}}{-}CH_3$$

$$Ar{-}N_2^{\oplus} + CH_3OH \longrightarrow Ar{-}N_2\bullet + H\dot{\overset{\oplus}{O}}{-}CH_3 \quad (p)$$

Bunnett et al.[7,51] consider eq. (p) to be more likely. We shall return to the fundamental problem of distinguishing between these two possibilities of generating the aryldiazo radicals in Section 7. Significantly, hydro-dediazoniation strongly predominates in alkaline methanol, *i.e.* in the presence of $CH_3O^{\ominus}Na^{\oplus}$[7,51].

A series of product analyses for experiments in the presence of radical scavengers such as 2-methyl-2-nitrosopropane and iodobenzene clearly demonstrate the intermediacy of aryl radicals. It is also remarkable that the *homolytic* dediazoniation generally predominates with diazonium ions rendered more electrophilic by suitable substitution at the aryl group. However, the effects of substituents on the rate of the homolytic reaction could not be correlated with any substituent constants (according to *Hammett*, *Taft*, *Swain*, *etc.*).

In contrast, the kinetics of the heterolytic component of dediazoniation in methanol responded to the same substituent effects as in water; the influence could therefore be interpreted in terms of the Swain substituent constants $\mathcal{F}$ and $\mathcal{R}$ (S_N1-type dediazoniation mechanism, (f)→(g); see Section 2).

With weakly electrophilic arenediazonium ions, the heterolytic mechanism predominates even in the absence of oxygen;

with chlorinated or brominated arenediazonium salts this occurs only in the presence of oxygen. Thus oxygen rapidly terminates the radical chain in these cases. Radical decomposition nevertheless prevails under oxygen with the *p*-nitrobenzenediazonium ion.

6. Behavior of Weakly Alkaline Aqueous Solutions of Diazonium Salts

Water is by far the most important solvent for diazonium salts. In the presence of *ca.* 10^{-2} mol/l or more mineral acid, dediazoniation proceeds almost exclusively *via* a S_N1-type mechanism involving the aryl cation[14,15,17] (cf. Section 2). Strongly alkaline (pH > 12) solutions of diazonium salts are very stable because—as shown[53] by *Hantzsch* in classical physical organic studies in the "pre-Ingold-Hammett" era[52]—they rearrange *via cis*-("*syn*"-)diazotates to the *trans*-("*anti*")-diazotates. It has long been known that diazonium salts decompose with comparative ease in the weakly alkaline range[54]. In spite of the considerable importance of such solutions for preparative work surprisingly little has been published about these dediazoniations.

The reason is soon discovered on making a serious attempt to investigate such a system: on the one hand, numerous polymeric products (diazo-resins) that are difficult to identify are formed at pH values between 6 and 11, and on the other hand these preparative and kinetic experiments are not readily reproducible. The material of the reaction vessel, light, and the atmosphere influence the product formation and the rate and order of the reaction to an extent rarely encountered in organic chemistry.

The dediazoniation of *p*-chlorobenzenediazonium tetrafluoroborate in $HCO_3^{\ominus}/CO_3^{2\ominus}$ buffers can be cited as an example[55,56]: in the presence of less than 10 ppb of O_2 it obeys first order kinetics in glass vessels, but zeroth order kinetics in Teflon vessels; between 50 and 100 ppb of O_2 a fast initial reaction slackens off after about 15% conversion; autocatalysis is observed on exposure to air, but a first order reaction once again in 100% O_2.

We know of three studies in which, under carefully selected conditions, the rate of dediazoniation peaks at the pH value corresponding to the pK_m value of the diazonium-*cis*-diazotate equilibrium[57-59]. This two-step equilibrium (q) is recognized[60] as unusual in that K_1 is smaller than K_2; hence there is no pH region in which the middle equilibrium species, the *cis*-diazohydroxide, accumulates to any extent. The experimental value pK_m corresponds to $1/2\ (pK_1 + pK_2)$.

$$Ar{-}N_2^{\oplus} \underset{-OH^{\ominus}}{\overset{+OH^{\ominus}}{\rightleftharpoons}} cis{-}Ar{-}N_2{-}OH \underset{+H^{\oplus}}{\overset{-H^{\oplus}}{\rightleftharpoons}} cis{-}Ar{-}N_2O^{\ominus} \qquad (q)$$

K_1 K_2

At $pH = pK_m$, the *cis*-diazohydroxide is actually present in very low concentration (normally < 0.1% of the analytical concentration of diazo compound); at this pH, however, a maximum of the possible concentration of diazohydroxide (Fig. 2) occurs. This provides substance for the supposition that dediazoniation proceeds *via* the diazohydroxide since the rate maximum of this reaction lies at $pH = pK_m$.

Moreover the equilibrium (r) at the same pH value shows a concentration maximum for the diazoanhydride (Fig. 2).

$$Ar{-}N_2^{\oplus} + Ar{-}N_2{-}O^{\ominus} \rightleftarrows Ar{-}N_2{-}O{-}N_2{-}Ar \qquad (r)$$

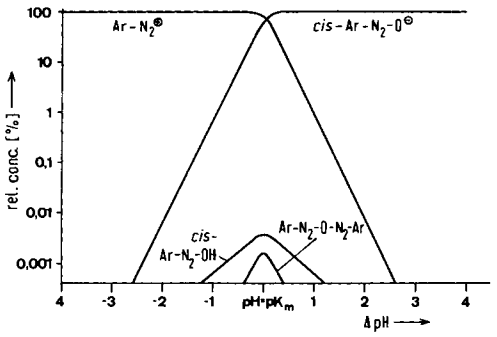


Fig. 2. Dependence of the relative concentration of the diazo equilibrium forms on the pH values (schematic) [56, 60].

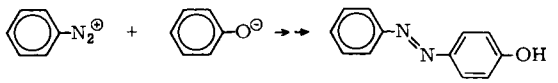
The maximum of the dediazoniation at $pH = pK_m$ can therefore be explained just as well in terms of a mechanism involving the diazoanhydride. Such an interpretation would correspond to the results obtained by *Rüchardt et al.*[48] for the Gomberg-Bachmann reaction in water/arene mixtures.

A logarithmic plot of the percentages of diazoanhydride [eq. (r)] and diazohydroxide present at equilibrium [eq. (q)] *versus* the pH value has slopes of 2:1 and 1:1[56] (Fig. 2) on both sides of the maximum. This should provide an opportunity of distinguishing between diazoanhydride and diazohydroxide as dediazoniation intermediates on the basis of the slopes of the logarithmic reaction rates as plotted against the pH value. However, the slopes are different on each side of the rate maximum and have fractional values instead of 1:1 and 1:2.



We shall have to await an accurate analysis before we know whether these fractional values are due to fractional reaction orders with respect to $[H^{\oplus}]$ and $[OH^{\ominus}]$ or to superposition of two or more mechanisms, each of which displays a different integral dependence upon the concentration of acid or base.

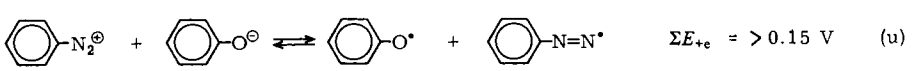
Fractional reaction orders with respect to the concentration of diazonium ion and/or other species suggest radical chain reactions. The occurrence of radical intermediates has been confirmed in various kinds of aqueous systems by ESR, CIDNP, kinetics, and product analyses. Since our survey[2] was published in 1973, numerous papers have appeared on this topic; only a few can be mentioned in the present discussion: apart from the dediazoniation in methanol considered in Section 5, a radical chain mechanism is compatible with the extremely thorough studies performed by *Rüchardt et al.*[61] on dediazoniation in aqueous solutions of $NaNO_2$ and with kinetic and spectroscopic measurements (including CIDNP) in mixtures of DMSO and pyridine[43] and of TFE and pyridine[62].

The problem of the initial step (cf. Section 5) could be solved for reaction in aqueous solution in the presence of nitrite ions[61] by invoking formation and radical decomposition of a *covalent* intermediate $Ar{-}N_2{-}NO_2$. This question remains to be answered in the case of adducts between diazonium ions and pyridine[62].

Experiments by *Becker et al.*[23,63] suggest that "free" electrons can be transferred from a donor to the diazonium ion: these authors observed that diazonium salts quench the fluorescence of pyrene (and other arenes) at a rate of $k_q = 2.5 \times 10^{10}$ mol l^{-1} s^{-1}. The pyrene radical cation and the arenediazo radical thus appear to be likely products of electron transfer. However, pyrene is a weak nucleophile; the concentration of its covalent product with the diazonium ion is estimated to lie below 0.01% at equilibrium. If electron transfer were to proceed *via* this potential intermediate present in such a low concentration then the measured rate constant could not be so large; however, dynamic fluorescence quenching in the excited state of the electron donor-acceptor complex preferred at equilibrium would fit the facts. Evidence supporting a diffusion-controlled electron transfer ($k = 1.8 \times 10^{10}$ to 2.5×10^{10} s^{-1}) was provided by pulse radiolysis.

The rate of heterolytic hydroxy-dediazoniation of type (f)→(d) is independent of pH in the pH range in which the diazo equilibria lie on the diazonium ion side (*i.e.* at pH < pK_m, cf. Fig. 2). Hence in weakly alkaline solution, the phenol corresponding to the diazonium ion is formed. At these pH values the phenol exists in equilibrium with the phenoxide ion and reacts readily with the diazonium ion to form the hydroxyazo compound *(15)*. The phenoxide ion has a redox

(15)



potential [eq. (s)] of the same order of magnitude as that estimated by *Waters*[64] for the diazonium ion⇄diazo radical equilibrium [eq. (t)]. Combination (u) of the two equations (s) and (t) reveals that formation of diazo radical and phenoxyl radical is favored in the optimum pH range (phenol-phenoxide equilibrium displaced towards phenoxide, diazo equilibria displaced towards the diazonium ion). *Bubnov et al.*[65] were able to detect radical intermediates in azo coupling of benzenediazonium salt and sodium phenoxide (in methanol) by means of ^{15}N-CIDNP.

E_{+e} = -0.45 V (s)

E_{+e} = > +0.6 V (t)

ΣE_{+e} = > 0.15 V (u)

Formation of phenol therefore *qualitatively* explains the complex kinetics of dediazoniation in weakly alkaline solution, in particular autocatalysis, the complex influence of oxygen (phenols undergo ready oxidative polymerization), and the formation of polymeric colored products containing considerable amounts of nitrogen.

7. Nucleophilic Solvation as a Mechanism-Determining Factor in Dediazoniations

Dediazoniations in a series of solvents have been described in Sections 2 to 6; these reactions exhibit a surprising and apparently inexplicable variety of mechanisms: there is not only *one* heterolytic and *one* homolytic decomposition pathway but several. Presumably, further mechanisms occur in other less thoroughly studied systems.

The observation[66] that methanediazonium ions are stable in the gas phase suggests that solvation plays an essential role in the dediazoniation of solutions of both aliphatic and aromatic diazonium ions.

The diazonium ion is an electrophilic reagent that is solvated in a special way insofar as *Ritchie*[67] failed to detect any reorganization of the solvation shell in the transition state of nucleophilic additions to the β-nitrogen (*e.g.* with $N_3^{\ominus}$, $CN^{\ominus}$, $OH^{\ominus}$).

It is not yet possible to define this "special kind of solvation" more precisely. However, in semiquantitative terms the concept of dual solvent parameters developed by *Gutmann*[45] can be applied to dediazoniations: solvents can behave as donors or as acceptors in the interactions with solutes. *Gutmann* recognized that these two properties can be determined independently with the aid of two suitable standard substrates and introduced two parameters, *i.e.* the donor number and the acceptor number (DN and AN, respectively). Depending upon the kind of solvation, one of the parameters can outweigh the other.

A similar approach was adopted earlier by *Koppel* and *Pal'm*[68] who sought to quantify the effect of the solvent by introducing four parameters which describe the nonspecific and the specific solvation as the result of the electrophilic and the nucleophilic properties of the medium. The latter were designated *E* and *B*.

On surveying the solvent systems considered in this article, it is seen that the ratio of heterolytic to homolytic reactions shifts in favor of formation of diazoaryl and aryl radicals along the series HFIP ≈ TFE < H_2O (acid) ≈ CH_3OH (acid) ≤ DMSO < HMPA; furthermore, radical formation in TFE, in water, and in DMSO is enhanced by pyridine. Nucleophilic additives such as phenoxide, $NO_2^{\ominus}$, and $OH^{\ominus}$ have a similar effect in water, as does methoxide in CH_3OH. This tendency to form radicals follows the series of *Gutmann*'s donor numbers (DN)[45], *Koppel* and *Pal'm*'s *B* values[68], and *Schleyer*'s N_{BS} nucleophilic indices[69] where they are known (Table 2).

Table 2. Solvent parameters.

Solvent	N_{BS} [69]	DN [45, 70]	B [68]	AN [45]
HFIP (97%)	−3.93	—	—	—
TFE (100%)	−2.78	—	—	—
H_2O	−0.26	*ca.* 30	123	54.8
CH_3OH	0.01	[a]	—	41.3
DMSO	—	29.8	193	19.3
Pyridine	—	33.1	220	14.2
HMPA	—	38.8	234	10.6

[a] The donor number for methanol is higher than 19.1, but lower than 33.8 [70].

Conversely, it could be deduced from the acceptor numbers (AN) of Table 2 that the lone pair of the β-diazo nitrogen acts as a donor in solvents having better acceptor properties, thus favoring heterolysis. However, since the rate of heterolytic dediazoniation is reported by *Swain et al.*[15,17], and also shown by our own kinetic measurements[28], to remain roughly constant in numerous solvents (aqueous sulfuric acid, glacial acetic acid, CH_2Cl_2, TFE, HFIP, fluorosulfuric acid), heterolysis seems much less susceptible to an acceptor effect than homolysis to a donor effect. A quantitative correlation between the donor number (according to *Gutmann*) and the rate of homolytic dediazoniation can hardly be expected because the donor numbers were measured for one particular system (acceptor properties of $SbCl_5$) and are therefore fundamentally incapable of accounting for specific effects which might be operative in the case of diazonium ions.

An insight into the kind of solvation of arenediazonium ions with DMSO is provided by the experiments cited in Section 3. Azo coupling experients in DMSO/H_2O mixtures[71] suggest that diazonium ions form more stable solvates with DMSO than with water.

It should be emphasized that this evidence only suggests that a specific nucleophilic solvation is necessary for homolytic dediazoniation; no information is forthcoming about the kind of interaction between the solvent molecule and the diazonium ion (covalent bonding, donor-acceptor complex, *etc.*).

This solvation is clearly essential for the actual electron transfer to the diazonium ion; however, it is not the only condition. The donor particle must also have a favorable redox potential, *i.e.* it must be capable of forming a relatively stable species on release of an electron. The nitrite ion, which is transformed into nitrogen dioxide, is an excellent example[61].

In this connection, *Becker et al.*[23] have compiled interesting correlations between oxidation potential of the donor and reduction potential of the diazonium ion. They were able to demonstrate that, of two fundamentally possible dediazoniation reactions, that reaction is favored in which the electron required for elimination of N_2 can be supplied with the lowest expenditure of energy. For the heterolytic reaction mode this will be "intramolecular" electron transfer from the aryl group to form an aryl cation with or without participation of an external acceptor solvent; in homolytic dediazoniation it is electron transfer from an external donor.

We have chosen the term "nucleofugic homolytic leaving group" to describe a group possessing both nucleophilic character and the ability to release an electron[2]. In principle, it should be possible to quantitatively predict the reactivity of such particles towards diazonium ions with the aid of a dual-parameter equation. One parameter serves as a measure for the donor property of the particle, and the other one is the redox potential. The complex nature of the kinetics of homolytic dediazoniations will most likely be a great obstacle in the way of our obtaining comparable rate constants referring only to the radical generation step.

Support of our own work cited in this survey by the "Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung" (Projects 2.245.69, 2.722.72, and 2.406-0.75) and by Ciba-Geigy AG and Sandoz AG is gratefully acknowledged. The author is also indebted to Professor Bunnett and Professor Rüchardt for communication of unpublished work, and to Professor Gutmann für suggestions concerning the last section of this article.

[30] The expression encounter complex comes from the consideration of the (bimolecular) addition A + B→(A, B)→A − B. Dediazoniation corresponds to the (monomolecular) dissociation reaction in which, owing to the principle of microscopic reversibility, the primary product of the actual dissociation is a complex *corresponding* to (A,B) and which should

therefore also be designated as an encounter complex, in spite of possible semantic confusion.

Photochemical Rearrangements and Fragmentations of Alkenes and Polyenes

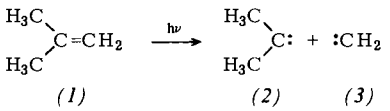
By Gerd Kaupp[*]

This article presents a systematic analysis of the numerous intramolecular reactions of electronically excited alkenes categorized according to substance class and reaction type. The rearrangements and fragmentations observed in simple alkenes are usually rediscovered in non-conjugated and conjugated dienes and polyenes, where they are accompanied by reaction types such as rearrangements involving several double bonds, cyclizations, and intramolecular cycloadditions. Geometrical factors largely determine which reaction of a series of energetically feasible competing processes actually takes place. The industrial syntheses of vitamin D utilize many of the reaction types to be discussed.

1. Introduction

Alkene photochemistry is an unusually complex and versatile field of study[1]. The reason lies in the generally high excess energies after absorption of light and the large number of basically possible deactivation processes still available even if attention is restricted to intramolecular photoreactions and the almost ubiquitous competing processes of luminescence, chemically non-productive deactivation, and *cis/trans* isomerization are disregarded. The wealth of existing material requires some kind of classification. There is still no theoretical concept available for reliable prediction of preferences between the numerous reaction types observed, although distinction between "allowed" and "forbidden" processes is now a closed chapter of chemistry[2]. Yet, arrangement of the material according to substance classes and reaction types permits a comprehensive treatment of preparative aspects in which common and distinguishing features of the individual types can be recognized. This could possibly further our understand-

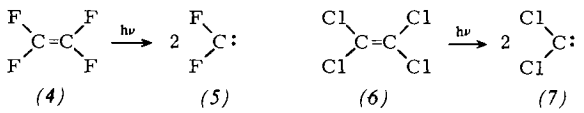
[*] Univ.-Doz. Dr. G. Kaupp
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)



ing of processes occurring on transformation of electronic excitation energy into vibrational energy.

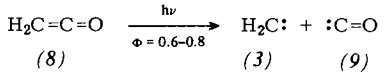
Photochemical syntheses are of particular value when it becomes possible in various cases to achieve a pronounced selectivity for one of the many possible reactions. The reaction conditions (cf. ref. [3]) and structural variation of the substrate can be used to modify or control the result of a reaction. Both approaches are used largely empirically and therefore require comparative experimentation. The present article is concerned mainly with reactions in liquid phase, which give good product yields or appear highly typical in some other way, and has a pronounced practical slant.

2. Monoenes

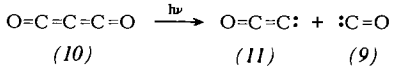


2.1. Cleavage of Double Bonds

Simple alkenes such as *(1)* (gas phase, $\lambda = 184.9$ nm) show only little tendency to undergo cleavage at the double bond to form two carbene fragments; most of the products are formed by dissociations of the C—H and C—C bonds[4].

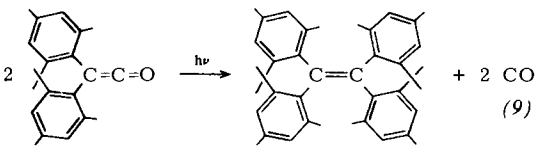


(1) *(2)* *(3)*

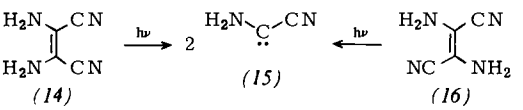


Double bond cleavage proceeds with better yields in polyhalogenated alkenes like *(4)*[5] and *(6)*[6] and in ketenes *(8)*[7] and carbon suboxide *(10)*[8].

(4) *(5)* *(6)* *(7)*



(8) *(3)* *(9)*

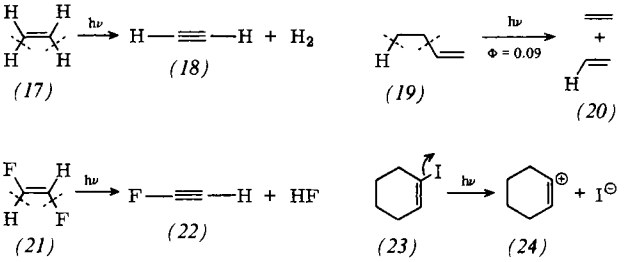


(10) *(11)* *(9)*

The resulting carbenes can be trapped as usual by added reactants, or they can dimerize. Thus, preparative interest attaches to the formation of *(13)* ($\lambda = 253.7$ nm)[9].

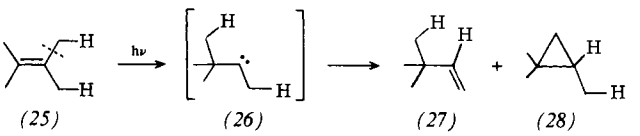
(12) *(13)* *(9)*

In the case of *(14)* and *(16)* double bond cleavage to give *(15)* could be accomplished at -196 °C[10]. However, this reaction type often appears to approach the limits of



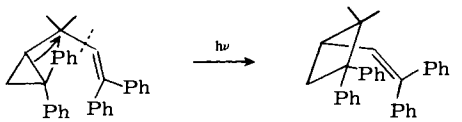
(14) *(15)* *(16)*

energetic feasibility in condensed phase. This is only rarely the case with the photocleavage of single bonds.

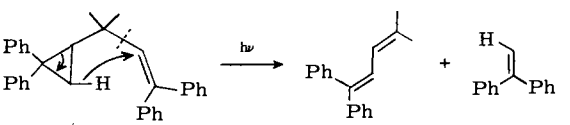


2.2. α-Cleavage

The photochemical cleavage of α bonds is widespread in the simplest alkenes. This is seen in the reactions of *(17)*[11], *(19)*[12], *(21)*[13], and *(23)*[14]. Formation of *(22)* was observed at as low a temperature as 10 K[13].

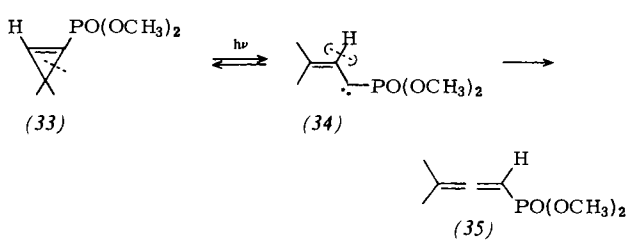


(17) *(18)* *(19)* *(20)* *(21)* *(22)* *(23)* *(24)*

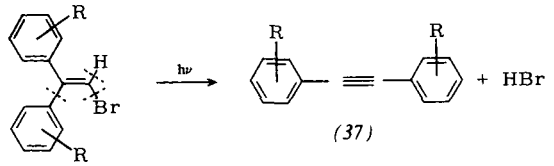


α-Bonds in more complicated molecules can also be cleaved by the action of light. Thus *(25)* gives *(27)* (17 %) and *(28)*

(25) *(26)* *(27)* *(28)*

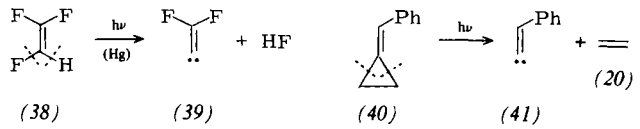


(29) *(30)*



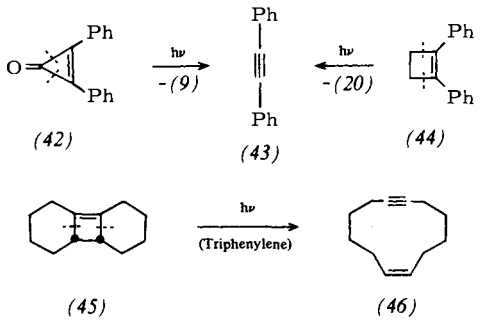
(29) *(31)* *(32)*

(24 %)[15], presumably *via* the carbene *(26)*; α-cleavages of *(29)* ($\lambda = 253.7$ nm) with rearrangement and fragmentation have been described as cyclopropyl-π-methane rearrangement[16]. α-Cleavage of *(33)*[17] gives the vinylcarbene *(34)*.



(33) *(34)* *(35)*

Formation of *(35)*[17] then also requires cleavage of an α-C—H bond. A total of three α bonds are cleaved on elimination of HBr from *(36)*. The yields of *(37)* vary between 50 and



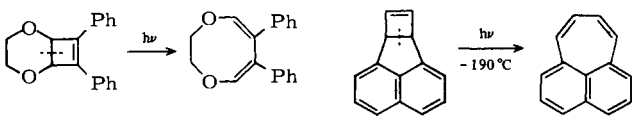
(36) R = o-, m-, p-OCH_3 (37)

86%[18]. The photoreaction of (36) could proceed *via* a vinylcarbene, like those from (38)[19] and (40)[20].

(38) (39) (40) (41) (20)

Other α-fragmentations can be achieved with cyclopropenones such as (42)[21] and cyclobutenes such as (44)[22] and (45)[2c,23]. It is especially remarkable that in dilute solution (44) is cleaved only to (43) and ethylene (20), and fails to form a (dihydro-)phenanthrene derivative or to undergo the ring opening to 2,3-diphenyl-1,3-butadiene which occurs

(42) (43) (44) (45) (46)

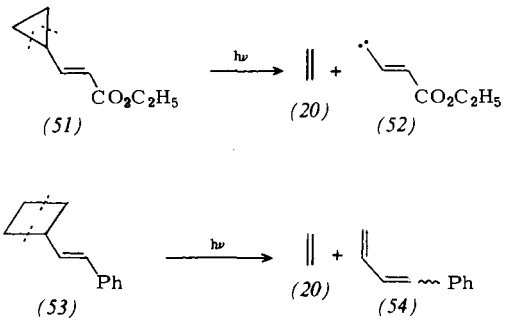


on heating to 100 °C. The α-cleavages described here are related to the long-known formation of alkyl and acyl radicals on photolysis of aldehydes and ketones[24].

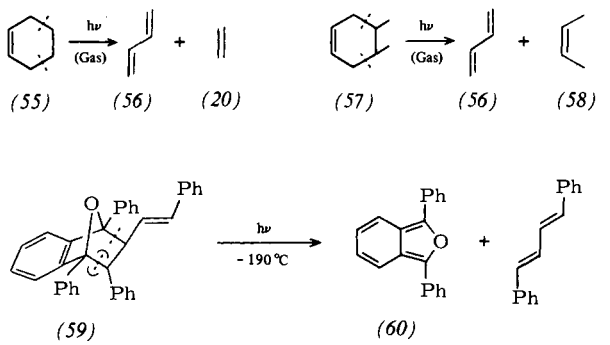
2.3. β-Cleavage

After electronic excitation of alkenes, β bonds can be cleaved (again as in carbonyl compounds). This opens up a greater variety of reaction types than α-cleavage.

2.3.1. Ring Opening

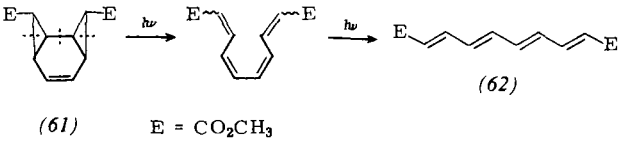


Photochemical ring opening of cyclobutenes to butadienes is comparatively rare. Synthesis of the dihydrodioxocin (48) (88%) is of preparative value[25]. Interestingly, (49) and related compounds in some cases react only from the second triplet level after absorption of two light quanta[26]. Furthermore, the slight tendency of cyclobutenes to undergo β-cleavage is significant if it is intended to perform [2+2] photocycloadditions with them[27].



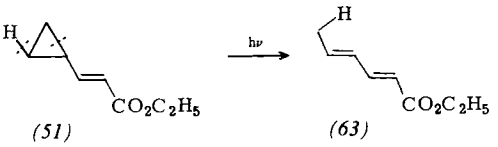
(47) (48), 88% (49) (50)

2.3.2. Fragmentations

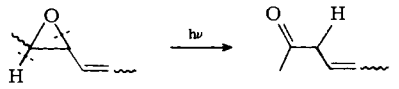


Photochemical cycloreversions of vinylcyclopropanes and vinylcyclobutanes lead to carbenes and alkenes, respectively. Compound (51) decomposes by cleavage of two β bonds. The carbene (52) then undergoes several secondary reactions (isomerization to the allene, to ethoxyfuran, and to ethyl cyclopropenecarboxylate)[28]. In the case of (53) a β and a γ bond are cleaved; this occurs even at −190 °C[29]. Further cycloreversions concern photochemical retro-Diels-Alder fragmentations of cyclohexenes. If such reactions are to be accomplished in solution [see, *e.g.* (55)[30] and (57)[31]] then quantum-consuming ring inversions must be suppressed by suitable substituents; (59) is an example[22,29]. The complicated cleavage of the eight-membered ring in the rigid, sterically hindered species (61) is to be classified as a [4+2+2] reaction[22].

(51) (20) (52) (53) (20) (54)

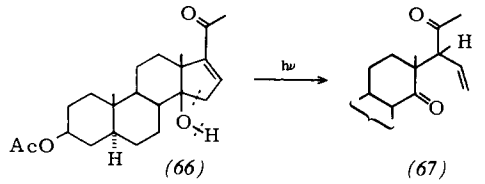


(55) (56) (20) (57) (56) (58) (59) (60)

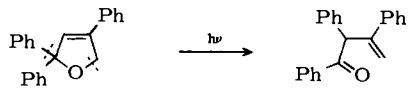


(61) E = CO_2CH_3 (62)

2.3.3. Opening of Three- and Five-Membered Rings with Substituent Migration

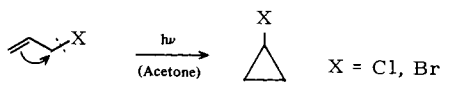


A reaction closely related to cycloreversion is the formation of open-chain isomers from odd-membered rings. Thus (51) reacts to give (63)[28]; of preparative significance are corresponding rearrangements of vinyloxiranes such as (64)[32]. In unsaturated five-membered rings, one or two β bonds can be photochemically cleaved, as shown by the reactions of (66)[33] and (68)[34].



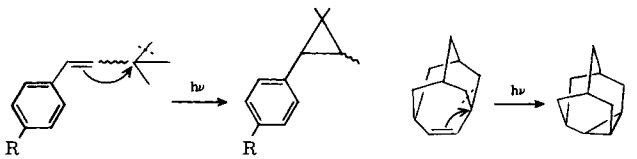
(51) (63)

(64) (65)



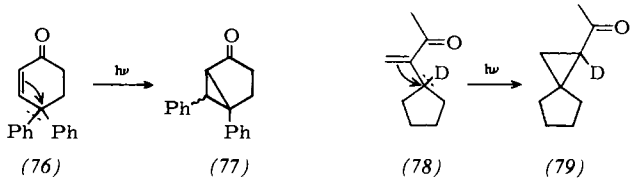
(66) (67)

(68) (69)



2.3.4. 1,2-Shifts

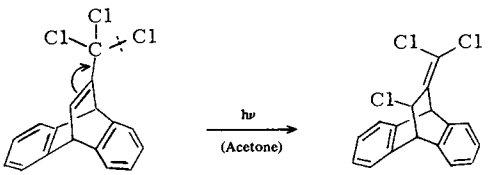
The β-cleavage of alkenes can be associated with a 1,2-shift of substituents; cyclopropane derivatives are obtained in this case. On irradiation in acetone, allyl chloride and allyl bromide give 17 and 10%, respectively, of cyclopropyl halides of type



(70) (71) X = Cl, Br

(71)[35]. Like halogen atoms, the alkyl groups can migrate in *(72)*[36] and *(74)*[37], the phenyl groups in *(76)*[38], and the H (D) atoms in *(78)*[39].

(72) (73) (74) (75)

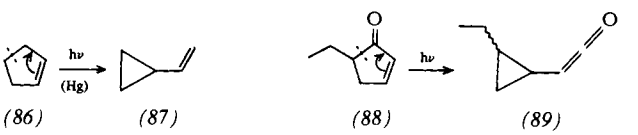


R = CN, H, OCH_3 *cis + trans*

(76) (77) (78) (79)

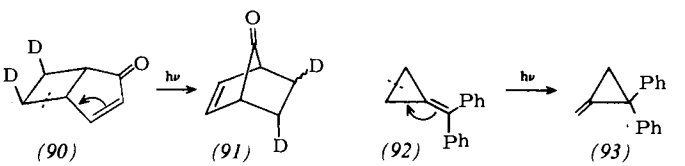
2.3.5. 1,3-Shifts

1,2-Shifts nearly always compete with allyl migrations (1,3-shifts), which also warrant synthetic interest. Thus double bonds can be pushed into exocyclic positions by migration

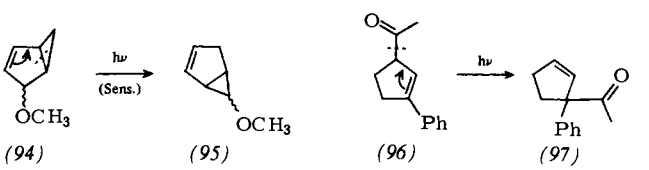


(80) (81), 95%

(82) (83) (84) (85)



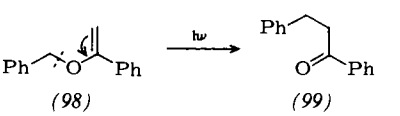
of halogen [cf. *(80)*][40] or H atoms [cf. *(82)* and *(84)*][41]; or ring contractions can take place to give energetic vinylcyclopropanes such as *(87)* and *(89)*, which release energy on reversion to cyclopentenes by valence-bond isomerization[42].



(86) (87) (88) (89)

cis + trans

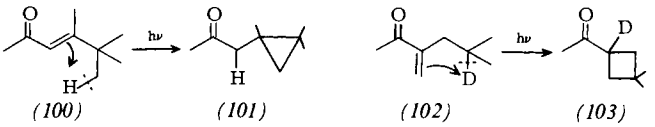
Ring contraction of *(88)* is not stereospecific[43]. Also of interest are ring expansions as in *(90)*[44] and migrations of three-membered rings as in *(92)*[20] and *(94)*[45] by 1,3-shifts



(90) (91) (92) (93)

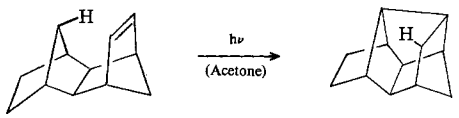
(94) (95) (96) (97)

after direct or sensitized excitation. Some uncertainty surrounds the question whether 1,3-acyl shifts like that of *(96)*[46] follow excitation of the alkene or the carbonyl group. Moreover, 1,3-shifts are also of preparative significance in the



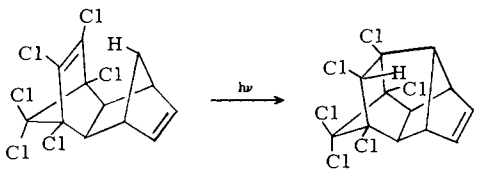
(98) (99)

transformation of enol ethers into ketones, as demonstrated by the reaction of *(98)*[47].



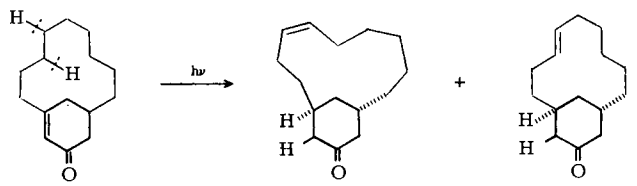
2.4. Intramolecular Hydrogen Transfer

If after electronic excitation β-, γ-, δ-, *etc.* hydrogen atoms are located in the proximity of a double bond, they can be transferred. Thus, the three-, four-, and five-membered rings in *(101)*[48], *(103)*[39,49], *(105)*[50], and *(107)*[51] are formed by intramolecular addition of C—H bonds. These

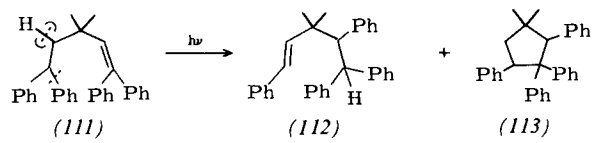


modes of reaction are favored by the geometry of the molecules in all known cases. The reactions probably proceed *via* diradicals after direct and sensitized excitation. A related reaction is observed in poly-1,2-butadiene (see Section 3.3).

(100) *(101)* *(102)* *(103)*

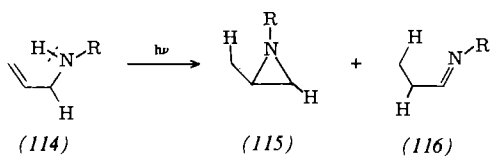


(104) *(105)*, 25%

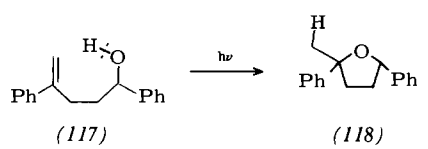


(106) *(107)*, 80%

Ring formation is not the only secondary reaction to ensue upon photochemical hydrogen transfer. Site exchange of a second hydrogen atom or of substituents can lead to formation of a new double bond while the original one is simultaneously saturated. Thus *(108)* gives *(109)* and *(110)* stereoselectively at the six-membered ring[52]. Compound *(111)* photolyzes to the isomer *(112)* in *tert*-butanol[53]; furthermore, addition of a C—phenyl bond to the double bond of *(111)* gives the cyclopentane derivative *(113)* (cf. Section 2.5)[54].

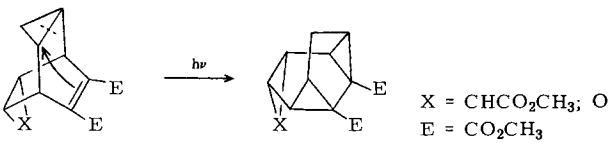


(108) *(109)* *(110)*



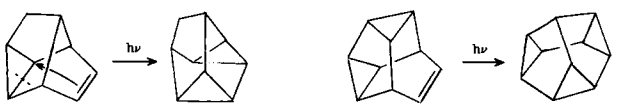
(111) *(112)* *(113)*

The concept of intramolecular hydrogen transfer is capable of extension. Thus both aziridine and imine formation occur in the case of the allylamine *(114)*[55]; addition of the O—H bond to the double bond of *(117)* leads to *(118)*[56].



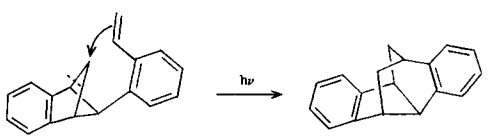
(114) *(115)* *(116)*

(117) *(118)*



2.5. Intramolecular C—C Addition

As shown by the reaction of *(111)* to *(113)*, suitably oriented C—C bonds can undergo intramolecular photoaddition to double bonds. If the pertinent bond is part of a ring this type of reaction leads *via* ring opening to two new bonds. This is exploited for the synthesis of highly strained polycycles which are almost inaccessible by other methods. Thus in *(119)* the *exo*-oriented three-membered ring reacts to form the trishomobenzene derivative *(120)*[57]. Compound *(121)*



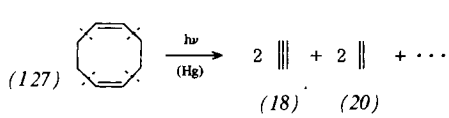
X = $CHCO_2CH_3$; O
E = CO_2CH_3

(119) *(120)*, quant.

(121) *(122)*, 30% *(123)* *(124)*, 5%

gives *(122)*[58], and *(123)* affords diademane *(124)*[59] possibly by this route. This reaction type is as expected not restricted to three-membered ring bonds. For example, *(125)* (accessible from *o,o'*-divinylstilbene) gives the polycyclic compound *(126)* by addition of a four-membered ring bond[60].

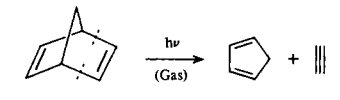
(125) *(126)*, 70%



3. Non-conjugated Dienes

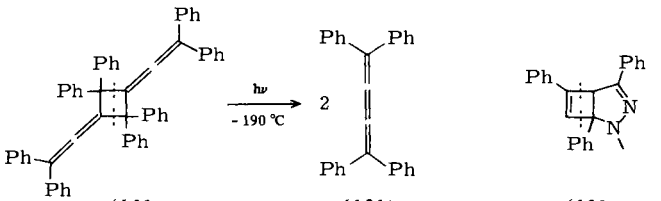
In principle, 1,4-, 1,5-, and 1,6-dienes should react just like simple alkenes after absorption of light. In addition, new pathways open up which involve both double bonds.

3.1. α-Cleavage



3.1.1. Fragmentations and Cycloreversions

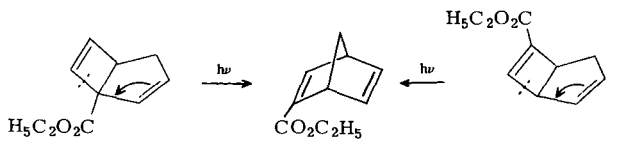
On sensitized excitation (Hg^3P_1), 1,5-cyclooctadiene *(127)* decomposes to acetylene and ethylene, among other products. This fourfold α-fragmentation possibly proceeds in the gas phase *via* electronically excited 1,3-cyclohexadiene[61].



(127) *(18)* *(20)*

In 1,4-dienes, the action of light can rupture bonds which are situated α to one double bond and β to the other one. This can be utilized for retro-Diels-Alder reactions of norbornadiene *(128)*[62] and substituted norbornadienes (in competition with quadricyclane formation)[63]. Cleavage of *(130)*[64] to give *(131)* takes place even at −190 °C[29]. The

(128) (129) (18)

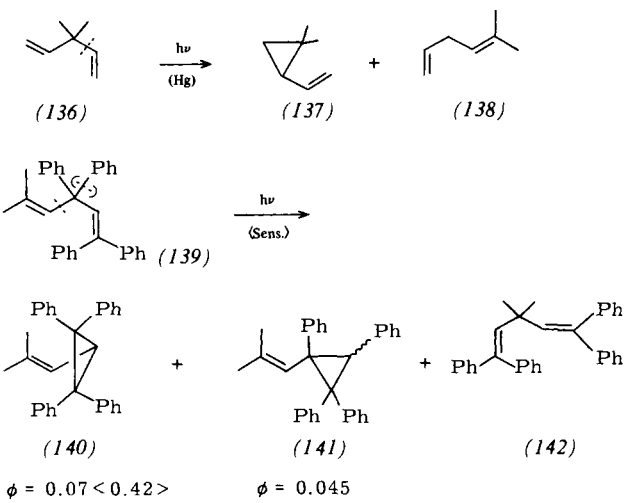


(130) (131) (132)

reaction of *(132)*[64a] can also be regarded as a [2+2] photocycloreversion.

3.1.2. 1,3-Shifts

1,3-Vinyl shifts can compete with fragmentation after α-cleavage of 1,4-dienes. The geometry of *(133)* and *(135)*[65] favors such a reaction course.



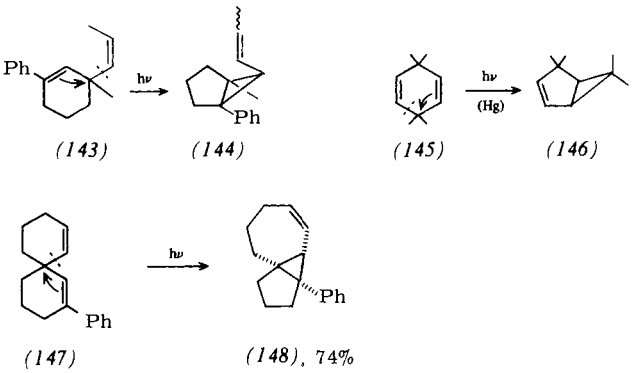
(133) (134) (135)

Further 1,3-vinyl shifts compete with di-π-methane rearrangement [cf. *(138)* and *(142)*].

3.1.3. Di-π-methane Rearrangement

α-Cleavage of 1,4-dienes can lead to 1,2-vinyl shifts in competition with fragmentation and 1,3-vinyl shifts. This reaction

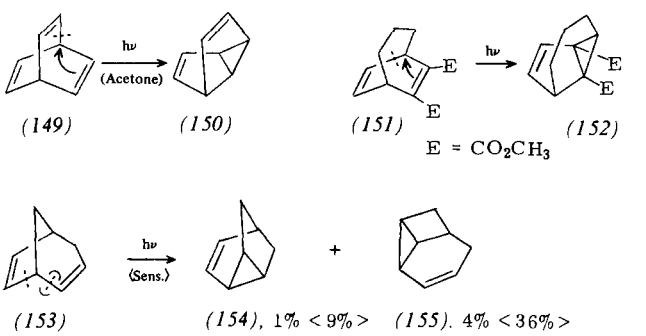
(136) (137) (138)



(139)

(140) (141) (142)

ϕ = 0.07 < 0.42 > ϕ = 0.045



type is known as di-π-methane rearrangement (see ref. [1], pp. 413ff.) and, like β-cleavage with 1,2-migration (see Sections 2.3.4 and 3.2.1), leads to cyclopropane derivatives. Thus, the sensitized excitation of *(136)* leads *via* a 1,2-vinyl shift to *(137)* (35%) and *via* a 1,3-vinyl shift to *(138)* (30%)[42,66], and the direct or sensitized irradiation of *(139)* affords *(140)* (1,2-vinyl shift) and *(141)* (1,2-phenyl shift), together with *(142)* (1,3-vinyl shift)[67]. We cannot consider here the various mechanistic concepts that have been proposed to account for the course of singlet or triplet di-π-methane rearrangements[2b,2c,68,69]. It should be pointed out, however, that far-reaching changes in molecular geometry take place and the temporal sequence of α-cleavage and three-membered ring formation need not be the same for all starting compounds.

If the geometrical conditions do not favor intramolecular [2+2] cycloadditions (see Section 3.3), then interesting polycyclic compounds (always containing three-membered rings) can be synthesized from cyclic 1,4-dienes by 1,2-vinyl shifts. Thus direct excitation of *(143)* gives *(144)* non-stereospecifically[70], *(145)* is transformed into *(146)* on sensitized irradiation[71], and *(147)* gives *(148)*[72]. Compounds *(149)*[73] and *(151)*[74] permit important syntheses in polycyclic photochemistry. Direct or acetone-sensitized excitation of *(153)* gives the regioisomers *(154)* and *(155)*[75].

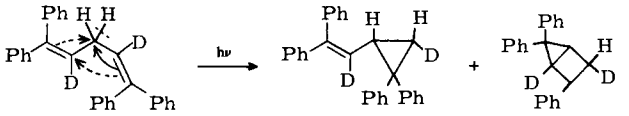
3.2. β-Cleavage

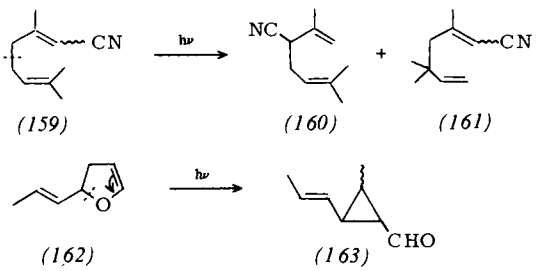


β-Cleavage of 1,5-dienes leads to two allyl radicals. This is shown by ESR studies on the photochemical degradation of poly-1,4-butadiene and poly-1,4-isoprene at −196°C[76].

The radicals are stabilized with considerable quantum yields by 1,2-shifts to form cyclopropane derivatives and recombination after the manner of 1,3- and 3,3-shifts according to the reaction scheme[77].

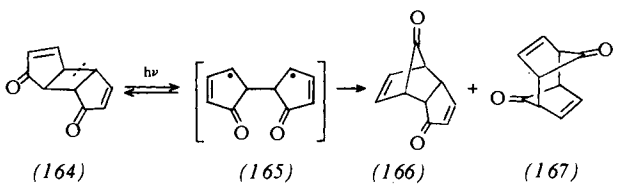
3.2.1. 1,2-Shift

Not only 1,5-dienes like poly-1,4-butadiene, but also 1,4-dienes, can react *via* 1,2-shifts (now no migration of the vinyl group as in the di-π-methane rearrangement; cf. Section 3.1.3). This was first demonstrated by the rearrangement of deuterium-labeled *(156)*. Formation of both *(157)* and *(158)*[78]



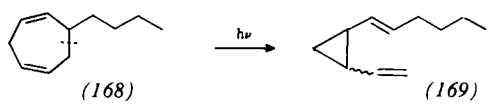
(156) *(157)* *(158)*

requires a 1,2-hydrogen shift. Accordingly, neither di-π-methane rearrangement nor intramolecular [2+2] cycloaddition take place.



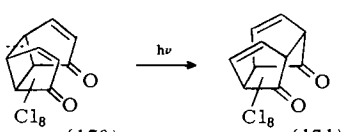
3.2.2. 1,3-Shift and 3,3-Shift

1,5-Dienes such as *(159)* which are essentially free from conformational restraints frequently undergo 1,3-shifts after electronic excitation[79]. Such behavior is observed with *(162)*[80] and in competition with *trans*-Cope rearrangement of *(164)*[81] [necessarily *via* the diradical *(165)*] to form *(166)* (1,3-shift) and *(167)* (3,3-shift). If photochemical 3,3-



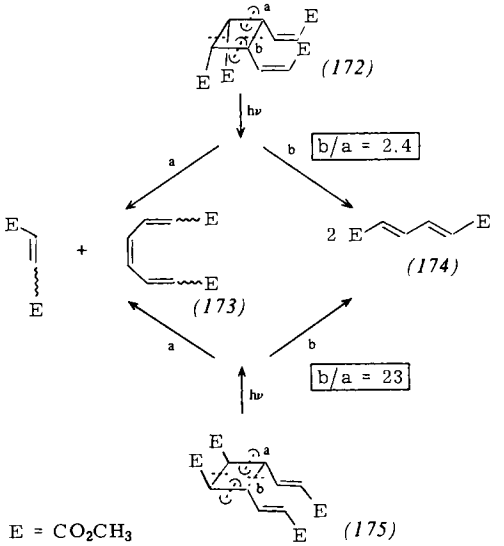
(159) *(160)* *(161)*

(162) *(163)*



(164) *(165)* *(166)* *(167)*

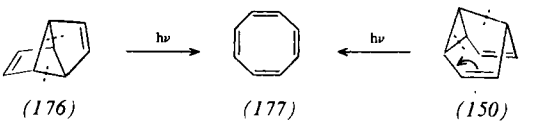
shifts are to take place preferentially, then a favorable conformational situation must exist, as in *(168)*[82] and *(170)*[83]. The geometry of both compounds precludes intramolecular [2+2] cycloaddition[69].



(168) *(169)*

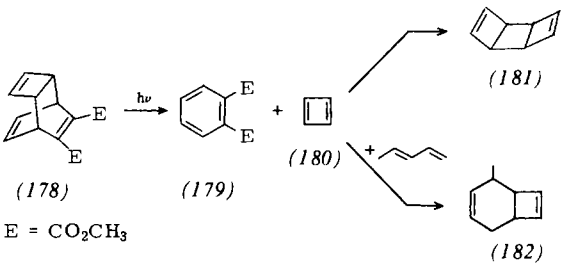
(170) *(171)*

3.2.3. Cycloreversions



β-Cleavage of 1,5-dienes leads to [2+2] and [4+2] cycloreversions if the pertinent bond is part of a four- or six-membered ring. Thus 1,2-divinylcyclobutane derivatives like *(172)* and *(175)* fragment at −190°C. The orientation depends upon the degree of steric hindrance of the absorbing chromophore[22].

(172) *(173)* *(174)* *(175)*

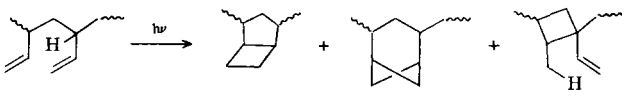


E = CO_2CH_3

Further β-cleavages leading to [2+2] and [4+2] cycloreversions are known to occur in the polycyclic compounds *(176)*[84] and *(150)*[85].

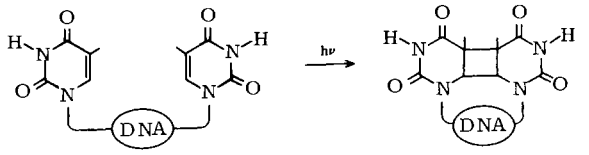
(176) *(177)* *(150)*

Particular mention should be made of the photo-retro-Diels-Alder reaction of *(178)*, which is shown by the dimerization and trapping products to involve formation of cyclobutadiene *(180)*[86]. (Low-temperature irradiation leads to intramolecular [2+2] cycloaddition[87]; cf. compound *(207)* having a similar skeleton in Section 3.3.)



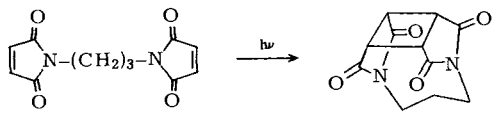
(178) *(179)* *(180)* *(181)* *(182)*

E = CO_2CH_3



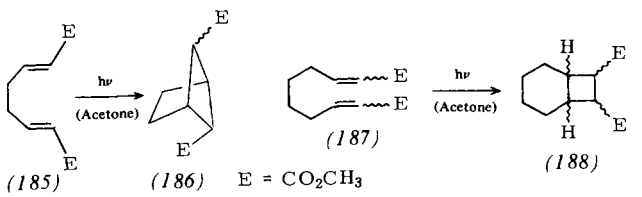
3.3. Intramolecular Cycloaddition

Intramolecular [2+2] cycloadditions of non-conjugated dienes are highly versatile and productive. They yield polycyclic compounds containing four-membered rings which are almost inaccessible by other pathways. Of comparable importance are aspects of polymer photochemistry and biophotochemistry. Thus on direct irradiation (253.7 nm) poly-1,2-butadiene loses its double bonds with a quantum yield of $\phi \approx 0.73$;

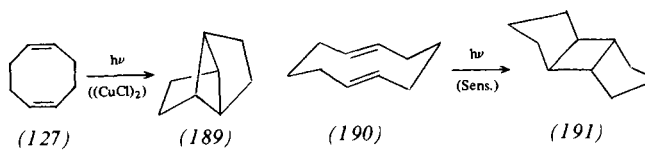


the 1,6-diene units form four-membered rings by parallel and crossed cycloaddition and γ-H transfer[77] (cf. Section 2.4). The same applies to poly-3,4-isoprene[77].

A photodynamic action is seen in the dimerization of pyrimidine bases, *e.g.* thymine, linked by strands of DNA, which also proceeds with sensitization. The resulting radiation

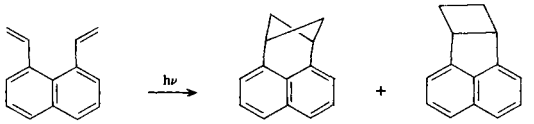


damage is only partly reversible. It can lead to mutations or to the death of the organism[88]. Numerous intramolecular models such as *(183)*[89] exist for these reactions; they show that the adoption of favorable conformations is indispensable.

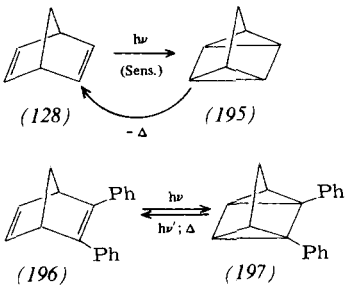


(183) *(184)*, quant.

Open-chain and monocyclic 1,5-dienes such as *(185)*[90] and *(127)*[91] prefer crossed cycloaddition, whereas 1,7- and 1,6-dienes such as *(187)*[92] and *(190)*[93], respectively, prefer



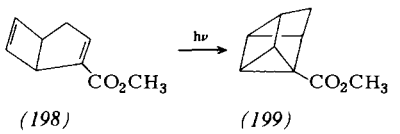
(185) *(186)* E = CO_2CH_3 *(187)* *(188)*



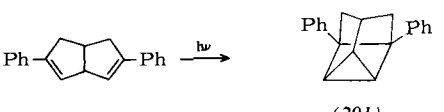
(127) *(189)* *(190)* *(191)*

parallel cycloaddition. This behavior most probably has mainly geometrical origins, and *(192)* accordingly undergoes both kinds of addition[94].

(192) *(193)* *(194)*

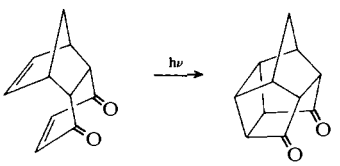


The geometrical requirements for cycloaddition by the kinetically elucidated intermediate mechanism[95] are well known in the case of polycyclic dienes[2c, 69]. Sensitized transformation of norbornadiene *(128)* into quadricyclane *(195)* has a quantum yield of 0.3—0.4 and can serve for storage of solar energy, since the chemically fixed energy (24 kcal/mol) can be liberated under the influence of heavy metal catalysts[96]. Numerous substituted norbornadienes such as *(196)* are photoreversibly converted into quadricyclanes on direct irradiation; this can usually be accomplished at −190 °C[69, 95].

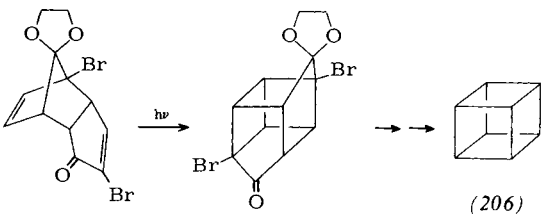


(128) *(195)*

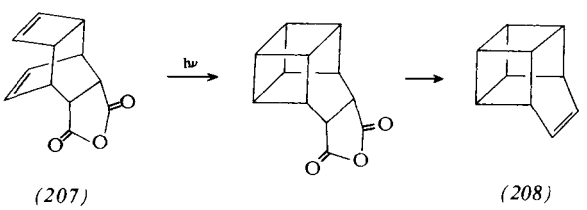
(196) *(197)*



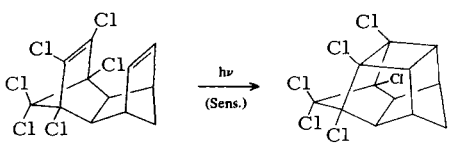
The range of structural variations of intramolecular [2+2] additions can only be hinted by a few examples [reactants *(198)*[97], *(200)*[98], *(202)*[99], *(204)*[100], *(207)*[101], *(210)*[102]]. (A recent survey is given in ref. [1], pp. 232ff.)



(198) *(199)*



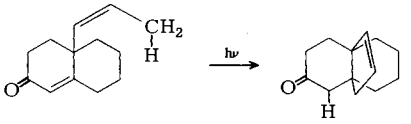
(200) *(201)*



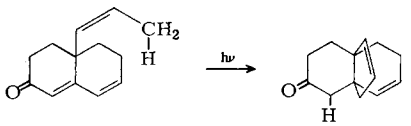
(202) *(203)*

(204) *(205)* *(206)*

(207) *(208)*



(209)

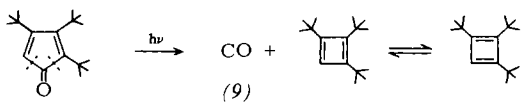


Particular mention should be made of the possibility of using 1,4-dienes with non-parallel double bonds, of the synthesis of cubane *(206)* and basketene *(208)*, and of the ecological aspects of the photoreaction of isodrin *(209)*[103].

3.4. Intramolecular C—H Addition

As in simple alkenes (see Section 2.4) non-conjugated dienes can engage in intramolecular addition of suitably oriented C—H bonds. This is used in photochemical syntheses of unsaturated [3.4.4]propellanes. Such reactions occur on short-wave irradiation ($\lambda = 253.7$ nm) of *(210)* and *(211)*[130a].

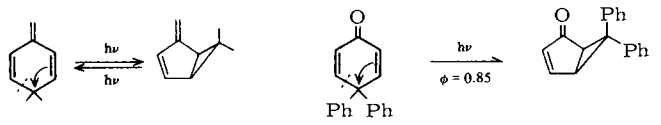
(210) 47%



(211) 33%

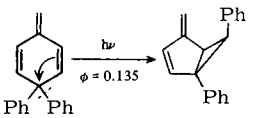
4. Cross-conjugated Polyenes

Mainly historic reasons, but also their importance in the photochemistry of santonin[104], justify a separate account of cross-conjugated polyenes although the types of reactions involved do not differ fundamentally from those of monoenes or non-conjugated dienes. Only on progressing to non-alternant hydrocarbons do new reactions become evident, such as are found for conjugated polyenes.



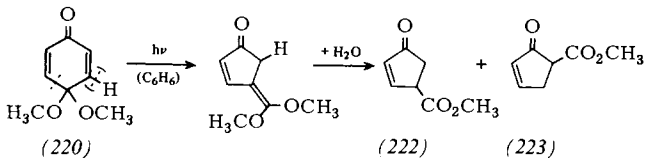
4.1. α-Cleavage

Photodecarbonylation of cyclopentadienones such as *(212)* [cf. the cyclopropenone *(42)*] at −196 °C leads *via* cleavage of two α bonds to cyclobutadiene derivatives[105]. Particular attention has been devoted to α-cleavages with 1,2-shift (cf.



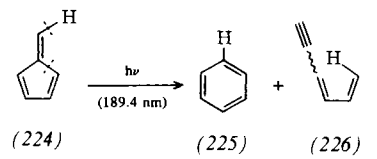
(212) CO + *(9)* *(213)*

Section 3.1.3) of cross-conjugated methylenecyclohexadienes such as *(214)* and cyclohexadienones such as *(216)*. They are transformed into homofulvenes[106] and homocyclopentadienones[107] on irradiation. The arrangement of substituents in *(215)* and *(217)* evidences migration of ring bonds. However, this is not always the case. Thus, irradiation of *(218)*

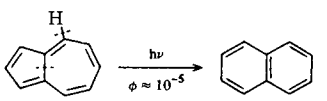


(214) *(215)* *(216)* *(217)*

proceeds with phenyl group migration to give *(219)*. The rearrangement of *(220)* is more complicated[108]: two α bonds migrate and the initial product *(221)* reacts with water to give *(222)* and *(223)* (15—20 %).

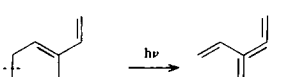


(218) *(219)*

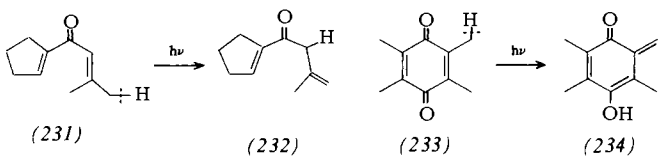


(220) *(221)* *(222)* *(223)*

Non-alternant hydrocarbons like fulvenes or azulenes also belong to the class of cross-conjugated polyenes. On photolysis of *(224)* in the gas phase[109] or of *(227)*[110], both α-C—H and α-C—C bonds are broken. The arenes *(225)* and *(228)* are formed by migration of the H atom along a double bond. Compound *(226)* probably arises by corresponding migration to the next-but-one C atom.



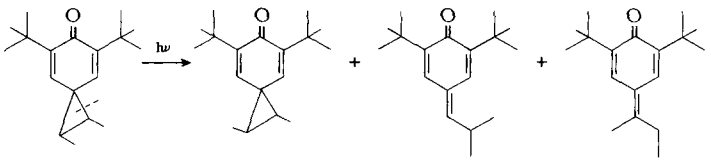
(224) *(225)* *(226)*



(227) *(228)*

4.2. β-Cleavage

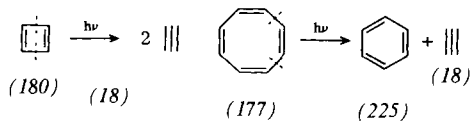
The action of light on cross-conjugated polyenes can also lead to cleavage of β bonds provided that the structural conditions are satisfactory. This is demonstrated by the ring opening of *(229)*[111], the 1,3-H shift of *(231)*[112], and the 1,5-H shift of *(233)*[113]. The isomerization of *(235)*[114] can be



(229) *(230)*

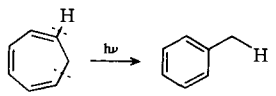
(231) *(232)* *(233)* *(234)*

interpreted in a corresponding manner: compound *(237)* is formed by migration of a γ-methyl group, and *(238)* by migration of a γ-H atom.



(235) (236) (237) (238)

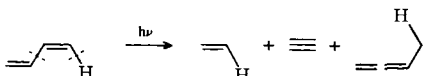
5. Conjugated Dienes and Polyenes



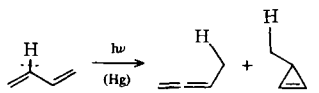
Numerous reactions of conjugated dienes and polyenes are vinylogous or cyclovinylogous to the processes already considered. In addition, structure-specific reactions become possible which involve two or more double bonds.

5.1. α-Cleavage

As in non-alternant hydrocarbons (see Section 4.1), internal and external α bonds of linearly conjugated polyenes can undergo cleavage following absorption of light. Two internal α bonds react in the case of cyclobutadiene *(180)* (at 8 K)[115] and cyclooctatetraene *(177)*[116], while two external α bonds (*i.e.* bonds lying outside the conjugated system) are affected in cycloheptatriene *(239)* (gas phase)[117].

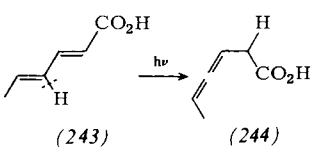


(180) (18) (177) (225) (18)

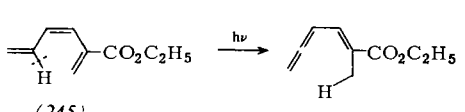


(239) (240), 98%

On gas-phase irradiation of *(56)* both fragmentation and α-H shift occur. The major products are *(18)*, *(20)*, and

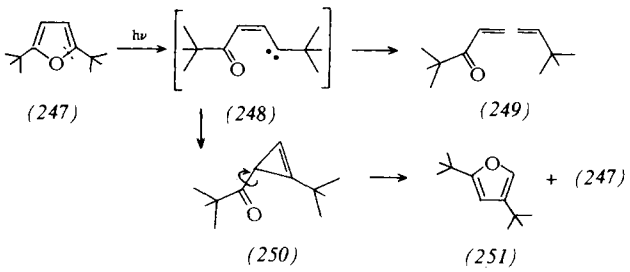


(56) (20) (18) (241)

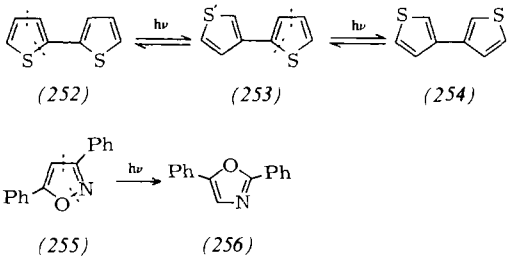


(56) (241) (242)

(241)[118], and on mercury-sensitized photolysis *(241)* and *(242)*[119]. In solution, the photolysis of sorbic acid *(243)*[120],

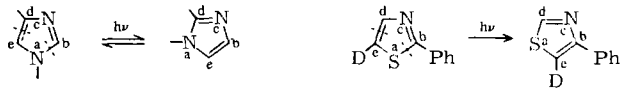


(243) (244)



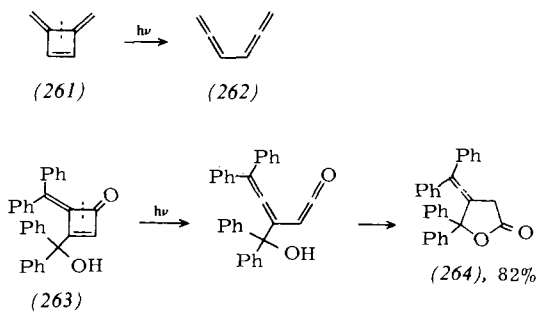
(245) (246), 70%

and that of 1,3,5-trienes such as *(245)*[121] or vitamin D_2 (see Section 5.9) affords allene derivatives. Allene derivatives can also arise on photolysis of furans such as *(247)*[112] if the carbene *(248)* presumably formed initially is stabilized by H migration. However, the reaction more often gives cyclopropene derivatives which can revert to furans. Thus *(247)*



(247) (248) (249) (250) (251) + (247)

forms the isomer *(251)* [presumably *via (250)*][122]. Related reactions are seen in the photochemical rearrangements of pyrroles[123], thiophenes[123], and isoxazoles[124]. The reactions of *(252)* and *(255)* can be cited as examples. Imidazoles

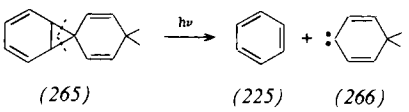


(252) (253) (254) (255) (256)

such as *(257)*[125] and thiazoles such as *(259)*[126] also undergo isomerizations involving α-cleavages after photoexcitation; however, no intermediates resembling *(248)* or *(250)* seem to be formed, but valence isomeric heterobicyclopentenes are postulated instead [compare the reaction of *(129)* in Section 5.5]. Overall, one single bond and one double bond are broken and formed afresh.

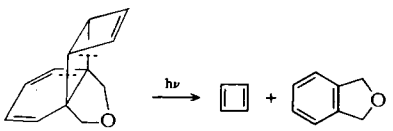
(257) (258) (259) (260)

The preparative versatility of α-cleavages is impressively demonstrated by the isomerization[29] of *(261)*[127] to bisallene *(262)*[128]. The methylenecyclobutenone *(263)* correspondingly reacts to give the keteneallene, which is transformed into the lactone *(264)* by intramolecular addition of the hydroxy group[129].



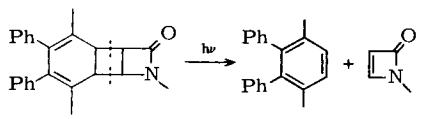
(261) (262) (263) (264), 82%

5.2. β-Cleavage

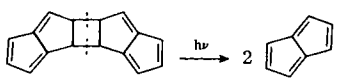


Photochemical cleavage of β bonds has been observed in many dienes and polyenes. This leads to fragmentations or isomerizations; interesting preparative applications exist for both reaction types.

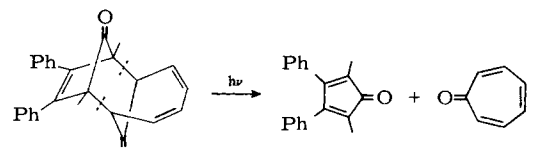
5.2.1. β-Cleavage with Fragmentation



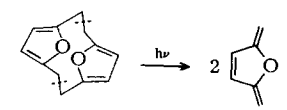
Cyclic dienes and trienes whose allylic C atoms also belong to another ring are suitable for the controlled production of reactive fragments which can be detected by spectroscopy. Characteristic reactions are those of *(265)*[130], *(267)*[131], *(269)*[132], *(272)*[133], *(274)*[134] and *(277)*[135]. After absorption of light, they proceed without further energetic activation and therefore take place at very low temperatures. The reaction course is unequivocally determined by geometrical factors[22]. The same applies to the synthesis of bullvalene *(280)*[136] and [16]annulene *(282)*[137]. In *(283)*, a compound having considerable conformational freedom, both fragmentation and valence isomerization are observed in the ratio a : b = 3 : 2[138]. For conformational reasons, *(285)* reacts by conrotatory opening of the bond common to both rings to give a diradical which reacts further to form not cyclodecatetraene but decapentaene *(286)* instead[139]. The success of [6+4] and [6+6] cleavages in *(274)* and *(277)* is related to the gain in steric freedom and the greatly limited conformational mobility in the reactant.



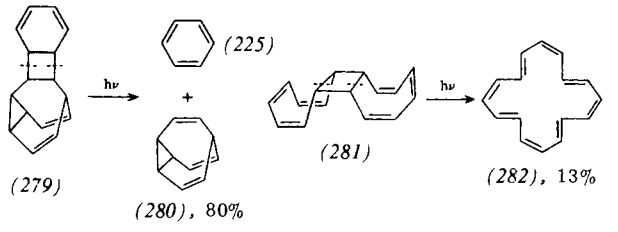
(265) *(225)* *(266)*



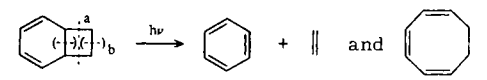
(267) *(180)* *(268)*



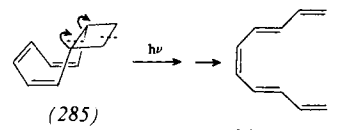
(269) *(270)* *(271)*



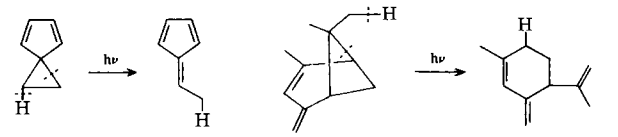
(272) *(273)*



(274) *(275)* *(276)*



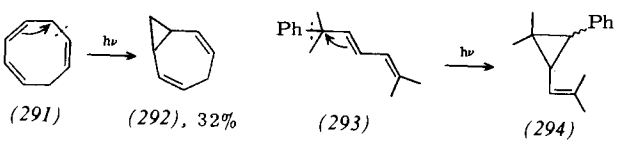
(277) *(278)*



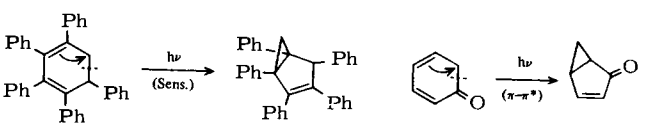
(283) *(225)* *(20)* *(284)*

(285) *(286)*, 50-80%

5.2.2. β-Cleavage with H Migration



Comparatively complicated rearrangements take place if β- or γ-H atoms migrate after cleavage of a β bond. Such is the case with *(287)*[140] and *(289)*[141] which react *via* ring opening and formation of a further double bond. These reactions resemble those in Section 2.3.3.

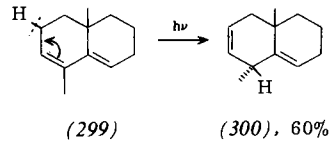


(287) *(288)*, 75% *(289)* *(290)*

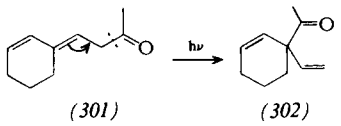
5.2.3. β-Cleavage with 1,2-Shift

As with monoenes (Section 2.3.4) and 1,4-dienes (Section 3.2.1) three-membered ring syntheses are also feasible with open-chain and cyclic 1,3-dienes. Vinyl[142], phenyl[143], alkyl[144], and acyl groups[145] can migrate, as shown by the examples *(291)*, *(293)*, *(295)*, and *(297)*, respectively. These reactions compete with 1,3-shifts among other processes.

(291) *(292)*, 32% *(293)* *(294)*

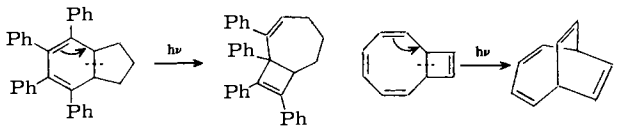


(295) *(296)* *(297)* *(298)*

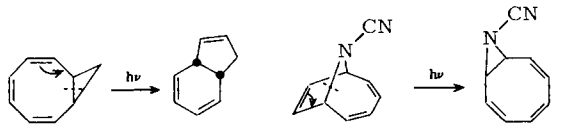


5.2.4. 1,3-Shift

Allyl migrations shorten the conjugated chain in polyenes. Apart from the migration of H atoms as in *(299)*[146] and acyl groups as in *(301)*[147], interest attaches to the far-reaching structural changes attending shifts of ring bonds in polycyclic compounds. Representative reactions are the rearrange-

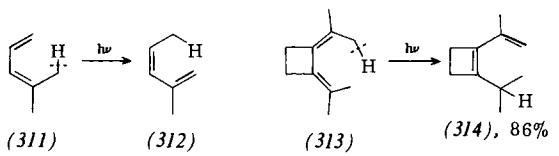


ments of *(303)*[148], *(305)*[149], *(307)*[150], and *(309)*[151]. It has not yet been established whether all these reactions proceed as one-quantum processes; however, the formulation chosen is especially clear.

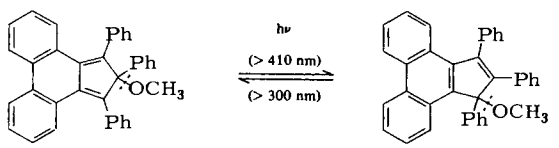


(299) *(300)*, 60%

(301) *(302)*

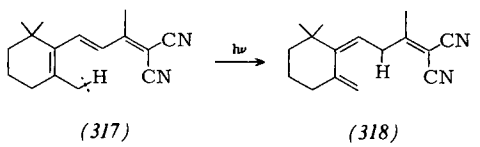


(303) *(304)*, 95% *(305)* *(306)*



(307) *(308)*, 12% *(309)* *(310)*

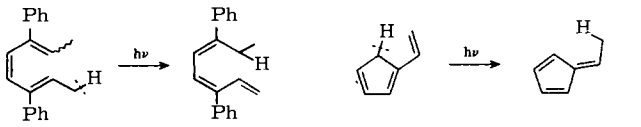
5.2.5. 1,5-Shift



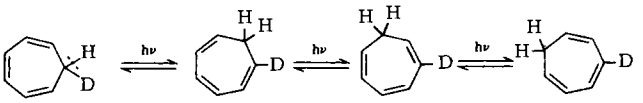
If 1,5-shifts are to effectively compete with allyl migrations then those conformers must be favored in which the reaction centers are spatially proximate. Thus the H atoms of *(311)*[152] and of *(313)*[153] and the methoxy group of the photochromic

(311) *(312)* *(313)* *(314)*, 86%

(315) *(316)*



(317) *(318)*

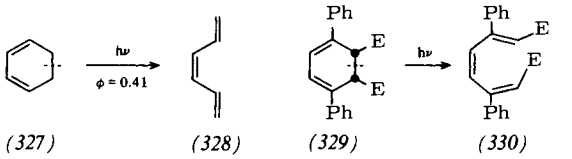


system *(315)*⇌*(316)*[154] migrate to the end of the conjugated system. The 1,5-shift is also favored in the triene *(317)*[155]. Once again, geometric factors play a decisive role[2c].

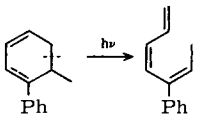
5.2.6. 1,7-Shift

Conformational conditions are even more important for 1,7-shifts. This mode of reaction can be promoted by bulky

(319) *(320)* *(321)* *(322)*, quant.



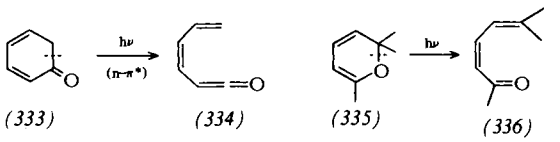
(323) *(324)* *(325)* *(326)*



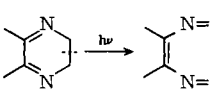
substituents, as in *(319)*[156], and by incorporation of double bonds in rings. Thus *(321)* reacts to give the fulvene *(322)*, and irradiation of *(323)* initially yields *(324)*. The latter product then forms *(325)* and ultimately *(326)*[157,158].

5.2.7. Ring Openings

1,3-Cyclohexadienes and higher dihydroannulenes can be transformed into extended polyenes by cleavage of the β-C—C bond. These reactions are cyclovinylogous to cyclobutene ring opening and open up manifold preparative possibilities. Formation of 1,3,5-hexatriene is favored above all when the substrate preferentially adopts the half-chair conformation rather than the half-boat conformation (see the reactions of lumisterol and ergosterol as against those of pyrocalciferol and isopyrocalciferol in Section 5.9). The reactions of *(327)*[159], *(329)*[156], and *(331)*[160] are typical for this kind of ring opening. Although preparative application generally affords



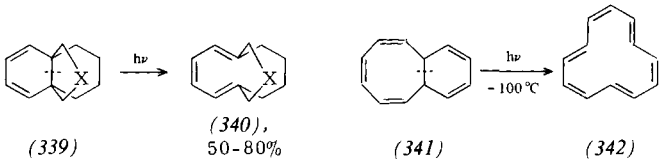
(327) *(328)* *(329)* *(330)*



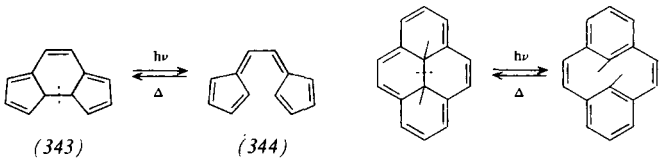
(331) *(332)*

E = CO_2CH_3

a mixture of stereoisomers, and the hexatrienes immediately undergo further photolyses (*e.g.* Section 5.7), it can nevertheless be demonstrated that ring opening is geometrically favorable and initially leads to *(328)*, *(330)*, and *(332)*, respectively. Incorporation of heteroatoms extends the scope of the reaction, as shown by the examples *(333)*[145], *(335)*[161], and *(337)*[161,162]. Moreover, the following selection of reactions

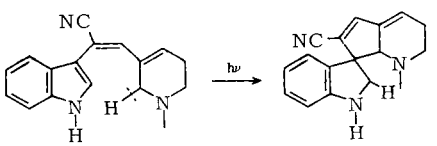


(333) *(334)* *(335)* *(336)*

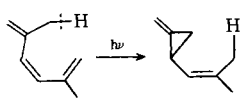


(337) *(338)*

demonstrates that ring opening by cleavage of β-C—C bonds is a suitable method for the synthesis of cyclic polyenes and of annulenes. Compound *(340)*[163] possesses two bridgehead double bonds. [12]Annulene *(342)*[164] must be prepared at low temperatures. Compound *(343)*[165] shows photochromic behavior, and the 16π-electron system *(345)*⇌*(346)*[166] represents an example of negative or inverse photochromism.



(339) *(340)*, 50-80% *(341)* *(342)*



(343) *(344)* *(345)* *(346)*

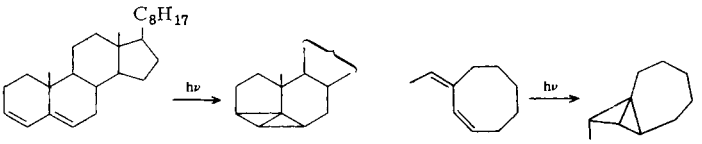
5.3. Intramolecular C—H Addition

Like simple alkenes (Sections 2.4 and 3.4), conjugated polyenes can also undergo intramolecular addition of suitably oriented C—H bonds. This is known to occur in 1,3,5-trienes with an alkyl group attached to C-2. The indole double bond of *(347)* reacts in this way to give the spiro-compound *(348)*[167]. In contrast, the reaction of *(349)* to form *(350)*[168]

(347) *(348)*

(349) *(350)*

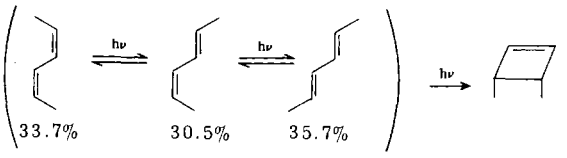
comprises a 1,4-addition of the C—H bond to the 1,3-diene component of the polyene system. The synthetic potential of these reaction types does not appear to be exhausted. Formation of toxisterols *(420)*, most likely by photolysis of precalciferol *(410)* (see Section 5.9, and ref.[168c]), corresponds to the 1,2-addition reaction of *(347)*.



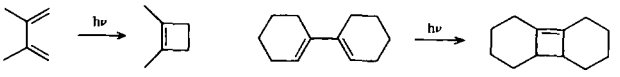
5.4. Bicyclobutane Formation

Irradiation of *(56)* leads to α-cleavage (see Section 5.1) and also to valence isomerization; the products are bicyclobutane *(351)* and cyclobutene *(352)*. Bicyclobutane formation is clearly disfavored although the compound can arise from the predominant *s-trans* conformation of *(56)* and does not require the higher-energy *s-cis*-conformer. The ratio of the yields of *(351)*/*(352)* is 1:16 in isooctane, 1:7 in ether, and 1:6 in ether in the presence of $(CuCl)_2$[169]. Cyclobutene ring closure is impossible in 3,5-cholestadiene *(353)*, which has fixed

(56) *(351)* *(352)*

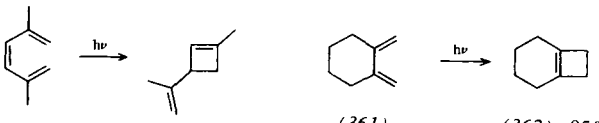


s-trans conformation, and the bicyclobutane *(354)* is formed in high yield[170]. The combination of exo- and endocyclic double bonds in *(355)* likewise facilitates the synthesis of *(356)*[171].



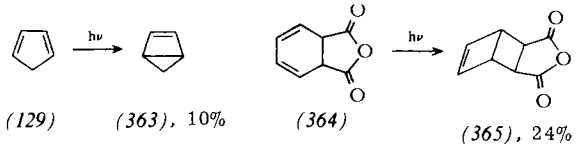
(353) *(354)*, 98% *(355)* *(356)*

5.5. Cyclobutene Ring Closure

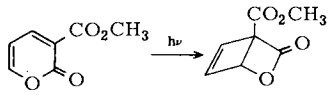


In open-chain 1,3-dienes, cyclobutene ring closure should be conrotatory for geometrical reasons, but disrotatory in cyclic 1,3-dienes (at least up to the seven-membered ring)[2c]. As a reaction compelled to proceed in one step, this cyclization has been the subject of detailed quantum mechanical calculations[2a,172]. In practice, however, the stereochemical result is influenced by generally fast *E*/*Z* isomerizations of the starting dienes. 2,4-Hexadiene (mixture of isomers) reacts to give *cis*-dimethylcyclobutene[173]; the synthesis of the parent compound *(352)* has already been mentioned in the preceding

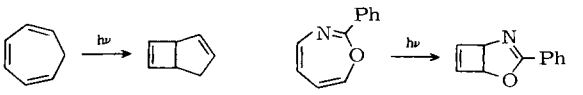
Section. The yields of cyclobutenes are higher when the presence of substituents or rings favors the *s-cis* conformations of the dienes [*(357)*[174], *(359)*[174], *(349)*[168a,b]] or forces such conformations [*(361)*[175]] (examples from vitamin D photochemistry are given in Section 5.9).



(357) *(358)*, 71% *(359)* *(45)*, 43%



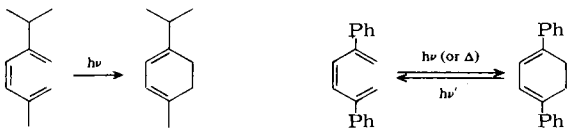
(349) *(360)* *(361)* *(362)*, 95%



Cyclobutene ring closures are numerous in cyclic 1,3-dienes[176]. The syntheses of *(363)*[177], *(365)*[178] (the starting material for Dewar benzene), and *(367)*[179] (that for methyl cyclobutadienecarboxylate), and ring contractions in cycloheptatrienes such as *(239)*[176] and corresponding heterocycles, *e.g.* *(369)*[180], warrant particular interest. The tendency to form cyclobutenes seems most pronounced in seven-membered

(129) (363), 10% (364) (365), 24%

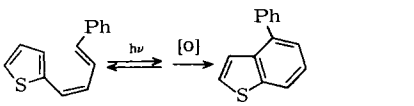
(366) (367)



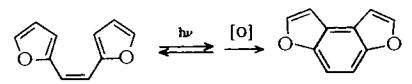
(239) (368), 50% (369) (370)

ring systems[181]. 1,3-Cyclohexadiene derivatives in the half-boat conformation (see Sections 5.2.6 and 5.9) also seem well suited for this reaction type. At moderately high temperatures almost all cyclobutenes regenerate the starting dienes with liberation of energy.

5.6. 1,3-Cyclohexadiene Ring Closure



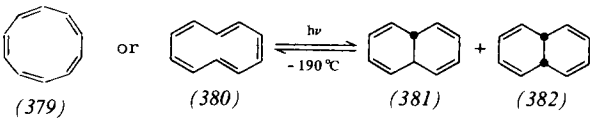
On photoexcitation, suitable 1,3,5-hexatrienes having a central *cis*-double bond cyclize not only to vinylcyclobutenes (cf. Section 5.5) but also to 1,3-cyclohexadienes. Substituents in position 2, as in *(371)*[168a,b] and *(373)*[182] are essential for good yields in the case of acyclic compounds. The necessary *s-cis,s-cis* conformers are also favored by introduction of one



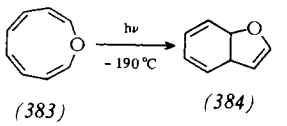
(371) (372) (373) (374)

or more double bonds into rings. This is utilized in the photolysis of precalciferol (see Section 5.9) and the syntheses of *(376)*[183] and *(378)*[184]. In the two last-mentioned cases, the reversible cyclization is followed by an oxidation step (with O_2, I_2, *etc.*). The principal application of this reaction lies in the synthesis of (dihydro-)phenanthrenes from *cis*-stilbenes with participation of benzene rings[185].

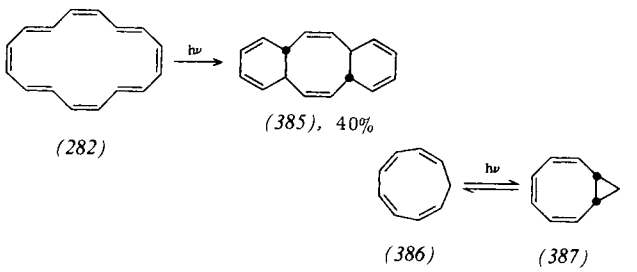
The ring contraction of annulenes and similar compounds is also of interest in connection with photolysis of alkenes.



(375) (376)



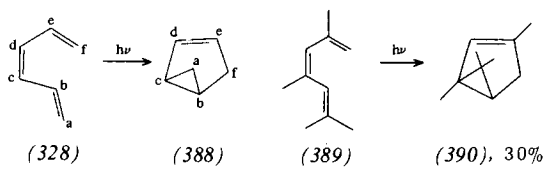
(377) (378)



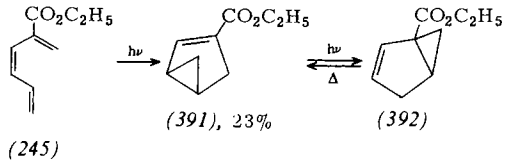
Compounds *(379)* or *(380)*[186] and *(383)*[187] form bicyclic products, whereas [16]annulene *(282)* undergoes double ring closure to give the tricyclic compound *(385)*[188]. Finally, unlike *(383)*, cyclononatetraene *(386)* is transformed into the cyclooctatriene derivative *(387)*[189] by cyclovinylogous ring closure.

(379) (380) (381) (382)

(383) (384)



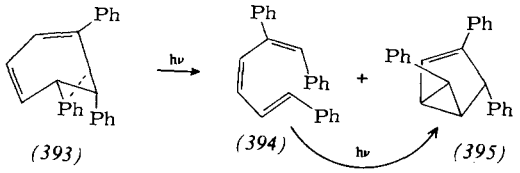
(282) (385), 40% (386) (387)



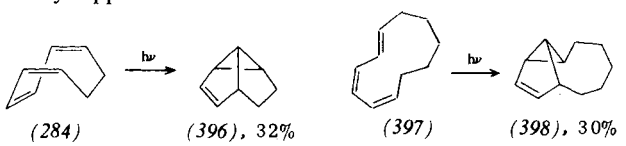
In view of the excess energy present after absorption of light, the observed selectivities are most probably once again conformational in origin.

5.7. Bicyclo[3.1.0]hexene Formation

1,3,5-Hexatrienes with a central *cis* double bond can generally undergo valence isomerization to bicyclo[3.1.0]hexenes, as is known to occur on formation of suprasterol from vitamin D_2 (see Section 5.9). This type of reaction is vinylogous to the formation of bicyclobutane from 1,3-dienes (Section 5.4)[190] and can be accomplished with *(328)*[191], although the yields are better with *(389)*[192] or *(245)*[121,193] since the conformers required for reaction are present in higher

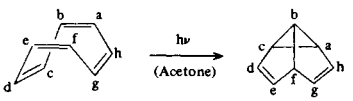


(328) (388) (389) (390), 30%



(245) (391), 23% (392)

equilibrium concentrations[2c,168a,b]. There is often no need to isolate the hexatrienes during preparation of the bicyclohexenes; instead, 1,3-cyclohexadienes such as *(393)* can be used as starting materials[194]. Compound *(395)* is also formed by photolysis of isolated *(394)*[194]. It remains to be established whether the β-cleavage of *(393)* with 1,2-shift contributes to the formation of *(395)* (cf. Section 5.2.3).



(393) (394) (395)

Cyclic polyenes such as *(284)*[195], *(177)*[196], and *(397)*[197] are also able to form bicyclo[3.1.0]hexenes. It appears to have been proved that the three-membered ring is formed before the five-membered ring in the synthesis of *(398)*[197]. However, it is uncertain whether this sequence always applies.

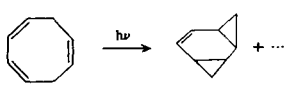
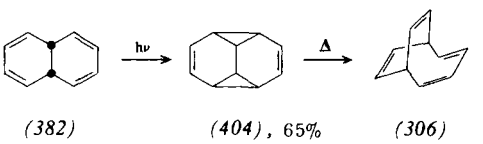
5.8. Intramolecular Cycloadditions

Intramolecular [2+2] cycloadditions of polyenes are utilized in the synthesis and transformations of sesquiterpenes of importance as fragrances and flavors. Thus the cross-photocycloaddition of *(399)* to give *(400)* is the starting point of a synthesis of α- and β-*trans*-bergamotene[198]; germacrene-D *(401)* is converted by parallel addition into β-bourbonene *(402)* on direct irradiation[199].

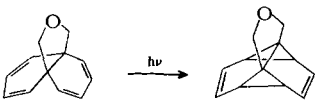


(399) *(400)*

(401) *(402)*



Intramolecular [4+2] cycloaddition of *(291)* is accompanied by various side reactions [*e.g.* giving *(292)*[138,200]].



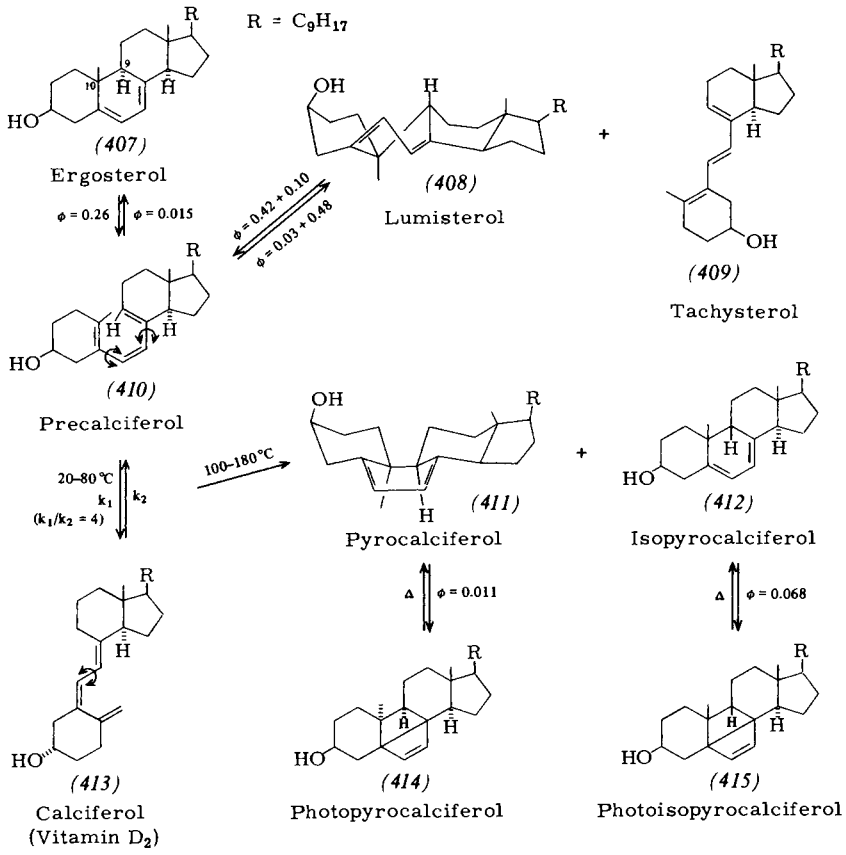
(291) *(403)*, 10%

Good yields are obtained from the [4+4] cycloaddition of *(382)* at −100°C to give *(404)*, which is transformed thermally into *(306)*[201]. Even more productive is the photoreaction of the propellane *(405)* at −78°C[202]. Above all, the last-named photocycloadditions appear to profit from an especially favorable geometrical situation.

Bispyrones[203] and 1,2,4-triazolo[4,3-*a*]pyridines[204] linked together by alkyl chains of various lengths contain

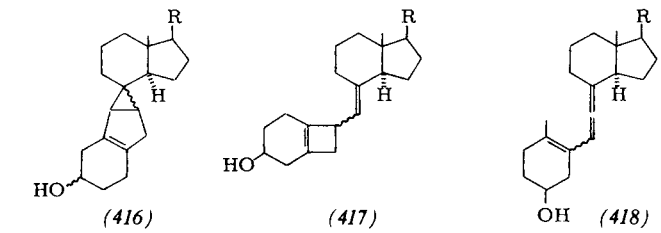
(382) *(404)*, 65% *(306)*

(405) *(406)*, 95%



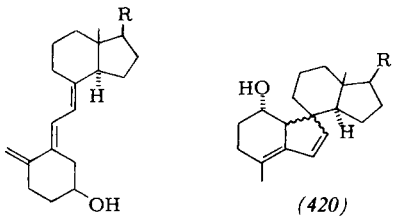
two separate polyene systems which react intramolecularly with each other by [2+2], [2+4], and [4+4] addition after absorption of light. These are borderline cases between intra- and intermolecular reactions.

The intramolecular [2+2] photocycloadditions of double bonds conjugated *via* two arene rings in *o,o'*-bis(2-arylvinyl)biphenyls, which lead to *trans,trans,trans*-1,2-diaryl-1,2,2a,10b-tetrahydrocyclobuta[*l*]phenanthrenes[205], are special cases.

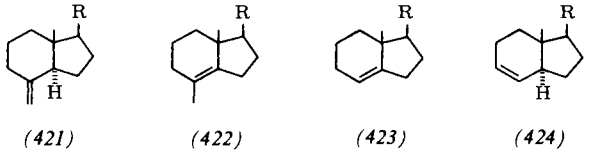


5.9. Photochemistry of Vitamin D

Conformational analysis acquired great importance in the complicated transformations occurring in the vitamin D series[206]. The industrial production of *(413)* (calciferol, vitamin D_2) involves irradiation of ergosterol *(407)* [preferred half-chair conformation as in *(408)*] generally in cooled ether solution. Opening of the cyclohexadiene ring results in conrotatory[2b] formation of precalciferol *(410)* which rearranges by a 1,7-H shift to calciferol *(413)* above 20°C. This product crystallizes and is separated off. The mother liquors contain *(407)*, *(408)*, and *(409)*. These compounds equilibrate with *(410)* on photolysis and can therefore be recycled to the process. In the photochemical cyclizations of precalciferol *(410)* the preferred lowest-energy *cZc*-helical conformation is responsible for the *trans* relationship of the substituents in positions 9 and 10 of *(407)* and *(408)* (conrotation). In contrast, *(411)* and *(412)* (formally disrotatory from precalciferol onwards) are obtained on heating of the 4:1 equilibrium mixture of *(413)* and *(410)*. Under these circumstances it appears that energetic conformers present in low concentrations play an active role and cyclize with a lower activation energy; similar behavior has been deduced from analysis of orbital symmetry for ring closures of hexatrienes[2b]. Unlike ergosterol *(407)* and lumisterol *(408)*, pyrocalciferol *(411)* and isopyrocalciferol *(412)* (with a half-boat conformation) undergo geometrically favorable cyclobutene ring closure to give the products *(414)* and *(415)* on irradiation, which revert to *(411)* and *(412)* on heating.



The need for cooling during photolysis of *(407)* and subsequent warming in order to form *(413)* is explained by the light sensitivity of *(413)*. As expected for *cZt* conformers, irradiation of *(413)* gives *(416)* (bicyclohexene formation), *(417)* (cyclobutene ring closure, two stereoisomers), *(418)* (α-H shift, two stereoisomers), and *(419)* (geometrical isomerization); some of these compounds are toxic. Furthermore, irradiation of *(407)*/*(410)* affords the toxisterols *(420)* [intramolecular C—H addition of *(410)*, three stereoisomers] as well as the fragmentation products *(421)*, *(422)* [α-cleavage of *(413)*], and *(423)*, *(424)*[207] [α-cleavage of *(410)*].



The transformation of *(407) via (410)* into vitamin D_2 *(413)* corresponds to the analogous photoreaction of 7-dehydrocholesterol *via* previtamin D_3 to form vitamin D_3. The latter is produced on a large scale as a food additive[208].

Suprasterol I and II

5,6-*trans*-Calciferol — Toxisterol

6. Outlook

The lively development of alkene photochemistry[209] which gathered considerable momentum in recent years has led to a large variety of reaction types. Many of them can be exploited in preparative work and on an industrial scale, or possess biological or ecological importance. No doubt other valuable types of reactions will be discovered which compete with those described in the present report. Classification of the available material according to compound classes and chemical results is no substitute for continued mechanistic and theoretical effort. However, such a classification provides a very convenient basis for a balanced treatment of the diverse and complex modes of reaction, without being overly influenced by the mere number of presently known examples. In this way valuable evidence is obtained concerning product-determining effects in photochemical deactivations, and questions of stereoselectivity as well as those of orientation- and regioselectivity can be approached empirically without requiring absolute calculations on the basis of quantum mechanical models.

Comparisons between characteristic examples of all known reaction types underline the unique features of special cases. Far from being a disadvantage, this procedure is a prerequisite for success in searching for new reaction types and in enhancing product yields by chemical modification or variation of reaction conditions. Conversely the approach adopted reveals which cases will give poor yields at best, owing to the excessive number of equally probable deactivation processes. A look at the possible modes of reaction can be just as important for settling unsolved problems as experimentally based mechanistic knowledge. Further practical applications and

a deeper understanding of alkene photolysis will doubtless require more detailed consideration of conformational effects.

I am indebted to my colleagues who participated in the cited studies by our research group: R. Dyllick-Brenzinger, H.-W. Grüter, E. Jostkleigrewe, K. Krieger, C. Küchel, K. Rösch, M. Stark, E. Teufel, and I. Zimmermann. Support of this work by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Selective Reactions with Organoaluminum Compounds

By Hisashi Yamamoto and Hitosi Nozaki[*]

With the aid of selected examples an overview is given of the development trends in highly discriminative reactions using organoaluminum compounds. 1) Isomerization of substituted oxiranes into allyl alcohols has been effected both stereo- and regioselectively by means of a new organoaluminum reagent, diethylaluminum 2,2,6,6-tetramethylpiperidide (DATMP); this reaction which provides a new route for the regiospecific transformation of allyl alcohols into 1,3-dienes. 2) A novel nonenzymic heterolysis of allylic phosphates of terpenoids has been effected by organoaluminum compounds and has enabled development of a new method for the selective synthesis of cyclic terpenes. 3) The reductive condensation of α-haloketones with carbonyl compounds in the presence of diethylaluminum chloride and zinc affords β-hydroxycarbonyl derivatives in good yields with exclusion of undesired self-condensations products.

1. Introduction

The problem of devising general synthetic methods for the selective or specific transformation of functional groups remains a major challenge despite extensive studies in this area for many years. During the past few decades the role of organometallic compounds in synthetic chemistry has become increasingly apparent. Particularly noteworthy has been the introduction and rapid acceptance of organosilicon, organoaluminum[1], and organic compounds of other non-transition metals as general and versatile reagents for the synthetic chemist. The value of these reagents lies in their ability to 1) render possible unique and otherwise unattainable transformations under mild conditions, 2) undergo a variety of modifications, and 3) afford the desired product in a selective or specific manner.

Although their role in the olefin oriented world of petrochemicals is well-established, organoaluminum reagents are relative newcomers as tools in selective organic syntheses. The characteristic properties of these reagents derive mainly from the high Lewis acidity of the organoaluminum monomers, which is directly related to the tendency of the aluminum atom to complete electron octets. Bonds from aluminum to electronegative atoms such as oxygen or the halogens are consequently strong: the energy of the Al—O bond is estimated to be 138 kcal/mol[2]. Indeed, nearly all alkylaluminum compounds react vigorously with oxygen or air. Trialkylaluminum compounds and dialkylaluminum halides are particularly reactive and often ignite spontaneously[3]. The strong Lewis acidity of organoaluminum compounds appears to account for their great tendency to form 1:1 complexes, even with neutral bases such as ethers. These properties (commonly identified with "oxygenophilicity") are of great value in the design of selective synthetic reactions. The coordination of a molecule invariably causes a change of reactivity, and the coordinated group may be activated or deactivated depending upon the type of reaction. Furthermore, on coordination of an organic molecule an auxiliary bond can become coupled to the reagent and promote the desired reaction. Our initial studies on the development of selective reactions utilizing these advantages of organoaluminum reagents are reviewed below.

2. Oxirane and Oxetane Ring Cleavage

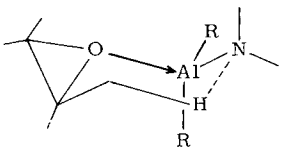
Organoaluminum compounds are strong Lewis acids and coordinate with neutral donor molecules to form stable complexes. Provided the bases do not bear acidic hydrogen atoms, the complexes can in most cases be distilled. The stability of 1:1 complexes with trialkylaluminum decreases in the sequence[4]:

$$Me_3N > Me_3P > Me_2O > Me_2S > Me_2Se > Me_2Te$$

Accordingly, it is possible to displace a weaker donor by one which is stronger[5],

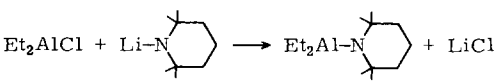
$$Me_3PO + Me_3Al{\leftarrow}OEt_2 \longrightarrow Me_3Al{\leftarrow}OPMe_3 + Et_2O$$

In some complexes the coordinated Lewis acid undergoes rearrangement under relatively mild conditions. Thus, complexes of ethylaluminum dichloride with trimethyl or triethyl phosphites are thermally unstable and rearrange to the corresponding phosphonate complexes *(1)*[6].



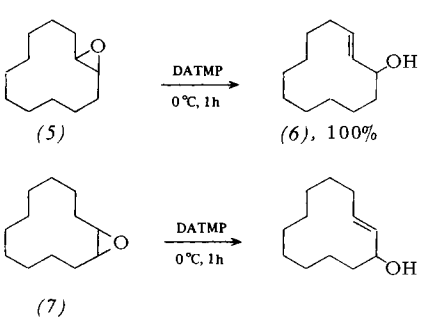
The formation of complexes with weakly basic ethers is reversible. With more strongly basic ethers, however, heating at sufficiently high temperature often brings about decomposition rather than dissociation to the original components of the complex. Depending upon the conditions and the substituents, oxirane derivatives are not only cleaved by many organoaluminum reagents but also undergo alkylation, reduction, or rearrangement[1].

The reaction of oxiranes with strong bases constitutes a well known synthetic method for the preparation of allyl alcohols. The method discovered by *Cope*[7], and further developed by *Crandall*[8] and *Rickborn*[9], involves isomerization with lithium diethylamide. Unfortunately, however, the proce-



dure requires undesirably high reaction temperatures and is rather nonselective in the sense that a methyl group on the ring usually contributes the proton to be removed. Accordingly, the double bond of the resulting allyl alcohol is rarely located in the main chain.

Since the oxirane ring is readily opened by organoaluminum compounds and since such compounds can be easily modified in various ways, it was of special interest to search for new aluminum reagents which would be suitable for the above mentioned transformation. At elevated temperatures, a variety of oxirane derivatives are isomerized by diisobutylaluminum hydride or triisobutylaluminum[10]; however, the reaction pattern is rather similar to that with lithium diethylamide in boiling benzene. A "pure" concerted *syn*-elimination would be desirable for this rearrangement, for then it would proceed in high yields, yet under such mild conditions that it could also be used with complex and multifunctional substrates. Our method is based on the strategy of simultaneous activation of both the oxirane ring and the proton to be removed. This idea is illustrated for the specific case of activation of an oxirane with dialkylaluminum amide [cf. *(2)*]. The proton transfer from substrate to amide is clearly more favored than in the case of other classical reagents, and the electrostatic forces ought to facilitate smoother rearrangement to the allyl alcohol.



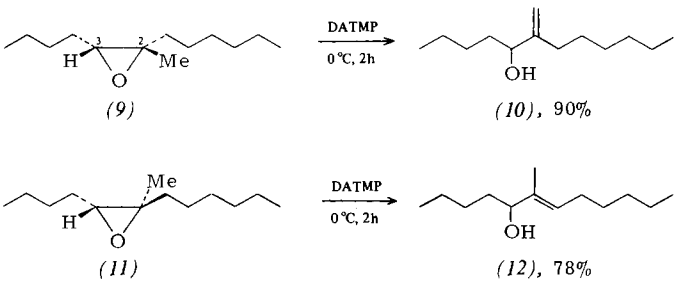
(2)

The realization of this rearrangement is in practice highly dependent upon the size of the substituents on the amide-nitrogen, since the enthalpy of formation of 1:1 complexes of aluminum amides with ethers is strongly influenced by the spatial bulkiness of these substituents[11]. A new organoaluminum reagent, diethylaluminum 2,2,6,6-tetramethylpiperidide (DATMP) *(4)*, is the reagent of choice and can be readily prepared from diethylaluminum chloride and the corresponding lithium amide *(3)*[12].

(3) DATMP *(4)*

Thus, on reaction with DATMP in benzene, (*E*)-cyclododecene oxide *(5)* is converted quantitatively within 1 h at 0 °C into (*E*)-2-cyclododecen-1-ol *(6)*. In contrast, under the same reaction conditions, the (*Z*)-isomer *(7)* afforded only 8% of the alcohol *(8)*. Treatment of a mixture of cyclopentene oxide, cyclohexene oxide, and cycloheptene oxide with DATMP at 0 °C merely resulted in the recovery of unchanged oxiranes. Thus, DATMP is virtually unreactive toward *cis*-2,3-disubstituted oxiranes.

(5) *(6)*, 100%



(7)

The reagent is very reactive toward 2,2,3-trisubstituted oxiranes such as *(9)* and *(11)*[12]. From observations the following selectivity rules can be derived:

Rule 1: The sole product is a secondary allyl alcohol.

Rule 2: The required proton is supplied by the alkyl group on C-2, which is located *cis* to the hydrogen atom on C-3.

Rule 3: The resulting double bond prefers the (*E*)-configuration.

(9) *(10)*, 90%

(11) *(12)*, 78%

The observed selectivity could be in keeping with a cyclic *syn*-elimination mechanism, in which ring opening is highly stereoelectronically demanding. As can be seen in Figure 1, the alternative approach of the organoaluminum compound from the side opposite to that of the hydrogen atom is strongly hindered by the alkyl groups R^2 and R^3. Hence, it can be concluded that the organoaluminum compound adds to the oxirane preferentially on the same side as hydrogen at C-3 ("steric approach control"). The favored direction of elimination is accounted for by the preferred abstraction of the hydrogen which enables a greater orbital overlap in the cyclic transi-

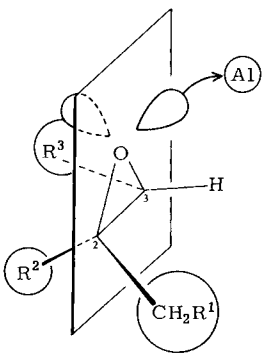


Fig. 1. Addition of an organoaluminum compound to an oxirane (selectivity rules 1 and 2).

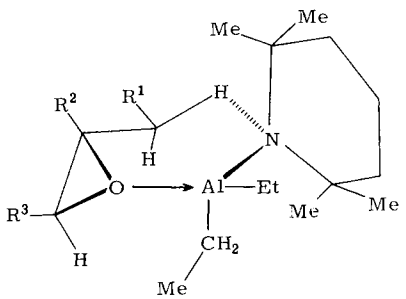

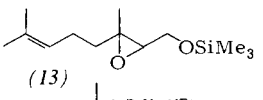

Fig. 2. Preferred conformation of an intermediary DATMP-oxirane complex (selectivity rule 3).

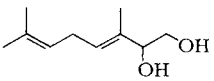
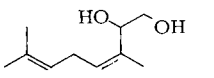
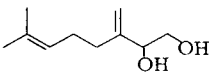
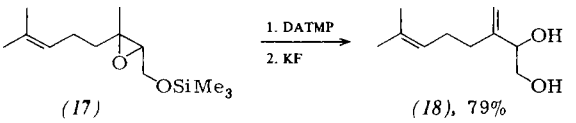






tion state. Figure 2 shows a view of the DATMP-oxirane complex in what appears to be the energetically most favorable conformation. This conformation is introduced with rigid stereochemical control by the indicated nonbonding interactions.

A considerable number of experimental findings are in accord with predictions based on the above speculations. One interesting example is the reaction of the trimethylsiloxymethyl-substituted oxirane *(13)*[13], obtained from geraniol. The yields of the diols *(14)*, *(15)* and *(16)* show dramatically that the selection rules 1 and 2 (Figure 1) are fulfilled by both DATMP and $(i\text{-Pr})_2$ N—$AlEt_2$, while selection rule 3 (Figure 2) is fulfilled only by DATMP. In contrast to *(13)*,



(13)

1. R_2N–$AlEt_2$

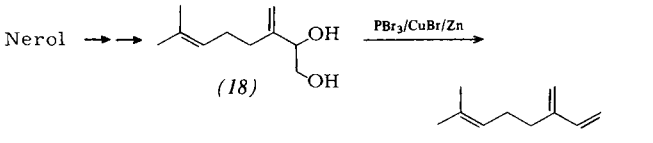
reaction of the isomeric oxirane *(17)* (prepared from nerol) with DATMP/KF affords only the diol *(18)* having the double bond in the side-chain[13].



(17) *(18)*, 79%

In principle, removal of both hydroxy groups of the resulting 3-ene-1,2-diol systems should provide naturally occurring trienic monoterpenes—ocimene from *(14)* and myrcene from *(18)*. However, the reaction with DMF-acetal and acetic anhydride and other potential reactions did not proceed smoothly; success was eventually obtained with a new one-pot operation, which involves initial bromination with a mixture of cuprous bromide and phosphorus tribromide in ether followed by debromination with zinc powder[13].

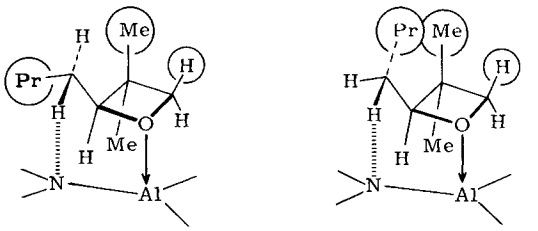
B: 1. $Me_2C(OMe)_2$; 2. Ac_2O; 3. $H^{\oplus}$; 4. PBr_3/CuBr/Zn

The enthalpy of formation for 1:1 complexes of organoaluminum compounds and oxiranes is probably greater than for the corresponding complexes with tetrahydrofuran and other cyclic ethers. The success of the DATMP promoted oxirane rearrangement may be attributed to this strong aluminum-ether coordination. As an extension of this work, it seemed logical to expect that four-membered oxetane rings might also be susceptible to the attack of aluminum amide and that a useful stereoselective route to homoallyl alcohols might thereby become available. This is indeed the case, as demonstrated by the reaction of 2-butyl-3,3-dimethyloxetane *(23)* with diethylaluminum methylanilide in boiling ben-

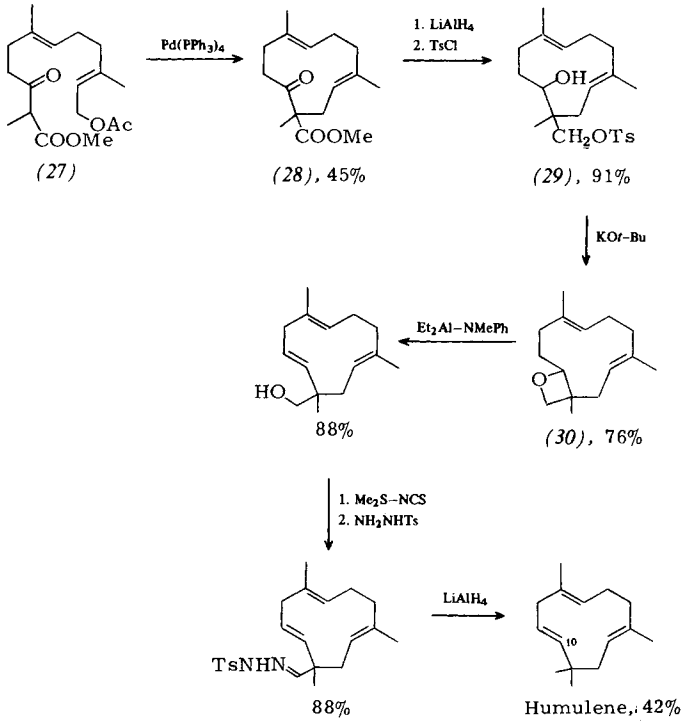
(23) *(24)*, 82%



(25) *(26)*, 95%

zene—despite the higher reaction temperature and longer reaction time required, the (*E*)-homoallyl alcohol *(24)* is formed in high yields and is completely homogeneous (>99% purity)—as is also the cyclic homoallyl alcohol *(26)*[14].

The high stereoselectivity (>99%) in the synthesis of the homoallyl alcohols from oxetanes can be rationalized analo-

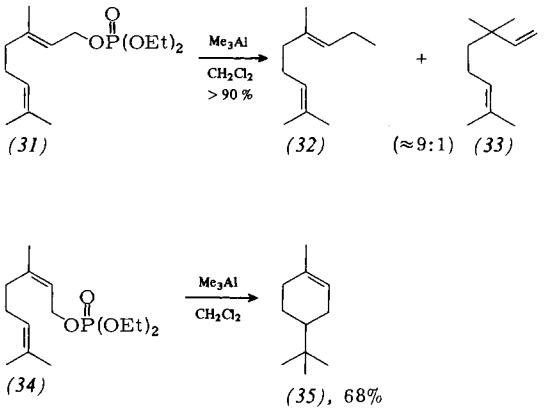


gously as in the aforementioned ring-opening of oxiranes to allyl alcohols. Thus, in the reaction with the oxetane *(23)*, the relative conformational energies of forms A and B should determine the product ratio (Fig. 3). The conformer A, which gives rise to the (*E*)-isomer *(24)*, appears to be favored in all respects; in the alternative structure B, severe nonbonded interactions develop between the *n*-propyl group and one of the methyl substituents of the oxetane ring which preclude formation of the (*Z*)-isomer of *(24)*.

A

Fig. 3. Two conformers of the complex from oxetane *(23)* and diethylaluminum methylanilide: A is strongly preferred over B.

With this methodology at hand, we could synthesize humulene, an important medium-ring sesquiterpene, in a highly stereoselective manner[14]. It should be pointed out that the protonation at C-10 can lead to a rather complicated rearrangement which will destroy the whole ring system.



3. Heterolysis of Allyl Phosphates

Since formation of a 1:1 complex is evidently an essential step before oxirane or oxetane rearrangement, we have sought to extend the investigation to other systems which also have a high tendency to coordinate with organoaluminum compounds. Among these, allyl phosphates are of outstanding interest for the following reasons:

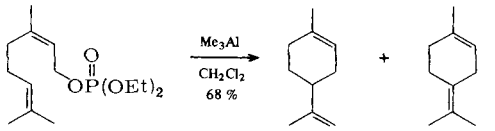
1. Trialkylaluminum-phosphane oxide adducts have exceedingly high enthalpies of formation (26–32 kcal/mol)[15], possibly because of the high polarity of the phosphorus-oxygen bond.

2. The considerable importance of phosphates in biological systems[16].

Reaction of diethyl(geranyl) phosphate *(31)* with trimethylaluminum in dichloromethane under argon leads stereospecifically to the isomeric dienes *(32)* and *(33)* in >90% yield[17]. A dramatic alteration in the course of the reaction occurs when the reaction is carried out with diethyl(neryl) phosphate as starting material. Although limonene and terpinolene are formed, the major product is the cyclohexene derivative *(35)*[17].

These striking observations demonstrate that either intermediary allylic carbocations strictly preserve their steric integrities in such transformations, or that a purely concerted mechanism is operative in the whole process.

In view of the efficiency of the mild and stereospecific heterolysis of allyl phosphates by trialkylaluminum compounds, the behavior of certain reagents of type R_2AlX (X = SR, NHR, or OR) has been studied systematically[17]. Treatment of geranyl or neryl phosphates in hexane with these aluminum reagents leads to regio- and stereospecific formation of substitution products. Examples illustrating the synthesis of sulfides, amines, and ethers in this way are cited in Table 1. It is important to note that both phosphates attack organoaluminum amides, alkoxides, and sulfides preferentially at the Al—N, Al—O, and Al—S bonds, respectively, leaving the C—Al bond intact. A similar effect has been observed in the protolytic cleavage of the Al—N bond[18]:



$$Et_2AlNH_2 + MeOH \longrightarrow Et_2AlOMe + NH_3$$

Table 1. Reaction of diethyl(geranyl)phosphate *(31)* and diethyl(neryl) phosphate *(34)* with 4 equivalents Me_2AlX in hexane. Yield = yield of isolated product.

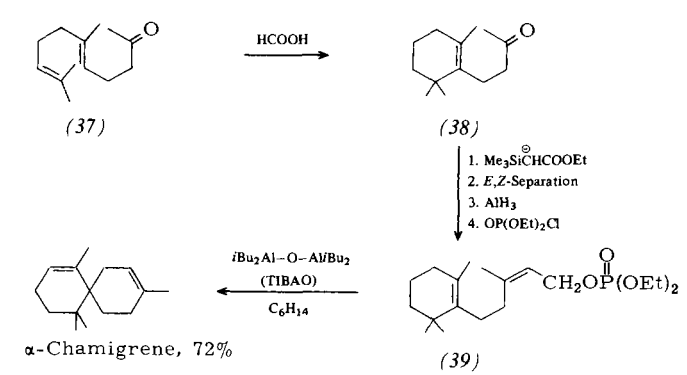
With the practical problem of selective heterolysis of allyl phosphates having been solved, we concerned ourselves next with biomimetic processes for the conversion of acyclic terpene derivatives into cyclic compounds. It was soon realized that aluminum compounds serve as useful reagents for such allylcation promoted cyclization reactions. The concept was first tested with a simple acyclic monoterpene, diethyl(neryl)phosphate *(34)*. In the presence of organoaluminum compounds of type R_2AlX (X = NHR or OR), and using dichloromethane as solvent, facile cyclization to limonene and terpinolene took place[17].



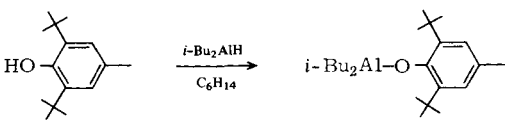
(34) Limonene Terpinolene

The pronounced effect of solvent on the course of reaction (compare with Table 1) must be related in part to the nature of the ion pair involved in the key step of the reaction. In nonpolar solvents a tight ion pair might be involved, though the possibility of a concerted process being operative has not yet been ruled out. In more polar solvents, however, the ion pair could be more widely separated and the cationic cyclization take place rather easily. Indeed, some solvation of trialkylaluminum by dichloromethane has been reported[19].

(36), R = *i*-Bu

It seemed logical to expect that much more stable counter ions might play a significant role in this kind of reaction. For preparing the cyclized products more selectively, we thus examined the behavior of tetraisobutyldialuminoxane, (TIBAO), which is readily obtained by the action of 0.5 equivalents of water on diisobutylaluminum hydride in THF followed by concentration *in vacuo*. It is assumed that the phosphate and TIBAO form a stable anionic chelate complex *(36)* containing a puckered six-membered ring. Reaction of the neryl ester *(34)* with excess TIBAO in dichloromethane (1 h at 0 °C and 3 h at 20 °C) afforded limonene and terpinolene in good yields[17]. The cyclization with TIBAO is not significantly affected by the solvent; in hexane or tetrahydrofuran the yields are 54 and 80% respectively[17]. A simple total synthesis of α-chamigrene has been successfully carried out with this powerful cyclization reagent[17].

(37) *(38)* *(39)* α-Chamigrene, 72%



So far, we have ignored the product selectivity in the cyclization of the dienes. Treatment of the neryl ester *(34)* with TIBAO in various solvent systems indeed affords limonene and terpinolene uncontaminated with acyclic hydrocarbons, but the observed limonene/terpinolene ratio strongly depends upon the nature of the solvent. In tetrahydrofuran, this ratio is as low as 63:37 (Table 2)[17]. Moderate selectivities have been achieved in less polar media; this must be due in part to a synchronized process, as is operative in nonpolar solvents.

Table 2. Relative yields of limonene and terpinolene in the reaction of diethyl(neryl) phosphate *(34)* with various organoaluminum compounds in different solvents.

Reagent	Solvent	Limonene/Terpinolene

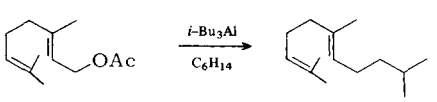
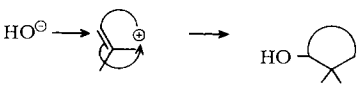
TIBAO [a]	CH_2Cl_2	88:12
Me_2AlOPh	CH_2Cl_2	86:14
$(Me_2Al)_2NPh$	CH_2Cl_2	80:20
$Me_2AlNHPh$	CH_2Cl_2	79:21
TIBAO [a]	THF	63:37



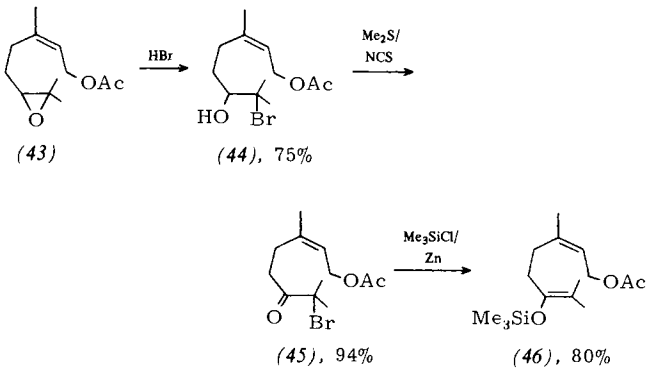
[a] Tetraisobutyldialuminoxane.

Terpinolene must have originated from a sequence featuring discrete molecular species with carbocationic character (terpinyl cations) as produced in polar solvents. Unfortunately, however, treatment of allyl phosphates in hexane with aluminum alkoxides or amides usually results in formation of substitution products rather than cyclic dienes (cf. Table 1). We therefore, turned our attention to organoaluminum compounds containing organic groups sufficiently bulky for preventing such substitution reactions. The most satisfactory reagent proved to be diisobutylaluminum 2,6-di-*tert*-butyl-4-methylphenoxide *(40)*[20]. Presence of the large alkyl substituents in the *ortho* position appears to be highly favorable for the present purpose because of significant frontal steric hindrance. When the neryl ester *(34)* was treated with this bulky aluminum reagent *(40)* in hexane at −78 °C, limonene was produced almost exclusively. Analysis of the crude product by GLPC showed it to contain 99% limonene and 1% terpinolene[20].



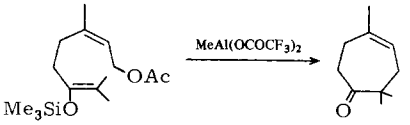
(40)

Since organoaluminum compounds form rather stable 1:1 complexes with esters[21], the reactions of allyl esters of acetic, formic, and carbonic acids were examined in detail. On the basis of the results obtained thus far, the reactions of these derivatives, e.g. *(41)*, qualify as important additions to the reactions of allyl phosphates. The hydrocarbon *(42)* is formed with 97% purity[22].

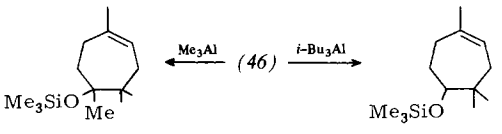


(41) *(42)*, 66%

The cyclization of neryl phosphate *(34)* leads to six-membered rings. If the more stable tertiary cationic center could be utilized, seven-membered rings would result. Since the *anti*-Markovnikov cyclization widely occurs in natural products—the most noteworthy being the enzymic formation of karahanaenone, humulene, and lanosterol (C-ring)—it was of special importance to search for systems which give *anti*-Markovnikov ring closure in biomimetic processes. It seemed reasonable to examine the behavior of silyl enol ethers as nucleophilic participants in terpene cyclizations, since a silyl enol ether ideally located in space for interaction with a developing cationic center should cyclize in a regiospecific manner.



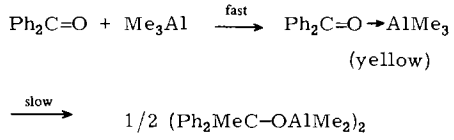
Since the neryl ester *(34)* has been shown to undergo facile organoaluminum-promoted cyclization to give limonene in good yields[17], we decided to examine the cyclization of the closely related enol ether *(46)* using several different organoaluminum reagents. Thus, upon treatment with methylaluminum bis(trifluoroacetate) in dichloromethane (10 min at 0°C and 3 h at 25°C) we obtained karahanaenone in 95% yield[23]. Reaction of *(46)* with trimethylaluminum resulted



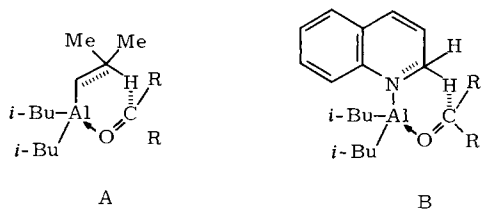
(43) *(44)*, 75% *(45)*, 94% *(46)*, 80%

in formation of the *C*-methylated cyclic silyl ether *(47)*. In contrast, when it was treated with triisobutylaluminum in

(46) Karahanaenone, 95%



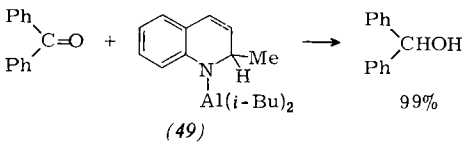
hexane, a dramatic alteration in the course of the reaction occurred: the predominant product was the silyl ether *(48)*, resulting from the unprecedented reductive cyclization.



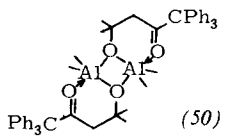
(47), 76% *(48)*, 71%

4. Reactions with Carbonyl Compounds

While the overall mode of reaction of trialkylaluminum reagents with carbonyl compounds parallels the reactions known for Grignard reagents, there are nevertheless significant differences. Thus, reaction of trialkylaluminum with a ketone (molar ratio 1:1) gives a long-lived monomeric 1:1 complex which very slowly decomposes unimolecularly to dimeric dialkylaluminum alkoxide[24]. The use of organoaluminum compounds in this sector has not yet been thoroughly investigated and it is probable that novel reactions will be found which have no parallel in the chemistry of the commonly used Grignard reagents.

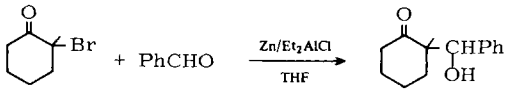


Hydride transfer from triisobutylaluminum to the carbonyl carbon occurs preferentially or exclusively from the less hindered side of the molecule. This remarkable steric approach control is ascribed to rate-determining decomposition of the ketone-triisobutylaluminum complex through the cyclic transition state A (Fig. 4)[25]. On the basis of this mechanism, we examined the reduction of ketones with organoaluminum compounds containing bulky groups, one of which was diisobutylaluminum 1,2-dihydroquinaldide *(49)*, which can be readily prepared from quinaldine and diisobutylaluminum hydride[26,27].



A B

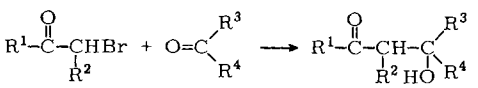
Fig. 4. Cyclic transition state of the reaction of ketones with triisobutyllithium (A) and diisobutylaluminum 1,2-dihydroquinaldide *(49)* (B).



(49)

For complexes of organoaluminum compounds and ketones yet another mode of reaction is possible. Ketones which can undergo enolization under the influence of organoaluminum compounds may then condense with further ketone. Hence condensation may compete with alkylation and reduction. The intermediary dimeric aluminum β-oxoenolate of type *(50)* is rather stable and in some cases could be isolated in pure crystalline form[28]. In principle, therefore, organoaluminum compound have vast potential as reagents for aldol-type condensations. However, this concept has not been generally accepted in preparative chemistry owing to the lack of a suitable method for converting a carbonyl compound into a reactive aluminum enolate.

(50)



With the aim of circumventing these limitations and utilizing the unique features of organoaluminum compounds more effectively, we are currently investigating aldol-type reactions promoted by aluminum reagents in the presence of zinc dust. An example is the reaction of ketone *(51)* with benzaldehyde[29]. The critical part of the process is the coupled attack

(51) *(52)*, 100%

on the α-haloketone by dialkylaluminum chloride and zinc dust which generates an aluminum enolate regioselectively. The reduction of the α-haloketone to enolate is clearly more favorable than the simple Reformatsky reaction. The aluminum enolate thus generated is sufficiently reactive to add to the carbonyl compounds present in the system. β-Oxoenolates are formed which, after workup yield the β-hydroxycarbonyl compounds. The reaction of two molecules of an α-haloketone with each other can be prevented if α-haloketone and carbonyl compound are simultaneously added to the organoaluminum compound at low temperature—provided the reduction proceeds sufficiently fast under acceptable conditions. In fact, the reaction of α-haloketones with a series of carbonyl derivatives is found to be a useful regioselective route to β-hydroxycarbonyl derivatives (Table 3)[29].

5. Closing Remarks

It was not the purpose of this progress report to consider all the known aluminum-promoted reactions individually but rather to present several new selective reactions based on the formation of 1:1 complexes of organoaluminum compounds with neutral Lewis bases. The selectivity is largely due to the presence of a coordinating group of the substrate which enables an adjacent functional group to react intramolecularly with a ligand of the aluminum. Thus, organoaluminum compounds effect selective functionalization using the principles, which to a very crude approximation, Nature incorporates in her enzymic processes. Even in our simple examples the selectivities achieved suggest that organoaluminum compounds have an important role to play in the synthetic methods of the future.

Special thanks are due to our able collaborators who have made many significant contributions to the planning of this research endeavor: Shin Tanaka, Arata Yasuda (Section 2), Yoshizo Kitagawa, Shinsuke Hashimoto, Satoshi Iemura, Akira Itoh, and Keiji Maruoka (Section 3 and 4). Production and Utilization of Amino Acids

By Yoshiharu Izumi, Ichiro Chibata, and Tamio Itoh[*]

The amino acid industry has been steadily expanding since monosodium glutamate was first marketed as a flavoring material in 1909. Its production has recently reached almost the 1 billion dollar level. Amino acids are produced by extraction from protein hydrolyzates, by fermentation with the aid of microorganisms, by enzymatic processes, and by chemical synthesis. To obtain natural L-amino acid, chemical synthesis generally requires two additional steps, *i.e.* optical resolution and racemization of the D isomer. The most important applications of amino acids include the fortification of plant food and feeds by supplementation of the deficient essential amino acid(s). Apart from their uses in the food industry, medical applications of amino acids (nutritional preparations and therapeutic agents) are becoming increasingly important.

1. Introduction

More than one hundred years ago, *Ritthausen* was engaged in the isolation of amino acids from gluten hydrolyzates at Königsberg. In 1866, he sent a specimen of crystalline glutamic acid to the mineralogist *Werther*, stating in an accompanying letter: "Dieselbe schmeckt deutlich sauer, etwas adstringend, erinnert aber im Nachgeschmack entfernt an concentrirten Fleischextract"[1]. However, use of glutamic acid as a flavoring material was not developed further in Germany. In 1908, the Japanese scientist *Ikeda* discovered that L-glutamic acid was the essential component of sea-tangle extracts, traditional Japanese soup stocks. Within a year, monosodium L-glutamate came onto the market as a culinary flavoring material. Since then the amino acid industry has continued to develop, with Japan retaining world leadership in this field.

All the amino acids occurring in proteins are now produced industrially. The total annual output of amino acids has a value of about $ 1000 million, and is still increasing. Table 1 summarizes the production methods, the output, and the approximate price of each amino acid.

The proteins essential for life are made up of about twenty kinds of amino acids. These amphoteric compounds contain at least one amino group and a carboxy group. Because of their characteristic properties, the applications of amino acids include such diverse fields as additives to foods and animal feeds, medical products, cosmetics, synthetic polymers, detergents, *etc.*

In 1974, the present authors published a book on the chemical synthesis and utilization of amino acids[2]. Another comprehensive book has also been published on microbial production of amino acids[3]. The present review mainly discusses recent advances in the industrial production and applications of amino acids.

Table 1. Survey of amino acid production (1977).

Amino acid	Method of production [a]	Quantity [t/a]	Price range [b]
L-Alanine	E	50–100	IV
L-Arginine(·HCl)	F, Ex	200–300	III
L-Asparagine	S	10–50	II
L-Aspartic acid	E	500–1000	II
L-Cysteine	S	50–100	III
L-Cystine	Ex	10–50	III
L-(2,4-Dihydroxyphenyl)alanine	S	100–200	II
L-Glutamine	F	200–300	III
L-Glutamic acid(Na)	F	250000	I
Glycine	S	3000	I
L-Histidine(·HCl)	F, Ex	50–100	V
L-Hydroxyproline	Ex	10–50	V
L-Isoleucine	F	10–50	V
L-Leucine	Ex	50–100	III
L-Lysine(·HCl)	F	25000	II
L-Methionine	S	50–100	III
DL-Methionine	S	100000	II
L-Phenylalanine	S	50–100	IV
L-Proline	F	50–100	V
L-Serine	E, S	10–50	IV
L-Threonine	F, S	50–100	IV
L-Tryptophan	S	50–100	V
L-Tyrosine	Ex	10–50	III
L-Valine	S, F	50–100	III

[a] Method of production: E, enzymatic; Ex, extractive; F, fermentative; S, synthetic.

[b] Price range: I, <4 $/kg; II, 4–20 $/kg; III, 20–40 $/kg; IV, 40–80 $/kg; V, >80 $/kg.

2. Production of Amino Acids

The history of amino acid production is typified by that of monosodium glutamate (MSG). In the first commercial production process for MSG in 1909, L-glutamic acid was separated as hydrochloride from wheat gluten hydrolyzed with hydrochloric acid. Production of MSG by isolation from protein hydrolyzate continued for some 50 years. In 1955, the microbial production of L-glutamic acid from simple materials such as glucose and ammonia was developed in Japan. Since then, this fermentation method has been applied to the production of a variety of amino acids. At the same time, methods of synthesis and optical resolution were also studied, and the synthetic production of glutamic acid could be launched in 1960. Meanwhile, other amino acids such as DL-methionine, glycine, and L-tryptophan are also manufactured in this way.

Amino acids can be produced by extraction from protein hydrolyzate, chemical synthesis, and microbial production. Enzymatic methods, such as production of L-aspartic acid from fumaric acid by aspartase and production of L-alanine from L-aspartic acid by aspartic-β-decarboxylase, have also been performed industrially. Further, continuous processes for enzymatic optical resolution and enzymatic synthesis have been developed using immobilized enzymes and immobilized microbial cells.

Most of the above mentioned techniques for the industrial production of amino acids were developed and introduced on an industrial scale in Japan. With the introduction of these production techniques, it became possible to produce economically various kinds of pure, optically active amino acids. As a result, the practical application of amino acids in various fields has been increasing year by year and has now become a viable branch of industry, which could be called the "amino acid industry".

2.1 Extraction Method

A certain amino acid can be separated from a protein hydrolyzate if its properties differ significantly from those of other amino acids present in the hydrolyzate. For instance, a cystine and tyrosine rich fraction can be readily separated from protein hydrolyzate by removing the fraction of water soluble amino acids, since cystine and tyrosine are sparingly soluble in water. Even today, cystine and tyrosine are still commercially produced by this simple separation method. Hydroxyproline is also produced by extraction (from gelatine hydrolyzate). The conventional separation method for production of arginine and histidine is now being replaced by microbial production.

2.2 Fermentation Method

The development of the fermentation method for production of amino acids, such as glutamic acid, began with screening programs for wild type microorganisms which could accumulate amino acids, given suitable media and cultural conditions. However, the kind of amino acid was limited and concentrations were low. Only on introduction of the methods of modern genetic biochemistry did it become possible to produce most amino acids by fermentation.

2.2.1. Use of Wild-Type Microorganisms

As a typical example, microbial production of L-glutamic acid will now be described.

In microorganisms, glutamic acid is formed by condensation of ammonia with α-oxoglutaric acid which in turn is formed from glucose *via* pyruvic acid (Fig. 1). Generally, microorganisms produce glutamic acid at just the level necessary to maintain life and growth. Certain microorganisms such as *Corynebacterium glutamicum* and *Brevibacterium flavum* have a very active enzyme system producing glutamic acid and excrete the amino acid from the cell. Since the first isolation of microorganism showing high glutamic acid productivity in 1955, the fermentation technique has greatly improved Nowadays, as much as 500 kg of L-glutamic acid can be

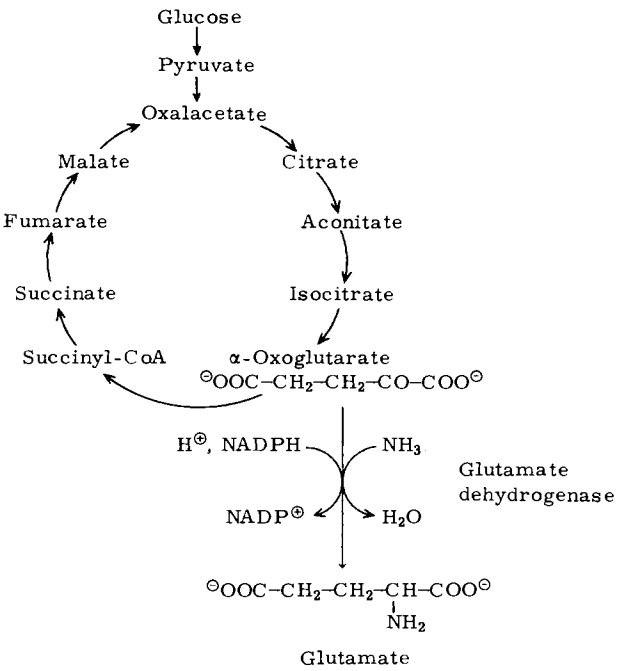

Fig. 1. Biosynthesis of glutamate.

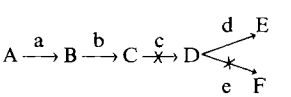
produced from 1 tonne of glucose. The less expensive carbon sources beet and cane molasses are used instead of glucose in the fermentation medium. Furthermore, acetic acid, ethanol, and *n*-paraffins are also utilizable for this purpose.



Fermentation is carried out as follows. To a sterilized tank (fermenter) are added an aqueous solution of carbon source as well as vitamins and minerals required for growth. After inoculation with a microorganism producing glutamic acid, air and ammonia are supplied to the vigorously stirred culture medium. The temperature is maintained at about 35 °C during this fermentation. After approximately 40 hours' culture, a large amount of glutamic acid has accumulated in the culture broth.

When the direct fermentative production of amino acids from sugar is difficult, appropriate intermediates are used. For example, isoleucine[4] and serine[5] are produced by fermentation in media containing D-threonine and glycine, respectively.

2.2.2. Use of Mutants

As stated in Section 2.2.1, only a limited number of amino acids can be produced by fermentation with wild-type microorganisms, since formation of amino acids is generally controlled by feedback mechanisms in microorganisms. This drawback can be overcome by using mutants accumulating an excess of specified amino acids. Several methods have been developed, as described below.

Use of auxotrophic mutants: Auxotrophic mutants, which lack one or more enzymes required for biosynthesis of an amino acid, can be used for microbial production of amino acids. The principle of the method is as follows: 1) amino

acid D-less mutant (the mutant requires amino acid D for growth) accumulates amino acid C owing to lack of enzyme c; 2) amino acid F-less mutant lacking enzyme e can be used for accumulation of amino acid E on another branched pathway.

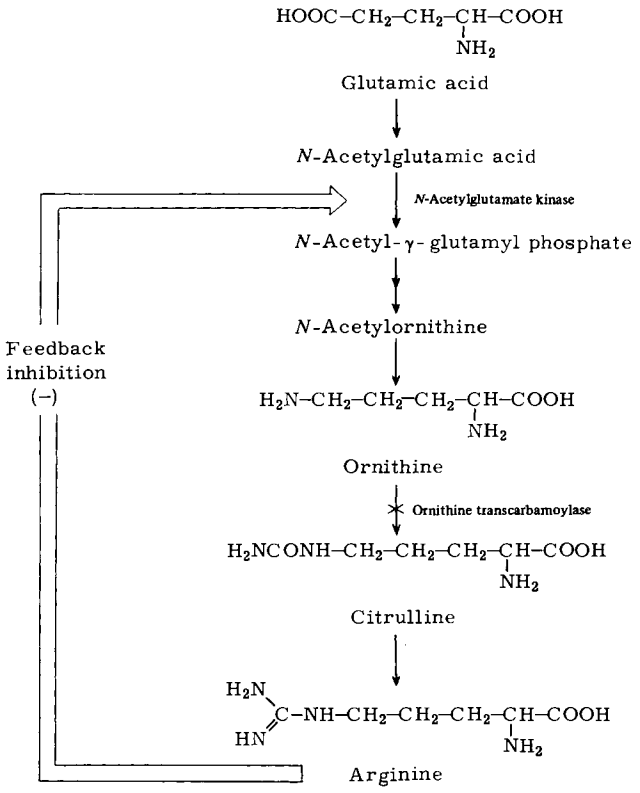


Fig. 2. Ornithine accumulation by a citrulline-deficient mutant of *Corynebacterium glutamicum*.

As shown in Figure 2, an example of the former case is the accumulation of ornithine by a citrulline-less mutant of *Corynebacterium glutamicum* which lacks ornithine carbamoyl transferase[6]. An example of the latter case is the accumulation of lysine by homoserine-less mutants of *Corynebacterium glutamicum* and *Escherichia coli*[7]. In these mutants, the lack of homoserine dehydrogenase blocks the pathway from aspartic semialdehyde to homoserine, leading to accumulation of lysine, the end product of a branched pathway. Other typical examples of the use of auxotrophic mutants are shown in Table 2.

Table 2. Accumulation of amino acid by auxotrophic mutants.

Product	Required amino acid	Microorganism	Ref.
Ornithine	citrulline	*Corynebacterium glutamicum*	[6]
Lysine	homoserine (threonine + methionine)	*Corynebacterium glutamicum*	[7]
Citrulline	arginine	*Bacillus subtilis*	[8]
Valine	leucine	*Corynebacterium glutamicum*	[9]
Threonine	methionine + isoleucine + diaminopimelic acid	*Escherichia coli*	[10]

Use of regulatory mutants: Growth of microorganisms can be inhibited by certain amino acid analogs. However, some microorganisms become resistant to these compounds by mutation. In these mutants, feedback control is lost and accumulation of excess amino acid occurs. These mutants are called regulatory mutants; some examples of the production of amino acids with their aid are shown in Table 3. Besides the above simple mutants, the use of polyauxotrophic mutants and auxotrophic regulatory mutants is steadily increasing[17].

Table 3. Accumulation of amino acids by regulatory mutants.

Product	Amino acid analog	Microorganism	Ref.
Arginine	2-thiazolealanine	*Brevibacterium flavum*	[11]
Methionine	ethionine + selenomethionine + methionine hydroxamate	*Corynebacterium glutamicum*	[12]
Isoleucine	isoleucine-hydroxamate	*Serratia marcescens*	[13]
Isoleucine	α-amino-β-hydroxyvaleric acid + *O*-methylthreonine	*Brevibacterium flavum*	[14]
Tryptophan	5-fluorotryptophan + tryptophan-hydroxamate	*Corynebacterium glutamicum*	[15]
Lysine	*S*-(2-aminoethyl)-L-cysteine	*Brevibacterium flavum*	[16]

2.3. Enzymatic Method

In the fermentation method amino acids are produced by use of the entire enzyme function of microorganisms. Using only part of this function, some amino acids can be produced from suitable intermediates by microbial enzymes.

For instance, the following reaction producing L-aspartic acid can be carried out with a cell suspension of *Escherichia coli* (Fig. 3). The reaction is catalyzed by the action of aspartase in microbial cells[18]. The resulting L-aspartic acid yields L-alanine on an industrial scale by the action of L-aspartate β-decarboxylase of *Pseudomonas dacunhae* cells[19].

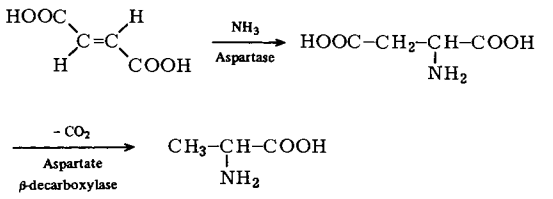

Fig. 3. Enzymatic formation of alanine from fumaric acid *via* aspartic acid.

With the aim of carrying out such enzyme reactions continuously, a technique has recently been developed for immobilization of microbial cells having high enzyme activity by entrapping into polymeric matrices[20]. Thus, L-aspartic acid is continuously produced in Japan using columns packed with immobilized microbial cells. This is the very first industrial application of an immobilized microbial cell system.

In the enzymatic synthesis of tryptophan from indole and pyruvate with tryptophanase, inosine is added to the reaction mixture to precipitate the resulting tryptophan as an insoluble tryptophan-inosine complex[21]. In this way tryptophan syn-

thesis is ensured. This is an interesting example of the application of reversible enzyme reactions.

An interesting enzymatic process for the production of L-lysine has been developed recently[22]. DL-α-aminocaprolactam is synthesized from cyclohexene, a by-product in the synthesis of caprolactam. Microbial L-aminocaprolactam hydrolase and aminocaprolactam racemase are simultaneously added to D,L-α-aminocaprolactam, resulting in its complete one-step enzymatic conversion into L-lysine as shown in Figure 4. Industrial application of this process is in progress; its economic competition with the recently developed microbial production of L-lysine seems very interesting.

Generally, enzymatic processes can be operated at higher concentrations and isolation of the products is also more simple than in the fermentation method. Therefore, the enzymatic method is advantageous when low-cost precursors are available and the reaction has a negative free energy.

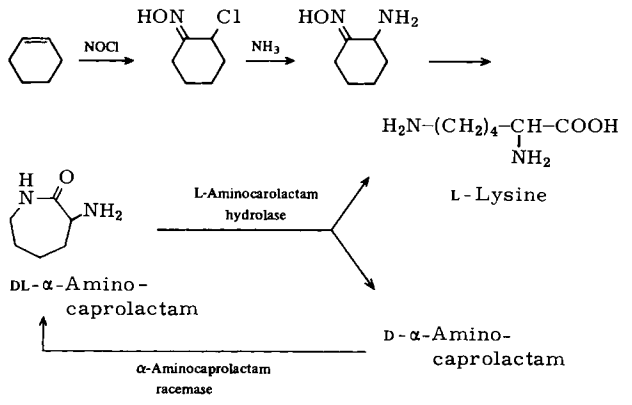

Fig. 4. Conversion of DL-aminocaprolactam into L-lysine.

This kind of interdisciplinary field between synthetic chemistry and biochemistry is a promising field for amino acid production.

2.4. Synthetic Method

Compared with the fermentation method, the synthetic technique can utilize a much greater variety of raw materials and processes. Furthermore, development of the chemical industry and technology promotes supplies of various materials at low cost and increases the competitive power of synthetic methods. For example, development of the petrochemical industry permitted large scale low-cost production of acrolein from propylene. This in turn made the synthetic production of methionine from acrolein economically feasible. However, the synthetic method requires a variety of raw materials produced by a highly developed chemical industry. This approach is therefore quite different from the fermentation method, which has no such limitations.

As described in Section 3, most applications exist for L-amino acids. Production of L-amino acids requires a combination of processes consisting of chemical synthesis, optical resolution and racemization of the D-amino acids. The two extra processes represent an economic disadvantage of the synthetic method. However, these demerits do not apply to glycine and methionine, because glycine has no asymmetric carbon and D- and L-methionines have almost equal nutritional value.

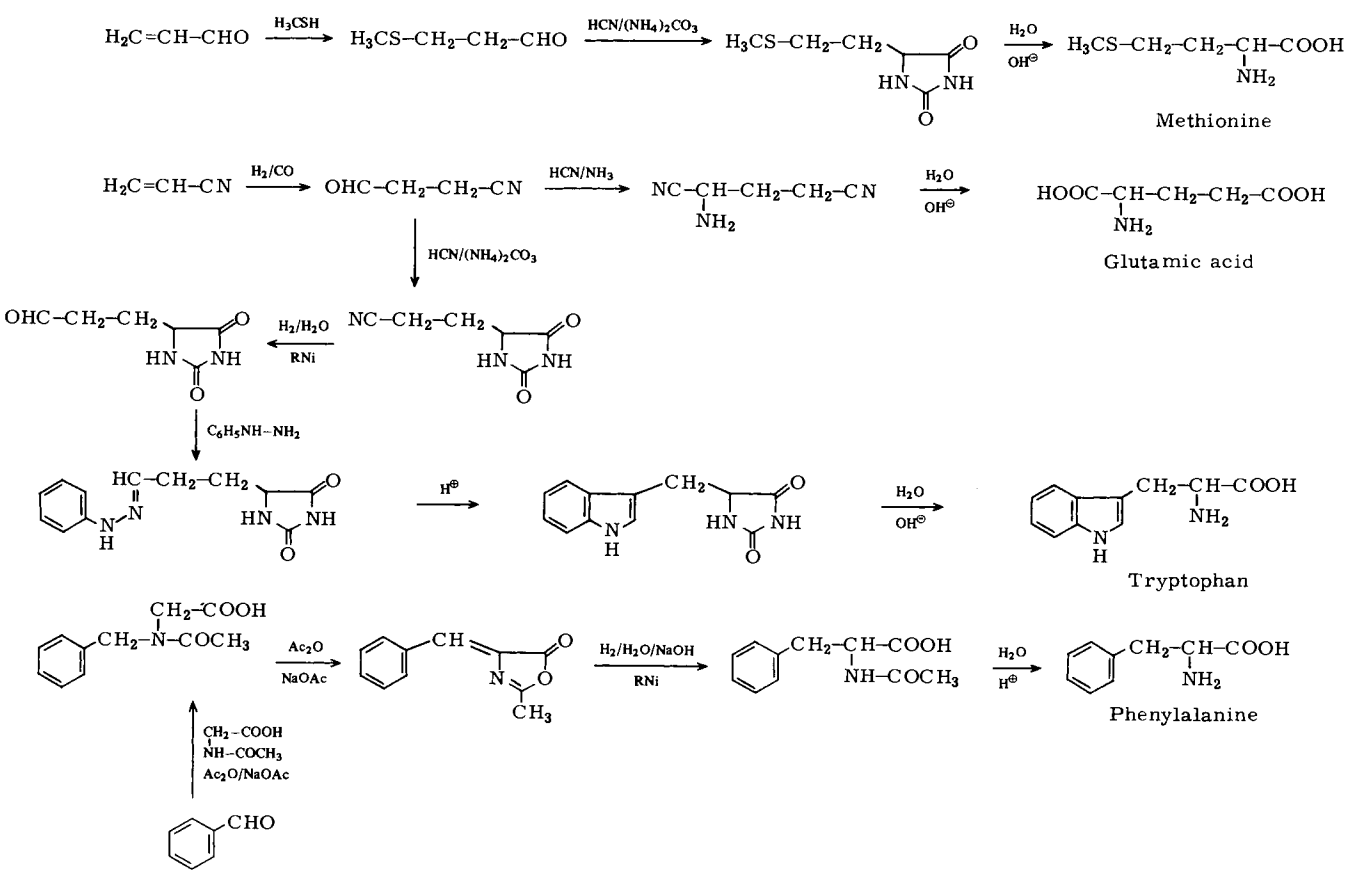

Fig. 5. Synthetic routes for some amino acids.

The industrial production of amino acids requires synthetic methods giving high yields. The Strecker method and the Snyder method meet the above requirements, and they both play a fundamental role in industrial production by chemical synthesis.

No practical fermentative methods have been developed for phenylalanine and tryptophan. These amino acids are therefore produced synthetically (Fig. 5); the value of this production method will be maintained over the near future. In spite of the disadvantages of synthetic methods, glutamic acid was synthesized on an industrial scale (Fig. 5) in Japan. Although the method was said to be competitive with the fermentative process, it has now been discontinued. The process for synthesis of methionine is also shown in Figure 5.

2.5. Optical Resolution

Optically active amino acids are obtained from synthetic DL-amino acids by optical resolution. Two techniques, *i.e.* the preferential crystallization procedure and the enzymatic procedure, are now employed. The former is based on preferential crystallization of the desired optically active isomer from a supersaturated solution of racemic amino acid on seeding with a small amount of the respective isomer. This procedure has been used for the resolution of glutamic acid and threonine. However, only few free amino acids can be resolved directly by this technique. In some instances, optical resolution of DL-amino acids becomes possible after conversion into appropriate salts or derivatives. One such example is the resolution of the ammonium salts of acylated tryptophan and acylated phenylalanine. Derivatives of aromatic sulfonic acids can also be resolved in this way, *e.g.* the sulfanilate of DL-lysine[23], the *m*-xylenesulfonate of DL-serine[24], and the anthraquinone-β-sulfonate of DL-lysine[25]. More recently, *N*-acyl-DL-proline[26] and DL-3-(3,4-methylenedioxyphenyl)-2-methylalaninehydrochloride[27] have also been resolved.

Although several methods are known for enzymatic resolution of DL-amino acids, the asymmetric hydrolysis of acyl-DL-amino acids by microbial aminoacylase is the only technique to have been adopted on an industrial scale. The method presently employed for the production of L-phenylalanine, L-tryptophan, L-valine, L-methionine, and L-2,4-dihydroxyphenylalanine (dopa) can be further improved by the use of immobilized enzyme systems. The aminoacylase is immobilized by ionic binding to a DEAE Sephadex support. The enzyme reaction is carried out continuously and automatically in columns packed with immobilized aminoacylase. This continuous production of optically active amino acids was developed in Japan and has been operated industrially since 1969. The flowsheet of the process is shown in Figure 6. Enzyme, substrate, and labor costs are low, and total production costs are more than 40% lower than for a conventional batch process using soluble enzyme.

2.6. Racemization

It is relatively easy to racemize optically active amino acids. Industrially, this is accomplished by heating aqueous solutions of amino acids or their salts at 150 to 250°C under pressure. *N*-Acetylamino acids are readily racemized at room

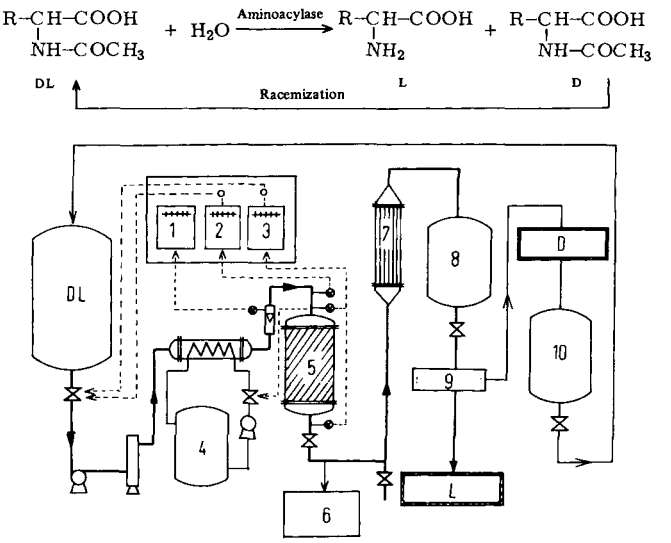

Fig. 6. Flow diagram for continuous production of L-amino acid by immobilized amino-acylase. DL, acetyl-DL-amino acid; L, L-amino acid; D, acetyl-D-amino acid; 1 to 3, measurement of flow rate, pH, and temperature; 4, hot water tank; 5, column containing immobilized amino-acylase; 6, automatic reaction recorder; 7, evaporator; 8, crystallizer; 9, separator; 10, tank for racemization.

temperature by treatment with acetic anhydride in acetic acid. In addition, amino acids are racemized by enzymes (racemases); however, this is not a general method.

2.7. Asymmetric Synthesis

The asymmetric synthesis of L- or D-amino acids is of great value because optical resolution becomes unnecessary. Among the known methods of asymmetric synthesis, enantio-differentiating (selective) catalytic reaction[28] seems to have industrial potential. In 1968, L-dopa was obtained by asymmetric synthesis using *Wilkinson's* complex catalyst carrying an optically active phosphane ligand as shown in Figure 7[29]. This practical method attracted attention because

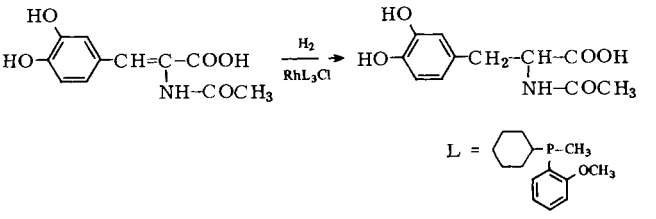

Fig. 7. Asymmetric synthesis of L-dopa.

the product is a relatively expensive amino acid, and the intermediate is fairly stable. Apart from economic aspects, asymmetric synthesis has the inherent restriction that the precursor carbon atom becoming the α-carbon atom of a desired amino acid must be sp^2 hybridized. Therefore, feasibility of asymmetric synthesis as an industrial process seems to be limited to a few special cases.

As described above in Sections 2.2, 2.3, and 2.4, the fermentation method, the enzymatic method, and the synthetic method are all employed for the production of amino acids. Fermentation methods using the latest techniques of microbial genetics afford numerous amino acids. An advantage of the fermentation method is the low cost of raw material; natural L-amino acids can be obtained from inexpensive carbon and nitrogen

sources. However, the fermentation method profits less on scale-up than the synthetic method. Furthermore, much labor and time is necessary for isolation or purification of the product because its concentration is generally low and by-products are often formed.

On the other hand, the synthetic method requires processes of optical resolution and racemization, since DL-amino acids are usually obtained. However, there are some advantages to be expected from large scale operation of the synthetic method, and isolation and purification of the product are easy.

It would be pointless to carry out enantio-differentiating Strecker or Snyder reactions, since both cyanohydrin and hydantoin are readily racemized during hydrolysis to amino acid. However, it would be a practicable method if enantio-differentiating catalytic hydrolysis were to become feasible. The enzymatic method for L-lysine production from DL-amino caprolactam (cf. Fig. 4) can be cited as an example. If the following reaction could be carried out with an enantio-differentiating catalyst, it would hold great promise for economic reasons and also because of its wide applicability:

$$R{-}CHO + R'CONH_2 + CO \xrightarrow[Co_2(CO)_8]{} R{-}\underset{\displaystyle NHCOR'}{\overset{\displaystyle |}{CH}}{-}COOH$$

Therefore, in the face of rising costs of plant construction and labor, synthetic methods appear, in some cases, more economical for the production of amino acids.

The enzymatic method assumes an intermediate position between fermentation and synthesis. Thus, it affords optically active amino acids and isolation is simple owing to high product concentrations. Moreover, the enzymatic method can be carried out continuously and automatically by employing immobilized enzyme or immobilized cell systems. Application of the enzymatic method to appropriate intermediates obtained by chemical synthesis also seems to be promising.

3. Utilization of Amino Acids

Amino acids are the main components of protein which is one of the three essential nutritional components.

All the amino acids occurring in proteins are in the L form, and only amino acids of this form are utilized in the living body. Thus, L-amino acids are usually[*] required for human and animal consumption.

3.1. Fortification

The nutritive value of protein depends on the quantity and balance of its constituent essential amino acids. Table 4 shows the estimated daily requirements of adults. We must take these essential amino acids daily and simultaneously; even if only one essential amino acid is supplied at an inadequate rate or at a different time from other amino acids, then the level of utilization of all the amino acids is lowered to that of the deficient amino acid ("limiting amino acid"). The amino acid content of most cereals is not well balanced. The nutritional value of protein can be improved by modification of amino acid balance; this is done by addition of small amounts of limiting amino acid(s) to food and feed. This amino acid fortification is significant not only nutritionally but also economically.

Table 4. Estimated daily amino acid requirements of adults[30].

Amino acid	Amount [mg/kg]
Isoleucine	10
Leucine	14
Lysine	12
Methionine + cystine	13
Phenylalanine + tyrosine	14
Threonine	7
Tryptophan	3.5
Valine	10

Amino acid fortification of animal feeds is practiced on a large scale. In particular, methionine and lysine are now indispensable for the production of animal feeds. In compound feeds, fishmeal or soybean meal generally serves as protein source. Although the amino acid composition of fishmeal is nutritionally good, prices and supplies fluctuate. The supply of soybean meal is more stable and its use in compound feeds is increasing. Methionine is the first limiting amino acid in soybean protein, and admixture of methionine very effectively improves its nutritional value. Methionine supplementation could also be applied to single cell protein (SCP) which is also low in methionine.

Almost all DL-methionine now produced is used for fortification of feeds and the demand for methionine is consequently increasing year by year. The annual world production of compound feeds supplemented with methionine is estimated as 200 million tons.

Corn is also an important vegetable protein source for animal feed, but like other cereal grains it is deficient in lysine. When the proportion of corn is high and that of soybean meal is small in a mixed feed, lysine supplementation is needed to increase nutritional efficiency. With the recent rise in price of soybean, lysine fortification has been increasing. The annual world demand for lysine is estimated to exceed 20 thousand tons.

Most cereals except corn, are deficient in threonine. In corn, tryptophan is also a limiting amino acid besides lysine. Hence tryptophan may be used for nutritional improvement in areas where corn is the staple diet.

The increase in world population and poor crops have had a serious impact on nutrition, especially on protein supplies. Better utilization of plant foods seems to be the most promising approach to the solution of this problem. Many studies have demonstrated that lysine fortification of foods such as bread and rice effectively raises the nutritional quality of cereal protein. However, lysine fortification has not been extensively applied to cereal products. Admixture of methionine and lysine to compound feed saves plant protein resources used for the production of animal protein. Food and feed compete with each other for the same limited resources.

With regard to world food supplies, we believe that a food crisis can be avoided if consumption of cereals and grains as foods and feeds is controlled on a world wide scale and efficient use is made of amino acids.

[*] Methionine is an exception (see Section 2.4).

3.2. Use of Amino Acids for Food Processing

The taste of foods is as important a factor as their nutritional value. Considering that amino acids provide one of the main contributions to food taste, the significance of amino acids in food processing is easily understood. The essential taste of foodstuffs is frequently due to free amino acids. In particular, L-glutamic acid, which is ubiquitous in animal and vegetable foods, can enhance or improve the taste and flavor of natural foodstuffs. This amino acid also synergistically intensifies the taste of nucleotides such as sodium inosinate, which are mainly responsible for the taste of animal foods[31]. Thus, sodium L-glutamate (MSG) is an indispensable additive for dehydrated soup and many other processed foods. It has been widely marketed, alone or combined with a nucleotide, for cooking or table-seasoning in Asian countries, the United States, and Latin America.

Besides glutamic acid, several other amino acids, such as L-aspartic acid, L-alanine, and glycine, are also employed to a lesser extent in food processing. L-Alanine and glycine, which exhibit a refreshing sweet taste, occur at high levels in shrimps and clams. So they are recognized to be essential taste components of fishery products.

Bitterness is one of the factors comprising a complex food taste. Many L-amino acids and peptides have a bitter taste. In cheese, for example, cyclo(L-tryptophanyl-L-leucyl) was found to be one of the bitter components[32]. Cyclo(L-valyl-L-phenylalanyl) is responsible for the bitterness of cocoa beans[33].

Since the accidental discovery of the pronounced sucrose-like taste of L-aspartyl-L-phenylalanine methyl ester (APM) in 1968, numerous reports and patents have appeared on sweet peptides. The practical use of APM, which is 150 times as sweet as sucrose, is now under development.

In food processing, the browning reaction gives rise to some special flavors or aromas. Heating of mixtures of finely divided carbohydrate, pentose, and sulfur-containing amino acids yields expanded porous products with meat-like flavor[34]. A chocolate-like flavor is formed by heating a branched-chain amino acid with sugars[35]. The browning reaction products from amino acid and sugar also exhibit a marked antioxidant effect[36].

In addition, amino acids have many other uses in food processing; meat preservation[37]; beer preservation[38], inhibition of denaturation of frozen meat[39], and improvement of the quality of sake[40].

3.3. Medical Uses

3.3.1. Nutritional Preparation

Since the introduction of parenteral infusion of crystalline amino acids in Japan in 1956, the use of pure amino acids in place of protein hydrolyzates has been increasing because the infusions based on crystalline amino acids show higher nutritional value and fewer adverse effects than those employing protein hydrolyzates. It is estimated that the annual world demand for these infusion preparations is 10 million vials containing 500 ml of a 5 to 10% amino acid solution. Most of the modern amino acid infusions contain approximately fifteen amino acids including the essential ones. The infusion is usually injected into a peripheral vein.

In 1968, *Dudrick et al.* reported a new technique in which relatively high concentrations of amino acids are injected *via* a central vein together with glucose, minerals, and vitamins[41]. This hyperalimentation technique permits adequate parenteral nutrition and has extended the use of amino acid infusions.

"Chemically defined diets" (CDD) have been developed for oral administration to patients with disorders of the digestive tract. Amino acids are used as the nitrogen source in these diets, in which all the necessary nutrients are supplied in chemically defined form.

3.3.2. Therapeutic Agents

Some amino acids playing specific physiological roles are used for therapeutic purposes. L-Arginine is related to biosynthesis of urea, and used for the treatment of hepatic disorders. Arginine administration is also said to be effective against male infertility resulting from arginine deficiency[42].

L-Tryptophan has been reported to be effective as a sleep inducer[43] and has been used as an antidepressant[44]. Oral administration of L-5-hydroxytryptophan improves the muscle tone of infants with Down's syndrome[45].

Gerber[46] has reported that large oral doses of L-histidine may relieve the symptoms of rheumatoid arthritis. L-Dopa is employed practically in the treatment of Parkinson's disease.

Amino acids are also utilized as raw materials for the synthesis of peptides used as medicines and diagnostics such as glutathion, thyrotropin releasing hormone (TRH), pentagastrin peptide, luteinizing hormone releasing hormone (LHRH), and so on.

3.4. Miscellaneous Uses

Various industrial uses of amino acids have been developed utilizing their physicochemical characteristics. Since industrial materials have to be low in price, inexpensive amino acids are used when suitable. Sodium acylglutamate is employed as a weakly acidic soap which has approximately the same pH as human skin. Poly-γ-glutamate is utilized as a coating material for artificial leather, to which it imparts a natural feel.

In addition, amino acids are employed in cosmetics as buffering or moisturizing agents.

4. Conclusion

The amino acid industry has grown to its present size as a result of technical innovations in manufacturing methods and in applications. However, it seems that this growth has now reached a plateau. This means that the first stage in the epoch-making developments of technology and marketing has now come to a close.

Manufacturing processes for amino acids have advanced rapidly in recent years. It can be said that the technology has reached a level at which almost all amino acids can be supplied to meet any demand, price remaining the only limit. The large market for amino acids, *e.g.* use of methionine, lysine, and monosodium glutamate as additives for foods

or animal feeds, is closely related to problems of world population and natural resources, together with changes in politics, social system, thought, and taste. It therefore seems difficult to predict future amino acid demands. Moreover, there are also economic restrictions; the lower the price the greater the demand, and the higher the price the smaller the demand. In spite of these problems, a favorable long term future can be predicted for the amino acid industry.

The Versatility of Tertiary Phosphane Ligands in Coordination and Organometallic Chemistry

By Ronald Mason and Devon W. Meek[*]

Tertiary phosphanes form kinetically stable complexes with formal oxidation states of the metal ranging from +IV to −I ("electronic versatility"). Variously substituted phosphanes and polydentate, chelate forming phosphanes and polyphosphanes can be synthesized ("steric versatility"). Studies on complexes containing such ligands provide, *inter alia*, useful information about the metal-phosphorus bond, about the steric effects of the phosphane ligand, and about reactions of coordinated phosphanes.

1. Introduction

A large number of alkyl- and aryl-phosphanes are now available following the pioneering syntheses of tertiary phosphanes and arsanes by *F. G. Mann*[1a] and *J. Chatt*[1b]. *Chatt*'s pioneering studies on organometallic and metal-hydride chemistry made extensive use of tertiary phosphane ligands to stabilize M—H, M—C, M—olefin, and M—acetylene bonds[1c]. A comprehensive discussion of the very large number of transition metal-phosphane complexes would require a large book; such extensive reviews are available[2]. Our objective in this article is to present a critical discussion of four currently important topics in the chemistry of transition metal complexes. Thus we present a reasonably objective survey of the minimum experimental observations needed to support our views on the nature of the metal-phosphorus

bond, the role of steric effects in phosphane complexes, special effects of polyphosphanes, and reactions of coordinated phosphanes.

The number and variety of tertiary phosphane complexes of transition metal ions that have been synthesized and characterized have accelerated rapidly during the past twenty years. Compared with neutral N- and O-donor ligands, the electronic versatility of tertiary phosphane ligands appears to be reflected in kinetically stable complexes with formal oxidation states of the metal ranging from +IV to −I[2]; this feature is often attributed to the metal-phosphorus bond having both σ- and π-components, the relative importance of which may be qualitatively anticipated from the Electroneutrality Principle.

The steric versatility of tertiary phosphanes derives from the purposeful variation of the substituent groups on phosphorus and from the synthesis of polydentate phosphanes, both of which can provide for a definition of particular stereochemistries and electronic configurations of complexes so that, *inter alia*, coordinatively unsaturated, reactive species of interest in homogeneous catalytic reactions can be isolated. More generally, these studies have ensured that the influence of steric effects on the thermodynamic and kinetic properties of transition metal complexes are being properly recognized and partially quantified after twenty years of almost total preoccupation with crystal and ligand field theories of electronic effects.

2. The Metal-Phosphorus Bond

A metal-phosphorus bond, like a transition metal-olefin bond, has from simple symmetry considerations alone, both σ- and π-components. We recognize now that metal to ligand π-bonding in olefin complexes is best discerned by considering the overall stereochemistry of the coordinated ligand, and not simply by the length of the coordinated bond[3]. The arguments for dπ-dπ bonding in metal-phosphane complexes are, for the most part, however, derived from equilibrium bond lengths since a metal-phosphorus bond distance is often suggested as being shorter than the sum of covalent radii and to be dependent on the nature of substituent groups. Some representatives of different coordination geometries are given in Table 1 to illustrate the effects of coordination symmetry (d^{10} systems) and different phosphane substituents (d^8 systems) on the M—P bond distances.

The internuclear distance in a metal-phosphorus bond should reflect the electronic configuration, oxidation state and coordination number of the metal; steric and electronic properties of the substituent groups on the tertiary phosphane; and the nature of the other ligands making up the coordination sphere. The only systematic study of the dependence of metal-phosphorus bond lengths on electronic configuration showed that in the complexes $[MCl_4L_2]$ and $[MCl_3L_3]$ (M = W, Re, Os, Ir, Pt; L = PMe_2Ph)[12a], the M—P bond lengths change by 0.05 Å per unit change of electron configuration while the corresponding M—Cl bond lengths change by only 0.01 Å (Fig. 1)[12b]; it was clear also that the break at the d^5 configura-

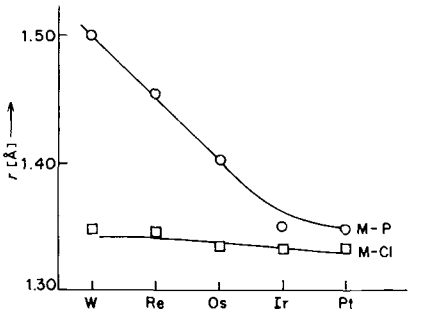

Fig. 1. Calculated metal covalent radii (—) in complexes of type $[MCl_4L_2]$ and $[MCl_3L_3]$ (L = PMe_2Ph); circles are the observed metal-phosphorus bond distances minus the covalent radius of phosphorus, 1.05 Å; squares are the observed metal-chlorine bond distances minus 0.99 Å, the covalent radius of chlorine.

tion is due to the population of metal-ligand antibonding levels. The experimental data received a quantitative explanation through a simple maximum overlap model[13], the essence of which was to establish that maximum overlap provides for the tertiary phosphane ligands pre-empting much metal 's' electron character in their σ-bonds. The radial dependence of the metal 6s electron wave function varies rapidly with electronic configuration; thus, metal covalent radii, calculated from both metal-phosphorus and metal-chlorine distances, reflect the observed results to better than 0.01 Å.

It is not surprising that bond lengths in complexes of metals in their +IV oxidation state show no evidence for metal

Table 1. Some metal-phosphorus bond lengths in d^8 and d^{10} metal complexes.

Electronic configuration	Complex	Approximate symmetry of ligand field	Bond length M—P [Å]		Ref.
d^8	$[RhH(PF_3)(PPh_3)_3]$	Trigonal bipyramidal	Rh—P(PF_3) Rh—P(PPh_3)	2.16(1) 2.34(1)	[4]
	$[RhH(PPh_3)_4]$	Pseudotetraedral		2.34(1) 2.34 or 2.39	[5]
	cis-$[PtCl_2\{Ph_2PCH_2CH_2P(CF_3)_2\}]$	Planar	Pt—P($P(CF_3)_2$) Pt—P(PPh_2)	2.168(3) 2.244(2)	[6]
d^{10}	$[Pt(Pcy_3)_2]$ [a]	Linear		2.231(4)	[7]
	$[Pt(PPh_3)_3]$	Trigonal		2.23—2.25(1)	[8]

to ligand π-bonding. Bond distances, however, have been cited as evidence of π-bonding effects in planar complexes of palladium(II) and platinum(II). *Mather et al.*[14], showed that there was a good correlation between Pt—P bond lengths and $^1J_{Pt\text{-}P}$ coupling constants and they also summarized plausible evidence that the coupling constants are dominated by the Fermi contact term and by the s-electron bond order in the platinum-phosphorus molecular orbital. Their data[14, 15] are shown in Figure 2 together with some representative data for platinum(0) complexes which, *prima facie*, should demonstrate condiserably more metal to ligand π-bonding.

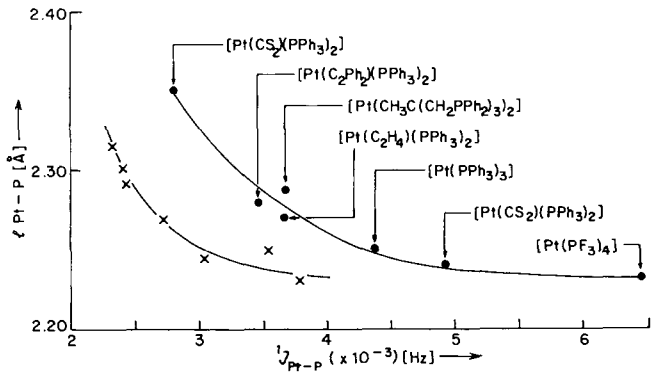

Fig. 2. Platinum-phosphorus bond lengths l (Pt—P) as a function of the coupling constants $^1J_{Pt\text{-}P}$. The curve with ×'s is *Pidcock*'s original correlation based on platinum(II) complexes [14]; the curve with •'s is our plot of data on formally platinum(0) complexes.

A bond length can be related to the σ- and π-bond orders,

$$l_{M-P} = \sigma_{(M)} + \sigma_{(P)} - k\pi_{M-P} \qquad (a)$$

where σ_M and σ_P are σ-covalent radii of the metal and phosphorus atoms, k is a constant and π_{M-P} is the metal-phosphorus π-bond order. *Coulson*[16] first showed for carbon-carbon bonds that σ(M) and σ(P) are a function of formal hybridization states, and he defined the σ-covalent radius as the distance from the nucleus to the centroid of electron density,

$$\sigma = \frac{\int r(\Psi(\lambda))^2 \, d\tau}{\int (\Psi(\lambda))^2 \, d\tau} \qquad (b)$$

where

$$\Psi(\lambda) = s + \lambda p.$$

Covalent σ-radii of phosphorus, using Clementi-Raimondi wave functions[17], can be calculated quite simply in this way. The formal hybridization states of the coordinated phosphorus lone pair orbitals in PF_3 and PPh_3 complexes can be estimated[16] from the respective F—P—F and C—P—C bond angles of 98 and 105°; obviously the PF_3 lone pair has more 's' electron character and the calculated centroid is 0.03 Å shorter than that for the PPh_3 ligand. This difference is almost sufficient to explain the metal-phosphorus bond length difference between $[Pt(PF_3)_4]$ and $[Pt\{CH_3C(CH_2PPh_2)_3\}_2]$, where we can assume initially that the metal σ-covalent radii are identical; therefore, at most only 0.03 Å should be attributed to $M_{d\pi} \rightarrow P_{d\pi}$ multiple bonding.

In the adducts $B_2H_4 \cdot 2PF_3$[18] and $B_2H_4 \cdot 2PPh_3$[19] the B—P bond lengths are 1.85(3) and 1.93(1) Å respectively; in these boron complexes π-bonding cannot be significant. The difference in the two B—P bond distances is comparable to that of the Pt—P bonds and again should be explained by σ-electronic effects. For $[Pt(PR_3)_2]$, $[Pt(PR_3)_3]$ and $[Pt(PR_3)_4]$ the Pt—P bond lengths show an essentially uniform increase of ≈0.02 Å as the metal changes its formal σ-hybridization state from sp to sp^2 to sp^3. Equation (b) for the covalent radii, coupled with the Basch-Gray wavefunctions[20], predicts exactly this difference in spite of the number of potential π-bonding orbitals varying from one complex to the next. The much larger difference in the rhodium(I)–phosphorus bonds[4, 5] is more difficult to analyze unequivocally, because of the very different σ-electron framework in $[RhH(PF_3)(PPh_3)_3]$ and $[RhH(PPh_3)_4]$.

Apart from fluoro-substitution at the phosphorus atom, the M—$P(R^1R^2R^3)$ bond length is not very sensitive to the substituent groups, R^1, R^2 and R^3, provided they are not very sterically demanding. Thus in *cis*-$[PtCl_2(PMe_3)_2]$ and *cis*-$[PtCl_2(PMe_2Ph)_2 \cdot HgCl_2]$ the Pt—P bond lengths are 2.248(9) and 2.255(5) Å, respectively[21, 22]; in *cis*-$[PtCl_2(CO)(PMe_2Ph)]$ and *cis*-$[PtCl_2(CO)(PPh_3)]$ they are 2.264(2) and 2.282(2) Å[23, 24]. However, such substituent changes have marked effects on reactivities.

The effect, on metal-phosphorus bond lengths, of varying the electronic properties of the ligands *cis*- and *trans*- to the bonds is, again, well documented for planar complexes of platinum(II). The Pt^{II}—Cl bond length has been widely used as a yardstick for measuring the relative *trans*-influences of coordinated ligands[25, 26]; the tertiary phosphane ligand is comparable, in its *trans*-influence, with hydride and σ-bonded carbon ligands, there being a simple correlation, in the absence of metal to ligand π-bonding, between a ligand's electronegativity and its *trans*-influencing properties[25]. Equally one can recognize, from a systematic survey of bond lengths in Pt(II) complexes[27], that the platinum-phosphorus bond is determined roughly by the σ-donor properties of the *trans*-ligand, the mean value ranging from 2.22 Å (*trans* to Cl), 2.29 Å (*trans* to C), 2.30 Å (*trans* to P), to 2.33 Å (*trans* to Ge). Not surprisingly, the range is only one-half that of the Pt^{II}—Cl bond length for the same variety of *trans*-ligands. This result can be anticipated from simple electronegativity considerations and from a molecular orbital view of the X—Pt—Y fragment, which imagines that the *trans*-influence on a particular ligand is greatest when it has maximum overlap with metal pσ-electrons.

The effect, on metal-phosphorus bond lengths, of changing ligands *cis* to the M—P bond is more difficult to delineate; it is certainly smaller in magnitude than that associated with their *trans*-influence. A clear cut demonstration of the *cis*-influence is available from the bond lengths in $[RhCl(PPh_3)_3]$[28, 29] and $[RhCl(C_2F_4)(PPh_3)_2]$[28]: the Rh—Cl bond lengths are identical, within experimental error, at 2.382(5) and 2.375(8) Å, while the Rh—P bond lengths (*trans* to P) average 2.328(4) and 2.372(8) Å, respectively. A similar picture is clear from the survey of *Manojlović-Muir* and *Muir*[27]: Pt^{II}—P bond lengths *cis* to σ- and π-donors (*e.g.* Cl^-) average 2.215(4) Å in complexes such as *cis*-$[PtCl_2(PR_3)L]$; if L be a weak Lewis acid (carbene, isocyanide) the bond length increases to 2.242(2) Å while for moderate

π-acceptors (L = CO), the bond length averages 2.272(8) Å; the Pt^{II}—Cl bond lengths vary by up to 0.04 Å in the opposite sense so that steric effects, according to *Muir* and *Muir*[27], can be discounted.

The question of interest is whether the *cis*-influence must be taken as reflecting π-acid behavior of the tertiary phosphanes, such as was suggested earlier[28]. There is now magnetic resonance evidence[30, 31] that the σ-bond formed between alkenes, alkynes and platinum(II) has a significant s-electron component and competition with a similarly demanding tertiary phosphane, but not with the chloride ligand, may be sufficient to rationalize the observed trends. Little of quantitative value, however, can be expressed at present.

In summary, we take the view that the electronic versatility of the phosphane ligand is largely a σ-electron effect, there being little evidence for π-bonding effects in the metal-ligand bond lengths. The Electroneutrality Principle will be satisfied when low valent metal ions use the relatively contracted 's' orbital on the phosphorus atom, high valent metal ions having more charge transfer through the σ-framework *via* the use of the more radially extended phosphorus 3p orbitals. Such a suggestion is consistent with the correlation between bond lengths and coupling constants shown in Figure 2 in that, for a given bond length, the $^1J_{Pt\text{-}P}$ value is greater for platinum(0) complexes than for platinum(II) complexes. The variation in s-p character is substantial when ligands with different substituent groups are coordinated to a given metal; for example, ESR studies on [CoL(TPP)] (TPP = tetraphenylporphyrin) show[32] that the percent s character changes from 68% when L is PF_3, to 51% (L = $P(OMe)_3$), to 36%, 28, and 27% when L = PMe_3, PMe_2Ph, and PEt_3, respectively; this would be an admirable extended series for crystallographic studies and correlation of metal-ligand bond lengths with independently determined electron distribution parameters.

3. Steric Effects of Tertiary Phosphane Ligands in Transition Metal Complexes

The distinction between electronic and steric effects of ligands is often no more than a semantic one. In the present context, an increase in substituent bulkiness will serve to increase the angle between substituent groups and will, in a formal way, localize more 'p' character in the phosphorus lone pair. An increase in the metal-phosphorus bond length will follow, which could have had its origins more directly from secondary (non-bonded) rather than primary valence interactions. Only rarely have these complementary effects been separated.

An obvious starting point in our discussion is the group of phosphane complexes of d^{10} ions (Ni^0, Pd^0 and Pt^0). *Musco et al.*[33] showed that the coordination number of the zerovalent palladium complexes may be 2, 3 or 4, the relative preference in forming coordinatively unsaturated species being $PMe_3 \approx PMe_2Ph \approx PMePh_2 < PPh_3 \approx PEt_3 \approx P(n\text{-}Bu)_3 < P(benzyl)_3 < P(i\text{-}Pr)_3 < P(cyclohexyl)_3 \approx P(t\text{-}Bu)_2Ph$; the sequence is obviously not well related to changing basicity but rather to the steric demands of the tertiary phosphanes. A very similar picture emerged from *Tolman*'s studies[34] of nickel(0) species: for the equilibria

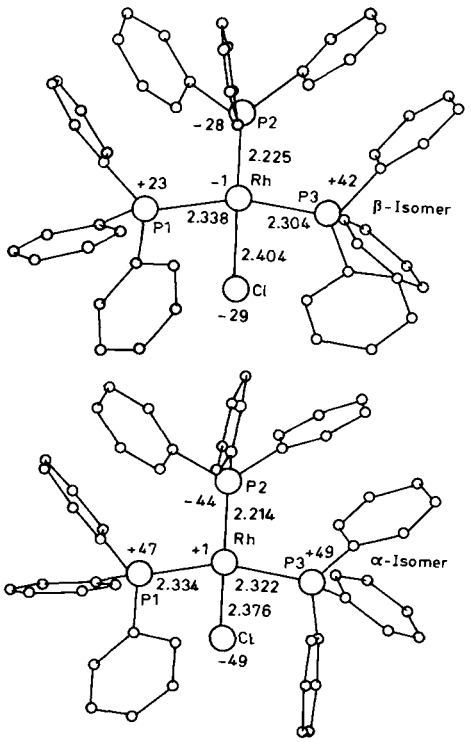
$$[NiL_4] \overset{K_d}{\rightleftharpoons} [NiL_3] + L$$

K_d ranges from $< 10^{-9}$ for PMe_3 at 70°C, 1.2×10^{-2} for PEt_3, 5×10^{-2} for $PMePh_2$ to > 10 for PPh_3. These important studies were complementary to an earlier attempt to define the steric requirements of a ligand in terms of its 'cone angle', the apex angle of a cylindrically symmetric cone centered at 2.3 Å from the phosphorus atom and enveloping, in a van der Waals contact sense, the outermost atoms of the ligand. Cone angles, measured relatively crudely from molecular models, vary from 118° (PMe_3) to values of 132°, 136° and 145° for PEt_3, $PMePh_2$ and PPh_3, respectively[35]. We shall return later to the cone angle concept; but, together with studies of the dissociation of copper(I)[36] and cobalt(I)[37] species, there seems little doubt left that ligand bulkiness, however it may be measured, is a dominant factor in determining the metal coordination number in solution and the bonding potential and reactivity of the coordinatively unsaturated species. A striking example of the latter has been the demonstration, by *Otsuka et al.*[38], that while $[Pd\{P(t\text{-}Bu)_2Ph\}_2]$ readily forms the dioxygen adduct $[PdL_2O_2]$, the somewhat more crowded fourteen electron species $[Pd\{P(t\text{-}Bu)_3\}_2]$ is stable.

Two other remarks should be made. The platinum-phosphorus bond lengths in $Pt(Pcy_3)_2$[6] and *trans*-$[PtH_2(Pcy_3)_2]$[39] (cy = cyclohexyl) are not significantly different at 2.231(4) and 2.25(1) Å respectively; since the *trans*-influence of the hydride and phosphane ligands are generally very similar, one can deduce that steric effects in the dihydrido complex are negligible. In *trans*-$[PtI_2(Pcy_3)_2]$[40], however, the Pt—P bond length increases to 2.371(2) Å compared with 2.315(4) Å in *trans*-$[PtBr_2(PEt_3)_2]$[41] and this may be fair evidence that *cis*-interactions can cause bond lengthening of the order of 0.05 Å or so. We need to enter the caveat that, electronically as well as sterically, the two halide ions make somewhat different demands on the metal. A much more important comment, however, relates to the observations that in many low-valent, electron deficient species there are non-primary valence interactions of carbon-hydrogen bonds with the metal[29]. Thus, two ortho-hydrogen atoms are positioned at *ca.* 2.7 Å from the metal in $[Pd\{P(t\text{-}Bu)_2Ph\}_2]$[42] and, with the phosphorus atoms, provide for a planar coordination geometry of the metal which persists in solution. These metal-hydrogen interactions appear to be necessary, if not sufficient, for facile intramolecular oxidative-addition reactions[43] and are further examined below.

Steric demands of coordinated phosphanes may be insufficient to provide for low coordination numbers but adequate to impose distortions from an anticipated coordination geometry. Tris(triphenylphosphane)rhodium(I) chloride is an important complex, from the standpoint of its catalytic properties[44] and its structural dimorphism[29]; the latter allows ligand conformations and coordination geometries to be examined in detail. Red crystals (α isomer) are obtained when a solution of triphenylphosphane in ethanol is added to an ethanolic solution of rhodium trichloride; an orange crystalline form (β isomer) is formed when the order of addition is reversed and the solution of rhodium trichloride is added very slowly to a concentrated solution of triphenylphosphane in ethanol. Molecular stereochemistries[29] are shown in Figure 3 and represent the atomic arrangements projected upon the mean

coordination planes. While the metal-ligand bond lengths in the two isomers are very similar (estimated standard deviations in the metal-ligand bond lengths average 0.005 Å), the distortions from planar coordination symmetry about the metal vary considerably between the isomers. The '*trans*' Cl—Rh—P bond angles are 156.2(2)° (α isomer) and 166.7(2)° (β isomer) while the '*trans*' P—Rh—P bond angles are 152.8(1)° and 159.1(2)°; the r.m.s. deviations, towards tetrahedrality, of the coordinated atoms from the mean coordination plane are 0.43 Å (α isomer) and 0.28 Å (β isomer). By contrast, the structural analysis of [RhCl(ttp)][45] shows it to be more planar, the r.m.s. deviation from the mean plane being only 0.08 Å with the metal-phosphorus bond lengths in the chelating triphosphane being systematically 0.02 Å shorter than those in $[RhCl(PPh_3)_3]$.



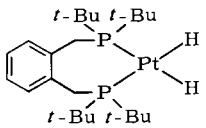


Fig. 3. Atomic arrangements, metal-ligand bond lengths [Å], and deviations from mean coordination planes [$\times 10^2$ Å] in the two isomers of $RhCl(PPh_3)_3$. Above: β-isomer, orange-colored crystals, metastable; below: α-isomer, red crystals, stable.

The orange (β) isomer is metastable with respect to the α form, being converted rapidly on refluxing. The stable isomer has the phenyl rings in a more close packed arrangement with a number of non-bonded H...H, C...H and C...C distances averaging 2.2 Å, 2.6 Å and 2.9 Å respectively; short intramolecular nonbonded C...H contacts between phenyl rings are absent in the metastable β-isomer, a significant result in relation to their importance in stabilizing the conformation of many organic molecules[46]. The solid surfaces enveloping the triphenylphosphane ligands deviate from conical symmetry, the anisotropy in the cone angles often amounting to some 10°. A variety of conformations, separated by small energy differences only, is open to substituent groups, provided there are concerted, cooperative motions of the groups.

The ground state geometries of α- and β-$[RhCl(PPh_3)_3]$ do not provide an obvious explanation for its facile dissociation[44,47], in solution, to $[RgCl(PPh_3)_2]$. The relative weakness of the chemically equivalent rhodium-phosphane bonds and the bond angles in the stable α-isomer of $[RhCl(PPh_3)_3]$ allow the plausible speculation that $[RhCl(PPh_3)_2]$ would be trigonal planar; another possibility would involve two *ortho*-hydrogen atoms occupying axial positions to form a trigonal-bipyramidal structure. A quasi-eighteen electron structure for the rhodium ion (see Section 5) would then follow, but there is no direct evidence for this suggestion[29], nor for an alternative one involving two-electron donation from a phenyl ring[47].

There are many examples of phosphane ligand steric effects on planar-tetrahedral isomerization of complexes[35,48]. Perhaps more interestingly, *cis-trans* isomerism in planar complexes of palladium(II) and platinum(II) was shown[49] to depend on the bulkiness of tertiary phosphane, arsane and stibane ligands. The effect has been elegantly exploited by *Shaw et al.* through the synthesis of macrocyclic tertiary biphosphane complexes[50]; long chain α,ω-biphosphanes of the type $(t\text{-Bu})_2P(CH_2)_nP(t\text{-Bu})_2$ ($n=9$, 10 or 12) form mono-, di- and tri-nuclear macrocyclic complexes with platinum metals in a way which has been interpreted in terms of favorable internal entropy and conformational effects. The structures[51] of these complexes illustrate the strain-free state of the macrocycles; the central methylene fragments have conformations which are identical to those in linear alkanes and long-chain fatty acids.

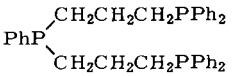
An interesting variation on the theme of determination of stereochemistry has provided the first *cis*-dihydride of platinum(II), *(1)*[52]. The seven-membered chelate rings allow

(1)

the *tert*-butyl groups to be sufficiently separated but its rigidity prevents the diphosphane from acting as a bridging ligand between two metal atoms.

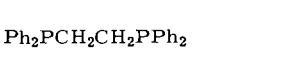
Apart from determining coordination numbers and symmetries, certain tertiary phosphanes or their derivatives have been used to stabilize unusual oxidation states of metals. The synthesis and structures of two planar iridium(II) complexes, *trans*-$[Ir\{(t\text{-Bu})_2PC_6H_4O\}_2]$ and *trans*-$[Ir\{(t\text{-Bu})_2C_6H_3(OMe)O\}_2]$ have been described[53]. Paramagnetic rhodium(II) complexes $[RhCl_2L_2]$ [L = Pcy_3, P(O-tolyl)$_3$] are available[54] but the reaction of rhodium trichloride with less bulky phosphanes provides the more conventional $RhCl_3L_3$ complexes[55].

4. Metal Complexes of Polyphosphane Ligands



As noted above, tertiary phosphane ligands appear to accommodate a wide range of properties in transition metal complexes, especially since the steric and electronic properties of the ligands can be varied relatively easily by changing the substituents on phosphorus. These advantages of a phosphane ligand can be emphasized by a properly designed chelating polyphosphane. During the past twelve years significant advances have been accomplished in the synthesis of polyden-

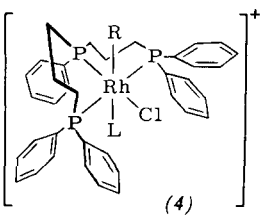
tate ligands. Whereas combinations of nitrogen, oxygen, and sulfur donors have utilized the "template effect"[56], polyphosphane ligands have, as yet, been prepared by more conventional organic methods involving Grignard reagents, alkali metal phosphides[57], or addition of a P—H bond to the double bond of a vinylphosphane[58, 59, 60]. In particular, a large number of "tripod-like" potentially tetradentate ligands of the type



have been investigated by the research groups of *Meek*[61], *Sacconi*[62], and *Venanzi*[63] (usually the connecting chains are *o*-phenylene, ethylene, or trimethylene and one or more of the donor atoms A, B, C, and D is phosphorus).

Many studies have shown that the structure, stability, and magnetic properties of the transition metal complexes of such chelating ligands are sensitive functions of both electronic and steric effects[64]. Compared to a monodentate phosphane, a polyphosphane ligand can provide simultaneously (i) more control on the coordination number, stoichiometry, and stereochemistry of the resulting complex, (ii) an increased basicity (or nucleophilicity) at the metal, and (iii) detailed structural and bonding information in the form of metal-phosphorus and phosphorus-phosphorus coupling constants. For example,

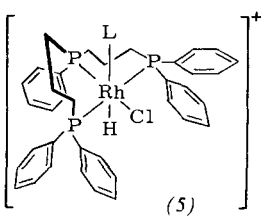
(2), ttp



(3), diphos

the trimethylene connecting linkages of triphosphane *(2)* (ttp) provide an ideal "chelate bite" for the larger transition metal ions. The P—Rh—P angles involving chelated rings are $90\pm1°$ in the three complexes $[RhCl(ttp)]$[45], $[RhCl(NO)(ttp)]^+$[45], and $[RhCl(N_2Ph)(ttp)]^+$[65], in contrast to "pinched" P—M—P angles of $82\pm1°$ for Rh^I, Ir^I, and Pt^{II} complexes of ligand *(3)* (diphos)[66, 67]. The 90° P—Rh—P bond angles permit maximum overlap of the phosphorus and rhodium orbitals, which undoubtedly contributes to the planar structure (see Section 3), dissociative stability, and basicity of $[RhCl(ttp)]$ as compared to the stoichiometrically analogous complex $[RhCl(PPh_3)_3]$[68]. The five-coordinate cations $[RhCl(NO)(ttp)]^+$ and $[RhCl(N_2Ph)(ttp)]^+$ are square-pyramidal; the most diagnostic and important structural features of the latter two complexes being that the $[RhCl(ttp)]$ fragment is arranged in the basal plane in both complexes; is similar to that in the parent compound; and that the M—N—O and M—N—N bond angles are bent, with Rh—N—O and Rh—N—N being 131(1)° and 125(1)°, respectively[45].

The structures of both these cations indicate that $[RhCl(ttp)]$ has undergone a single-site oxidative addition and converted the NO^+ and N_2Ph^+ groups, respectively, into the NO^- and N_2Ph^- ligands. This interpretation is also supported by the ^{31}P-NMR spectra *(vide infra)*. Comparable reactions are not available with complexes of equivalent monodentate phosphanes.

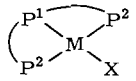


Chemical studies also show that the rhodium atom in $[RhCl(ttp)]$ is quite basic (nucleophilic). The metal center readily functions as a Lewis base toward both neutral acids (*e.g.*, SO_2, BF_3, CO, O_2, X_2, HX, CH_3X, and TCNE) and cationic acids (*e.g.*, CH_3^+, CH_3CO^+, $C_2H_5^+$, and H^+) to give stable, five-coordinate complexes of the type $[RhCl(ttp)\cdot A]$ and $[RhCl(ttp)\cdot A]^+$, respectively[45, 69]. The chelating triphosphane ligand *(2)* (ttp) has increased the apparent basicity of the metal center to the point that $[RhCl(ttp)]$ mimics the reactions of phosphane complexes of iridium(I), *e.g.* $[IrCl(CO)(PPh_3)_2]$ and $[IrCl(PPh_3)_3]$, more closely than it resembles other rhodium-arylphosphane complexes[70].

Although the cationic hydride and methyl complexes $[RhCl(H)(ttp)]^+$ and $[RhCl(CH_3)(ttp)]^+$ are formally analogous, they show striking differences in the tendency to bond a sixth ligand (*e.g.*, CO, CH_3CN, or C_2H_5OH)[69]. The cation $[RhCl(CH_3)(ttp)]^+$ does not form adducts with molecules such as DMSO, SO_2, or C_2H_5OH, whereas the analogous rhodium-hydride cation is stable only as six-coordinate complexes of the type $[RhClHL(ttp)]^+$ *(5)*. Both the methyl and hydride cations add carbon monoxide or acetonitrile and give isolable six-coordinate complexes, but the relative tendency to add CH_3CN or CO is much stronger for the hydride case. The marked difference in chemical properties may be due to different structures of the two complexes [cf. *(4)* and *(5)*].

(4)

R = CH_3, C_2H_5
L = CH_3CN, CO



(5)

L = C_2H_5OH, CH_3CN, THF, CO

X-ray results on both the complexes $[RhCl(NO)(ttp)]^+$ and $[RhCl(N_2Ph)(ttp)]^+$ show that a phenyl group on each of the three phosphorus atoms is projected down and forms a small cavity *trans* to the apex ligand[45, 65]. Thus, the most probable metal site for addition of a bulky ligand (*e.g.*, CH_3^+) would be on "top" of $[RhCl(ttp)]$, whereas the small hydride ligand is added after coordination of a solvent molecule and apparently can fit into the cavity, giving a different diastereomer. The basic nature of $[RhCl(ttp)]$ is also demonstrated by protonation and alkylation reactions on a series of *p*-substituted phenyldiazo complexes. IR and ^1H-NMR spectra on $^{15}N{-}{-}^{14}N{-}Ar$ and $^{14}N{-}{-}^{15}N{-}Ar$ isotopically labelled compounds shows that the most basic nitrogen atom is adjacent to rhodium[71, 72], in contrast to the situation in M—N=N—Ph type complexes, where protonation occurs on the nitrogen atom adjacent to the aryl group[73].

The ligand *(2)* (ttp) is well designed for determining the *trans*-influence of ligands *via* ^{31}P-NMR spectra, especially when the metal center has a magnetic nucleus. As a result of the trimethylene connecting chain between phosphorus atoms. P—P coupling through the chain is nearly always <1 Hz[74, 75]. Thus, a planar Rh^I or Pt^{II} complex of type *(6)* gives both $^1J_{M-P^1}$ and $^1J_{M-P^2}$, which reflect simultaneously the *trans*- and *cis*-influence of ligand X. Table 2 shows a marked decrease in Pt—P coupling *trans* to X in the series

$Cl > CH_2CN > H > CH_3$[74], which gives a generally accepted *trans*-influence order. The Pt—P coupling constants for phosphorus atoms *cis* to the same X ligands increase, ableit much

(6)

less rapidly. From our discussion of the correlation between Pt—P bond lengths and Pt—P coupling constants, one could expect to see a significantly longer Pt—P_1 bond distance in the methyl complex compared to the Cl case.

Table 2. ^{31}P coupling constants [74] of $[Pt(ttp)X]^+$ complexes.

X	J [Hz] Pt—P^1 ±2 Hz	Pt—P^2 ±2 Hz	P—P ±1 Hz
Cl	3217	2284	26
I	3230	2319	26
CH_2CN	1911	2445	32
H	1678	2524	29
CH_3	1626	2611	32

A more extensive series of Rh(ttp) complexes has been examined by ^{31}P-NMR[69, 75, 76], and Table 3 presents the data for selected examples. As in the platinum complexes, the relative chemical shifts of P^1 and P^2, as well as the Rh—P^1 and Rh—P^2 coupling contstnts, are sensitive indicators of the bonding properties of the ligand *trans* to P^1 (note that the magnitudes of the Rh—P coupling constants are about one-tenth of the corresponding Pt—P coupling constants, a reflection of the difference in the magnetogyric ratio of the two metals). Figure 4 shows the large change of the chemical shift of P^1 when chloride is replaced by CO, the data on $[Rh(CH_3CN)(ttp)]^+$ showing that the large change is not

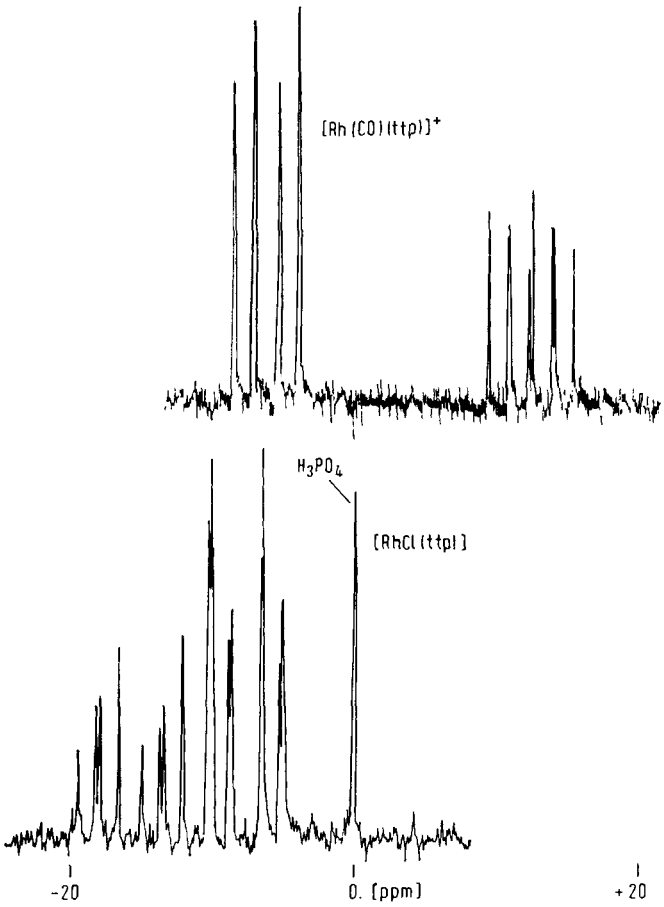


Fig. 4. ^{31}P-NMR spectra (proton-noise-decoupled) of $[Rh(CO)(ttp)]^+$ in acetone (above) and [RhCl(ttp)] in benzene (below) relative to 85% H_3PO_4 as external standard.

Table 3. ^{31}P-NMR data for Rh(ttp) complexes.

Compound	Solvent	δ [ppM] [a] P_1	P_2	P—P	J [Hz] [b] Rh—P^1	Rh—P^2	Ref.
[RhCl(ttp)]	THF, $[D_6]$-acetone	15.8	8.0	52.0	163.0	129.0	[75]
$[Rh(N_3)(ttp)]$	THF, $[D_6]$-benzene	16.78	7.33	53.6	152.2	131.6	[75]
$[Rh(ttp)(CH_3CN)]PF_6$	Acetone, $[D_6]$-acetone	12.45	8.93	52.4	151.5	123.0	[75]
$[Rh(ttp)(CO)]PF_6$	Acetone, $[D_6]$-acetone	−12.01	6.46	52.0	113.3	114.3	[75]
$[RhCl(NO)(ttp)]PF_6$	CH_2Cl_2, $[D_6]$-acetone	10.8	2.1	30	139	106	[76]

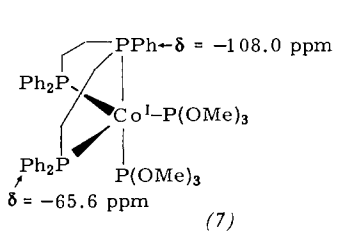
$[RhHCl(CO)(ttp)]PF_6$	CH_2Cl_2, $[D_6]$-acetone	1.1	4.9	38	90	81	[76]

[a] Value relative to external 85% H_3PO_4, with positive numbers being downfield from the standard.
[b] Resolution for the coupling constants of the first four compounds is 0.4 Hz, for the last three compounds ±1 Hz.



due simply to the formation of a cation. The magnitudes of the Rh—P coupling constants decrease when rhodium(I) is oxidized to rhodium(III)[75, 77]. A correlation between Rh—P bond distances and $^1J_{Rh-P}$ values, similar to the platinum examples discussed in Section 2, will probably develop when more data on rhodium-phosphane complexes become available. In the case of [RhCl(ttp)], the $^1J_{Rh-P}$ values of 163.0 and 129.0 Hz correspond to Rh—P bond distances of 2.201(2) and 2.288(1) Å[65], respectively, while the $^1J_{Rh-P}$ values of 139 and 160 Hz correspond to Rh—P bond distances of 2.282(4) and 2.374(3) Å, respectively, in the five-coordinate nitrosyl cation $[RhCl(NO)(ttp)]^+$[65]. The Rh—P coupling constants for $[Rh(CO)(ttp)]^+$ suggest that the larger *trans* influence of carbon monoxide would be significantly longer than for [RhCl(ttp)] and comparable to the Rh—P^2 distances.

P^{31} coordination chemical shifts ($\Delta = \delta_{complex} - \delta_{free\ ligand}$) depend on the ring size in chelated phosphane ligands. Large downfield shifts are generally observed for 5-membered chelate rings (Table 4). If a phosphorus atom is the bridgehead of two or three 5-membered rings as in *(7)* and *(8)*, respectively,

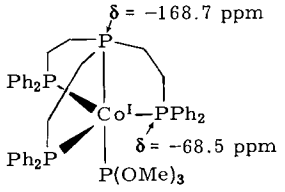


Table 4. ^{31}P-NMR data [78] for complexes of the type $[W(CO)_4\{Ph_2P(CH_2)_nPPh_2\}]$.

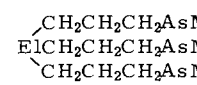
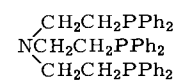
	$n=1$	$n=2$	$n=3$
$\delta_{complex}$ [ppm]	+ 23.6	− 40.1	0.0
$\delta_{free\ ligand}$ [ppm]	+ 23.6	+ 12.5	+ 17.3
Δ [ppm]	0.0	− 52.6	− 17.3
$^1J_{W-P}$ [Hz]	202	231	222

the large downfield shift is nearly additive for each additional chelate ring[78,79].

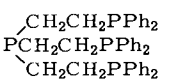


(7)

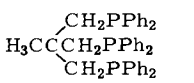


(8)

Poly(tertiary phosphane) ligands can be used to determine magnetic states and coordination stereochemistries by varying the types of donor atom sets, the chelate bite angle, and by introducing sterically demanding substituent groups. For example, wide variations in the nature of the ligand donor set (*e.g.* N_4, N_3P, N_2P_2, NP_3, and P_4) have been achieved by *Sacconi et al.*[62] and *Meek et al.*[61,80,81] through the use of "tripod-like" ligands.



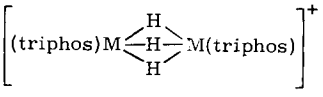
Owing to their extremely flexible nature, tripod ligands such as *(9)*—*(12)*, which contain either ethylene or trimethylene connecting chains, can form complexes with different coordination numbers (six[82,83], five[61,81,84,85] and four[87,88]) and different stereochemistries (octahedral[82,83], trigonal bipyramidal[61,81,84,86], square pyramidal[85],



(9), El = P, As, Sb

(10), np_3

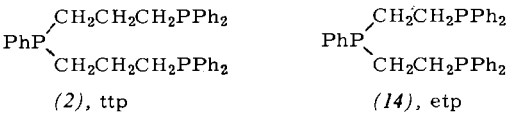
(11), pp_3



(12), triphos

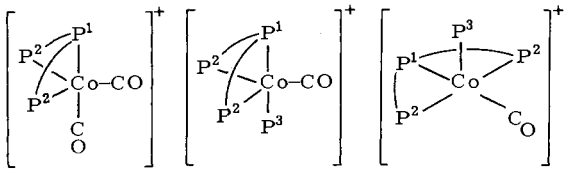
planar[87], trigonal pyramidal[88], and distorted tetrahedral[89]). Such flexible ligands permit the metal to dictate the preferred coordination number and geometry. The structure of $[CoI(np_3)]I$ is a distorted square pyramid[85], whereas the structure of the analogous nickel(II) complex $[NiI(np_3)]I$ is a trigonal bipyramid[84], with crystallographic C_3 symmetry. These two complexes serve to illustrate a general trend among low-spin, five-coordinate nickel(II) and cobalt(II) complexes of tripod ligands—that the nickel complexes are more often trigonal bipyramidal.

The spin state of the metal atom in five-coordinate cobalt(II) and nickel(II) complexes is determined, to some extent, by the nature of the donor set[62b]. In general, combinations of four heavy donors (*e.g.* P, As, S, Se) give low spin, trigonal-bipyramidal Co^{II}, Ni^{II}, and Co^{I} complexes[61,62,63,81]. Ligands containing one or more nitrogen or oxygen donor groups give more variations in the magnetic ground state, the structure, and the number of polydentate ligand atoms actually bonded to the metal. A correlation between the spin state and the coordination geometry has been found for certain donor sets[62]. Cobalt(II) and nickel(II) complexes of the ligand (np_3) *(10)* shows just how sensitive the spin state is to changes in the donor set. For example, the $[CoX(np_3)]Y$ complexes (X = Cl or Br; Y = X, BF_4, PF_6, or BPh_4) are high-spin; NCS complexes and all iododerivatives, except for $Y = BPh_4$, are low-spin. In contrast, *all* the $[NiX(np_3)]Y$ complexes are low-spin[90]. If the tripod ligand is changed to the tetraphosphane pp_3 *(11)* all of the Co^{II} and Ni^{II} complexes become low-spin. This results from the changing nature of the apical ligand: phosphorus is a softer donor (higher nucleophilicity constant[62b]) than nitrogen and tends to produce low-spin complexes. The same spin-state trend is shown also by the cobalt(I) complexes $[CoX(pp_3)]$ and $[CoX(np_3)]$, where the two compounds are on opposite sides of, but are close to, the magnetic crossover point[91].



Attainment of the 18-valence-shell electronic configuration is also an important factor in determining the coordination number of phosphane complexes of metals in the latter half of the transition series[92,93]. This point is illustrated nicely by the structures of $[Pt^0(triphos)_2]$[10] and by the series $[M(NO)(np_3)]X$ (M = Fe, Co, Ni; X = I, NO_3, BF_4 or BPh_4)[94]. The platinum(0) complex has only four of the six phosphorus atoms bonded to the platinum[10]. In the nitrosyl series, the iron complex has a trigonal-bipyramidal geometry, whereas the cobalt and nickel complexes are tetrahedral, the central nitrogen atom of the ligand in these two cases being non-coordinated[94].

Stabilization of unusual metal oxidation states can be achieved relatively easily with polydentate phosphane ligands. For example, interesting tetrahedral nickel(I), d^9, and cobalt(I), d^8, complexes of general formula [MX(triphos)] are obtained when the metal salts are reduced with $NaBH_4$ in the presence to the [MI(triphos)] complexes. In the absence of a coordinating anion, the "tripod-like" symmetry of this triphosphane ligand leads to binuclear hydride complexes of type *(13)*[96].



(13), M = Fe^{II}, Co^{II}

One can modify the coordination stereochemistry for a given donor set (*e.g.* P_3X_2) around a metal ion simply by changing the number of methylene groups in the connecting chains of a polyphosphane ligand. Such a study with the flexible ligands *(14)* (etp) and *(2)* (ttp) permitted the effect of the chelate ring size on the preferred structure of some five-coordinate cobalt(I) complexes to be determined[79]. The details of the stereochemistry and exchange processes for the complexes $[Co(CO)_2(etp)]X$, $[Co(CO)_2(ttp)]X$, $[Co(CO)(etp)L]X$ and $[Co(CO)L(ttp)]X$ ($X = BF_4$ or PF_6; $L = P(OMe)_3$, PPh_2H, PPh_2Me, PEt_3, or PPh_3) depend on

(2), ttp *(14)*, etp

both the monodentate ligand and on the triphosphane ligand. For example, the $[Co(CO)(etp)L]^+$ and $[Co(CO)_2(etp)]^+$ complexes are trigonal-bipyramidal with the equatorial positions occupied by a carbonyl ligand and the two terminal phosphorus atoms (P^2) of the triphosphane ligand; the axial positions are occupied by the central phosphorus atom (P^1) of the triphosphane and either a carbonyl *(15)* or a monophosphane ligand (P^3) *(16)*[79,97]. The monocarbonyl $[Co(CO)L(ttp)]^+$ complexes have square-pyramidal structures with L at the axial position. The change from square-pyramidal coordination geometry in $[Co(CO)\{P(OMe)_3\}(ttp)]^+$ *(17)* to

(15) *(16)* *(17)*

trigonal-bipyramidal in $[Co(etp)\{P(OMe)_3\}_2]^+$ can be attributed to the decrease in chelate bite angle of the ligand *(14)* (etp). As a consequence of the smaller bite angle in 5-membered chelate rings, the central phosphorus atom must either be pulled in abnormally close to the metal in a square-pyramidal geometry or be free to adopt a different coordination geometry where the central phosphorus atom is more equivalent to those of the terminal phosphorus atoms (P^2), *e.g.* as in the trigonal-bipyramidal geometries *(15)* and *(16)*.

The stereochemistry[98–103] and intramolecular exchange processes[98,102,103] of a number of five-coordinate complexes of cobalt(I) have been investigated. The preferred geometry in most cases appears to be based on a trigonal-bipyramid[98,99,104], although square-pyramidal complexes are also known[100,105]. With monodentate ligands, there are only small energy differences between the two limiting structures for d^8 pentacoordinate complexes[98]; in addition, structures intermediate between the idealized trigonal-bipyramidal and square-pyramidal structures are fairly common. Polyphosphane ligands can increase the intramolecular rearrangement energy sufficiently to freeze the exchange of phosphorus nuclei on the NMR time scale. Whereas, monodentate PR_3 and $P(OR)_3$ ligands produce non-rigid cobalt(I) complexes, the $[Co(CO)L(etp)]^+$ cations (L = a monodentate PR_3 or $P(OR)_3$ ligand) are stereochemically rigid in solution at room temperature[79]. One can obtain more detailed stereochemical information on the complexes from the P—P coupling constants than is possible with fluxional complexes of similar types of monodentate ligands.

The reduced dissociation tendency of chelating polyphosphane ligands permits synthesis of mixed d^{10} complexes of the type [M(triphosphane)(monophosphane)] (M = Ni^0, Pd^0, and Pt^0)[106]. Structural information and inferences regarding the hybridization around the metal can be obtained from the ^{31}P-NMR data. The Pt—P coupling observed for the triphosphane ligand *(12)* (triphos) in the [Pt(triphos)(monophosphane)] complexes decreases systematically from 3098 ± 2.4 to 2867 ± 2.4 Hz as the electronegativity of the monodentate phosphane changes from PPh_3 to PF_3, whereas the Pt—P coupling for the monodentate phosphane increases rapidly in the series PPh_3 (5400 Hz) < $P(OCH_2)_3CCH_3$ (6787 Hz) < $P(OPh)_3$ (9150 Hz) < PF_3 ($\approx$9500 Hz)[106]. The large difference in Pt—P coupling constants observed in the Pt(triphos)PR_3 complexes must be related to differences in the two types of Pt—P bonds, in particular to significantly different values of α^2_{Pt} in the expression for the Fermi contact term. As the triphosphane ligand limits expansion of the P—Pt—P angles to about 93—95°[107–111], those three Pt—P bonds will have a smaller s-character than "tetrahedral" Pt—P bonds; the remaining Pt—P bond will be hybridized to include more s-character and exhibits a larger coupling constant.

Complexes of polyphosphane ligands illustrate, finally, a control on the coordination behavior of ambidentate ligands such as the thiocyanate ion. Many different monodentate ligands have been used to determine the factors that influence the ambidentate nature of the SCN^- ion, but the relative importance of σ-bonding, π-bonding, or steric effects of the ancillary ligands is still unresolved in detail[112]. The uncertainty remains because it is impossible to change the electronic effects of substituents on donor atoms over a wide range independently of steric effects. The three closely related chelating ligands *(18)*, *(19)* and *(20)* were used to define a *cis*-arrangement of two thiocyanate ligands in the palladium(II) complexes, to have a 90° P—Pd—L angle within the chelate ring,

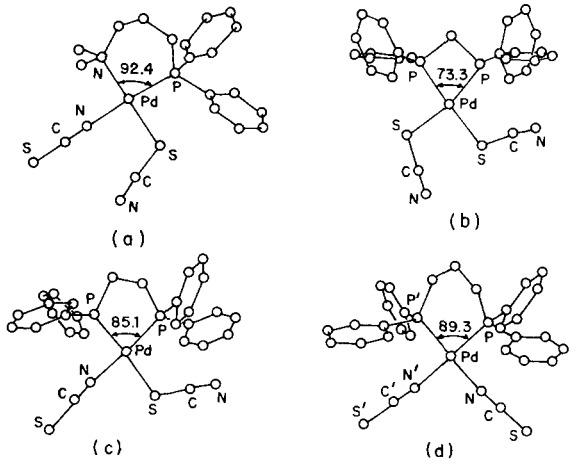
$Me_2PCH_2CH_2CH_2NMe_2$ *(18)*

$Me_2PCH_2CH_2CH_2PMe_2$ *(19)*

$Me_2PCH_2CH_2CH_2AsMe_2$ *(20)*

and to have a dimethylphosphino-ligand common to all three complexes[113]. In dichloromethane solution, the nitrogen and arsenic derivatives give *(18)* and *(19)* complexes containing *both* N- and S-bonded thiocyanate groups, while both thiocyanate groups are N-bonded in the case of the diphosphane ligand. If one makes the reasonable assumption that the NMe_2 and $AsMe_2$ groups are not effective π-acceptors, these "mixed" thiocyanate complexes are apparently consistent with the argument that the phosphane group is a good π-acceptor; thus it should influence the *trans*-thiocyanate group to be N-bonded[112]. However, strong phosphorus σ-bonding *via* p-orbitals would also favor a N-bonded thiocyanate group *trans* to the phosphorus atom, as we have discussed above.

The structure of [Pd(SCN)(NCS)L], where L is $Ph_2PCH_2CH_2CH_2NMe_2$, is shown in Figure 5a[114]. The structure has the N-bonded thiocyanate *trans* to P and the S-bonded thiocyanate *trans* to N. This case does not distinguish between the σ- *vs* π-bonding nature of phosphorus, however, as both effects give the same result here. In an effort to control the donor properties of the bidentate ligand, *Meek* and *Li* prepared a series of palladium thiocyanate complexes containing the three chelating diphosphane ligands $Ph_2P(CH_2)_nPPh_2$, where $n = 1$, 2, and 3[113b,115]. All three ligands contain equivalent donor groups, and Figures 5b—5d show the remarkable trend that was found in the structures



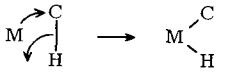


Fig. 5. Perspective drawings of the molecular structures of: (a) $Pd(SCN)(NCS)(Ph_2PCH_2CH_2CH_2NMe_2)$; (b) $Pd(SCN)_2(Ph_2PCH_2PPh_2)$; (c) $Pd(SCN)(NCS)(Ph_2PCH_2CH_2PPh_2)$; and (d) $Pd(NCS)_2(Ph_2PCH_2CH_2CH_2PPh_2)$.

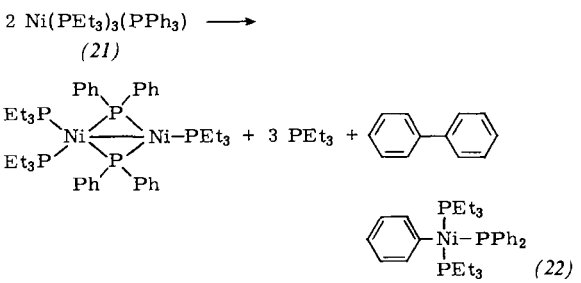
of the three palladium thiocyanate complexes, namely, that the mode of thiocyanate bonding changes from S,S for $n=1$, to S,N for $n=2$, to N,N for $n=3$ as the chelate P—Pd—P angle increases from 73.3 to 89.3°[115,116]. These angular changes are easily interpreted in terms of increasing steric effects adjacent to the thiocyanate groups as the chain length between the phosphorus atoms increases. The regular change in the bonding mode of the thiocyanate ion is explicable in terms of steric effects, without involking any π-bonding arguments.

5. Some Reactions of Coordinated Tertiary Phosphane Complexes

The metallation of carbon-hydrogen and phosphorus-carbon bonds of coordinated tertiary phosphane ligands is an important example of intramolecular oxidative addition reactions which have implications for mechanistic proposals in homogeneous and heterogeneous catalysis[117]. A number of possible mechanisms of oxidative addition exist[118] but, in general, and in the particular context of the metallation of carbon-hydrogen bonds, a coordinatively unsaturated species is obviously necessary. As was anticipated some time ago[43], the carbon-hydrogen bond must be in close proximity to the metal, the geometry being such as to encourage speculation of a concerted three center addition mechanism such as

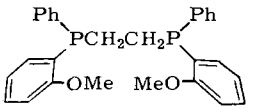


Sterically demanding phosphanes provide readily, as we have noted, for coordinatively unsaturated species and may often force a carbon-hydrogen bond into a suitable precursor state prior to metallation. The subtlety of steric control of metallation is illustrated by the reactions of $[PtCl_2(PhCN)_2]$ with tertiary phosphanes: with di-*tert*-butyl(neopentyl)phosphane, the neopentyl group is readily metallated but with di-*tert*-butyl(*n*-propyl)phosphane, L, a simple mixture of *cis*- and *trans*-complexes, $[PtCl_2L(PhCN)]$, is produced[119]. No metallated product was formed from the slightly more crowded complex, $[PtCl_2(t\text{-}BuCN)\{P(t\text{-}Bu)_2(n\text{-}Pr)\}]$ although the dimeric complex $[Pt_2Cl_4\{P(t\text{-}Bu)_2(n\text{-}Pr)\}_2]$ undergoes slow hydrogen-deuterium exchange, at the 3-position of the *n*-propyl group in strong acid media[120]; this exchange appears to be regiospecific with the concomitant suggestion that the reaction proceeds *via* a cyclometallated species, perhaps similar to the binuclear complex formed from the metallated neopentylphosphane.

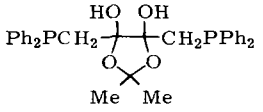
Although the geometries of non-primary valence interactions of carbon-hydrogen bonds with metals and of cyclometallated species are well known, the precise nature of the interactions and of the mechanistic details of the oxidative addition remain uncertain. A quasi-covalent view of the interactions imagines that the carbon-hydrogen σ-bond is a two-electron donor in a polycentric interaction with the electron-deficient metal. Tertiary phosphane complexes of palladium(0), platinum(0), rhodium(I), and palladium(II), for example, achieve an eighteen-electron configuration for the metal if this kind of accountancy is adopted. No phosphane complexes demonstrate the strong interactions observed in pyrazolyl borate complexes of molybdenum[121], where the carbon-hydrogen-metal bonds (M...H ≈ 2.1 Å) are competitive energetically with metal-olefin bonds. With the longer M...H 'bonds' of 2.5 to 2.7 Å in tertiary phosphane complexes, it is presumably more appropriate to think of the interaction as predominantly an electrostatic one, which could still be sufficient to satisfy the electrostatic potential requirements of the metal[29].

So far as electronic effects in cyclometallation are concerned, it is apparent—albeit from, as yet, limited data—that both electrophilic and nucleophilic pathways may be followed[122]. The ease of cyclometallation is dependent upon the metal basicity[123] and, in essence, its electron density as determined by the Lewis acid-base properties of the remaining ligands in the coordination sphere, a feature well illustrated by the varied reactions of $[IrClL_3]$ (L = *para*-substituted arylphosphanes), complexes which have interest in their catalytic dehydrogenation reactions[124].

Insertion of metals into phosphorus-carbon bonds of coordinated tertiary phosphanes remains largely at a descriptive stage. The stability of binuclear and polynuclear μ-phosphido complexes of d^8 and d^9 systems obviously contributes to the cleavage process. Refluxing of $[IrH(CO)(PPh_3)_3]$ in *n*-heptane gives $[Ir(CO)PPh_3(\mu\text{-}PPh_2)_2]_2$, a complex with a metal-metal bond length of 2.55 Å and a formal metal-metal double bond[125]. Triosmium complexes with μ-phosphido, μ-phenyl and μ-dehydrobenzene ligands have been characterized from the reaction of dodecarbonyltriosmium with triphenylphosphane[126,127]. Many other examples of oxidative-addition reactions presented by $Os_3(CO)_{12}$ have been described subsequently and used to suggest the proposition that reactions of organometallic clusters may be similar to those at surfaces



of transition metals[128, 129]. A satisfying study of phosphorus-carbon bond cleavage is the recent one by *Fahey* and *Mahan*[130]: the reaction of the nickel complex *(21)* is assumed to proceed *via* the intermediate *(22)*, through a reversible oxidative addition of the metal to triphenylphosphane.



6. Outlook

Our discussion has not suggested that metal to phosphorus π-bonding is nonexistent; rather that its importance in determining equilibrium molecular parameters may have been overemphasized in the past. Further correlations of bond geometries with metal-phosphorus coupling constants and, where appropriate, with ESR data should limit further the remaining ambiguities of interpretation. The cone angle concept could undoubtedly be extended in its utility by realistic molecular mechanics calculations while SCF calculations of the relation between chelate ring sizes and conformations and imposed metal coordination geometries could provide for more sophisticated ligand design.

This article reflects the activity, during the past decade, in four areas of the chemistry of the later transition metals; an obvious growth area is that of asymmetric synthesis *via* homogeneous catalysis[131–133]. Impressive results have been obtained with complexes of *P,P'*-bis(*o*-methoxyphenyl)-*P,P'*-diphenylethylenediphosphane *(23)*, a ligand which is chiral

(23)

(24)

at both phosphorus atoms[134]. The catalyst is uniquely effective in the homogeneous hydrogenation of α-acylaminoacrylic acids. High optical purities can be obtained also with catalysts which are not chiral at phosphorus but have a chiral substituent; examples are rhodium(I) complexes of the diphosphane, 4,5-bis(diphenylphosphinomethyl)-2,2-dimethyl-1,3-dioxolan-4,5-diol *(24)* (DIOP), which are useful for asymmetric hydrogenation and hydrosilylation reactions[135].

A final note is necessary by way of recognizing evidence that tertiary phosphane complexes of the earlier transition metals, particularly molybdenum and tungsten, are providing much interest in connection with their activation of dinitrogen[136, 137] and carbon-hydrogen bonds[138]. It may be here that polydentate phosphane ligands will be particularly important in such chemical reactions by controlling preferred electron configurations and geometries of coordinatively unsaturated species.

We are grateful to all of our research colleagues whose contributions, over the years , are obvious from this Review. We acknowledge combined financial support from the Science Research Council (RM) and the National Science Foundation (DWM). Finally RM is grateful to the Ohio State University for the tenure of a Distinguished Visiting Professorship, during which this paper was written.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

A Stable Thiiranimine[**]

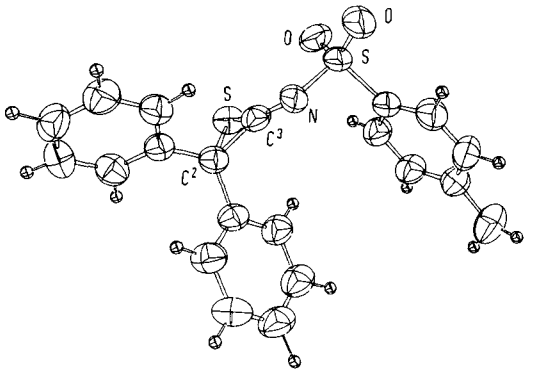
By *Gerrit L'abbé, Jean-Paul Dekerk, Jean-Paul Declercq, Gabriel Germain*, and *Maurice Van Meerssche*[*]

Aziridinimines are known[1] and a successful synthesis of a stable oxiranimine has been claimed recently[2]. The sulfur analogs, thiiranimines, have not yet been reported, although many examples of their open-chain dipolar isomers have been isolated[3], and both the ring-closed and open-chain forms have been postulated as reactive intermediates[4]. In principle, thiiranimines would be accessible from the thermal interaction of diazoalkanes with isothiocyanates, but all the publications on the subject only report the formation of the aromatic 1,2,3-thiadiazoles[5]. We describe here the first synthesis and characterization of such a species.

When equimolar amounts of tosyl isothiocyanate and diphenyldiazomethane are allowed to react in anhydrous ether at 0°C, nitrogen evolution occurs and at the end of the reaction *(1)* is isolated in 67% yield upon cooling of the solution to a low temperature. In addition, a small amount (*ca.* 1%) of 4,4-diphenyl-5-tosylimino-1,2,3-trithiolane (structure determined by X-ray analysis), m. p. 186–187°C, is also obtained from the residue by column chromatography on silica gel with benzene/ethyl acetate (95:5) as the eluant.

(1)

The new three-membered ring *(1)* exhibits IR (KBr) absorptions at 1700(m) and 1630 cm^{-1} (s), while in the ^{13}C-NMR spectrum ($CDCl_3$) the ring-carbon absorptions are found at $\delta = 46.5$ (sp^3-*C*) and 170.7 ppm (*C*=N). The result of an X-ray structure analysis[6] is shown in Figure 1.



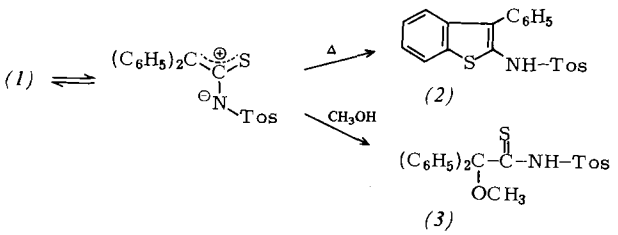


Fig. 1. Molecular structure of thiiranimine *(1)* in the crystalline state.

The thiirane ring features a large S—C^2 distance (194 pm compared with 181 pm for the sum of the covalent radii) and short C^2—C^3 (147 pm) and S—C^3 (170 pm) bonds; a situation also observed for α-lactams[7] and diaziridinimines[8]. The exocyclic C=N bond has a normal length of 127 pm[9], and the tosyl group is located in the *cis* position with respect to the C^3—S bond (*Z* isomer). The internal ring angles are 47.2° (at S), 58.1° (at C^2), and 74.7° (at C^3). As expected, the four atoms, S, C^2, C^3 and N are almost coplanar.

In its chemical reactions, *(1)* is cleaved at the unusually long S—C^2 bond. Thus, when a chloroform solution of *(1)* is allowed to stand at room temperature for 3 d, the benzo[*b*]-thiophene *(2)*, m.p. 55–56°C, is obtained in quantitative yield. The latter is also formed as side product during the synthesis of *(1)* if the reaction is carried out, or the product worked up, without cooling. Methanolysis of *(1)* furnishes *(3)* as yellow crystals, m.p. 128–130°C in quantitative yield. The structures *(2)* and *(3)* were assigned on the basis of elemental analysis and spectral evidence.

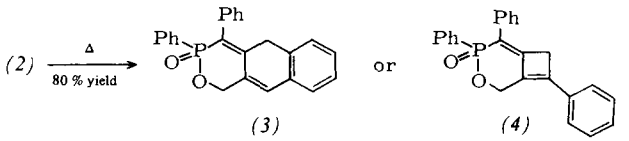
Intramolecular Cycloaddition of a "P=O-Activated" Acetyleneallene Derivative[**]



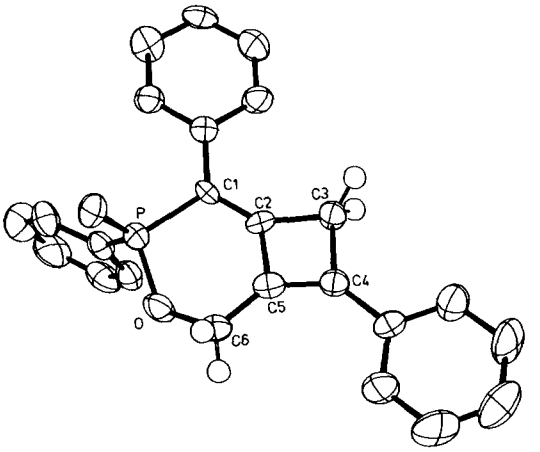
By *Werner Winter, Albert Scheller, Thomas Butters*, and *Walter Holweger*[*]

In an attempt to synthesize the phosphonous diester *(1)* from 3-phenyl-2-propyn-1-ol and dichloro(phenyl)phosphane, instead of obtaining the desired product we isolated the phosphinate *(2)* [column chromatographic purification, yield 65%, yellowish oil; IR: 2250 (C≡C stretching), 1950 and 1920 (typical for allenes), 1220 (P=O), 1020 cm^{-1} (P—O—C); $^{31}P\{^1H\}$-NMR: $\delta=-32.5$ (H_3PO_4 ext., CH_2Cl_2, 36.43 MHz); ^{1}H-NMR: $\delta=7.1$–8.0 (m, 15 arom.H), 5.03 (d, $J_{PH}=21$ Hz, P—OCH_2), 5.00 (s, =C=CH_2); MS: $m/e=370$ (M^+)].

As previous examples have shown, reaction of phosphorus(III) halides with α-hydroxyacetylenes leads to allenic phosphane oxides *via* nucleophilic attack of the phosphorus at the triple bond and subsequent propargyl rearrangement[1]; the formation of *(2)* can be explained analogously. The phosphinate *(2)* is unstable at room temperature and on standing transforms into a yellow strongly fluorescing crystalline isomer. In boiling toluene the transformation is already complete within 1 h. The spectroscopic data for the new compound [m.p. 215 °C; IR: 1195 cm^{-1} (P=O), no allene and acetylene bands; $^{31}P\{^1H\}$-NMR: $\delta=-21.4$ (H_3PO_4 ext., CH_2Cl_2); ^{1}H-NMR: $\delta=3.70$ (m, —CH_2—); 5.20 (m, P—OCH_2), 7.2—8.0 (m, 15 arom.H); ^{13}C-NMR: $\delta=37.4$ (d, —CH_2—, $^3J_{PC}\approx12$ Hz), 63.2 (d, P—OCH_2, $^2J_{PC}\approx8$ Hz), 127—132 (m, arom.C) TMS int.] are consistent with structures *(3)* and *(4)*.

The presence of a s-*trans*-1,4-diphenylbutadiene structural unit follows, above all, from the UV absorption maximum (335 nm, $\log\varepsilon=4.32$, EtOH), calculated according to the

Woodward-Fieser rules[2] to be 329 nm, both for *(3)* as well as *(4)*. Only the X-ray structural analysis[3] of the yellow crystals permits unequivocal decision in favor of structure *(4)* (cf. Fig. 1).



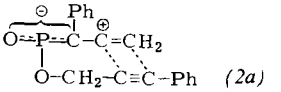


Fig. 1. ORTEP plot of the cycloaddition product *(4)*; the hydrogen atoms of the phenyl rings have been omitted for clarity. The bond lengths in the bicyclic skeleton are: P—C1 1.802(6), P—O 1.605(5), C1—C2 1.35(1), C2—C3 1.54(1), C3—C4 1.55(1), C4—C5 1.36(1), C5—C6 1.48(1), C5—C2 1.46(1), and C6—O 1.49(1) Å.

To our knowledge, the formation of 4-oxo-4,5,8-triphenyl-3,4λ^5-oxaphosphabicyclo[4.2.0]octa-5,8-diene *(4)* constitutes the first example of a spontaneous cycloaddition of non-perhalogenated acetyleneallene components and is reminiscent of the cycloaddition of ketenes with olefins[4].

We assume that the reaction *(2)* → *(4)* is a $[2_s+2_a]$ process on the basis of the following findings: a) the course of the reaction is largely independent of the polarity of the solvent, b) the bonding in the allene moiety of *(2)* appears to resemble that in the active vinylium form of ketenes[5] if a "P=O activated" resonance structure *(2a)* is assumed,

(2a)

and c) in the educt *(2)*, the steric conditions prerequisite for an orthogonal proximation of the terminal allene double bond to the triple bond are optimally fulfilled.

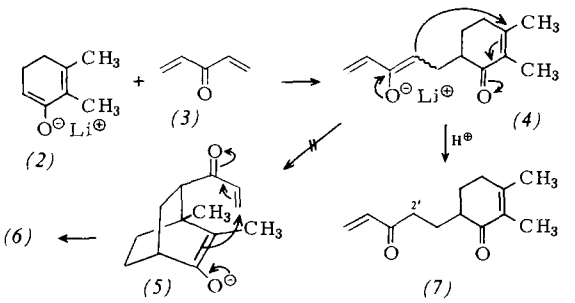
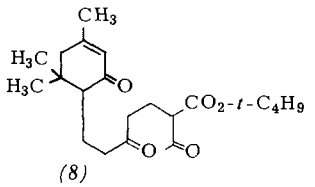
Divinyl Ketone as Michael Acceptor

By *Dietrich Spitzner*[*]



In the course of our investigations on the synthesis of tricyclic sesquiterpenes such as seychellene *(1)* we attempted the preparation of the closely related compound 3,8-dimethyltricyclo[5.3.1.$0^{3,8}$]undecan-2,6-dione *(6)* in one operation *via* three consecutive Michael additions.

(1), X = CH_2
(6), X = O, O on C-6 instead of CH_3 and H



In view of the previous finding that a cyclohexadienolate of type *(2)*, generated under kinetically controlled conditions, reacts with acrylates *via* double Michael addition to give 5-oxobicyclo[2.2.2]octane-2-carboxylates[1], we used instead of an acrylate the potentially divalent Michael acceptor divinyl ketone *(3)*[2].

It is known[3] that in the aprotic Michael addition, polymerization proceeds much faster than the addition reaction with the desired donor. Nevertheless, we obtained a 1:1 adduct (EI-MS: $m/e = 206$, M^+) of *(2)* and *(3)*. Both the IR spectrum [film; 3100 (C=CH_2), 1670 cm^{-1} (enone)] as well as the 270-MHz ^{1}H-NMR spectrum[4] [$CDCl_3$; $\delta = 6.40$—5.81 (ABX, vinyl), 2.72 (t, 2'-H), 2.36 (br. s), 1.89 (br. s, CH_3), 1.75 (br. s, CH_3), several multiplets between 2.36 and 1.55] and especially the ^{13}C-NMR spectrum[4] [$CDCl_3$; $\delta = 200.4$ (two CO groups distinguishable only on addition of Yb(fod)$_3$); 153.6, 136.3, 130.2, 127.8 (olefinic C); 44.6 (CH); 37.0, 31.5, 27.8, 24.3, (CH_2); 21.0, 10.8 (CH_3)] afford proof of formation of *(7)*, *i.e.* that only the first of the three possible additions takes place. Intramolecular secondary additions leading to *(6)* do not occur.

While *(3)* is capable of undergoing double Michael addition under the usual conditions, it reacts with anions such as *(2)* as monovalent acceptor under aprotic conditions, and thus proves to be a possible C-5 synthon for terpene and steroid syntheses. By way of example, an adduct analogously synthesized from *(3)* and isophorone reacts regioselectively with *tert*-butyl acetoacetate under conventional protonic conditions to give the monoadduct *(8)* (55.6 %), which after hydrolysis and decarboxylation can be subjected to further aldol condensation[5].

Trialkylsilyl groups in the α-position[3] of *(3)* should have a pronounced effect on the course of this aprotic Michael addition.

(8)

Experimental:

A solution of *(3)* (1.3 equiv.) in THF is added dropwise at −70 °C in the presence of an inert gas to a tetrahydrofuran solution of *(2)*, prepared from 2,3-dimethyl-2-cyclohexene *(9)* and lithium isopropyl(cyclohexyl)amide[1] (molar ratio 1:1.1). The mixture is stirred at this temperature for 15 min and then neutralized with 1 N HCl and extracted with ether. The oil obtained after drying and concentration of the organic phase is distilled in a bulb tube: After removal of forerunnings (mainly unreacted *(9)*), *(7)* distils over at 90—110 °C/0.03 torr as a pale yellow oil (18 %) which crystallizes on storage in an ice-box.

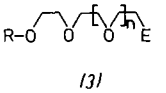
Complexes of Short-Chain Oligo(ethylene Glycol Ethers) Bearing only *One* Rigid Donor End Group[**]

By *Ulrich Heimann* and *Fritz Vögtle*[*]

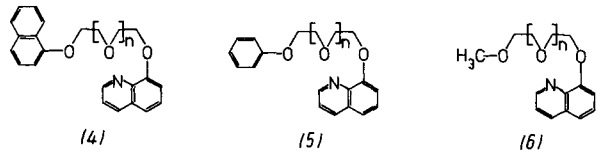
While simple oligo(ethylene glycol dimethyl ethers) such as pentaglyme *(1)*, $n = 3$, are reported[1] not to form crystalline complexes with salts of alkali and alkaline earth metals[2], such complexes are readily obtained with "noncyclic crown ethers" *(2)*, $n \geq 1$, which are rendered rigid by aromatic donor end groups (E)[3].



(1)

(2)

This communication considers whether *a single* donor end group E suffices to permit isolation of crystalline complexes of alkali metal ions. If this is the case, the next question to be answered concerns the minimum length of the oligo(ethylene glycol ether) chain in the limiting case.



(3)

Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn (Germany)

[**] Work supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We found that one end of the oligo ether chain may exhibit less donor strength if the other donor end group E is a strong coordinating one. Thus, in the case of tetra- and hexa-dentate neutral ligands *(4)–(6)* with an 8-quinolyloxy group at one end of the chain and a 1-naphthyloxy, phenoxy, or even methoxy group at the other end, we still obtained crystalline complexes with a series of salts (Table 1). Just one effective end group was also sufficient to permit isolation of crystalline alkali metal ion complexes in the case of *(7)–(9)*.

(4) *(5)* *(6)*

(7) *(8)* *(9)*

The chain segment adjacent to E can enclose the cation in a planar fashion; a second donor end group is apparently not required[4] for formation of crystalline complexes but can nevertheless exert a stabilizing action and, above all, raise the complexation constant[5].

Table 1. Ligands synthesized and their complexes with alkali metal salts.

Ligand [a]	Chain length *n*	Complex [a, b] with	Stoichiometry	m. p. [°C]
(4a)	2	$NaClO_4$	1:1	130–131
(4b)	3	KSCN	1:1	152
(5a)	2	$NaClO_4$	1:1	124–125
(5b)	3	KSCN	1:1 [c]	91– 92
(6a)	1	NaSCN	1:1	142
(6b)	2	$NaClO_4$	1:1	116–118
(6c)	3	KSCN	1:1	88–90
(7a)	2	[d]		
(7b)	3	$NaClO_4$	1:1	99–100
(8a)	2	[d]		
(8b)	3	$NaClO_4$	1:1	73–74
(9a)	2	[d]		
(9b)	3	$NaClO_4$	1:1	102

[a] Correct analytical data and/or high resolution mass spectra were obtained for all ligands and complexes.
[b] All complexes are colorless.
[c] Also contains 0.5 mol of H_2O.
[d] Alkali metal salts complexed; however no simple stoichiometry between ligand and salt could be detected.

Comparison of the ^{1}H-NMR spectra of the naphthol ether *(4a)* and the phenol ether *(5a)* provides information about the arrangement of the ends of the chain carrying no donor group in the complex: while a large upfield shift of the α- and β-quinoline protons is observed on transition from the free ligand to the complex in the case of *(4a)*, only the α-quinoline proton exhibits an upfield shift in the complex of *(5a)*. Since spatial proximity can be assumed between the quinoline and the naphthalene ring and the benzene ring, respectively, the difference can be interpreted as due to the larger anisotropic region of the naphthalene ring. The mutual orientation of the chain ends in the novel complexes and the arrangement of the central ion and the donor centers are being examined by means of X-ray structure analysis[4].

It is possible, by variation of the donor end group E and of the lipophilic chain end, to construct a whole series of ligand/complex topologies. These systems permit almost continuous variation of the balance between lipophilic and hydrophilic properties, and of complex stability constants and complexation kinetics[6]. Such versatility is significant for some potential applications[7].

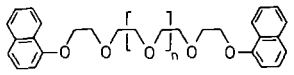
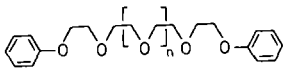
Alkaline Earth Metal Complexes of Simple Oligo(ethylene Glycol Ethers)[**]

By *Heinz Sieger* and *Fritz Vögtle*[*]

This study of the relation between structure and complexation of simple neutral ligands was instigated by the following observations: a) glyme compounds of type *(1)* do not form[1] crystalline alkali metal ion complexes and b) "noncyclic crown ethers" *(2)* bearing rigid donor end groups (Do = donor center in the end group) readily form such complexes[1].



(1) *(2)*



The key question arising from X-ray structure comparisons of several complexes of ligands *(2)*[2] is: how short can the chain be and what is the minimum donating ability of the chain ends required for oligo(ethylene glycol ethers) to still just form crystalline complexes with alkali or alkaline earth metal salts?

Careful crystallization experiments showed that the polyethers *(3)* and *(4)* bearing two donor-free but rigid aryl groups at their ends and containing *at least five* ether oxygen atoms ($n \geq 1$) gave crystalline complexes, especially with alkaline earth metal ions. Some of the complexes, including the alkali metal ion complex of *(3c)*, are listed in Table 1.

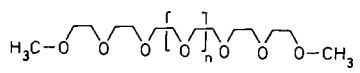
(4)

Table 1. Crystalline alkaline earth and alkali metal ion complexes of the oligo(ethylene glycol ethers) synthesized [6].

Ligand [a]	Abbreviation	Complex [a] with	Stoichiometry [b]	m. p. [°C]
(3a)	$O_5(Naph)_2$	$Ca(SCN)_2 \cdot 4\,H_2O$	[c]	163
(3b)	$O_6(Naph)_2$	$Ba(SCN)_2 \cdot 2\,H_2O$	1:1:1	120
(3c)	$O_7(Naph)_2$	$NaClO_4$	1:1	111
(3d)	$O_8(Naph)_2$	$Ba(SCN)_2 \cdot 2\,H_2O$	1:1:1	117
(4a)	$O_6(Ph)_2$	$Ba(SCN)_2 \cdot 2\,H_2O$	$1:1:\frac{1}{2}$	138–141
(4b)	$O_7(Ph)_2$	$Ba(SCN)_2 \cdot 2\,H_2O$	$1:1:\frac{1}{2}$	135
(4c)	$O_8(Ph)_2$	$Ba(SCN)_2 \cdot 2\,H_2O$	1:1	111–115
(5a)	$O_7(Me)_2$	$Ba(SCN)_2 \cdot 2\,H_2O$	1:1	141–142
(5b)	$O_8(Me)_2$	$Ca(SCN)_2 \cdot 4\,H_2O$	1:2:1	160 (dec.)



[a] Correct analytical data and/or high resolution mass spectra were obtained for all ligands and complexes.
[b] Ligand: salt: H_2O.
[c] This recrystallizable complex gives reproducible values on elemental analysis from which no simple stoichiometry can be deduced.

If the oligooxaalkane chain in *(3)* and *(4)* is shortened to only four oxygen atoms ($n=0$) no crystalline complexes are obtained—in accord with *Pedersen*'s findings[5a].

Solid/liquid phase transfer of permanganate and liquid/liquid phase transfer of picrate[3] by ligands with donor-free chain ends in organic phases is considerably less pronounced than in the case of ligands *(2)* having two donor end groups. A corresponding effect is noted with the complex stabilities of the neutral ligands *(3)* and *(4)*[4].

Formation of a pseudocyclic compound or a helix during complexation of the weak ligands *(3)* and *(4)* in solution can be deduced from the upfield shift of the signals of the aromatic and aliphatic protons in the ^{1}H-NMR spectrum ($CDCl_3$). With a sufficiently long chain (six CH_2CH_2O units) the complexation is recognizable only from the upfield shift of the aliphatic CH_2 groups.

Encouraged by the discovery that short-chain oligo(ethylene glycol diaryl ethers) *(3)* and *(4)* ($n \geq 1$) form crystalline alkaline earth metal ion complexes, we examined complex formation with the well known oligo(ethylene glycol dimethyl ethers) *(1)* (glymes)[3]. In spite of repeated attempts[5], no crystalline complexes of alkali and alkaline earth metal ions could so far be isolated. It is therefore highly surprising that we have now obtained crystalline complexes of heptaglyme and even hexaglyme [with $Ca(SCN)_2$ and $Ba(SCN)_2$]; relevant data are listed in Table 1.

(5)

Although they have low complexation constants, the oligo(ethylene glycol diaryl and dialkyl ethers) *(3)*, *(4)*, and *(5)* are of interest *e.g.* for microelectrode systems[1] owing to their expected high selectivity[4] towards ions of alkali and alkaline earth metals. The ligands *(3)*–*(5)* indicate a borderline of complexation as regards crystallization of the complexes; however, they also number among the simplest ligand systems on reducing the chain length. Isolation of the new complexes shows that glymes not only "interact" with solvents and cations (solvation-association effects)[3] but also form defined complexes whose study seems to be fundamental.

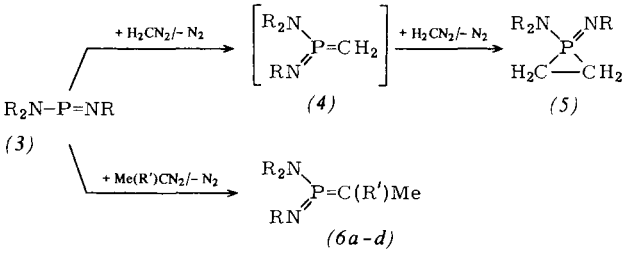
Novel Diylides Containing Tricoordinate Phosphorus[**]



By *Edgar Niecke* and *Dirk A. Wildbredt*[*]

In contrast to the classical phosphorus ylides, the methylenephosphoranes *(1)*, compounds of tricoordinate λ^5-phosphorus containing a PC double bond[1] *(2)* have hitherto only been postulated as unstable intermediates[2].

(1) (2)

Thus the intermediacy of the methylenephosphorane *(4)* in the reaction of bis(trimethylsilyl)aminotrimethylsilyliminophosphane *(3)* with diazomethane was suggested merely by orientionally specific cycloaddition to form the λ^5-phosphirane *(5)*[2b]. We have now been able to isolate the homologous aminoiminomethylenephosphoranes *(6a–d)* by subjecting α-alkylated diazoethanes to this reaction.

R = $SiMe_3$
R' = Me*(a)*, CH_2Me*(b)*, $CHMe_2$*(c)*, CMe_3*(d)*

The new compounds *(6)* of tricoordinate λ^5-phosphorus with two different ylidic centers are colorless thermally stable liquids which are largely resistant to atmospheric moisture.

PCR′	19.70 (12.5)	25.72 (13.1)	29.00 (13.6)	34.67 (9.7)
		14.17 (14.2)	21.69 (13.5)	30.71 (11.0)

[a] 30% solution in CH_2Cl_2 (^{31}P, ^{1}H) or 60% solution in $CDCl_3$ (^{13}C), with H_3PO_4 as external (^{31}P) or TMS as internal standard (^{1}H, ^{13}C), 25°C. [b] On the basis of the rotational barriers of the PC double bonds, positional isomers are present in the ratios 2:1 *(6b)*, 5:1 *(6c)*, >10:1 *(6d)*; the reported data apply to the preferred isomer.

The coordination number 3 at the phosphorus atom is apparent from the downfield shift of the ^{31}P-NMR signal on going from *(1)* to *(6)* and the deshielding of the ^{31}P nucleus as compared with correspondingly substituted bis(imino)phosphoranes (δ = 45–55)[5].

In the ^{1}H- and $^{13}C\{^{1}H\}$-NMR spectra[6], the signals of the trimethylsilylimino group and of the methylene carbon atom exhibit double splitting as a result of interaction with only one phosphorus atom. Noteworthy is the chemical shift for the sp^2-hybridized carbon (δ value *ca.* 80), which indicates a lower electron density at the carbanionic center [(p–p)π bonding contribution] of *(6)* compared with that of *(1)*. Owing to the different hybridization of the phosphorus atom in *(6)* and in *(1)* it cannot be said how reliably the large magnitude of $^{1}J_{CP}$ (>200 Hz) can be regarded as indicating only slight polarity of the phosphorus-carbon double bond.

Examination of molecular models underlines the importance of steric effects in the stabilization of coordinatively unsaturated phosphorus in *(6)*; such effects also explain the kinetic inhibition of the [2+2] cycloadditions *(6)*→*(7)* and *(6)*→*(8)*. Steric constraints likewise preclude a [2+1] cycloaddition on further reaction with diazoalkane in analogy to *(4)*→*(5)*. Instead, the adduct *(10)* is formed; the iminophosphoranes *(10a,d)*[7] may be formed from the intermediate zwitterions *(9a,d)*.

Experimental

A solution of diazoalkane $Me(R')CN_2$[8] [*(a)–(c)* in diethyl ether, *(d)* in tetrahydrofuran] cooled to −40°C is added dropwise to ice-cooled, stirred bis(trimethylsilyl)aminotrimethylsilyliminophosphane *(3)* (8.0 g, 29 mmol) until the reaction solution turns pink. Stirring is continued for 1 h at room temperature, the solvent is removed *in vacuo*, and the residue purified by fractional distillation. The procedure yields 7.5 g (80%) of *(6a)*, 5.0 g (55%) of *(6b)*, 8.5 g (85%) of *(6c)*, or 8.3 g (80%) of *(6d)*.

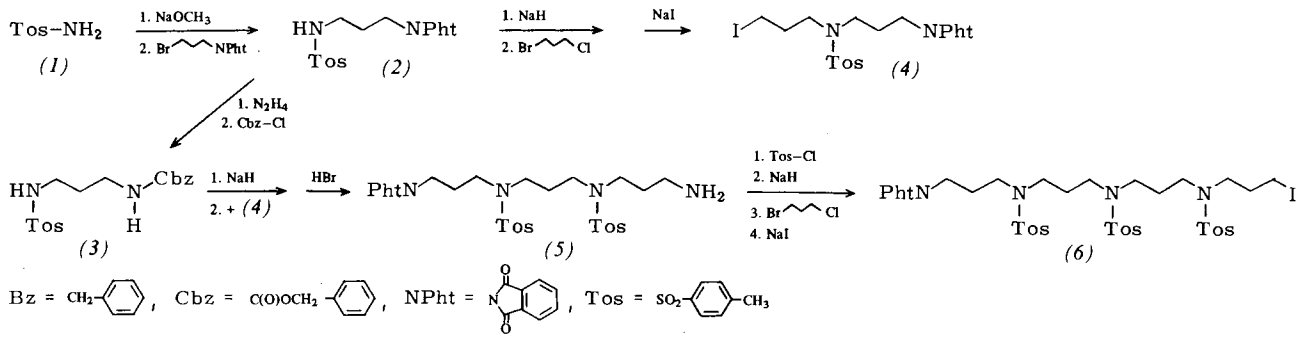
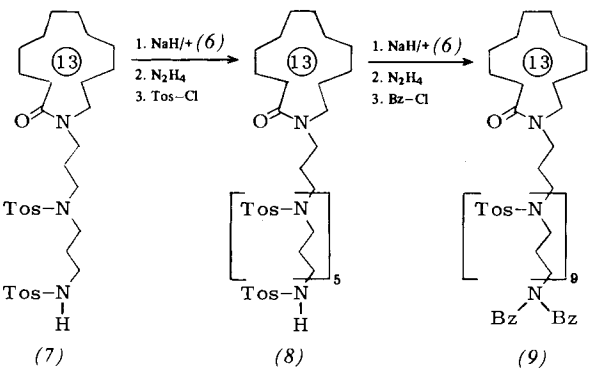
Use of the "Zip" Reaction for the Synthesis of a 53-Membered Polyaminolactam[1]



By *Urs Kramer, Armin Guggisberg, Manfred Hesse*, and *Hans Schmid* (deceased)[*]

We recently reported the ring expansion of a 13-membered lactam with a 3-aminopropyl substituent linked to nitrogen to give a 17-membered aminolactam[2]. If two such ring-expansion units combined as 7-amino-4-azaheptyl substituent are linked to the nitrogen atom, ring expansion to a 21-membered diaminolactam is possible[2]. In order to check whether this reaction can be generalized—*i.e.* whether any desired number of ring-expansion units linked together can be used for the construction of even larger rings—we chose as our new goal the synthesis of the 53-membered ring *(11)*. Other than in previous experiments (stepwise method: repeated addition of acrylonitrile followed by catalytic hydrogenation)[2] we decided to use the "fragment condensation method". As primary building block we used *(6)*, prepared according to Scheme 1: Alkylation of the sodium salt of *p*-toluenesulfonamide *(1)*

[*] Prof. Dr. M. Hesse, Dipl.-Chem. U. Kramer, A. Guggisberg, Prof. Dr. H. Schmid (deceased)
Organisch-chemisches Institut der Universität
Rämistrasse 76, CH-8001 Zürich (Switzerland)



with *N*-(3-bromopropyl)phthalimide affords the trimethylenediamine derivative *(2)* (55 % yield). *(2)* can be converted, on the one hand, into 7-iodo-1-phthalimido-4-tosyl-4-azaheptane *(4)* (79 %) by alkylation with 1-bromo-3-chloropropane/NaH and subsequent treatment with NaI, or on the other, into *(3)* (71 %) by hydrazinolysis and benzyloxycarbonylation. Coupling of *(3)* and *(4)* with NaH and cleavage of the benzyloxycarbonyl group with HBr/glacial acetic acid affords *(5)* (96 %), whose tosylation, alkylation with 1-bromo-3-chloropropane/NaH and subsequent treatment with NaI leads to the 15-iodo-1-phthalimido-4,8,12-tritosyl-4,8,12-triazapentadecane *(6)* in 87 % yield.

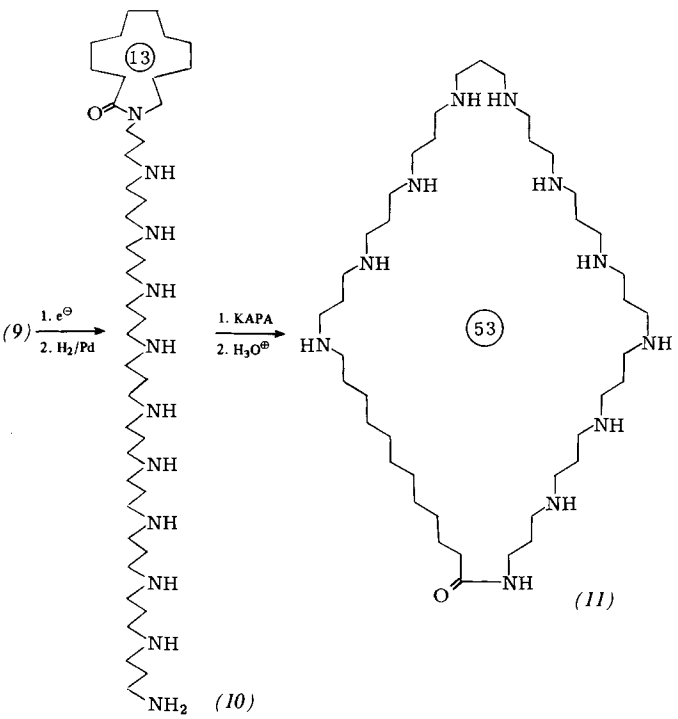
Scheme 1

The previously reported[3] ditosyllactam derivative *(7)* can be alkylated with *(6)* (Scheme 2), and on subsequent hydrazinolysis and tosylation is converted into *(8)* (61 %). Further alkylation, of the sodium salt of *(8)*, with *(6)* yields a nonatosylphthalimide, whose molecular weight has been determined by addition (alkali-metal ion) field desorption mass spectrometry[4a] to be $[M+Na]^+ = 2310 \pm 6$ (calcd. 2306)[4b,c]. Hydrazinolysis and benzylation [phase transfer reaction: benzyl chloride and benzyl(trimethyl)ammonium hydroxide in H_2O/CH_2Cl_2] of this intermediate affords the derivative *(9)* (68 %). Electrolytic detosylation[5] of *(9)* to the *N*,*N*-dibenzylamine (FD-MS of the hydrochloride: $[M+1]^+ = 948$[4c]) and subsequent hydrogenolysis yields 1-(39-amino-4,8,12,16,20,24,28,32,36-nonaazanonatriacontyl)-1-azacyclotridecan-2-one *(10)* (FD-MS of the free base: $[M+1]^+ = 768$[6]).

Scheme 2

Treatment of *(10)* with potassium (3-amino)propylamide/1,3-diaminopropane (KAPA[7]; 45 min) and acidic workup leads to the 1,5,9,13,17,21,25,29,33,37,41-undecaazatripentacontan-42-one *(11)* in 38 % yield (Scheme 3); FD-MS of the hydrochloride: $[M+1]^+ = 768$[4c], of the *N*-decaacetyl compound: $[M+Na]^+ = 1210$[6]; total yield of *(11)* w.r.t. *(2)*: 7.5 %. The low yield of the last step compared to other transamidation reactions[2] is due to the formation of side-products in the transamidation[3,8] and losses during purification of the extremely polar reaction product.

The above compounds were characterized by IR and mass spectra [*(1)* to *(5)*, *(7)*, *(8)*] and, in part, by ^{1}H-NMR spectra; their purity was confirmed by TLC and elemental analysis.



The macrocycle *(11)* differs from the isomeric educt *(10)* in its spectroscopic and TLC properties in the same way as the structurally related 21- and 33-membered polyaminolactams differ from their isomeric precursors[2,9]:

a) In the TLC analysis [silica gel (Merck); $CHCl_3/CH_3OH$/25 % ammonia = 3:5:3] a larger R_f value is found for *(11)* than for *(10)*, while the corresponding *N*-acetyl derivatives show exactly the opposite chromatographic properties ($CHCl_3/CH_3OH = 1:1$).

b) In the Fluram test[10] for primary amines, *(10)* shows a strong bright green fluorescence at 360 nm, while *(11)*, containing only secondary amino groups, does not fluoresce.

c) The IR spectrum ($CHCl_3$) of *(10)* is characterized by a band at 1620 cm^{-1} (*N*,*N*-disubstituted amide), that of *(11)* by amide I and amide II bands at 1660 and 1515 cm^{-1} (*N*-monosubstituted).

Scheme 3

As could be shown in investigations on model compounds[3], the transamidation of *(10)* to *(11)* proceeds as a "zip" reaction[2], *via* stepwise attack of a *N,N*-disubstituted amine nitrogen at the lactam carbonyl carbon, with successive formation and opening of a six-membered ring, and ring expansion by four members. The end product is the resonance stabilized amide anion (with enclosure of the terminal amino group). Our findings show that the "zip" reaction can be used for the synthesis of macrocycles of any desired size containing the structural element $-(CH_2)_3-N-$.

Anodic NN Linkage by Oxidation of Anions of Primary and Secondary Amines[**]

By *Reinhold Bauer* and *Hartmut Wendt*[*]

The preparation of hydrazine or substituted hydrazines by anodic oxidation of ammonia or alkyl- and aryl-amines usually gives only very poor yields. The reason for this is that hydrazines are generally more readily oxidized than amines and are therefore largely decomposed if formed at the anode.

Grinstead[1] has shown that anodic oxidation of the imidodisulfate ion affords the hydrazinetetrasulfonate ion.

We have now found that amide ions *(1)* can be oxidized at potentials that lie about 1 V lower than those of amines. Pertinent data are listed in Table 1, which also shows that the anodic halfwave potential of the tetraalkylhydrazines *(3a)* lies between those of the corresponding amines and amide ions. This is one of the conditions for preparation of hydrazines by anodic oxidation of amine anions.

The anodic polarograms of the amide ions *(1)* reveal irreversible 1e steps. This suggests that anodic oxidation of *(1)* generates the aminyl radicals *(2)*, which then dimerize to the hydrazines *(3)*.

$$\underset{(1)}{R^1R^2N^{\ominus}} - e^{\ominus} \longrightarrow \underset{(2)}{R^1R^2N^{\bullet}} \qquad \begin{matrix}(a)\text{: } R^1 = R^2 = \text{Alkyl} \\ (b)\text{: } R^1 = \text{Alkyl},\ R^2 = H\end{matrix}$$

$$2\ R^1R^2N^{\bullet} \longrightarrow \underset{(3)}{R^1R^2N{-}NR^2R^1}$$

Potentiostatically controlled oxidation of lithium dibutylamide at Pt anodes in tetrahydrofuran does indeed produce tetrabutylhydrazine in 45% current yield (cf. Table 2).

Table 1. Anodic halfwave potentials of primary and secondary alkylamines and their anions in tetrahydrofuran at C electrodes ($E_{1/2}$ [mV] *versus* saturated calomel electrode).

R^1	R^2	R^1R^2NH	R^1R^2NLi	$R^1R^2NNR^2R^1$
n-C_4H_9	H	+1150	−160	—
cyclo-C_6H_{11}	H	+1260	+ 50	—
t-C_4H_9	H	+1210	− 95	—
n-C_4H_9	n-C_4H_9	+ 940	−120	+300

Table 2. NN coupling products on anodic oxidation of anions of primary and secondary amines.

R^1	R^2	Product	Anode potential [a] [mV]	Yield [b] [%]
n-C_4H_9	H	Azobutane	+300	33 (38)
cyclo-C_6H_{11}	H	Azocyclohexane	+300	23 (26)
t-C_4H_9	H	2,2'-Azoisobutane	+300	25 (31)
n-C_4H_9	n-C_4H_9	Tetrabutylhydrazine	+ 50	38

[a] *Versus* aqueous saturated calomel electrode.
[b] Yields after workup; values in parentheses determined by gas chromatography (3% SE-30 on Varaport 30).

In contrast, the anions of primary alkylamines *(1b)* yield the azoalkanes *(4)*. We explain this observation by assuming that the hydrazines *(3b)* which have lower pK values than the amines are transformed, in the presence of excess amide ions, into the readily oxidizable hydrazide ions and thence oxidized to the azoalkanes *(4)*.

$$2\ RHN^{\ominus} - e^{\ominus} \longrightarrow 2\ RHN^{\bullet} \longrightarrow \underset{(3b)}{RHN{-}NHR}$$

$$(3b) + RHN^{\ominus} \longrightarrow RHN{-}NR^{\ominus} + RH_2N$$

$$RHN{-}NR^{\ominus} - 2\ e^{\ominus} + RHN^{\ominus} \longrightarrow \underset{(4)}{RN{=}NR} + RH_2N$$

Experimental

The anodic syntheses are performed under N_2 as protective gas.

Lithium cyclohexylamide (0.02 mol), prepared in a divided electrolysis cell with a Pt anode and a Pt cathode by reaction of cyclohexylamine with an equivalent amount of n-butyllithium at −30°C, is electrolyzed in an electrolyte consisting of anhydrous tetrahydrofuran (100 ml) and lithium perchlorate (5.3 g) at −10°C at a controlled potential (Table 2). After consumption of 0.04 F the solution is neutralized with acetic acid and, after removal of solvent, azocyclohexane is isolated from polymeric products and supporting electrolyte by extraction with n-hexane. Purification is accomplished by column

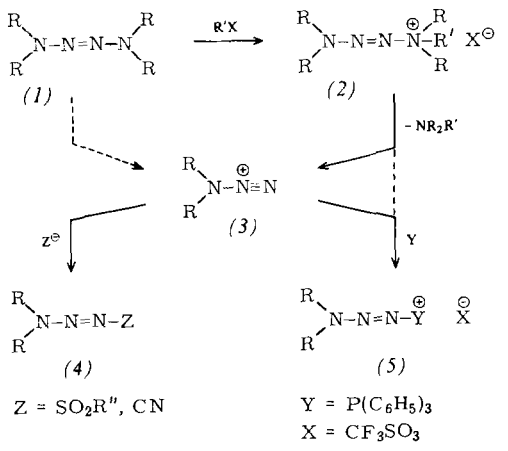
Triazene Transfer with Activated 2-Tetrazenes[1]



By *Ernst Stöldt* and *Richard Kreher*[*]

Tetraalkyl-2-tetrazenes *(1)*[2], which exhibit relatively high thermal stability, fragment in the presence of electrophiles [protic and Lewis acids, triethyloxonium and nitrosyl tetrafluoroborate[3a], alkylating and acylating reagents, ketenes, and isocyanates[3b]]. Electrophilic attack at the terminal dialkylamino group leads to an activated onium intermediate *(2)* from which the positively charged leaving group and the preformed N_2 molecule are generally eliminated. Intermediate formation of *N*-diazonium ions *(3)* should be detectable by competitive trapping reactions with nucleophiles[4]. The preparative consequence of this reaction sequence is transfer of a triazene group by activated 2-tetrazenes *(2)*.

Electrophilic alkylation of tetramethyl-2-tetrazene *(1)*, R = CH_3, affords isolable pentaalkyltetrazenium salts *(2)* with R' = CH_3, C_2H_5. Reaction with methyl iodide gives crystalline *(2a)*[5] whose structure was established by analysis and spectroscopy. Replacement of the halogen atom by the complex tetraphenylborate anion gives a relatively stable tetrazenium salt *(2b)*, while the explosive salt *(2c)* is formed with triethyloxonium tetrafluoroborate. Considerable advantages are offered by methylation of the tetrazene *(1)* with methyl trifluoromethanesulfonate to give the spectroscopically characterized trifluoromethanesulfonate *(2d)*, which can be used directly for triazene transfer.

The reaction of pentaalkyltetrazenium salts *(2)* with anionic nucleophiles [Z = arenesulfinate] always leads to exchange of the trialkylammonium group. This provides a preparative entry to sulfonyltriazenes *(4)*[6]; the reaction with cyanide proceeds analogously to give 1-cyano-3,3-dimethyltriazene *(4)*, Z = CN. These transformation products result formally from a coupling reaction of the *N*-diazonium ion *(3)* with the anionic nucleophile. Available evidence is insufficient for an unequivocal decision between the mechanistic alternatives—two-step S_N reaction of the activated tetrazenium ion *(2)* or dissociation reaction *via* the electrophilic intermediate *(3)*.

On reaction of *(2)* with neutral nucleophiles [triphenylphosphane], replacement of the trialkylammonium group affords the remarkably stable onium salts *(5)*; the triazene structure is again retained. An analogous transfer reaction is possible with the tetrazene *(1)* after activation with acetyl chloride.

2-Tetrazenium salts *(2)*, R = CH_3 [8]

(2a), R' = CH_3 and X = I, yield 60%, m.p. 64–65 °C (dec.) (precipitated from *n*-pentane); ^{1}H-NMR ($CDCl_3$, −30 °C): τ = 6.35 (s, CH_3), 6.40 (s, $3CH_3$), 6.77 (s, CH_3).—*(2b)*, R' = CH_3 and X = $(C_6H_5)_4B$, yield 62%, m.p. 89–91 °C (dec.) (ethanol, ether); ^{1}H-NMR (CD_3NO_2, −5 °C): τ = 2.63 (mc, 8CH aromatic), 3.02 (mc, 12CH aromatic), 6.57 (s, CH_3), 6.83 (s, $3CH_3$), 6.90 (s, CH_3).—*(2c)*, R' = C_2H_5 and X = BF_4, yield 57%, m.p. 34–35 °C (dec.) (dichloromethane); ^{1}H-NMR ($CDCl_3$, −30 °C): τ = 6.27 (q, *J* = 7.5 Hz, NCH_2), 6.41 (s, CH_3), 6.69 (s, $2CH_3$), 6.78 (s, CH_3), 8.61 (t, *J* = 7.5 Hz, CCH_3).—*(2d)*, R' = CH_3 and X = CF_3SO_3, explosive decomp. at *ca.* 0 °C; ^{1}H-NMR ($CDCl_3$, −40 °C): τ = 6.45 (s, CH_3), 6.63 (s, $3CH_3$), 6.83 (s, CH_3).

1-Arenesulfonyl-3,3-dimethyltriazenes *(4)*, R = CH_3 and Z = SO_2R''

(4a), R'' = C_6H_5, yield 78%, m.p. 89 °C (ethanol); ^{1}H-NMR ($CDCl_3$): τ = 2.08 (mc, 2CH aromatic), 2.47 (mc, 3CH aromatic), 6.44 (s, CH_3), 6.78 (s, CH_3).—*(4b)*, R'' = *p*-$CH_3C_6H_4$, yield 92%, m.p. 145–146 °C (ethanol); ^{1}H-NMR ($CDCl_3$): τ = 2.19 (d, *J* = 8.5 Hz, 2CH aromatic), 2.72 (d, *J* = 8.5 Hz, 2CH aromatic), 6.47 (s, CH_3), 6.82 (s, CH_3), 7.61 (s, CH_3).—*(4c)*, R'' = *p*-$NO_2C_6H_4$, yield 89%, m.p. 189–190 °C (dec.) (ethanol); ^{1}H-NMR ($CDCl_3$): τ = 1.70 (mc, 4CH aromatic), 6.36 (s, CH_3), 6.70 (s, CH_3).—*(4d)*, R'' = *p*-$CH_3OC_6H_4$, 50%, m.p. 121 °C (ethanol); ^{1}H-NMR ($CDCl_3$): τ = 2.15 (d, *J* = 9.0 Hz, 2CH aromatic), 3.03 (d, *J* = 9.0 Hz, 2CH aromatic), 6.13 (s, CH_3), 6.45 (s, CH_3), 6.79 (s, CH_3).—*(4e)*, R'' = *p*-$CH_3CO{-}NH{-}C_6H_4$, yield 78%, m.p. 181 °C (dec.) (methanol); ^{1}H-NMR (D_6-DMSO): τ = −0.25 (s, br, NH), 2.22 (s, 4CH aromatic), 6.45 (s, CH_3), 6.82 (s, CH_3), 7.89 (s, CH_3).

1-Cyano-3,3-dimethyltriazene

(4), R = CH_3 and Z = CN, yield 73%, m.p. 33 °C, (diethyl ether/*n*-pentane); ^{1}H-NMR ($CDCl_3$): τ = 6.33 (s, CH_3), 6.72 (s, CH_3); IR (film): $\tilde{\nu}$ = 2195 cm^{-1} (CN); UV (dichloromethane): λ_{max} = 268 nm ($\log\varepsilon$ = 4.14).

1-Triphenylphosphonio-3,3-dimethyltriazenetrifluoromethanesulfonate

(5), R = CH_3, yield 58%, m.p. 179–180 °C (ethanol); ^{1}H-NMR ($CDCl_3$): τ = 2.27 (mc, 15CH aromatic), 6.15 (s, CH_3), 6.33 (s, CH_3).

Triazene transfer can be accomplished directly with tetramethyl-2-tetrazene *(1)* on reaction with *p*-toluenesulfinic acid in a two-phase medium. An independent route to 3,3-dimethyl-1-tosyltriazene *(4b)* is opened by the reaction of diethyl phosphate *N',N'*-dimethylhydrazide with *N,N*-ditosylhydroxylamine[7] which can act as a nitrosation agent and as a precursor for arenesulfinate ions in the presence of triethylamine. This reaction scheme probably involves intermediates similar to those occurring in the transformation of activated tetrazenium ions *(2)*.

Facile Synthesis of Functionally Substituted Cyclopentenones and Butenolides from Functional Vinyl Carbanions[1]

By *Richard R. Schmidt* and *Jörg Talbiersky*[*]

Functional cyclopentenones and butenolides are of considerable importance as synthons in the chemistry of natural products. Numerous approaches to their synthesis have already been developed[2].

A new facile route starts from ethyl β-(1-pyrrolidinyl)acrylate *(1)*[3], which is transformed almost quantitatively into the β-alkoxycarbonylvinyllithium derivative *(2)* in a kinetically controlled reaction with *tert*-butyllithium below −100 °C. Surprisingly, under these conditions *(1)* hardly undergoes Michael addition and does not react at the ester group. Thus a functionalized C_3 synthon becomes accessible which has good nucleophilic and electrophilic properties. For this reason, ring closures with polar multiple bond systems which proved difficult or impossible with the vinyllithium derivative *(5)* described previously[4] should proceed readily. This is confirmed by the following reactions.

Reaction of *(2)* with α,β-unsaturated carbonyl compounds leads to functionalized 2-cyclopenten-1-ones *(3)* [cf. Table 1]. It should be noted in particular that Michael additions to the CC double bond of the β-aminoacrolein derivatives [products *(3c)* and *(3d)*] can be accomplished with the reagent. Equally surprising is the scope of the reaction of *(2)* with carbonyl compounds as hetero-multiple bond systems. Cyclizations to give the functionalized 2-buten-4-olides *(4)* are observed not only with aldehydes but also with normal esters [Table 1]. Thus the β-ethoxycarbonylvinyllithium derivative *(2)* proves to be a readily accessible equivalent of cyclopropenone, which is known to yield [3+2] cycloadducts by insertion of multiple bond systems—formally *via* the zwitterion *(6)*[5].

Table 1. Products of type *(3)* or *(4)* [a].

Experimental

Compound *(1)* (0.68 g, 4 mmol) is dissolved under N_2 in anhydrous tetrahydrofuran (50 ml). To this solution, cooled to −113 °C, is added dropwise a solution of *tert*-butyllithium in *n*-pentane (3 ml, 5.1 mmol; *ca.* 1.7 M solution). After 15 min the olefin or carbonyl compound (8 mmol) is added[6]. The solution is rapidly warmed to room temperature and stirred for a further 3 h[7]. After workup with water/chloroform, the dried (Na_2SO_4) $CHCl_3$ extract is evaporated down in a water-pump vacuum and the crude product is fractionated in a bulb tube [*(4a)*], recrystallized from ethyl acetate/light petroleum [*(4b)*], or chromatographed over silica gel. Eluent: ethyl acetate [*(3d)*, *(4e)*], benzene/acetone 7:3 [*(3c)*], ethyl acetate/light petroleum (low) 12:4 [*(4a)*], 10:2 [*(3e)*], ethyl acetate/methanol/light petroleum 7:1:14 [*(3a)*, *(3b)*].

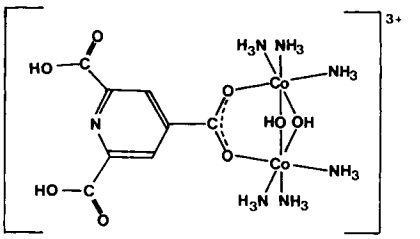
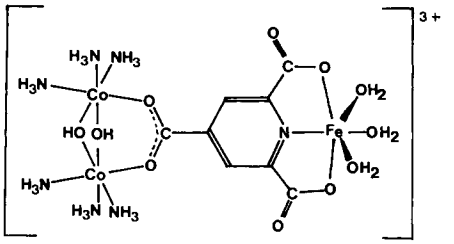
Intramolecular Electron Transfer from Iron(II) to Cobalt(III) through 2,4,6-Pyridinetricarboxylate as Mediating Bridging Ligand[**]



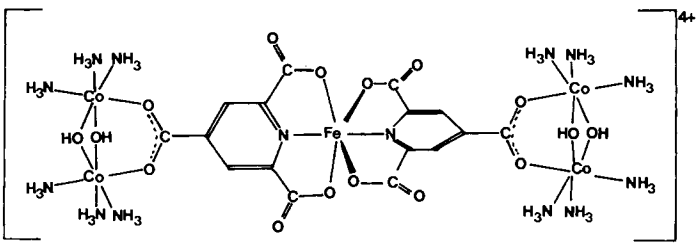
By *Horst Bertram* and *Karl Wieghardt*[*]

First order rate constants of electron transfer (ET) between two metal ions occurring within an encounter complex[1] or a true precursor complex[2] (inner-sphere reactions) have been determined by kinetic studies on redox reactions in only few cases. The activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of these intramolecular processes are considered to be important for further development of the theory of ET reactions[3].



The red dinuclear Co^{III} complex *(1)* reacts with an excess of colorless $[Fe(OH_2)_6]^{2+}$ in O_2-free solutions of perchloric acid ($[H^+]=0.05$ to 1.0 mol/l) to form the violet 1:1 complex *(2)*:

$$(1)+[Fe(OH_2)_6]^{2+} \rightleftharpoons (2)+3H_2O+2H^+ \qquad (a)$$



The absorption spectrum of *(2)* shows a maximum at $\lambda_{max}=525$ nm, $\varepsilon=900$ l/mol cm. Solutions of *(2)* can be stored for several hours at 25 °C without decomposition; *no* reduction of Co^{III} takes place with concomitant oxidation of Fe^{II}.

$[(Co^{III})_2]^{3+}$ *(1)*

$[(Co^{III})_2 Fe^{II}]^{3+}$ *(2)*

$[(Co^{III})_2 Fe^{II}(Co^{III})_2]^{4+}$ *(3)*

At higher pH values (4 to 7) and with an excess of *(1)*, however, an intensely violet 2:1 complex is formed which probably has the structure *(3)* ($\lambda_{max}=557$ nm, $\varepsilon=2350$ l/mol cm):

$$(2)+(1) \overset{K}{\rightleftharpoons} (3)+3H_2O+2H^+ \qquad (b)$$

Complex *(3)* decomposes by a first-order process to form one Co^{II} and one Fe^{III} ion per complexed cation *(3)*:

$$[(Co^{III})_2Fe^{II}(Co^{III})_2]^{4+} \xrightarrow{k_{et}} [Co^{II}Co^{III}Fe^{III}(Co^{III})_2]^{4+} \qquad (c)$$

The kinetics of the reaction was measured using pseudo-first order conditions with an excess of *(1)* in a phthalic acid buffer (pH 5.5, ionic strength 0.04 mol/l) (Fig. 1). The dependence of the rate constant k_{obs} [s^{-1}] upon the complex concentration $[(Co^{III})_2]$ at constant $[H^+]$ can be described by equation (d), derived formally for a mechanism according to eq. (b) and (c):

$$k_{obs}=\frac{k_{et}K[(Co^{III})_2]}{1+K[(Co^{III})_2]} \qquad (d)$$

When $K\cdot[(Co^{III})_2] \gg 1$, the reaction rate is independent of $[(Co^{III})_2]$ and $k_{obs}=k_{et}$.

Figure 1 shows that this condition is fulfilled for $[(Co^{III})_2] \geq 5\times10^{-4}$ mol/l and pH = 5.5 in the temperature range investigated. The intramolecular ET rate constant k_{et}

[*] Prof. Dr. K. Wieghardt, Dipl.-Chem. H. Bertram
Insitut für Anorganische Chemie der Technischen Universität
Callinstrasse 9, D-3000 Hannover 1 (Germany)
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

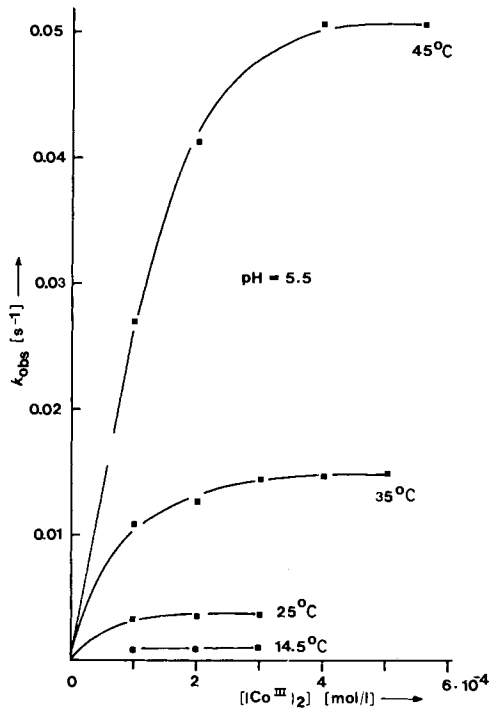


Fig. 1. Dependence of the rate constant k_{obs} on the concentration of complex *(1)* ($[Fe(OH_2)_6^{2+}] = 0.2 \times 10^{-4}$ mol/l, pH = 5.5 (phthalic acid buffer), ionic strength = 0.04 mol/l).

was determined at 14.5 (0.8×10^{-3}), 25 (3.7×10^{-3}), 35 (14.6×10^{-3}), and 45 °C ($50.7 \times 10^{-3}\,s^{-1}$). The activation parameters are calculated as $\Delta H^{\neq} = 24.0 \pm 0.2$ kcal/mol, $\Delta S^{\neq} = 11 \pm 1$ cal/mol K.

The proposed mechanism is substantiated by the following experiment: the change in absorption ($\lambda = 540$ nm) of a solution of *(1)* and $[Fe(OH_2)_6]^{2+}$ in the ratio of 2:1 plotted as a function of pH shows (Fig. 2) that formation of complex *(3)* is complete at pH > 4.5. A plot of the rate constant k_{obs} *versus* the pH value of the same solution follows as parallel course: a limiting value ($3.9 \times 10^{-3}\,s^{-1}$) is reached at pH 4.5 which corresponds to the value of k_{et} for decomposition of *(3)*; at low pH values k_{obs} becomes zero.

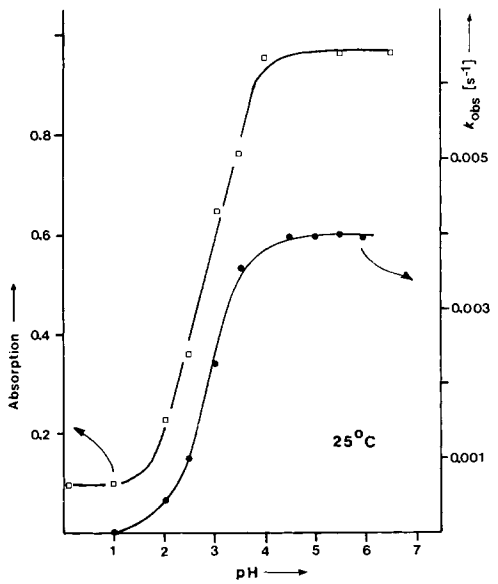

Fig. 2. a) Dependence of the absorption at $\lambda = 540$ nm of a solution of *(1)* (2×10^{-4} mol/l) and $[Fe(OH_2)_6]^{2+}$ (1×10^{-4} mol/l) on the pH value at 25 °C (□); b) dependence of the rate constant of decomposition of *(3)*, k_{obs}[s^{-1}], in the same solution, on the pH value at 25 °C (●).

In structures *(2)* and *(3)* the redox-active metal ions Fe^{II} and Co^{III} are separated by about 860 pm by the organic ligands; there is no experimental evidence for direct interaction between the two centers. Now *(2)* is redox-inactive whereas *(3)* undergoes intramolecular electron transfer yielding Co^{II} and Fe^{III} (an intermolecular decomposition of *(3)* by an outer-sphere process is not consistent with the observed kinetics). The reducing action of Fe^{II} in the coordination of *(2)* is apparently insufficient to put an electron into the LUMO of the organic ligand. This mechanism only becomes possible on further coordination of *(2)* with *(1)* ("chemical" or radical ion mechanism[3]).

Thus electron transfer proceeds through the organic ligand, which may be reduced, thereby generating a transient radical cation[4, 5]:

$$(3) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [(Co^{III})_2\text{—}\dot{L}^{-}\text{—}Fe^{III}(Co^{III})_2]^{4+} \xrightarrow{k_2} \text{Products} \qquad \text{(e)}$$

($\dot{L}$ = reduced pyridinetricarboxylate ligand)

The observed rate constant k_{et} can represent two limiting cases if the reaction proceeds according to (e): if k_{-1} is much greater than k_2, the $k_{et} = K_1 \cdot k_2$ ($K_1 = k_1/k_{-1}$). In contrast, if k_2 is greater than k_{-1}, then $k_{et} = k_1$, *i.e.* formation of the radical cation is rate determining. No decision is yet possible as to which of the two alternatives is actually encountered.

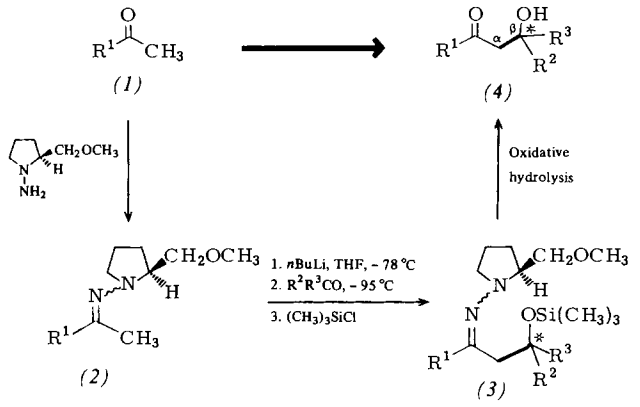
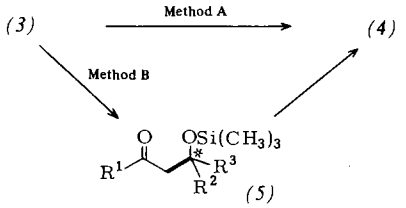
Regiospecific and Enantioselective Aldol Reactions[**]



By *Herbert Eichenauer, Edgar Friedrich, Werner Lutz*, and *Dieter Enders*[*]

The aldol reaction[1] is one of the basic methods for CC linkage and its intramolecular version one of the principal techniques for preparing five- and six-membered rings. The synthetic utility of intermolecular aldol reactions has hitherto been limited by side reactions. While directed[2] and regiospecific[3] aldol reactions have meanwhile been developed, there are still no generally applicable diastereo-[4] and enantioselective procedures available[5].



We now report the first regiospecific and enantioselective aldol reactions *(1)* → *(4)*. The ketones *(1)* are first transformed into the chiral hydrazones *(2)*[6], metalated with *n*-butyllith-

ium in tetrahydrofuran, treated at −95 °C with carbonyl compounds, and the resulting adducts silylated by chlorotrimethylsilane to form the doubly protected ketols *(3)*. Oxidative hydrolysis finally affords the chiral ketols *(4)* in good chemical yields and enantiomeric excesses of 31–62%.

Two approaches were used for the step *(3)*→*(4)*: reaction with 30% hydrogen peroxide at pH 7 in methanol leads directly to the ketols *(4)* (method A); alternatively, the silylated ketols *(5)* are initially produced by sensitized photooxidation[7] in tetrahydrofuran and reductive hydrolysis; compounds *(5)* can readily be cleaved to give *(4)* (method B). The results are summarized in Table 1[8].

The absolute configuration of the optically active ketols *(4)* is not yet known; the enantiomeric excesses were determined by NMR spectroscopy. The new asymmetric C—C linkages occur regiospecifically at the less substituted α-carbon atom of the ketones *(1)* (chiral center at β-C).

General procedure

The new hydrazones *(2)* are produced by known methods[6]. A 1.6 M solution (6.2 ml) of *n*-butyllithium in *n*-hexane is added to a stirred solution of *(2)* (10 mmol) in tetrahydrofuran (25 ml) at −78 °C. The reaction mixture is warmed to 0 °C over 1 h and then cooled to −95 °C. Aldehyde or ketone (10 mmol) is then added dropwise and the temperature allowed to rise to −20 °C over 12 h. Chlorotrimethylsilane (10.5 mmol) is added at −60 °C, and the mixture stirred for 1 h at room temperature. Workup with CH_2Cl_2, drying over sodium sulfate, and removal of solvent gives *(3)* as a viscous oil.

Cleavage by method A: (3) is dissolved in methanol (20 ml) and stirred with buffer (pH 7, 10 ml) and 30% hydrogen peroxide (10 ml) for 2–24 h at 20–80 °C (TLC check). Workup with ether, drying over magnesium sulfate, and removal of solvent gives the ketols *(4)* which are purified by distillation.

Cleavage by method B: (3) is dissolved in tetrahydrofuran and cleaved as already described[7] by sensitized photooxidation at −78 °C (irradiation time 4.5–10.5 h) followed by reduction with dimethyl sulfide and hydrolysis. Workup with CH_2Cl_2, drying over sodium sulfate, removal of solvent, and distillation furnishes the ketols *(5)*. Solvolysis in methanol (5 ml) containing a catalytic amount of HCl (5–10 min, 20 °C), neutralization with sodium hydrogen carbonate and workup with CH_2Cl_2 gives the ketols *(4)*, which are purified by distillation or recrystallization.

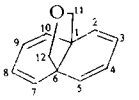
The Berson-Willcott Rearrangement of 11,11-Dimethyltricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene and Its Radical Anion[**]

By *Fabian Gerson, Walter Huber*, and *Klaus Müllen*[*]

The nature of the frontier orbitals of a molecule is of prime importance for the discussion of its valence isomerizations[1]. It is therefore of interest to investigate the way in which the formation of the corresponding radical anion affects such a conversion. While mechanistic studies of this kind have thus far been mainly restricted to pericyclic reactions of the $n\pi+\sigma\rightarrow(n+1)\pi$ type[2], the present work on 11,11-dimethyltricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene *(1)*[3] permits the first comparison between the *Berson-Willcott*[4] rearrangement of a norcaradiene derivative and the analogous valence isomerization of its radical anion.



As has been observed by *Vogel et al.*[5], thermolysis of *(1)* leads to 5,5-dimethylbenzocycloheptene *(3)*. This reaction, which proceeds *via* the transient valence isomer *(2)*, mimics the rearrangement described by *Berson* and *Willcott* for the parent cycloheptatriene-norcaradiene system.

(1) *(2)* *(3)*

We investigated the kinetics of the thermolysis of *(1)* by monitoring the intensities of the ^{1}H-NMR signals of *(1)* and *(3)* in the range of 150 to 190 °C. The resulting activation parameters are listed in Table 1[6].

Reduction of *(1)* with potassium in 2-methyltetrahydrofuran below −110 °C enabled us to record the ESR spectrum of the primary radical anion *(1)*$^{\bullet\ominus}$[7]. The similarity between the hyperfine data of *(1)*$^{\bullet\ominus}$ (Table 2) and those of the radical anion of the reference compound *(4)*[8] indicates that *(1)*$^{\bullet\ominus}$, like *(4)*$^{\bullet\ominus}$, contains two separate butadiene π-systems[9].

(4)

Upon warming of the solution of *(1)*$^{\bullet\ominus}$ above −110 °C, the spectrum of the primary radical anion was gradually replaced by that of a secondary paramagnetic species. This spectrum, which also appears on direct reduction of *(3)*, has been analyzed by the ENDOR technique[7]; its hyperfine data (Table 2) are fully consistent with the structure of the radical anion *(3)*$^{\bullet\ominus}$[10].

Table 1. Activation parameters for the valence isomerizations *(1)*→*(3)* and *(1)*$^{\bullet\ominus}$→*(3)*$^{\bullet\ominus}$.

	k (25 °C) [s^{-1}]	log A	E_a [kJ/mol]	$\Delta H^{\neq}$ (25 °C) [kJ/mol]	$\Delta S^{\neq}$ (25 °C) [J/mol·K]
(1)→*(3)*	≈10^{-12}	13.4±0.3	150±2	147±2	4±4
(1)$^{\bullet\ominus}$→*(3)*$^{\bullet\ominus}$	≈10^3	13±2 [a]	46±8 [a]	43±8 [a]	20±20 [a]

[a] Large range of error is due to the very rapid course of the reaction.

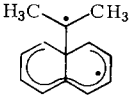


Table 2. ^{1}H- and ^{39}K coupling constants [G], a_{H_μ} and a_K, respectively, for the radical anions *(1)*$^{\bullet\ominus}$, *(4)*$^{\bullet\ominus}$, and *(3)*$^{\bullet\ominus}$.

	a_{H_μ}									a_K
	μ = 2, 5, 7, 10				3, 4, 8, 9				11 (12)	
(1)$^{\bullet\ominus}$	4.16				1.75				0.25 [a]	0.22
(4)$^{\bullet\ominus}$	3.80				1.51				0.45 [b]	0.20
μ =	6	7	8	9	4	3	2	1	5	
(3)$^{\bullet\ominus}$	7.34	2.68	4.93	4.55	0.21	4.05	1.40	3.16	0.86 [a]	0.17

[a] Six methyl protons. [b] Four methylene protons.

Starting from *(1)*, the ESR signals of both radical anions were readily observed in the range of −100 to −70 °C and thus the kinetics of the valence isomerization *(1)*$^{\bullet\ominus}$→*(3)*$^{\bullet\ominus}$ could be deduced from the changes in the signal intensities. The pertinent activation parameters (Table 1) differ strikingly from corresponding values for the rearrangement *(1)*→*(3)*. In the case of the radical anion, the rate constant k (25 °C) is higher by a factor of 10^{15}, and the activation enthalpy $\Delta H^{\neq}$ (25 °C) lower by *ca.* 100 kJ/mol, than for the neutral compound.

It has been concluded from the stereospecificity of the thermolysis of structurally related compounds of lower symmetry that the isomerization *(1)*→*(3)* proceeds concertedly[11]. On the other hand, the considerable enhancement of the rate constant for the radical anion can be easily rationalized if one assumes the biradical *(5)*•• and its reduced form *(5)*$^{\bullet\ominus}$ to be intermediates in *(1)*→*(3)* and *(1)*$^{\bullet\ominus}$→*(3)*$^{\bullet\ominus}$, respectively[12].

(5)••

Beyond the mechanistic aspects, such an enhancement has potential preparative applications. Reduction and subsequent reoxidation would yield a valence isomer of the neutral compound under relatively mild conditions.

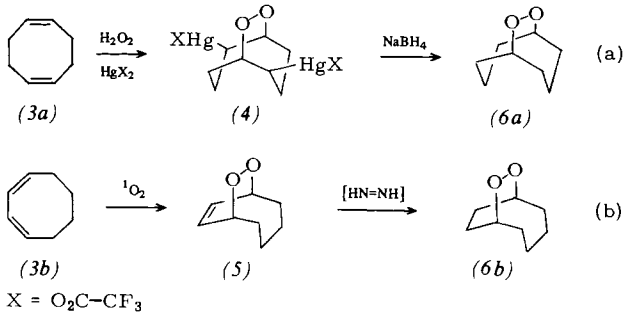
[9] This finding also permits unequivocal assignment of the coupling constants to the two sets of four equivalent ring protons in $(1)^{\cdot\ominus}$.
[10] The assignment of the coupling constants to the eight single ring protons in $(3)^{\cdot\ominus}$ is largely based on correlation with π-spin populations calculated according to the *McLachlan* procedure [*A. D. McLachlan*, Mol. Phys. *3*, 233 (1960)].
[11] *F. G. Klärner*, unpublished work, quoted in ref. [5b].
[12] In contrast to $(1)^{\cdot\ominus}$ where the additional electron occupies the lowest *antibonding* orbital of one butadiene π-moiety, in $(5)^{\cdot\ominus}$ such an electron enters the *nonbonding* orbital of the nonatetraenyl π-system. The difference in π-energies (0.62β in the HMO model) would facilitate the opening of the three-membered ring in the radical anion $[(1)^{\cdot\ominus} \rightarrow (5)^{\cdot\ominus}]$ relative to the neutral compound $[(1) \rightarrow (5)^{\cdot\cdot}]$ and thus lower the activation energy.

Regioselective Synthesis of Isomeric Bicyclic Peroxides[**]



By *Waldemar Adam, A. John Bloodworth, Henny J. Eggelte*, and *Mark E. Loveitt*[*]

Monocyclic peroxides *(1)* have recently been shown to serve as useful synthons for the preparation of unusual organic molecules[1]. Equally importantly they constitute valuable precursors of the mechanistically interesting diradicals[2]. The geometrical contraint in bicyclic peroxides *(2)* is expected to impart new synthetic and mechanistic behavior, but unfortunately no general and convenient methods are presently available for the preparation of such compounds.

(1)   *(2)*

In this communication we describe potentially general routes to isomeric bicyclic peroxides involving: a) reaction of non-conjugated cyclic dienes with hydrogen peroxide and mercury bis(trifluoroacetate) (peroxymercuration) followed by reduction with $NaBH_4$[3], and b) photooxygenation of conjugated cyclic dienes followed by reduction with azodicarboxylate[4].

These complementary and regioselective peroxybicyclizations are illustrated for the saturated compounds 9,10-dioxabicyclo[3.3.2]decane (1,5-epidioxycyclooctane) *(6a)* and 7,8-dioxabicyclo[4.2.2]decane (1,4-epidioxycyclooctane) *(6b)*, respectively.

When the diene *(3a)* was added to a mixture of hydrogen peroxide (85—95 %) and mercuric trifluoroacetate in CH_2Cl_2 at room temperature, equal amounts of the bicyclic peroxide *(4)* and the corresponding bicyclic ether were formed [use of $Hg(NO_3)_2 \cdot H_2O$[3] in this particular case affords only the ether]. The products were separated by dissolving the mixture in benzene, whereupon crystals of the pure (solvated) peroxide were precipitated[5]. Reduction of *(4)* in CH_2Cl_2 with $NaBH_4$ in aqueous NaOH gave the previously unknown cyclic peroxide *(6a)*[6], together with an approximately equal amount of 4-cycloocten-1-ol. Catalytic hydrogenation of *(6a)* over Pd/C led quantitatively to the known *cis*-1,5-cyclooctanediol[7], m.p. 73–75 °C.

On the other hand, photooxygenation of the diene *(3b)* in CH_2Cl_2 with tetraphenylporphyrin as sensitizer gave the known[8] unsaturated peroxide *(5)*, which on reduction with azodicarboxylate[4] in methanol afforded the previously unknown saturated peroxide *(6b)*[9]. Catalytic hydrogenation of *(6b)* over Pd/C gave quantitatively the known *cis*-1,4-cyclooctanediol[10], m.p. 81—83 °C.

For the first time saturated bicyclic peroxides with medium-sized rings have become conveniently available from readily accessible starting materials. Furthermore, *(6a)* is the first bicyclic peroxide to be prepared that does not contain a 1,2-dioxane ring.

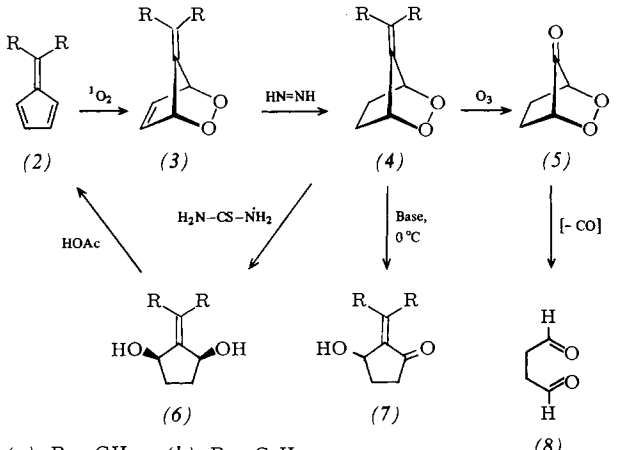
Trapping of Unstable Fulvene/Singlet Oxygen Adducts by Reduction with Diazene[**]



By *Waldemar Adam* and *Ihsan Erden*[*]

We recently reported that diimide (diazene) selectively reduces the double bond in the unstable endoperoxides *(1a)* and *(1b)*, derived respectively from singlet oxygenation of cyclo-

pentadiene[1] and 1,4-dimethylnaphthalene[1b], without severing the labile peroxide linkage. This novel, selective reduction should constitute a convenient and effective chemical tool for the characterization of unstable endoperoxides derived from singlet oxygenations since the basic peroxide skeleton is preserved. Furthermore, it offers a unique entry into unusual and hitherto inaccessible cyclic peroxides. We demonstrate the feasibility and potential of this methodology with the unstable peroxides *(3a)* and *(3b)*, formed from 6,6-dimethyl- and 6,6-diphenylfulvene, respectively.

Singlet oxygenation of 6,6-disubstituted fulvenes *(2)* leads to a complex mixture of products, postulated to be derived from the labile epidioxyfulvene *(3)* by rearrangement[2]. NMR evidence for the intervention of *(3)* could be secured when the singlet oxygenation was carried out at −70 °C; but above −20 °C the unstable *(3)* afforded the previously observed complex product mixture[3].

On treatment of a CH_2Cl_2 solution of *(3a)*, prepared from 6,6-dimethylfulvene *(2a)* by photo-oxygenation at −78 °C with tetraphenylporphyrin as sensitizer and a General Electric 400W sodium lamp, with diimide which was generated *in situ* at −78 °C as described previously[1a], the stable cyclic peroxide *(4a)* was isolated in 63% overall yield as white needles (m.p. 53 °C) after recrystallization from CH_2Cl_2/CH_3OH (1:3). Structural proof for *(4a)* rests on satisfactory elemental analysis, spectral data[4] and chemical transformations. Thus, reduction with thiourea in CH_3OH at 0 °C gave the diol *(5a)*[5], which could be dehydrated back to the fulvene *(2a)* on refluxing in acetic acid for one hour. On treatment with triethylamine in CH_2Cl_2 at 0 °C, *(4a)* is converted into *(7a)*[6].

Similarly, *(2b)* gave the cyclic peroxide *(4b)* in 88% overall yield on photo-oxygenation and diimide reduction at −78 °C, m.p. 77–78 °C (from 2:1 C_6H_6/CH_3OH)[7]. The reactions of the phenyl derivatives *(4b)*→*(6b)*[8] and *(6b)*→*(2b)* could be accomplished under the same conditions as used for the methyl derivatives. *(4b)* can be converted into *(7b)* by treatment with methanolic KOH at 0 °C[9].

Ozonolysis of *(3a)* and *(3b)* in CH_2Cl_2 at −78 °C in the presence of tetracyanoethylene produced an unstable substance which exhibited proton resonances at $\delta = 2.0$ (m, 4H) and 4.38 (m, 2H), besides acetone and benzophenone. When the ozonolyzate was allowed to warm up to −10 °C, the substance decarbonylated cleanly into succinaldehyde *(8)*. On the basis of these facts we assign the compound the novel epidioxyketone structure *(5)*. Interestingly, *(5)* decarbonylates with emission of light; it can therefore be regarded as a "energy reservoir".

Trapping of Unstable α-Pyrone/Singlet Oxygen Adduct by Reduction with Diazene[**]

By *Waldemar Adam* and *Ihsan Erden*[*]

Unstable endoperoxides such as the singlet oxygen adducts of cyclopentadiene[1a], fulvenes[1b], and furans[1c] can be conveniently and selectively reduced to their respective dihydroendoperoxides, thus preserving the bicyclic structure without severing the peroxide bond. This reductive trapping technique has now been extended to the hitherto unknown and unstable endoperoxide of α-pyrone *(2)*. Presently we report on the chemistry of these unusual bicyclic endoperoxides.

On photo-oxygenation of α-pyrone *(1)* in CH_2Cl_2 at 0°C using tetraphenylporphyrin as sensitizer and a General Electric 400 W sodium lamp resulted in slow consumption of the α-pyrone as monitored by subambient ^{1}H-NMR spectroscopy. After 12 h essentially all the α-pyrone had been consumed and the characteristic multiplets at δ = 5.9–6.3 and 7.0–7.5 of the 1,3-diene were replaced by broad singlets at δ = 6.80 (olefinic H) and 5.02 and 6.25 (bridgehead H). When allowed to warm up to 30°C, carbon dioxide was rapidly evolved and the above proton resonances were replaced by two multiplets at δ = 10.25 (aldehydic H) and 6.48 (olefinic H) corresponding to the signals of malealdehyde *(4)* as confirmed by an authentic sample[2]. These results suggested intervention of the novel and thermally labile cyclic peroxide *(2)* as an intermediate in the singlet oxygenation of *(1)*. We decided to isolate and purify it and confirm its structure.

Low temperature chromatography of the photo-oxygenated α-pyrone reaction mixture on silica gel at −40°C and elution with CH_2Cl_2 afforded pure *(2)*[3]. Efforts to recrystallize it at low temperature failed. Reduction of *(2)* with excess diimide in CH_2Cl_2 at −78°C[1a,4] followed by column chromatography on silica gel at −20°C and eluting with CH_2Cl_2 gave the saturated cyclic peroxide *(3)*[5]. This new compound is thermally considerably more stable than its unsaturated precursor *(2)*; decarboxylation of *(3)* to succinaldehyde on heating at 140°C was confirmed by IR and ^{1}H-NMR spectroscopy on an authentic sample.

An interesting feature of *(3)* was its emission of light during decarboxylation to succinaldehyde[6]. Thus, either *(3)* stores sufficient energy so that simultaneous peroxide bond fission and decarboxylation leads to electronically excited succinaldehyde directly or the intermediary bicyclic dioxetane *(6)* is first formed on decarboxylation of *(3)*. Subsequent ring opening of the dioxetane *(6)* would be expected to afford electronically excited succinaldehyde[7].

Isomerization with Methyl Migration in Trimethyl Phosphite-Arsenido and -Antimonido Complexes of Transition Metals[1]

By *Wolfgang Malisch* and *Reinhard Janta*[*]

The E atom in complexes of the type $Cp(CO)_2(PR_3)M-E(CH_3)_2$ (M = Mo, W; E = As, Sb; R = CH_3) is a center of unusually high basic activity which is manifested in a pronounced tendency to react with electrophiles[2]. The electron rich state of the E atoms is also responsible for the *irreversible isomerization* with a methyl shift from the R_3P ligand to the arsenido or antimonido function which we have observed in derivatives with R = OCH_3.

The isomerizing complexes *(2)* are accessible by reaction of the tricarbonyl precursors *(1)*[3] in benzene with equimolar amounts of trimethyl phosphite at 25°C [*(1a)*] or 50°C [*(1b)* and *(1c)*]. Under these conditions only the CO group in the *trans position* relative to the σ-bonded $(CH_3)_2E$ group is replaced[4].

Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

The rearrangement *(2)*→*(3)* which is readily observed by ^{1}H-NMR spectroscopy sets in at room temperature in the presence or absence of solvent, can be thermally accelerated, and proceeds with retention at the transition metal[4]. It is complete within 7 d in the case of *(2a)* in $CHCl_3$ (0.46 M solution, 25 °C). Rate-determining factors are not only the concentration of the trimethyl phosphite complex but also the nature of its E and M atoms and the solvent polarity [k_{rel} ($CHCl_3$, 25 °C) for As:Sb = 2:1, Mo:W = 1:1.5; $CHCl_3$:C_6H_6 = 350:1]. These observations and the fact that an equimolar mixture of *(2a)* and *(2b)* rearranges just as fast as pure *(2b)* [catalytic action of *(2b)*] unequivocally indicate *intermolecular* site exchange of the methyl group.

The composition and structure of the crystalline, deep and pale yellow complexes *(2)* and *(3)*, respectively, have been confirmed by elemental analysis and mass, IR, and NMR (^{1}H, ^{13}C, ^{31}P) spectra. Compounds of the same isomeric type exhibit almost identical $\delta(^{31}P)$ and $J(^{31}P^{183}W)$ values[5]. These data are therefore very suitable for rapid identification of the isomers which differ especially in their solubility properties. Unlike *(2)*, the thermally stable rearrangement product is soluble only in polar solvents ($CHCl_3$, CH_3CN).

The O→As(Sb) methyl shift presented in this communication transforms a phosphite into a phosphonate ligand (with concomitant formation of a trimethylarsane(-stibane) ligand)[6] without assistance by alkyl halides as is generally required[7]. Compared with the few known examples of direct P=O bond formation as a result of methyl migration[8], the reaction proceeds under astonishingly mild conditions. It therefore follows that the donor strength of transition metal units endows 5B atoms with a striking ability to take over methyl groups.

In accord with this interpretation, the bismetallostibanes *(5)* accessible from trimethyl phosphite and dinuclear complexes *(4)*[9] by double *trans*-CO substitution isomerize even more readily than the systems in the monometal series, since the basic acceptor center is now exposed to the influence of *two metal donor ligands*. In the case of *(5b)*, the antimony bridge is methylated so quickly that *(5b)* itself can only be detected as an intermediate by spectroscopy.

According to the νCO absorption bands, the bridged complexes *(5)* exist in solution as a mixture of several conformers.

Experimental

(5a): $P(OCH_3)_3$ (295 mg, 2.37 mmol) is added to a solution of $[C_5H_5(CO)_3Mo]_2SbCH_3$[9] (505 mg, 0.79 mmol) in benzene (30 ml) and the mixture is stirred at room temperature for 2 h (evolution of CO!). Addition of pentane (20 ml) to the filtered solution which has been evaporated down to half its volume precipitates a solid which is washed with cold pentane (5 ml) and dried in an oil-pump vacuum; yield 756 mg (91%) of *(5a)*.

(6a): Compound *(5a)* (371 mg, 0.45 mmol) is heated in benzene (20 ml) to 60 °C for 6 h. Insoluble products are filtered off, the solvent is removed under vacuum, and the solid residue washed with pentane (4 ml); yield 302 mg (81%) of *(6a)*.

^{1}H-NMR (TMS int.): *(5a)* in C_6D_6: δC_5H_5 5.11 (d, 10H), $^3J_{HCMP}$ 1.2; δCH_3OP 3.4 (d, 18H), $^3J_{HCOP}$ 11.6; δCH_3Sb 2.4 (s, 3H). *(6a)* in $CDCl_3$: δC_5H_5 5.19 (d, 5H), $^3J_{HCMP}$ 1.2; δCH_3OP 3.29 (d, 9H), $^3J_{HCOP}$ 12.0; δC_5H_5* 5.23 (d, 5H), $^3J_{HCMP}$ 0.8; δCH_3OP 3.95 (d, 6H), $^3J_{HCOP}$ 10.8; δCH_3Sb 1.65 (s, 6H).—$^{31}P\{^1H\}$-NMR (C_6D_6, H_3PO_4 ext.): *(5a)* δ = 197; *(6a)* δ = 187, 120*.—IR (νCO in C_6H_6): *(5a)* 1919 (s), 1898 (s), 1848 (vs), 1840 (Sh), 1810 (vs) cm^{-1}; *(6a)* 1940 (Sh)*, 1929 (s), 1876 (s)*, 1855 (Sh) cm^{-1} (*absorptions of the $Cp(CO)_2M$—$P(O)[OMe]_2$ group).

coordinated pseudohalide complex of boron linked *via* nitrogen.

$$(C_6H_5)_4P[NSOF_2] + B(NSOF_2)_3 \rightarrow (C_6H_5)_4P[B(NSOF_2)_4]$$
(1) *(2)* *(3)*

When tetraphenylphosphonium difluorooxosulfimidate *(1)*[3] (0.44 g, 1.0 mmol) and boron tris(difluorooxosulfimidate) *(2)*[4] (2 g, 6.4 mmol) are condensed together in a glass trap at −80 °C and the product mixture is allowed to warm to room temperature over 12 h, stirred for a further 5 to 6 h and the excess of *(2)* removed by pumping (48 h), *(3)* is obtained in quantitative yield as a white crystalline solid whose X-ray diagram differs from that of *(1)* and whose elemental analysis proves it to be pure *(3)*. The ^{1}H-NMR spectrum is compatible with that of *(1)* and of $(C_6H_5)_4PCl$; the ^{19}F-NMR spectrum shows a singlet at $\delta = -51.8$ (in acetonitrile, rel. $CFCl_3$ ext.). Together with the IR spectrum (3028 w, 1590 m, 1450 vs, 1342 w, 1320 w, 1260 s, 1192 m, 1113 s, 1003 m, 940 vs, 785 vs, 756 m, 728 vs, 695 s, 590 m, 560 m and 530 s cm^{-1}; KBr pellet) the ^{11}B-NMR spectrum, in particular, with a signal at $\delta = 7.96$ (in $[D_3]$-acetonitrile, rel. $BF_3 \cdot OEt_2$ ext.), provides evidence for the tetracoordination of the boron. This experimental value corresponds to that expected according to a Scheme described by *Nöth* and *Vahrenkamp* for the chemical shift as a function of the electronegativity of the ligand atoms X in $BX_4^{\ominus}$ complexes[5].

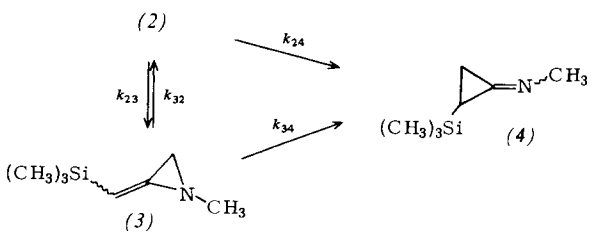
Enantioselective Synthesis and Thermal Reorganization of an Optically Active Methyleneaziridine[**]

By *Helmut Quast* and *Carlos A. Weise Vélez*[*]

The routine application of conclusions reached for hydrocarbons to the corresponding hetero systems can be inadmissible in the case of strongly perturbed pericyclic reactions[1]. While the thermal isomerization of methylenecyclopropanes is known to be largely stereospecific with inversion at the migrating carbon atom[2], nothing is known about the stereochemistry of the thermal reorganization of heteromethylenecyclopropanes apart from the racemization of optically active 2,3-di-*tert*-butylcyclopropanone[3a] and the rearrangement of optically active allene oxide intermediates[3b]. We have now found that the methyleneaziridine—cyclopropanimine rearrangement[4] also proceeds stereospecifically.

The optically active methyleneaziridine *(−)-(2)* could be synthesized in 36—48% yield by lithiation of *(1)*[5] using 1.08 equivalents of *sec*-butyllithium in pentane at −125 °C in the presence of 9.10 equivalents of *(S,S)*-(+)-1,4-bis(dimethylamino)-2,3-dimethoxybutane [(+)-DDB] as auxiliary chiral agent[6] and subsequent reaction with 1.05 equivalents of chloro(trimethyl)silane at −125 to −20 °C. Enantioselective metalations have hitherto rarely been observed[7].

(1) *(−)-(2)*



After repeated fractional distillation in a 20-cm Spaltrohr® column (b.p. 52.5 °C/75 torr), *(−)-(2)* proved to have a purity of 98% (GC) and a specific rotation of $[\alpha]_{405}^{20} = -86.27°$ ($[(-)-(2)] = 0.348$ mol/l in $[D_6]$-benzene). Integration of the trimethylsilyl ^{1}H-NMR signals in benzene using Pr(facam)$_3$[8] as shift reagent revealed an enantiomer excess of 12.4±1%.

Solutions of *(2)* in $[D_6]$-benzene were heated in sealed NMR sample tubes previously treated with *O,N*-bis(trimethylsilyl)acetamide and degassed at 10^{-5} torr. In the case of racemic *(2)* the thermolysis was monitored ^{1}H-NMR spectroscopically on *a single* sample by measurement of the trimethylsilyl signals, while in the case of *(−)-(2)* *nine* identical samples were firstly measured ^{1}H-NMR spectroscopically and then polarimetrically at 405 nm under strict exclusion of moisture. At 120.0 °C thermolysis of *(2)* afforded the diastereomeric methyleneaziridines *(3)* and cyclopropanimines *(4)* in the constant isomeric ratios *(E)-(3)*:*(Z)-(3)* = 86:14 and *(E)-(4)*:*(Z)-(4)* = 56:44, respectively. Decomposition of *(4)* into methyl isocyanide and trimethylsilylethene[4] was not observed at 120 °C but only at 140 °C and above, albeit to a small extent. However, at 120 °C unknown secondary products of *(4)* were very slowly formed (trimethylsilyl singlets at $\delta_H = 0.05$, 0.11, 0.29), which after 24 h only amounted to 6—10% of the total product mixture and were added to *(4)* in the kinetic evaluation.

The structures of *(2)* and its rearrangement products *(3)* and *(4)* follow from the IR and ^{1}H-NMR spectra (Table 1). IR ($\tilde{\nu}$, cm^{-1}) *(2)*: 1790, 1760 (gas phase); *(3)*: 1735, *(4)*: 1773 (both in C_6D_6). ^{1}H-NMR (C_6D_6; δ_H) *(E)-(4)*: −0.08 ($(CH_3)_3Si$); *(Z)-(4)*: −0.02 ($(CH_3)_3Si$). Both diastereomeric cyclopropanimines *(4)* show overlapping multiplets at δ_H = 0.3—1.5 and 3.2—3.3 belonging to two $ABCX_3$ systems. In the case of *(3)* the configuration was determined on the basis of the allyl coupling constants, while in the case of *(4)* the predominant diastereomer was assigned the *(E)*-configuration. Noteworthy is the coupling constant of $^4J = 0.4$ Hz between 3-H and the *N*-methyl group of *(2)* which, with this order of magnitude, is obviously observable only if the *trans* invertomer predominates.

Owing to the irreversibility of the rearrangement to cyclopropanimines[9] and the constant *E*:*Z* ratios in the case of both *(3)* and *(4)*, four rate constants were sufficient for the description of the thermal reorganization of *(2)*. Starting

Scheme 1:

from approximate values, obtained from initial data of the thermolysis of *(2)* and of a 5:95 mixture of *(2)* and *(3)*, by

[b] In CCl_4; the data of the ABX_2 system were optimized using the program LAOCOON III [9].
[c] $^4J_{(3\text{-}H,N\text{-}CH_3)} = 0.4$ Hz.

means of a program developed for the computation and drawing of mol fraction—time curves based on the solutions of the differential equations corresponding to Scheme 1[10], we obtained the optimized constants listed in Table 2.

Table 2. Rate constants of the thermal reorganization of methyleneaziridine *(2)* according to Scheme 1 in [D$_6$]benzene at 120.0°C.

Thermolysis of	Rate constants × 10^5 [s^{-1}]			
	k_{23}	k_{32}	k_{24}	k_{34}
racemic *(2)* [a]	6.20	0.36	2.80	0.165
(−)-(2) [b]	5.90	0.37	3.60	(0.02)

[a] One sample consisting of 0.063 ml of *(2)* in 0.520 ml of [D$_6$]benzene + 0.010 benzene.
[b] Nine identical samples; $[(-)\text{-}(2)] = 0.348$ mol/l.

Table 2 shows satisfactory agreement between the data obtained in different ways. The trimethylsilyl group at the double bond stabilizes *(3)* by 9.2 kJ/mol compared to *(2)*. From the rate constants it can be estimated that initially very little *(4)* is formed (after 10 h only 4%, total 30—35%) *via* achiral *(3)* and that only negligible racemization of *(−)-(2)* occurs in this way.

In the thermolysis of *(−)-(2)* the mol fractions $x(i)$ after 10 h were: $x(2) = 0.06$, $x(3) = 0.56$, $x(4) = 0.35$ and x(secondary products of *(4)*) = 0.03. But α_{405} had only decreased from $\alpha_0 = -4.330°$ to $-2.03°$ [path length = 10 cm]. *(4)*, and thus also the optically active species, was selectively and completely removed *without altering any of the other components* (IR and ^{1}H-NMR spectra) by treating a sample of *(−)-(2)* [$x(4) = 0.35$, $\alpha_{405} = -1.720°$], previously heated for 22.6 h, with water. Consequently, only *(4)* was optically active and, like the educt *(−)-(2)*, levorotatory; however, the enantiomer excess of *(−)-(4)* could not be determined. Assuming that no direct racemization[3a] of *(−)-(2)* takes place, the maximum possible contribution to α_{405} arising from *(−)-(2)* can be calculated according to $\alpha_{(2)} = \alpha_0 \exp -(k_{23} + k_{24})t$. Thus, for *(−)-(4)* a minimum rotation of $\alpha_{(4)} = (\alpha - \alpha_{(2)})/x(4) = -5.59 \pm 0.15°$ (from 5 measurements during the first 5 h, $[(-)\text{-}(4)] = 0.348$ mol/l in [D$_6$]-benzene) is obtained, which is considerably greater than the initial value α_0 and therefore indicative of a high degree of stereospecificity for the methyleneaziridine—cyclopropanimine rearrangement. Since on geometrical grounds retention at the migrating carbon atom, C-3 in *(2)*, is highly improbable, inversion must have occurred as in methylenecyclopropanes[2].

Difluoroarsoranes and Homologous Compounds $R'R_2EF_2$ (E = As, Sb, Bi) by Oxidative Direct Fluorination of Organoarsanes, Organostibanes, and Organobismuthanes[**]

By *Ingo Ruppert* and *Volker Bastian*[*]

Selective gas phase fluorinations of organoelement compounds are comparatively rarely exploited reactions in preparative chemistry[1]. The observed oxidative fluorination of the phosphorus in tertiary phosphanes[2] without significant formation of side-products has now been extended for the first time to its higher homologs.

$$Ph_2E\text{–}R + F_2 \xrightarrow{CFCl_3} \underset{\displaystyle F}{\overset{\displaystyle F}{Ph_2E}}\text{–}R$$

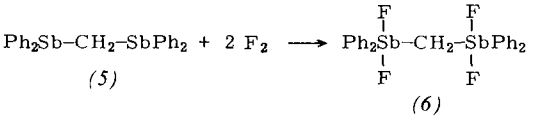
[**] Fluorinated Organoelements: Oxidative Liquid-Phase Direct Fluorination, Part 3.—Part 2: *I. Ruppert*, Chem. Ber., in press.

Surprisingly, despite the decreasing strength of the E—C bond on going from P to Bi, not only the usual competition from side-chain halogenation but even fluorinating cleavage of the element-carbon bond can be largely suppressed under the mild reaction conditions[3].



Direct fluorination simplifies the conventional two-step chlorine/fluorine exchange with metal fluorides [*(2d)*[4a], *(2e)*[4b]] and is preparatively comparable with the fluorination by sulfur tetrafluoride[4c] previously described only for *(2b)*. Its wide range of application can be illustrated using as example the bis(difluoroarsoranes), a previously unknown class of substances.

(3) *(4a-c)* *(4d-f)*

n = 1: R = Me*(a)*, Et*(b)*, *i*Pr*(c)*, Ph*(d)*;
n = 2: R = Ph*(e)*;
n = 3: R = Ph*(f)*

Both phenylated and the more readily substituted alkylated ditertiary bisarsanes *(3)* containing methyl bridges of varying lengths can be converted in good yields into their tetrafluorides by a stream of fluorine diluted with an inert gas. The bisstibane *(5)* reacts similarly.

(5) *(6)*

Depending on the substrate reactivity and the solubility of the partially fluorinated intermediates only part of the fluorine passed into the system will actually be consumed. On the other hand, uncontrolled over-fluorination attacks the alkyl moiety non-specifically[5]; hence, it is necessary to use well defined amounts of fluorine.

In the case of *(3b)* and *(3c)* the reaction course is difficult to monitor by ^{1}H-NMR spectroscopy because of the high proportion of phenyl or complex alkyl signals[6]. Educt, difluoride intermediate[7], and product, however, can easily be detected by $^{13}C\{^1H\}$-NMR spectroscopy; it not only guarantees recognition of the reaction end-point (shift parameters in Table 1), but also permits a simple structural diagnosis based on fluorine-carbon coupling constants. Thus, the pseudotriplet of the α-alkyl C atom or the triplet of the α,β-phenyl C atoms and the quintet splitting of the monomethylene bridge afford proof that two F atoms coordinate each As center. This constitution also applies—at least in solution—in the case of the methylated parent compound *(4a)*, though its physical properties (higher melting point, lower solubility) in comparison with *(4b—d)* is surprising[8]. A fluorine exchange caused by traces of hydrogen fluoride, which leads to merging of the significant couplings to a broad singlet, can be suppressed by carrying out the measurement at low-temperature or, more simply, by addition of a little triethylamine.

Attempts to fluorinate the arsanes *(7)* or *(8)* without rupturing the As—H or As—As bond have so far failed. Instead, the trifluorodiphenylarsorane *(9)*[9] was obtained from the hydride *via* the isolable intermediate *(8)*.

(7) *(8)* *(9)*

Experimental

A stream of diluted fluorine (max. 20 ml F_2 to 100 ml Ar per min) is passed into a magnetically stirred solution of 30 mmol *(1a—e)*, *(3a—f)* or *(5)*[10] in 150—200 ml anhydrous $CFCl_3$ (Solidex-glass flask with delivery tube and fitted with a multiple-coil condenser, −90 °C circulatory cooling). Only in the case of *(3a—c)* is the reaction solution additionally cooled to −78 °C. As shown by $^{13}C\{^1H\}$-NMR monitoring, the reaction is complete only after addition of a 2- to 2.5-fold excess of fluorine; however, excessive over-fluorination must be avoided in the preparation of the alkylated bis(difluoroarsoranes) *(4a—c)*. Workup of the products depends upon their solubility in $CFCl_3$: In the case of *(4b, c)* the $CFCl_3$ is first removed and the remaining viscous

[1] On the problems of elemental fluorination cf. *E. K. S. Liu, R. J. Lagow*, J. Am. Chem. Soc. *98*, 8270 (1976).
[2] *I. Ruppert, V. Bastian*, Angew. Chem. *89*, 763 (1977); Angew. Chem. Int. Ed. Engl. *16*, 718 (1977).
[3] In contrast, alkylarsanes are already cleaved at moderate temperatures by Cl_2, Br_2 or I_2; this halodemetalation of the alkyl moiety has recently been developed into a new synthetic method: *T. Kauffmann, H. Fischer, A. Woltermann*, Angew. Chem. *89*, 52 (1977); Angew. Chem. Int. Ed. Engl. *16*, 53 (1977).
[4] a) *G. O. Doak, G. G. Long, L. D. Freedman*, J. Organomet. Chem. *4*, 82 (1965); b) *F. Challenger, J. F. Wilkinson*, J. Chem. Soc. *121*, 91 (1922); c) *W. C. Smith*, J. Am. Chem. Soc. *82*, 6176 (1960).
[5] Accordingly, in the spectra of *(4a—c)* higher fragmentations of low intensity are also observed which derive from molecular ions $M^+ + n\,18$ $(= M^+ - nH + nF;\ n = 1, 2)$.
[6] These are caused by additional ^1H-^1H coupling of diastereotopic methylene-[*(3b)*] and methyl protons [*(3c)*].
[7] Apart from the expected $^{13}C\{^1H\}$-NMR spectrum, with a triplet for the α-C atoms of the difluoroarsorane moiety with slight deshielding of the dialkylarsane moiety, the difluoride intermediate can be recognized by its ^{19}F-NMR signal, which is shifted upfield by about 5 ppm compared to that in *(4a—d)*.
[8] This finding points to an isomeric fluoroarsonium trifluoroarsenate structure in the solid state.
[9] At room temperature *(9)* shows a trigonal-bipyramidal array of differently fixed fluorine atoms: ^{19}F-NMR ($CDCl_3$): $\delta = -72.3$ [d, $^2J(F_e - F_a) = 73$ Hz, F_a], -94.9 [t, F_e], as previously found by *E. L. Muetterties, W. Mahler, K. J. Packer, R. Schmutzler*, Inorg. Chem. *3*, 1298 (1964). Thus, the more recent findings on a non-freezable ligand exchange [*L. B. Littlefield, G. O. Doak*, J. Am. Chem. Soc. *98*, 7881 (1976)] could not be confirmed.

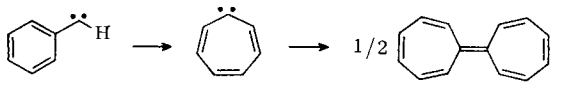
ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

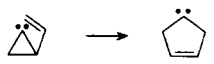
The structure and properties of amorphous ("glassy") metals and alloys are reviewed in an article by *P. Chaudhari* and *D. Turnbull*. Certain metals and alloys can be put into the glassy form by quenching the melt to $T < T_g$, condensation of the gas or diluted solution onto a substrate kept at $T < T_g$, or radiation of the crystalline solid at $T < T_g$ (T_g = glass transition temperature). The electrical, magnetic, and mechanical properties as well as the superconductivity of various metallic glasses including, *inter alia*, those of Ge, Zr, Hf, Ir, Os, Ru, and of Co/P, Cu/Cr, Ni/Nb, and Gd/Co alloys are discussed and their technical potential outlined. [Structure and Properties of Metallic Glasses. Science *199*, 11—21 (1978); 114 references]

[Rd 998 IE]



Transition-metal thiocarbonyls and selenocarbonyls form the subject of a review article by *I. S. Butler*. Compounds containing the CS ligand can be obtained by direct reaction with CS_2 (example: $RuBr_3(PPh_3)_2 \cdot MeOH \rightarrow RuBr_3(CS)(PPh_3)$), reaction with CS_2/PPh_3 ($[IrCl(C_8H_{12})]_2 \rightarrow$ *trans*-$IrCl(CS)(PPh_3)_2$), treatment with thiophosgene, or with *O*-esters of chlorothiocarbonic acid. The CSe ligand can be similarly inserted. CS can also function as bridge ligand; the corresponding CSe complexes have so far not been reported. Only very few complexes containing multiple CS or CSe ligands are known, in contrast to CO complexes. [Transition-Metal Thiocarbonyls and Selenocarbonyls. Acc. Chem. Res. *10*, 359—365 (1977); 73 references]

[Rd 1000 IE]

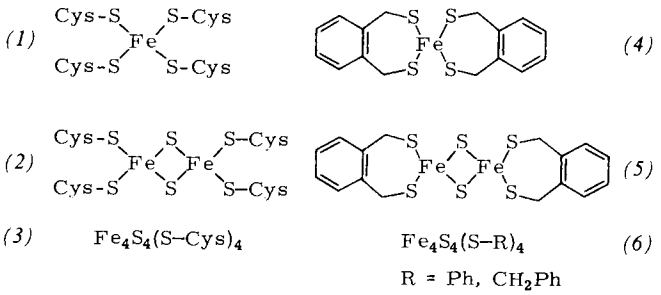


Transfer RNA is the topic to which a complete issue of Accounts of Chemical Research has been devoted. After an introduction by *A. Rich* and *P. R. Schimmel* (pp. 385—387; 24 references), *A. Rich* reviews the three-dimensional structure and biological function of tRNA (pp. 388—396; 29 references). *B. R. Reid* and *R. E. Hurd* deal with NMR investigations (pp. 396—402; 34 references) and *J. A. McCloskey* and *S. Nishimura* with modified nucleosides in tRNA (pp. 403—410; 101 references). *P. R. Schimmel* reports on the recognition process between tRNA and aminoacyl-tRNA synthetase (pp. 411—418; 49 references) and *W. H. McClain* on the terminal seven steps of the biosynthetic pathway leading from DNA to tRNA (pp. 418—425; 29 references). [Acc. Chem. Res. *10*, No. 11 (1977)]

[Rd 1 IE]

Carbene-carbene rearrangements in solution are reviewed by *W. M. Jones*. In such reactions the carbene initially formed is first converted into a second carbene, which then yields products containing only tetravalent carbon. In rearrangements of Type I (only these are described) the "divalency" formally shifts from the carbene carbon to another carbon atom. Rearrangements of Type II are limited (with one excep-

(I)



(II)

tion) to rearrangement of vinylcyclopropylidenes to cyclopentylidenes. Here, the same carbon atom functions as carbene carbon atom before and after the rearrangement. [Carbene-Carbene Rearrangements in Solution. Acc. Chem. Res. *10*, 353—359 (1977); 32 references]

[Rd 999 IE]

Synthetic approaches to the active sites of iron-sulfur proteins is the title of an article by *R. H. Holm*. Studies on synthetic analogs can, *inter alia*, lead to recognition of the smallest structural unit which exhibits the properties of the natural protein, and the influence of the "biological" matrix on the Fe—S coordination unit can be investigated. So far four types of coordination units have been demonstrated in Fe—S proteins; three of these are *(1)*, *(2)*, and *(3)* (having a cubane-like molecular skeleton), whose structurally characterized synthetic analogs are *(4)* to *(6)*. (The charges of the structural units have been omitted.) [Synthetic Approaches to the Active Sites of Iron-Sulfur Proteins. Acc. Chem. Res. *10*, 427—434 (1977); 74 references]

The Prins reaction, *i.e.* the reaction of alkenes with aldehydes in the presence of an acid catalyst, is the theme of an article by *D. R. Adams* and *S. P. Bhatnagar*. Depending on the conditions the Prins reaction leads to 1,3-dioxanes, 1,3-diols, unsaturated alcohols and/or their secondary products; they can

(1)

all be derived from the cation *(1)*. By careful choice of reaction conditions it is possible to obtain a major product in good yields instead of the usual complex mixture of products. [The Prins Reaction. Synthesis *1977*, 661—672; 94 references]

[Rd 4 IE]

BOOK REVIEWS

Ullmanns Encyklopädie der technischen Chemie (Ullmann's Encyclopedia of Industrial Chemistry). Edited by *E. Bartholomé*, *E. Biekert*, *H. Hellmann*, *H. Ley* (deceased) and *W. M. Weigert* (deceased). Vol. 12: Fungicides to Hydroxylamine. Verlag Chemie GmbH, Weinheim–New York 1976. 4th edit., xvi, 727 pp., 304 figs., 185 tables, half leather, DM 430.00.

This is the sixth alphabetical part of the fourth edition[*]. A characteristic that is particularly noticeable in this volume is the large number of technologically oriented entries, exemplified by topics of applied electrochemistry such as galvanic cells (63 pages, including a section on fuel cells), electroplating (67 pages), and semiconductors (31 pages), by agricultural topics such as cereals and cereal products (17 pages), animal feedstuffs (25 pages), fungicides (14 pages), and herbicides (19 pages), and by soft drinks (26 pages). Further entries from the field of technology are those dealing with floor coverings (18 pages), antifreezes (6 pages), hair preparations (29 pages), skin cosmetics (11 pages), and most entries on wood (altogether 60 pages). In addition, most of the other entries also contain technological data. This shows that the new "Ullmann" gives a more complete coverage of industrial chemistry than did the previous editions. This of course includes problems of the environment and questions of safety in the preparation and use of chemicals.

The following entries may be mentioned from the field of inorganic chemistry: gallium, germanium, gold, hafnium (including their important compounds and—in the case of gold—alloys), hard metals, glass and glass ceramics (50 pages), plaster (27 pages), and the following entries from the field of metal processing: casting (17 pages) and cast iron (7 pages). Organic chemistry is represented by entries on furan, glycerol, guanidine, urea (18 pages), gelatin (10 pages), natural and synthetic resins (altogether 31 pages), and fuel oils (27 pages), and pharmaceutical chemistry by an entry on cardiovascular preparations (46 pages).

As in the previous volumes, the treatment is clear, concise, and sound. There are many cross references, both in the text and by the entries treated elsewhere (*e.g.* at the entry "Yeasts", we find the reference "see under Proteins").

It should be stressed, in conclusion, that there is no other work giving such detailed description of industrial chemistry as a whole.

Ulfert Onken [NB 399 IE]

Interpretation of Carbon-13 NMR Spectra. By F. W. *Wehrli* and *T. Wirthlin*. Heyden. London–New York–Rheine 1976. 1st Edit., xvi, 310 pp., bound, DM 59.50.

There are already many standard works on ^{13}C-NMR spectroscopy which, however, serve mainly as data compilations: the present work is really the first *textbook* on the subject, and thus fills a gap.

The "Basic Principles" give the usual introduction and a description of instruments (21 pages, 23 references). It is a little difficult to understand why the authors do not mention quadrature phase detection, offered by two spectrometer manufacturers, when they discuss the folding of spectra on two pages. The next chapter, "The Spectral Parameters" (42 pages, 92 references) consists of tabulated data. All the incremental systems used for the calculation of substitution effects are presented clearly. Regrettably, the latest views on the way the γ-effect operates (p. 28) could not be incorporated. The third chapter, "Assignment Techniques" (65 pages, 105 references), deals predominantly with the various recording

[*] Cf. Angew. Chem. Int. Ed. Engl. *16*, 202 (1977).

techniques by which the problems of assignment can be solved. Particularly useful is the section entitled "Second Order Effects in Off-Resonance Spectra", in which the authors explain why off-resonance spectra exhibit unusual splitting in certain cases. The fourth chapter, "Nuclear Spin Relaxation" (23 pages, 33 references), gives a very concise account of ^{13}C spin relaxation, which differs from the otherwise less theoretical approach used in the book. However, the statement that ^{13}C-NMR signals relax with a single exponential time constant (p. 129) is true for methylene and methyl groups only if the cross correlation is ignored.

Chapter 5, "Applications" (124 pages, 136 references), constitutes the main part of the book and will soon find its way into courses on ^{13}C resonance spectroscopy. The principles given elsewhere in the book can here be put into practice in numerous aptly chosen exercises, some of which relate to polymers and biopolymers. The solutions to these exercises are discussed in detail in an Appendix. This chapter could be even more useful if it had a better layout. There is only a subject index, but that contains all the important entries.

An altogether successful, high quality book, essential for libraries and recommended as a manual to those who deal routinely with ^{13}C-NMR spectra.

Stefan Berger [NB 400 IE]

Organic Chemistry of Drug Synthesis. By *D. Lednicer* and *L. A. Mitscher*. John Wiley and Sons, New York–London 1977. 1st Edit., xvii, 471 pp., bound, £ 16.90.

This book is intended for undergraduates studying medicinal chemistry (where this is offered as a course), pharmaceutical chemists, and organic chemists interested in medical problems. After a short introduction, the authors describe in 21 chapters (432 pages) the synthesis and biological action of common drugs tested and/or used in the United States. The book differs from comparable accounts in that, apart from the chapter on local anesthetics, the chemical structure forms the basis of the classification and discussion of the pharmacological action. More specifically, we can learn here *e.g.* about prostaglandins, steroids, tetracyclines, morphine derivatives, benzodiazepines, phenothiazines, β-lactam antibiotics, benzyl and benzhydryl derivatives, phenethyl- and phenylpropylamines, arylacetic and arylpropanoic acids, arylethenes, monocyclic and polycyclic arenes, acyclic compounds, and heterocyclic compounds with five- or six-membered (condensed) rings. The book ends with a 15-page Cross Index of Drugs and an 8-page Glossary of the relevant terms. The literature is covered up to 1971/72, and in some cases up to 1974.

Though compact, the work is often stimulating and can be considered to complement the standard works of *Burger* and *Ehrhart-Ruschig*, to which one should turn for a more detailed study, even according to the authors of this book. A particular shortcoming of the latter is that the chemical formulas are often numbered wrongly.

Bernard Unterhalt [NB 403 IE]

Applications of Biochemical Systems in Organic Chemistry. Vol. 10. Edited by *J. B. Jones*, *C. J. Sih*, and *D. Perlman*. John Wiley and Sons, New York–London 1976. Part I: 1st Edit., xii, 505 pages, bound, £ 24.25. Part II: 1st Edit., x, pages 506–1065, bound, £ 26.65.

Part I was written by the editors and three other authors, and Part II by 14 authors; These are either organic chemists with special interest in enzyme catalysis and particularly its steric aspects, or biochemists sailing close to chemistry. Since most organic chemists still largely ignore techniques of biological nature, this work is not without certain missionary zeal. The stress, particularly in Part I, is on the use of enzymes for asymmetric syntheses, while biotransformations by microorganisms, surveyed in the latest books, are treated only briefly.

The first chapter in Part I is aimed at familiarizing chemists with the utilization of biochemical systems. Many readers will profit from the section on the specificities of enzyme reactions.

Chapters 2 and 3 (59 and 38 pages, respectively) describe the use of microorganisms and survey the possible reaction types.

Chapter 4, with 394 pages the longest in the book, deals with asymmetric syntheses and enzymatic resolution of racemates. The authors describe in particular proteases oxidoreductases (especially the various alcohol dehydrogenases). There is extensive tabulated material relating to substrate specificity and stereospecificity, collected from widely scattered sources. Much space is devoted to the preparation of compounds that are made chiral by stereospecific isotope substitution. The authors also discuss in detail the application of biochemical methods to the determination of configurations.

Part II is less uniform than Part I. Most of the chapters are less instructive for practical work, but the book makes stimulating reading. *Rose* and *Hanson* give an excellent 45-page account of the stereochemistry of enzyme reactions from the mechanistic and evolutionary points of view, this being an extended version of an article published in 1975 in Accounts of Chemical Research.

A. I. Scott gives a 63-page treatment of biogenetic reaction types, and particularly oligomerization and cyclization with the incorporation of C—C double bonds, as well as rearrangements.

Guthrie devotes a long chapter (103 pages) to numerous aspects of catalysis, and deals with enzyme models and related subjects. In a 60-page account, *Cram* first discusses the bonds in complex formation and then mainly his work on host-guest chemistry, where he mentions many previously unpublished results as well. *Hamilton* describes enzymatic redox reactions and their models in the hope that these enzymes will gain application as reagents in organic chemistry. The last five chapters are again devoted mainly to practical aspects, such as the use of cell-free enzyme systems for organic syntheses on a large scale, affinity chromatography, immobilized enzymes, syntheses with reagents on solid carriers, and enzymatic syntheses of compounds labeled with isotopes other than ^{2}H or ^{3}H.

In all, there are more than 2600 references to research papers and review articles. Each volume has a subject index for Parts I and II. The two Parts are independent, but the distribution of the material between them is somewhat unclear. For the specialist this work brings together many facts and ideas; for the newcomer it can be an excellent catalyst for using biological systems in preparative organic chemistry.

Helmut Simon [NB 405 IE]

Molecular Symmetry and Group Theory. By *A. Vincent*. John Wiley and Sons, London–New York 1977. 1st Edit., ix, 156 pp., bound, £ 5.90.

The author first describes the symmetry elements and symmetry groups, and then deals in the next chapters with the representation of these groups by matrices, determination of the characters of a representation, and resolution of a reducible representation into irreducible ones. He then demonstrates how group theory can give valuable information about chemical bonds and molecular vibrations. All this is presented by the method of programmed learning, *i.e.* in small steps, each followed by a progress-test question and the correspond-

ing answer. If the reader does not give the right answer, he is told which part of the book he should consult again. In some cases no mathematical proof is offered, but the author does state expressly that he finds it more important for the reader to use the mathematical method correctly than to be able to prove all the theories.

The book is a really successful attempt at presenting the scientist with this important and relevant mathematical subject in the most rational manner possible, in such a way that the methods can be used correctly for the solution of problems. It is therefore highly recommended to everyone interested in molecular structure.

H. G. Zachmann [NB 406 IE]

Iminium Salts in Organic Chemistry. Part 1. Edited by *H. Böhme* and *H. G. Viehe*. Vol. 9 in the series Advances in Organic Chemistry, Methods and Results. John Wiley and Sons, New York-London, 1976. 1st Edit., xi, 631 pp., bound, $ 32.00.

In the first chapter, entitled "The Electronic Structure of Iminium Ions" (21 pages), *P. A. Kollman* gives the results of quantum-mechanical calculations on the electronic structure, geometry, rotation barriers, and spectroscopic properties of these ions. In the second chapter, "Structure Determination of Iminium Salts by Physical Methods" (82 pages), *R. Merényi* discusses experimental results given in tabulated form and examines possible equilibria of the type:

$$R_2N{-}CR'_2{-}X \rightleftharpoons [R_2N{=}CR'_2]^{\oplus}X^{\ominus}$$

H. Böhme and *M. Haake*'s third chapter, "Methyleniminium Salts" (117 pages), is fundamental from the preparative point of view. The authors concentrate on the dissociated "*N*-chloromethylamines", and their full account of the methods of preparation will impress even the expert, with its brief description of the physical properties and comprehensive treatment of the reactions.

In the fourth chapter, "The Vilsmeier-Haack-Arnold Acylations. C—C Bond-Forming Reactions of Chloromethyleniminium Ions" (117 pages), by *C. Jutz*, the emphasis is placed on the reactions between dissociated "dichloromethylamines" (derived from amides) and aliphatic compounds. They go beyond the Vilsmeier-Haack formylation, since they give not only aldehydes but also many other products. In Chapter 5, "Chemistry of Dichloromethyleniminium Salts (Phosgeniminium Salts)" (77 pages), *Z. Janousek* and *H. G. Viehe* discuss the dissociated "trichloromethylamines", which are in the same oxidation state as carbamic acid and whose study did not start until 1970. The three replaceable chlorine atoms and the ease of chlorination and aminomethylation open up very wide synthetic possibilities.

The sixth chapter, "α-Haloenamines and Keteniminium Salts" (112 pages), by *L. Ghosez* and *J. Marchand-Brynaert*, deals with covalent α-chloroenamines, which very readily dissociate into ketenimmonium chlorides. Their chemistry is characterized by nucleophilic substitutions of the chlorine atom (aminoalkylenation), enamine-type reactions, and cycloadditions. Chapter 7, "*N*-Heteroiminium Salts" (54 pages), by *J. Elguero* and *C. Marzin*, is devoted to immonium salts with heteroatoms (O, S, N) attached to the nitrogen, examples being derivatives of hydrazines, hydroxylamine, and sulfenic acid amides.

This outstanding book is the first to give such a comprehensive and authoritative account of immonium salts. However, in places one would welcome a more elegant use of formulas and a word or two about the contents of Part 2.

Günter Opitz [NB 398 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

Fundamentals of Chemical Relaxation. By *H. Strehlow* and *W. Knoche*. Vol. 10 of the series "Monographs in Modern Chemistry". Edited by *H. F. Ebel*. Verlag Chemie, Weinheim 1977. x, 133 pp., bound, DM 68.—.—ISBN 3-527-25722-5

Das Arbeiten mit ionenselektiven Elektroden. By *K. Cammann*. Vol. 13 of the series "Anleitungen für die chemische Laboratoriumspraxis". Edited by *F. L. Boschke, V. A. Fassel, W. Fresenius, J. F. K. Huber, E. Pungor, W. Simon*, and *T. S. West*. Springer-Verlag, Berlin 1977. 2nd, revised and enlarged edition, xii, 227 pp., bound, DM 76.—.—ISBN 3-540-07947-5

The Use of Chemical Abstracts: A Descriptive Guide to the Organisation. Development and Use of Chemical Abstracts and its Associated Indexes. By *M. B. M. Campbell*. Griffith University Library, Nathan, Queensland 1977. vi, 37 pp., paperback, $ 3.50.—ISBN 0-86857

ESR Spectroscopy in Polymer Research. By *R. Rånby* and *J. F. Rabek*. Vol. 1 of the series "Polymers—Properties and Applications". Edited by *H.-J. Cantow, H. J. Harwood, J. P. Kennedy, J. Meissner, S. Okamura, G. Olivé*, and *S. Olivé*. Springer-Verlag, Berlin 1977. xiv, 410 pp., bound, DM 112.—.—ISBN 3-540-08151-8

Grundlagen der Technischen Elektrochemie. Erweiterte Fassung eines Dechema-Experimentalkurses. By *E. Heitz* and *G. Kreysa*. From the "reprotext" series. Verlag Chemie, Weinheim 1977. xiv, 290 pp., paperback, DM 48.—.—ISBN 3-527-25754-3

Quantitative Mass Spectrometry in Biochemistry and Medicine

By W. D. Lehmann and H.-R. Schulten[*]

The current state of quantitative analysis with the mass spectrometer in biochemistry and medicine is reviewed. The basic principles of mass spectrometry, the latter's combination with chromatography, the development of sensitive, exact, and in particular specific mass-spectrometric methods of detection, and the principle of dilution with stable isotopes are illustrated by examples. The most important fields of application are: the pharmacokinetics of drugs and active metabolites, investigation of metabolic pathways, supporting of medical diagnoses and enhancement of their specificity, and finally checking the quality of simpler quantitative processes in clinical chemistry.

1. Introduction

This article is concerned with methods of mass spectrometry (MS) and their applications to quantitative analysis in biochemistry and medicine. The measurement processes and their results are presented with the aid of instructive examples and discussed. References to literature containing further information give a survey of the most important investigations of the last 10 years without being complete in the strict sense.

Basically, the advantage of the mass spectrometer as a detection system in qualitative and quantitative investigations is that a high sensitivity is achieved, combined with a high specificity. The quantitative mass-spectrometric determination is always based on the identification of compounds. In complex mixtures, such as occur for example in biological samples, mass-spectrometric analysis is still preceded by a purification and separation process. In this way, a reliable quantitative determination of amounts of material in the microgram to picogram range is achieved.

Many publications have appeared on the possibilities of the most widely used combinations of gas chromatography (GC) and MS (see, for example[1–17]). The most recent results of research into the metabolism of drugs[18–21], the biochemical and medical applications of stable isotopes[22, 23, 273], and quantitative mass spectrometry[24, 286] have been published in a series of conference reports. These relatively new methods have exerted a pronounced influence on drug research in the last few years[25–32]. In the sector of clinical chemistry[33–45] the investigations are centered on the qualitative and semi-quantitative detection of anomalous metabolic products (see Section 7.4). Quantitative measurements, such as precision isotope analysis of the respired air, likewise provide diagnostically valuable information (cf. Section 8.1). Since in biochemistry and medicine there is very often an interest in substances present in very low concentrations together with many other compounds, and moreover the amount of sample available is usually small, the advantages of the mass-spectrometric method of detection are particularly impressive in this field.

2. Basic Principles of Quantitative Mass Spectrometry

The performance of quantitative analyses with the mass spectrometer sets particular demands on the measurement principle. The signal intensity depends not only on the amount of the sample but also on a number of experimental parameters such as the ionization yield, focusing of the ion beam, the transmission of the apparatus, and the amplification factor of the detector. Since it is difficult to determine all these magnitudes individually and to keep them constant over a relatively

[+] To whom correspondence should be addressed.

long period, in practice use is always made of a comparative measurement of ion currents. This comparison of the intensities of the signals of the test substance (unknown concentration) and a standard (known concentration) can be performed in several ways:

1) In the first place, a calibration curve of the signal intensities (signal heights or areas) is drawn up as a function of the amount of substance and the unknown concentration is determined from the intensity of the signal by means of this standard curve. Here quantitative determination requires a comparison of two separate measurement processes, calibrated solutions of known concentration being used as an *external* standard.

The added-standard method may also be used. After the sample has been divided into two equal parts, a known amount of the compound to be determined quantitatively is added to one of them. The signal intensities of the untreated sample and of the sample with the added standard are then compared. Since the two parts of the sample must be processed and analyzed separately, this process is included among those with an external standard.

2) If a reference substance in known amount is added directly to the sample to be analyzed and is worked up and analyzed together with the substance of the sample, the process is said to be based on an *internal* standard. If one common type of ion is used for detecting the sample and standard (single ion monitoring), the sample and the standard must be fed into the ion source in succession. This can be done, for example, by separation in a gas chromatograph. With the simultaneous or overlapping introduction of the sample and standard into the ion source, separate recording can be performed, *e.g.* by the detection of selected types of ions (selected ion monitoring, multiple ion monitoring).

Compounds labeled with stable isotopes are in general very suitable as internal standards, since they are clearly distinguishable mass-spectrometrically from the unlabeled compound but are chemically practically identical with it. Homologs or even only chemically similar compounds may also serve as internal standards. In all cases before quantitative analysis the suitability of the selected internal standard should be checked by means of a calibration curve (see Section 4.2).

Before the description of some early investigations, those areas will be introduced whose development is closely related to the advances in the field of quantitative mass-spectrometric analysis.

2.1. Improvement of Microanalytical Separation Processes and Their Coupling or Combination with Mass Spectrometry

For a quantitative determination, the compound concerned must be introduced into the mass spectrometer in the purest possible form (apart from any internal standard used). The gas chromatograph is the separating system most frequently combined with the mass spectrometer. After *Henneberg*'s first experiments[46] with direct coupling of the two instruments, *Ryhage*[47] and *Watson* and *Biemann*[48] developed efficient coupling units (separators) which, on the one hand, reduce the pressure at the outlet of the gas chromatograph to the low value in the ion source of the mass spectrometer and, on the other hand, enrich the sample relative to the carrier gas. Chemical compounds whose thermal lability or low volatility do not permit a gas-chromatographic separation, and which cannot be converted into derivatives[49] with good gas-chromatographic properties, may be worked up before mass-spectrometric analysis *e.g.* by thin-layer, column, or high-pressure liquid chromatography (HPLC)[50]. The application of such a process yields, in addition to purification, additional analytical information (retention time, R_f value) which can be used to confirm the quantitative analysis[51].

2.2. Development of Mass-Spectrometric Recording Techniques for Quantitative Analysis

Several techniques have been developed and tested for measuring the intensities of several ion signals during a time that is limited by the size of the sample:

Repeated passage through a preselected mass range (repetitive scan) by varying the magnetic field strength or the accelerating voltage.

Detecting of selected ions which are focused on the detector in turns and in rapid sequence by variation of the accelerating voltage (selected ion monitoring). The use of GC-MS coupling with this type of ion detection is often called mass fragmentography.

Detection of only one ionic species (single ion monitoring). When an internal standard is used, this type of detection requires that at least two compounds are introduced into the ion source in succession, for example by gas-chromatographic separation.

Use of a multiple detector. Here usually two ionic species are recorded simultaneously under constant instrumental conditions.

The detection sensitivity of these processes for an ion signal rises to the degree in which the proportion of the measuring time of the signal in the total measuring time is increased. Both in the detection of only one ionic species and in the use of a multiple detector an optimum detection sensitivity is achieved, since here this proportion amounts to 100%.

2.3. Availability of Compounds Labeled with Stable Isotopes

In recent years biochemicals labeled with stable isotopes have become commercially available because of the enrichment of the stable isotopes of hydrogen, carbon, nitrogen, oxygen, sulfur, *etc.*, carried out on a large scale in the United States[52]. Such compounds have proved to be outstanding as internal standards for quantitative MS investigations. The increasing demand in the last few years has led to a fall in the price of these compounds; thus, 1 g of [D_1]-glucose now costs about DM 400 and 1 g of [1-^{13}C]-glucose about DM 3000. Since microgram amounts of the standard at the most are needed for one quantitative determination, these costs amount to only pfennigs per analysis.

2.4. Coupling of Mass Spectrometer to a Computer

The time required for the recording and processing of the results in mass-spectrometric analyses is considerably reduced by coupling the mass spectrometer to a computer. This permits the treatment of a larger number of samples and creates the prerequisites for routine analysis, *e.g.* in the clinical field.

The recent development of also using the computer for the control and monitoring of the analytical parameters leads to a simplified and better-reproducible operation of the mass spectrometer. Against these advantages there are two disadvantages: on the one hand, the costs of a computer system are of the same order of magnitude as those of a mass spectrometer, and secondly, the complexity of the analytical system and therefore also its susceptibility to breakdown is increased.

3. Early Mass-Spectrometric Investigations with the Detection of Selected Ions on Biochemically Important Compounds

3.1. Specific Recording of the Components in Mixtures

In magnetic mass spectrometers a mass spectrum is usually produced by varying the magnetic field strength. However, it is also possible to focus ions of different masses on the detector by changing the accelerating voltage at a constant magnetic field. Since a voltage can be switched between preselected values considerably faster and more reproducibly than a magnetic field (because of magnet inertia and hysteresis), in magnetic mass spectrometers the accelerating voltage is varied preferentially in order to detect selected ions.

The repeated stepwise variation of the accelerating voltage was used by *Nier et al.*[53] as early as 1948 for the continuous mass-spectrometric monitoring of mixtures of inorganic gases. This type of detection was first used for recording biochemically interesting compounds in 1966, by *Sweeley et al.*[54]. The authors constructed an attachment for the mass spectrometer which permitted the accelerating voltage to jump back and forth between two adjustable values and therefore made possible an almost simultaneous recording of two ionic species of different mass. The aim of this procedure was separate recording of compounds whose mixture could be separated by gas chromatography only partially or not at all. The authors achieved this by the mass-spectrometric detection of selected pairs of ions in the eluate of the gas chromatograph. One of the mixtures investigated is shown in Figure 1.

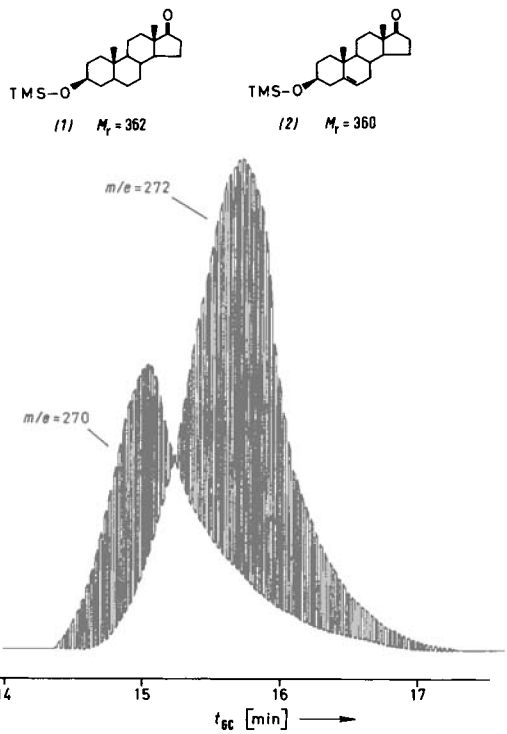

Fig. 1. Separate recording of the trimethylsilyl (TMS) derivatives of epiandrosterone *(1)* and dehydroepiandrosterone *(2)* by recording two selected ionic species (m/e = 272 and 270) with GC-MS. The two substances were partly separated by gas chromatography (t_{GC} = elution time). The mass spectrometer was adjusted in such a way that first with full accelerating voltage the ion with the smaller mass was focused on the detector by variation of the magnetic field. The accelerating voltage was then reduced to such an extent that the heavier ion encountered the detector. During the analysis the accelerating voltage jumped back and forth between the normal value and the adjusted lower value. The line joining the corresponding signal maxima gives two ion-current profiles which permit separate detection of the two compounds (after [54]).

In the same way, in mixtures of glucose and [D_7]-glucose *Sweeley et al.*[54] determined the proportion of the deuterated compound in microgram samples with an accuracy of about 5 %.

In the following years several improved units for varying the accelerating voltage were described[55–65].

In the case of the quadrupole mass spectrometers frequently used today[66] selected kinds of ions are detected by varying the quadrupole field, *i. e.* likewise only by changing electric fields (see also Section 5.3 and 6.2).

3.2. Qualitative Detection of a Drug and its Metabolites

In the first applications of the detection of selected ionic species, *Hammar et al.*[67] identified the drug chlorpromazine and three of its metabolites in human blood with a GC-MS combination. Although two of these metabolites were present in such low concentrations that no complete mass spectrum could be recorded, they could be identified by the fact that the ion-current profiles of three selected ions showed the same intensity ratio as in the mass spectra of the synthetic reference substances and that the retention times of the sample and the reference substance were also in agreement. Obviously with regard to the possibility of being able to identify compounds by the relative intensities of mass-spectrometric *fragments*, the authors called this technique mass fragmentography. In the original literature about 15 terms are found for this technique[68, 69], those most frequently used being mass fragmentography and selected ion monitoring. Here we shall use the terms single ion monitoring and selected ion monitoring, and shall call the results of the measurements selected ion-current profiles.

3.3. Isotopic Dilution and Quantitative Determination

When nanogram amounts are injected into a packed GC column frequently no signal can be obtained at the outlet because of self-absorption and thermal losses. If, however, a form of the compound labeled with stable isotopes is simultaneously injected in a large excess, the absorption capacity of the column acts on the total amount of labeled and unlabeled forms and thus considerably reduces the loss of the unlabeled form. The use of isotope-labeled analogs as carriers in a GC-MS combination permits the detection of compounds in the picogram range[17]. According to recent investigations this frequently described carrier effect does not seem to be a general phenomenon[280].

In a methodological investigation, *Samuelsson et al.*[70] used the addition of a compound labeled with a stable isotope (stable isotope dilution) to increase the sensitivity of a GC-MS combination and simultaneously to perform a *quantitative* detection. They added a trideuterated prostaglandin in approximately 1000-fold excess to a sample containing the undeuterated form and recorded the ion-current profile of the corresponding ions with $m/e = 470$ and 473. A prerequisite for a quantitative determination performed in this way is that the labeled compound added in large excess contains only a very small amount of unlabeled component. In the investigation cited, the proportion of the $[D_0]$ compound in the $[D_3]$-prostaglandin amounted to 0.39%; when this was taken into account, it was possible to determine quantitatively the $[D_0]$ component present in the sample. The limit of detection was about 3 ng, *i.e.* a mixture of 3 μg of the $[D_3]$ component and 3 ng of the unlabeled compound was injected into the gas chromatograph.

The handling of very small samples is facilitated by the use of capillary columns instead of packed columns in GC-MS. In quantitative investigations with amounts of substance with which absorption in the separating system plays a subordinate role, an approximately equimolar ratio between the sample and the standard is selected, since this gives a higher accuracy.

The first quantitative determination of a steroid hormone, *i.e.* an *endogenous* compound, by the detection of selected ionic species was performed by *Siekmann et al.*[71]. By using dideuterated estrone as an internal standard, it was possible to determine the estrone concentration in pregnancy plasma down to 200 ng/2.5 ml. This investigation also showed the high specificity and the high detection sensitivity of this technique (between 1 ng and 50 pg for the steroid hormone investigated).

A little later, *Gaffney et al.*[72] tested a quantitative determination of nortriptyline, *i.e.* an *exogenous* compound, by the same method. This drug is used in the treatment of mental disorders. As the internal standard the authors used both dideuterated nortriptyline and a sulfur "homolog" of this compound. After extraction from blood samples and conversion of the secondary amines to trifluoroacetyl (TFA) derivatives, the compounds were each detected by means of a selected ion after GC separation (see Fig. 2).

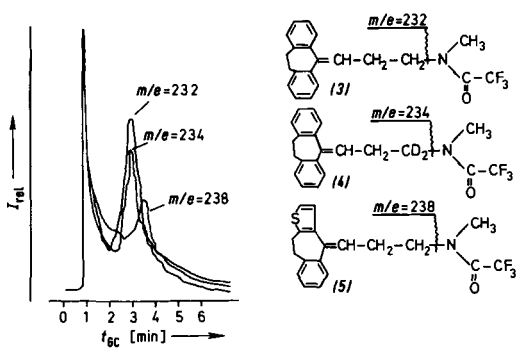

Fig. 2. Analysis of plasma extract containing nortriptyline, $[D_2]$-nortriptyline, and a sulfur "homolog" of this compound in the form of the trifluoroacetyl (TFA) derivatives *(3)*, *(4)*, and *(5)* respectively in the ratio of 1:1:1 (t_{GC} = elution time). The detection of the selected ions with $m/e = 232$, 234, and 238 shows that deuterated and undeuterated nortriptylene are eluted after the same retention time and are recorded with the same sensitivity, while the sulfur-containing compound is eluted later and gives a smaller signal. In quantitative determination in blood plasma it was found that the deuterated compound is more suitable as an internal standard, since at its selected mass there is a smaller superimposition of accompanying substances (after [72]).

In these early investigations quantitative determination was by no means the center of interest. However, on this basis a large number of quantitative mass-spectrometric investigations with a biochemical-medical orientation have been developed.

4. Prerequisites for Quantitative Microanalysis

4.1. Workup and Internal Standard

Although the workup procedure in each determination process must be adapted to the particular sample and the compounds to be detected, certain common features can be described.

A measured amount of the internal standard is added to the sample, *e.g.* a body fluid or homogenized tissue, immediately after it has been collected, and is uniformly distributed in the sample. If part of the compound to be detected is not present in the free form but *e.g.* as a conjugate with glucuronic acid, sulfuric acid, *etc.*, or is bound to a protein (which is frequently the case with drugs), hydrolysis is then carried out to cleave these conjugates (*e.g.* with strong acids or alkalis or enzymatically). If no conjugate is present, or if only the free fraction of the compound is to be determined, the sample is extracted without this step. The extraction is usually carried out by shaking with an organic solvent, which forms a separate phase from the aqueous sample solution[73-75], or by a combination of chromatography and extraction. After the concentration of this extract by removing the solvent under a stream of an inert gas, the mixture of substances must be separated in a special step unless the substance to be detected is already present at such a high concentration that a direct mass-spectrometric analysis can be performed. Suitable methods of separation are gas chromatography, thin-layer chromatography, and high-pressure liquid chromatography, but before GC separation in general the compounds to be detected in the extract must be converted into derivatives in order to increase their volatility and thermal stability. After separation, the sample substance is introduced into the mass spectrometer and is analyzed quantitatively, *e.g.* by the detection of selected ions (see Fig. 3).

In practice a number of purification steps is frequently necessary[38]. Consequently, for quantitative determination the use of an internal standard is the method of choice. A suitable internal standard must on the one hand be as similar as possible to the compound to be determined, so that the concentration ratio adjusted immediately after the sample collection is not changed by workup but, on the other hand, it must be clearly distinguishable mass-spectrometrically from the sample substance. Without an internal standard the yields of each individual extraction and conversion step would have to be determined, while with the use of this standard a single measurement of the concentration ratio of the sample substance and the internal standard is sufficient. The usefulness of an internal standard and of the analytical process can be checked by investigation of calibration mixtures.

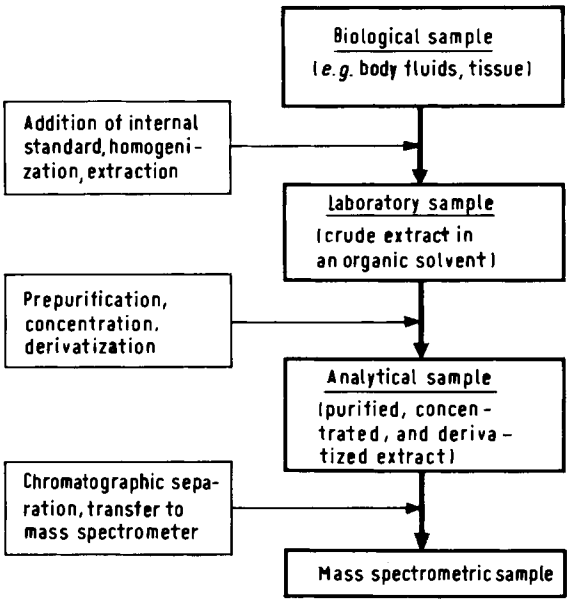

Fig. 3. Schematic process for workup of biological samples for quantitative mass-spectrometric analysis.

fluid (CSF). 5-HIAA is an important degradation product of 5-hydroxytryptamine, a biogenic amine involved in the mechanism of signal transmission in the nervous system.

The course of the calibration curve in Figure 4 shows that $[D_2]$-5-HIAA is a good internal standard. In the investigation of five samples amounts of 8—32 ng of 5-HIAA/ml CSF were found. The mean error of the means determined from 5 measurements in each case was 6 % at 20 ng and 1—2 % for larger amounts.

Figure 5 shows a different position of the calibration curve in connection with the detection of an ionic species and the use of a compound of similar structure as an internal standard. *Walle et al.*[78] determined the amount of the drug propanolol and its active metabolite 4-hydroxypropanolol in human blood plasma. For this purpose they used GC-MS and the detection of a common fragment ion of the drug, metabolite, and standard.

In order to ensure the specificity of the whole detection process and to test the proportionality between the amount of substance and the analytical results, calibration curves should be constructed before the quantitative determinations.

4.2. Calibration Curves

As the basis of quantitative mass-spectrometric determinations, it should be checked on calibration mixtures made up of the sample substance and the standard whether linearity exists between the composition of the mixture and the measured values, *i.e.* the ratio of the signal height or areas in the ion-current profile, in the concentration range of interest. In accordance with the conditions of analysis of authentic samples, these calibration mixtures are usually made up by adding different amounts of the sample substance to a constant amount of internal standard. Fig. 4 shows a calibration curve drawn up by *Bertilsson et al.*[76] by this method. By means of a GC-MS combination and the detection of selected ionic species, these authors determined the concentration of 5-hydroindole-3-acetic acid (5-HIAA) in human cerebrospinal

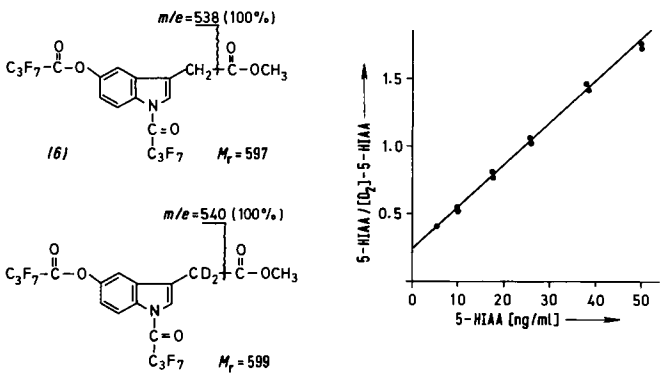

Fig. 4. Calibration plot (based on signal heights) for checking a quantitative assay. Calibration mixtures were prepared and analyzed that contained in each case 40 ng/ml of internal standard ($[D_2]$-5-hydroxyindole-3-acetic acid, $[D_2]$-5-HIAA) and different amounts of 5-hydroxyindole-3-acetic acid (5-HIAA) in synthetic cerebrospinal fluid (CSF) [77]. The plot shows linearity between the analytical values and the 5-HIAA concentration. The intercept on the ordinate agrees with the assumption that the internal standard contained 20 % of the $[D_0]$ component. For the GC separation it was necessary to make the bis(heptafluorobutyryl) (HFB) methyl ester derivatives *(7)* and *(6)* (after [76]).

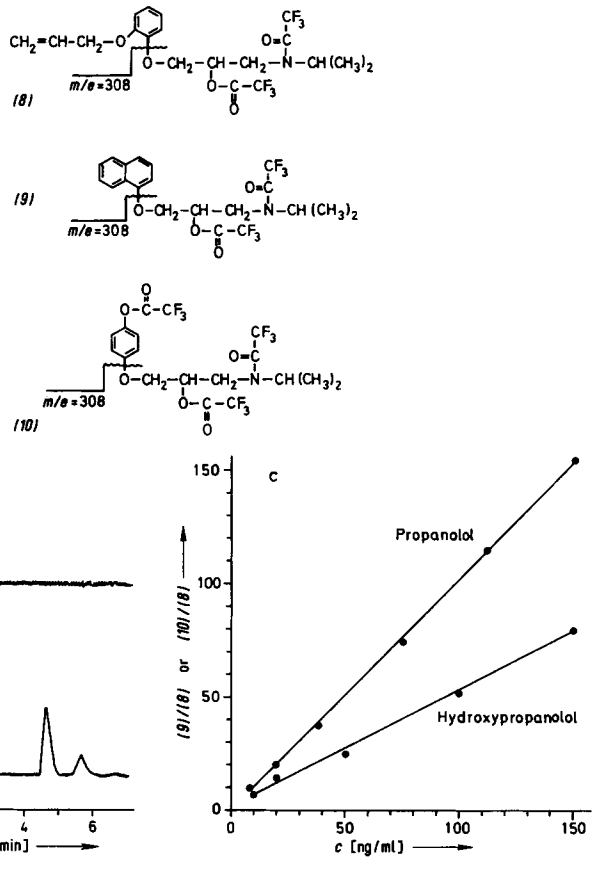

Fig. 5. Calibration plots (based on signal areas) and ion-current profiles for the quantitative determination of propanolol and 4-hydroxypropanolol [in the form of the trifluoroacetyl (TFA) derivatives *(9)* and *(10)* with oxprenolol [in the form of the TFA derivative *(8)*] as internal standard. A) Blank value of the ion current at $m/e = 308$ in the analysis of plasma without the administration of propanolol and without the addition of the internal standard; B) after the administration of propanolol and addition of *(8)*; C) the calibration plots pass through the origin, since no other ions with $m/e = 308$ interfere. The slope of *ca.* 1 in the plot for propanolol shows that the sensitivities for components *(8)* and *(9)* are practically the same. The slope of the calibration curve of *(10)* is only about half as large, which indicates loss of the substance during working up and separation (after [78]).

In general, the calibration curves are plotted from the measurements by the method of least squares. The use of compounds labeled with stable isotopes as internal standards almost invariably gives plots with a slope of unity (within the accuracy of the measurements), passing through the coordinate origin if the standard contains practically no unlabeled component and there is no superimposition of impurity ions. When compounds labeled with ^{13}C, ^{18}O, ^{15}N, *etc.*, (but not deuterium-labeled compounds) are used and the work is carried out at relatively high concentrations (>10 ng/ml), under certain conditions calibration curves need not be constructed[28]. Such compounds show optimal chemical similarity to the unlabeled analog to be determined. No disturbances due to replacement of the labeled by unlabeled atoms or to isotope effects are to be expected.

5. Comparison of Mass-Spectrometric Techniques for Quantitative Determinations

5.1. Accuracy, Precision, and Sensitivity

The *accuracy* of a measurement represents its deviation from the true value. Systematic errors always affect measurements in one direction and therefore affect accuracy, while fluctuations arising statistically average out with increasing number of measurements.

The *precision* gives a measure of the reproducibility of the measurements when the same sample is analyzed repeatedly. The precision is expressed as the relative or absolute standard deviation of the arithmetic mean of a set of measurements[79].

The *sensitivity* of a measurement is described by the ratio of the recorded magnitude of the signal to the amount of sample used. In mass spectrometry it is given, for example, as coulomb/μg.

In what follows the mass-spectrometric detection techniques used for quantitative analysis will be described in the sequence of increasing precision and sensitivity.

5.2. Repetitive Scanning of a Preselected Mass Range

Comparative measurements of the intensity of several ionic species can be carried out without additional apparatus by repetitive scanning of a preselected mass range (repetitive scan) (see, for example[80]). With relatively large amounts of the sample, at a constant total ion current, the signal intensities can be compared directly (see Sections 6.3 and 10.3). If, because of the small sample size or because of the nature of the sample introduction (*e.g.* by direct GC coupling), the total ion current cannot be kept constant over the period of a few mass scans, after the measurement the ion-current profiles of individual types of ions can be reconstructed from the recorded mass spectra. This can be done effectively only when the results are fed into and processed by a computer (see Section 6.2). In this case the areas of the ion-current profile are usually used for the comparative measurements.

The scanning of a mass range yields less accurate values than the processes described below[81,82], since a large part of the measurement time is not used for recording the ions of interest. In addition to this, there is the fact that to record undistorted mass spectra certain adjustments of the resolving power and the time constant of the amplification system must be maintained that do not permit an adjustment to the optimum sensitivity. These disadvantages can, however, be partially compensated if only a small section of the mass spectrum is scanned and a multichannel analyzer is used for accumulation of the signals[268,271].

5.3. Detection of Selected Ions

The precision of the determination of the intensity of selected ions with a magnetic mass spectrometer depends on the stability of the magnetic field, the accelerating voltage, and the amplification system, and also on the amount of the sample. In the nanogram range the precision is of the order of 1–2 % if approximately equal amounts of the sample and the standard compound are present. In the case of amounts of substance in the microgram range the precision increases, whereas in the subnanogram range a precision of only about ±10 % is obtained. The decrease in precision with smaller amounts used for analysis is due to the increase in the statistical fluctuations of the ion current and the difficulties in reproducible handling of very small samples. The best values reported are a precision of about ±0.3 % for an amount of 3 ng and ±10 % for 30 pg[83]. These figures were obtained with a combination of a capillary-column GC and MS.

Comparable precisions have been found on working with a quadrupole mass spectrometer[84]. As compared with magnetic instruments, this has the advantage that the times for the jumps between the preselected masses are still shorter and that ions of any desired mass can be selected (in the case of the magnetic instrument the smallest selected mass must amount to at least some 60 % of the highest mass). On the other hand, in the quadrupole apparatus when the masses are far apart a correction must be made for the mass dependence of the ion transmission.

The main sources of error in quantitative determinations lie in adsorption-desorption effects in the separating system or in the glassware used and, especially, in the comparatively simple metering of the internal standard. In the preparation of the standard solutions and in the measuring out of an aliquot—typical amount 20 μl—to be added to the sample, errors amounting to a few percent may quite easily arise. This applies above all to the case in which a relatively large number of samples is processed and routine measurements, *e.g.* in the clinical field, are performed over a relatively long time.

5.4. Detection of Only One Type of Ion (Single Ion Monitoring)

Referred to the analysis of the same amounts of substance, in the detection of only one type of ion a greater precision is always achieved than in the detection of several selected ions, since in the first case 100 % of the measurement time is utilized for recording. In a comparative study on the quantitative analysis of a barbiturate by these two methods, *Lee* and *Millard*[85] showed that the increased precision has an effect only in the region of amounts of substance smaller than 1 ng. In the subnanogram range the authors achieved the greatest precision by adding to the sample a related barbi-

turate as an internal standard and a deuterated derivative in excess as a carrier for the GC separation, and performed the quantitative determination by detecting a common fragment ion of the sample and standard.

5.5. Simultaneous Detection with a Multiple Detector

Precision isotope determinations can also be carried out with a precision of up to $1:10^5$ by means of special mass spectrometers. For this purpose, however, large amounts of sample, comparison with a standard mixture of accurately known isotope distribution, and recording with a multiple detector are necessary. Multiple detectors usually record two types of ions simultaneously, and because of their construction they are limited to a relatively low range of masses. They are particularly suitable for gas analysis, *e.g.* for the precision measurement of the amount of ^{13}C or ^{18}O in CO_2, where the ions of masses 44 and 45 or (44+45) and 46 are collected simultaneously (see Section 8.1).

6. Examples of Application: Quantitative Determination of Drugs

6.1. GC-(EI)MS Coupling—Determination of the Steady-State Blood Level of Imipramine and Desipramine

The tricyclic compound imipramine *(11)* is frequently used for the chemotherapy of mental disorders. The individual response to this drug differs widely, so that the same daily dose may be therapeutically effective, ineffective, or even toxic.

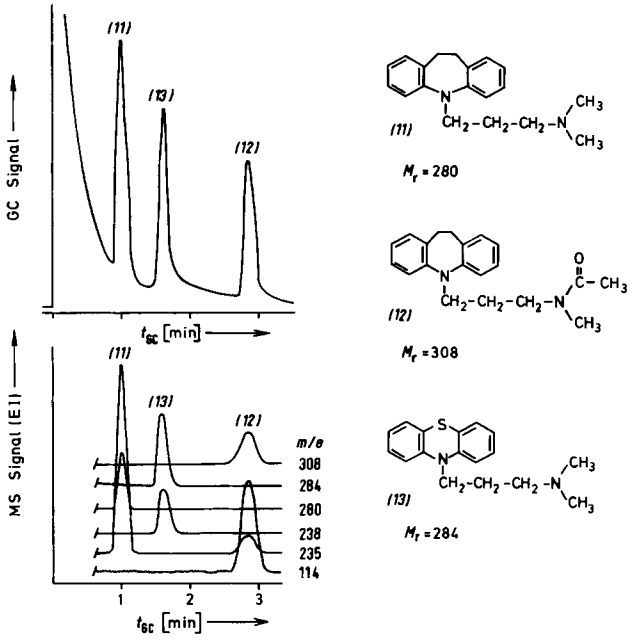

Fig. 6. Gas chromatogram and selected ion-current profiles of an extract from blood plasma after the administration of imipramine *(11)*. For the gas-chromatographic separation the metabolite desipramine was converted into the acetyl derivative *(12)*. On the basis of the EI spectra the following ions were selected for the recording (relative intensities [%] in parentheses): $m/e=280$ (20) and 235 (73) for imipramine *(11)*; $m/e=308$ (30), 235 (10), and 114 (100) for acetyldesipramine *(12)*; $m/e=284$ (17) and 238 (13) for promazine *(13)*. Since the ion-current profiles were recorded with a quadrupole mass spectrometer, it was possible to choose fairly well separated maximum and minimum recorded masses (after [86]).

In the determination of the concentrations of imipramine and its demethylated metabolite desipramine in blood samples of various patients receiving the same daily dose, again large individual variations can be found. For example, *Belvedere et al.*[86], using a combination of a gas chromatograph and an electron impact (EI) mass spectrometer and the detection of selected ionic species, investigated the steady-state plasma concentrations of imipramine *(11)* and desipramine in patients receiving a constant daily dose of imipramine. As the internal standard they used promazine *(13)*, a chemically related compound. The calibration curves showed linearity between the compositions of the mixtures and the analytical results in the range of concentrations of 5—200 ng/ml plasma. Figure 6 shows the elution behavior of the compounds and the form of the selected ion-current profiles.

The sensitivity of the process reaches about 5 ng/ml plasma. In the investigation of one patient it was possible to show that about one week after adjustment to a daily dose of 75 mg of imipramine a constant blood level equal to about 70 ng/ml of imipramine and about 15 ng/ml of desipramine was achieved.

6.2. GC-(CI)MS Coupling—Determination of the Steady-State Blood Level of Imipramine and Desipramine

In an almost simultaneous study, *Claeys et al.*[87] also determined the plasma concentrations of imipramine and desipramine with a constant daily dose. For both compounds the authors synthesized a tetradeuterated internal standard and used chemical ionization (CI)[88,89] with methane as the reaction gas, since in the CI(CH_4) mass spectra the $[M+H]^+$ ions appear with 100% relative intensity. In contrast, the EI mass spectra show only molecular ions of lower intensity. The mode of detection used was fast repetitive scanning of

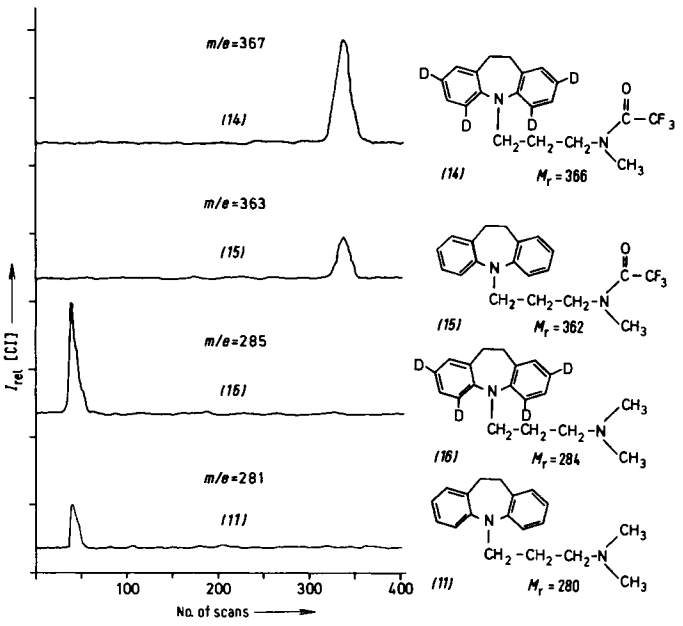

Fig. 7. Reconstructed ion-current profiles of imipramine *(11)*, trifluoroacetylated desipramine *(15)*, and their deuterated derivatives *(16)* and *(14)* as internal standards in the GC-(CI)MS investigation of a plasma sample. The CI quadrupole mass spectrometer was coupled directly to a computer, which recorded the mass spectra in rapid sequence (100 spectra per minute) and then reconstructed the ion-current profiles of the selected signals at $m/e=280$, 284, 362, and 366 from these and displayed them (after [87]).

a preselected mass range and computer reconstruction of the selected ion-current profiles from the stored results. (The ion-current profiles so obtained are frequently called "mass chromatograms"[90, 91].) The investigation was carried out with a quadrupole mass spectrometer coupled directly with a gas chromatograph and a computer. Figure 7 shows an example of the ion-current profile.

Investigation of six patients who had been adjusted to a daily dose of between 250 and 350 mg of imipramine *(11)* gave values between 55 and 290 ng/ml for the constant blood level achieved. The ratio between the drug and the demethylated metabolite desipramine varied between 0.5 and 1.85 in these patients. In this relatively small group of patients no correlation could be determined between the measured concentrations and the therapeutic result. However, in more recent detailed clinical investigations such a relationship has been found[92, 93].

6.3. (EI)MS with Direct-Inlet Systems—Pharmacokinetics of Cyclophosphamide in Single Dose Therapy

Cyclophosphamide *(17)* is one of the most frequently used antitumor drugs[94, 95]. It has been possible to identify some of its metabolites by selected ion monitoring (see for example[95]). Cyclophosphamide is administered in high single doses (between 10 and 100 mg/kg body weight[96]). Because of the resulting high concentrations in the blood and urine, the drug can be determined quantitatively with a mass spectrometer without a preliminary chromatographic separation. *Jarman et al.*[97] investigated the pharmacokinetics of cyclophosphamide *(17)* in blood by adding to the samples the tetradeuterated derivative *(18)* as the internal standard, extracting the plasma samples with dichloromethane, and introducing the evaporated extract into an electron impact (EI) mass spectrometer by the direct inlet system. The results of this investigation are shown in Figure 8.

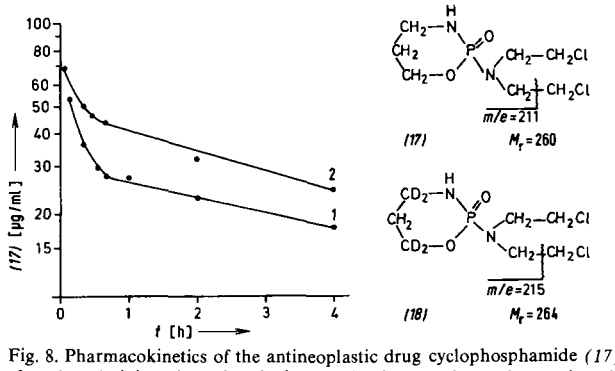

Fig. 8. Pharmacokinetics of the antineoplastic drug cyclophosphamide *(17)* after the administration of a single dose (patient 1, 12.5 mg/kg; patient 2, 27.8 mg/kg). The concentration scale is graduated logarithmically; the half-life of the drug can be calculated from the slope of the linear part of the curve. For the quantitative determination, at constant total ion current, a small mass range containing the fragment ions of masses 211 and 215 of the sample substance *(17)* and of the standard *(18)* was scanned repeatedly (after [97]).

The authors found a precision of 1% at concentrations greater than 10 µg/ml and deviations of 10% at 1 µg/ml. At still lower concentrations the signals of other compounds interfere, so that a purification of the extract would be necessary. This work shows that at relatively high concentrations of a drug the specificity of the mass spectrometer together with the method of dilution with a standard labeled with a stable isotope alone (without previous chromatographic separation) is sufficient for reliable quantitative determination.

6.4. GC-(EI)MS Coupling—Pharmacokinetics of a Single Dose at a Constant Daily Dose

When drugs are used over a long period they frequently accumulate in the tissue in a storage form—for example bound in the tissue (*e.g.* to protein)—and thus maintain a certain blood level for a time after the administration of the drug has been stopped. *Sullivan et al.*[98] succeeded in detecting the different availabilities of permanent doses and a pulse dose of a drug by quantitative mass-spectrometric measurements. For this purpose they gave dogs a daily dose of about 60 mg of the analgesic propoxyphene and on the 20th day replaced this dose by an equal amount of $[D_2]$-propoxyphene. The changes in the concentrations of the two components in plasma samples were then followed as a function of time. They were determined quantitatively by coupled GC-(EI)MS, selected ion monitoring, and the heptadeuterated compound as the internal standard. The calibration plots were linear and showed a high precision of the determination (standard deviation 0.5—2%). The differences between the changes in concentration can be seen in Figure 9.

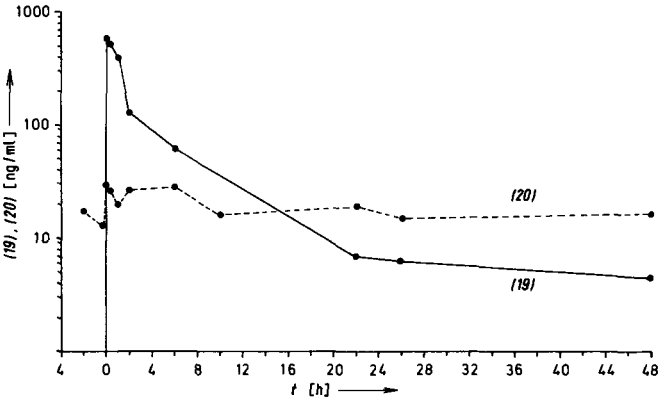

Fig. 9. Pharmacokinetics of a single dose of $[D_2]$-propoxyphene *(19)* (5.5 mg/kg) on day 20 (time 0) in dogs given a constant daily dose of $[D_0]$-propoxyphene *(20)* (also 5.5 mg/kg). After a steep rise of the level of the deuterated drug *(19)*, its concentration fell substantially faster than that of the $[D_0]$ drug *(20)*. This means that there is a relatively large depot of tissue-bound $[D_0]$-propoxyphene *(20)*, from which an almost constant concentration of the $[D_0]$ component is maintained in the blood (after [98]).

The investigation showed that, by labeling with stable isotopes, it is possible to distinguish doses of a drug administered at different times and also to elucidate their specific pharmacokinetics.

6.5. Brief Review of Other Determinations of Drugs

Most quantitative determinations of drugs have been performed with GC-(EI)MS. The use of thin-layer chromatography as a purification technique in combination with mass spectrometry is rarer[99]. Just like (EI)MS, (CI)MS is occasionally used with the direct-inlet system[82, 100–102]. Only the names of other preparations or drugs determined quantitatively will be given here, in alphabetical order: acetani-

lide[103,274], amphetamine[105-107,275], amobarbital[276], amylobarbitone[104], bromisoval metabolites[108], bupivacaine[277], cannabis compounds[109-111], capsaicine[112], diphenylhydantoin[278], ephedrine[114], ethanol[113], guanethidine[115], ketamine[279], lidocaine[102,116], methadone[119], methaqualone[117,118], methylphenidate[120], morphine[121-123], nortriptyline[124], octopamine[280], pentazocine[125], phencyclidine[126,281], phenformin[127], phenylbutazone[282], pinazepam[128], pirbuterol[129], propanetheline[283], propoxyphene[130,131], salbutamol[132], terbutaline[133], trazodone[134], verapramil[284], and vincamine[285]. The aim of such investigations is, for example, the measurement of therapeutically active concentrations, determination of the pharmacokinetics of drugs and their active metabolites, measurement of the rate of excretion, and the determination of the concentration ratio of a parent drug to its metabolites.

By labeling drugs with stable isotopes it is also possible to observe isotope effects in the *in vivo* metabolization (see, for example, [135-137]). For its recognition, after the administration of, for example, a 1:1 mixture of unlabeled and labeled drugs the isotope distribution in the metabolites or the drug itself is followed. Particularly large effects appear if there are several approximately equally justified degradation pathways and in one of them the rate constant is altered by the isotopic labeling (metabolic switching). The isotope effects in *in vivo* metabolization observed hitherto always related to the replacement of hydrogen by deuterium, in which, because of primary isotope effects, the enzymatic degradation of the labeled compound was retarded.

In many cases the described combinations of chromatographic and mass-spectrometric methods give a differentiated and more reliable insight into the course and the kinetics of drug metabolism than has been possible by other methods.

7. Examples of Application: Quantitative Determination of Endogenous Compounds

The advantages described in the preceding section also apply to the determination of endogenous compounds, *i.e.* compounds produced by the body itself, since the same measurement procedure is used for the direct quantitative determination of these compounds. Since many important compounds in body fluids and tissues are present in very small concentrations, and in the collection of samples from patients the available amount of the sample is limited, the use of isotopically labeled carriers is particularly important in such cases.

7.1. GC-(EI)MS Coupling—Determination of an Endogenous Compound in the Urine, Plasma, Cerebrospinal Fluid, and Brain and Liver Tissues

With only slight variations in the extraction and preparation of the samples, *Sjöquist et al.*[138] were able by means of a GC-MS method to measure the concentrations of 4-hydroxy-3-methoxyphenylglycol (HMPG), the most important metabolite of norepinephrine in samples of human and animal origin. The use of the trideuterated compound as an internal standard gave values of good precision (see Figure 10 and Table 1).

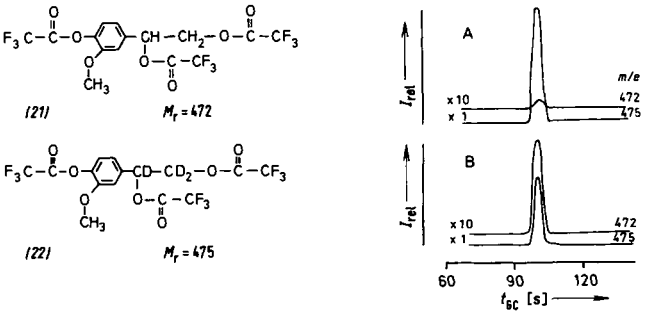

Fig. 10. Example of a quantitative determination of 4-hydroxy-3-methoxyphenylglycol (HMPG) with [D_3]-HMPG as an internal standard; the compounds were analyzed in the form of the tris(trifluoroacetyl) (TFA) derivatives *(21)* and *(22)*. A) Ion-current profiles of $m/e = 472$ and 475 of the internal standard *(22)* to check its contribution to the mass of the undeuterated compound (here 0.8%). B) Ion-current profiles of $m/e = 472$ and 475 in the measurement of a rat brain tissue extract (after [138]).

Table 1. Concentration of 4-hydroxy-3-methoxyphenylglycol (HMPG) in body fluids and tissues (after [138]).

Sample	HMPG [nmol/ml] or [nmol/g]	No. of determinations	Rel. standard deviation [%]
Man			
Plasma	0.056 ± 0.003	18	5.4
Urine	7.4 ± 0.21	20	2.8
Cerebrospinal fluid	0.073 ± 0.006	16	8.2
Rat			
Urine	24 ± 0.86	6	3.6
Brain	0.26 ± 0.016	10	6.2
Liver	0.099 ± 0.013	6	13

According to Table 1, the HMPG concentrations in the individual samples differed considerably. These values apply to the total HMPG concentration, *i.e.* they are sums of free and conjugated forms of the compound; before working up, the samples had been hydrolyzed enzymatically with sulfatase. By subtracting the concentration found without hydrolysis it is possible to determine the proportion of the compound present in conjugated form. In man this amounts to respectively about 94% and 90% in the urine and plasma, while in the cerebrospinal fluid it is 25%.

7.2. Quantitative High-Resolution Mass Spectrometry—Determination of Steroids with the Direct Inlet System and an External Standard

The tissue of human ovaries contains relatively high concentrations of steroid hormones in comparison with other tissues. *Snedden* and *Parker*[139] introduced freeze-dried tissue sections of ovaries *via* the direct-inlet system into an EI mass spectrometer and used a reproducible heating program going up to about 220°C to vaporize the volatile constituents of the sample. They obtained signals for estrone, estradiol, and progesterone, and found that at a mass-spectrometric resolution of 10000 no signals of other compounds interfered. During an evaporation process, by selected ion monitoring they recorded the ion-current profiles of one ion each of the three steroids investigated and one ion of the calibration substance perfluorotributylamine to check the exact mass position. The quantitative determination was performed by comparing the areas of the ion-current profile with the corresponding areas

of calibration measurements performed separately, *i.e. via* an external standard. The amounts of the steroids detected were between 10 and 50 ppm referred to the weight of the dried tissue; the standard deviation was about 20 %, which must be ascribed partly to the external calibration and partly to the fact that no homogenization of the tissue samples was performed. This investigation, and also an earlier one by the same authors[140], shows that in certain cases it is possible to use, in place of a separation, an increase in the mass-spectrometric resolution for specific and also quantitative determinations. In some cases high-resolution mass spectrometry has also been used in a GC-MS coupling for quantitative measurements[141, 142].

7.3. Spark-Ionization Mass Spectrometry—Quantitative Determination of Metals

The determination of inorganic constituents such as metals in biological material is an important analytical task. Spark-ionization mass spectrometry is a very versatile and sensitive method for the detection of metals. Since a photographic plate is used in most cases as the detector, the quantitative detection is more laborious than with electrical recording, but it is also suitable for routine operation[143, 144]. Measurements with internal[145, 146] and external[147] standards have been performed. *Ball et al.*[148] have determined a large number of elements, mostly metals, in the ash of mammalian blood by spark-ionization mass spectrometry and high resolution. For quantitative determinations calibration plots were constructed, correlating the degree of photographic blackening with the amount of sample. Some of the results are shown in Table 2.

Table 2. Metal content of the ash of mammalian blood determined quantitatively by spark-ionization mass spectrometry. 20 other elements are not given here (after [148]).

Element	Concn. [μg/ml] (wet weight)
Na	1930
Mg	59
Al	0.32
K	2250
Ca	44
Cr	0.07
Mn	0.35
Fe	1050

The range of error of the measurements is given as 15 %; this is due partly to calibration with an external standard and partly to the evaluation of the photographic plate, which alone causes errors of between 2 and 5 %. Recently, however, very sensitive determinations of metals in the form of porphyrin chelates by EI-MS were reported, in which multiply-deuterated porphyrin chelates were used as internal standards[149].

In biochemical analysis the isotope dilution technique has also been used for the quantitative determination of calcium[150], lead[151], and potassium[152].

7.4. Recording of Metabolic Profiles

An important question in the quantitative determination of endogenous compounds is that of the diagnostic value of the concentrations measured. Extensive investigations in which many metabolic products were determined simultaneously (metabolic profiling)[37, 75, 153] have shown that the concentrations that have to be regarded as normal values have a relatively wide range of variation. These natural variations are due to individual metabolic and to dietary differences.

Deviations in the metabolic profile of the urine, which frequently go far beyond the normal range of fluctuations, are caused by a number of congenital metabolic disorders[34, 35, 40, 41]. Here, because of some genetic defect, the organism may be unable to synthesize an enzyme, so that a certain substance can no longer be degraded normally in the body; this leads to a considerably increased excretion of this substance or of some unusual degradation products. Figure 11 shows the metabolic disturbance in the well-studied disorder known as phenylketonuria (PKU), which is characterized by the absence of the enzyme needed to convert phenylalanine *(23)* into tyrosine *(24)*. Patients with PKU therefore show extremely high urine concentrations of phenylalanine *(23)*, phenylpyruvic acid *(25)*, and other aromatic carboxylic acids, which are not hydroxylated in position 4. In addition, 4-hydroxyphenylpyruvic acid and 4-hydroxyphenyllactic acid are present in increased concentrations because of secondary enzyme inhibition.

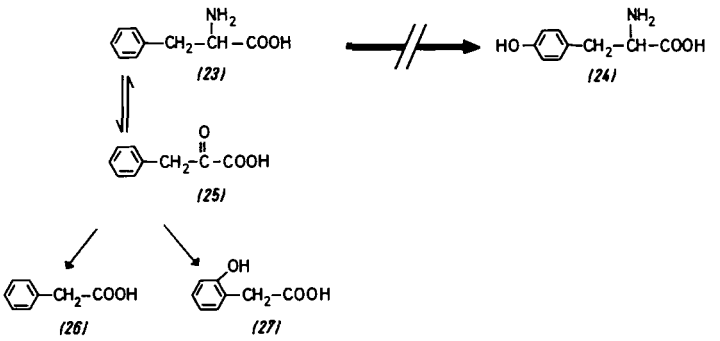

Fig. 11. Scheme of the hereditary metabolic disease phenylketonuria (PKU). The capacity for the synthesis of the enzyme that normally hydroxylates phenylalanine *(23)* to tyrosine *(24)* is lacking (metabolic block) (after [230]).

The recording of metabolic profiles by GC-MS is of particular importance for the early recognition of congenital metabolic defects in newborn babies and children. The occurrence of unusual compounds in high concentrations frequently causes, for example by competitive inhibition of other enzyme systems[154], severe disturbances in physical and mental development. On early recognition, these consequences can be almost completely avoided by a suitable diet—in the case of PKU, for example, by a phenylalanine-poor diet.

Quantitative mass spectrometry plays only a subordinate role in the recognition of congenital metabolic diseases, since the deviations are usually so great that they can be recognized directly from the gas chromatogram and in some cases can be determined quantitatively. Attempts have been made to develop computer-supported GC-MS analyses for diagnosing pathological abnormalities in the metabolic profile, so that even relatively large groups of patients can be investigated in routine analysis[155].

7.5. Determination of Other Endogenous Organic Compounds

The quantitative determination of endogenous compounds occupies an area as wide as that of drugs and their metabolites. Two of the best-investigated classes of compounds are steroids[156-175] and prostaglandins[176-187]. The distribution of biogenic amines[154,188-200], metabolically related compounds[201-211], and quaternary ammonium cations[287-291] in body fluids and tissues has similarly been intensively investigated. Other substances determined quantitatively by mass spectrometry include a number of amino acids[212-216], bile acids[217-219], carboxylic acids excreted in the urine[37,75,220], and a tetrasaccharide[221], which was also found in the urine.

8. Determination of Stable Isotopes in Metabolic Products

8.1. The Respiration Test: Precision Measurement of Carbon-13 Abundance

In the quantitative determinations already mentioned the main attention was directed at the measurement of the concentrations of organic compounds. For this purpose, directly after collection of the sample, by the addition of an internal standard labeled with stable isotopes a certain isotope ratio was generally produced artificially and was analyzed. It is also possible to provide an organism with a compound having a known isotope ratio as a substrate and to follow its degradation by measuring the isotope ratio in a metabolic product. A very promising field of application of this principle is the ^{13}C respiration test, *i.e.* the precise determination of ^{13}C in the CO_2 of expired air after the administration of compounds enriched in ^{13}C. A series of investigations has been performed with ^{14}C-labeling and following of the radioactivity in the expired air. Because of the absence of radiation the use of stable isotopes is also preferred here, particularly since results of informative value are obtained by both techniques. For example, *Shreeve et al.*[222] came to this conclusion in a test of the function of liver microsomes in which the subjects were fed with galactose labeled with both ^{13}C and ^{14}C. A reduced elimination of $^{13}CO_2$ or $^{14}CO_2$ shows a disturbance of microsomal function.

Since in the respiration test an adequate amount of the sample is available, intense ion currents constant over relatively long measurement times can be obtained in the mass-spectrometric analysis. The recording is carried out by means of a double detector which, in the case of the analysis of ^{13}C in CO_2, collects the ions of masses 44 and 45 simultaneously. If the isotopic composition of the sample is determined relative to a standard mixture of accurately known composition, a precision of up to $1:10^5$ can be achieved. Thus, the precision of the method exceeds the natural range of fluctuation of the abundance of ^{13}C in respired air[223,224], which is the factor limiting the sensitivity of the respiration test.

The possibilities of the method may be illustrated on an interesting example of its application due to *Lacroix et al.*[225-227], who performed a respiration test after the administration of *naturally* ^{13}C-labeled glucose. They found a $^{13}C/^{12}C$ ratio of 0.01085 in the CO_2 of the respired air of six subjects who had fasted overnight. In contrast, glucose obtained from maize, after combustion to CO_2, shows a higher ^{13}C abundance, namely 0.01100. For the experiment the subjects were given 100 g of this glucose dissolved in 400 ml of water, and subsequently samples of blood were collected at regular intervals for determining the glucose concentration and samples of respired air for the carbon isotope analysis. The results of these measurements are given in Figure 12.

The precision of the mass-spectrometric isotope analysis of carbon dioxide is so high that relatively small deviations in the isotope ratio of glucose from a natural source can

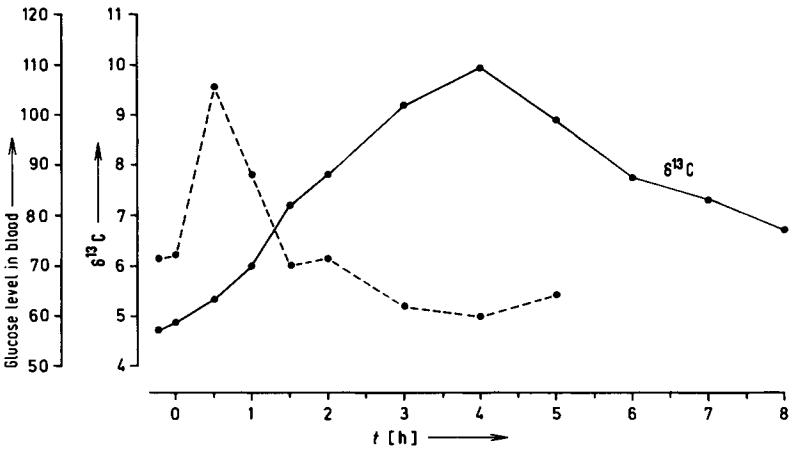

Fig. 12. Time variation of the blood level of glucose (---) and of the $^{13}C/^{12}C$ ratio $\delta^{13}C$ (—) in the expired air after the administration of 100 g of maize glucose (mean values for six subjects with normal glucose metabolism). The ^{13}C abundance is expressed relative to a standard with the ratio $^{13}C/^{12}C = 0.010806$, where

$$\delta^{13}C = 10^3 \left(\frac{(^{13}C/^{12}C)_{sample}}{(^{13}C/^{12}C)_{standard}} - 1 \right)$$

Expressed in these units, the maize glucose used after combustion to CO_2 showed a $\delta^{13}C$ value of 17.9 ± 0.3 (after [225]).

still be determined indirectly through biological degradation. As a result of a special synthetic pathway in plants, glucose obtained from maize and from sugar cane exhibits a higher ^{13}C content than glucose obtained from sugar beets, the ^{13}C abundance of which is only slightly above the mean ^{13}C abundance in the CO_2 of respired air.

Similar diagrams can be drawn up with substantially smaller amounts of glucose highly enriched with ^{13}C. In the case of persons with a disturbed glucose metabolism (*e.g.* diabetes), the glucose concentration curve shows a higher maximum and the ^{13}C curve a considerably flatter shape. Such experiments, in which enzyme activities can be determined indirectly with ^{13}C labeling with no exposure to radiation, are particularly important for the investigations on children and pregnant women.

A ^{13}C analysis of CO_2 through the detection of selected ions was used by *Sano et al.*[228] to determine ^{13}C-labeled compounds in urine samples. For this purpose the authors coupled a gas chromatograph *via* a pyrolyzer to a mass spectrometer, so that the organic samples were analyzed mass-spectrometrically after complete combustion. The $^{13}C/^{12}C$ ratio was given directly as an analog signal, so that the occurrence of a ^{13}C-labeled compound in the GC eluate could be recognized as a peak.

8.2. Investigation of Metabolic Pathways with Stable Isotopes

Stable isotopes find an elegant application in the *in vivo* study of metabolic degradation and synthesis pathways[229]. After loading of an organism with specifically-labeled substrates, the mass-spectrometric analysis of the metabolic products can give their content of labeled atoms; often, by showing the fragmentation, the mass spectrum also provides information on the position of the labeled atoms within the molecule.

Curtius et al.[230] were able to show on patients with PKU (see Fig. 11) that after administering deuterated phenylalanine only metabolites such as phenylpyruvic acid *(25)*, phenylacetic acid *(26)*, and 2-hydroxyphenylacetic acid *(27)* occurred in deuterated form in the urine, while no 4-hydroxylated products contained deuterium. This confirmed the presence of a metabolic block between phenylalanine and tyrosine. Using the isotope-labeling technique, *Curtius et al.* also investigated the degradation pathways of a series of aromatic carboxylic acids under the action of the intestinal flora. The use of stable isotopes of carbon[231], oxygen[232], nitrogen, *etc.*, is to be preferred to deuterium labeling in such studies, because of the substantially smaller isotope effects in *in vivo* transformations and because of the very stable incorporation of these atoms.

9. GC-MS as a Reference Method for Quantitative Determinations

Because of its sensitivity and range of application, the GC-MS combination competes with a number of other methods in quantitative determinations: gas chromatography, preferably with an electron-capture detector, radioimmuno methods[233], and fluorometric and photometric processes. *Björkhem et al.*[234] compared the determination of the urine estriol concentration by three methods. The estriol concentration in the urine of pregnant women is followed as a routine measure in pregnancies at risk, since it gives important information on possible complications. The authors used GC-MS as a reference method to check two simpler processes in clinical biochemistry. As the internal standard they used dideuterated estriol, which was converted into the trimethylsilyl derivative *(29)* for the GC separation.

After the construction of a standard curve, quantitative determinations in the concentration range of 2—50 μg/ml urine could be performed with a relative standard deviation of 6 %. In routine clinical analysis the concentration of estriol is generally determined by gas chromatography or photometrically. For a comparison, samples were analyzed by GC-MS, by GC alone, and photometrically. Figure 13 shows the correlation between the results of GC-MS and GC alone.

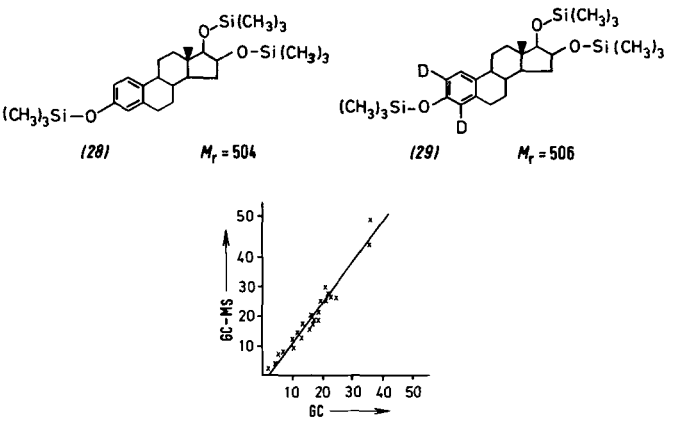

Fig. 13. Comparison of the analytical values in the quantitative determination of estriol by a gas-chromatographic method and a GC-MS combination (numerical values everywhere in [μg/ml]). The correlation coefficient of the results is 0.97 (after [234]).

The investigation showed that the routine methods used for estriol are sufficiently accurate and specific. It may be concluded from a series of comparative quantitative investigations[235–243] with the methods mentioned above that, because of its high specificity, GC-MS can in many cases be used for controlling simpler routine processes. Likewise, in testing new quantitative assays it is often a reliable reference method.

10. Quantitative Measurements with Modern Ionization Techniques

10.1. Atmospheric-Pressure Ionization (API)

Atmospheric-pressure ionization[244–247] is a variant of chemical ionization in which the ion source is at atmospheric pressure. The sample substance (which may include a solvent) is evaporated in the heated inlet system under normal pressure and then passes rapidly into the neighborhood of a very small opening which leads to the analyzer section held under high vacuum. On the normal-pressure side of the opening primary ions are produced in the gas by a radioactive source or by an electric discharge, and these form ions from the sample molecules by a series of secondary ion-molecule reactions. Both positive and negative ions are produced, which pass with the pressure gradient into the analyzer section

together with neutral particles. There the ions are accelerated by electric lenses and are focused into an ion beam.

Since according to the principle of chemical ionization negative ions can be obtained in relatively high yields, an example may be given here in which negative ions were used for a quantitative determination. *Horning et al.*[28] determined the concentration of the drug diphenylhydantoin *(30)* in samples of human plasma by API mass spectrometry. The authors used the triply-^{13}C-labeled compound *(31)* as an internal standard, carried out extraction with dichloromethane, and injected part of this extract without preliminary separation into the inlet system of an API mass spectrometer. Figure 14 shows the mass spectrum obtained.

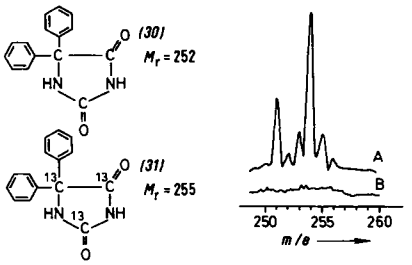

Fig. 14. API mass spectrum of the negative ions of a plasma extract (A) and the corresponding blank (B) of the pure solvent dichloromethane. The two intense ions are the $[M-1]^-$ ions of the drug diphenylhydantoin *(30)* (m/e=251) and of the ^{13}C-labeled internal standard *(31)* (m/e=254). The signal of the internal standard corresponds to an absolute amount of substance of 480 pg. The concentrations of sample and standard were respectively 10.4 and 24 μg/ml plasma. The quadrupole mass spectrometer was used for detection by repetitive scanning of the range m/e=245—260. The results were recorded by a computer and presented at the end of the analysis (after [28]).

In the case of the diphenylhydantoins only the $[M-1]^-$ ions appear in the API spectrum of negative ions. Because of the relatively high plasma concentration, it was possible to perform a quantitative determination without preliminary separation (cf. Section 6.3). This method is so sensitive that the part of the sample investigated corresponded to a content of only 20 nl of plasma. For combining API with a method of separation, its direct coupling with a liquid chromatograph has been described[248].

10.2. Field Ionization (FI)

The principle of field ionization[249–251] consists in the detachment of an electron from organic molecules in an extremely high electric field (several 10^7 V/cm). In this method of ionization only a relatively small amount of excitation energy is transferred, so that the field-ionization mass spectra show a lower relative intensity of the fragment ions and a higher relative intensity of molecular ions in comparison with electron impact mass spectra[246, 247]. In comparison with EI and chemical ionization, field ionization yields considerably smaller ion currents. In relation to the sensitivity of the FI method, this disadvantage is compensated to some extent by the fact that the few ion species occurring in the FI spectra carry a high proportion of the total ion current. *Reynolds et al.*[118] increased the sensitivity of FI by two modifications: they used a special emitter localized in the immediate neighborhood of the direct inlet system for the ion production and

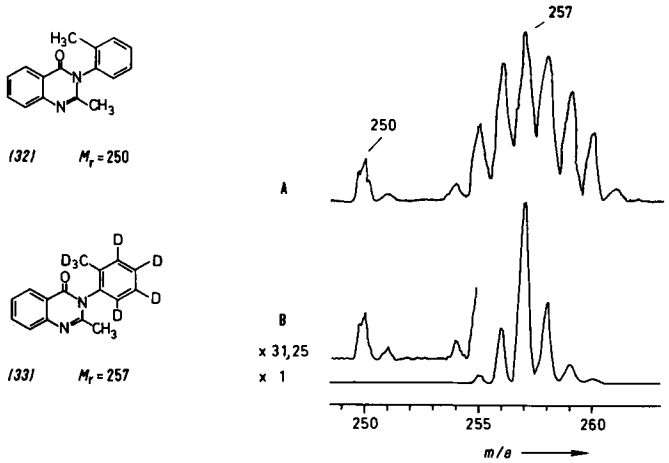

Fig. 15. FI mass spectrum of the molecular ion group of methaqualone *(32)* and [D_7]-methaqualone *(33)*, recorded by a multi-channel analyzer with ion counting. A) Logarithmic recording; B) linear recording at various sensitivities; the more sensitive trace corresponds to maximum scale deflection of 256 ions, and the less sensitive one to a maximum scale deflection of 8000 ions. The concentration of the unlabeled compound *(32)* was found to be 20 mg/ml urine. The urine extract was purified by chromatography and evaporated *via* the direct inlet (after [118]).

a multichannel analyzer for counting the ions. In this way, with an internal standard, the above authors were able to determine the drug methaqualone *(32)* in urine samples down to a concentration of a few ng/ml. Figure 15 shows an FI mass spectrum recorded for the quantitative determination.

The investigation demonstrated that with special methods of ion detection even with relatively weak ion currents it is possible to perform sensitive quantitative determinations.

10.3. Field Desorption (FD)

In field desorption, as in FI, the ions are produced in a strong electric field. However, the sample is not supplied to the emitter through the gas phase, as in FI, but at the beginning of the analysis it is present in the adsorbed state on the emitter surface. Field desorption permits gentle ionization of highly polar compounds and those of low volatility[252, 253], especially of salts[254–256], since there is no separate evaporation process of the sample. The mass spectra frequently show only the molecular ion or a cluster ion formed by the attachment of a cation to the molecule. Protons and especially alkali metal cations[257–259], are suitable for this process (cationization). For this reason the molecular ion group frequently carries the total current in FD, which is a favorable situation for quantitative analysis since it gives optinum sensitivity and reduces the disturbances due to impurities, and in addition no structurally significant fragments are necessary.

The often very short-lasting, and in the case of polar compounds also fluctuating, ion currents in field desorption demand integrating recording for a quantitative determination. Investigations with photographic[260–263] and electrical[262, 264–266] recording have shown that it is possible to carry out quantitative measurements by field desorption with good precision by using standards labeled with stable isotopes. Figure 16 shows the first results of the quantitative determination of cyclophosphamide *(17)* with the use of a deuterated standard *(34)*.

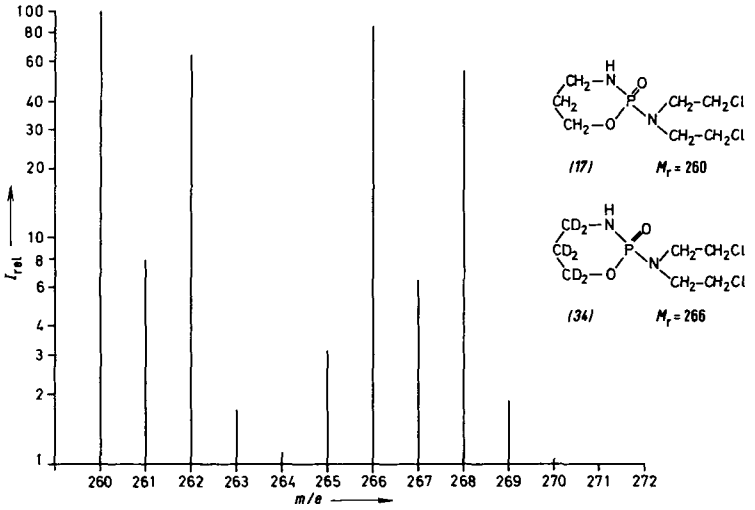

Fig. 16. FD mass spectrum of the molecular ion group of a mixture of $[D_0]$-cyclophosphamide *(17)* and $[D_6]$-cyclophosphamide *(34)* in the ratio of 1:0.85. Photographic detection with a resolution of about 15000 was used for recording the spectrum. Quantitative evaluation of the degree of blackening gives values with errors of about 5 % (after [260]).

By means of high-resolution mass spectrometry the specificity of mass-spectrometric detection can be raised to such an extent that quantitative determinations in untreated biological samples actually become possible (see Section 7.2). Figure 17 shows the desorption profile of a model mixture of homovanillic acid *(35)* and its isotopically labeled analog *(36)* obtained by high-resolution FD-MS.

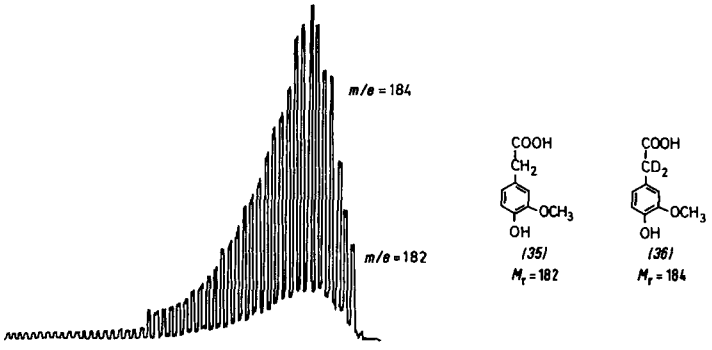

Fig. 17. Quantitative high-resolution FD mass spectrometry of $[D_0]$-homovanillic acid *(35)* with $[D_2]$-homovanillic acid *(36)* as internal standard. The desorption profiles were recorded with a linear increase in the emitter heating current and variation of the accelerating potential. The sample mass was 400 and 100 ng, respectively, at a mass spectrometric resolution of 12000. *(35)*:*(36)* (theoret.) = 1:4.35; *(35)*:*(36)* (exp.) = 1:4.60 (+5.7 %). (This determination was performed with a double focusing Varian MAT 731 mass spectrometer.)

Integrating recording of FD ion currents for quantitative measurements is most advantageously performed by the use of a multi-channel analyzer which accumulates the signals and thus averages the relative intensities. This technique permits direct isotope analysis of labeled and unlabeled organic molecules[268], which is demonstrated in Figure 18 for the protonated molecule of the antitumor drug methotrexate.

When analyzing natural products containing a large number of carbon atoms (>50) the precision of such a direct isotope analysis is sufficient to detect a slight natural depletion in

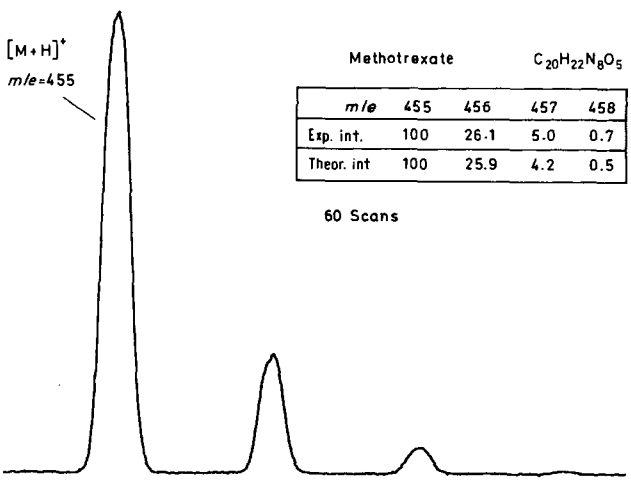

Fig. 18. $[M+H]^+$ ion group of methotrexate, recorded by FD-MS and accumulation of 60 cyclic magnetic scans. Good agreement is found between the observed relative intensities and those calculated from the natural isotopic abundances.

the ^{13}C abundance[268]. This effect is also found in a precision isotope analysis of carbon from plant material[23, 225].

FD-MS shows an extremely high sensitivity for organic and inorganic cations, especially for alkali metal cations[269, 270]. Therefore, even complex mixtures containing these ions in ppb concentrations can be analyzed successfully without pretreatment[271]. Precise and sensitive determination of the trace element lithium, which is used for the chemotherapy of some affective disorders, is an example of metal analysis in the biomedical field. Figure 19 shows the determination of the normal lithium level in human plasma, which has been performed by stable isotope dilution and accumulation of the FD ion currents with a multi-channel analyzer.

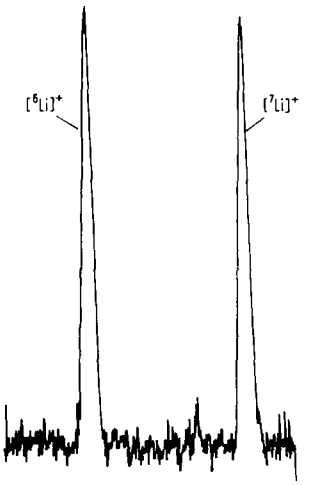

Fig. 19. Original trace of a $[Li]^+$ determination by FD-MS. 23 cyclic magnetic scans were accumulated by a multi-channel analyzer. A known amount of an isotopically enriched lithium salt was used as internal standard. Standard: ^6Li 88.4 %; ^7Li 11.6 %. Natural abundance: ^6Li 7.5 %; ^7Li 92.5 %. Quantitative evaluation gave a lithium concentration of 13.4 µg/l in the human plasma investigated. The sample amount for the measurement was 2 µl plasma.

For a quantitative analysis of organic compounds sample amounts between one nanogram and some micrograms are sufficient—depending on the purity of the sample and the compound under investigation. The sensitivity for a number

of organic and inorganic cations is about three orders of magnitude higher. The results obtained so far show that FD-MS is a useful method for assessing quantitative problems in the area of biochemistry and medicine[267, 272].

11. Evaluation and Prospects

Specific, sensitive, and quantitative detection of low-molecular biochemically important compounds in biological samples is possible with the aid of mass spectrometry. The main impetus for the expansion of quantitative analyses with the mass spectrometer in recent years came from the greater availability of compounds labeled with stable isotopes that are required as internal standards for quantitative determinations. The unobjectionable stable isotopes can generally replace radioactive isotopes in many *in vivo* investigations on human subjects, since sensitive mass-spectrometric methods are available for the detection of stable isotopes. A wide application of the method is opposed by the relatively high costs of the purchase and operation of a mass spectrometer. In addition to this, today in general there are the costs of a data-processing system, which are of the same order as those of the spectrometer itself. This expenditure is justified by the versatility of the combined system, which allows the solution of analytical problems in biochemistry and medicine that would otherwise be difficult or impossible. For these reasons a rapid further development and successful use of quantitative mass spectrometry in the described fields must be expected.

We are indebted to the Deutsche Forschungsgemeinschaft for the generous financial support of the present work. We should also like to thank Priv.-Doz. Dr. A. Niederwieser, Prof. Dr. H.-Ch. Curtius, of the University Pediatric Clinic, Pediatric Hospital, Zürich, and Priv.-Doz. Dr. L. Siekmann, Institute of Clinical Biochemistry, Bonn University, for a critical review of the manuscript and valuable information.

Photoacoustic Spectroscopy of Condensed Matter

New analytical methods (11)

By R. B. Somoano[*]

Photoacoustic spectroscopy is a new analytical tool that provides a simple nondestructive technique for obtaining information about the electronic absorption spectrum of samples such as powders, semisolids, gels, and liquids. It can also be applied to samples which cannot be examined by conventional optical methods. Numerous applications of this technique in the field of inorganic and organic semiconductors, biology, and catalysis have been described. Among the advantages of photoacoustic spectroscopy, the signal is almost insensitive to light scattering by the sample and information can be obtained about nonradiative deactivation processes. Signal saturation, which can modify the intensity of individual absorption bands in special cases, is a drawback of the method.

1. Introduction

Photoacoustic spectroscopy (PAS) is a new analytical tool that provides scientists with information about the electronic absorption spectrum of solids, semisolids, gels, and liquids. The photoacoustic effect (PA effect) was first discovered by *Alexander G. Bell* in 1881[1], but interest in the phenomenon subsequently waned. Recently, however, renewed interest in the PA effect in solids has emerged and it has been demonstrated that PAS may be a very useful analytical technique for the study of condensed matter. Much of this initial work was done by *A. Rosencwaig* of Bell Laboratories[2]. The purpose of this article is to give a state-of-the-art description of PAS which will illustrate its usefulness and limitations. Some of the more interesting and important results of concern to the nonspecialist will also be described in this article.

Pasadena, California 91103 (USA)

2. The Photoacoustic (PA) Effect

In a typical PA experiment, a sample is enclosed in an airtight non-resonant cell along with a sensitive microphone (Fig. 1a). The cell also contains air or any other gas at atmospheric pressure. The sample is illuminated with periodically modulated monochromatic light of wavelength λ. A typical modulation or chopping frequency f is 100 Hz. If the sample absorbs light of wavelength λ, electrons will be excited to higher states (Fig. 1b). After a brief time, the electrons decay back to the ground state by radiative and/or nonradiative processes (Fig. 1c). The PA effect is due solely to the *nonradiative decay processes*. When the electrons decay nonradiatively, a periodic heat distribution (of frequency f) is created in the sample at the point of absorption. This thermal distribution then diffuses throughout the sample in all directions (Fig. 1a). That part of the heat which diffuses to the sample surface gives up its thermal energy to the surrounding air. Only a very thin ($\approx$1 mm) boundary layer of air responds to this heat input and it periodically expands and contracts as it

is heated and cooled at frequency f. This thin layer of air then acts as an acoustic piston on the remaining column of air, creating pressure fluctuations which are detected by the microphone as the PA signal.

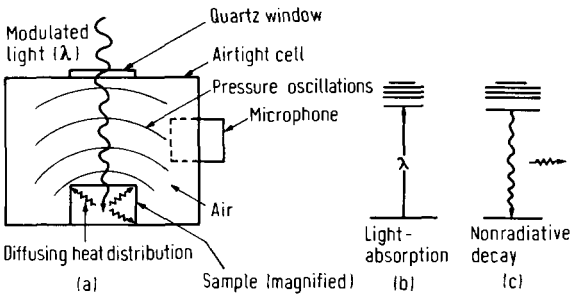

Fig. 1. A schematic of the photoacoustic (PA) effect. a) Diffusing heat distribution (⇝) and detection of the pressure fluctuations (the PA signal). The sample size relative to the cell and microphone has been magnified in order to show the diffusing thermal distribution. b) Light absorption and c) nonradiative de-excitation (cause of heat flow).

Thus, the PA process may be summarized as follows: 1) Absorption of periodically modulated light of wavelength λ; 2) nonradiative decay to create a periodic heat distribution; and 3) thermal diffusion to the sample-air interface to create pressure fluctuations (the PA signal). At wavelengths where no absorption occurs, no PA signal will be created. Thus, the PA signal correlates with the optical absorption and a plot of the microphone output *versus* λ gives the absorption spectrum.

There are several important features of the PA process:

1) In contrast to conventional optical spectroscopy, the PA effect is dependent upon both the excitation of excited states as well as their decay processes. If excited electrons decay solely by radiative modes (*i.e.*, if they fluoresce strongly), no PA signal will be generated. Hence, PAS provides information about the nonradiative decay modes and serves as a complementary tool to fluorescence spectroscopy.

2) The PA signal is quite insensitive to light scattered by the sample. Unlike conventional optical spectroscopy where scattered light gives rise to unwanted and misleading signals, in PAS only the absorbed light leads to a PA signal. Scattered light affects the PA signal only indirectly by reducing the amount of light incident upon the sample which might be available for absorption. This is of consequence only in very weakly absorbing or highly reflecting samples[3].

3) Because of the thermal diffusion process the photoacoustic signal is dependent upon both the optical and thermal properties of the sample. This feature is quite important and leads to certain limitations of PAS, such as signal saturation which will be discussed in Section 5.

Several other points concerning the PA effect should be mentioned. The effects of sample mass, particle size, sample reflectivity, and the use of gases other than air have been studied[4, 5]. Very small sample masses ($\approx 10^2$ μg) may be used. The PA signal increases at all wavelengths as the particle size decreases because power absorption and thermal transfer efficiency improve as the surface area increases. Thus, a finely ground sample will yield a larger PA signal than a single crystal or polycrystal of the same material. Highly reflecting samples are undesirable and must usually be ground to improve sample absorption. Finally, gases other than air offer no significant improvement although the use of higher pressures should enhance the signal.

In summary, PAS is a simple nondestructive technique providing qualitative information about the electronic absorption spectrum of samples such as powders, gels, semisolids, and liquids which might otherwise be unsuitable for study by conventional optical techniques.

3. Experimental Apparatus

The apparatus required to detect the PA effect is quite simple. The basic components are: light source, monochromator, PA cell, microphone, associated optics (lenses and mirrors), and electronics. Figure 2 shows a schematic drawing of a typical apparatus. A reasonable PA signal is only obtained with a sufficiently intense light source. Therefore, most PA spectrometers utilize a 1000 W xenon source although sources

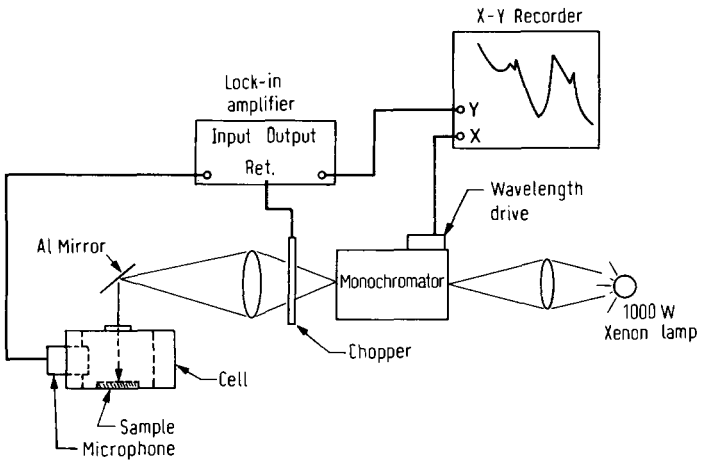

Fig. 2. Schematic of a single beam photoacoustic spectrometer.

of 350 watts or greater will also give reasonable PA signals if all other components are optimized. (The reason for using a xenon source will be discussed later.) To achieve a high light throughput, the monochromator is usually a $\frac{1}{4}$ meter instrument with a large f-stop (*e.g.*, f/3). A wavelength drive can be mounted on the monochromator. An important requirement for the PA cell is that the sample chamber volume be small (a few cm^3) and airtight. The small volume enhances the effects of pressure fluctuations, and hence the PA signal. The cell may be made of stainless steel, brass, aluminum, lucite, *etc.* Each material has certain advantages and disadvantages, depending upon its reflectivity and absorption spectrum and the nature of the samples to be studied. If absorption data below 300 nm are desired, quartz lenses and windows are required. The sample may be loaded horizontally or vertically into the cell. The cell should be so designed that it may be disassembled for occasional cleaning.

Microphones for use in a PA cell are usually $\frac{1}{2}$" to 1" in diameter and of either an electret or condenser design. The microphone is a crucial element of the apparatus and should have a flat frequency response between 10—10^4 Hz. The voltage output of the microphone is fed into a phase-sensitive lock-in amplifier for amplification and signal processing and then to an X-Y recorder. The phase of the PA signal

(with respect to the reference signal from the lock-in amplifier) is usually adjusted to maximize the PA signal at some arbitrary wavelength.

There exists considerable flexibility in the arrangement of the components described above. For example, the chopper might be placed between the monochromator and light source, a laser may be used, the arrangement of the microphone with respect to the sample can be varied, *etc.*

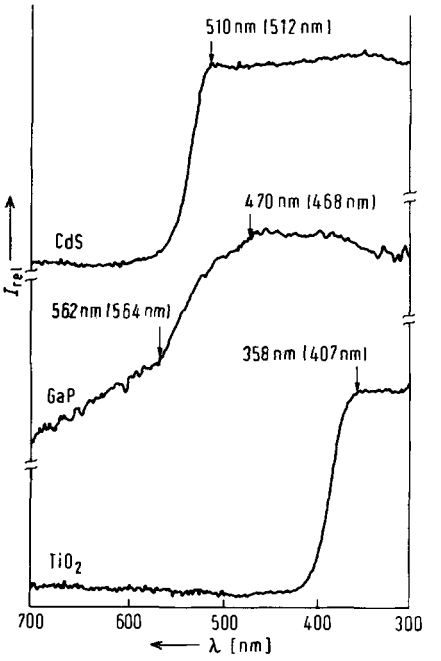
The apparatus just described is essentially a single beam instrument, and the spectral structure of the light source at various wavelengths will thus be superimposed on the sample spectrum. To correct this, one first runs a spectrum of a highly opaque sample such as carbon black. The PA signal will be in the saturation regime (see Section 5) and hence constant with wavelength. The only structure in a carbon black PA spectrum will therefore originate from the xenon light source. One then runs the sample spectrum and removes the light source structure by dividing the sample spectrum by the carbon black spectrum. This may be done point by point, by hand or with a small computer. An alternative method is to utilize a double beam instrument in which the light beam is split between the sample and a carbon black reference. A xenon light source is preferred because it is quite intense in the visible-UV region with relatively little structure, and this facilitates the normalization procedure. With a xenon light source, PA spectra may be obtained from 230 to *ca.* 1500 nm. At the present time, there are no light sources sufficiently intense in the IR (other than lasers) to provide PA spectra in this region.

4. Applications

Althogh PAS is still in its infant stage, numerous exciting and important applications in various scientific fields have already emerged. These new applications were motivated by the ubiquitous need to obtain qualitative information about the electronic excitation spectrum in a simple, quick, nondestructive manner for samples in various physical states (*e.g.*, crystalline, amorphous, gel, *etc.*). As long as the sample is not highly reflecting, PAS will give information about the bulk electronic excitation spectrum. The samples may be inorganic or organic, metals, semiconductors, or insulators.

4.1. Inorganic and Organic Semiconductors

An example of the use of PAS to study some rather conventional materials involves the investigation of inorganic semiconductors. Figure 3 shows PA spectra of several well-known semiconductors. The sharp increase in the PA signal is due to transitions between the valence and conduction bands. The arrows mark the position of the "knee" in the PA spectrum which corresponds to the value of the absorption edge, or energy gap, of the semiconductor. Values of the energy gap obtained by conventional means are shown in parenthesis. Several points concerning these spectra should be made: 1) The PA technique gives the correct spectrum for both direct (CdS) and indirect (GaP) bandgap semiconductors; for GaP, both kinds of band gap transitions are revealed; 2) the samples consist of powders taken off the shelf without further purification, or single crystals which were ground up to reduce the reflectivity and increase the surface area; 3) the sample mass was a few milligrams; and 4) each spectrum was obtained in a few minutes. These points emphasize the ease and convenience with which data of importance for the optical and



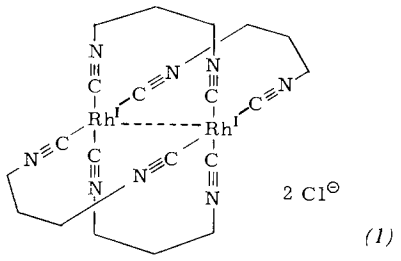


Fig. 3. Photoacoustic spectra of the inorganic semiconductors CdS, GaP, and TiO_2. The arrows indicate the location of the absorption edge. The numbers in parentheses indicate values of the absorption edge obtained by conventional means. The two values for GaP correspond to the indirect band gap (562 nm) and the direct band gap (470 nm).

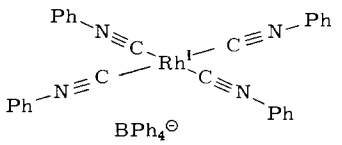
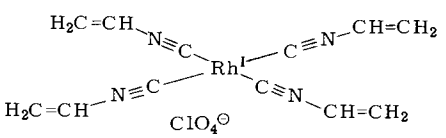


electrical properties of semiconductors may be obtained without the need for high purification or high vacuum techniques. In addition, one can differentiate between different crystalline phases of the same material, such as the rutile and anatase phases of TiO_2[6]. By utilizing PAS at low temperatures, it should be possible to detect excitonic structure as well as the occurrence of phase transitions. The above semiconductors are also of interest for use as electrodes in photoelectrochemical cells to convert solar energy into electrical and chemical energy. Thus, PAS provides a convenient tool for the physicist or chemist to quickly screen, characterize, and correlate the optical properties of numerous semiconductors for use in new and novel systems.

Organic and organometallic semiconductors may also be investigated using PAS. These materials are of interest in the field of quasi-one-dimensional (1 D) conductors. The compounds consist of weakly coupled chains of molecular units and may exhibit very high electrical conductivity parallel to the chains. The compounds may be metallic if the atoms or molecules are uniformly spaced along the chain. However, quasi-one-dimensional metallic chains are fundamentally unstable with respect to certain lattice distortions (*Peierls'* instability). Thus, in some compounds the chains will distort in such a manner that the atoms or molecules form dimers, trimers, tetramers, *etc.* This distortion, or transition, can occur at temperatures above or below room temperature. The compounds with distorted chains are semiconductors since the nonuniform spacing of the molecules along the chain opens up a gap at the Fermi level in the electronic energy spectrum.



Thus, the electrical and magnetic properties are crucially dependent upon the chain structure. The compounds are usually darkly colored powders. Single crystals, which are difficult to obtain, take the form of very small needles (a few mm long) making conventional optical studies very difficult.

(1)

(2)

(3)

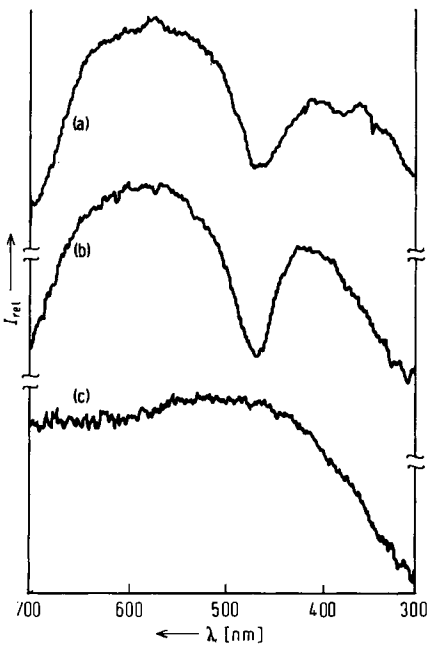


Fig. 4. Photoacoustic spectra of several organorhodium compounds. a) Dirhodium complex *(1)*; b) rhodium complex *(2)*; c) rhodium complex *(3)*. The absorption band at 575 nm in (a) and (b) is associated with the formation of dimers.

PAS may be utilized to gain an insight into the structural characteristics of these materials. Figure 4 shows the PA spectra of several rhodium organometallic compounds. Figure 4a shows the PA spectrum of an interesting rhodium-"bridged" dimeric compound *(1)*, in which the rhodium atoms are physically bound into a dimeric structure by bridging ligands. The bridging dimers are not part of a chain structure in this compound. However, the interesting feature is the presence of the strong absorption band at 575 nm which is due to the dimeric structure[7]. A similar band is found in the solution spectrum. Figures 4b and 4c show PA spectra of the rhodium compounds *(2)* and *(3)*. The rhodium atoms are square planar coordinated by isocyanide ligands, (R—CN), and stack to form rhodium chains in contrast to the dimer *(1)*. Nevertheless, the PA spectra of tetrakis(phenyl isocyanide)rhodium tetraphenylborate *(2)* (Fig. 4b) reveals the same strong rhodium-rhodium band at 575 nm indicating a dimeric chain structure. The room temperature electrical conductivity of this material is quite low ($\sigma \approx 10^{-10}\,\Omega^{-1}\,cm^{-1}$) as would be expected for the nonuniform (dimeric) spacing along the chain. In contrast, the PA spectrum of tetrakis(vinyl isocyanide)rhodium perchlorate *(3)* (Fig. 4c), does not reveal any sign of the dimer, suggesting that this material contains chains of uniformly spaced rhodium atoms. Indeed, the electrical conductivity of this compound at room temperature ($\sigma \approx 2\ \Omega^{-1}\cdot cm^{-1}$) is the highest known for any rhodium chain complex[8]. All of the structural information deduced from the PA spectra of Figure 4 have been fully confirmed by single crystal x-ray diffraction studies[8]. Similar results have been obtained on iridium chain complexes[9].

In summary, PAS provides a very simple technique for gaining an insight into the structural and electrical properties of quasi-1D conductors without having to grow single crystals or perform X-ray measurements. In this way, many new potentially conducting compounds may be screened without the expenditure of excessive time and funds.

4.2. Metals

PAS may be used to study metals if the reflectivity is first diminished by grinding or through the use of powders. Because

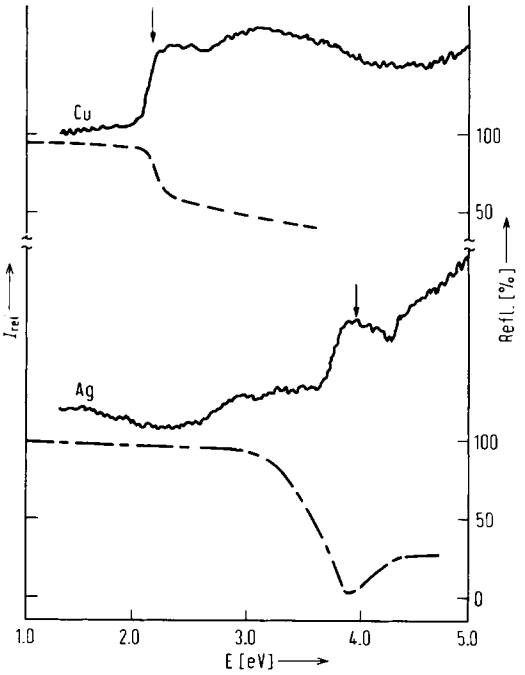

Fig. 5. Photoacoustic spectra of copper and silver (from ref. [2]). The arrows mark the location in the PA spectrum where reflection loss occurs. The normal reflectivities of Cu (---) and Ag (–·–) as measured by conventional means are also shown [vertical scale ("Refl.") on the right side of the figure].

of the very large absorption coefficients of metals, the absorption spectrum cannot be obtained by PAS (see Section 5); however, the presence of the metal (*e.g.*, on a surface) may be detected by its loss of reflectance which may result from interband transitions, a plasma resonance, *etc.* Figure 5 shows the PA spectra of Cu and Ag as well as their normal reflectivity. The sharp structure in the PA spectra as indicated by the arrows occurs at the point of reflection loss and can serve as a signature for the presence of a particular metal. The structure in the PA spectra also emphasizes the care one must take in the choice of materials for use in the construction of a PA cell (see Section 3).

4.3. Biological Studies

One of the most promising areas for the use of PAS is in the study of biological systems. Many biological samples contain water, proteins, and other lipid materials which readily scatter light, thus hindering the use of conventional optical techniques. Extensive extraction processes are required to separate out the material of interest for study by ordinary optical methods. Since scattered light is not a serious problem in PAS, biological samples may be readily studied, without extensive processing, by this technique. An example is the detection and study of oxyhemoglobin in human blood. Fig. 6 shows

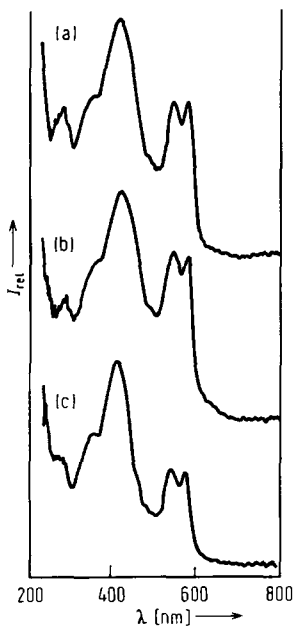

Fig. 6. Photoacoustic spectra of human blood after various stages of processing. a) Whole blood; b) whole blood after plasma removal; c) extracted hemoglobin (→ oxyhemoglobin).

the PA spectra of human blood after various stages of processing[2]. The sample in Figure 6a is simply a smear of whole blood, while the samples in Figures 6b and 6c are of red blood cells freed from plasma and of extracted hemoglobin, respectively. The characteristic spectrum of oxyhemoglobin is quite apparent and the time consuming extraction processes normally used to obtain a blood sample suitable for study by conventional optical means have been eliminated. Similar studies may be carried out on other hemo-proteins such as cytochrome c and catalase[6] with considerable ease.

Complex biological systems such as intact plant matter may be conveniently studied by PAS. Figure 7 shows the PA spectrum of dried spinach leaf and reveals the chlorophyll bands at 450 and 650 nm. Thus, plant growth mechanisms and abnormal processes may be studied in intact and living matter by PAS.

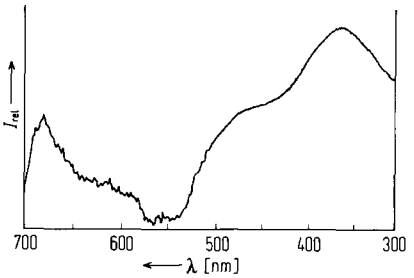

Fig. 7. Photoacoustic spectrum of spinach leaf.

Another use of PAS is in the identification of various bacterial states. It is quite difficult to examine bacterial cultures by conventional optical means because of excessive light scattering by the bacteria. However, the samples are quite suitable for study by PAS. The PA spectrum of *Bacillus subtilis Var. niger* (a common airborne bacterium) in the spore state contains a strong absorption band at 410 nm. This band is absent when the bacterium is in the vegetative state. Thus, PAS enables the detection and discrimination of various bacterial states and allows one to characterize, monitor, and detect bacteria in various stages of development.

PAS may also be used in the study of human and animal tissues in order to obtain valuable information about pathology and disease processes. Only a few examples of PA studies of biological systems have been mentioned here. Yet PAS will probably find its greatest use in the fields of biology and medicine.

4.4. Studies on Catalysis and Chemical Reactions

An important area where PAS is being utilized at present is in the study of photochemical processes and catalysis. An example involves the investigation of the reaction of transition metal complexes with polymeric ligands to form anchored catalysts which have been used to catalyze hydrogenation and hydroformylation of olefins. PAS has been used to investigate the electronic structure of these metal-polymer complexes in order to elucidate chemical processes and structure-reactivity relationships. An example of a PA study of a model catalytic system involving a well characterized compound, hexacarbonyltungsten $W(CO)_6$, is shown in Figure 8.

The PA spectrum of $W(CO)_6$ is shown both before and after photochemical reaction with polyvinylpyridine. Figure 8a shows the PA spectrum of $W(CO)_6$ and reveals the singlet-triplet ligand field transition at 350 nm as well as the corresponding singlet-singlet transition at 310 nm[10]. Figure 8b shows the PA spectrum of $W(CO)_5L$, where the ligand L is NH_3. This compound is formed upon irradiation of $W(CO)_6$ in the presence of the ligand and is shown in order to demonstrate the effect of ligand substitution in $W(CO)_6$. The characteristic singlet-triplet and singlet-singlet transitions at 457 and 416 nm, respectively, of $W(CO)_5NH_3$[10] are observed in the

form of a broad absorption band from 375 to 475 nm. Figure 8c shows the PA spectrum of the photoproduct of $W(CO)_6$ and polyvinylpyridine and clearly reveals the $W(CO)_5$-pyridine absorption band similar to that seen in Figure 8b. The polymer-anchored $W(CO)_5$ species has been observed to catalyze olefin isomerization and hydrogenation[11]. Thus, PAS may be used to study and characterize solid state photoproducts where conventional optical and structural (*i.e.*, X-ray) techniques would be totally inadequate.

An example of a less well understood, but potentially useful polymer anchored catalyst involves the transition metal cluster complex, dodecacarbonyltetrarhodium, $Rh_4(CO)_{12}$. Figure 9 shows the PAS of (a) $Rh_4(CO)_{12}$, (b) the photoproduct of the reaction of $Rh_4(CO)_{12}$ solution with polyvinylpyridine, and (c) the thermal product (*i.e.*, as for (b) but not exposed to UV radiation). The polymer-metal complexes of Figures 9b and 9c are both found to be hydroformylation catalysts, but the phototriggered catalyst (Fig. 9b) is considerably more active. This extra activity is associated with an absorption band (shoulder) at 600 nm which is absent from the spectrum of the less active thermal catalyst. Upon prolonged exposure

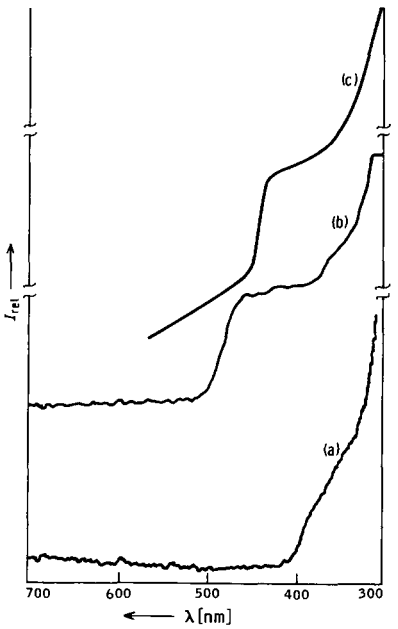

Fig. 8. Photoacoustic spectra of hexacarbonyltungsten complexes. a) $W(CO)_6$; b) $W(CO)_5NH_3$; c) $W(CO)_6$ polyvinylpyridine complex. The complexes in (b) and (c) are photoproducts.

to air, the phototriggered catalyst decomposes as indicated by the loss of the 600 nm absorption. Its PA spectrum then resembles that of the thermal catalyst and exhibits correspondingly less catalytic activity[12]. Similar studies are being carried out with $Co_4(CO)_{12}$.

Another use of PAS in this field has been to detect the degree of reduction of metals reacted on polymeric substrates. By using PAS to monitor the reaction of, say, potassium tetrachloroplatinate with polyvinylpyridine, one may easily tell when the tetrachloroplatinate has been fully reduced to platinum metal. The use of PAS in catalysis studies is just starting, but there is every indication that it will prove to be a valuable tool.

PAS has also been used for the study of chemically treated controlled pore glasses. These materials are growing in importance in the fields of chemical synthesis and analysis. Functional groups such as metal chelation reagents, acid-base indicators, and enzymes can be attached to the surface of the glass and used in a variety of chemical reactions. However, techniques for definitive characterization of the attached functional groups are rather primitive and ineffective. PAS has been used to determine the presence of these groups and to monitor subsequent chemical reactions and identify photochemical degradation processes.

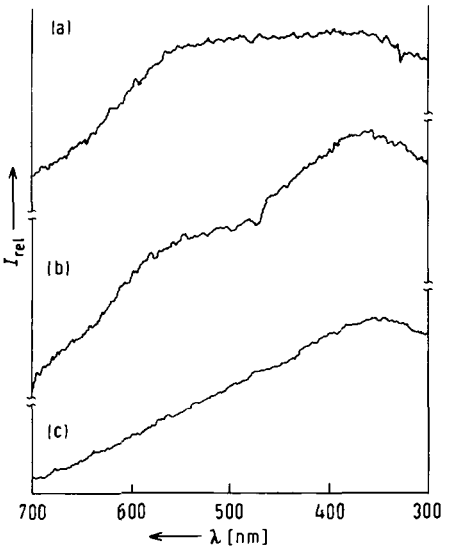

Fig. 9. Photoacoustic spectra of dodecacarbonyltetrarhodium complexes. a) $Rh_4(CO)_{12}$; b) photoproduct of reaction of $Rh_4(CO)_{12}$ solution with polyvinylpyridine; c) same as for (b) but not irradiated with UV light (*i.e.*, a thermal product).

Numerous other applications of PAS (*e.g.*, de-excitation studies of fluorescent systems and surface studies) have been discovered and the reader is referred to the literature for additional information[2, 6].

5. Limitations of PAS

There are several limitations to PAS which result in its being a less quantitative tool than conventional spectroscopic techniques. For example, one is not able to measure absorption coefficients conveniently and, in some cases, the PA spectra may contain structure due to both absorption and reflection losses. Also, the lack of suitable light sources prevents PA studies in the far IR. However, the main limitation of PAS is signal saturation[5] and arises from the contribution of thermal diffusion processes to the PA effect. Since this limitation is quite important and provides additional insight into the PA effect, it will be described briefly.

Consider a sample in a PA cell with cylindrical geometry (Fig. 10). The illuminated surface is also the surface for thermal transfer to the surrounding gas. The sample is characterized by an optical absorption coefficient β [cm^{-1}], which is a function of wavelength. The sample surface is irradiated by periodically modulated light of intensity I where I_0 is the

$$I = I_0 \cos \omega t,$$

incident light flux from the monochromator, and $\omega = 2\pi f$ is the modulation frequency in radians/s. The optical power absorbed by the sample is proportional to

$$\beta e^{-\beta l} I_0 \cos \omega t$$

where l is the distance into the sample from the illuminated surface where optical absorption occurs.

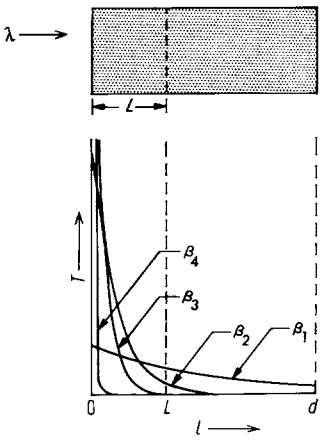

Fig. 10. Schematic of a sample model and the magnitude of the initial heat distribution. β_1 corresponds to nonzero transmission, β_2 to transmission approaching zero but before saturation, $\beta_3 = a_s$ to the onset of saturation, and finally β_4 to approaching full saturation. $L = 2\pi/a_s$ (see text).

When a state excited during absorption decays thermally (*i.e.*, non-radiatively) a periodic increase in the temperature occurs at the point of optical absorption. Thus, an initial heat, or temperature, distribution is created in the sample whose magnitude is also proportional to $\beta e^{-\beta l}$ and periodic with frequency ω. This initial heat distribution will diffuse away from its source (the point of optical absorption) in all directions. However, its initial magnitude will be diminished by a factor of $e^{-a_s x}$ due to thermal damping processes as it diffuses throughout the solid. The term a_s is the thermal diffusion coefficient in cm^{-1}, and is given by

$$a_s = (\omega/2\alpha_s)^{1/2} \qquad (1)$$

where α_s is the thermal diffusivity in cm^2/s and x is the distance from the point of optical absorption. Thus, only that portion of the sample within a distance $L = 2\pi/a_s$ of the thermal transfer surface will be effective in transferring its thermal energy to the surrounding gas. Those portions of the sample deeper than L cannot contribute to the PA signal because of thermal damping. The distance into the sample for which optical absorption takes place is governed by optical damping (*i.e.*, the optical absorption coefficient β in $e^{-\beta l}$). For low values of β, (*e.g.*, β_1 in Fig. 10) much of the heat distribution is created outside of L and cannot contribute, resulting in a low PA signal. As β increases, to say, β_2, the initial heat distribution moves into the region bounded by L (as well as closer to the thermal transfer surface) and a larger PA signal occurs. Thus, the variation of the PA signal with β occurs because the initial heat distribution moves in and out of the "responsive" region bounded by L as β varies. For $\beta = \beta_3 = a_s$, all of the heat distribution is created within L and further increases in β only move the distribution closer to the surface. Thus, the PA signal ceases to change significantly as β changes and this marks the onset of *saturation*. For higher values of β, *e.g.*, β_4, the distribution is pinned against the illuminated surface and the PA signal does not vary with further increases in β. This is the condition for full saturation and occurs for opaque materials such as carbon black. Thus, whenever $\beta < a_s$, the PA signal will be proportional to β and the electronic absorption spectrum will be measured. When $\beta \gtrsim a_s$, the PA signal will be insensitive to β and remain constant until β decreases. However, when $\beta \gtrsim a_s$ (*i.e.*, near the saturation region), the absorption spectrum may still be obtained by exploiting the frequency dependence of a_s in equation (1). By using higher chopping frequencies ω, a_s may be increased to a value greater than β and the true optical absorption spectrum can be obtained by the PA effect. This beneficial effect is counteracted by the fact that the PA signal decreases in magnitude as ω increases and this limits the high frequencies one may use. The frequency dependence of the magnitude of the PA signal may also be used as a diagnostic tool to indicate when saturation is occurring in opaque samples ($\beta d \gg 1$, where d is the depth of the sample). When one is in the saturation region, the magnitude of the PA signal varies as ω^{-1}. At higher frequencies, or when $\beta < a_s$ and saturation is not occurring, the PA signal varies as $\omega^{-3/2}$ at a given wavelength.

An order of magnitude estimate of the value of β which may lead to saturation can be obtained from the thermal diffusivity, α_s. For most materials and liquids, α_s varies from 10^0 to 10^{-3} cm^2/s, and a_s (at $\omega/2\pi = 100$ Hz) from *ca.* 10 to 500 cm^{-1}, respectively. For $\omega/2\pi = 10^3$ Hz, a_s varies between *ca.* 50 and 2000 cm^{-1}. Thus, any value of $\beta \gtrsim 5000\ cm^{-1}$ may lead to saturation for chopping frequencies of *ca.* 10^3 Hz. This order of magnitude of β as well as the frequency dependences of the PA signal mentioned above have been confirmed experimentally[5].

These results are summarized in Figure 11 which shows hypothetical optical absorption and PA spectra. Saturation is assumed not to occur for $\beta < 10^4\ cm^{-1}$. Thus, in the wave-

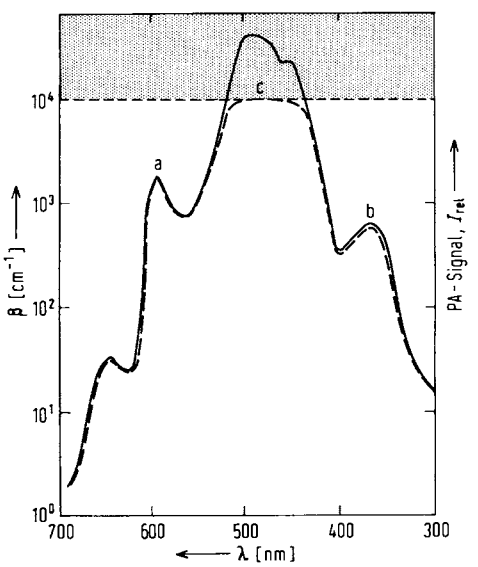

Fig. 11. Comparison of optical absorption (—) and PA (---) spectra of a hypothetical sample, showing the effect of signal saturation. Saturation occurs in the gray zone.

length region where $\beta < 10^4\ cm^{-1}$, the PA spectrum will yield the true optical absorption spectrum. Also, the frequency dependence of the PA signal will be given by $\omega^{-3/2}$ at any wavelength in the region, such as at points a and b. In the wavelength region where $\beta > 10^4\ cm^{-1}$, saturation will occur and the true optical absorption peak height will not be observed in the PA spectrum. The frequency dependence of the PA signal in this range (*e.g.*, at point c) will be given by ω^{-1}. Thus, PAS always gives the *location* of the absorption peaks, but both the absolute and the relative peak heights may not be interpretable in terms of conventional spectroscopic theories.

6. Future Applications of PAS

In the near future, it is quite likely that PAS will become a common and useful analytical tool in many scientific laboratories. Its ease of use and versatility can only increase its areas of application. Examples of some new areas are: 1) low temperature studies of organic and inorganic compounds—modification of a PA cell for low temperature work should be quite straightforward; 2) single crystal studies, using polarized light, of strongly colored materials which could not be readily examined by conventional optical techniques; 3) the use of transform techniques, *e.g.*, the Hadamard transform to improve the signal to noise ratio when the source intensity becomes weak as in the near IR; 4) in the field of catalysis, the characterization of heterogeneous metal oxides and oxide mixtures may prove to be an important application. Similarly, PAS may prove advantageous in the monitoring of surface reactions of metallic catalysts such as platinum and platinum-rhodium combinations which are used in automotive exhaust systems and hydrogenation and hydroformylation reactions; and 5) the exploitation of the phase dependence of the PA signal. This last area appears to be one of the more exciting facets of PAS and could provide an opportunity to obtain more quantitative information from the PA effect. At the present time, typical PA spectrometers measure only half of the information content of the signal (*i.e.*, the amplitude portion). The phase dependence of the PA signal arises from two sources: (a) the lifetime of the excited state and (b) the time it takes for the heat distribution to thermally diffuse to the sample-air interface. If one could prepare a series of samples with approximately the same thermal decay rates, then by measuring the shift in phase of a particular absorption band in the series, information concerning excited state lifetimes and photo- and thermochemical rates and processes could be obtained. Such measurements have already been carried out successfully on gaseous samples[13]. Similarly, by examining the in-phase and out-of-phase (90°) spectrum of a given sample, one can obtain information about the gross macroscopic structure of the sample. This type of measurement has already been done by *Kirkbright*[6] on samples of spinach leaf. He was able to demonstrate the existence of the layered structure of the leaf (*i.e.*, the waxy cuticle plus leaf interior) from such phase measurements. The phase dependence of the PA signal is also an area where additional theoretical effort is needed[14].

In summary, PAS appears quite likely to become a valuable analytical tool. New uses for the technique in various scientific fields are emerging at a rapid rate. In particular, the fields of chemistry, geology, biology, and medicine appear to be the most promising areas for use of PAS in the future.

The author is indebted to A. Rembaum, A. Gupta, and D. Lawson for valuable suggestions and critical reading of the manuscript. Thanks are due to A. Rosencwaig and J. F. McClelland for useful discussions and permission to use some of their figures. Some of the data presented in this paper resulted from a research program at the Jet Propulsion Laboratory, California Institute of Technology, sponsored by NASA Contract NAS7-100.

^{17}O-NMR Spectroscopy as a Structural Probe

By Walter G. Klemperer[*]

^{17}O-NMR spectroscopy has found limited application as a structural probe due to the experimental problems associated with a quadrupolar nucleus having low natural abundance. A survey of data obtained from systematic studies of structurally related compounds shows, however, that large chemical shift differences are usually obtained for structurally nonequivalent nuclei, and that characteristic chemical shift values are observed for specific chemical environments. The present day availability of ^{17}O enriched materials and Fourier transform NMR instrumentation should allow extensive application of the ^{17}O-NMR technique to structural problems in the immediate future.

1. Introduction

Oxygen, the earth's most abundant chemical element, forms compounds with all the elements except helium, neon and argon. The structure of oxygen-containing compounds is consequently a subject of widespread significance. Since the first observation of ^{17}O nuclear magnetic resonance signals in 1951[1], numerous applications of the technique have been reported. Compared to ^{1}H-, ^{13}C-, ^{19}F-, ^{31}P-, and ^{11}B-NMR, however, ^{17}O-NMR has received little attention as a structural probe. This neglect is not surprising, since ^{17}O has both a low natural abundance and an appreciable electric quadrupole moment, rendering it difficult to observe *via* NMR spectroscopy. Nonetheless, recent advances in NMR instrumentation and an increased availability of ^{17}O enriched materials have alleviated these difficulties, promising renewed interest in the ^{17}O-NMR technique.

This review is concerned with demonstrating the largely unexploited power of ^{17}O-NMR spectroscopy as a structural probe. First, the potential of the technique is discussed in terms of the physical properties of the ^{17}O nucleus. A review of reported ^{17}O-NMR chemical shifts and their sensitivity to structural environment follows. Finally, a brief attempt is made to define unexplored areas where ^{17}O-NMR may provide structural information which is difficult or impossible to obtain using other techniques.

2. Scope and Limitations of the Technique

Of the naturally occurring oxygen isotopes, only ^{17}O possesses nuclear spin ($I = 5/2$)[1,2]. Due to its electric quadrupole moment ($Q = -2.6 \times 10^{-26}$ cm^2)[3,4] and its low natural abundance (0.037 %)[5], the ^{17}O nucleus is one of the more difficult nuclei to observe by NMR spectroscopy. These two properties of the isotope, however, are compensated by the large chemical shifts observed for ^{17}O, which aid in the resolution of quadrupole broadened resonances, and the reactivity of oxygen, which simplifies the synthesis of isotopically enriched compounds.

2.1. Quadrupolar Broadening

For diamagnetic systems in the absence of rapid site exchange processes, the linewidths of ^{17}O resonances observed in solution are usually limited by quadrupole relaxation rates. The quadrupole relaxation time, T_1, is a function of the electric field gradient q and the asymmetry parameter η at the nuclear site as well as the rotational correlation time τ_c for the molecule as a whole[6]:

$$\frac{1}{T_1} = \frac{3}{125}\left(1 + \frac{\eta^2}{3}\right)\left(\frac{e^2 Q q}{\hbar}\right)^2 \tau_c \qquad \text{(a)}$$

Equation (a) holds under conditions where isotropic molecular tumbling is rapid on the NMR time scale ($\tau_c \ll \omega_0^{-1}$, where ω_0 is the nuclear larmor frequency). Since η, Q and q are constants for a given oxygen site within a molecule, T_1 may be increased to obtain line narrowing only by reducing τ_c, *i.e.* by causing the molecule under study to tumble more rapidly in solution. For a spherical molecule in a continuous medium, the Stokes-Einstein-Debye equation[7] relates τ_c to temperature T, solution viscosity η, and the molecular radius a:

$$\tau_c = \frac{4\pi\eta a^3}{3kT} \qquad \text{(b)}$$

Although equation (b) has limited quantitative significance for real systems, it may in general be used qualitatively to relate sample conditions to observed linewidths. First, raising solution temperature lowers τ_c and leads to line narrowing. Second, line narrowing results from a lowering of solution viscosity, which may be achieved by using a solvent having low viscosity, using low concentration of sample in the solvent, and raising solution temperature. Finally, equation (b) indicates that increased molecular radius implies greater linewidths, with the general consequence that smaller molecules will yield better resolved spectra.

In summary, ^{17}O-NMR linewidths may be minimized to yield optimum spectral resolution by observing resonances at elevated temperature and low sample concentration in a solvent having low viscosity. Note that line narrowing also improves the signal-to-noise ratio for a given integrated signal intensity.

2.2. Sensitivity

The low natural abundance of ^{17}O limits observation of its NMR signals in unenriched samples to pure liquids or concentrated solutions. When dealing with large molecules, the use of pure liquids or concentrated solutions implies high viscosity, which in turn implies broad resonances and limited resolution (see Section 2.1). Consequently, large molecules must be observed in dilute solutions, leading to a sensitivity problem. This problem may be overcome by ^{17}O enrichment and/or extensive signal accumulation using Fourier transform NMR (FT-NMR) techniques. The precise balance between degree of enrichment and amount of signal accumulation will depend upon the relative time and cost factors involved in each alternative.

A brief discussion of the FT-NMR technique[8, 9] is warranted in light of the widespread availability of FT-NMR instrumentation and the improved signal-to-noise ratios which this technique yields relative to continuous wave (CW) techniques. The rapid quadrupole relaxation of ^{17}O nuclei rules out the use of long delay times between the end of each RF pulse and the beginning of data collection without significant loss of sensitivity. As a result, incomplete spectrometer recovery following the RF pulse ("pulse breakthrough") leads to baseline distortions in transformed spectra. Although this problem may be overcome under certain circumstances through judicious selection of delay times and software manipulation[10, 11], a general instrumental solution is lacking at present. Whenever possible, samples should not be observed in dilute aqueous solutions where the strong solvent resonance aggravates the above mentioned problems, and efforts should be made to increase T_1 (see Section 2.1), thus allowing longer delay times to be used.

3. Applications

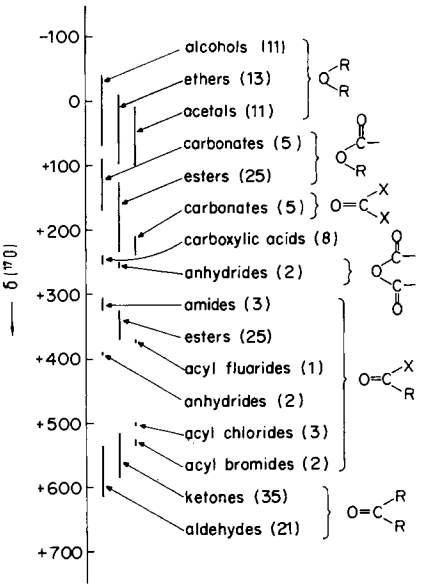
In this review, no attempt will be made to provide an exhaustive tabulation of known ^{17}O-NMR chemical shifts. Instead, attention will be focussed on classes of compounds where sufficient data are available such that structure features may be correlated with chemical shift values. Analysis will proceed on an empirical basis, the objectives being the generation, interpretation, and application of ^{17}O-NMR chemical shift scales. As a result, calculations of chemical shift values, correlations of ^{17}O-NMR chemical shifts with ^{13}C- and ^{14}N-NMR chemical shifts, and correlations of ^{17}O-NMR chemical shifts with UV and IR absorption frequencies will not be reviewed. All chemical shifts $\delta(^{17}O)$ quoted below are in parts per million relative to pure H_2O, with positive values indicating downfield shifts. Due to the large linewidths of most ^{17}O resonances, errors of about 3 ppm are usually associated with chemical shift values. Many chemical shifts reported in the early literature are inaccurate, and values quoted in this review have been selected after careful comparison of all available data.

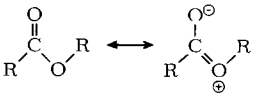
3.1. Oxygen Bonded to Main Group Elements

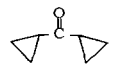
Systematic ^{17}O-NMR studies of compounds containing oxygen bonded to main group elements have dealt largely with group 4b—7b compounds due to their thermodynamic and kinetic stability. In this section, only those compounds will be considered which contain oxygen bonded solely to main group elements. When an oxygen is bonded to two or more atoms belonging to different groups, its chemical shift value will be discussed under the group of the atom which has the highest group number.

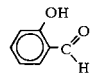
3.1.1. Group 4b

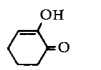
The vast majority of ^{17}O-NMR studies on group 4b compounds have treated compounds containing oxygen bonded only to carbon and/or hydrogen. A chemical shift scale which summarizes available data is shown in Figure 1. Chemical shifts not included in Figure 1 are listed in Table 1. All measurements were obtained from either pure liquids or solutions where solvent effects are negligible.

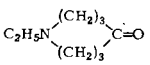












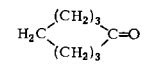


Fig. 1. An ^{17}O-NMR chemical shift scale for carbon compounds. The parenthesized numbers indicate the number of chemical shifts which have been measured for each type of compound. In grouping together classes of compounds on the far right, R represents a hydrogen atom or a carbon atom bonded to carbons, hydrogens, halogens and/or oxygens in the form of alkoxy or aryloxy substituents, and X represents an amino, alkoxy, aryloxy or halide substituent. To simplify the chart, chlorocarbonates have been classified as esters, and orthoesters and ketals have been classified as acetals (all data were obtained from references [11, 12, 15—17, 19 and 20]).

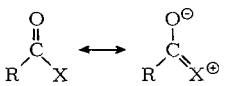
Examination of Figure 1 reveals a clear correlation between C—O π bond order and downfield chemical shift[12, 21]. The chemical shifts for bridging oxygens undergo downfield displacements when R substituents (see Figure 1) are replaced by π accepting acyl substituents which introduce π character into the bridging oxygen's C—O bond:

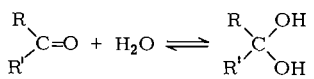


Thus bridging oxygen resonances in carbonates and esters appear downfield relative to the corresponding resonances in alcohols, ethers, and acetals. An even greater downfield

Table 1. ^{17}O-NMR chemical shifts for carbon compounds.

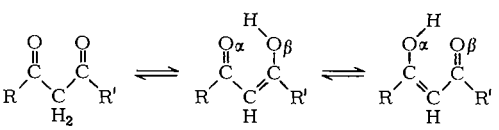
Compound		δ(^{17}O) Bridging	δ(^{17}O) Terminal	Ref.
(1)		+241		[12]
(2)		+237	+530	[12]
(3)	CO_3^{2-}		+192	[13]
(4)			+472	[14]
(5)			+498	[15]
(6)		+ 52	+495	[16]
(7)			+516	[17]
(8)			+576	[17]
(9)	$Mn_2(CO)_{10}$		+355	[18]
(10)	$Ni(CO)_4$		+362	[18]
(11)	$Co(NO)(CO)_3$		+377	[18]
(12)	$Fe(CO)_5$		+388	[18]
(13)	$Fe(NO)_2(CO)_2$		+418	[18]

shift is observed for anhydrides, where bridging oxygens are bonded to two π acceptors. Similar effects control chemical shift values for terminal oxygen resonances. Carbonyl chemical shifts are displaced upfield by π donor substituents which weaken the C—O π bond:



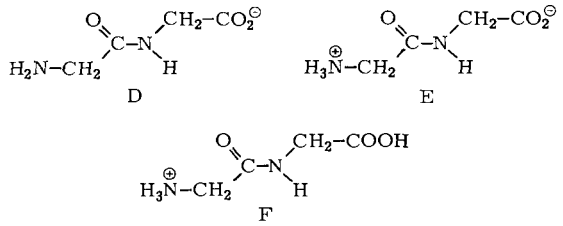
This effect is cumulative, and when two π donors are introduced, as in carbonates, terminal oxygen resonances are substantially displaced upfield and appear in the region characteristic of bridging oxygens in esters and anhydrides. The substituent effects which control chemical shift values within the ranges delineated in Figure 1 have been discussed in detail by several workers[12, 15, 19, 20].

It is instructive to consider the chemical shifts listed in Table 1 within the context of the chemical shift scale shown in Figure 1. In the furan heterocycle, π delocalization leads to a large downfield shift of the bridging oxygen resonance relative to normal ether resonances [see compounds *(1)* and *(2)*]. If chemical shifts are assumed to depend linearly on π bond order, the chemical shift of about +600 ppm for aliphatic aldehydes (π bond order of about 1) relative to water (π bond order of 0) implies a chemical shift of about +200 ppm for CO_3^{2-} (π bond order of 1/3). The observed chemical shift for CO_3^{2-}, +192 ppm, is in agreement with this crude prediction, further supporting the general correlation between π bond order and chemical shift discussed above. The carbonyl resonance in compound *(4)* is upfield from the characteristic range for ketones, reflecting a weakening of the C—O π bond by the two cyclopropyl substituents. In compounds *(5)* and *(6)*, the carbonyl resonances are shifted upfield by hydrogen bonding interactions. These interactions may also be observed as solvent effects. The acetone oxygen resonance, for example, can be displaced up to 50 ppm upfield by protic solvents[15, 22]. Transannular interactions in cyclic ketones have been monitored by ^{17}O-NMR in an analogous manner[17]. In compound *(7)*, transannular interaction of the amine nitrogen with the carbonyl group shifts the ketone resonance 60 ppm upfield relative to the ketone resonance in *(8)* where the amine nitrogen is absent.



For the sake of completeness, chemical shifts for several transition metal carbonyls have been included in Table 1. If a valence bond model is assumed, the variations in chemical shift observed for compounds *(9)*—*(13)* may be interpreted as reflecting relative magnitudes of π backbonding interactions:

Several studies have utilized ^{17}O-NMR to probe equilibria between organic species. When aldehydes or ketones enter aqueous solution, an equilibrium is established between carbonyl and *gem*-diol structures:

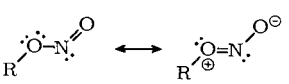


Since carbonyl and alcohol resonances are separated by approximately 550 ppm, this equilibrium can be monitored by ^{17}O-NMR[23]. The equilibrium between the keto and enol forms of β-diketones has been investigated in a similar fashion[16]:

A B C

For symmetric diketones (R = R'), only one resonance is observed for the enol forms B and C since tautomerism is rapid on the NMR time scale. When R ≠ R', two resonances, corresponding to the nonequivalent α and β oxygens, are observed for the enol forms. The chemical shift values for the O_α and O_β resonances may then be used to calculate the relative concentrations of B and C.

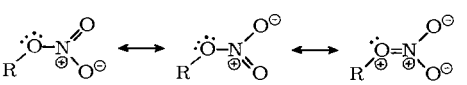
Recently, *Irving* and *Lapidot*[24] reported the pH dependence of ^{17}O-NMR chemical shifts of aqueous glycylglycine. Glycylglycine exists in anionic, zwitterionic, and cationic forms under basic, neutral, and acidic conditions, respectively:



D E F

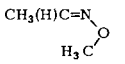
The carboxylate oxygen resonance behaves in a typical[22] fashion, shifting 19 ppm upfield upon protonation of D or E. The amide oxygen resonance, however, behaves in a more unusual fashion, shifting 6 ppm upfield when the carboxy group of F is deprotonated and shifting a further 16 ppm upfield when the ammonium nitrogen is deprotonated. These shifts presumably reflect the influence which neighboring charges have on the character of the C—O and C—N bonds. Formation of the negative carboxylate group enhances C—N π bonding by stabilizing the resulting positive charge on nitrogen. This enhanced C—N π bonding diminishes C—O π bonding, resulting in an upfield shift of the amide oxygen resonance. Deprotonation of the ammonium group removes positive charge from the vicinity of the carbonyl carbon, allowing the C—O bond to become more polar. The C—O π bond is thus weakened, shifting the amide oxygen resonance upfield.

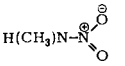
^{17}O-NMR spectroscopy has also been used to study the kinetics of oxygen exchange reactions between carbonyl compounds and water. When rates are slow, oxygen exchange may be measured by dissolving ^{17}O enriched compound in unenriched water and following the decay of the ^{17}O-NMR signal intensity as a function of time. Alternatively, unenriched compound may be dissolved in enriched water, and the increase in signal intensity monitored. A number of β-diketones and simple ketones have been investigated using these techniques[17, 25–27]. When oxygen exchange rates are rapid, ^{17}O resonances are broadened and the degree of broadening may be related to the exchange rate. Oxygen exchange between acetaldehyde and water under acidic conditions has been studied in this fashion[28].

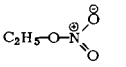


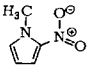
3.1.2. Group 5b

Chemical shift data for representative nitrogen compounds are summarized in Table 2. As in carbon compounds, chemical shift values are determined largely by π bonding effects[12, 15, 29, 32, 37]. Bridging oxygen resonances are observed furthest downfield in nitrites *(28)*, where π bonding is appreciable:









(28)

A lesser but nonetheless significant effect is observed for bridging oxygens in nitrates *(19)*:

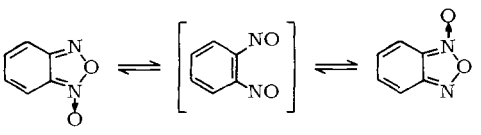
(19)

Table 2. ^{17}O-NMR chemical shifts for nitrogen compounds.

Compound		δ(^{17}O) Bridging	Dioxo terminal	Monoxo terminal	Ref.
(14)		+ 35			[12]
(15)		+157			[12]
(16)			+420		[29]
(17)			+425		[29]
(18)			+443		[30]
(19)		+340	+470		[31]
(20)			+519		[32]
(21)			+535		[32]
(22)	 [a]		+560 to +620		[12, 15, 33–36]
(23)			+670		[13]
(24)		+350		+475	[12]
(25)		+460			[12]
(26)	$(CH_3)_2N-N^{=O}$			+660	[29]
(27)	$(C_2H_5)_2N-N^{=O}$			+683	[12]
(28)	$R-O-N^{=O}$ [b]	+420 to +513		+790 to +838	[12, 29]
(17)	$O_2N-N^{=O}$			+885	[29]
(29)	$Cl-N^{=O}$			+915	[29]

[a] R = alkyl or phenyl; [b] R = alkyl.

Compounds *(24)* and *(25)* provide further examples of π delocalization effects.



Within the class of compounds X—NO_2 which contain dioxo terminal oxygens, chemical shifts are displaced upfield as N—O π bonding is weakened by X—N π bonding. The considerable degree of N—N π bonding in *(16)* and *(17)* is reflected in chemical shifts which lie close to the +410 ppm[19] value observed for NO_3^-. The greatest downfield shifts are observed for the terminal oxygens in compounds containing the —N=O moiety. Here again, resonances are shifted upfield as X—N π bonding increases in X—NO. Further substituent effects in nitro compounds and nitrites have been discussed in detail, and most trends can be interpreted in terms of π delocalization and hydrogen bonding effects[12, 15, 29, 32, 34, 35, 37].

^{17}O-NMR spectroscopy has been used to study charge distributions in deprotonated nitro compounds[30, 33, 36–38]. When nitromethane is deprotonated, for example, its ^{17}O-NMR chemical shift is displaced 405 ppm upfield as a consequence of extensive negative charge delocalization onto oxygen:

In the case of dinitro- and trinitromethane, deprotonation leads to upfield displacements of 180 and about 75 ppm, respectively. These smaller displacements are a result of charge delocalization over a greater number of nitro groups. Similar chemical shift changes are observed upon deprotonation of other nitroalkanes, nitramines, and nitropyrroles.

Dynamic processes in nitrogen compounds have also been examined. At room temperature, benzofurazan oxide displays two ^{17}O resonances corresponding to its terminal and bridging oxygens. As the sample temperature is raised, however, these resonances broaden and coalesce into a single resonance. This observation is consistent with fluxional behavior[39][*]:

^{17}O-NMR chemical shifts have been measured for a number of compounds containing phosphorus-oxygen bonds[12, 13, 15, 40], but since these chemical shifts lie in a rather narrow range, systematic analysis is difficult. In the case of hypophosphorous, phosphorous, and phosphoric acids and esters, for example, all reported resonances lie between +38 and +102 ppm. Greater variations in chemical shift are observed within the family of compounds OPX_nCl_{3-n} (Table 3). Although the effects of various X substituents in $OPCl_2X$ parallel the effects of the same substituents on chemical shifts in the RCOX family (Fig. 1), these trends are no longer maintained in the further substituted compounds $OPClX_2$ and OPX_3.

In contrast with the carbon and nitrogen compounds discussed thus far, coupling constants have been measured in several phosphorus compounds. ^{17}O—^{31}P coupling constants ranging from 90 to 308 Hz have been reported[12, 15, 40], and an attempt has been made to correlate coupling constants with phosphorous-oxygen bond strengths[40]. In view of the limited number of data available, however, this correlation must be viewed as tentative.

Table 3. ^{17}O-NMR chemical shifts for related phosphorus compounds [a].

	X=Br	X=F	X=OCH$_3$	X=N(CH$_3$)$_2$
$OPCl_2X$	+232	+177	+167	+150
	(+17)	(−38)	(−48)	(−65)
$OPClX_2$	+245	+127	+124	+125
	(+30)	(−88)	(−91)	(−90)
OPX_3	+259	+ 66	+ 68	+ 73
	(+44)	(−149)	(−147)	(−142)

[a] The numbers in parentheses are chemical shifts in ppm relative to $OPCl_3$, which has a +215 ppm chemical shift relative to H_2O. All data are from ref. [40], except the $OP(OCH_3)_3$ shift which is from ref. [15].

[*] This long known behavior has already been investigated ^{1}H- and ^{13}C-NMR spectroscopically.

3.1.3. Group 6b

Although it is difficult to rationalize the large chemical shifts found for compounds containing oxygen-oxygen bonds [see Table 4, compounds *(30)* to *(34)*], the ability of ^{17}O-NMR spectroscopy to unambiguously distinguish between nonequivalent oxygens has found application in mechanistic studies[42, 43]. *Solomon et al.*[42], for example, studied the CsF catalyzed reaction of OF_2 with COF_2 to form CF_3OOOCF_3 by reacting ^{17}O enriched OF_2 with unenriched COF_2 and also reacting unenriched OF_2 with enriched COF_2. In the first case, the CF_3OOOCF_3 product displayed only the central oxygen resonance, whereas only the peripheral oxygen resonance was observed in the second case. These results support the following mechanism:

$$F_2CO + CsF \rightarrow Cs^{\oplus}F_3CO^{\ominus}$$
$$F_3CO^{\ominus} + OF_2 \rightarrow F_3COOF + F^{\ominus}$$
$$F_3CO^{\ominus} + F_3COOF \rightarrow F_3COOOCF_3 + F^{\ominus}$$

[a] Bridging oxygen. [b] Terminal oxygen. [c] Peripheral oxygen. [d] Central oxygen. [e] Triplet. [f] 30% aqueous solution.

Far more chemical shift data are available for sulfur containing compounds [see Table 4, compounds *(35)* to *(49)*]. Within the family of four coordinate S^{VI} compounds *(35)* to *(42)*, terminal oxygen chemical shifts may be rationalized in terms of π bonding effects. The resonance for SO_4^{2-} *(39)*, however, is anomalous in this respect, lying slightly downfield from the $SO_2(OCH_3)_2$ *(40)* and SO_2F_2 *(41)* resonances. Analogous trends are apparent in the remaining terminal oxygen resonances [compounds *(43)* to *(47)*]. Here the resonance for dimethyl sulfoxide *(47)* provides the most striking anomaly, lying 163 ppm upfield from the terminal oxygen

resonance for dimethyl sulfite *(46)*. A possible explanation for this anomaly is provided by *Coulson*'s analysis for d orbital participation in main group compounds[46]. Sulfur 3d orbitals are sufficiently contracted to participate significantly in π bond formation only when the formal charge on sulfur is high. In dimethyl sulfite, the three oxygen substituents raise the formal charge on sulfur sufficiently, whereas the single electronegative substituent in dimethyl sulfoxide is apparently unable to. The bridging oxygen chemical shifts in compounds *(38)*, *(40)*, *(46)*, *(48)*, and *(49)* are ordered approximately as expected: π acceptor substituents lead to downfield shifts.

^{17}O-NMR spectroscopy has been applied to stereochemical problems in sulfur chemistry by several workers. *Jackson* and *Taube*[45] attempted to characterize the complex equilibria present in the SO_2/H_2O system, but the low level of ^{17}O enrichment available was insufficient to allow complete, unambiguous interpretation. *Solomon et al.*[43], investigated the reaction of SO_2 with O_2F_2 using ^{17}O-NMR techniques. The oxygens in SO_2F_2 product were shown to originate from the SO_2 not the O_2F_2, and the oxygens in FSO_2OSO_2F product were shown to originate from both O_2F_2 and SO_2, randomized in the product. Further applications will be discussed in the next section.

3.1.4. Group 7b

As was the case for compounds containing oxygen-oxygen bonds (see Section 3.1.3), compounds containing oxygen-fluorine bonds display large downfield chemical shifts [see Table 5, compounds *(50)* to *(52)*]. Since the observation of ^{17}O—

Table 5. ^{17}O-NMR chemical shifts for fluorine and chlorine compounds.

^{19}F coupling aids in assigning resonances, ^{17}O-NMR spectroscopy has proved to be a useful structural probe for oxygen-fluorine compounds. Detailed studies of the "O_3F_2" system[41,47], which yields resonances at +647, +971, and +1512 ppm, implicated mixtures of O_2F_2 *(52)* and "$(O_2F)_n$" as opposed to discrete O_3F_2 species. Although the "$(O_2F)_n$" species could not be assigned a definite structure, the NMR data were interpreted in terms of a dimeric FO_4F structure. ^{17}O-NMR spectroscopy was also used in labeling experiments which demonstrate that O_2F_2 reacts with SO_2 to form FSO_2OOF *(51)* *via* an OOF intermediate derived from the O_2F_2 reactant[43].

The ^{17}O-NMR data available for chlorine compounds [Table 5, compounds *(53)* to *(60)*] illustrate two interesting effects. First, the fact that $HClO_4$ *(57)* in acidic aqueous solution and ClO_4^- *(58)* in basic aqueous solution display identical chemical shifts reflects the nonbasic character of the perchlorate ion. Second, the observation of ^{17}O—^{35}Cl spin-spin splitting in ClO_4^- but not in ClO_3^- illustrates the factors which usually prevent the measurement of coupling constants between ^{17}O and quadrupolar nuclei, here ^{35}Cl. In ClO_4^-, the ^{35}Cl nucleus is in a tetrahedral environment where the electric field gradient is zero and quadrupolar relaxation is inhibited. Thus the lifetimes of the individual ^{35}Cl spin states are long enough to produce splitting of the ^{17}O resonance. In ClO_3^-, however, the C_{3v} ^{35}Cl environment allows for rapid quadrupolar relaxation of the ^{35}Cl nucleus, and the lifetimes of the individual ^{35}Cl spin states are too short to generate multiplet structure in the ^{17}O-NMR spectrum.

3.2. Oxygen Bonded to Transition Elements

^{17}O-NMR spectroscopy has been employed frequently to determine transition metal ion hydration numbers and water exchange rates, but the technique has received relatively little application in structural studies. Most stereochemical studies have dealt with polynuclear, anionic oxo complexes (polyoxoanions) of the early transition elements in their highest oxidation states. In spite of their structural complexity, these polyoxoanions often yield well resolved ^{17}O-NMR spectra since large chemical shifts are observed and samples often may be observed at elevated temperatures in nonviscous solvents. Most polyoxoanions are prepared in aqueous solution, and ^{17}O enrichment is therefore easily obtained.

3.2.1. Group 5a

Of the fully oxidized group 5a metals, only vanadium forms tetrahedral oxoanions in aqueous solution. The vanadate ion, VO_4^{3-}, displays a ^{17}O-NMR multiplet at +568 ppm with $J(^{17}O—^{51}V) = 61.6$ Hz[50]. At about pH = 13, an additional symmetric doublet appears at +700 ppm which has been assigned to the ion $O_3VOVO_3^{4-}$[50].

Polyvanadate equilibria in acidic aqueous solution have also been studied. At pH 5.5—6.0, $V_{10}O_{28}^{6-}$ is the predominant species, in equilibrium with smaller amounts of metavanadate, $V_4O_{12}^{4-}$. At lower pH, the metavanadate concentration decreases, and the $V_{10}O_{28}^{6-}$ anion becomes protonated. These equilibria have been studied using ^{17}O-NMR spectroscopy[51]. Interestingly, the pH dependence of ^{17}O-NMR chemical shift values for $V_{10}O_{28}^{6-}$ (Table 6) reveals the location of protonation sites in the anion. Since protonation of an oxygen weakens its O—V bonds, its chemical shift is displaced upfield. The chemical shifts for unprotonated oxygens shift downfield since their O—V bonds are strengthened in order to maintain approximately constant total bond order at vanadium. Consequently, the observed chemical shift displacements resulting from acidification of aqueous $V_{10}O_{28}^{6-}$ (Table 6) demonstrate that protonation occurs at oxygens O_B and O_C (Fig. 2A).

Time dependent ^{17}O-NMR spectra of unenriched $Na_6V_{10}O_{28}\cdot 18H_2O$ dissolved in ^{17}O enriched water yield information regarding the mechanism of oxygen exchange between $V_{10}O_{28}^{6-}$ and water[51]. Initially, only a metavanadate resonance is observed at +925 ppm, but as the system approaches equilibrium, the $V_{10}O_{28}^{6-}$ resonances appear at equal rates. This result indicates that oxygen exchange in $V_{10}O_{28}^{6-}$ proceeds *via* reversible dissociation to metavanadate.

Table 6. ^{17}O-NMR chemical shifts for selected groups 5a and 6a polyoxoanions.

	Anion	Structure [a]	Ref.	Solvent	δ(^{17}O) [b]	Ref.

[a] Letter identifies idealized structure shown in Fig. 2; [b] Parenthesized letter is the assignment of the resonance using the labeling scheme given in Fig. 2; [c] Isostructural with $Mo_6O_{19}^{2-}$.

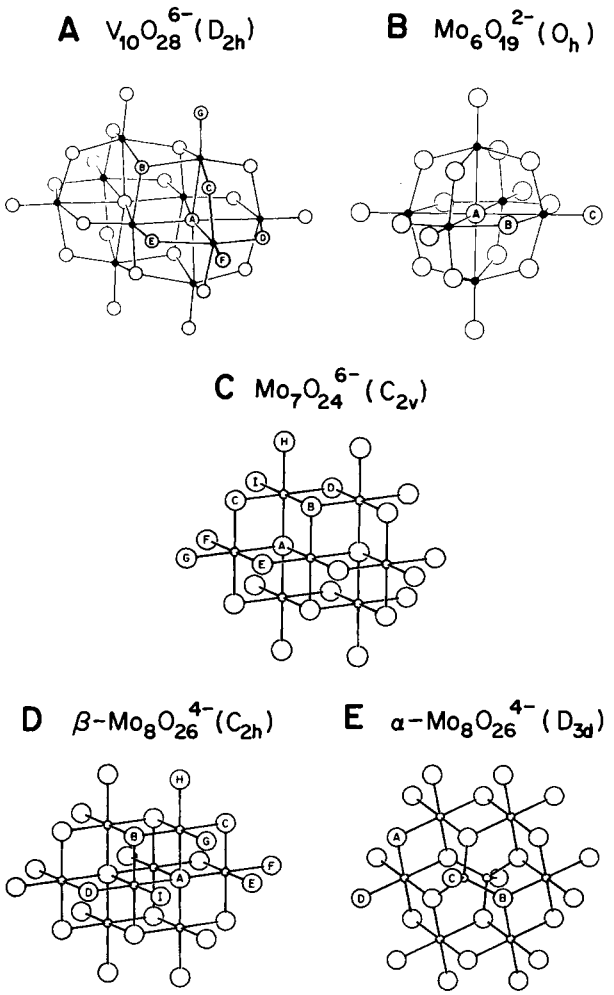

Fig. 2. Idealized structures of some polyoxoanions which indicate the oxygen labeling scheme used in Table 6. The point group symmetry for each idealized structure is indicated in parenthesis. For detailed structures, see the references given in Table 6.

^{17}O-NMR spectroscopy has found little application in polyniobate and polytantalate chemistry. Resonances have been observed (Table 6) for $Nb_6O_{19}^{8-}$ and $Ta_6O_{19}^{8-}$, however, and more extensive studies of these systems should yield results analogous to those obtained in the polyvanadate system.

3.2.2. Group 6a

A large number of ^{17}O-NMR chemical shifts have been reported for group 6a oxoanions and polyoxoanions[13, 44, 45, 50–54, 62, 71]. Since an exhaustive survey of these data is beyond the scope of this review, only selected results will be discussed in detail. Emphasis will be placed on methods for assigning resonances in complex spectra.

Kidd[62] has demonstrated that ^{17}O-NMR chemical shifts for hexavalent chromium compounds are determined largely by metal-oxygen π bond order. A plot of chemical shifts for CrO_2Cl_2 (+1460 ppm), $O_3CrOCrO_3^{2-}$ (+1129 ppm terminal oxygens, +354 ppm bridging oxygen), and CrO_4^{2-} (+835 ppm) *versus* π bond orders derived from simple valence bond formulas shows an approximately linear relationship between π bond order and downfield chemical shifts. Similar trends are observed for hexavalent, four-coordinate molybdates: the MoO_4^{2-} resonance appears at +532 ppm[44, 64], and the terminal and bridging oxygen resonances for $O_3MoOMoO_3^{2-}$ appear at +715 and +248 ppm, respectively[67].

Assignment of resonances for complex polymolybdates and polytungstates containing six coordinate Mo^{VI} and W^{VI} is more difficult. The polymolybdates *(64)* to *(67)* (see Table 6) provide representative examples of the procedures used to analyze complex spectra. The $Mo_6O_{19}^{2-}$ anion *(64)* contains three types of oxygens (see Fig. 2B): Six terminal oxygens with $d_{Mo-O} = 1.68$ Å (O_C), twelve doubly bridging oxygens with $d_{Mo-O} = 1.93$ Å (O_B), and one six-fold bridging oxygen with $d_{Mo-O} = 2.32$ Å (O_A). Assuming π bond order increases as d_{Mo-O} decreases, the three observed resonances may be assigned as in Table 6. This assignment is consistent with the observed intensities and with the very narrow linewidth observed for the sixfold bridging oxygen, which is in an octahedral environment where quadrupolar relaxation has been inhibited.

The $Mo_7O_{24}^{6-}$ anion *(65)*, although it contains nine symmetry nonequivalent types of oxygens, displays only five ^{17}O resonances. Assigning all of the terminal oxygen to the +821 ppm resonance leaves five types of oxygens to be assigned to the four remaining resonances. Assuming that the more metals an oxygen atom bridges, the further upfield its resonance lies, the +123 and +338 ppm resonances are assigned to the fourfold and threefold bridging oxygens respec-

tively. This leaves two resonances at +400 and +758 ppm to be assigned to the three types of doubly bridging oxygens. One type of doubly bridging oxygen (O_E) has an unusually short bond distance ($d_{Mo-O}=1.74$ Å) to the molybdenum which has no terminal oxygens, and the +758 ppm resonance is assigned to this type of oxygen. Although the assignments are consistent with those found in simpler compounds (see below) they cannot account for the approximately equal intensities of the +338 and +400 ppm resonances. This discrepancy may indicate an incorrect assignment.

The resonances for the β-$Mo_8O_{26}^{4-}$ anion *(66)* are assigned in a similar fashion, and the relative intensities implied by these assignments are consistent with the observed intensities. The α-$Mo_8O_{26}^{4-}$ anion provides an additional complexity since it contains both four- and six-coordinate molybdenums. The terminal oxygen resonances are assigned using intensity arguments, and the +396 ppm resonance is assigned to the doubly bridging oxygen bonded to two molybdenums, each of which has two terminal oxygens, by analogy with the previous compounds. This leads to assignment of the +495 ppm resonance to the triply bridging oxygen bonded to the four coordinate molybdenum. Comparison of these assignments with the bond distances in α-$Mo_8O_{26}^{4-}$ yields a self-consistent picture where shorter Mo—O bonds imply larger downfield shifts. Figure 3 summarizes the data which have been obtained for oxygens bonded only to six-coordinate Mo^{VI}. There is no overlap

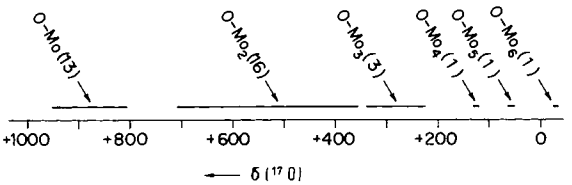

Fig. 3. An ^{17}O-NMR chemical shift scale for oxygens bonded to six-coordinate molybdenums in Mo^{VI} polyoxoanions. Chemical shift ranges are labeled O—Mo_n, where n = the number of molybdenums that type of oxygen is bonded to. The numbers in parenthesis indicate the number of chemical shifts used to determine each range (all data were obtained from references [53, 54, 66, and 70]).

between the chemical shift regions associated with each type of oxygen, but this separation is unlikely to be maintained as further data are measured. Although discussion here has proceeded entirely in terms of polymolybdates, analogous data have been obtained for polytungstates[52, 68–71] where similar factors determine chemical shift values.

Dynamic ^{17}O-NMR techniques were first applied to group 6a compounds in two independent studies of oxygen exchange in the aqueous $CrO_4^{2-}/Cr_2O_7^{2-}$ system. In the first study, by *Figgis et al.*[63], evidence was obtained for nucleophilic attack of CrO_4^{2-} on $Cr_2O_7^{2-}$ leading to substitution at Cr^{VI}:

$$Cr^*O_4^{2-} + O_3CrOCrO_3^{2-} \rightarrow O_3Cr^*OCrO_3^{2-} + CrO_4^{2-}$$

This interpretation must be viewed with skepticism, however, since the investigators incorrectly assumed equal linewidths for the terminal and bridging oxygen resonances in $Cr_2O_7^{2-}$ in the absence of oxygen exchange. *Jackson* and *Taube*[45] independently studied the effect of acidification on the linewidths observed for dichromate and solvent resonances in aqueous $Cr_2O_7^{2-}$, and provided strong evidence for the rapid acid catalyzed equilibrium:

$$Cr_2O_7^{2-} + H_2O \rightleftharpoons 2HCrO_4^-$$

More recently, temperature dependent ^{17}O-NMR spectra for α-$Mo_8O_{26}^{4-}$ (see Fig. 2E) were reported which display differential line broadening consistent with rapid reorientation of the tetrahedral MoO_4^{2-} subunits on the NMR time scale[54]. ^{17}O-NMR spectroscopy has also been applied in the structure determinations of $(C_6H_5As)_2Mo_6O_{24}^{4-}$[65] and $(C_6H_5As)_4Mo_{12}O_{46}^{4-}$[66]. The effects of paramagnetic ions on ^{17}O-NMR chemical shifts have been studied in a series of isostructural polytungstates $M^{n+}W_{10}O_{36}^{(12-n)-}$, where $M^{n+}=Ce^{3+}$, Ce^{4+}, Pr^{3+}, Th^{4+}, and U^{4+}[68, 71]. These results demonstrate the feasibility of observing chemical shifts in paramagnetic polyoxoanions and open up new areas for investigation.

4. Areas for Future Investigation

Within the vast areas of oxygen chemistry yet to be systematically investigated by ^{17}O-NMR spectroscopy, three classes of compounds deserve special consideration. First of all, dioxygen complexes of the transition elements warrant reexamination by ^{17}O-NMR techniques. Despite several attempts[72–75], resonances for $^{17}O_2$ in these complexes have never been detected. The failure to observe resonances in dioxygen complexes has been attributed to line broadening due to slow molecular tumbling[75]. A systematic study of small dioxygen complexes in nonviscous solvents at low concentration and elevated temperature should allow this difficulty to be circumvented. Transition metal organometallic compounds are a second class of compounds which have rarely been examined by ^{17}O-NMR spectroscopy[18]. Chemical shifts for nitrosyl and carbonyl ligands are likely to be quite sensitive to stereochemical environment. Finally, polynuclear oxo compounds and alkoxides are obvious candidates for further ^{17}O-NMR investigations. In view of the successes achieved with polyoxoanions of the groups 5a and 6a metals (see above), analogous studies of other polyoxoanions and alkoxides in general are likely to be fruitful.

Sodium-23 Nuclear Magnetic Resonance Spectroscopy

By Pierre Laszlo[*]

With the availability of Fourier transform spectrometers, ^{23}Na-NMR spectroscopy has become an important tool. It affords direct insight into solvation and ion pairing phenomena, both in organic and in bio-inorganic systems. Monitoring the chemical shifts and linewidths of ^{23}Na signals gives access to binding constants, reorientational correlation times and the microdynamics of the sodium coordination shell. The binding of other cations can also be studied by ^{23}Na-NMR spectroscopy, in competition experiments.

1. Introduction

Sodium, the 6th most abundant element on our planet, is present in rocks and in oceans, in the upper atmosphere and in many organisms. Sodium is indeed essential to life, as we know it.

Selective permeability[1-3], a vital function of the cellular membrane, occurs together with operation of the physiological sodium-potassium pump[4-11]. The normal cell maintains a sodium-poor and potassium-rich cytoplasm, with respect to its saline environment. These concentration gradients are buttressed by the "burning" of adenosine triphosphate. A mechanism proposed for the sodium expulsion and the potassium entry involves conformational changes in the ATPase molecules present in the cell membranes[12].

[*] Prof. Dr. P. Laszlo, Institut de Chimie
Université de Liège, Sart-Tilman
par 4000 Liège (Belgium)

Active transport of sodium and potassium across cellular membranes accompanies such various phenomena as the firing of a nerve[13], muscular contractions[14-17], and the activity of the brain[18], bioluminescence[19], accumulation of amino acids in the cells[20], salt and water transport in kidneys[21].

The four cations of greatest biological importance are Na^+, K^+, Ca^{2+} and Mg^{2+}[1]. There exists a wealth of metallic cations having quasi-identical ionic radii, and very similar chemical properties to K^+, or Ca^{2+}, or Mg^{2+}, which they can readily replace (isomorphous substitution[1]).

Unfortunately, such replaceable cations are simply not available for the sodium cation. To quote *Williams*[1]: "Sodium complexes can be studied directly by NMR using ^{23}Na. Relatively little work has been done in this field as yet. Unfortunately a search of the Periodic Table shows that no other cation is likely to mimic the properties of sodium closely so that a detailed understanding of its biochemistry must depend on an extension of the NMR method and not on isomorphous substitution. Lithium does not replace sodium in a biological system. The differences between the two are exemplified by the use of lithium salts in the treatment of nervous disorders".

^{23}Na-NMR spectroscopy is an extremely convenient and, of course, direct means for studying interactions between Na^+ and organic or bio-molecules. For sodium-23, its natural abundance of 100%, and an intrinsic NMR sensitivity of only a factor of 10 less than that of the proton, make it 525 times more sensitive than carbon-13, extensively used in the study of organometallic, organic and biological molecules. With ^{23}Na-NMR spectroscopy, routine examination of centimolar and even millimolar solutions is possible. For comparison, the physiological concentration of Na^+ in a body fluid such as blood serum is approximately decimolar.

2. Instrumental Techniques

The sodium-23 resonance frequency is 26.452 MHz for a magnetic field $\mathbf{B}_0 = 2.35$ tesla (*i.e.* one at which protons resonate at 100 MHz). The question is whether it is more advantageous to record spectra in the slow sweep [or continuous wave (CW)] mode, or in the Fourier (FT) mode.

The relative gain (FT/CW) achieved with the FT method (see Table 1) can be calculated with the aid of the Ernst and Anderson equation[22].

Table 1. Gain (FT/CW) achieved with a typical acquisition time = 5 T_1, and a spectral window of 6000 Hz (> 250 ppm). The gain was calculated according to the Ernst-Anderson equation [22].

Gain (FT/CW)	Linewidth [Hz]
6.4	15
2.5	100
0.8	1000

The continuous wave method only becomes competitive with linewidths close to 1 kHz. According to our experience, *ca.* 80% of the samples examined have resonance linewidths ranging between 5 and 100 Hz; hence, a FT spectrometer is clearly superior. One operates with 90° pulses having a time duration of about 9 μs, corresponding to an examining field $\mathbf{B}_1 = 24.7$ G[23]. This is equivalent to gaining access to a frequency range of 28 kHz without distortion of the spectrum[24]. The actual spectrum occupies a small fraction of this range.

The resolution is given by the inverse of the acquisition time[23], and is of the order of 1.5 Hz: again this is sufficient, since the narrowest lines observed in practice have a width of about 5 Hz.

The actual time required to obtain useful spectra, with a signal-to-noise ratio above 20, is specified in Table 2.

Table 2. Typical recording times with a "90 MHz" and with a "250 MHz" instrument (corresponding to $\mathbf{B}_0 = 2.12$ and 5.88 tesla, respectively).

Linewidth [Hz]	Sample concentration [mol/l]	Recording times at $\mathbf{B}_0$ = 2.12 tesla	5.88 tesla
10	10^{-2}	0.5 h	1 pass
500	10^{-2}	(impossible at present)	12 h
500	10^{-1}	12 h	2 h

3. The Sodium-23 Chemical Shift

^{23}Na chemical shifts are measured with reference to an external standard: an aqueous solution of sodium chloride enclosed in a capillary[25]. After extrapolating to infinite dilution and correcting for difference in magnetic susceptibility[26] between the capillary and sample tubes, the chemical shifts are accurate to ±0.2 ppm, or with slightly more effort to ±0.05 ppm.

The *usual* range for ^{23}Na chemical shifts is *ca.* 40 ppm, *i.e.* rather small for a heavy nucleus, but in line with the small electrical polarizability of the Na^+ cation. However, this range was greatly extended by *Ceraso* and *Dye*[27,28], who obtained a spectrum containing separate signals for the cryptated sodium cation and the sodium anion (Fig. 1) by co-dissolving metallic sodium and the [2.2.2]cryptand (see Table 3)[29] in an organic solvent[30].

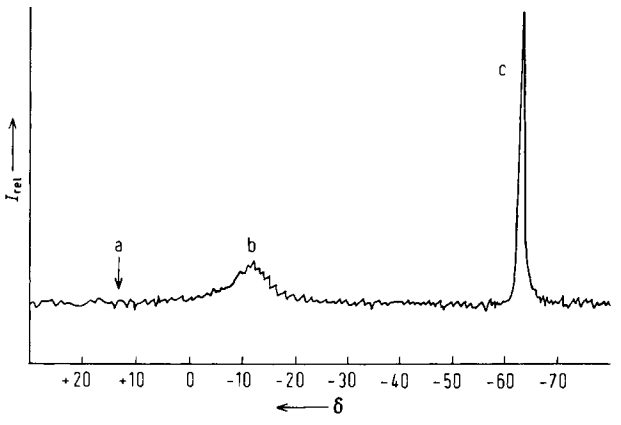

Fig. 1. ^{23}Na-NMR spectrum of a solution of Na[2.2.2]cryptand$^+$Na$^-$ (*ca.* 0.3 M) in ethylamine at 1.4 °C. External standard is saturated aqueous NaCl [27]. a): Na^+ in ethylamine; b) Na[2.2.2]cryptand$^+$; c): Na^-.

The signal of the sodium anion is shifted 63 ppm upfield from the aqueous NaCl reference, is solvent-independent when measured in THF, methylamine and ethylamine and is, within experimental error, the same as that calculated for the gaseous anion[31]: the two electrons in the 3s orbital shield the 2p electrons from the influence of the solvent.

The chemical shift of the sodium cation, on the other hand, is strongly solvent-dependent[32–36]. Thus, *Erlich* and *Popov*[34] found that the ^{23}Na chemical shift can be correlated with the Gutmann donicity (or donor number)[37] of the solvent over a range of almost 20 ppm (see Fig. 2).

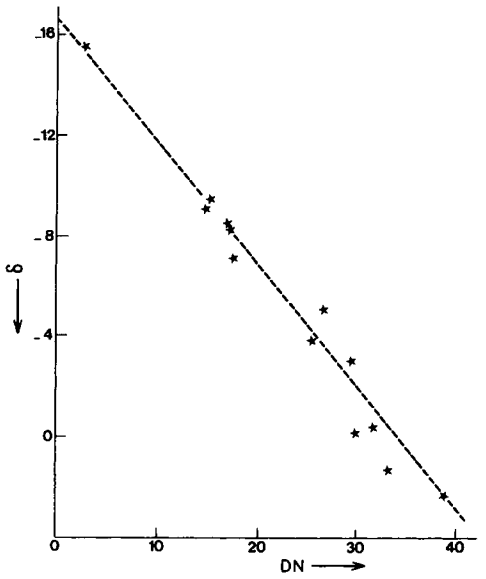

Fig. 2. Chemical shift of Na^+ as a function of the solvent donor number (DN) [37].

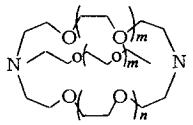
Water, a highly-structured solvent, defies this relationship, which, in turn, has been used to determine the donicities of a series of amine solvents[35].

When a gaseous sodium atom ionizes to Na^+, and this is then solvated, the diamagnetic contribution to the chemical shift changes at most by only 10 ppm[31,32,38–40]. In contrast, the paramagnetic term contributes *ca.* 50 ppm to the chemical shift[32,41–43].

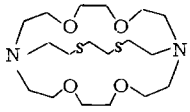
This appears paradoxical, since Na^+, like the F^- ion, has no unpaired electrons in p-, d- or f-orbitals, and therefore should have a vanishing paramagnetic contribution to nuclear shielding. In order to account for the observed solvent shifts, it is necessary to assume that electrons are donated by the solvent into a 3p orbital of the sodium atom[32].

This paramagnetic term amounts to *ca.* −270 ppm per unit electronic charge[32], in compliance with the downfield shift observed as the solvent becomes a better electron donor (Fig. 2).



Are electrons truly transferred from the outer s and p orbitals of solvent molecules into the vacant outer p orbitals of the sodium ion?

Very substantial electron transfers of this type are indeed indicated by approximate calculations of the CNDO-INDO type, applied to the interaction of Na^+ with one or several ligand molecules such as water, ammonia, or formaldehyde[44]. More refined calculations of the *ab initio* type, however, reveal only very small degrees of electron transfer: for instance, in the interaction of Na^+ with water molecules, only the first H_2O molecule coordinated to Na^+ by its oxygen atom has a bond that is not purely ionic[45].



In all the cases which have been carefully investigated, an electrostatic description is adequate for bonding between Na^+ and coordinating dipolar molecules. The ion-dipole is the dominant attractive term. It is counter-balanced by the dipolar repulsion of the ligands[46]. There is no need to postulate substantial amounts of covalency. Thus a full understanding of the sodium-23 chemical shift for the solvated Na^+ cation fails here: the experimental finding of a correlation with the solvent donicity[47,48] (Fig. 2), and the theoretical calculation of the (dominant) paramagnetic term both assume covalent bonding which, to all intents and purposes, is vanishingly small.

Resolution of this problem requires more sophisticated calculations of the ^{23}Na chemical shift for Na^+ in solution, which have yet to be performed. An example will illustrate the relatively poor understanding we actually have of sodium-23 chemical shifts: the spread in chemical shifts for Na^+ encapsulated by various antibiotic ionophores, such as valinomycin, monensin or monactin is almost 25 ppm[49]! Synthetic ionophores of the cryptand type act likewise; depending upon the size of the cavity, *i.e.* upon the precise oxygen-sodium distances, the sodium-23 chemical shift changes by more than 20 ppm[50] (Table 3).

Table 3. Chemical shifts of Na^+ in some cryptates [50].

(2), $m = 1$; $n = 0$
(3), $m = n = 1$

(4)

Cryptand	Sodium cryptate	$\delta(^{23}Na)$
(1)	Na[2.1.1]cryptand$^+$	+11.15
(2)	Na[2.2.1]cryptand$^+$	− 4.25
(3)	Na[2.2.2]cryptand$^+$	−11.40
(4)	Na[2.2.2']cryptand$^+$	− 6.2

4. Lineshapes and Linewidths

In general, lineshapes are true lorentzian (Fig. 3). Super-lorentzian lines are observed only in special cases (see Section 5). A lorentzian absorption is characterized by its height (I_{rel}), and width at half-height $\Delta\nu_{1/2}$. In the fast modulation region, *viz.* when the longitudinal T_1 and transverse T_2 relaxation times are equal, the peak height is directly proportional to the Na^+ concentration in the sample[51] (Fig. 4).

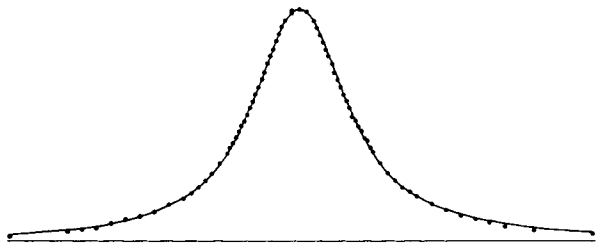

Fig. 3. Lineshape of a ^{23}Na-NMR signal. The curve is the actual experimental absorption; the points are calculated for the best lorentzian curve with identical width at half-height.

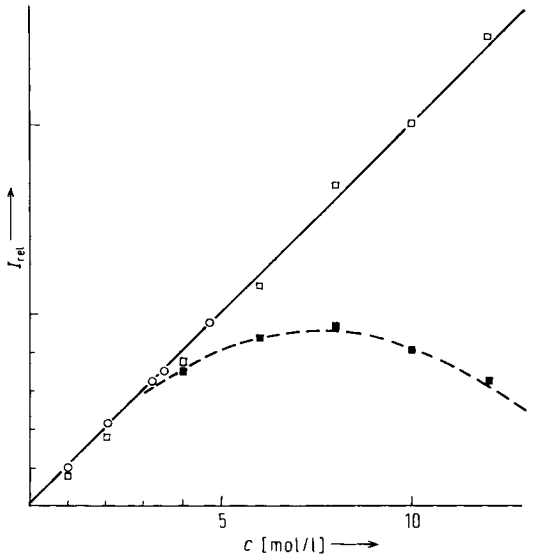

Fig. 4. Peak height (I_{rel}) of the ^{23}Na-NMR signals in aqueous solution. ○ NaCl; ■□ NaOH; (□ optimized γH_1 amplitude, ■ γH_1 constant). The peak height is an arbitrary unit, chosen to make the slope equal to one [51].

The linewidth $\Delta\nu_{1/2}$ is related to T_2, by:

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} \qquad \text{(a)}$$

If T_1 is indeed equal to T_2 because of motional narrowing, a linewidth measurement ($\Delta\nu_{1/2}$) is more practical and is equally as accurate as the direct determination of a relaxation time[52] (Fig. 5).

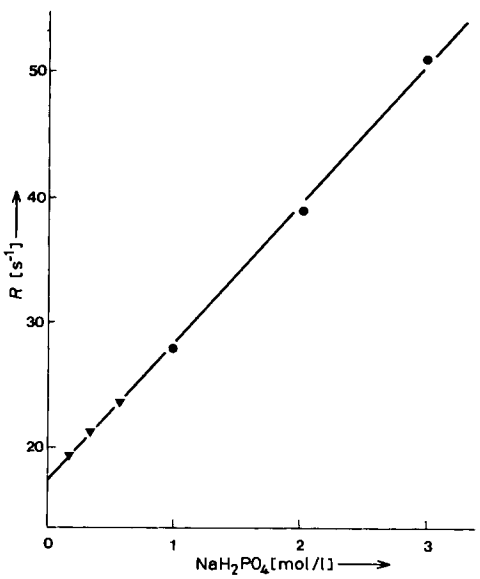

Fig. 5. Comparison of relaxation rates R, determined either from the linewidth (▼) or from a T_1 measurement (●). Sample: aqueous NaH_2PO_4 solution [52].

For instance, measurement of the linewidth of the ^{23}Na-signal in a sample of sodium heparinate at 62.86 MHz gives a value of 60 Hz, corresponding to a T_2 value of 5.305 ms. The longitudinal relaxation time T_1 is measured separately: $T_1 = 5.08$ ms. Given uncertainties of 5 % on the linewidth determination and of 10 % on the evaluation of the relaxation time, the agreement is indeed satisfactory[53].

In many cases, linewidths vary linearly with the bulk viscosity of the sample. For example, if NaCl is dissolved in a water/glycerol mixture (whose viscosity can be altered by a factor of 20 by altering the composition), the linewidth of the ^{23}Na-signal closely follows the viscosity, within ±30 %[54] (Fig. 6).

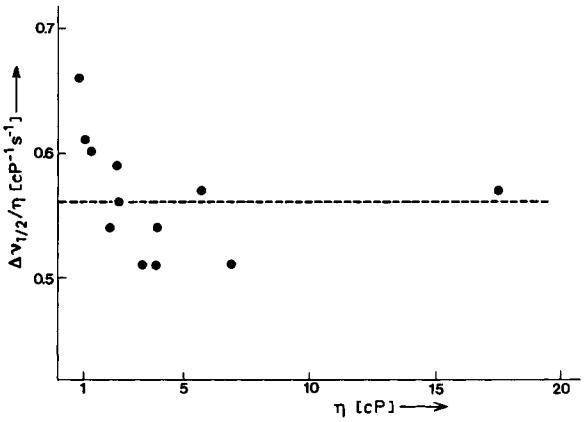

Fig. 6. A plot of the linewidth divided by the viscosity as a function of viscosity for water/glycerol mixtures; the dashed horizontal line corresponds to ideal Debye-Stokes-Einstein behavior. Sample: NaCl.

Hence, a standard procedure is to correct the relaxation rates $R_i = T_i^{-1}$ $(i = 1,2)$ for changes in relative viscosity[55], by normalizing the observed linewidths (or relaxation times) to a standard viscosity.

5. Mechanism of Quadrupolar Relaxation[56]

Since its spin number is greater than unity ($I = 3/2$), sodium-23 has an electric quadrupole moment eQ: the nucleus distorts, and instead of a spherical distribution of charge, we have a prolate or oblate ellipsoidal distribution of charges.

In the presence of an electric field gradient eq at the nucleus, *i. e.* whenever the distribution of electric charges in the sodium coordination sphere is asymmetric, an interaction is set up; the product $\chi = (eQ \cdot eq)/\hbar$ has the dimension of an energy, is called the quadrupole coupling constant, and in the case of the sodium-23 nucleus is of the order of 1 MHz.

With a spin number $I = 3/2$, the ^{23}Na nucleus can assume $2I + 1 =$ four orientations in a magnetic field $\mathbf{B}_0$. The projections of the spin vector I along the $\mathbf{B}_0$ axis have the values $m_I = -3/2, -1/2, +1/2$ and $+3/2$. The transitions between the corresponding energy states are degenerate in the absence

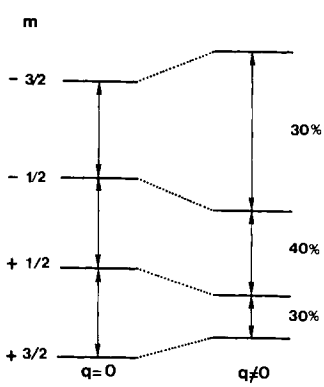

Fig. 7. Energy states for a spin 3/2 nucleus in the absence (left) and in the presence (right) of a quadrupolar interaction.

of an electric field gradient at the nucleus ($q=0$). The degeneracy is lifted by the quadrupolar interaction ($q\neq 0$) (Fig. 7).

The resultant three transitions should show up as three equidistant lines, the central line with 40% of the total intensity, and the outer lines having each 30% of the total intensity. The distance between two consecutive lines is

$$\frac{e^2qQ}{\hbar}\cdot\frac{(3\cos^2\theta-1)}{4}$$

where θ is the angle between the magnetic field $\mathbf{B}_0$ and the direction of the electric field gradient q.

In normal liquids, this angle θ fluctuates over all possible values due to fast reorientational motions. For isotropic rotational diffusion, with a vanishing asymmetry parameter for the electric field gradient, and with extreme motional narrowing, the three transitions collapse to a single line having a linewidth $\Delta\nu_{1/2}$. The relaxation rate $R_i=T_i^{-1}$ $(i=1,2)$ is then given by:

$$R_i=\pi\Delta\nu_{1/2}=\frac{2\pi^2}{5}\left(\frac{e^2qQ}{\hbar}\right)^2\cdot\tau_c \qquad \text{(b)}$$

where τ_c is a correlation time describing the reorientation of the quadrupolar interaction between the ^{23}Na nucleus and the local electric field gradient.

Equation (b) can be employed in many applications, and is the only one we shall discuss in this introductory and general presentation. It relates the experimentally accessible quantity $\Delta\nu_{1/2}$ to the product of two distinct unknowns: the quadrupole coupling constant χ and the correlation time τ_c.

In many liquids[57,58], and in aqueous solutions[59,60], at atmospheric pressure, reorientational correlation times for solute or solvent molecules increase linearly with the ratio of the shear viscosity to temperature η/T. Quantitative, or semi-quantitative, agreement with the Debye-Stokes-Einstein model[61]:

$$\tau_c=f_r\frac{V\eta}{k_BT};\ f_r=1$$

is obtained, provided the microviscosity factor f_r[62] is given a value of *ca.* $\frac{1}{5}$[50], between the values characteristic of the slipping[63] or sticking[64] solute-solvent boundary conditions.

Likewise there exist systems in which the sodium-23 relaxation R_i is affected predominantly by viscosity changes in the solution and the corresponding variations in the correlation time τ_c, while alterations in the quadrupole coupling constant χ can be neglected[25,54,65-66]. However, in order to derive values either for the correlation time τ_c or for the interaction energy χ from the measured linewidth $\Delta\nu_{1/2}$, a precise knowledge of the other term—either χ or τ_c—is necessary.

Take the problem of evaluating the quadrupole coupling constant χ, which is "a measure of the electric-field gradient at the nucleus, a quantity usually negligible to first order in other experiments. Thus, one has a rather unique probe with which to determine the charge distribution around the solute species (Na^+) of interest. Unfortunately, it is very difficult to compute the field gradient at the nucleus in terms of the charge distribution outside the ion because of the large and intractable effect of the closed-shell electrons, the so-called antishielding factor"[67].

It does not suffice to calculate the electric field gradient q at the sodium nucleus: the 1s, 2s and 2p electrons are polarized by the electric field from the adjoining point charges. This distortion of the electronic distribution around the sodium nucleus effectively magnifies the active field gradient by a factor $1-\gamma_\infty$, the antishielding Sternheimer factor[68-70], which has a value of 5.1—5.8 for ^{23}Na[71,72] (see also the Appendix).

It is then straightforward to compute for a electrostatic model[68,73,74] the quadrupole coupling constant arising from a point charge Z (a.u.) at a distance r(m) from the quadrupole moment Q(m^2) through an intervening dielectric (ε):

$$\chi=\frac{0.52\times10^6}{3I(2I-1)}\cdot(1-\gamma_\infty)\cdot\frac{2\varepsilon+3}{5\varepsilon}\cdot\frac{QZ}{r^3} \qquad \text{(c)}$$

Equation (c) can be applied to the interaction of hydrated Na^+ with an anionic end-group such as $-CO_2^-$ or $-SO_3^-$: at a distance of 4.9 Å, corresponding to the solvent-separated ion pair, the quadrupole coupling constant χ has a value of 0.011 MHz, according to this approach[75]. Similar treatments are applicable when the sodium ion interacts with a dipole, rather than with a point charge[68,73-75].

If however the sodium cation is surrounded by four or six identical solvent molecules, then there cannot be any contribution to a local electric field gradient from this first solvation sphere with tetrahedral or octahedral symmetry. One would then expect, from equation (b), a vanishing sodium-23 linewidth in pure solvents in which Na^+ is symmetrically solvated[67]. This expectation is not fulfilled, and finite linewidths obtain[76-83]. Why? What is the origin of the electric field gradient, when the first-order terms cancel, and only second-order terms are present?

Various models have been proposed. In the collision model, an electric field gradient occurs at each ion-solvent molecule collision, with attendant loss of spherical symmetry of the ion[39,41]. In the solvent exchange model, migration of a solvent molecule from the first solvation sphere into the bulk solution creates a vacancy: the electrostatic field gradient arises from coordinative unsaturation[84]. Thirdly, in the electrostatic model, the electric field gradient at the nuclear site is caused by the electric point dipoles of the surrounding solvent molecules and the point charges of other ions present in solution[78,85,86]. The electronic distortion is incorporated in this model, not as a specific effect, but through the Sternheimer multiplication factor[68-70]. The electrostatic model accounts successfully for a wide variety of experimental results relative to relaxation rates of quadrupolar nuclei[72,87-92].

Hubbard has pointed out that relaxation of spin $\frac{3}{2}$ nuclei should occur, not as a simple exponential decay, but rather as the sum of two exponentials[93,94]. In practice, deviation from a single exponential is often very small[92]. However in systems such as biological tissues, in which anisotropic regions may extend through distances of the order of 100 Å, and the motional narrowing condition is not obeyed, the residual triplet splitting (Fig. 7) shows up in the sodium-23 resonance signal as a super-lorentzian absorption, with prominent wings. Deconvolution of such a line yields a sharp

component, with 40% of the total intensity, superimposed upon a broader line which accounts for 60% of the total intensity (Fig. 7). These two lines correspond in width to the two distinct exponential curves, with differing relaxation times[93]. A number of investigators concluded from such observations, too hastily, the presence of *ca.* 40% Na^+ ions in the free state, and 60% in a bound state, attached to biological macromolecules[95–107]. In actual fact[108,109], cellular Na^+ ions are surprisingly unrestrained, despite the microviscosity of their environment, and their motion is slowed down by a mere factor of 3 to 8 compared to extracellular ions: Na^+ ions are essentially free in biological tissues[110].

Back to the problem of evaluating the quadrupole coupling constant χ [Eq. (c)]! There are two agencies enabling a good estimate of the viscosity-dependent correlation time τ_c to be made. One is with ionophores, in which the correlation time for reorientation of the whole complex can be obtained from a separate probe such as T_1 values for ^{13}C or D nuclei: this approach has been applied to cryptates[29], yielding a linear correlation between the ^{23}Na chemical shift and the quadrupole coupling constant χ[50]. The second involves tight ion pairs in which both partners rotate as a unit[111]; again it is possible to determine the correlation time in the anion from ^{13}C or D relaxation times. This procedure has been applied by us to the sodium salt of 5′-adenosine monophosphate[112]: comparison of the ^{23}Na linewidth of 50 Hz with the correlation time of 140 ps, derived from the ^{13}C T_1 values[113], yields a χ value of 0.5 ± 0.1 MHz for Na^+ complexed to a monophosphate in water solution.

6. Application to Characteristics of Na^+ Solvation

Interactions between the sodium cation and its ligands are almost purely electrostatic[44–46,114], and lack directional character. Given the opportunity, Na^+ wraps itself into a sheath of coordinating molecules and draws their donor atoms, such as oxygen or nitrogen, to within van der Waals contact. Sodium-oxygen distances of 2.4—2.6 Å, closely corresponding to the sum of the ionic radius of Na^+ (0.95 Å)[115] and the van der Waals radius for oxygen (1.40 Å), are frequently observed on X-ray structural analysis of Na^+ complexes with crown ethers and ionophoric antibiotics[116–121]. Water molecules occupy the remaining vacant sites at Na—O distances between 2.29 and 2.35 Å[122], very close to the values calculated by *ab initio* methods[45].

Hydration numbers for the Na^+ cation in the range 3—6 have been obtained from a variety of methods, including sodium-23 chemical shifts and relaxation measurements, and with different assumptions[25,45,46,89,123–129]; whereas the hexaaqua ion exists in the gas phase[45,46,128], a coordination number closer to 4 is more likely in aqueous solutions[25,89,125,126]. This coordination number of 4 applies also for solvation with somewhat more voluminous solvent molecules such as methanol[126], tetrahydrofuran[130–131], dimethyl sulfoxide[132], dimethyl acetamide[132], and pyridine[133]. For the more bulky hexamethylphosphoric triamide, a solvation number of 3 has been reported[134,135].

Measurement of the ^{23}Na linewidth for $NaClO_4$ in a series of oxygen-containing ether and alcohol solvents displays Debye-Stokes-Einstein behavior, and yields a Stokes radius for the solvated Na^+ of 3.6 ± 0.7 (3σ) Å[65], in accord with the conductimetric measurements by *Szwarc et al.*[136] of 3.95 ± 0.5 Å (THF) and 3.2 ± 0.4 Å (monoglyme = 1,2-dimethoxyethane); the Monte Carlo value for $Na^+(H_2O)_6$ is 3.4 ± 0.3 Å[129]. The corresponding NMR Stokes volume of $120 \pm 20\,ml \cdot mol^{-1}$ is clearly much too small for the rigid assembly[137] of four THF molecules or two monoglyme molecules (each with two oxygens) coordinated to the sodium cation. One is dealing instead with a spherical particle centered on sodium, of radius *ca.* 3.75 Å. This value can be regarded as the sodium-oxygen distance (*ca.* 2.35 Å) augmented by the van der Waals radius of the oxygen atom (1.40 Å): the sodium solvation shell is kinetically labile; fast exchange of solvent molecules between the first solvation sphere and the bulk of the solution proceeds at a rate commensurate with that of the overall reorientational motion[84], while maintaining the oxygen heteroatoms at van der Waals contact with the Na^+ ion. In the solvation shell, water or methanol solvent molecules indeed turn their dipoles towards the sodium cation[72].

Competition between different donor solvent molecules for coordination to the sodium cation is easily studied using ^{23}Na-NMR spectroscopy. The change in the ^{23}Na chemical shift can be monitored as a function of composition in binary

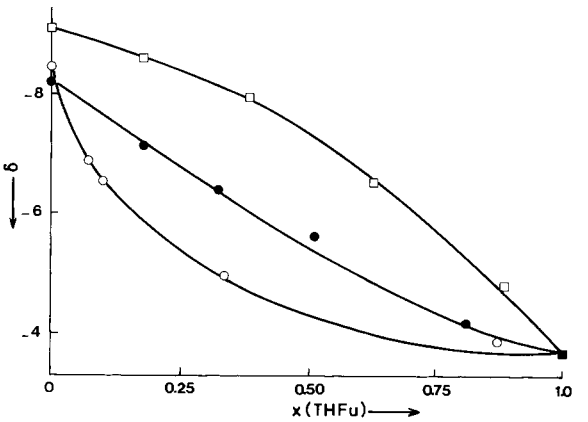

Fig. 8. ^{23}Na chemical shift for $Na^+ClO_4^-$ in binary mixtures of monoglyme (○), diglyme (●) and triglyme (□) in competition with 2-tetrahydrofuranmethanol (THFu), as a function of composition (given as mole fraction x (THFu)) [137]. In a qualitative sense, diglyme is almost as good a donor as 2-tetrahydrofuranmethanol, monoglyme is worse, and triglyme is better.

solvent mixtures (Fig. 8)[138]. Preferential solvation by one of the component solvent molecules occurs[32,139,140]. The iso-solvation point[141] is the midpoint between the chemical shifts in the pure A and B solvents. It serves as an index for preferential solvation: for instance, the sequence

$$[(CH_3)_2N]_3PO \gg [(CH_3)_2N]_2CO > (CH_3)_2SO > C_5H_5N > CH_3CN \gg CH_3NO_2$$

has been obtained[140]. It represents the solvating ability of a solvent in a mixture. Pure solvents can be highly structured, to the detriment of their apparent donor ability: dimethyl sulfoxide is a prime example[142].

A more quantitative treatment, first proposed by *Stengle et al.*[141] and fully developed by *Covington*[143] assumes stepwise displacement of solvent A by solvent B, and that the

observed chemical shift is the weighted average for the species present and changes by the same increment whenever a B molecule removes an A molecule from the coordination sphere. This treatment also demands that solvents A and B have similar dielectric constants, that the solutions be ideal, and that the equilibrium constants for the successive equilibria be related only statistically[132]. Whereas all the examples of sodium solvation that have been studied so far appear to satisfy these conditions[138–140], one case of Ag^+ solvation shows breakdown of the incremental chemical shift hypothesis[144].

In mixtures of tetrahydrofuran and 2-tetrahydrofuran methanol (THFu), a bidentate ligand, the ^{23}Na chemical shift changes monotonically with the composition. Of the following models: 4THF → 4THFu, 4THF → 3THFu, 4THF → 2THFu, only the latter accounts for the observed data. It is the only model consistent with tetracoordination of Na^+ by the oxygen heteroatoms in the solvent molecules[145]. Thermodynamic parameters are derived from the data, and the values of $\Delta G°$ for transfer of Na^+ between the various solvents[138, 145]:

$$THF < CH_3OH < monoglyme < diglyme < triglyme < glycol$$

follow a sequence very close to that observed by *Arnett et al.*[146] for the calorimetric heat of complexation of Na^+ by hydroxy and ether solvents, in acetone solution:

$$THF < methanol < monoglyme < diglyme < glycol < triglyme$$

The sodium-23 chemical shift itself (for sodium tetraphenylboron) gives an excellent correlation with the free energy of transfer (of sodium chloride) from pure water in a series of binary water/glycerine diacetate mixtures[147].

In Covington-type treatments[143] symmetry numbers for the various pathways interconverting the limiting structures $(Na^+)_{mA}$ and $(Na^+)_{nB}$ present in the pure A and B solvents are extracted from the experimental data. Their comparison with calculated values leads to inferences about the nature and number of intermediate structures: for instance, in the competition between THFu and the glymes, a single bicyclic intermediate is present with diglyme and triglyme, while several monocyclic intermediates occur with monoglyme—presumably because of angular constraints[138]. Examination of the ^{23}Na-NMR linewidths, corrected for viscosity changes, confirms this conclusion[148].

In comparison to the symmetrical limiting structures $(Na^+)_{mA}$ or $(Na^+)_{nB}$, intermediate structures with solvation shells made up partly of A molecules, partly of B molecules, lack symmetry. In the less symmetrical structures the resulting electric field gradient translates (Section 5) into significant increases of the linewidth[149], which in turn can be used as an independent confirmation of conclusions based upon chemical shifts. Often, in ^{23}Na-NMR spectroscopy, chemical shifts and linewidths mutually check one another, thus making it a highly reliable tool. It then becomes possible to ascertain the mechanism of $A \rightleftharpoons B$ solvent exchange: an associative mechanism is consistent with the data obtained in binary mixtures of THFu with THF, the glymes and other oxygenated solvents[138, 148].

7. Application to the Structure and Microdynamics of Ion Pairs

A fundamental dichotomy is that between *tight* and *loose* ion pairs, with a number of operational criteria to distinguish between either structural type on the basis of spectroscopic data or reactivity measurements[150].

^{23}Na-NMR spectroscopy can also be applied, often with interesting results. For instance, the ^{23}Na absorptions for $NaB(C_6H_5)_4$ appear consistently 6—8 ppm upfield from those of $NaBH_4$ (both in ether solutions[66]). Also, the tetraphenyl borate (but not the hydroborate) has a concentration-independent chemical shift in numerous non-aqueous solvents[33–36]. These convergent criteria point to the existence of a loose ion pair $Na^+[B(C_6H_5)_4^-]$ in solvents such as the glymes[151]; this conclusion agrees with previously obtained evidence from conductimetry and optical spectroscopy[25,150].

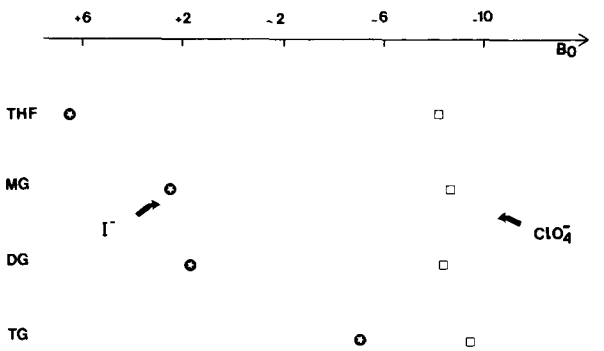

Fig. 9. Solvent-dependence of the ^{23}Na chemical shift of Na^+I^- and $Na^+ClO_4^-$: in tetrahydrofuran (THF), monoglyme (MG), diglyme (DG), and triglyme (TG) [152].

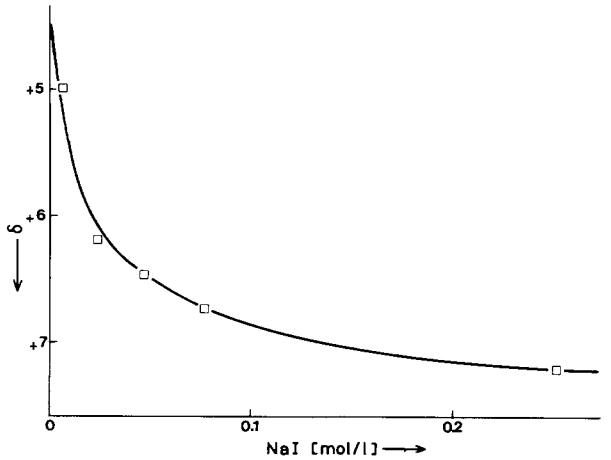
Also interesting is the comparison between $NaClO_4$ and NaI (Fig. 9): the perchlorate exists as loose, solvent-separated ion pairs in THF and the glymes. For the iodide, tight ion pairs predominate in THF, and loose ion pairs in triglyme, with intermediate positions of the tight⇌loose equilibrium in monoglyme and diglyme[152].

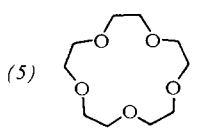
Replacement in the sodium coordination sphere of the counter-ion by a solvent molecule leads to a high-field shift when the anion is a better electron donor than the solvent molecules[153]. A down-field shift is observed when the anion is a poorer electron donor than solvent molecules[153]. Such is the case with highly delocalized anions (ClO_4^-, PF_6^-, $B(C_6H_5)_4^-$) when displaced by solvent molecules which are better donors[153].

The observation of tight or loose ion pairs depends markedly upon the nature of the solvent: for NaI, the concentration-independence of the chemical shift led *Popov*[36] to conclude the presence of loose ion pairs in DMSO, while in the iso-dielectric solvent sulfolane tight ion pairs are present, as follows from the concentration-dependent chemical shift. The relevant characteristic is the donor ability: the donor numbers are 29.8 for DMSO *versus* 14.8 for sulfolane.

Aggregation of tight ion pairs introduces a second counter ion in the sodium coordination sphere, and therefore affects the chemical shift. For instance, sodium iodide shows a concentration-dependent chemical shift in THF solution (Fig. 10),

which we analyzed[152] in terms of predominant dimer formation. These $(NaI)_2$ species are characterized by a Stokes radius of *ca.* 5 Å, significantly higher than that of 3.7 Å for the Na^+ cation (from $NaClO_4$) solvated also by THF molecules[65].





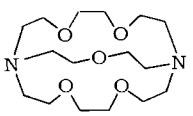


Fig. 10. Change in ^{23}Na chemical shift as a function of concentration (for NaI in THF): the resonance moves upfield with decreasing concentration [152].

When a tight A^-, Na^+ ion pair is co-dissolved with a sodium-specific neutral ligand, such as the crown ether

(5)

(2)

[15]crown-5 *(5)*[154] or the [2.2.1]cryptand *(2)*[29], the following equilibria are present (L = ligand molecule)[155,156]:

$$A^-, Na^+ + L \rightleftharpoons A^-, Na^+, L$$
$$A^-, Na^+ + L \rightleftharpoons A^-, L, Na^+$$
$$A^-, Na^+, L \rightleftharpoons A^-, L, Na^+$$

The externally-perturbed ion pair A^-, Na^+, L coexists with the internally-perturbed (separated) ion pair A^-, L, Na^+. Thus, *e.g.*, the reactivity of the sodium enolate of ethyl acetoacetate on alkylation with reagents such as C_2H_5I is greatly increased in the presence of one equivalent of the [2.2.2]cryptand *(3)* or 10 equivalents of [18]crown-6 ether, and becomes equivalent to that of the free ion[157,158]. Intuitively, the species

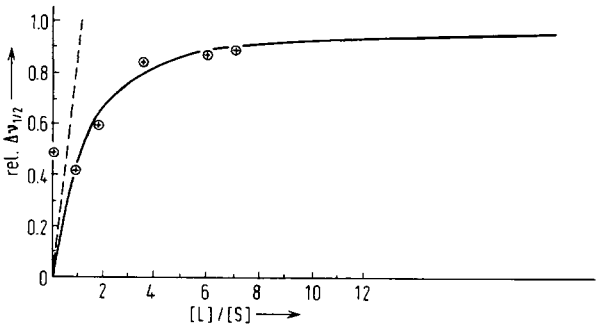

Fig. 11. Normalized linewidth rel. $\Delta\nu_{1/2}$ of the ^{23}Na-NMR signal of the sodium enolate of ethyl acetoacetate (S) as a function of added [2.2.1]cryptand *(2)* (L) in THF solution containing 10 % C_6D_6 at 30 °C. This plot corresponds to limiting values of the normalized linewidth of 1917 $cP^{-1}s^{-1}$ in the absence of L and of 136 $cP^{-1}s^{-1}$ for sodium cryptate. The equilibrium constant for sodium cryptation in this experiment is 161/mol.

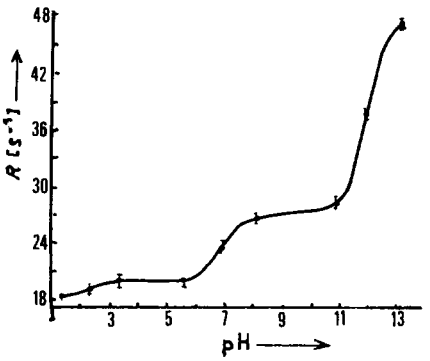
to be associated with the highest reactivity ought to be the internally-perturbed A^-, L, Na^+ ion pair. Indeed, chemical shifts and normalized linewidths (Fig. 11) strongly suggest[159] that the dominant species in the presence of more than one equivalent of the cryptand is the cryptand-separated ion pair in which the sodium cation is cryptated, thus increasing the reactivity of the counter-ion. When L is the [15]crown-5 ether, a crowned ion pair A^-, Na^+, L appears to be formed[159], with a reactivity equivalent to that of the free anion[160,161].

In aqueous solutions, sodium salts dissociate almost completely. In general, the ^{23}Na chemical shift differs little from that for the free sodium ion under the same conditions. Fortunately, the ^{23}Na linewidth is highly sensitive to the restriction of reorientational motion caused by ion pairing; even small amounts of ion pairs can thus be detected quite reliably. This is illustrated for phosphate counter-ions by the pH dependence of the ^{23}Na relaxation rate (Fig. 12)[162].



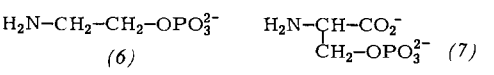


Fig. 12. pH-dependence of ^{23}Na relaxation rate $R_1 = 1/T_1$ in NaCl/sodium phosphate solutions (0.20 mol/l) [162].

The sodium cation binds to PO_4^{3-} above pH = 13, to HPO_4^{2-} between pH = 8 and 11, and to $H_2PO_4^-$ between pH = 3 and 6; the pK_a values for the successive ionizations of phosphoric acid are 2.1, 7.2 and 12.4[163], in good agreement with the inflexion points in the titration curve of Figure 12. This curve suggests a limiting value of *ca.* 50 Hz for binding to the PO_4^{3-} ion. Using the literature value $\log\beta = 0.59$ (at 25 °C)[164] for the global equilibrium

$$PO_4^{3-} + 3\,Na^+ \overset{\beta}{\rightleftharpoons} PO_4^{3-}, 3\,Na^+$$

and 5 Hz as the linewidth characteristic of *free* sodium, one obtains a relaxation rate R_1 for *bound* sodium of *ca.* $80\,s^{-1}$ which, together with the quadrupole coupling constant $\chi = 0.5$ MHz appropriate for interaction of Na^+ with a phosphate group[112], leads to a correlation time τ_c of about 70 ps for reorientation of the PO_4^{3-}, Na^+ pair. By comparison, the correlation time for reorientation of $PO_3F_2^-$—a somewhat similar system—is *ca.* 40 ps[165], *i.e.* of the same order of magnitude.

(6) *(7)*

James and *Noggle*[162] have used 2-aminoethyl phosphate (phosphoethanolamine) *(6)* and *O*-phosphonoserine *(7)* as

models for the basic moieties of two prominent phospholipidic carriers in membranes: binding of Na^+ follows the sequence phosphate > *O*-phosphonoserine > phosphoethanolamine, and correlates directly with the charge-to-radius ratio of the anions. However, Na^+ interacts only weakly with the potential carrier phosphatidyl serine, in the form of an aqueous dispersion, at physiological pH[162].

There are many experimental situations in which the sodium cation is in rapid exchange between *free* and *bound* states. The observables, either a chemical shift or a linewidth, are the weighted average quantities. For instance, the relaxation rates $R_i = 1/T_i$ $(i = 1,2)$ are related, as in the cases above, by:

$$R_{(i)\,obs} = x_f R_{(i)\,f} + x_b R_{(i)\,b}$$

where subscripts f and b refer to the *free* and *bound* states respectively, and the x are mole fractions.

Binding of the sodium cation to biological molecules has special importance, and is dealt with in the following section.

8. Application to the Binding of Na^+ and Other Cations to Biomolecules

Historically, *Jardetzky* and *Wertz*[77] were the first to investigate complexation of Na^+ by organic chelating ligands. The observed line broadenings[77] correlate with stability constants K_f for the complexes, as obtained by potentiometric titration using ion-sensitive glass electrodes[166]: the values of K_f range from 0.2—0.3 for amino acids such as DL-alanine or L-leucine through 1.9 for malic acid to 2.7 for pyruvic acid.

These early findings[77] on a very extensive series of samples, including the contents of a hemolyzed red blood cell, were indeed sufficiently exciting that other groups entered the field. *Eisenstadt* and *Friedman*[167] examined further the ion pairing of Na^+ with sulfate. *James* and *Noggle*[168] conclude, contrary to *Jardetzky* and *Wertz*[77], that the Na^+-histidine interaction is very weak. Assuredly, the *Jardetzky* and *Wertz*[77] exploratory linewidth measurements were made in the face of substantial magnetic field inhomogeneity[167], which does not appear to explain the failure of *James* and *Noggle*[168] to find a histidine complex.

From the pH dependence of the relaxation rate R_1, stability constants K_f are obtained[168] (25 °C; $\mu = 0.7$—1.0) for *N'*-(2-hydroxyethyl)ethylenediamine-*N*,*N*,*N'*-triacetic acid (HEEDTA, $K_f = 8.7 \pm 0.9$ l/mol) and for nitrilotriacetic acid (NTA, $K_f = 9.6 \pm 1.5$ l/mol). Using the calculated R_1 values for the *bound* state, the quadrupole coupling constant χ for the Na^+-aminopolycarboxylate complexes in aqueous solution is about 4 MHz[168].

Na^+-binding to simple carbohydrates in aqueous solution is very weak, unless an axial-equatorial-axial sequence of OH groups is present[169–171]; thus *Andrasko* and *Forsén* found significant ^{23}Na line broadenings only with *cis*-inositol ($K_f \simeq 1.2$ l/mol)[172]. In non-aqueous solvents with low dielectric constants, the interaction is both stronger and less specific. We have used amine solvents, such as pyridine or isopropylamine, in order to generate substantial electric field gradients at the sodium nucleus: Na^+ is coordinated on one face by nitrogen heteroatoms from solvent molecules, and on the other face by oxygen heteroatoms from two (or three) OH groups of the sugar molecule[173]. The stability constants K_f for the complexes are in the range 5—20 l/mol for a variety of simple carbohydrates[173]. In pyridine solution, at 290 K, the sodium linewidth characteristic of the complex increases from 800 ± 150 Hz for hexopyranoses to 2000 ± 400 Hz for the disaccharide lactose, in line with the expected approximate doubling of the reorientational correlation time as the molecular weight (volume) increases by a factor of about 2[174].

The interaction of Na^+ with polysaccharides has also been investigated. With heparin, a glycosaminoglycan, the pH dependence of the ^{23}Na linewidth, with an equivalence point of 4.5, indicates predominant binding by the carboxyl groups[53]. At least two carboxyl groups situated on different rings chelate a given Na^+ ion: the dissociation constants K_d for the ion pairs are in the range 5—20 mmol/l, *i.e.* weaker by an order of magnitude than the sodium binding by citrate ($K_d = 300$ mmol/l), using the same ^{23}Na-NMR technique[53]. Other cations bind to the same sites in competition with Na^+. For instance, in aqueous solution, Ca^{2+} forms much stronger complexes than Na^+ with a simple sugar such as ribose[172] or with a mucopolysaccharide such as heparin[53] (Fig. 13).

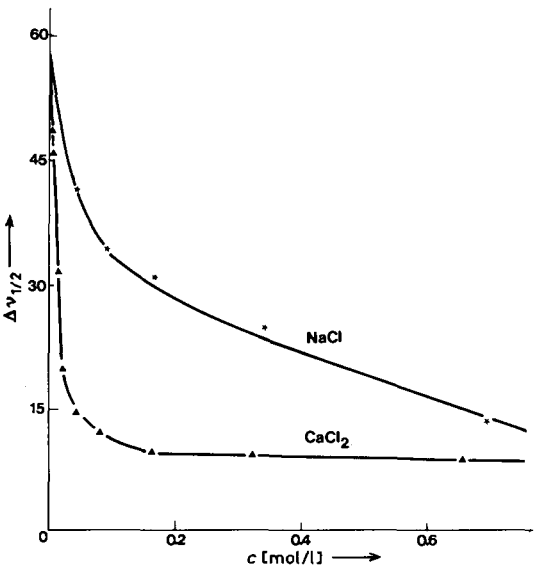

Fig. 13. Linewidth of the ^{23}Na-NMR signal of sodium heparinate as a function of added NaCl or $CaCl_2$ [53]. c = concentration of the respective salt.

From such competition experiments, taking advantage of the high sensitivity of ^{23}Na-NMR spectroscopy, one can study the binding of many inorganic and organic cations to biomolecules, by following the changes of the ^{23}Na linewidth as another cation is added to the solution. With heparin, for example, cation fixation follows the sequence: $Ca^{2+} > Cu^{2+} > Co^{2+} > Sr^{2+} > Mg^{2+} > Ni^{2+} > Be^{2+} > K^+ > NH_4^+ > Na^+ > Li^+ > N(CH_3)_4^+ >$ acetylcholine[53].

This finding that glycosaminoglycans bind cations at specific sites[53,175] is relevant to the long-standing question of site binding *versus* atmospheric binding in counter-ion binding to polyelectrolytes[176–178]. An illuminating analogy presents itself: tight ion pairs for site binding, and loose, solvent-separated ion pairs for atmospheric binding[179].

Leyte et al.[180–182,187,188] have conducted a joint experimental and theoretical study of the binding of alkali metal

ions by polyelectrolytes. The ^{23}Na relaxation rate for polyphosphates increases with the molecular weight of the polymer up to a degree of polymerization of about 60; it then remains constant[180,181]. This sets a lower limit to the applicability of the rigid rod model for a polyelectrolyte: the polymer is treated as a uniformly charged rod of radius a, from which originates a radially directed electric field. The relaxation rate is proportional to the average value of the square of this radial electric field acting on the sodium nucleus. Using the analytical solution of the Poisson-Boltzmann equation, an equation is derived for the relaxation rate of ^{23}Na in polyelectrolyte solutions as a function of the degree of neutralization α[182]. This leads to values of $a=2.8$ Å, too small to be physically realistic, since a should correspond to the sum of the hydrated radii of polyion and sodium counterion, *i.e.* 5.6 Å[183]. Hence the counterion condensation concept of *Manning*[184–186] is to be preferred: the net charge density of the polyion is maintained at a constant value by condensation (*i.e.* atmospheric binding) of the counter-ions; counter-ions will condense until this critical value is reached. Given a mean distance d between charged groups, the linear charge density parameter

$$\xi = \frac{e^2}{\varepsilon \cdot KT \cdot d}$$

is approximately equal to $7.1\,d^{-1}$ in water solution, with unit charges. The critical value is $\xi=1$; with $\lambda=\alpha\cdot\xi$ a fraction $(\lambda-1)/\lambda$ of the counter-ions condenses on the polyelectrolyte. This treatment predicts that the relaxation rate should increase proportionately to the square of the degree of neutralization α, as indeed observed for the Na^+-polyphosphoric acid interaction[187]. All the Na^+ ions are atmospherically bound on a polyphosphate rod, with a distance $d=2.6$ Å between charged groups, at a distance of *ca.* 3 Å from the axis[187].

Competition with divalent ions was also studied, using a polyelectrolyte characterized by $\lambda=2.85$. Ba^{2+} ions condense or bind on the poly-anion until the effective value of λ is $\frac{1}{2}$; excess Ba^{2+} and all Na^+ cations remain free in solution. Using ^{23}Na relaxation as an indirect means of monitoring Ba^{2+} interaction with poly(styrenesulfonic acid), the divalent ions condense with, rather than bind to the charged polymer[188].

Condensation of Na^+ ion around the charged polymer, rather than specific binding on well defined sites, also occurs with the nucleic acids: both with soluble RNA[189] as with DNA[190], the ^{23}Na relaxation rate increases from a value of *ca.* 18 Hz for free Na^+ to a value of about 170—220 Hz for bound Na^+. If the Na^+ ions were rigidly bound to the slowly reorienting nucleic acid macromolecule, the expected relaxation rate would be increased to a minimum of 15000 Hz. Furthermore, the correlation time inferred for the DNA-Na^+ system from measurements at three different frequencies is 5.5 ps[190], *i.e.* only marginally greater than for the hexaaqua ion. This led *Reuben*[191] to conclude: "Thus, because of short lifetimes of the macromolecular complexes of sodium, the relaxation rate of ^{23}Na cannot be used in studies of macromolecular dynamics in solution".

Obviously, such a sweeping statement should not and does not apply to macromolecular binding sites were two or more groups chelate the Na^+ cation. For instance, parvalbumin is a calcium-binding protein having two Ca^{2+} ions tightly bound ($K_d \approx 10^{-7}$ mol/l) per molecule (rel. molecular mass $\approx$ 12000). Removal of a single calcium ion maintains the conformational integrity of parvalbumin: the sodium cation attaches itself to the vacant binding site, with a binding constant $K=30$ l/mol; its apparent correlation time $\tau_c \approx 3\times10^{-9}$ s, very close to that of the protein as inferred from ^{13}C relaxation times[192], indicates that the cation-protein complex reorients as a single entity devoid of kinetic lability[193]: the lifetime of this complex is approximately 20 times longer than τ_c[193]. The *off* rate $k_- = 2\times10^7\,s^{-1}$ and the *on* rate $k_+ = 0.6\times10^9\,l\,mol^{-1}\,s^{-1}$.

The activation energies for decomplexation of Na^+ attached to macrocyclic polyethers in various solvents[194,195] and for cryptates in water[196] or ethylenediamine solution[28,197] are observed in a rather narrow range of 12.2 ± 1.1 kcal/mol.

From the ion pairing of Na^+ with phosphate groups, the self-assembly of the 5′-GMP nucleotide has been studied[112,198]: the apparent correlation time increases, depending upon the conditions, by a factor 20—50, corresponding closely to the degree of aggregation. Transition from the monomeric state to an ordered n-mer can be effected by decreasing the temperature[112], increasing the 5′-GMP concentration[112], or by the presence of K^+ ions[198]. These aggregates may have served as templates for the prebiotic appearance of nuclei acids[199].

9. Micelles and Membranes

The early 1970's saw several reports on the triplet splitting of the ^{23}Na resonance in liquid crystals[75,200,201]

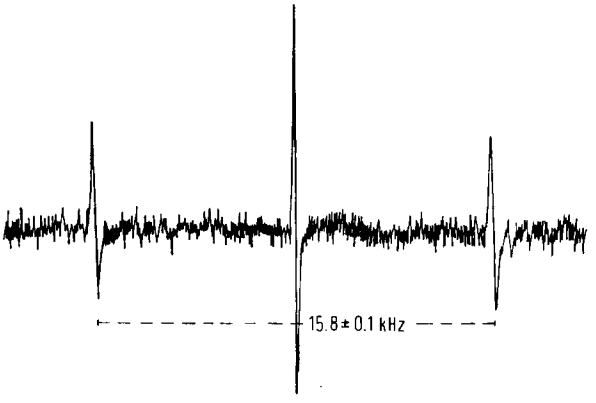

Fig. 14. ^{23}Na-NMR signal of a lyotropic nematic phase; frequency 8.0 MHz. The temperature of the probe was 26.4 ± 0.1 °C [201].

as a function of local order (Fig. 14). The Na^+ ions are attached, part of the time, to polar groups which are highly ordered. The quadrupole splitting reflects anisotropic motion over long times, *i.e.* greater than a microsecond. The separation between the outer lines is proportional to the product of the quadrupole coupling constant and an order parameter S[202], the degree of orientation of the electric field gradient axis.

It is thus possible to use counterion binding by Na^+ to explore the surface of mesophases and amphiphiles, and to derive information about local geometries. For instance, a separation of the counterion from the anionic polar heads by distances greater than 5 Å is characteristic for solvent-

separated ion pairs[75]. For surfactant mesophases containing a long-chain sodium alkyl sulfate or sulfonate, the order parameter S is close to unity[203]; this implies that the electric field gradient is colinear with the mesophase director, *i.e.* that the hydrated Na^+ interacts equally with the three oxygens, as expected from a simple RSO_3^-, Na^+ interionic attraction[75, 203]. Conversely, when the anionic amphiphiles have carboxylate end groups, the Na^+ ions insert themselves between the polar end groups; the electric field gradient and the director make an average angle close to the magic angle (54°44′), and S approaches zero[208, 209]. Numerous detailed studies have appeared[75, 204–210], exploiting these concepts on the basis of an excellent theoretical framework[203]. Mapping of the quadrupole interaction as a function of composition for ternary aqueous amphiphile solutions has been performed in a number of cases[209].

The critical micelle concentration (CMC) is readily apparent from the sharp change in the chemical shift (Fig. 15)[211] or in the relaxation rate[212]: when plotted against the inverse amphiphile concentration, it has the characteristic appearance of two straight line segments intersecting at the CMC. In order to account for such behavior, a two-site model is sufficient: there is fast exchange between the free and the bound Na^+. In addition, it is assumed that the pseudophase separation model describes micelle formation, and that condensation of the sodium counterions on the polar head groups is concentration-independent.

Multiple-quantum transitions have been encountered in the ^{23}Na-NMR spectra of lyotropic liquid crystals[213].

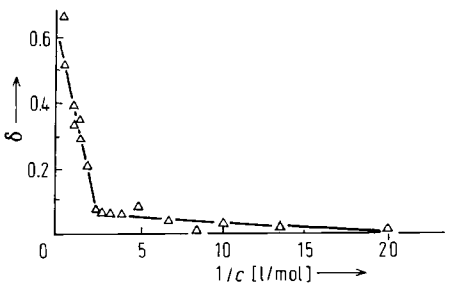

Fig. 15. ^{23}Na chemical shift as a function of the inverse concentration of a soap (sodium *n*-octanoate). Standard: 0.5 M NaCl [211].

10. And from There?

It is a useful exercise to look back at the 10 years or so during which applications of ^{23}Na-NMR spectroscopy have been explored. Sparse numbers of investigations characterize this period, at least until the advent of Fourier transform techniques. Often, slowly growing dissatisfaction follows an initial burst of enthusiasm. The reasons for this are numerous: the lack of understanding of the components of the chemical shift, the necessity of gathering a wealth of extraneous data such as magnetic susceptibilities, equilibrium constants, viscosities, *etc.* which complicates measurements and which precludes immediate answers, the under-development of model calculations for the quadrupole coupling constant. All contribute to this unhappy state of the art.

Further, chemists have been used to nuclear magnetic resonance of covalently-bound nuclei (^{1}H, ^{13}C, ^{19}F, ^{31}P ...), and are less familiar with the leaps and bounds of an ion fancying itself as a free agent.

However, this very conceptual break may prove itself the saving grace for ^{23}Na-NMR spectroscopy: the electrostatic interaction commends itself by its extreme simplicity. Thus the difficulties pointed out in the preceding paragraph might be overcome by relatively easy solutions, and I foresee an explosive growth in the field of ^{23}Na-NMR spectroscopy in the years to come. It may even be exploited in the building of scanners for malignant tumors[214]!

Appendix

Since a variety of numbers have been quoted in the literature for the ^{23}Na quadrupole moment Q (as well as for the Sternheimer anti-shielding factor $(1-\gamma_\infty)$), differing by up to 50 %—which will lead to a 100 % discrepancy in estimates of T_2 or the linewidth $\Delta\nu_{1/2}$—we have undertaken a critical survey. We feel that values of Q close to 0.15 barn (0.15×10^{-24} cm^2) are erroneous[215–219]. Taking the experimental values obtained for the atom in the 3p or 4p state[220, 221], and corrected for the anti-shielding contribution, yields values of $Q=0.10\times10^{-24}$ cm^2[222], in excellent accord with results from calculations[223]. The Sternheimer anti-shielding factor $(1-\gamma_\infty)$ has a value close to 5.8[222, 224], somewhat larger than previously-quoted figures[72, 75, 225].

I thank Professor Horst Kessler (University of Frankfurt), Professor Jacques Reisse (Free University of Brussels), Professor Robin K. Harris (University of East Anglia, Norwich, UK), Dr. Bob Hirst (Goodyear Research, Akron, Ohio) and Dr. J. E. Anderson (Ford Motor Co., Dearborn, Michigan) for brief but valuable suggestions. My gratitude goes to my co-workers, who relished the challenge of a foray into new territories: Miss Agnès Paris, Dr. A. Cornélis, Dr. C. Detellier, Dr. J. Grandjean, and L. Herwats. Financial support of our work by Fonds de la Recherche Fondamentale Collective, Brussels, is gratefully acknowledged.

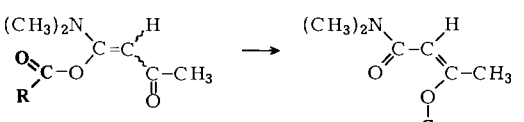
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

A New Method for Selective Activation of Amino, Hydroxy, and Mercapto Carboxylic Acids at the Carboxyl Group: Preparation of Thiol and Selenol Esters



By *Hans-Joachim Gais* and *Thomas Lied*[*]

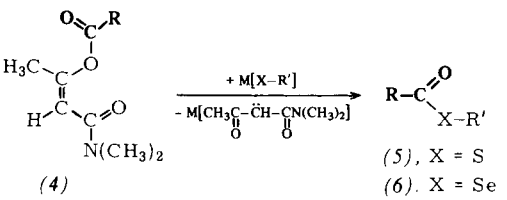
Synthetic objectives in the field of macrolides prompted us to search for new very mild methods of broad applicability for the chemoselective activation of polyhydroxy carboxylic acids—a key reaction in the lactonization of macrolide seco-acids. We now report such a procedure for activating amino, hydroxy, and mercapto carboxylic acids by transformation into activated enol esters *(4)* with 4-dimethylamino-3-butyn-2-one *(1)*[1] and their use as acyl transfer reagents in the synthesis of thiol and selenol esters *(5)* and *(6)*, respectively.

The acetylene derivative *(1)*, readily accessible by reaction of 4-dimethylamino-3-buten-2-one[2] with bromine and subsequent elimination of HBr, reacts with an equimolar amount of benzoic acid *(2a)* in tetrahydrofuran in the presence of a 100-fold excess of methanol, ethanol, 2-propanol, or *tert*-butyl alcohol at −60 to 0°C with exclusive addition of the carboxyl group to the triple bond. The primary adduct *(3a)* is not isolable; it rapidly rearranges quantitatively[1,3] to *N,N*-dimethyl-(*Z*)-3-benzoyloxycrotonamide *(4a)* which can be isolated in >95% yield. No addition of *(1)* to alcohols is observed[4].

(1)

(3) *(4)*

After prolonged reaction in the presence of an equivalent amount or an excess of benzylamine, *(1)* and *(2a)* do not give *(4a)* but, apart from *N,N*-dimethylacetoacetamide, *N*-benzylbenzoamide in 96% yield. Selective formation of *(4a)* is followed in this case by acyl transfer[5] with amide formation[6].



Reaction of structurally highly diverse hydroxy carboxylic acids *(2b—o)* [with primary, secondary, and tertiary alcoholic and phenolic OH groups] and amino *(2p—r)* and mercapto acids *(2s)* with *(1)* at −50°C in anhydrous tetrahydrofuran leads rapidly and almost quantitatively to the corresponding enol esters *(4)* (Table 1)[7].

Table 1. Synthesis of enol esters *(4)* from *(1)* and *(2)*.

	Carboxylic acid *(2)*	Enol ester *(4)*	Yield [%]
(b)	Mandelic acid	*(b)*	96
(c)	α-Hydroxycyclohexanecarboxylic acid	*(c)*	93
(d)	Glycolic acid	*(d)*	93
(e)	Quinic acid	*(e)*	94
(f)	D(−)-Tartaric acid	*(f)*	98 [a]
(g)	12-Hydroxystearic acid	*(g)*	95
(h)	Ricinelaidic acid	*(h)*	96
(i)	(*Z*)-L-Serine	*(i)*	97
(j)	Cholic acid	*(j)*	98
(k)	*p*-Hydroxyphenylacetic acid	*(k)*	96
(l)	*p*-Hydroxycinnamic acid	*(l)*	97
(m)	Salicylic acid	*(m)*	97
(n)	*m*-Hydroxybenzoic acid	*(n)*	93
(o)	*p*-Hydroxybenzoic acid	*(o)*	94
(p)	Anthranilic acid	*(p)*	96
(q)	*m*-Aminobenzoic acid	*(q)*	95
(r)	*p*-Aminobenzoic acid	*(r)*	93
(s)	β-Mercaptopropionic acid	*(s)*	91

[a] Yield of dienol ester.

Even with an excess of *(1)* no reaction occurs with the hydroxyl, amino, or mercapto group. The non-isolable primary adducts *(3)* resist detection by NMR spectroscopy even at −60°C in accord with earlier reports[1,7]. The enol esters *(4)* are stable at room temperature, and generally crystallize readily and resist hydrolysis. On reaction with the Li, Na, and K salts of primary, secondary, and tertiary aliphatic thiols and of thio- and seleno-phenol in tetrahydrofuran at 0°C

(4) *(5)*, X = S; *(6)*, X = Se

Table 2. Synthesis of thiol and selenol esters, *(5)* and *(6)*, from *(4)*.

Enol ester *(4)*	*(5)* and *(6)*		Yield [%] [a]
(b)	*(5b)*	R′=C_6H_5	89
(c)	*(5c)*	R′=C_6H_5	83
(f)	*(5f)*	R′=C_6H_5	72 [b]
(g)	*(5g)*	R′=C_6H_5	91
		R′=C_6H_{11}	79
		R′=$C(CH_3)_3$	84
	(6g)	R′=C_6H_5	88
(h)	*(5h)*	R′=C_6H_5	78
(j)	*(5j)*	R′=C_6H_5	83
(k)	*(5k)*	R′=C_6H_5	89
(r)	*(5r)*	R′=C_6H_5	81

[a] Yields of isolated pure compounds, not optimized. [b] Yield of dithiol ester.

[*] Dr. H.-J. Gais, T. Lied

Petersenstrasse 22, D-6100 Darmstadt (Germany)

they rapidly afford the thiol and selenol esters *(5)* and *(6)*, respectively, in good yields (Table 2).

The enol esters *(4b)*, *(4c)*, and *(4f)* of α-hydroxy carboxylic acids are exceptions; their transformation into *(5b)*, *(5c)*, and *(5f)*, respectively, is best accomplished with thiophenol in the presence of 10 mol % of 4-dimethylaminopyridine[8]. The alkali salt of *N*,*N*-dimethylacetoacetamide accompanying *(5)* or *(6)* is easily removed by filtration (or—after neutralization—*N*,*N*-dimethylacetoacetamide is removed by washing with water). Activation with *(1)* and acylation to give *(5)* and *(6)* can be carried out as a one-pot reaction without isolation of *(4)*[9].

Procedure

(*Z*)-*N*,*N*-Dimethyl-3-(3α,7α,12α-trihydroxy-5β-cholanoyloxy)crotonamide *(4j)*: A solution of cholic acid *(2j)* (4.08 g, 10 mmol) in anhydrous THF (20 ml) is added to a stirred solution of *(1)* (1.16 g, 10.5 mmol) in anhydrous THF (30 ml) at −50 °C with exclusion of moisture. After 20 min at −50 °C, the mixture is allowed to warm to room temperature and then evaporated down *in vacuo*. Recrystallization of the residue from chloroform/*n*-hexane gives 5.08 g (98 %) of colorless crystals, m.p. 166—167 °C.

S-Cyclohexanethiol ester of 12-hydroxystearic acid *(5g)*: A solution of Li cyclohexanethiolate (1.28 g, 10.5 mmol) in anhydrous THF (20 ml) is added to a solution of *(4g)* prepared from *(1)* (10.5 mmol) and *(2g)* (10 mmol) in anhydrous THF (50 ml). After 1 h at 0 °C, precipitated Li *N*,*N*-dimethylacetoacetamide is filtered off and the filtrate washed with water after addition of ethyl acetate (100 ml). After drying over $MgSO_4$ and removal of solvent, the residue is dissolved in methylene chloride and filtered over silica gel (Kieselgel 60, Merck). The oil crystallizes on concentration to give 3.14 g (79 %) of colorless crystals, m.p. 37—38 °C.

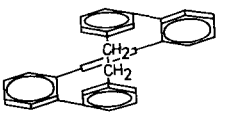
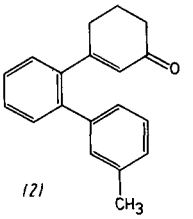
[9] Correct elemental analyses were obtained for all compounds listed; the IR and NMR data are compatible with the structures.



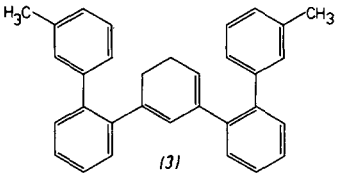
A New Helical Molecular Skeleton [**]

By *Fritz Vögtle* and *Erich Hammerschmidt* [*]

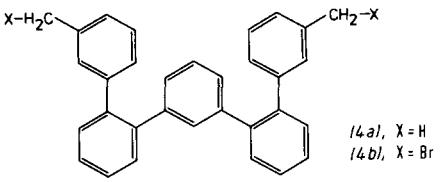
We wish to report a helical sequence of non-annelated aromatic rings *(1)* in which the screw shape of the molecule is imposed by a clamp (*K*) at the ends of a chain made up of five phenylene units[1]:



(1)



(1a)



Our strategy for synthesizing this hitherto unknown hydrocarbon with the shortest possible clamp *(1a)* (Table 1) resembles that used by *Woods et al.*[2] for the preparation of the *m*-terphenyl system. 3-Ethoxy-2-cyclohexen-1-one was converted by treatment with 3′-methylbiphenyl-2-lithium or -2-magnesium iodide *via* the intermediates *(2)*, *(3)*, and *(4a)* [dehydrogenation of *(3)* with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone] into the bromide *(4b)* [NBS bromination of *(4a)*], which was smoothly cyclized by the new thioacetamide method[4] under high-dilution conditions[3a] to form the sulfide *(1c)*. Pyrolysis of its sulfone *(1d)* at 500 °C/5×10^{-5} torr gives the hydrocarbon *(1a)*. Reaction of the dibromide *(4b)* with ethane-1,2-dithiolate leads to the cyclic sulfide *(1e)*, whose sulfone *(1f)* likewise affords *(1a)* on pyrolysis[3].

[a] Composition confirmed by correct elemental analyses and mass spectra.
[b] 80 MHz; in $CDCl_3$ at 35°C; the δ-values apply to the H atoms indicated in the second column of the table.
[c] The compound contains no diastereotopic bridge protons.
[d] Sparingly soluble.

Halogenation and subsequent elimination transforms *(1a)* into the alkene *(1b)* clamped by one CC double bond.

The (temperature dependent) ^{1}H-NMR spectra of the ring systems *(1a)*, *(1b)*, *(1d)*, *(1e)* show the molecules to be helical at low temperatures: the signals of the benzylic CH_2 protons of *(1a)*, *(1d)*, *(1e)* appear as singlets at room temperature but display considerable broadening on cooling[5]. Splitting of this singlet to an AB system can be observed with the sulfone *(1d)* ($T_c\approx-55$°C). Thus, as in the helicenes[1], interconversion between minus (*M*) and plus (*P*) helices is observed, albeit below room temperature:

The ^{1}H-NMR absorption of the terminal *m*-phenylene rings of the alkene *(1b)* are shifted downfield relative to *(1a)*. This is in accord with the widening of the bond angle at the (*Z*)-stilbene group expected for *(1b)* and the consequent increase in the distance between the *m*-phenylene rings.

As in a helical *o*-quaterphenyl skeleton prepared on a former occasion[1,6], the racemization barrier of compounds *(1)* depends upon the nature and the length of the clamp *K*: the sulfone exhibits the highest $(P)\rightleftharpoons(M)$ transition threshold (cf. Table 1).

In the UV spectra, the transition from the open-chain hydrocarbon 3,3''''-dimethyl-1:1',2':1'',3'':1''',2''':1''''-quinquephenyl *(4a)* ($\lambda_{max}=237.5$ nm, $\log\varepsilon=4.73$) to *(1a)* ($\lambda_{max}=234$ nm, $\log\varepsilon=4.67$), and the transition from *(1a)* to *(1b)* ($\lambda_{max}=233$ nm, $\log\varepsilon=4.88$) are accompanied by a hypsochromic shift (in $CHCl_3$)[7]. The former can be explained in accord with the results of *Woods et al.*[2b] for open-chain polyphenylenes by a diminished coplanarity of the rings. In the second case, a reduction of the bathochromic effect appears to prevail, which is due to π-π interactions induced by clamping by the CH_2CH_2 chain as a result of bond angle widening in the stilbene system *(1b)*. In the former case the π-π interactions appear to be overcompensated by biphenyl twisting.

We consider the significance of studies on such new (flexible) helical systems to lie not only in stereochemical parallels to the helicenes and spectroscopic and theoretical interest in helical compounds of varying pitch and number of turns, but above all in the fact that comparison with space filling models provides information about the quality of agreement between such models and the intramolecular dynamic stereochemistry, and especially the flexibility of aromatic rings and structural units. Predictions about such intramolecular processes in the numerous conceivable "phenylen*icenes*"[8] yet to be synthesized are thus facilitated.

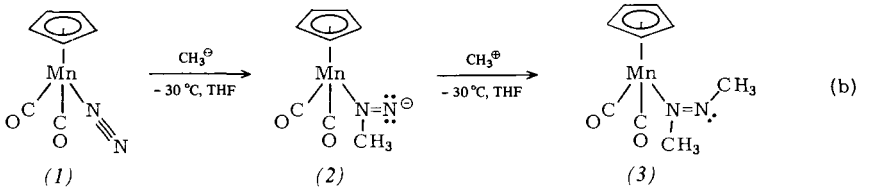
Consecutive Nucleophilic and Electrophilic Attack on N_2 Ligands: Synthesis of Azo Compounds from Molecular Nitrogen[1]

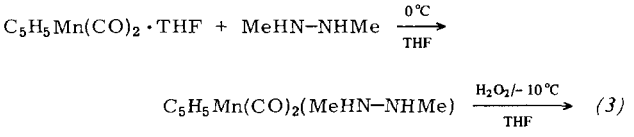
By *Dieter Sellmann* and *Woldemar Weiss*[*]

The catalytic reduction of molecular nitrogen to organic nitrogen compounds under mild conditions is not yet possible. We recently found the reduction of coordinated dinitrogen by bases ($X^{\ominus}$) and subsequent protonation to represent a new reaction of the N_2 molecule[2].



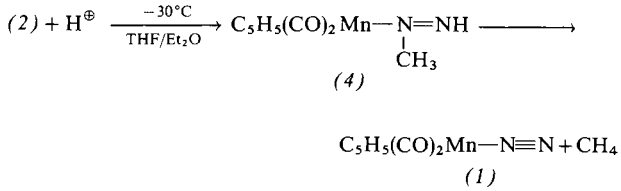
This reaction proceeds at low temperatures and appears to be of fundamental importance with regard to our under-

[*] Prof. Dr. D. Sellmann, Dr. W. Weiss
Laboratorium für Anorganische und Analytische Chemie der Gesamthochschule
Warburger Str. 100, Bauteil J, 4790 Paderborn (Germany)

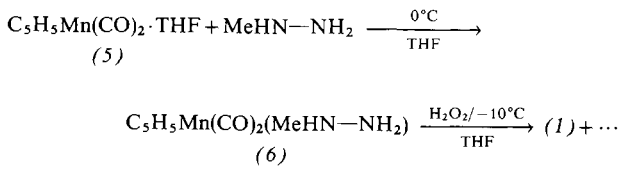


standing of the mechanism and catalysis of N_2 reduction; the reaction steps can be observed separately and the N_2-coordinating metal center is preserved in the course of the N_2 reduction, as has been shown by the reaction of $C_5H_5Mn(CO)_2N_2$ with LiC_6H_5 and H_2SO_4 to give the phenyldiazene complex $C_5H_5Mn(CO)_2[N(C_6H_5)=NH]$[2].

In order to prove the general validity of reaction (a) we have also investigated the nucleophilic addition of alkyl anions with $LiCH_3$. Owing to the instability of alkyldiazene complexes, the addition product formed cannot be detected by subsequent protonation. However, its appearance is unequivocally established by alkylation with methyl cations to yield an azomethane complex.



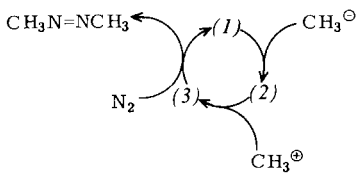
In the first step of reaction (b) the ν_{N_2} and ν_{CO} bands of *(1)* at 2165, 1962, and 1908 cm^{-1} respectively in the IR spectrum disappear while two new ν_{CO} absorptions at 1853 and 1730 cm^{-1} are observed, which we attribute to the adduct *(2)*. In the second step, methylation by $(CH_3)_3OBF_4$ yields complex *(3)*; after chromatography (SiO_2/toluene/−50 °C) and separation from decomposition and by-products, *e.g.* the carbene complex $C_5H_5Mn(CO)_2[C(OCH_3)CH_3]$, *(3)* is isolated as analytically pure red crystals (yield 14 %), which are moderately air- and heat sensitive, soluble in polar as well as nonpolar organic solvents, and may be recrystallized from acetone at 10°/−78 °C. Independent synthesis from *N,N'*-dimethylhydrazine yields an identical product.



The IR spectrum of *(3)* in acetone shows two ν_{CO} bands of equal intensity at 1925 and 1860 cm^{-1}; in KBr two characteristic ν_{CH} bands are seen at 2998 and 2930 cm^{-1} and an intense $\nu_{N=N}$ band due to the azomethane ligand at 1518 cm^{-1}. The ^{1}H-NMR spectrum (60 MHz, $(CD_3)_2CO$, 36 °C, rel. TMS) shows three signals of the correct intensity at $\delta=4.46$ (C_5H_5 ring) and $\delta=4.18$ and 4.00 (two nonequivalent methyl groups). Hence, the azomethane ligand must be coordinated *via* one nitrogen lone pair and not "side-on", a conclusion which is additionally supported by the strong $\nu_{N=N}$ band in the IR spectrum. In the mass spectrum (42 eV, $T_S=30$ °C) the molecular ion is observed at $m/e=234$; after loss of CO, $[C_5H_5Mn(CH_3N=NCH_3)]^{+\cdot}$ is observed as the first fragment ion.

Protonation of the adduct *(2)* with HCl or H_2SO_4 results, even below −30 °C, in violent evolution of gas and regeneration of *(1)*, probably due to

The intermediacy of the methyldiazene complex *(4)* is supported by the reaction of the corresponding methylhydrazine complex *(6)*.



By analogy with the equilibrium[3] *(1)* + THF ⇌ *(5)* + N_2 in tetrahydrofuran solution, a similar equilibrium should also exist between *(1)*, *(3)*, and N_2. Indeed, on applying N_2 pressure to ethereal solutions of the azomethane complex *(3)* the following reaction is observed:

The formation of *(1)* is proved by IR spectroscopy, and that of the azomethane liberated by gas chromatography and mass spectrometry.

Thus, in principle, azomethane can be synthesized catalytically from molecular nitrogen according to the following cycle:

Extensive repetition of this catalytic cycle, however, is impeded by side reactions which destroy the $C_5H_5Mn(CO)_2$ catalyst after a short time.

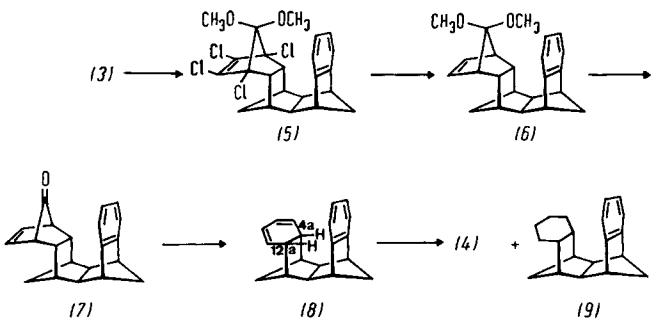
An Unusual Benzene/Benzene Through-Space Interaction[**]



By *Horst Prinzbach, Gottfried Sedelmeier, Carl Krüger, Richard Goddard, Hans-Dieter Martin,* and *Rolf Gleiter*[*]

The β-parameters[1] recently determined on the basis of models for the 1,6-diene *(1)* and its homo-derivative *(2)* would indicate unusual through-space interactions between benzene/ethylene and benzene/benzene moieties in the compounds *(3)* and *(4)*, respectively. We report here on the synthesis and X-ray structure analysis of *(4)* and on the PE spectroscopic investigation of *(3)* and *(4)*.

(1) *(2)* *(3)* *(4)*

We have prepared the hexacyclic compound *(4)*[2] from *(3)*[3] *via* the intermediates *(5)*—*(8)*. Addition of tetrachlorocyclopentadienone dimethyl acetal (*o*-dichlorobenzene, 180 °C, 14 h; m.p. 163—164 °C, 80 %), dehalogenation (Na/*t*-BuOH/tetrahydrofuran, 65 °C, 16 h; m.p. 126—127 °C, 60%), hydrolysis (40% sulfuric acid, CH_2Cl_2, 20 °C, 60 h; m.p. 135 °C, 95 %), and CO-elimination (xylene, 140 °C, 5 h; m.p. 139—140 °C, 65 %) proceed without complication. However, the last step must be carried out under unusual conditions: the sterically shielded hydrogen atoms 4a(12a)-H ($\tau = 8.17$)[4] are eliminated only on heating the mixture of *(8)* and to 250 °C a large excess of 10% Pd/C. Gas-chromatographic separation (10 % SE30, 4 m, 190 °C, He) of the mixture affords *(4)* [m.p. 174—175 °C, 85 %; ^{1}H-NMR ($CDCl_3$): $\tau = 3.55$ (m, 8H), 6.8—7.0 (m, 6H), 8.0 (d, $J = 8.0$ Hz, 2H), 8.23 (d, 2H); ^{13}C-NMR ($CDCl_3$): $\delta = 144.4$, 125.3, 123.5, 59.0, 46.6, 45.9] and *(9)* [m.p. 92—93 °C, 15 %].

Noteworthy, in view of the through-space interaction in *(4)*, is the longwave absorption between 270 and 310 nm ($\varepsilon \approx 300$) in the UV spectrum, which is absent in the case of indan[5] and *(9)*. Very similar effects observed in other compounds were previously ascribed, as in "janusene"[6], to CT transitions.

The geometry of *(4)* was determined by X-ray structure analysis[7a] (Fig. 1): benzene/benzene compression in the molecule is reduced by widening of the angles between the planes I/II (184.7°)[7b], II/III (119.0°), III/IV (133.1°), IV/V (118.4°), and V/VI (183.7°). Thus, the interplanar angle between the two benzene rings is 18.6°; the distances d_1 and d_2 are 3.04 and 3.82 Å, respectively.

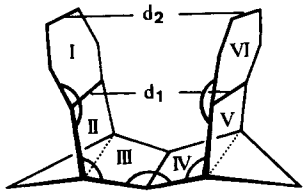


Fig. 1. Crystal structure of the hexacyclic compound *(4)*.

Analysis of the PE spectra of *(3)* ($IP_{i,v} = 8.0$, 8.85, 9.10, 10.0 eV) and the reference compounds *(10)* ($IP_{i,v} = 8.30$, 8.70, 9.60 eV)[8] and *(11)* ($IP_{1,v} = 8.60$, corrected for transannular strain $IP_{1,v}^{corr} = 8.9$ eV[1], gives $H_{i,j}(3) = -0.45$ eV and $\beta(3) = \sqrt{2}H_{i,j} = -0.64$ eV (Fig. 2).

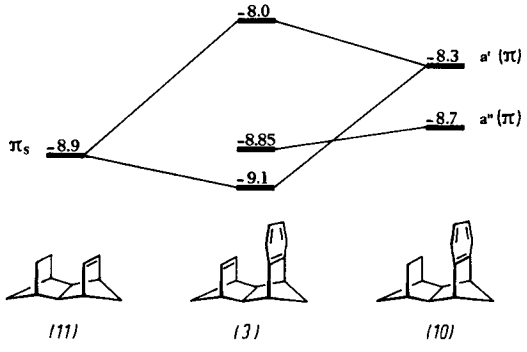

Fig. 2. Orbital correlation diagram for the compounds *(3)*, *(10)*, and *(11)*.

The first four bands in the PE spectrum of *(4)* can be readily reproduced using the basis energies of *(10)* and assuming an average interaction integral of $\beta_{AV} = -0.5$ eV: -7.8 ($b_2(\pi)$), -8.2 ($a_2(\pi)$), -8.8 ($a_1(\pi)$), -9.2 ($b_1(\pi)$) (Fig. 3). This assignment is confirmed by a MINDO/3 calculation[9].

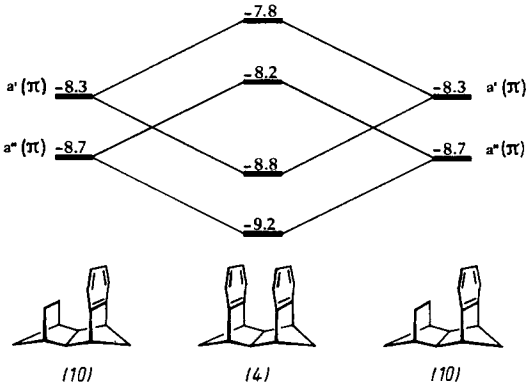

Fig. 3. Energy levels of *(4)* derived from the experimentally determined vertical ionization potentials [eV] of *(10)* using a resonance integral $H_{i,j} = \beta_{AV} = \langle 2p_i/\mathcal{H}/2p_{i'}\rangle = -0.5$ eV.

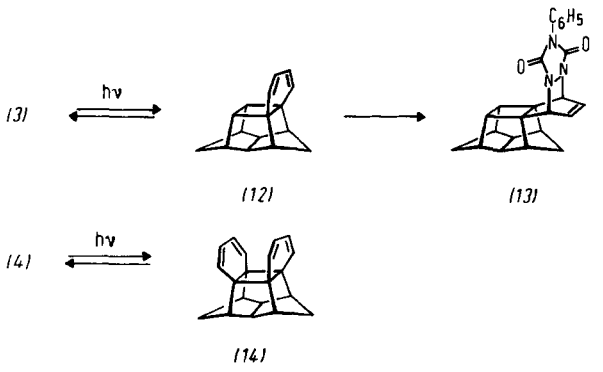

This analysis is based on the assumption that $\langle 2p_i/\mathcal{H}/2p_{i'}\rangle = \beta_{AV}$ for all i 2p(π) atomic orbitals. However,

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

on the basis of the structural data of *(4)* (Fig. 1) it would be more realistic to use $\beta' = \beta_{4a,6a} = \beta_{10a,12a} > \beta'' = \beta_{1,10} = \beta_{4,7} > \beta''' = \beta_{2,9} = \beta_{3,8}$. This gives $H_{i,j}(a'(\pi)) = \frac{1}{2}(\beta' + \beta''')$ and $H_{i,j}(a''(\pi)) = \frac{1}{6}(\beta' + 4\beta'' + \beta''')$. Now, using the ratio of the β-parameters corresponding to the ratio of the overlap integrals $\beta' : \beta'' : \beta''' = 3:2:1$ gives $H_{i,j}(a'(\pi)) = H_{i,j}(a''(\pi))$, *i.e.* assumption of an equal average β_{AV} value for $a'(\pi)$ and $a''(\pi)$ is permissible.

At $\beta = -0.5$ eV, *(4)* shows a benzene/benzene interaction comparable with that previously found only in [2.2]paracyclophane ($\beta = -0.5$ to -0.7 eV), in [2.2.2](1,3,5)cyclophane ($-0.4 < \beta \leq -0.7$ eV) and in [2.2]metacyclophane ($\beta \approx -1.2$ eV)[10]. The homoconjugation in *(3)*, with $\beta = -0.64$ eV, is expectedly still more pronounced ($\beta(3) > \beta_{AV}$). According to preliminary photolysis experiments[2], on acetone-sensitized excitation *(3)* undergoes [2+6]-cycloaddition to give *(12)*, and on direct excitation *(4)* undergoes [6+6]-cycloaddition to give *(14)*.

(12) is isolated from the photolysis equilibrium *e.g.* as the *N*-phenyltriazolinedione adduct *(13)* [m.p. 230°C; ^{1}H-NMR (360 MHz, $CDCl_3$): $\tau = 2.5$–2.75 (5H), 2.65 (2H), 4.98 (2H), 7.13 (2H), 7.43 (2H), 7.66 (2H), 7.84 (2H), 8.15, 8.49 (AB, $J = 10$ Hz), 8.26, 8.40 (AB, $J = 10$ Hz)].

Aluminum Tris(dihydrogen Phosphate)[**]

By *Rüdiger Kniep* and *Michael Steffen*[*]

The Al_2O_3—P_2O_5—H_2O system contains several ternary (actually quasiternary) orthophosphates; depending upon the $Al_2O_3 : P_2O_5$ ratio they are respectively designated as acidic (< 1), neutral ($= 1$), or basic (> 1) aluminum phosphate hydrates (APH's). Basic and neutral APH's occur as minerals; the aqueous solutions of acidic phases are commonly used as inorganic binders[1]. While the variety of crystalline basic and neutral APH's has already been extensively established by crystal structure analyses[2], identification of the crystalline acidic phases has been limited mainly to studies of the system at variable temperatures[3]. $Al(H_2PO_4)_3$ is the longest known[4] acidic APH and is now also the first phase of this group of compounds to have its crystal structure elucidated.

$Al(H_2PO_4)_3$ crystallizes as ditrigonal prisms (up to several cm in length) on evaporation of viscous solutions (formation of aggregation polymers[5]) of aluminum in concentrated phosphoric acid (Al:P = 1:5) at 50°C. The crystals are strongly hygroscopic and melt at 243°C (DTA). They were sealed in glass capillaries for the X-ray investigation.

The structure[6] is made up of isolated AlO_6 octahedra stacked with corner sharing $O_2P(OH)_2$ tetrahedra to form "columns" $^1_\infty[Al(H_2PO_4)_3]_n$ parallel to the crystallographic *c* axis (Fig. 1a). These "columns" are linked together by hydrogen bonds (cf. also Fig. 1b); each OH group acts simultaeously as a proton donor and a proton acceptor.

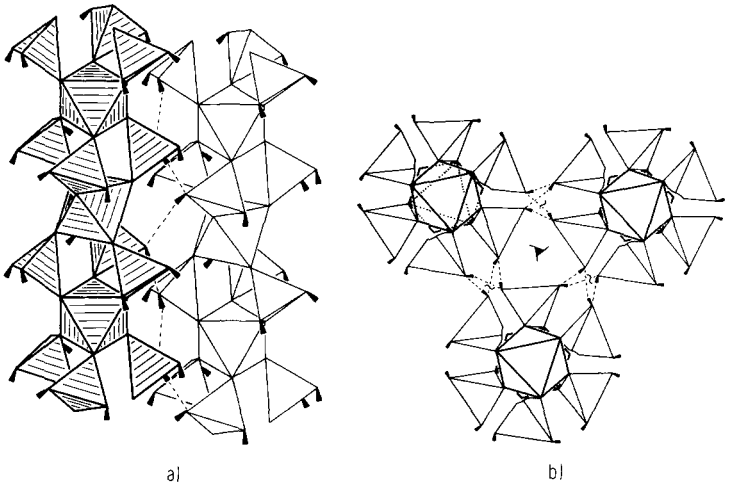

Fig. 1. a) Two structural units $[Al(H_2PO_4)_3]_n$ in a polyhedral representation with intermolecular hydrogen bonds (dashed lines); one such unit is emphasized by hatching. b) Section from the crystal structure of $Al(H_2PO_4)_3$ viewed along one of the threefold screw axes (hydrogen bonds shown as dashed lines).

Principal (averaged) distances [Å] and angles [°]:

Al—O	1.884(2)	O—Al—O	89.8(1)
P—O	1.535(2)	O—P—O	109.3(1)
P—OH	1.579(3)	HO—P—O	107.5(1)
O—H	0.83(5)	HO—P—OH	105.9(1)
H...OH	1.92(5)	O—H...OH	163(4)

Interestingly, the heavy atoms alone appear to form an almost centrosymmetric structure which is rendered significantly acentric only by the orientation of the protons (cf. Fig. 1a: all the protons are directed "downwards").

Institut für Anorganische Chemie und Strukturchemie der Universität
Universitätsstrasse 1, D-4000 Düsseldorf (Germany)

[**] This work was supported by the Government of North Rhine-Westphalia.

By use of the Guinier-Simon technique, a phase transition is shown to take place in $Al(H_2PO_4)_3$ at 60 °C; the very slight change of the powder diagram suggests that this change is due to proton reorientation. Since the structure is acentric and also contains a polar axis, ferroelectricity should be possible.

An Arsinidene as a Cubane-Type Structural Unit: Synthesis and Structure of $[(CO)_3Fe—AsCH_3]_4$[**]

By *Erika Röttinger* and *Heinrich Vahrenkamp*[*]

The phosphinidene and arsinidene groups RP and RAs are isoelectronic with the sulfur and selenium atoms, respectively, suggesting that there should be some structural relationship between the transition metal complexes having RP and RAs, on the one hand, and S and Se, on the other, as bridging ligands. This is the case for some complexes with metal-metal bonds[1], but not for others. Thus there are still no chalcogen analogs of the dinuclear μ_2-phosphinidene and μ_2-arsinidene complexes described by *Huttner et al.*[2], and the large number of complexes having a cubane skeleton of four metal and four sulfur atoms[3] have no RP or RAs counterparts. We are confident that expected analogies will be substantiated by directed syntheses and now report the Fe_4As_4-cubane *(1)* as a relevant example.

The thermolability of the As—H bond in complexes[4] was utilized in the production of complexed μ_3-methylarsinidene in *(1)*. The stoichiometric Fe:As ratio was already present in the starting complex $(CO)_4Fe \cdot CH_3AsH_2$, which decomposes slowly at room temperature, and rapidly on heating, to form *(1)*. The appearance of only two IR bands in the CO region (2025 (s) and 1985 (m) cm^{-1}) reveals the iron atoms of product *(1)* to have C_{3v} symmetry, and a singlet in the ^{1}H-NMR [$\delta = 1.32$ rel. TMS internal (in benzene)] shows the four arsenic atoms to be equivalent. The molecular ion appears at very low intensity in the FD mass spectrum, the principal fragment being $[(CO)_3Fe—AsCH_3]_2^+$. Compound *(1)* crystallizes from benzene/cyclohexane mixtures as $[(CO)_3Fe—AsCH_3]_4 \cdot 0.75\,C_6H_{12}$, which was used for a structural determination[5].

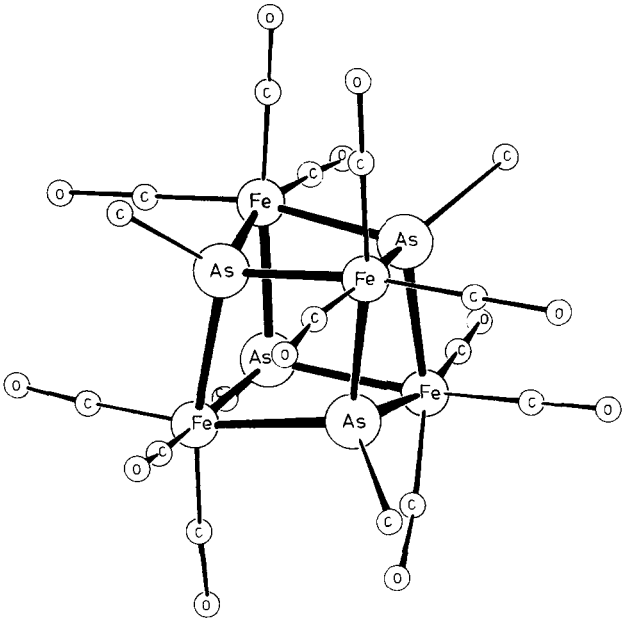

Fig. 1. Molecular structure of tetra-μ_3-methylarsanediyltetrakis(tricarbonyliron) *(1)*.

The molecules of *(1)* (cf. Fig. 1) are located on threefold axes in the crystal. In contrast to the comparable complexes $[(CO)_3Re—SCH_3]_4$[6], $[(CO)_3Os—O]_4$[7], and $[(CO)_3Co—Sb]_4$[8], they thus have the maximum possible symmetry. Like the other complexes, *(1)* also exhibits approximate non-crystallographic T_d-$\bar{4}3m$ symmetry and a distortion of the cubane skeleton arising from the tendency of the $M(CO)_3$ units to adopt octahedral geometry and the main group element units to assume tetrahedral geometry. The angles at iron and arsenic are accordingly $75.9 \pm 0.1°$ and $102.6 \pm 0.2°$, respectively. The Fe—As bond lengths of 241.1 ± 0.5 pm are normal, no metal-metal bonding occurring according to the 18-electron rule.

The Fe_4As_4-cubane *(1)* warrants particular attention on account of the analogy with Fe_4S_4 cubanes. It is our aim to reproduce their varied chemistry[3] by preparative and electrochemical reactions with *(1)*.

Procedure

A solution of CH_3AsH_2 in benzene (10 ml, 1.5 M) is added to a suspension of $Fe_2(CO)_9$ (1.82 g, 5.0 mmol) in benzene (70 ml) and the mixture stirred until all the $Fe_2(CO)_9$ has dissolved and the formation of $(CO)_4Fe \cdot CH_3AsH_2$ can be detected by NMR spectroscopy (1 d). Complete conversion into *(1)* is accomplished by refluxing for 4 h. Removal of solvent and recrystallization from *n*-hexane affords crude *(1)* (960 mg, 83 %) containing varying amounts of solvent. Crystals of homogeneous composition are obtained by column chromatography (4 × 50 cm) with cyclohexane on silica gel and subsequent recrystallization from cyclohexane/benzene.

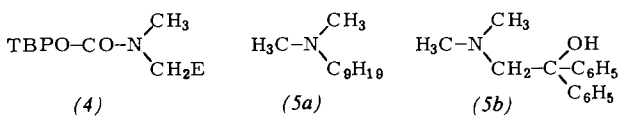
2,4,6-Tri-*tert*-butylphenoxyl (TBPO) as Sterically Active Carbonyl-Protecting Group—A New Nucleophilic Dimethylaminomethylating Reagent

By *Dieter Seebach* and *Tillmann Hassel*[*]

Given adequate steric protection[1] of the carbonyl group of amides such as *(1)*, it proves possible to accomplish their deprotonation at the α-*N*—CH_3 and —CH_2 groups with strong bases such as *sec*-butyllithium[1,2]. Organolithium derivatives accessible in this way can only be designated as nucleophilic aminoalkylating reagents if the products obtained with electrophiles can be cleaved to give amines. We have now found this condition to be fulfilled by the 2,4,6-tri-*tert*-butylphenoxyl group (TBPO) in the *N*,*N*-dimethylcarbamate *(2b)* in which the carbonyl C atom has been displaced from the two protecting *o*,*o'*-*tert*-butyl groups by an oxygen in comparison with *(1)*.



(1), R = C_2H_5, $CH(CH_3)_2$, $C(CH_3)_3$

TBPO–COX

(2a), X = Cl

(2b), X = $N(CH_3)_2$

(3)

(4)

(5a)

(5b)

Reaction of tri-*tert*-butylphenol and phosgene[3] gives the chlorocarbonate *(2a)* (*ca.* 50 %) which quantitatively affords *(2b)* (m.p. 121 °C) on treatment with two mol. equiv. of dimethylamine[3]. On stirring of a cooled (ice bath) solution of *(2b)* and tetramethylethylenediamine (TMEDA) (0.1 M in each reagent) in tetrahydrofuran for 90 min with *sec*-butyllithium (10 % excess) quantitative formation of a clear colorless solution of the lithium compound takes place, according to ^{1}H-NMR analysis of a deuterolyzed sample. Compound *(3)* reacts with alkyl halides and aldehydes or ketones to give the carbamates *(4)* of the higher amines *(4a—d)* and amino alcohols *(4e—h)* in the yields listed in Table 1 (recrystallized or chromatographed analytically pure products). The structures *(4)* are confirmed by IR and ^{1}H- and ^{13}C-NMR spectra. Cleavage of the carbamates *(4)* to tertiary amines *(5)* can be accomplished with lithium tetrahydridoaluminate in boiling dioxane; the reaction can be carried out with the crude products *(4)* [*(4b)* pure, gives *(5a)*[4], 51 % after 24 h, 75 % conversion; *(4h)* crude, gives *(5b)*[5], 68 % based on *(2b)* after 6 h].

Table 1. Carbamates *(4)* prepared by reaction of the lithium compound *(3)* with electrophiles.

Electrophile	E in product	*(4)*	Yield [%]	M.p. [°C]
Iodomethane	CH_3	*(4a)*	71	78—79
1-Iodooctane	n-C_8H_{17}	*(4b)*	87 [a]	Oil [a]
Benzyl bromide	$CH_2C_6H_5$	*(4c)*	35 [b]	132
2-Iodopropane	$CH(CH_3)_2$	*(4d)*	32	61—63
Hexanal	CH(OH)-n-C_5H_{11}	*(4e)*	80	111—112
Cyclohexanone	$C(OH)(CH_2)_5$	*(4f)*	63	150
Benzaldehyde	$CH(OH)C_6H_5$	*(4g)*	50 [b]	128
Benzophenone	$C(OH)(C_6H_5)_2$	*(4h)*	61 [c]	122

[a] See the conversion into the known CH_3I adduct of *(5a)*. [b] Not optimized. [c] Cf. higher yield of *(5b)* obtained without purification of *(4h)*.

The TBPO carbonyl group is a regenerable[6] group for acidification of amines[1], and is readily accessible from commercially available materials. The lithium compound *(3)* acts as a $(CH_3)_2NCH_2^{\ominus}$ synthon on cleavage to tertiary amines such as *(5)*[7]. Other cleavage reactions are possible, and other amines can be used.

Reactivity of a Sulfonium Ion in Layer Silicates of Montmorillonite Type

By *Jürgen Gosselck* and *Ingfried Stahl*[*]

The intercalation of organic compounds in layer silicates has been known for a long time. Both neutral molecules and organic cations—including sulfonium ions[1]—can be intercalated[2]. We have now examined the reactivity of a

[*] Prof. Dr. J. Gosselck, Dr. I. Stahl
Bereich Organische Chemie (ONM) der Gesamthochschule
Heinrich-Plett-Strasse 40, D-3500 Kassel (Germany)

R_3S^+ ion incorporated into Na-bentonite—a layer silicate of montmorillonite type[3]—and compared it with that of the free salt.

In order to ensure that the reactions do indeed take place *within* the layers we incorporated the *S*-benzyltetrahydrothiophenium ion as a fixed reactant and allowed it to act upon uncharged organic molecules of known intercalating ability. This cation was selected because a sample of bentonite charged therewith was found to give tetrahydrothiophene almost quantitatively by thermal fragmentation on heating to 220 °C. With ethanol as trapping reagent for the benzyl cation suspected as intermediate, we obtained the corresponding benzyl ether. On reaction with arenes in excess (glass autoclave, 220 °C, 12 h) benzyl derivatives were formed in good yields in all cases (Table 1). Under similar conditions but in the absence of Na-bentonite, *S*-benzyltetrahydrothiophenium bromide does *not* react with arenes.

Table 1. Reactions of *S*-benzyltetrahydrothiophenium-bentonite with benzene and benzene derivatives.

Reactant	Products	Overall yield [%]	T [°C]	t [h]
Benzene	Diphenylmethane	60	220	12
		72	220	24
Toluene	*o*- and *p*-Tolyl-phenylmethane [a]	35	220	4
Anisole	*o*- and *p*-Methoxyphenylphenylmethane [b]	85	220	12
		73	220	12
Chlorobenzene	*o*- and *p*-Chlorophenylphenylmethane [c]	37	220	12
Bromobenzene	*o*- and *p*-Bromophenylphenylmethane [d]	40	220	12
p-Xylene	Xylylphenylmethane	77	220	12

[a] Ratio of *ortho* to *para* compound as determined by gas chromatography and ^{1}H-NMR spectroscopy—40:60; [b] 38:62; [c] 32:68; [d] 33:67.

Incorporation of the *S*-benzyltetrahydrothiophenium ion into Na-bentonite from aqueous solutions of the bromide can be accomplished at pH 6.5—7. The basal spacing of the treated bentonite after drying to constant weight at 130 °C/0.05 torr is 14.25 Å as against the original value of 10.1 Å[4].

The exchange capacity of bentonite was determined by stirring defined amounts of dissolved sulfonium salt and bentonite together for 45 min; after filtration and washing, the unconsumed sulfonium salt was determined as the sulfonium reineckate. The yields listed in Table 1 are based on an exchange capacity of 66.5 mmol of $[(CH_2)_4SCH_2C_6H_5]^+$/100 g of Na-bentonite.

Since the presence of bromide ions was ruled out by analytical studies on the bentonite charged with sulfonium ion (Na_2CO_3 extraction)—*e. g.* on the basis of adsorption effects—the reactions must be cationoid and proceed within the layers. The 001 interferences of the reacted bentonites show that the layer structures are largely preserved. After reacting once, the bentonite still exhibited *ca.* 50 % of its original exchange capacity (31.3 mmol/100 g). After recharging, it reacted once again with arenes to give equally high yields.

Hexafluorophosphate of the Bis(naphthalene) Radical Cation

By *Heinz P. Fritz, Helmut Gebauer, Peter Friedrich*, and *Ulrich Schubert*[*]

In conjunction with studies on the radical intermediates of anodic substitution reactions we have now obtained red-violet needles of approximate composition $(C_{10}H_8)_2PF_6$ in current yields up to 60 % at platinum electrodes in the electrolyte system CH_2Cl_2/0.02 M Bu_4NPF_6, containing naphthalene in 0.01 M concentration, at −45 °C in an undivided cell at voltages of 10−8 V and current densities of 0.5—2 mA cm^{-2} within 16 h. The chisel-tip shaped crystals can be washed with cold dichloromethane and dried in a high vacuum, but persistently give C values that are too low. They decompose at 65 °C in a sealed tube and on exposure to air smell strongly of naphthalene, which is liberated (visible under a microscope). The mass spectrum exhibits signals for naphthalene, PF_4^+, and binaphthyl, suggesting a possible reaction path of this radical cation salt.

The X-ray structure analysis[1] of the salt $(C_{10}H_8)_2PF_6$ commands particular interest. Apart from confirming the composition, it should reveal what interactions are responsible for the stabilization of the radical cations in the crystal. We found that the naphthalene units are stacked parallel to the *c* axis of the tetragonal unit cell (cf. Fig. 1). Successive $C_{10}H_8$ units are mutually twisted by 90°; the axis of rotation passes through the center of the molecule. The distance between the naphthalene planes of 320 pm is the smallest yet found between arene rings (van der Waals distance of aromatic compounds 340 pm[2], graphite 335 pm, ferrocene 325 pm) and indicates pronounced interaction between the π-electron systems. The interstices between four stacks of naphthalene units are occupied by PF_6^- ions in such a manner that they are surrounded by four $C_{10}H_8$ molecules as nearest neighbors, the naphthalene planes and one octahedral plane being parallel

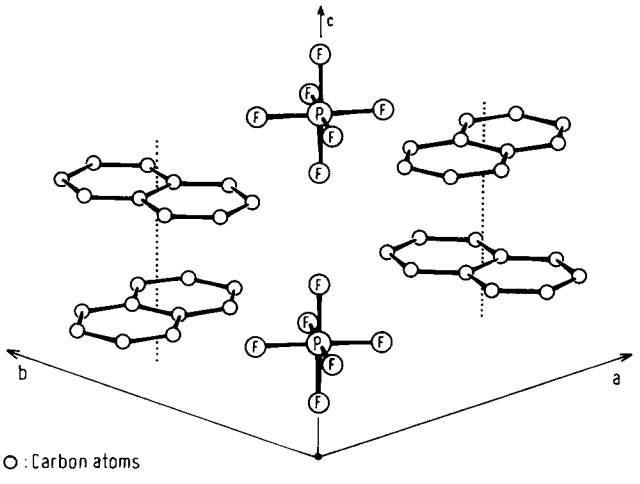

Fig. 1. Contents of a unit cell of $(C_{10}H_8)_2PF_6$. The P atoms are sited on the diagonals of the unit cell, and the centroids of the naphthalene systems on straight lines parallel to the *c* axis.

to one another. The shortest distances between anions and cations are F···H distances of 251 pm (sum of the van der Waals radii 255 pm[2]).

$(C_{10}H_8)_2PF_6$ has the first proven columnar structure of hydrocarbon units with precise stacking.

Tris[(*N,N,N',N'*-tetramethylethylenediamine)-lithium]hexamethylerbate(III) and -lutetate(III)[1]

By *Herbert Schumann* and *Jochen Müller*[*]

Alkyl-transition metal compounds can be stabilized by the presence of complexing bases and by formation of peralkylated "ate" complexes. Thus *Wilkinson et al.* recently showed that alkyl compounds of uranium are accessible by the latter approach[2], and *Lappert et al.* succeeded in preparing lanthanoid complexes of the type $[LiL_4][M(CH_2SiMe_3)_4]$[3]. While aryl compounds such as $Li[LaPh_4]$[4] or $[Li(thf)_4][Lu(C_6H_3Me_2)_4]$[5] have also been known for some time, the synthesis of peralkyl derivatives has so far been beset with insurmountable difficulties.

Using *N,N,N',N'*-tetramethylethylenediamine (tmen) as a stabilizing base, it has now proved possible to synthesize the first peralkylated complexes of the lanthanoid series containing only methyl ligands. Dropwise addition of an ethereal solution of methyllithium to a suspension of erbium trichloride or lutetium trichloride in diethyl ether and a stoichiometric amount of the diamine affords good yields of the reaction products $[Li(tmen)]_3[ErMe_6]$ and $[Li(tmen)]_3[LuMe_6]$, as analytically pure, pink or white crystals which can be freed from excess methyllithium by recrystallization:

$$MCl_3 + 6\ LiCH_3 + 3\ tmen \xrightarrow[-3\ LiCl]{} [Li(tmen)]_3[M(CH_3)_6]$$

M = Er, Lu; tmen = $(CH_3)_2NCH_2CH_2N(CH_3)_2$

The new compounds are extremely sensitive to air and moisture; however, they exhibit surprising thermal stability and decompose only slowly at their melting point of 138 to 139 °C (M = Er) and 141 to 142 °C (M = Lu). Hydrolysis and alcoholysis expectedly liberate 6 mol of methane (CH_3D on reaction with D_2O) per mol of lanthanoid (detected by gas analysis). The IR spectra show mainly the bands of the coordinated diamine; Raman spectra could not be recorded, even at −100 °C, owing to decomposition of the complexes in the laser beam; no structural information could be obtained for the paramagnetic erbium compound by NMR spectroscopy. However, the ^{1}H-NMR spectrum of the diamagnetic lutetium compound (complete 4f shell) shows a singlet for the methyl groups bound to lutetium at $\delta = -1.18$ rel. TMS in addition to the peaks of tetramethylethylenediamine ($\delta CH_2 = 2.30$, $\delta CH_3 = 2.23$).

Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

Experimental

A suspension of methyllithium (75.1 mmol) in diethyl ether (60 ml) is added dropwise over 1 h to a suspension of $ErCl_3$ or $LuCl_3$ (11.5 mmol) in ether (60 ml) and *N,N,N',N'*-tetramethylethylenediamine (34.5 mmol) at room temperature. After 2 hours' stirring, LiCl is filtered off and most of the compound, which is only moderately soluble in ether, is washed out of the residue (3 × 50 ml Et_2O). The combined ethereal solutions are concentrated to $^1/_3$ of their volume, whereupon part of the product precipitates. Precipitation is completed at −30 °C and the precipitate filtered off at that temperature. Recrystallization (Et_2O/−30 °C) affords $[Li(tmen)]_3[ErMe_6]$ or $[Li(tmen)]_3[LuMe_6]$ in 30 to 40 % yield.

C_4Li_4, Tetralithiotetrahedrane?

By *Gerhard Rauscher, Timothy Clark, Dieter Poppinger*, and *Paul von Ragué Schleyer*[*]

Dill pointed out that the strain in small-ring cycloalkanes should be relieved by σ-donating, π-accepting substituents, and hence suggested that tetralithiotetrahedrane *(1)* should be a relatively stable species[1]. We now present a report summarizing our progress towards the realization of this suggestion. In view of the interest in the tetrahedrane problem and numerous synthetic failures[2], our results, although not definitive, are encouraging.

(1) *(2)* *(3)*[4]

C–C 1.538 Å, C–Li 1.829 Å calc.

C–C 1.473 Å, C–H 1.069 Å calc.[3]

Both theoretical and experimental approaches have been employed. When a 0.01 M solution of dilithioacetylene *(3)*[4, 5] in liquid ammonia is irradiated at −45 °C for 6 h with a high pressure mercury lamp, the original C_2Li_2 ^{13}C-NMR peak at $\delta = 75.0$ disappears and is replaced by a singlet at $\delta = 57.2$. This position, which is consistent with the expected sp hybridization of a tetrahedrane carbon[2], does not shift in dimethylformamide solution. Evaporation of the ammonia yields a solvent-free microcrystalline powder[6] which is stable

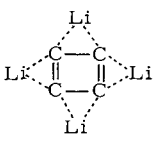
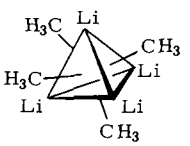
under argon at −20°C, but decomposes slowly at room temperature. In a mull or in solution in ammonia or dimethylformamide, the product gives IR and Raman spectra quite different from those of C_2Li_2. A chemical reaction definitely has taken place, but hydrolysis of the product gives acetylene in quantitative yield. Although trimers like hexalithiobenzene or hexalithioprismane would give but a single ^{13}C-NMR resonance, the following evidence favors dimers based on tetralithiotetrahedrane or tetralithiocyclobutadiene instead: In field desorption mass spectra[7] only peaks at $m/e=76$ ($C_4{}^7Li_4$) and 75 ($C_4{}^6Li^7Li_3$) were found. Within the inherent limitations of the method, the isotopic ratio agreed with theory. No peaks corresponding to $[C_2Li_2]_n^+$, $n=1$, $n\geq 3$, were observed. Dilithioacetylene did not give the $m/e=76$ and 75 peaks, but ions of $m/e=38$ and 37 were observed instead. We conclude that irradiation of *(3)* gives the dimer C_4Li_4.



$$2C_2Li_2 \xrightarrow[NH_3]{h\nu} C_4Li_4 \xrightarrow[(\approx 100\,\%)]{H_2O} 2C_2H_2$$

$\delta(^{13}C)=75.0$ $\qquad$ $\delta(^{13}C)=57.2$



What is the structure of C_4Li_4? Although we hope to solve this question experimentally, *ab initio* molecular orbital calculations on isolated C_4Li_4 isomers are revealing. Besides *(1)*, we surveyed seven other possibilities with high symmetry at the minimal basis set level (RHF/STO-3G) employing the Gaussian 70 series of programs[8]. The structures were based on those of corresponding C_4H_4 isomers investigated previously[3b]. *(1)*, and the two most stable singlets found, *(4)* and *(5)*, were then fully optimized. The calculated geometries are shown in *(1)*, *(4)*, and *(5)*. The absolute energies are −178.63982, −178.74371, and −178.76442 Hartree (a. u.), respectively. Calculations with the split valence 4-31G basis set[8] on the STO-3G optimized structures gave absolute energies of −180.66590, −180.74831, and −180.79084 Hartree. Although *(5)* is indicated to be 26.7 kcal/mol more stable than *(4)*, the observed ^{13}C chemical shift would seem to rule out such olefinic structures[9]. Furthermore, hydrolysis of *(5)* would be expected to give cyclobutadiene which is known to dimerize rather than to dissociate[2e]. The available evidence indicates, on the other hand, that tetrahedrane should decompose to acetylene[2f].

(4), T_d

(5), D_{2h}

(6), T_d

C–C 1.592 Å		C–C 1.619, 1.376 Å	C–C 3.68 Å
C–Li 1.937 Å	calc.	C–Li 1.903, 1.792 Å	C–Li 2.31 Å

The hypothetical reactions below provide a means of evaluating the effect of Li substitution[1]. On this basis relative instability of *(2)* (195.5 kcal/mol; RHF/STO-3G)[3b] is reduced sharply by lithium substitution to 67.1 kcal/mol in *(1)*[11]. However, our calculations indicate that face-centered tetralithiotetrahedrane *(4)* is 65.2 kcal/mol *more stable* than *(1)*. The remarkably low relative instability of *(4)*, 1.9 kcal/mol, is a consequence of the stabilization of the tetrahedrane "bent bond" orbitals by lithium.

$4(CH_3)_3CX \rightarrow C_4X_4 + 6C_2H_6$

(2) X=H	+195.5 kcal/mol
(1) X=Li	+ 67.1 kcal/mol
(4) X=Li	+ 1.9 kcal/mol

Calculations at the minimal basis STO-3G level are not definitive; they tend to exaggerate the involvement of p-orbitals on lithium and to give C—Li distances which are somewhat short[12]. Nevertheless, lithium shows a general preference for bridging positions, as is shown by available X-ray[13] and calculations[4, 14], *e.g.* that for C_2Li_2 *(3)*[4].

The tetralithiotetrahedrane structure *(4)*, with lithium on the faces of a tetrahedron of carbon atoms, is reminiscent of the X-ray structure of $(CH_3Li)_4$ *(6)*[10], where methyl groups bridge the faces of a tetrahedron of lithium atoms.

The dimerization of acetylene to tetrahedrane is a photochemically allowed reaction[2c]; the nature of the photochemical process involving C_2Li_2 has yet to be delineared in detail. It is easy to visualize how the perpendicular approach of two bridged C_2Li_2 units *(3)* might yield *(4)*. Attempts to synthesize tetrahedrane derivatives by such perpendicular acetylene photodimerizations have not succeeded in the past[15], but it should be much easier to produce a strain-free product than a highly strained one. Our present evidence seems most closely in accord with a tetrahedrane structure *(4)* for C_4Li_4; we are gathering more definite information.

Experimental

Carefully cleaned Li metal (0.7 g) was dissolved in 100 ml of purified anhydrous ammonia at −50°C. Acetylene, also carefully purified, was slowly introduced just until the blue color of the solution disappeared (*ca.* 20—30 min). An argon flush eliminated any excess acetylene. The resulting 0.01 M Li_2C_2 solution in a quartz vessel was irradiated for 6 h at −45°C with a TQ150 Hanovia Hg-high pressure lamp.

The reaction course could be followed by ^{13}C-NMR spectroscopy: the C_2Li_2 singlet at $\delta=75.0$ was replaced by the C_4Li_4 singlet at $\delta=58.2$. The Raman-active C≡C vibration at 1885 cm^{-1} also disappears. The white ammonia-free powder, which can be obtained by evaporation of the solvent, is sensitive to air and moisture, decomposes slowly at room temperature, but is stable under argon at −20°C. In the solid or in solution in NH_3 or DMF, the product absorbs in the IR at 688, 612, and 448 cm^{-1}. Hydrolysis gives C_2H_2 in 98.4 % yield (gasiometrically) based on the amount of lithium used initially.

The field desorption measurements were made on a Varian MAT 311A mass spectrometer by using a combined EI/FI-ion source. The optimization of the conditions of measurement (in particular the anode current and the source potential) was achieved through visual control as well as by measurement of the total ion current in the relevant m/e region. In spite of strong fluctuations of the short-lived ion current (due to the microscopic fine structure of the emitter, the distribution of the sample on the emitter surface, and the physical properties of the sample), cyclic scanning of the $m/e=75$ and 76 peaks showed conclusively by means of the $^6Li/^7Li$ isotopic ratio that $[Li_4C_4]^+$ was present. The observed relative intensities of the $m/e=75/76$ peaks were between 0.2 and 0.4; the calculated $C_4{}^6Li^7Li_3/C_4{}^7Li_4$ ratio is 0.29. Species corresponding to $[(C_2Li_2)_n]^+$ with $n=1$ or $n\geq 3$ were never observed under any conditions[7].

Deprotonation-Hydride Elimination as a Method of Dehydrogenation[1]

By *Manfred T. Reetz* and *Franz Eibach*[*]

In spite of the many dehydrogenation and aromatization agents available, conventional methods fail in some cases. If reactive arenes are formed, they undergo Diels-Alder reactions with dehydrogenation agents such as chloranil or dichlorodicyano-*p*-quinone[2, 3]. Dehydrogenations with sulfur, trityl perchlorate, iodine, or palladium are sometimes also of no preparative utility, *e.g.* in the synthesis of 9,10-dialkylanthracenes[4].

We have developed a new dehydrogenation procedure, based on deprotonation-hydride elimination. Potassium fencholate *(1)* serves as base and fenchone *(2)* as hydride acceptor[5]. Since fencholate is regenerated in the aromatization

[*] Doz. Dr. M. T. Reetz, Dipl.-Chem. F. Eibach
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg (Germany)

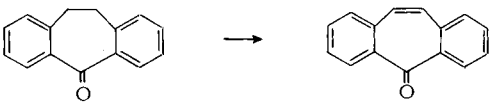

Table 1. Aromatization by fencholate-fenchone. The reaction is performed with 15—20 mol % of potassium fencholate *(1)* and an amount of fenchone equivalent to the quantity of dihydroarene in DMSO at 90°C; at 70°C in the case of benzene.

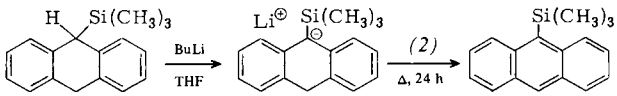
Dihydroarene	Reaction time [h]	Arene	Yield [%] [a]
1,2-Dihydronaphthalene	22	Naphthalene	95 (77)
3,4-Dihydronaphthalene	22	Naphthalene	90 (70)
9,10-Dihydroanthracene	25	Anthracene	98 (80)
9,10-Dimethyl-9,10-dihydroanthracene	30	9,10-Dimethyl-anthracene	96 (78)
9-Ethyl-10-methyl-9,10-dihydroanthracene	30	9-Ethyl-10-methylanthracene	92 (75)
5,12-Dihydrotetracene	40	Tetracene	— (85)
1,3-Cyclohexadiene	120	Benzene	68 (—)
1,4-Cyclohexadiene	120	Benzene	68 (—)
5,6-Diphenyl-2,3-dihydropyrazine	40	2,3-Diphenylpyrazine	75 (52)

[a] Yields in parentheses refer to isolated compounds; other values determined by ^1H-NMR or GC.



step, only catalytic quantities are required. Some smooth dehydrogenations are listed in Table 1. Remarkably good yields are obtained, even in critical cases such as 9,10-dimethyl- and 9-ethyl-10-methylanthracene[6] and tetracene[2].

In contrast to aromatization, dehydrogenation to form olefins is usually *unsuccessful* because potassium fencholate is too weak a base[7]. Certain C—H acidic compounds are exceptions; for example, the ready conversion of *(3)* into *(4)* (90 % yield).

(3) *(4)*

Although our method fails with the trimethylsilyl derivative *(5)*[7], transformation into *(6)*[8], which defies conventional methods, could nevertheless be accomplished by the deprotonation-hydride elimination technique: reaction with *n*-butyllithium followed by fenchone *(2)*[5] gives *(6)* in 80 % yield.

(5) *(6)*

Procedure

Fenchone *(2)* (0.91 g, 6 mmol) is dissolved in anhydrous DMSO (30 ml), treated with potassium hydride (*ca.* 0.04 g, 1 mmol) at room temperature, and stirred vigorously for 30 min. After addition of 9-ethyl-10-methyl-9,10-dihydroanthracene (1.11 g, 5 mmol), a clear dark red solution is obtained which is heated to 90 °C until reaction is quantitative (30 h). The reaction solution is hydrolyzed with water and extracted twice with ether (with benzene in the case of ether-insoluble arenes). The organic phase is subsequently shaken several times with water to remove residual DMSO. After drying with $MgSO_4$ the ether is removed and the residue recrystallized from ethanol.

$[(S_2)_2Mo(S_2)_2Mo(S_2)_2]^{2-}$, a Novel Complex Containing only S_2^{2-} Ligands and a Mo—Mo Bond

By *Achim Müller, Wulf-Otto Nolte*, and *Bernt Krebs*[*]

Molybdenum-sulfur compounds occur in redox-enzymes whose action involves electron transitions $Mo^{VI} \rightleftharpoons Mo^{V}$[1]; only under special conditions are lower oxidation states of molybdenum obtained in biological systems. In this connection, reactions are of interest in which Mo^{VI} is reduced to Mo^{V} only by S^{2-} or (S_n^{2-})[2] (further reduction is also not expected here).

Red-black $(NH_4)_2[(S_2)_2Mo(S_2)_2Mo(S_2)_2]\cdot 2H_2O$ *(1)* can be prepared by reduction of molybdate(VI) (or thiomolybdates) with polysulfide ions in aqueous solution and could be characterized by elemental analysis, DTA, TG, and magnetic measurements, its ESCA and IR spectrum along with a single crystal structure analysis. *(1)* is diamagnetic and exhibits absorption bands due to the anion at 530 [m; ν(S—S)], 340 and 360 cm^{-1} [w; ν(MoS)]. The positions of the ν(MoS) bands show the absence of the terminal Mo—S bonds with π-bonding contributions[3a] which have so far only been found in the case of Mo^{VI}[3b]. The compound is stable and is moderately soluble in water (decomposing after a short time[4]).

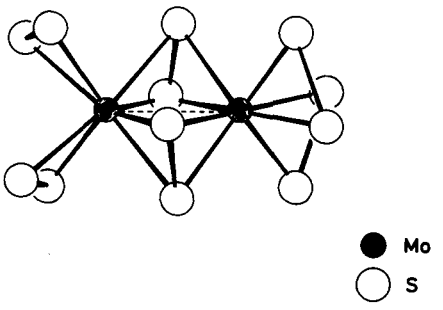

Fig. 1. Structure of the complex anion $[(S_2)_2Mo(S_2)_2Mo(S_2)_2]^{2-}$ in crystals of *(1)*.

(1) crystallizes in the rhombic space group Pnna-D_{2h}^6 with $a=21.613$, $b=13.127$, $c=12.576$ Å and $Z=12$. According to the X-ray structure analysis the asymmetric unit of the unit cell contains two crystallographically independent dimeric anions $[(S_2)_2Mo(S_2)_2Mo(S_2)_2]^{2-}$ (cf. Fig. 1). Both the Mo^{V} centers are dodecahedrally (distorted) surrounded by eight sulfur atoms (four disulfide groups). The "side-on" bonding of all the S_2^{2-} ligands to the central atom is slightly asymmetric with two slightly different Mo—S distances [2.382(4)...2.454(4) and 2.463(4)...2.507(4) Å]. The S—S bond lengths of 2.035(6)...2.063(6) Å correspond to a normal single bond. The Mo—Mo distances in the ions amount to 2.826(2) and 2.828(2) Å, which together with the magnetic properties suggest a central Mo—Mo bond[5]. Thus, molybdenum has the unusual coordination number 9. A similar kind of bonding of disulfide groups to a Mo^{VI} center (with a coordination number of 7) was observed in $[MoO(S_2)_2(COS—COO)]^{2-}$[6].

Experimental

Into an aqueous ammonia solution (dilute, 30 ml) of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (2 g) is passed H_2S until saturation (any precipitated $(NH_4)_2MoS_4$ can be redissolved by heating). This red solution is added to a saturated ammonium polysulfide solution. A precipitate slowly separates from this reaction mixture kept in a closed container (long needles growing out of the crystal mass)[7]. The substance is washed several times with ethanol, with ether, and with carbon disulfide, and dried over P_4O_{10} at normal pressure (yield *ca.* 80%; needles 5–10%)[8].

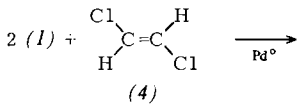
lylation of alkynes is one of the most straightforward routes to these compounds, but the product is often accompanied by 1,2-disilylethanes[1]. Condensation between a hydrosilane and a haloethene requires drastic conditions[2], while treatment of vinylic Grignard reagents with chlorosilanes requires solvents such as ether, THF, or HMPA to promote the reaction[3].



We have found that vinylsilanes and vinylenebissilanes can be conveniently prepared by the reaction between a disilane and a haloethene in the presence of a homogeneous palladium(0) catalyst. Vinylsilanes *(3)* (Table 1) were prepared by heating a mixture of a chloro(methyl)disilane *(1)*[4], a haloethene *(2)*, and tetrakis(triphenylphosphane)palladium(0)[5] as catalyst in a sealed reaction vessel or an open apparatus. Thus Pd^0-catalyzed reaction of (*E*)-1,2-dichloroethene *(4)* with two equivalents of *(1)* gives vinylenebissilane *(5)* (Table 1).

(3a) - (3d)

(4)

(5a), *(5b)*

Table 1. Vinylsilanes *(3)* and vinylenebissilanes *(5)* prepared.

Cpd.	R	*n*	X	Yield [%] [a]	*E*:*Z*
(3a)	H	1	Cl	45	
(3b)	H	2	Cl	56	
(3c)	Ph	1	Br	85 (76)	
(3d)	Ph	2	Br	83 (72)	
(5a)		1		86	9:1
(5b)		2		80 (50)	9:1

[a] Yields determined by GLC; isolated yields given in parentheses.

The hitherto unknown vinylenebissilane *(5b)* is expected to be a precursor of novel siloxane polymers.

Experimental

Synthesis of *(3c)*: A mixture of *(1a)* (8.39 g, 42 mmol), (*E*)-*(2b)* (7.35 g, 40 mmol), and Pd^0 catalyst (0.24 g, 0.2 mmol) is refluxed under nitrogen for 1 h with stirring. The mixture is diluted with *n*-pentane (40 ml) and the precipitated catalyst filtered off. Evaporation of low boiling materials and subsequent distillation gives (*E*)-*(3c)* (6 g) in 99 % purity. The product was identified by its ^{1}H-NMR, IR, and mass spectrum.

Synthesis of *(5b)*:*(4)* (32 g, 340 mmol), *(1b)* (131 g, 700 mmol), and the palladium(0) catalyst (1.16 g, 1.0 mmol) were introduced into a stainless steel vessel. The vessel was flushed with nitrogen, sealed and heated at 180 °C for 15 h. Work-up gave 36 g of (*E*)- and (*Z*)-*(5b)* (9:1) in 98 % purity as a colorless liquid. (*E*)-*(5b)*: ^{1}H-NMR (CCl_4) $\delta = 0.56$ (s, 12H), 6.77 (s, 2H); IR (neat) 2950, 1405, 1255, 1000, 840, 815, 790, 650 cm^{-1}; mass spectrum (70 eV): $m/e = 212$ (M^+).

(*Z*)-*(5b)*: ^{1}H-NMR (CCl_4) $\delta = 0.56$ (s, 12H), 6.82 (s, 2H); IR (neat) 2950, 1405, 1255, 925, 840, 810, 800, 695, 650 cm^{-1}; mass spectrum (70 eV): $m/e = 212$ (M^+).

Molecular Structure of $[Mn(CO)_4NSOF_2]_2$— A Dinuclear Transition Metal Complex Containing Difluorooxosulfimidato Bridges[**]

By *Bruno Buss, Dieter Altena, Rüdiger Mews*, and *Oskar Glemser*[*]

Preliminary studies on the dimeric species $[M(CO)_4NSOF_2]_2$ with M = Mn, Re ans $NSOF_2$ groups as bridging ligands failed to establish whether the metal atoms are linked *via* nitrogen-sulfur-oxygen bridges or only by the nitrogen atoms of the $F_2S(O)$=N ligands[1]. In the last-mentioned case, these complexes should possess a structure analogous to $[Mn(CO)_4Br]_2$[2]. The donor strength of the ligand and the effect of coordination on the NS bond also remain to be established.

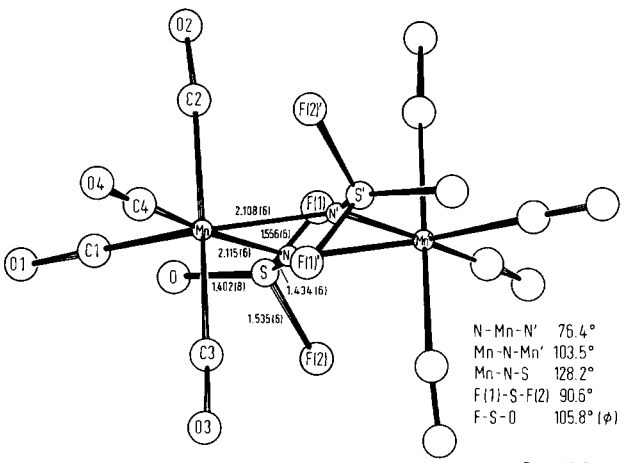

Fig. 1. Molecular structure of the dinuclear manganese complex $[Mn(CO)_4NSOF_2]_2$ with principal bond lengths [Å] and angles [°].

[*] Prof. Dr. O. Glemser, Dr. B. Buss, Dr. D. Altena, Priv.-Doz. Dr. R. Mews

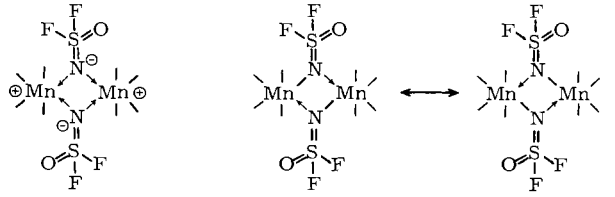
Tammannstrasse 4, D-3400 Göttingen (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft.

An X-ray structure analysis[3] of the manganese complex has now shown the isolated molecule to contain two octahedral units joined by a shared edge (cf. Fig. 1).

The central moiety containing the Mn, N, and S atoms is almost planar, while the Mn_2N_2 four-membered ring is exactly planar, showing that the nitrogen atoms no longer possess a stereochemically effective lone pair. All the Mn—N distances are equal within the limits of error and somewhat longer than would correspond to a single bond (based on the covalent radius of 1.39 Å for Mn^0[4]). Both the Mn···Mn' distance of 3.318(2) Å and the angle in the central portion of the molecule show that no direct metal-metal bond is present; the small N—Mn—N' angle (76°) even suggests a repulsive interaction between the two Mn atoms.

The $NSOF_2$ group serving as bridge has a strongly distorted tetrahedral symmetry. The S—O and S—F bond lengths closely resemble those in other compounds R—$NSOF_2$[5]. The very short N—S bond of 1.434(6) Å corresponds to a bond order of *ca.* 2.5[6] and indicates strong d_π-p_π bonds between sulfur and nitrogen; it is *ca.* 0.05 Å shorter than in $ClNSOF_2$[5a] and—within the limits of error—of the same length as in $(CO)_5ReNSOF_2$[5b]. The $NSOF_2$ groups of $[Mn(CO)_4NSOF_2]_2$ can be formally regarded as four-electron donors [cf. *(1a)*], and in the compounds R—$NSOF_2$ with R = Cl and $Re(CO)_5$ as two-electron donors. However, the surprisingly large Re—N—S angle of 140° in $(CO)_5ReNSOF_2$ suggests a bonding contribution from the nitrogen lone pair; in $ClNSOF_2$, on the other hand, the lone pair is fully effective (Cl—N—S: 114°)[5a].

There are two possible ways of describing the bonding: the manganese atoms have the oxidation number +1 in *(1a)* and 0 in *(1b)*, the $NSOF_2$ group being considered as a four- or three-electron donor. No decision in favor of either of these two alternatives is possible on the basis of available experimental evidence.

(1a) *(1b)*

The bonds of the CO ligands correspond to those in other carbonyl complexes[7]; nevertheless, the *trans* effect (Mn—C_{eq} = 1.807 Å, Mn—C_{ax} = 1.899 Å) is relatively pronounced.

N,N-Dichlorourethane—A Selective Chlorination Reagent; Synthesis of Corticoids

By *Yehuda Mazur* and *Zvi Cohen*[*]

Continuing our studies on the selective functionalization of steroid molecules[1], we searched for a simple method to introduce a functional group at C_{11} in deoxycorticoids, to replace the microbiological method commonly used for this purpose.

We have now found that saturated steroids can be selectively chlorinated with *N,N*-dichlorourethane (DCU).

DCU is a stable, distillable, but highly reactive pseudohalogen which is easily prepared by reacting urethane with chlorine[2]. This compound was found by *Chabrier*[3] to add to olefins, giving the unstable *N*-chloro-*N*-(β-chloroalkyl)carbamates, which can be readily reduced to the *N*-(β-chloroalkyl)-carbamates. We observed that cyclohexane on exposure to light in the presence of DCU is converted into chlorocyclohexane and urethane and that benzene solutions of adamantane and DCU on irradiation with a sunlamp gave 1-chloroadamantane in high yields. Reaction of DCU with steroids resulted mainly in chlorination at C-9:androstane-3β,17β-diyl diacetate was converted into a mixture of tertiary chlorides, which after dehydrochlorination with $AgClO_4$ gave the corresponding 9(11)- and 14-androstene derivatives in 40 and 9 % yield, respectively[4]. In the case of steroids with dihydroxyacetone side chains, DCU proved to be even more selective. We have chosen *(1a)* and *(2a)* as starting compounds; these compounds are intermediates in the preparation of the medically useful 16α- and 16β-methylcorticoids[5].

(1a) *(1b)*

(2a), R = H
(2b), R = CF_3CO

(2c) *(2d)*

[*] Prof. Dr. Yehuda Mazur, Zvi Cohen
Department of Organic Chemistry, The Weizmann Institute of Science
Rehovot (Israel)

The diacetate *(1a)*[5] was irradiated in the presence of DCU in benzene and then dehydrochlorinated with $AgClO_4$; the only product was the corresponding 9(11)-pregnene derivative *(1b)* (yield 41 %). For the synthesis of the 9α-fluoro-16β-methylcorticoid *(2d)*, the acetate *(2a)*[5] was converted into the bis(trifluoroacetate) *(2b)*[4], which was then treated with DCU, and finally with $AgClO_4$. Subsequent hydrolysis of the trifluoroacetyl groups with NaN_3 in methanol[6] and oxidation with pyridinium chlorochromate afforded the known ketone *(2c)*[7a] [55 % yield based on *(2b)*], which is easily converted into the glucocorticoid *(2d)*[7b].

There is a close analogy between the halogenation reactions with DCU and those with iodobenzenedichloride[8]: both reactions proceed by a free radical chain mechanism involving photochemically generated chlorine atoms. These chlorine atoms serve as hydrogen abstracting radicals, as seen by comparing the reactivity of the tertiary and the primary hydrogens in 2,3-dimethylbutane. In chlorinations with DCU this ratio was found to be 89:1 in CS_2, 50:1 in benzene and 9:1 in the absence of a solvent while the respective ratios for reactions with chlorine at comparable temperatures and concentrations as found by *Russell*[9] were 109:1, 49:1 and 4:1.

N-Monochlorourethane, which occurs as intermediate, can also serve as a chlorination reagent, however it is much less effective than DCU.

Procedure

Synthesis of *(1b)*. A solution of *(1a)* (1 g, 2.04 mmol) and DCU (0.65 g, 4.12 mmol) in dry benzene (150 ml) flushed with N_2 was irradiated with a 160W-sunlamp for 10 h in an atmosphere of N_2. The reaction mixture was washed with $NaHSO_3$, dried, and evaporated to dryness. The residue was dissolved in acetone (150 ml) and treated with an aqueous solution of $AgClO_4$ (6 g in 60 ml). The precipitate formed was filtered off, the solvent evaporated and the residue extracted with ether and washed with water. Subsequent column chromatography (dry SiO_2, CH_2Cl_2) afforded *(1b)* (0.41 g, 41 %), m.p. 138—139 °C, $[\alpha]_D = -15°$, ^{1}H-NMR ($CDCl_3$): $\delta = 0.95$ and 5.32 (H at C-19 and C-9).

Organic Syntheses Using Sheet Silicate Intercalates: Low-temperature Conversion of Olefins to Secondary Ethers[**]

By *John M. Adams, James A. Ballantine, Samuel H. Graham, Richard J. Laub, J. Howard Purnell, Paul I. Reid, Wafa Y. M. Shaman*, and *John M. Thomas*[*]

We have discovered that a range of cation-exchanged montmorillonites will smoothly convert 1-alkenes *(1)* to the corresponding secondary ethers *(2)* when hexane solutions of the olefin are refluxed in presence of the solid montmorillonite for 5—10 h.

(a), R = *n*-C_4H_9; *(b)*, R = *n*-C_5H_{11}; *(c)*, R = *n*-C_6H_{13}

GLC, mass spectrometry and the ^{1}H-NMR spectrum established the identity of the product. It cannot be efficiently produced by any other known preparative method. Chromatographic separation of the diastereoisomers was possible.

A range of definitive experiments[1] demonstrated that the source of the ether oxygen was the interlamellar water (hydration sphere of inorganic cation) and that reaction takes place in the interlamellar region, there being an optimal water content for a given cation of the original sheet silicate (see Fig. 1).

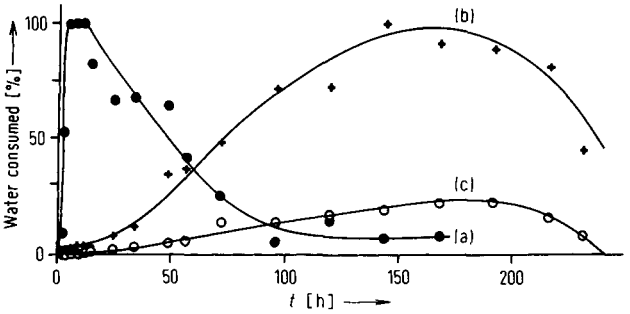

Fig. 1. Yield of ether (expressed as percentage consumption of interlamellar water) as a function of time for clays with (a) one layer (b) two layers and (c) three layers of water between the aluminosilicate sheets. 0.5 g clay was used in each case with 5 g hex-1-ene.

The montmorillonite principally used in the work had a cation-exchange capacity of 66 mequiv/100 g of air-dry aluminosilicate, but tests on montmorillonites from a number of different sources showed that all were effective for the conversion *(1)*→*(2)*. In the preliminary experiments described here, a considerable excess of alkene over aluminosilicate was employed. Yields of up to 65 %, based on consumed

[**] Work supported by the Science Research Council.

1-alkene, and of up to 100 %, based on available interlamellar water, could be obtained.

Numerous ions facilitate the conversion, the most efficient being Cu^{2+}, Fe^{2+}, Fe^{3+}, Cr^{3+}, and Al^{3+}. For Cu^{2+} the optimal metal : water ratio is *ca.* 1 : 12. Even though the conditions in the interlamellar regions are crucial, the role of the silicate sheet itself is not unimportant since a Cu^{2+}-exchanged sheet phosphate, $Cu(UO_2PO_4)_2 \cdot 6H_2O$, the Cu^{2+} analog[2] of the mineral autinite[3], $Ca(UO_2PO_4)_2 \cdot nH_2O$, does not effect conversion of the alkene.

Experimental

Cation exchange of the montmorillonite is effected by treatment with aqueous solutions (0.3 M —1.0 M) of appropriate cations for 48 h. The clay is then washed free of excess cation with de-ionized water, surplus water is decanted off and the clay dried at 80 °C, then ground to pass through an ASTM 150 mesh sieve.—A 250 ml round-bottom flask, fitted with reflux condenser and mechanical stirrer is charged with a solution of 1-alkene *(1)* (6.4 g) in *n*-hexane (12 ml) and with cation-exchanged montmorillonite (1 g), and the mixture is stirred and refluxed for up to 24 h. The cooled solution is filtered free from clay and analyzed by gas-liquid chromatography (3 meter column packed with 3 % PEG 20M on Chromosorb G; known quantity of nonan-5-one as standard). The ether *(2)* can be isolated by preparative gas-liquid chromatography.

Alkali Metal Salts of RC(O)-Substituted Cyclononatetraenyl Anions: Aromatic [9]Annulene Anion or Olefinic Nonafulvene Structure as Function of Gegenion and Solvent[**]

By *Gernot Boche* and *Frank Heidenhain*[*]

Alkali metal salts of acceptor-substituted cyclononatetraenyl anions can exhibit the character of an aromatic or of an olefinic 10 π electron system—*e.g. (2)* or *(3)*[1]. We report here on such compounds containing RC(O)-substituents. Structurally they are of interest regarding the constitution of metal enolates[2] and of RC(O)-substituted azonines[3]. Furthermore, these compounds are intermediates for the synthesis of nonafulvenes[1b].

Reaction of 9-acetyl-*cis,cis,cis,cis*-cyclonona-1,3,5,7-tetraene *(1)*[4] with *potassium* bis(trimethylsilyl)amide in tetrahydrofuran at −78 °C led to the anion *(2)*, whose aromatic character is confirmed by spectroscopic and chemical data. ^{1}H-NMR (THF, δ rel. TMS int.): 6.83 (m, H^2 to H^7), 7.75 (d, H^1 and H^8, $J = 12.5$ Hz); ^{13}C-NMR *(vide supra)* 107.2, 111.7, 112.3, 114.8, 117.0 (C^9), 205.1 (C^{10}); the signals of *(2)* thus appear in the range of the aromatic all-*cis*-[9]annulene anion[1a] (^{1}H-NMR: $\delta = 7.02$; ^{13}C-NMR: $\delta = 109.5$). The high thermal stability of *(2)*—no isomerization takes place even on heating at 60 °C for four days—is consistent with the NMR findings.

A completely different result was obtained on reaction of *(1)* with *lithium* bis(trimethylsilyl)amide. In this case all data were consistent with the product having the fulvene structure *(3)*. ^{1}H-NMR *(vide supra)*: 5.02 (dd, H^4 and H^5, $J = 12.5$ and 3.5 Hz), 5.37—5.88 (m, H^2, H^3, H^6, H^7), 6.33 (d, H^1 and H^8, $J = 12.5$ Hz); ^{13}C-NMR *(vide supra)*: 116.0 (C^9), 124.3—130.6 (C^1 to C^8), 146.8 (C^{10}). The isomerization to the dihydroindene derivative *(4)*, observable with a halflife of 14 min in tetrahydrofuran at 50 °C, is in accord with the NMR findings.

Reaction of *(2)* or *(3)* with trimethylchlorosilane in tetrahydrofuran at −78 °C afforded the silyl enol ether *(5)* in 95 % yield. ^{1}H-NMR ($CDCl_3$, −25 °C, δ rel. TMS int.): 0.23 (s, $Si(CH_3)_3$, 1.95 (s, CH_3), 5.47 (dd, H^4 and H^5, $J = 12.5$ and 3.5 Hz), 5.66—6.07 (m, H^2, H^3, H^6, H^7), 6.27 (d, H^1 and H^8, $J = 12.5$ Hz); ^{13}C-NMR *(vide supra)*: 116.0 (C^9), 122.5—129.0 (C^1 to C^8), 150.2 (C^{10}). With these spectroscopic data and the facile isomerization ($\tau_{1/2}$ in $CDCl_3$ at 50 °C: 3 min) to *(6)*[5], which is also accessible from *(4)* and trimethylchlorosilane, the silyl enol ether *(5)* also affords supporting evidence for the fulvene structure of the lithium compound *(3)*.

The tendency of the lithium cation to form strong contact ion pairs with the enolate oxygen[2, 6] is dramatically illustrated by the breakdown of the aromatic character in *(3)*. Almost as in the silyl enol ether *(5)*, the nine-membered ring barely possesses any negative charge. The corresponding sodium compound in tetrahydrofuran at room temperature also behaves similarly to *(3)*. In the case of the potassium compound *(2)*—as opposed to "normal" potassium enolates[6]—however, drastic changes take place. The steric demands of the nine-membered ring and the tendency toward charge delocalization lead to cleavage of the weak contact ion pair and formation of a solvent-separated ion pair. Its presence in *(2)* is suggested by the fact that THF solutions of *(3)* containing hexamethylphosphoric triamide or dimethyl sulfoxide show the same ^{1}H-NMR spectrum as *(2)*. Aromaticity thus becomes an ion-pair effect[7]!

Noteworthy is the different extent of perturbation caused by the RC(O) group on the aromatic 10 π electron perimeters of the [9]annulene anion and the azonine: whereas there is hardly any noticeable effect in the case of the solvent-separated anion *(2)*, RC(O)-substituted azonines are to be characterized as olefins[3].

As the high yield (95 %) of silyl enol ether *(5)* shows, RC(O)-substituted cyclononatetraenyl anions provide a convenient entry to the nonafulvenes[1b]. Thus, reaction of *(2)*

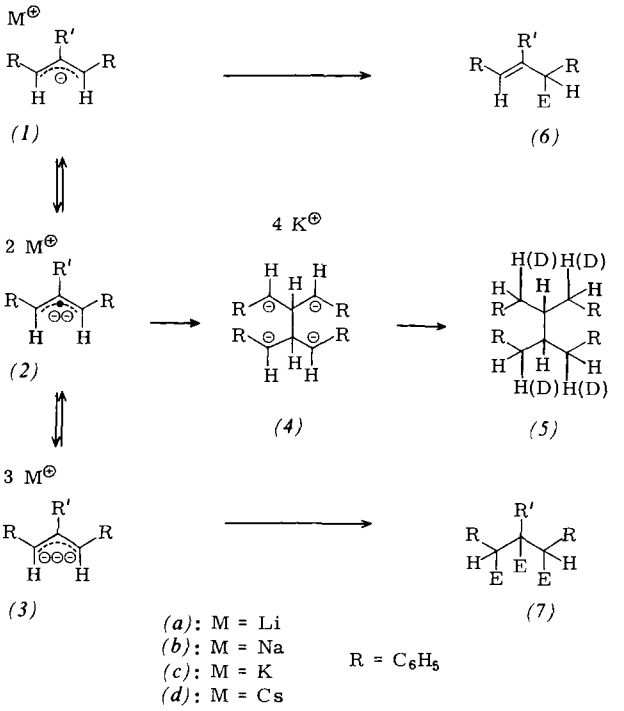
Reduction of 1,3-Diphenylallyl Anions *via* Dianion Radicals to Trianions with Lithium, Sodium, Potassium, and Cesium as Gegenions[**]



By *Gernot Boche* and *Klaus Buckl*[*]

Electron transfer reactions are of special interest both from a preparative as well as from a mechanistic point of view. We recently reported the oxidation of allyl anions to allyl radicals[1]; we now wish to describe their reduction to allyl dianion radicals and allyl trianions.

Reaction of 1,3-diphenylallyllithium[2] *(1a)*, R′=H, with potassium in tetrahydrofuran (THF) led, after 3—10 hours' stirring at room temperature and workup with D_2O, to the fourfold deuterated hydrocarbon *(5)* in 15±5% yield[3], whose constitution was confirmed by an independent synthesis[4]. Since *(5)* was formed from the tetraanion *(4)*, which in turn was produced by dimerization of the dianion radical *(2c)*, R′=H, this reaction sequence observable only in the case of *(1a)*, R′=H, demonstrates primary electron transfer. The nondimerized dianion radical was further reduced to the trianion *(3c)*, R′=H, whose structure could be proven by protonation with H_2O or deuteration with D_2O to *(7)*, R′=H, E=H[5a] or D[5b].

Triphenylallyllithium[6] *(1a)*, $R'=C_6H_5$, can be reduced with Li-, Na-, and K-naphthalene[7] and with lithium, sodium, potassium, or cesium. In no case was dimerization of the dianion radicals *(2a—d)*, $R'=C_6H_5$, observed—presumably for steric reasons—but exclusive formation of the reddish brown *(3a—c)*, $R'=C_6H_5$, or black *(3d)*, $R'=C_6H_5$, allyl trianions.

Structural proof was again provided by reaction with electrophiles. Thus, protonation with H_2O gave the hydrocarbon

(7), E=H, $R'=C_6H_5$[5a], while reaction with D_2O afforded the corresponding trideuterio compound *(7)*, E=D, $R'=C_6H_5$ (95% yield in both cases). Reaction with dimethyl sulfate gave the trimethyl compound *(7)*, $E=CH_3$, $R'=C_6H_5$, in 84% yield.

However, not all electrophiles react in this way: Diethyl sulfate affords the olefin *(6)*, $E=C_2H_5$, $R'=C_6H_5$, in 42% yield, while reaction with methyl iodide and with trimethylchlorosilane leads to the olefins *(6)*, $E=CH_3$ or $Si(CH_3)_3$[6], $R'=C_6H_5$, in 91% and 81% yield, respectively. The allyl trianion *(3)*, $R'=C_6H_5$, is therefore a nucleophile, which is particularly prone to undergo electron-transfer reactions.

This property was also manifested by the reaction with electron acceptors. Thus, iodine was converted into iodide, and nitrobenzene into the nitrobenzene dianion[8], the allyl trianion *(3)*, $R'=C_6H_5$, giving rise to the allyl anion *(1)*, $R'=C_6H_5$.

Thus, we have been able to prepare the first trianion *(3d)*, $R'=C_6H_5$, with $Cs^{\oplus}$ as gegenions and which is stable in THF, even at room temperature[9]. The parent carbon skeleton of the trianions *(3)*, $R'=C_6H_5$, displays a further peculiarity: Since the corresponding allyl cation is also accessible[10], it can be obtained in five different oxidation states. Polarographic investigations are in progress.

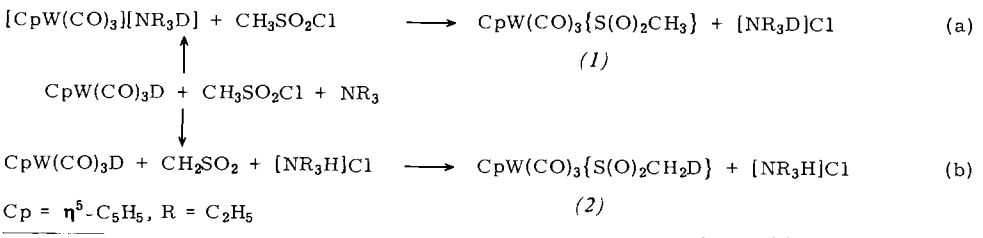
[9] a) Trilithium compounds: cf. *e.g. W. Priester, R. West*, J. Am. Chem. Soc. *98*, 8421, 8426 (1976); *J. J. Bahl, R. B. Bates, W. A. Beavers, C. R. Launer, ibid. 99*, 6126 (1977) and references cited therein; b) *C. F. Koelsch, ibid. 79*, 4439 (1957), prepared a trisodium compound, *E. G. Janzen, J. G. Pacifici, ibid. 87*, 5504 (1965), the corresponding tripotassium compound; c) *E. Grovenstein Jr., Th. H. Longfield, D. E. Quest, ibid. 99*, 2800 (1977), have described a dianion containing $Cs^{\oplus}$ gegenions in which both negative charges are separated from each other.
Note added in proof (March 15, 1978): 1,3-Diphenyl-2-azaallylsodium is also reduced, *e.g.* with lithium, to give the corresponding trianion. The intermediate dianion radical leads to a CC connected dimer in 10±5% yield.

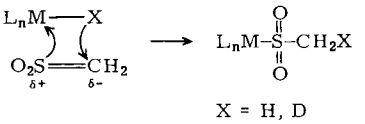
[10] Warming the allyl bromide *(6)*, E = Br, R′ = C_6H_5, in cyclohexane leads to formation of 2,3-diphenylindene; the 1,2,3-triphenylallyl cation must occur as intermediate [cf. *C. F. Bergmann*, J. Org. Chem. *6*, 543 (1941)].



Demonstration of "Sulfene" Insertion into the Metal-Hydrogen Bond

By *Ingo-Peter Lorenz*[*]

The *S*-oxides of thiocarbonyl derivatives are of preparative and theoretical interest[1, 2]. The parent compounds $H_2C{=}SO$ and $H_2C{=}SO_2$ ("sulfine" and "sulfene") are extremely unstable and are distinguished by the numerous possible reactions which they can undergo *in situ*. A "sulfene insertion" into the metal-hydrogen bond was recently described as the first sulfene reaction in complex chemistry[3] and has now been demonstrated by D-labeling experiments.



Earlier reactions of the hydrides η^5-$C_5H_5M(CO)_3H$ (M = Cr, Mo, W) with methanesulfonyl chloride[3, 4] did not lead to the desired product η^5-$C_5H_5M(CO)_3\{S(O)_2CH_3\}$, which, in the case of M = W, were formed only after addition of a tertiary amine[3]. Here, two reaction paths were possible: firstly, the stabilizing quaternization of the amine, which facilitates attack of the sulfonyl chloride; secondly participation in the reaction of sulfene (thioformaldehyde *S,S*-dioxide).

The reaction of η^5-$C_5H_5W(CO)_3D$ with CH_3SO_2Cl and triethylamine—as sulfene generator[1a]—was carried out in order to clarify the problem. Actually, only the monodeuterated methanesulfinato-*S* compound η^5-$C_5H_5W(CO)_3\{S(O)_2CH_2D\}$ *(2)*, and protonated ammonium chloride are formed. Thus the reaction path (a) *via* base-catalyzed intermolecular HCl- or DCl-elimination is ruled out, and the path (b) *via* intramolecular HCl-elimination and sulfene insertion is confirmed:

The physical properties of *(2)* resemble those of the undeuterated complex *(1)*. Composition and structure follow from elemental analysis, molecular weight determination (408, osmometric in CH_2Cl_2), and mass, IR and ^{1}H-NMR spectra. The mass spectrum (70 eV, 120 °C) shows the molecular ion at *m/e* = 413 (^{184}W) with low intensity, together with the complete series of fragment ions, and the recombination product $[\eta^5$-$C_5H_5W(CO)_3]_2$ as ion with greatest mass. In the IR spectrum (solid/KBr) a sharp band appears at 2355 cm^{-1} which is assigned to the CD stretching vibration; in the region of the terminal CO ligands there appear ν(CO) bands of the classes $A_1 + E$ or $A' + (A' + A'')$ characteristic for C_{3v}- or C_s local symmetry at 2057 (s) and 1969 (vs), 1960 (sh) cm^{-1} (in $CHCl_3$ solution) respectively; the sulfinato-*S* coupling follows from the position and frequency difference of the SO_2 stretching absorptions: $\nu_{as}(SO_2)$ at 1205 (sh), 1196 (vs) and $\nu_s(SO_2)$ at 1056 (s), 1039 (m) cm^{-1} (solid/KBr). The ^{1}H-NMR spectrum of *(2)* shows two singlets at δ = 5.84 (C_5H_5) and 2.74 (CH_2) in the correct intensity ratio ($CDCl_3$ solution, $\delta_{TMS} = 0$), that of the triethylammonium chloride arising in the formation of *(2)* shows the multiplet signals expected to appear on account of the *N*-proton.

MO-SCF-CNDO calculations for sulfene indicated extensive participation of the dipolar ylide resonance form[2a]. The resulting strong *C*-nucleophilicity and *S*-electrophilicity is apparent from the ready decomposition and pronounced reactivity of the compound. As expected, sulfene reacts with a metal-hydrogen bond to form a *sulfinato-S* complex:

The reaction mechanism is accordingly interpreted as electrophilic attack of the sulfur atom and is by no means so complicated as that of a SO_2-insertion into the metal-carbon bond[5]. The analogous reaction of sulfine (thioformaldehyde *S*-oxide) to give *sulfenato-S* complexes is presently under investigation. Both molecules and their derivatives ought also to be suitable species for the promotion of ring closure and addition reactions as well as complex stabilization[6].

Experimental

All operations must be carried out under nitrogen using anhydrous and oxygen-free solvents.

To a stirred solution of η^5-$C_5H_5W(CO)_3D$[7] (1.34 g, 4 mmol) in tetrahydrofuran (20 ml) at −40 °C is added dropwise, firstly 0.69 g (6 mmol) CH_3SO_2Cl, and then 1.65 ml (12 mmol) $N(C_2H_5)_3$. The mixture is allowed to warm to 25 °C, stirred for a further 1 h, and the suspension evaporated to dryness. The residue is taken up in *ca.* 30 ml CH_2Cl_2, and the resulting solution filtered and evaporated to dryness. After dissolution of the residue in 15 ml CH_2Cl_2 the solvent is carefully removed by passage of N_2. Orange colored needles

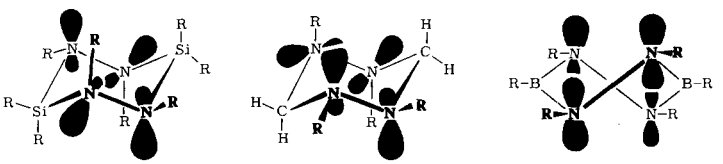
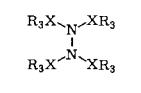
Structural Changes during the Oxidation of B-, C-, Si-, and P-Substituted Hydrazines[1, 2]

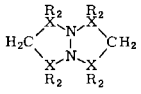
By *Hans Bock, Wolfgang Kaim, Andrzej Semkow*, and *Heinrich Nöth*[*]

Hydrazines belong to the few classes of compounds, which, despite the absence of multiple bonds, can be oxidized to stable radical cations. Energy differences and changes in electron distribution[3] accompanying these redox reactions may be discussed on the basis of photoelectron and electron spin resonance spectra (Table 1: PE- and ESR data): PE spectroscopically measurable ionizations in the gas phase occur "vertically", *i.e.* so rapidly that the molecular structure will not change, whereas oxidation in solution leads "adiabatically" to radical cations in their energetically preferred conformation.

The low N-ionization energies of the B-, C-, Si- and P-substituted hydrazines (Table 1) and their splittings $\Delta IE_{1,n}$ as a function of the dihedral angle ω between the nitrogen electron pairs n_N can be rationalized as follows: the smaller the effective nuclear charge of the substituent atom X and/or the stronger the n_N/σ_{NX} interaction, the lower the value of IE_1. The more the dihedral angle deviates from $\omega = 90°$ the more will the increased n_N/n_N interaction energetically raise the ground state of the neutral molecule M, and the more will the improved charge delocalization lower the ground state of the resulting radical cation $M^{\bullet\oplus}$. More detailed information may be gathered from the corresponding PE ionization energies: the two N-electron pair ionizations of tetramethylhydrazine are split by ± 0.28 eV about $IE_1(n_N) = 8.55$ eV of trimethylamine[4f]. Replacement of H_hC- by $(H_3C)_mSi$ substituents lowers all the N-ionization energies. The different splittings $\Delta IE_{1,n}$ for hydrazine derivatives with varying dihedral angles ω between the N-electron pairs[2, 4b, 4c] are evident: open chain derivatives with $\omega \rightarrow 90°$ display only small differences $\Delta IE_{1,2}$ while the flattened five-membered rings with $\omega \rightarrow 0°$ exhibit considerable differences $\Delta IE_{1,2}$. Among the six-membered ring derivatives with the preferred conformations







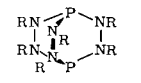


Table 1. Molecular properties of X(= B, C, Si, or P)-substituted hydrazines containing $n = 2$, 4 or 6 nitrogen electron pairs. PE data: N-ionization energies IE_n, and splitting $\Delta IE_{1,n}$ [eV]. ESR data: N-, H- and X-coupling constants a^{14}_N, $a_H^{NCH_3}$ and a_X [mT].

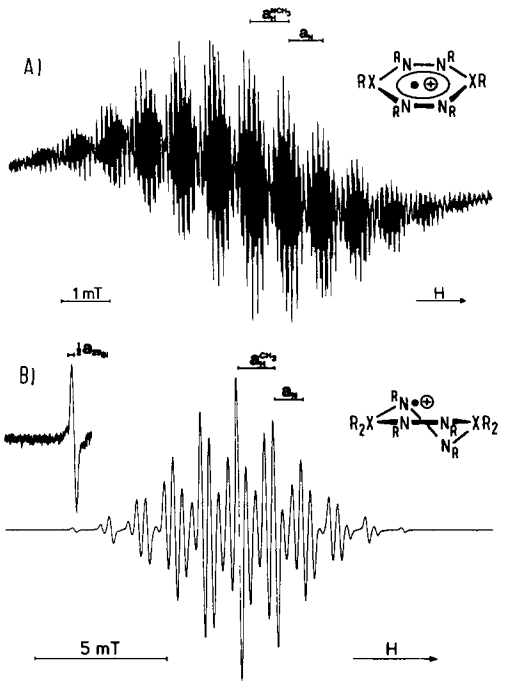
the presumably[2] (*N-N*)equatorial-axial R_2Si compound shows only a small splitting; for the (*N-N*)diequatorial-(*N-N*)diaxial H_2C-derivative[6a] a considerably larger value $\Delta IE_{1,4}$ results and the four N-ionizations of the "*twist*"-tetraazadiboracyclohexane[4b] are distributed over 3.32 eV (Table 1). In the case of the bicyclic phosphane, with staggered S_6

arrangement of the methyl groups[6c], the given energy region $\Delta IE_{1,6}$ contains additionally one P-electron pair ionization[4e].

In solution, the radical cations of B-, C-, Si- and P-substituted hydrazines can be generated with $AlCl_3$ in CH_2Cl_2[2, 4a, 7]. Their ESR spectra differ considerably: Thus, that of the oxidized B_2N_4 six-membered ring expectedly exhibits its numerous lines (Fig. 1:A), whereas that of the Si_2N_4 six-membered ring unexpectedly shows only a few (Fig. 1:B).



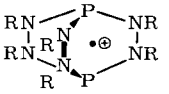


Fig. 1. Completely different ESR spectra of hydrazine radical cations may result, even if their overall topology as well as the recording conditions (T = 225 K) are similar: A) The dark-blue radical cation of hexamethyl-1,2,4,5-tetraaza-3,6-diboracyclohexane (X = B) exhibits an ESR spectrum which can be satisfactorily simulated with the quoted coupling constants of equivalent 4 N-, 12 H- and 2 B-nuclei [2]. B) The colorless radical cation of octamethyl-1,2,4,5-tetraaza-3,6-disilacyclohexane (X = Si) unexpectedly exhibits only coupling of equivalent 2 N- and 6 H-nuclei and of one ^{29}Si nucleus of natural abundance 4.7%.—The results show that within the ESR time scale of $\approx 10^{-6}$ s the spin density is distributed over both RN—NR bridges in $R_6B_2N_4^{\oplus\bullet}$ but over only one such bridge in $R_8Si_2N_4^{\oplus\bullet}$. Like the iso-π-electronic benzene radical anion; the B_2N_4 radical cation is therefore most likely planar, whereas only one of the RN—NR bridges should be flattened in the Si_2N_4 six-membered ring.

The ESR coupling constants (Table 1) assigned[2] by careful spectra simulation as well as ENDOR measurements afford, *inter alia*, the following information: The still resolved $(H_3C)_m$Si-methyl proton coupling (Fig. 1: B) confirms extensive spin delocalization (cf. *e.g.* [2, 4a]). The spin density, however, is located predominantly in the RN—NR bridges, as indicated *e.g.* by the comparably large sums of the coupling constants of the dimethylhydrazine radical cation[8a] (cf. Table 1):

$\sum_N a_{14_N}$ = 2.412 mT

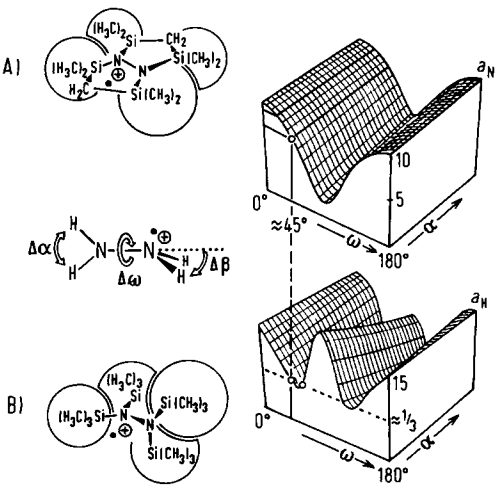
$\sum_H a_H^{NCH_3}$ = 9.090 mT

$\sum_N a_{14_N}$ = 2.94 mT

$\sum_H a_H^{NCH_3}$ = 7.56 mT

In the six-membered ring derivatives, the spin density at the heteroatoms X is only low[8b]; that in each of the individual RN—NR bridges is of comparable size (Table 1). The differing spin distribution over one, two or three RN—NR bridges are rather due to steric effects (Fig. 1 and Table 1). Thus, in the case of the C- and Si-tetraazacyclohexane radical cations a boat conformation at the R_2X groups is sterically as disadvantageous as a rapid spin exchange between the different types of RN—NR bridges *via* transition of one "half-chair" conformation into the other. On the contrary, the trigonal planar arrangement of the $RB(NR—)_2$ halves favors flattening of the B_2N_4 six-membered ring.

From the PE and ESR data (Table 1) it follows that the hydrazine radical cations investigated are stabilized by planarization. In the case of unsubstituted $N_2H_4^{\oplus\bullet}$ this is reflected by an INDO open-shell hypersurface[9] whose total energy minimum is calculated for a completely planar structure (cf. Fig. 2).



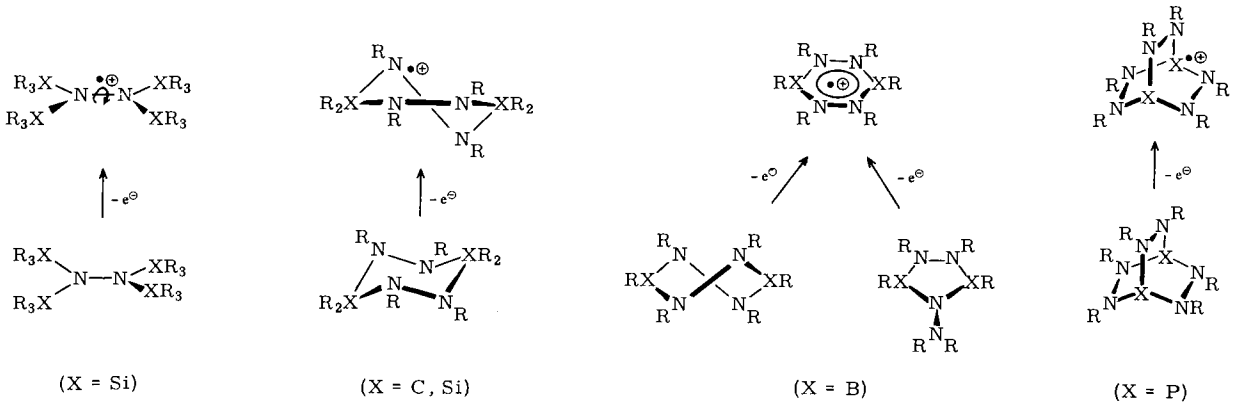


Fig. 2. For the hydrazine radical cation $H_2N—NH_2^{\oplus\bullet}$, INDO open-shell calculations [9] predict a minimum on the total energy hypersurface for planar geometry (D_{2h}). Additionally calculated coupling constants depend predominantly on the dihedral angle ω: on twisting to ω = 90°, the coupling constant a_{14N}^{INDO} reaches a minimum (A), a_H^{INDO} a maximum (B). Comparison with the measured ESR data a_{14N} and a_{29Si} (Table 1)—in the silylated hydrazines Si is adjacent to N—provides information on the structure of the oxidation product in solution: starting from the presumably planar bicyclic tetrasilylhydrazine radical cation, the three-dimensional a_X^{INDO} tables yield a dihedral angle ω ≈ 45° for the open chain tetrakis(trimethylsilyl)hydrazine radical cation, both from the difference $\Delta a_{14N} = 8.62 - 7.52 = 0.9$ mT (A) as well as from the ratio $a_{29Si}^{chain}/a_{29Si}^{ring} = 1.6/5.0 \approx 1/3$ (B). Apparently, the bulky $(H_3C)_3Si$-substituents prevent the energetically favored complete planarization of the $X_2N—NX_2^{\oplus\bullet}$ skeleton.

Comparison of the ESR data of tetrasilylated hydrazine radical cations (Table 1) based on the calculated coupling constants a_X^{INDO}, suggests for the open-chain oxidation product in solution a structure with reduced dihedral angle (Fig. 2: a_N and a_H). The energetically favorable complete planarization is obviously prevented by the bulkiness of the $(H_3C)_3Si$ substituents.

Altogether, the following structural changes are observed during the oxidation of B-, C-, Si- and P-substituted hydrazines:

(X = Si) (X = C, Si) (X = B) (X = P)

The remarkable stability of the dark blue radical cation $R_6B_2N_4^{\oplus\bullet}$ with a planarized 7π-electron system is underlined by the fact that the ESR spectrum of the six-membered cyclic radical cation (Fig. 1: A) is also recorded on oxidation of the isomeric R_2N-substituted five-membered ring.

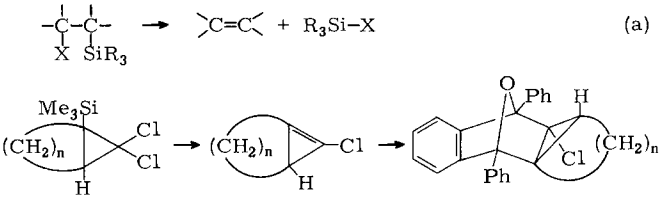
[9] The computer program contains a Davidson-Fletcher-Powell subroutine, which has been used for optimization of the N—N bond length. The coupling constants were calculated with the hyperfine constants $Q_N = 53.9864$ and $Q_H = 37.9356$ mT.



ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

The mechanism of biological methylation of metals is examined by *J. M. Wood, A. Cheh, L. J. Dizikes, W. P. Ridley, S. Rackow*, and *J. R. Lakowicz*. Mercury pollution has directed interest to biogenic organometallic compounds. Such compounds readily accumulate in tissues and are poisonous, usually towards the central nervous system. Alkylmetal compounds stable towards water and formed biologically are known for Hg, Sn, As, Se, Te, Pd, Au, Tl, and Pb. The main emphasis of the article is on the mechanisms of formation, especially for those elements which are widespread in the biosphere. [Mechanisms for the Biomethylation of Metals and Metalloids. Fed. Proc. *37*, 16—21 (1978); 41 references]

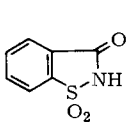
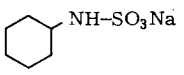
Alkene synthesis *via* β-functionalized organosilicon compounds is the subject of a review by *T. H. Chan*. The synthetic potential of reaction (a), first reported some 30 years ago, has only recently been recognized. The method has proved very suitable for the synthesis of α,β-unsaturated esters, aldehydes, and nitriles. In addition, strained and very reactive alkenes have



(a)

(1), n = 4,5,6



nitriles. In addition strained and very reactive alkenes have also been prepared in this way, *e.g.* cyclopropenes and the "anti-Bredt alkene" *(1)* having a bridgehead double bond. [Alkene Synthesis *via* β-Functionalized Organosilicon Compounds. Acc. Chem. Res. *10*, 442—448 (1977); 66 references]

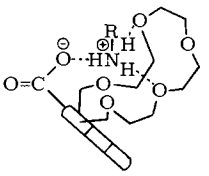
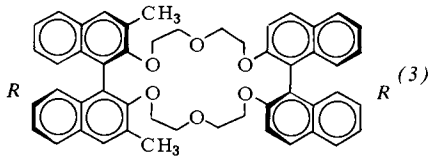
The relationship between steroid hormones and the growth and development of plants is considered by *J. M. C. Geuns*. It has long been known that steroid hormones of animal origin can stimulate plant development and growth and are metabolized by plants. Recently, steroid hormones and related compounds have been isolated from plants, *e.g.* sex hormones, corticoids, pentacyclic triterpenoids, saponins, digitonin, and tomatin. Although biological activity has been proved, it is difficult to quantify because steroids dissolve poorly and nonreproducibly in aqueous media. [Steroid Hormones and Plant Growth and Development. Phytochemistry *17*, 1—14 (1978); 156 references]

[Rd 11 IE]



Prediction of the spatial structure of a protein from the amino acid sequence is possible in principle. *M. J. E. Sternberg* and *J. M. Thornton* consider the various approaches to this goal. The main problem is the large number of possibilities: a small protein with only 50 amino acids can exist in some 10^{50} different conformations. The predictions concentrate mainly upon the secondary structure of the amino acid chains and how the natural folding processes could proceed. Use is made of simple models for the conformation of the protein and of energetic aspects of interatomic interactions. [Prediction of Protein Structure from Amino Acid Sequence. Nature *271*, 15—20 (1978); 59 references]

[Rd 6 IE]



The design of host-guest complexes with synthetic hosts is the topic of an article by *D. J. Cram* and *J. M. Cram*. These complexes can be regarded as models for enzyme-substrate complexes. A typical example is the crystalline complex *(2)* formed from the host *(1)* and the *tert*-butylammonium ion. The structure of *(2)* has been established by X-ray methods. The incorporation of steric barriers endows the host molecule with the ability to recognize structures. Optically active hosts such as *(3)* are capable of chiral recognition and can remove one enantiomer preferentially, *e.g.*, from a mixture of enantiomeric salts of primary amines. [Design of Complexes between Synthetic Hosts and Organic Guests. Acc. Chem. Res. *11*, 8—11 (1978); 28 references]

Conformational studies on hexahydropyridazines are considered by *S. E. Nelsen*. Compounds such as the 1,2-dimethyl derivative *(1)* are good models for quantitative studies on the influence of the dihedral angle θ between the lone pairs on conformational equilibria and rate constants. A value of $\theta = 90°$ is preferred in many compounds with neighboring hetero atoms (*gauche* effect). *(1ee)* ($\theta \approx 180°$) appears to be ruled out; however, *(1ae)* and *(1aa)* ($\theta \approx 60°$) are sterically destabilized by axial substituents. Interconversions of the conformers of *(1)* and similar compounds have been examined above all by PE and ^{1}H- and ^{13}C-NMR spectroscopy, cyclic voltammetry at low temperatures, and dipole moment measurements. [Conformational Studies of Hexahydropyridazine Derivatives. Acc. Chem. Res. *11*, 14—20 (1978); 38 references]

(1ee) *(1ae)* *(1aa)*

[Rd 8 IE]

The physical characterization of cytoplasmatic gluco- and mineralosteroid receptors is reviewed by *M. K. Agarwal*. Lipophilic steroid molecules are assumed to migrate through the cell membrane and to encounter a receptor of high affinity (K_d *ca.* 10^{-10} mol/l) and low capacity in the cytoplasm. While the receptor appeared to be homogeneous on density gradient centrifugation and gel filtration, chromatography on ion exchangers showed it to consist of proteins which are heterogeneous with regard to their charge. It remains to be established why receptors are so labile *in vitro*, how the receptor-hormone complex permeates the nuclear membrane, and how it interacts with a likewise still hypothetical acceptor in the nucleus. [Physical Characterization of Cytoplasmatic Gluco- and Mineralo-Steroid Receptors. FEBS Lett. *85*, 1—8 (1978); 54 references]

BOOK REVIEWS

Electron Spectroscopy: Theory, Techniques, and Applications. Vol. 1. Edited by *C. R. Brundle* and *A. D. Baker*. Academic Press, Inc., London—New York 1977. xv, 459 pp., various figs. and tables, bound, $ 46.90.

Although photoelectron spectroscopy began really to flourish only in 1970 with the advent of commercial spectrometers, this spectroscopic method has now become so widely diversified that a series of volumes must be planned if the various

types and applications of (photo)electron spectroscopy are to be brought again under one roof. The editors promise that this will result in cross-fertilization of the experimental and theoretical approaches.

After a general introduction to photoelectron spectroscopy by the editors, *R. L. Martin* and *D. A. Shirley* describe in Chapter 2 some aspects of the theory of photoemission and *W. L. Jolly* explains the model ideas used in the field of X-ray photoelectron spectroscopy of inorganic substances (Chapter 3). In the following Chapters 4 to 6 *W. C. Price* (small molecules), *E. Heilbronner* and *J. P. Maier* (organic molecules), and *R. L. Dekock* (inorganic molecules) devote themselves to the possible applications of UV photoelectron spectroscopy in the gas phase. Chapters 7 and 8, on high-temperature UPS investigations *(J. Berkowitz)* and coincidence experiments *(M. E. Gellender* and *A. D. Baker)* put the reader in touch with special techniques of current UV photoelectron-spectroscopic research.

The following sections can be particularly recommended: Chapter 1; the considerations in Chapter 2 on the influence of relaxation and correlation on ionization cross-sections; the discussions in Chapter 4 on the intensity of photoelectron spectra; the presentation of theory, experimental aspects, and band assignment in Chapter 6, the clear description of the angular distribution of photoelectrons in Chapter 7; and the explanation of the connections between resolution and signal intensity in one- and two-parameter measurements in Chapter 8. In addition, the individual chapters afford an insight into the special types of research and photoelectron-spectroscopic viewpoints of the authors. All in all, the reviewer has had great pleasure from this volume and can heartily recommend it to every chemist interested in photoelectron spectroscopy.

Armin Schweig [NB 407 IE]

Gedächtnis und Lernen in psychologischer Sicht (Memory and Learning from the Psychological Point of View). Vol. I. Biologie des Lernens (Biology of Learning). Vol. II. By *H.-J. Flechtner*. S. Hirzel Verlag, Stuttgart 1976. Vol. I: 2nd Edit., x, 354 pp., 5 figs., paperback, DM 25.00; Vol. II: 1st Edit., xii, 483 pp., 34 figs., paperback, DM 25.00.

The author's original aim was to write a "Biochemistry of Memory", but he collected so much material that a third volume, "memory", still has to appear.

The material is presented from the psychological and neurological points of view. According to *Mandell*, the course of development of neurophysiology shows a "shift from electricity to juice". About 100 pages of the first volume are devoted to definitions and the description of problems, while the other 250 pages deal with learning. The objective school in psychology is presented in a historical treatment. There is a clear account of how *Bechterew*'s and *Pavlov*'s reflexology gave rise to behaviorism. Concepts like operant conditioning and positive or negative reinforcement, which are associated with *Thorndike* and *Skinner*, are necessary for understanding thought processes. The chapter entitled "Psychology of Learning" describes storage, recall, forgetting, and unlearning.

The chapters in the second volume are called "Fundamentals", "Localization of Learning", "Assimilation and Processing", "Engrams", and "Learning and Having Learned". These deal with the morphological, chemical, and biochemical aspects needed for understanding the way the nervous system operates.

What is confusing is that the numbered references appearing in the footnotes (in Vol. I alone 1–499) are not given under the same numbers at the end of the book (294 references in vol. I and 422 in vol. 2). Footnotes like "a. a. O. S. 73" make things even more difficult, and the frequently used abbreviations, like TrmS for transmitter substance and SgS for situation stimulus, should have been listed at the beginning. However, the reader will find a great deal of valuable information in these two volumes.

Götz F. Domagk [NB 401 IE]

Fundamentals of Integrated GC-MS. Chromatographic Science Series, Vol. 7. By *B. J. Gudzinowicz, M. J. Gudzinowicz,* and *H. F. Martin.* Marcel Dekker, Inc., New York—Basel 1976. Part I: Gas Chromatography. vii, 382 pp., numerous figs. Sfr. 124.—; Part II: Mass Spectrometry. vii, 326 pp., numerous figs., Sfr. 117.—.

The first two parts of the three-part work (the third part on the GC-MS combination has not yet appeared) are concerned in almost epic form with mainly theoretical aspects of gas chromatography and mass spectrometry.

Poorly selected practical examples with page-long reproduction of original tables without critical discussion or authors' opinion appear to be arbitrarily chosen. Outdated methods, *e.g.* the introduction of liquid samples into the mass spectrometer through a gallium sinter (Part II, pp. 23—25), are described at length, while the important application of glass capillaries in investigations of scarcely volatile substances and problems connected therewith are hardly touched upon. One gains the impression that the authors have indeed collected much of the older literature, but themselves have not the experience and above all the ability to make critical evaluations. Otherwise we would not have, for example, formulas featuring oxygen atoms with nine electrons (Part II, p. 123), to select only one crass example. Purchase of these two volumes cannot be recommended.

Gerhard Spiteller [NB 416 IE]

Gas-Solid Reactions. By *J. Szekely, J. W. Evans,* and *H. Y. Sohn.* Academic Press, New York 1976. 1st Edit., xiii, 400 pages, bound, $ 39.50.

The aim of this book is to give an introduction into the technique of gas-solid reactions.

The work is divided into eight chapters; the first is an introductory one and the second deals with mass and heat transfer for a single core in a gas stream and with diffusion processes in the pore system of a solid. It also surveys the microkinetics of heterogeneous chemical reactions and discusses reaction-induced changes in the structures of solids.

The third chapter gives a detailed account of the way a reaction proceeds on a nonporous single core in a gas stream, and introduces the "shrinking-core" model.

The fourth chapter is devoted to reactions of porous solids, and the authors discuss here separately the reactions that lead to complete vaporization of the solid and reactions that give solid end products.

The fifth chapter deals with solid-solid reactions in which a gaseous intermediate is formed.

The sixth chapter describes both some experimental techniques important in the investigation of gas-solid reactions and some of their applications. We find here an account of methods for measuring reaction rates, characterizing porous solids, and determining diffusion coefficients and effective diffusion coefficients.

The findings established for the single core are extended to fixed and fluidized-bed reactors in the seventh chapter.

The eighth and final chapter deals with gas-solid reactions of major industrial importance, such as the blast-furnace process and the gasification of coal.

Each chapter includes a long list of references covering the literature up to 1974. The value of the book is enhanced by the many figures, diagrams, and tables correctly fitted into the text. The worked examples in the individual chapters facilitate understanding of the material.

The book is a readable and comprehensive survey of the technique of gas-solid reactions, and is recommended to anyone who wants to understand this field.

Rainer Moormann [NB 402 IE]

Modern Practice of Chromatography. By *R. L. Grob*. John Wiley & Sons, Ltd., New York—London 1977. 1st Edit., xv, 654 pp., numerous figs., bound, £ 16.00.

This work, edited by *Robert L. Grob*, is the most comprehensive existing collection of contributions on the applications of gas chromatography. The individual chapters, written by experienced specialists, describe in three main parts (and in great detail, but not always with consideration of the most recent literature—capillary gas chromatography is mentioned only marginally in the theoretical part) the theory, the technology, and the applications of gas chromatography. About two-thirds of the volume are devoted to theory, qualitative and quantitative analysis, description of apparatus, procedures for sample injection, detectors, and computers. This is the first book to collect so completely such a large number of new technical developments. Emphasis should be laid on the chapters about detectors, instrumentation, and data collection; great advances have been made in recent years in these areas. The chapter dealing mainly with applications includes trace analysis (environmental analysis), examination of foods, clinical analysis, and analysis of drugs, for which work standard methods have been worked out for preparation of the samples and formation of derivatives as well as standardized conditions for separations; therein lies the particular value of this section. Minor redundancies have not been wholly avoided in the text.

The book is supplemented by a chapter on physicochemical applications of gas chromatography, where the posssible application of gas chromatography to the determination of thermodynamic quantities is pointed out, a feature rarely known to the analyst and yet of great interest.

This volume, well worth its price, offers the user of gas chromatography in a wide range of fields a wealth of experience and stimulation.

Wilfried A. König [NB 412 IE]

Structure-Solubility Relationships in Polymers. Edited by *F. W. Harris* and *R. B. Seymour*. Academic Press, New York 1977. 1st Edit., xiii 271 pp. bound, $ 13.00.

A symposium with the same title was held by the American Chemical Society—their 172nd—between August 30 and September 3, 1976. The revised and shortened versions of 21 lectures delivered there were collected in book form and printed by Academic Press Rapid Reproduction. This has given us a book which is up to date and gives a representative cross-section of research in this field.

The summarizing contributions have retained their lecture character; modern solubility theories are discussed in conjunction with the experimental results in easily comprehensible form, and at the same time more emphasis is placed on outlining the problems involved, thus making them also accessible to those who do not work in this field. In addition, the large number of references listed make further reading possible.

The authors work in a variety of places, ranging from industrial laboratories to universities, and therefore some of the polymers discussed are unusual as model substances. This is an advantage for the reader, because he can follow the development of the problem and treatment from the specific characteristics of the polymer in question.

The editors have succeeded in giving a picture of current knowledge in a limited space. From the very beginning, the book is suitable for the interested reader who works with polymers in general, while for the specialist it presents a broad basis for future research.

K. C. Berger [NB 404 IE]

Blutzuckersenkende Sulfonamide – Standort der modernen Substanzen im Vergleich zu älteren Antidiabetika (Hypoglycemic Sulfonamides—Status of Modern Substances Compared with Older Antidiabetic Agents). By *E. Haupt*. Verlag Chemie, Weinheim—New York 1977. 1st edit., viii, 169 pp., 58 figs., 3 tables, boards, DM 34.—.

The author's Habilitation Thesis, now presented in book form, is an attempt to define the position of hypoglycemic sulfonamides on the basis of pharmacodynamic, clinical, and experimental-clinical investigations. The history of the discovery and development of this class of substances is reported in an introductory chapter, where, however, the important development work carried out during 1951—1953 at the Leipzig and Jena university clinics (literature in *A. Kleinsorge*, Dtsch. Med. Wochenschr. *101*, 467 (1976)) was conspicuous by its absence.

The following sulfonylurea derivatives were investigated in the present study: tolbutamide, glibornuride, glisoxepide, and glibenclamide. The important results include the following: no differences were noticeable on oral administration in the kinetics of insulin secretion or in the course of the blood sugar curves; these findings apply both to healthy subjects and to diabetics. Secondary failure of the sulfonylurea monotherapy occurred to the same extent with all the derivatives studied; the "younger-generation" preparations active in milligram doses did not differ in this respect from the older substances. Secondary failure occurred mostly in patients who were severely overweight. The time at which failure occurs depends on the duration of the diabetes therapy and not on the time of appearance of the diabetes mellitus. Each year 5—10 % of all treatments must be broken off because of secondary failure. In the pharmacological investigations, glibenclamide given intravenously had a different effect from the other substances: it induced a distinct insulin secretion, of delayed onset and long duration, with corresponding later decrease of blood sugar (this effect occurred in both healthy and diabetic persons). It is still unclear why the action of glibenclamide is "tolbutamide-like" on oral administration and "glibenclamide-like" when injected intravenously. The difference from literature findings that indicate specific glibenclamide action also by the oral route still requires explanation (cf. *S. Raptis et al.*: 8th Kongr. Dtsch. Diab. Ges., Munich 1973).

Clinical importance attaches to the discussion of the problem of secondary failure; it confirms the finding that the insufficiency of pancreatic β cells, at first incomplete, later becomes complete. An appeal is made to diabetics specialists in clinical and general practice to compensate patients under positive long-term treatment with weight reduction, so that the secondary failure may be delayed.

Those interested in this book will be especially doctors and chemists concerned with sulfonylurea derivatives in industrial and other research laboratories.

Synthesis and Biological Properties of Prostaglandin Endoperoxides, Thromboxanes and Prostacyclins

By K. C. Nicolaou, G. P. Gasic and W. E. Barnette[*]

Dedicated to Professor E. J. Corey on the occasion of his 50th birthday

Prostaglandins continue to be a major and fast-developing area of research in the chemical and biological sciences. Increasing evidence has recently prompted some researchers to suggest that the important physiological actions of these hormones are exerted by their unstable arachidonic acid pathway intermediates, the endoperoxides, thromboxanes, and prostacyclin. The importance of these substances in physiology and medicine and the challenge they pose to synthetic chemistry place them in the forefront of chemical and biochemical investigation. Current biological research has greatly benefited by synthetic advances which have made available large quantities of some of these naturally occurring intermediates and several analogs with increased stabilities. Following a brief review of the primary prostaglandins, the present article describes recent biosynthetic developments, partial and total syntheses of prostaglandin endoperoxide analogs, thromboxane B_2, and prostacyclins, and the biological properties of these molecules.

1. Introduction

Prostaglandins (PG), naturally occurring unsaturated hydroxylated fatty acids with a prostanoid 20-carbon skeleton, have been implicated as local hormones in a multitude of important physiological processes[1–4]. Amongst their ranks these substances boast of very beneficial members, such as prostacyclin, which appears to inhibit thrombus formation, while the elevated levels of other members may be harmful, for example causing pain and inflammation. Since their discovery, rapidly expanding research has thrust prostaglandins into the forefront of attention and future research may apply the acquired knowledge to such areas in medicine as thrombosis, asthma, gastric ulceration, blood pressure regulation, inflammation, and shock. A large share of the credit for the development of this field must be given to the chemists who elucidated the structures of the known prostaglandins, synthesized them, and are continually preparing new analogs which facilitate physiological research and may prove pharmacologically useful.

Their history dates back to more than forty years ago when *U. S. von Euler* and *M. Goldblatt* independently discovered a new factor, present in genital glands and human semen, which displayed vasodepressor and smooth muscle stimulating activity[5, 6]. *Von Euler* showed that the biological activity was due to a lipid soluble material with acidic properties and provisionally termed it "prostaglandin". Almost three decades elapsed between the discovery of the biological activity associated with prostaglandins and the structural elucidation of two of them. Hampered by technical difficulties in the isolation of prostaglandins and interest in other natural products such as antibiotics and steroids, investigation remained dormant for a long time. In 1960, *Bergström* and *Sjövall* isolated the crystalline PGE_1 and $PGF_{1\alpha}$ from sheep seminal vesicles[7]. Within a few years, *Bergström* and his students isolated and

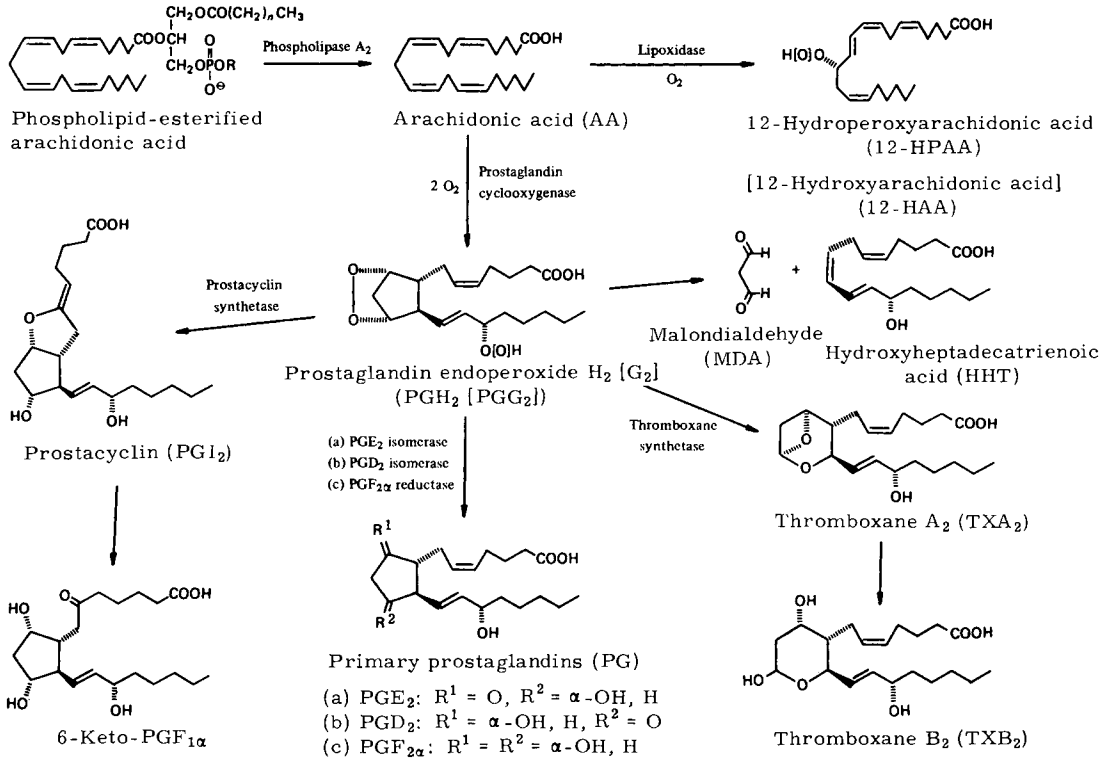

Fig. 1. The arachidonic acid peroxidation pathways: Biogenetic relationship between arachidonic acid and prostaglandin endoperoxides, prostacyclin, prostaglandins and thromboxanes.

elucidated the structure of thirteen different prostaglandins[8,9]. It was at this point, when the isolation and structural determination proved that prostaglandins were responsible for the observed biological activity, that the field came to life.

The next advance came in the biological area. *Bergström*'s group[10] and *Van Dorp*'s group[11] simultaneously demonstrated that these compounds were biosynthesized from polyunsaturated fatty acids (*e.g.* arachidonic acid, Fig. 1). *Anggärd* and *Samuelsson*[12] showed that guinea pig lung homogenates incubated with arachidonic acid simultaneously produced $PGF_{2\alpha}$ and PGE_2 without interconversion. Further work in *Samuelsson*'s laboratory led to the discovery that the oxygens attached to C-9 and C-11 originated from the same molecule of oxygen, and that an endoperoxide was the likely intermediate[13]. Despite the extensive research conducted in *Samuelsson*'s and *Van Dorp*'s laboratories, it was not until 1973 that *Samuelsson* isolated the endoperoxide intermediate, PGH_2[14,15]. Subsequently, an additional endoperoxide with a hydroperoxy group at the C-15 position was isolated and named PGG_2[15,16]. The isolation of the endoperoxides was achieved by blocking the isomerase enzyme with mercury(II) *p*-hydroxybenzoate and rapid extraction to remove them from the aqueous environment. In contrast to the previously discovered prostaglandins, the endoperoxides have a short half-life of about five minutes in biological (aqueous) systems.

In the meantime, synthetic chemists launched an all out attack on these molecules. The first total syntheses of prostaglandins started to appear in the late 1960's and by the early 1970's these highly desirable substances became relatively abundant by total synthesis. Professor *E. J. Corey* of Harvard University, whose name became almost synonymous with prostaglandins, undoubtedly deserves the most credit for the synthetic work in this area. Indeed, his syntheses are among the first, the most elegant and most practical routes to prostaglandins. A great plethora of other routes and analogs soon became available. In fact, so much synthetic work has been done in the prostaglandin area that the verb "to prostaglandize" has humorously been introduced by prostaglandin chemists to mean "to beat something to death!" A number of reviews on the synthesis of the primary stable prostaglandins are already in the literature[17] and it is not the intention of this article to deal with these works.

With the finding that the effects of the endoperoxides on airway and vascular smooth muscle were considerably greater than PGE_2 and $PGF_{2\alpha}$, the attention in research has shifted from the relatively stable prostaglandins to the unstable arachidonate pathway (Fig. 1) intermediates[18]. Interest in these intermediates was further enhanced by the observation that the endoperoxides possessed the ability to induce rapid and

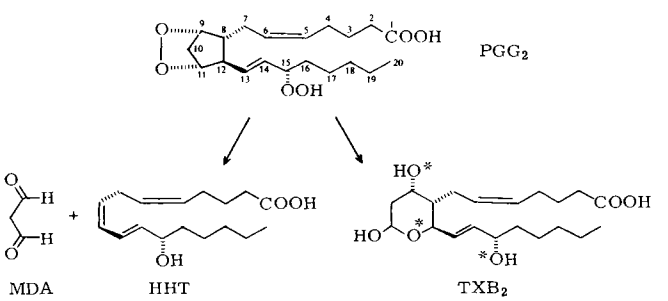

Fig. 2. Major metabolites of prostaglandin G_2 (PGG_2) in platelets: malondialdehyde (MDA), 12-hydroxy-5,8,10-heptadecatrienoic acid (HMT) and thromboxane B_2(TXB_2).

irreversible aggregation of platelets, an activity not shared by their stable counterparts[14, 16]. Several stimuli of platelet aggregation (collagen, thrombin, ADP) activate an endogenous platelet phospholipase which releases esterified arachidonic acid[19]. This free acid is instantaneously peroxidized by lipoxidase and cyclooxygenase enzymes which utilize molecular oxygen. The physiological importance of the endoperoxides, produced by platelet cyclooxygenase, has been established, since a mild hemostatic defect in a patient was found to be due to a platelet cyclooxygenase deficiency[20].

In 1969 *Piper* and *Vane*[21] described the release of a rabbit aorta contracting substance (RCS) from guinea pig lung, but again several years elapsed (1975) before *Samuelsson et al.* identified this extremely unstable molecule[22]. Two acids, thromboxane B_2(TXB_2) and 12-hydroxy-5,8,10-heptadecatrienoic acid (HHT), and malondialdehyde (MDA) were found to be the major metabolites of PGG_2 when incubated with human platelets[23, 24] (Fig. 2). Incubation of arachidonic acid with platelets under $^{18}O_2$ led to the formation of thromboxane B_2(TXB_2) labeled with ^{18}O in the three positions shown in Figure 2. In the conversion of PGG_2 to thromboxane B_2 in platelets, an extremely unstable intermediate (thromboxane A_2 $(TXA)_2$, $t_{1/2} = 30$ s) with properties similar to *Vane*'s RCS was detected by trapping experiments (Fig. 3). Thus, methanol, ethanol, or sodium azide competed with H_2O to afford the thromboxane B_2 derivatives with the hemiacetal hydroxyl group substituted by methoxy, ethoxy and azido groups, respectively. These data are in agreement with the strained bicyclic structure assigned to thromboxane A_2, which is expected to be very susceptible to nucleophilic attack at the acetal carbon to yield thromboxane B_2 or its derivatives (Fig. 3). This thromboxane A_2 structure is also in agreement with the findings that the carbon 5,6,8,9,11,12,14,15 hydrogens of arachidonic acid and PGG_2 are retained in the conversion to thromboxane B_2. Furthermore, addition of CH_3OD to platelets incubated with arachidonic acid led to the formation of mono-*O*-methylthromboxane B_2 lacking a *C*-bound deuterium atom. Therefore, the dihydropyran structure A (Fig. 3) can be excluded. Similarly, the carbonium ion B can be excluded due to its expected extremely short lifetime in aqueous medium. With the entry of thromboxane A_2 into the class of unstable intermediates (Fig. 1) the question arises as to which physiological effects are caused by endoperoxides and which are caused by thromboxanes.

However, endoperoxides are not solely converted to thromboxanes, since *Vane et al.* recently discovered that a microsomal fraction of arterial walls transforms endoperoxides into an unstable, hitherto unknown substance initially designated as PGX[1]. This latest prostaglandin was subsequently renamed PGI_2 (cf. Fig. 14) at the 1977 Prostaglandin Conference in Vail (Colorado). In most respects, its biological activity is the opposite of thromboxane A_2, inducing potent inhibition of platelet aggregation and smooth muscle relaxation. The enzyme which generates PGI_2 predominates in vascular tissue[25]. Its formation by cultured endothelium is inhibited by several fatty acid hydroperoxides (*e. g.* 15- and 12-hydroperoxyarachidonic acids, derived from platelets, see Fig. 1)[26–28].

Although the structure of this arachidonic acid pathway metabolite was postulated by *Pace-Asciak* and *Wolfe*[29] in 1971, the chemical structure of this potent inhibitor of platelet aggregation was just recently identified by *Johnson et al.*[30]

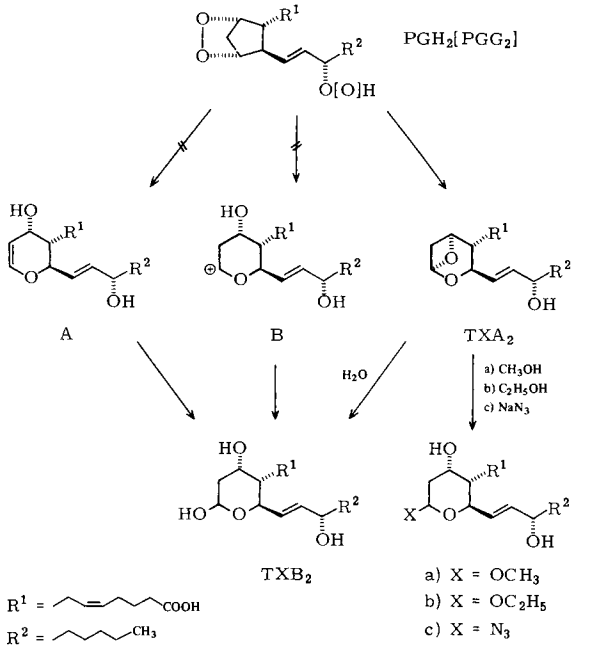

Fig. 3. Thromboxane A_2(TXA_2): Structural assignment and occurrence in metabolism.

and *Corey et al.*[31] (Fig. 4). Since the structure contains a second ring system, the name "prostacyclin" was adopted. Prostacyclin is rather unstable in aqueous, acidic or neutral media, breaking down to 6-keto $PGF_{1\alpha}$[32], in equilibrium with its lactol form (Fig. 4).

Vane and *Moncada* recently reported that prostacyclin is generated by human arterial and venous tissue from arachidonic acid *via* PGG_2 or PGH_2[2] (Fig. 4). Furthermore, they have proposed a daring homeostatic hypothesis whereby the endoperoxides serve as substrates for the generation of two labile substances with diametrically opposite biological effects.

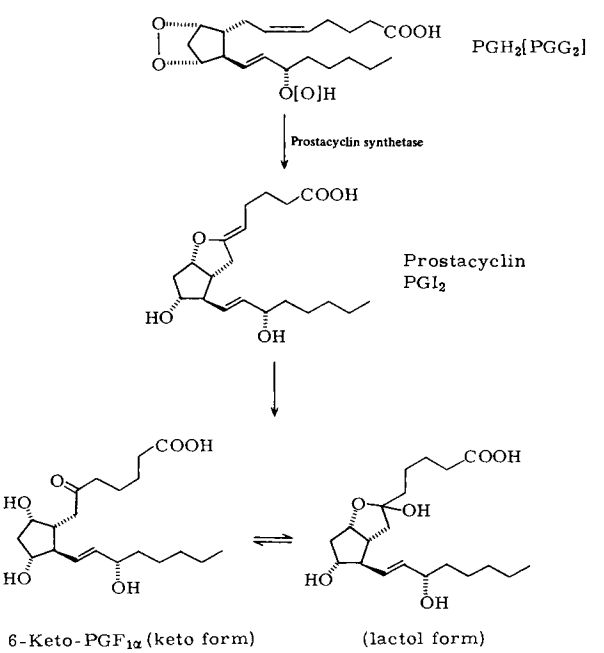

Fig. 4. Biosynthesis and degradation of prostacyclin (PGI_2, see Fig. 14).

Thromboxane A_2 generated by platelets promotes aggregation while prostacyclin produced by vascular endothelium inhibits aggregation. As corollaries they propose that 1) the basal formation of prostacyclin by vascular endothelium may be important in the maintenance of the normal integrity of vessel walls by inhibiting the adherence of platelets, 2) prostacyclin may normally limit thrombus formation, and 3) when a vessel wall is damaged, the formation of a normal hemostatic plug may be assisted by diminished prostacyclin production.

In addition to its effects on platelets, prostacyclin may play a crucial role in preventing gastric ulceration by inhibiting secretion, in blood pressure regulation by control of vascular tone, and in inflammation by inhibiting protease secretion of polymorphonuclear leucocytes. These and several other important physiological processes may be regulated by the opponent actions of thromboxane A_2 (TXA_2) and prostacyclin (PGI_2). As in the case of cyclic AMP and cyclic GMP one could invoke a similar "ying-yang" hypothesis for the diametrically opposed effects of these two substances derived from endoperoxides.

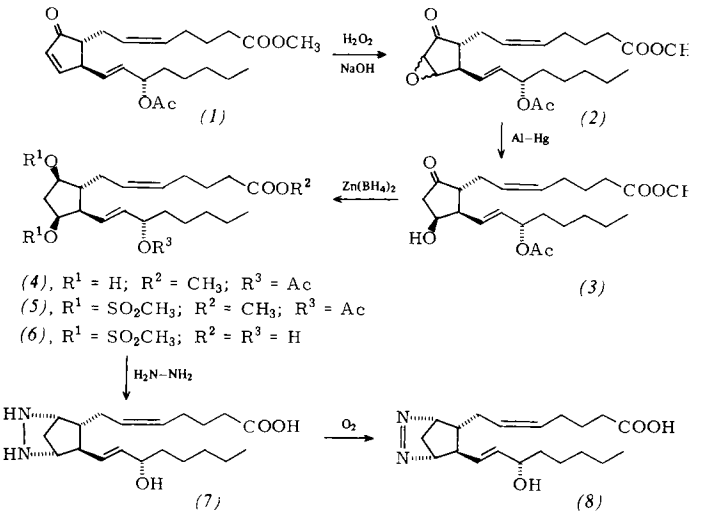

Fig. 5. Synthesis of the 6,9-azo-PGH_2 analog *(8)* from the PGA_2 derivative *(1)*.

2. Synthesis

Soon after the isolation and characterization of the prostaglandin endoperoxides H_2(PGH_2) and G_2(PGG_2) in the early 1970's[14–16] and when it was realized that these hormones were in several instances more potent than the primary prostaglandins, the design and synthesis of stable analogs of these molecules became a highly desirable goal. The synthetic chemists met this challenge with imagination successfully and rapidly, producing the first prostaglandin endoperoxide analogs in 1975. Interest in this area intensified after the isolation of thromboxanes in 1975 (*Samuelsson et al.*[22]) and prostacyclin in 1976 (*Vane et al.*[1]) and the demonstration of their remarkable biological activities. At the time that this article is being written both the prostaglandin endoperoxides H_2 and G_2 and thromboxane A_2 remain unsynthesized. The most important syntheses of prostaglandin endoperoxide analogs, thromboxane B_2 and prostacyclins reported to date are discussed below.

2.1. Prostaglandin Endoperoxide Analogs

One of the first and rather exciting developments in this area of research was the arrival of the 9,11-azo PGH_2 analog *(8)*, a highly potent and stable biological mimic of the prostaglandin endoperoxides. The first synthesis of this molecule was carried out by *Corey et al.*[33], as outlined in Fig. 5, starting from the prostaglandin A_2 derivative *(1)*, available in large quantities from the soft coral *Plexaura homoalla*[34].

The methyl ester acetate *(1)* was first converted into a mixture of the α- and β-epoxides *(2)* with basic hydrogen peroxide and then into a mixture of 11α- and 11β-hydroxy-9-oxo compounds, with aluminum amalgam, from which the β-isomer *(3)* was isolated in 29 % yield by chromatography[35]. Reduction of the 9-oxo group was effected by $Zn(BH_4)_2$ to give the diol *(4)* as the predominant product from which the dimesylate hydroxy acid *(6)* was prepared by mesylation [to *(5)*] followed by base hydrolysis. Treatment of the dimesylate *(6)* with excess hydrazine in *tert*-butanol/ethanol (3:1) under reflux for 12 h resulted in the formation of the hydrazine derivative *(7)* which was converted without isolation to the azo-PGH_2 analog *(8)* by copper(II) acetate-catalyzed air oxidation.

Widespread interest in the azo-PGH_2 analog *(8)* rapidly developed due to its high stability and remarkable potency as a biochemical mimic of the prostaglandin endoperoxides. The demand for this synthetic molecule prompted further work directed towards its synthesis, and in 1976 *Corey et al.*[36] reported a total synthesis of this molecule in its racemic form (Fig. 6). The key intermediate *(9)* was prepared from diethyl azodicarboxylate and methyl cyclopentadienecarboxylate dimers by heating in chlorobenzene at 125 °C for 50 h.

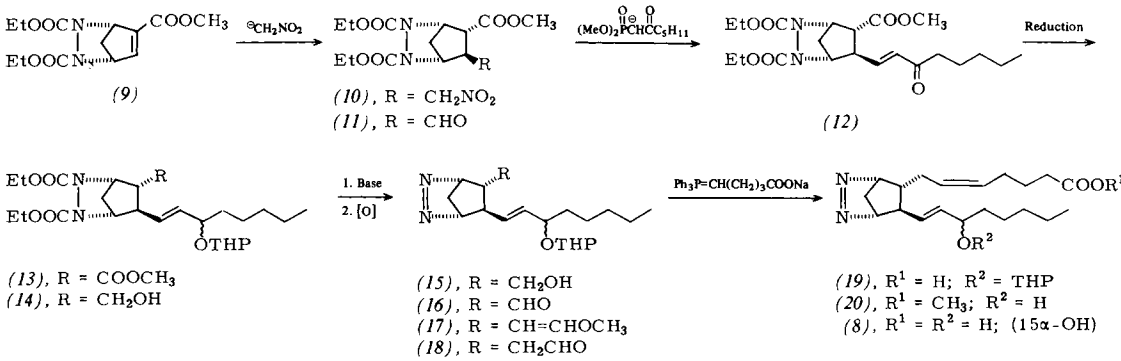

Fig. 6. Total synthesis of the 6,9-azo-PGH_2 analog *(8)*.

These conditions allow both a retro-Diels-Alder reaction of the dimers to the corresponding monomers and formation of cross adducts with the azodicarboxylate, under reversible and thermodynamic control leading to good yields of the unsaturated ester *(9)*.

Cuprate reagents failed to produce the desired products from *(9)* due to rapid β-elimination of the nitrogen bridge after the initial conjugate attack. However, conjugate addition of nitromethane was successfully carried out under carefully controlled conditions to afford the nitro compound *(10)*. The aldehyde *(11)*, obtained from *(10)* by sequential treatment with potassium hydroxide, magnesium sulfate and potassium permanganate, was converted into the enone *(12)* by the standard Emmons-Horner method and subsequently reduced with lithium selectride and protected as the tetrahydropyranyl ether *(13)* (mixture of C-15 epimers). The methyl ester *(13)* was saponified to the corresponding acid and converted to the alcohol *(14)* by $NaBH_4$ reduction of the corresponding ethyl formate mixed anhydride. Treatment of *(14)* with a strong base followed by copper(II) acetate-catalyzed air oxidation led to the azo compound *(15)*. Oxidation to the aldehyde *(16)* and subsequent condensation with methoxymethylene(triphenyl)phosphorane furnished the enol ether *(17)*. The aldehyde *(18)*, derived from *(17)* under neutral conditions [$Hg(OAc)_2$/KI] underwent the usual Wittig reaction for the attachment of the upper side chain to yield *(19)*. Esterification of *(19)* with diazomethane and removal of the tetrahydropyranyl ethers afforded the methyl esters *(20)* as a mixture of the 15α- and 15β-isomers, which could be separated chromatographically. Base hydrolysis of the 15α-alcohol led to racemic 9,11-azo-PGH_2 analog *(8)*, whereas the 15β-epimer was converted by the potassium hyperoxide/[18]-crown-6 method[37] *via* its mesylate, into the desired isomer *(8)* in high yield.

In 1975 *Bundy*[38] (Upjohn, USA) reported the stable PGH_2 analogs *(24)* and *(25)* (Fig. 7). The synthesis of *(24)* exploits an interesting, benzophenone-sensitized, photoaddition of methanol to PGA_2 *(21)*. The predominant product of this reaction[39], ketone *(22)*, was reduced selectively to the 9α-hydroxy compound with lithium perhydro-9b-boraphenalyl hydride and subsequently esterified with diazomethane and tosylated at the primary hydroxyl group to afford the tosylate *(23)*. Exposure to aqueous-methanolic potassium hydroxide led to the desired PGH_2 analog *(24)*. Synthesis of the isomer *(25)* (Fig. 7) was accomplished by conversion of the PGE_2 methyl ester *(26)* into the 9-methylene derivative *(28)* by treatment of the 11,15-bis(trimethylsilyl ether) *(27)* of *(26)* with *N*-methylphenylsulfonimidoylmethyl magnesium chloride and subsequent reductive elimination (Al—Hg) of the intermediate β-hydroxysulfoximide. Protection of the hydroxyl groups of *(28)* as triphenylsilyl ethers and selective hydroboration of the exocyclic methylene with 9-boracyclo[3.3.1]-nonane (9-BBN) resulted in the formation of the primary alcohol *(29)*, which upon mesylation and removal of the silyl groups led to the monomesylate *(30)*. Treatment of *(30)* with aqueous methanolic potassium hydroxide led to the PGH_2 analog *(25)*.

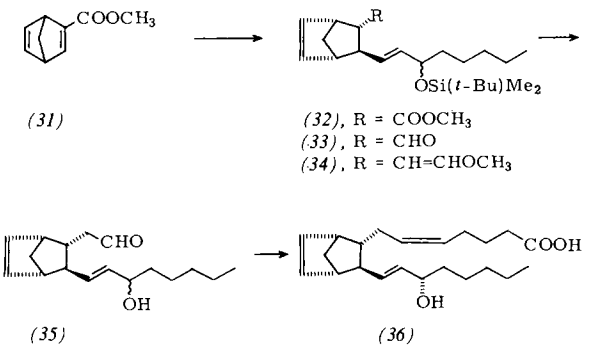

Fig. 8. Synthesis of the 9,11-etheno-PGH_2 analog *(36)*.

Later, the 9,11-etheno-PGH_2 analog *(36)* was prepared and its physiological properties investigated (Fig. 8). The first total synthesis of this stable biological mimic of prostaglandin endoperoxides was reported by *Corey et al.*[40]. These authors

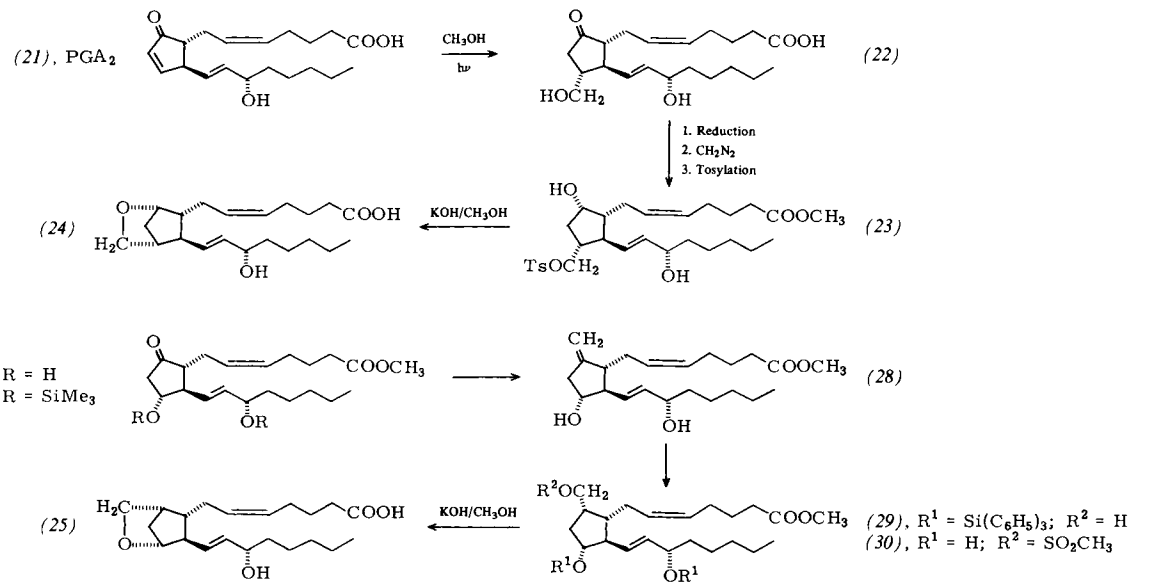

Fig. 7. Synthesis of the epoxymethano-PGH_2 analogs *(24)* and *(25)*.

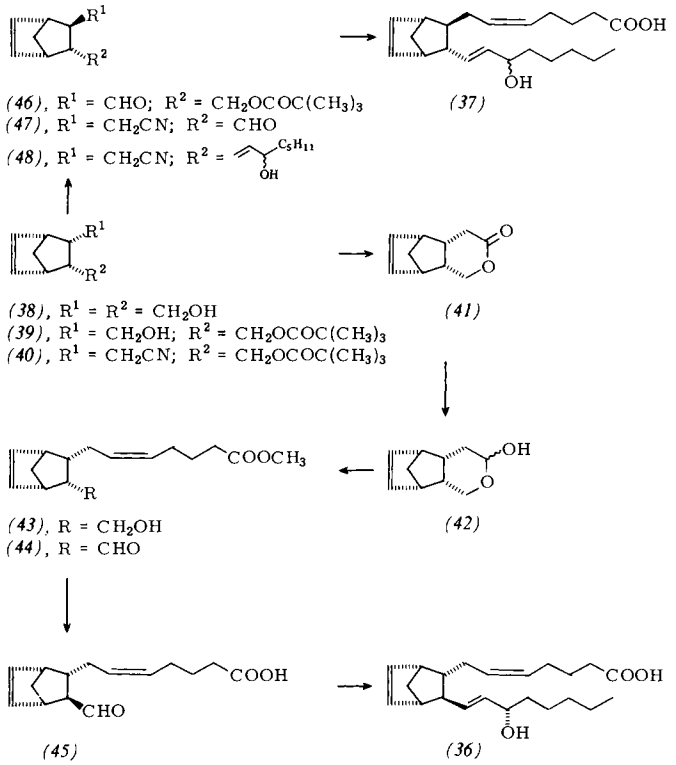
started with the adduct of cyclopentadiene and methyl propiolate *(31)* which underwent conjugate addition (from the *exo* side) with the mixed cuprate reagent derived from (±)-*trans*-3-(*tert*-butyldimethylsiloxy)-1-octenyllithium and the 1-pentynylcopperhexamethyl phosphorus triamide complex to afford *(32)*. Reduction with diisobutylaluminum hydride (DIBAH) produced a mixture of the aldehyde *(33)* and the corresponding alcohol which was treated with pyridinium chlorochromate to afford pure aldehyde *(33)*. Condensation of this aldehyde with methoxymethylene(triphenyl)-phosphorane led to the enol ether *(34)*, which was converted into the hydroxyaldehyde *(35)* on acid treatment. The 15α- and 15β-epimers of *(35)* after chromatographic separation were separately converted into the PGH_2 analog *(36)* and its 15β-epimer respectively, by condensation with the sodium salt of 4-carboxybutyl(triphenyl)phosphorane. The 15β-hydroxy isomer was transformed into the 15α-hydroxy isomer by the potassium hyperoxide method[37]. Thus, esterification (CH_2N_2), conversion into the 15-mesylate and treatment with excess potassium hyperoxide in the presence of [18]crown-6 effected clean inversion of the stereochemistry at C-15 to afford the natural epimer *(36)*, making this route a completely stereocontrolled synthesis.



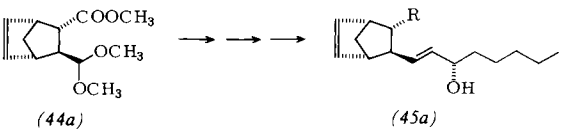


Fig. 9. Synthesis of the etheno-PGH_2 analogs *(36)* and *(37)*.

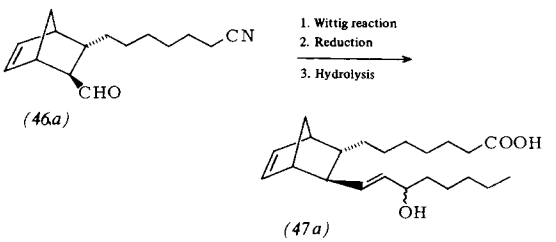
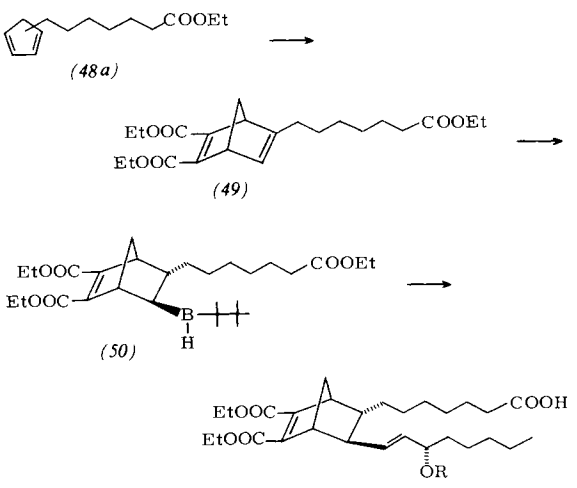
A second route to the 6,9-etheno-PGH_2 analog *(36)* was reported by a Japanese group[41], who also synthesized the 8,12-epimer *(37)*[41] starting with norbornene adducts as key intermediates (Fig. 9). The synthesis of *(36)* and *(37)* begun with the half acylation of the *cis* diol *(38)* with pivaloyl chloride to give the monoester *(39)* which was converted *via* its tosylate into the cyanoester *(40)*. Hydrolysis of *(40)* followed by treatment with hydrochloric acid afforded the lactone *(41)*, which upon reduction with DIBAH gave the lactol *(42)*. The standard Wittig reaction for attachment of the upper prostaglandin side chain[42] followed by esterification with diazomethane led to the alcohol *(43)*. This intermediate, after Collins oxidation to the aldehyde *(44)* and epimerization with pyridineacetic acid in refluxing benzene, afforded the *exo* aldehyde *(45)*. Attachment of the lower side chain by known methods[42] furnished the PGH_2 analog *(36)*.



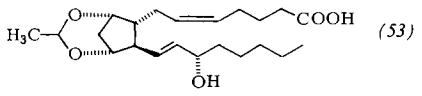
The 8,12-*epi*-etheno-PGH_2 analog *(37)* was prepared[41] by similar reactions as outlined in Figure 9. Thus, the alcohol *(39)* was oxidized with Collins reagent and the resulting aldehyde epimerized to *(46)*, which upon reduction, tosylation and cyanation followed by deprotection of the alcohol and oxidation gave the *endo* aldehyde *(47)*. Emmons-Horner condensation followed by reduction with $Zn(BH_4)_2$ led to *(48)* (mixture of diastereoisomers). Finally, reduction of the cyano group with DIBAH and reaction of the resulting aldehyde with the appropriate ylide[42] led to *(37)*, obtained as a mixture of C-15 epimers.

A series of prostaglandin endoperoxide analogs *(45a)* were synthesized and tested for biological activity by a British group[43] (ICI). The previously known bicyclo[2.2.1]heptene ester *(44a)*[44] containing the necessary functionality in the correct steric arrangement, was elaborated by the well established procedures for prostaglandin synthesis to a number of analogs *(45a)* with variations in the upper side chain (R).



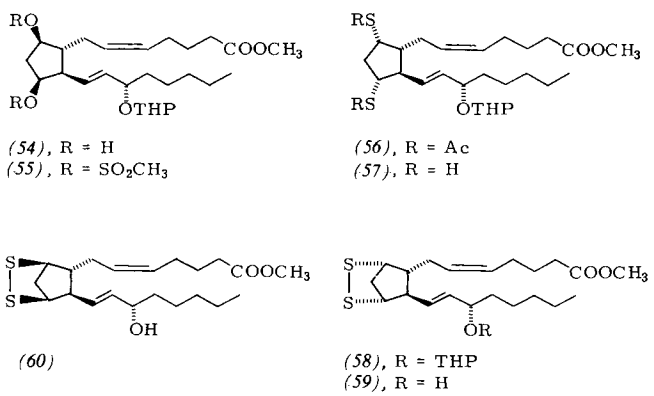
The 9,11-etheno-PGH_1 analog *(47a)* was the first prostaglandin endoperoxide analog to be synthesized. This molecule was reported as early as 1971 by *Corey et al.*[45], who carried out the synthesis of both the 15-diastereoisomers in their racemic forms from the major product *(46a)* of the Diels-Alder reaction of cyclopentadiene and *trans*-9-formyl-8-nonenenitrile. Condensation of the aldehyde *(46a)* with dimethyl 2-oxoheptylphosphonate followed by reduction of the resulting enone with $NaBH_4$ gave the expected two 15-epimeric alcohols. Base hydrolysis of the nitrile function led to the two diastereoisomers of *(47a)* in high overall yield.

The prostaglandin endoperoxide analog *(52)* has recently been described[46] although no biological data were reported. Its synthesis proceeded from the alkylated cyclopentadiene isomers *(48a)*, which underwent Diels-Alder reaction with



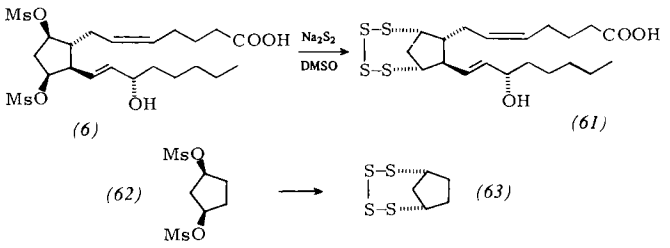
diethyl acetylenedicarboxylate to afford the bicyclo[2.2.1]heptadiene *(49)* as the predominant product. Hydroboration with thexylborane to give the presumed intermediate *(50)*, followed by sequential treatment with 3-(α-ethoxyethoxy)-1-octyne, sodium hydroxide and iodine led to *(51)* as a mixture of

isomers. Finally, removal of the ethoxyethyl group by acid treatment followed by high pressure liquid chromatography afforded pure *(52)* and its 15-epimer.



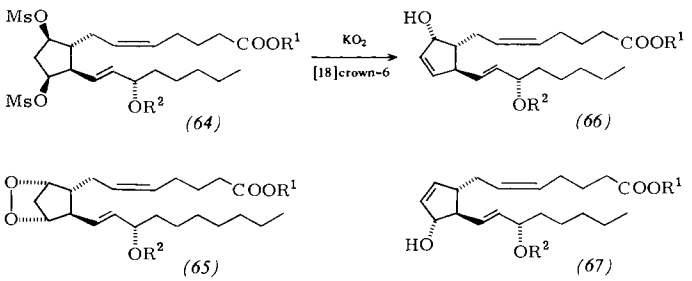
(48a) *(49)* *(50)* *(51)*, R = $CH(OEt)CH_3$ *(52)*, R = H

The same group[47] reported the synthesis and biological properties of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)-acetal *(53)* (two diastereoisomers) prepared from $PGF_{2\alpha}$ and acetaldehyde in the presence of 0.1 % HCl.



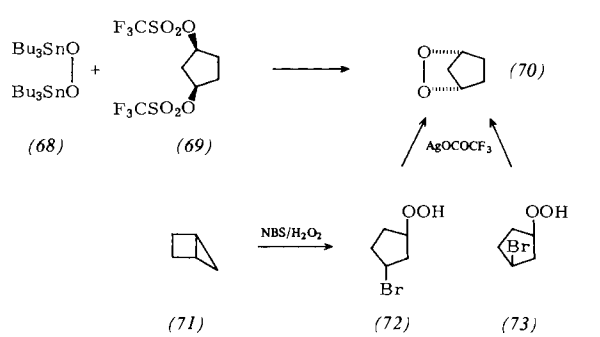
(53)

Recently the methyl ester *(59)* of the endodisulfide analog of PGH_2 and its 9,11-epimer were reported by *Hayashi et al.*[48] of the Ono company (Japan). The starting material for the synthesis of *(59)* was the 9β,11β-diol *(54)*, which was first dimesylated to give *(55)* and then reacted with excess sodium thioacetate leading to the dithioacetate *(56)*. Removal of the acetyl groups with anhydrous potassium carbonate in absolute methanol followed by oxidation of the intermediate dithiol *(57)* with manganese dioxide at low temperatures afforded the disulfide *(58)*. The methyl ester *(59)* of the disulfide PGH_2 analog was obtained after removal of the tetrahydropyranyl group by mild acid treatment. The 9β,11β-dithio analog *(60)* of PGH_2 was also synthesized starting from the 15-tetrahydropyranyl ether of $PGF_{2\alpha}$ methyl ester and following a similar sequence of reactions[48].



(54), R = H *(55)*, R = SO_2CH_3 *(56)*, R = Ac *(57)*, R = H *(60)* *(58)*, R = THP *(59)*, R = H

The reaction of disodium disulfide with the dimesyloxyhydroxy acid *(6)* produces smoothly, after air oxidation, the 6,9-endotetrasulfide analog *(61)*[49] of PGH_2. Interestingly enough this novel PGH_2 analog with the bulky 9,11-bridge behaves as a potent biochemical mimic[49] of the prostaglandin endoperoxides. Following the same methodology the interesting parent bicyclic system *(63)* was produced from 1,3-cyclopentylene dimesylate *(62)*[49].

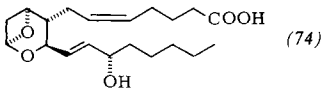


(6) *(61)* *(62)* *(63)*

To date, both prostaglandin endoperoxides H_2 and G_2 remain elusive by chemical synthesis. Attempts[50] to prepare a PGH_2 derivative such as *(65)* from the dimesylate *(64)* ($R^1 = CH_3$, H; R^2 = Ac, Si(*t*-Bu)Me_2, H) by displacement with hyperoxide failed, apparently due to the relatively drastic conditions of this method. Instead, the formation of the two isomeric allylic alcohols *(66)* and *(67)* was observed, although some endoperoxide could have been formed and not detected.

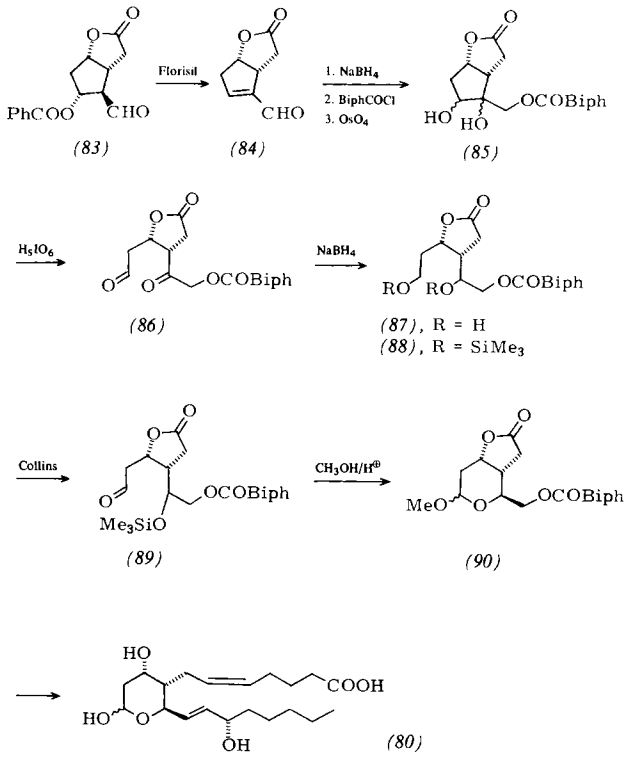
(64) *(66)* *(65)* *(67)*

Recent reports of new and milder synthetic methodology for the construction of endoperoxides are encouraging in connection with the PG endoperoxide problem. *Salomon* and *Salomon* have developed a novel method for the synthesis of dialkyl peroxides employing bis(tri-*n*-butyltin) peroxide[51] and used it to synthesize 2,3-dioxabicyclo[2.2.1]heptane *(70)*[52], the strained bicyclic peroxide nucleus of prostaglandin endoperoxides. Thus, treatment of the bis(triflate) *(69)* with bis(tri-*n*-butyltin) peroxide *(68)* under vacuum and trapping the volatile products at −78 °C, resulted in the isolation of *(70)* in 13 % yield. *Porter* and *Gilmore*[53] also developed



(68) *(69)* *(70)* *(71)* *(72)* *(73)*

a mild procedure that allowed them to prepare the parent bicyclic endoperoxide system *(70)* from bicyclopentane *(71)*. According to this method exposure of *(71)* to *N*-bromosuccinimide in the presence of 98% hydrogen peroxide in ether at −41 °C led to bromohydroperoxides *(72)* and *(73)* (1:1) as the major products. Treatment at the *trans* compound *(72)* with silver trifluoroacetate led quantitatively to 2,3-dioxabicyclo[2.2.1]heptane *(70)*. On similar treatment the *cis* isomer *(73)* also produced *(70)*, though at a much slower rate and in lower yield.



2.2. Thromboxanes

While the labile thromboxane A_2 *(74)* or any of its analogs, remain unsynthesized by chemical means, a great deal of synthetic work leading to the stable thromboxane B_2 *(80)* has already been reported. These works include partial syntheses from prostanoid precursors, total syntheses and syntheses from optically active monosaccharides.

(74)

The first thromboxane B_2 syntheses came from the Upjohn group (USA) in 1976. *Schneider* and *Morge*[54] reported an elegant and rather short route to thromboxane B_2 *(80)* from 9,15-diacetoxy-$PGF_{2\alpha}$ methyl ester *(75)*. The key step in this synthesis was a regioselective cleavage of the cyclopentane ring induced by lead tetraacetate and facilitated by the homoallyl alcohol moiety. Thus, rupture of the 11,12-bond in this fashion led to an unstable aldehyde which was protected as the dimethyl acetal *(76)* with trimethyl orthoformate and

the 4-biphenylcarboxylate was hydroxylated with osmium tetroxide to afford *(85)*. Cleavage of this diol with paraperiodic acid led to the rather unstable aldehyde *(86)* which was reduced directly with $NaBH_4$ to afford *(87)*. Differentiation of the two hydroxyl groups of *(87)* was achieved by Collins oxidation

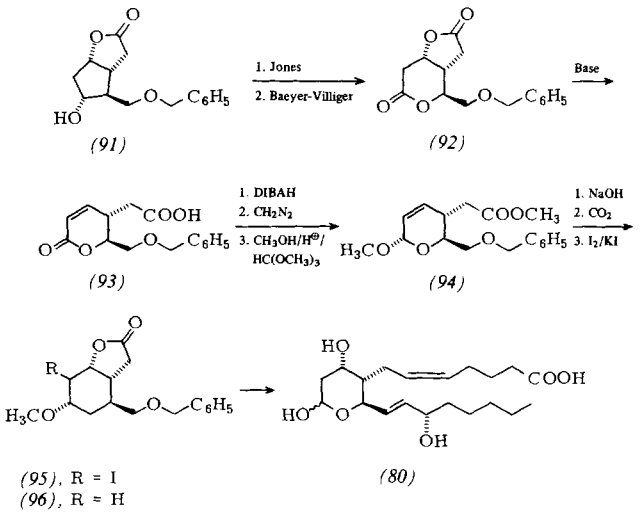
pyridine hydrochloride in methanol. Removal of the acetates with methanolic sodium methoxide afforded *(77)*, whereas aqueous base gave the trihydroxy acid *(78)*. Treatment of *(77)* with acetic acid/water/tetrahydrofuran (4:2:1) led to a mixture of thromboxane B_2 methyl ester *(79)* and its cyclic methyl acetal *(81)*. Crystalline thromboxane B_2 *(80)* was obtained as the major product along with its methyl acetal *(82)* by acid hydrolysis of *(78)* employing tetrahydrofuran/water/85% phosphoric acid (12:10:1).

Starting from the prostanoid precursor *(83)*, the Upjohn group[55] developed a second route to thromboxane B_2 *(80)*. Treatment of *(83)* with florisil resulted in the formation of *(84)* which after reduction with $NaBH_4$ and protection as of its bis(trimethylsilyl ether) *(88)*, leading to the aldehyde *(89)*. Treatment of this intermediate with acid in methanol gave the acetal *(90)*, which was transformed to thromboxane B_2 *(80)* by the conventional prostaglandin methodology[42].

Yet another synthesis of thromboxane B_2 *(80)* was developed by the Upjohn group[56] starting with the prostanoid intermediate *(91)* (Fig. 11). Jone's oxidation followed by a Baeyer-Villiger reaction with *m*-chloroperbenzoic acid gave the dilactone *(92)* which on treatment with a base led to *(93)*. Reduction with diisobutylaluminum hydride (DIBAH), esterification with diazomethane and dissolution in methanol containing hydrogen chloride and trimethyl orthoformate, afforded *(94)* as the major product. Conversion of *(94)* to



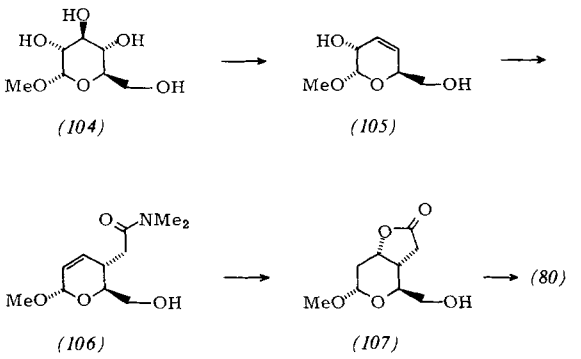


Fig. 11. Synthesis of thromboxane B_2 *(80)* from the bicyclic lactone *(91)*.

the γ-lactone *(96)* was achieved by saponification followed by iodolactonization and reductive removal of the iodine from the intermediate iodolactone *(95)* with tri-*n*-butyltin hydride. *(96)* was then converted into thromboxane B_2 *(80)* by a multistep sequence following standard prostaglandin methodology.

Canadian workers[57] have described a stereospecific total synthesis of crystalline thromboxane B_2 *(80)* from D-glucose taking advantage of the functionality and stereochemistry present in this sugar (Fig. 12).

known[59] and highly efficient sequence into the unsaturated derivative *(105)*. Claisen rearrangement of *(105)* by heating with excess *N,N*-dimethylacetamide dimethylaminal in diglyme, resulted in the stereospecific formation of the dimethylamide *(106)*. Treatment of this material with iodine readily afforded the corresponding iodolactone, which was deiodonated with tributyltin hydride leading to the hydroxylactone *(107)*, previously used as an intermediate for the synthesis of thromboxane B_2 *(80)*[54–57].

A total synthesis of (±)-thromboxane B_2 *(80)* which does not involve the intermediacy of a prostanoid precursor was developed by *Corey et al.*[60]. In this sequence, outlined in Figure 13, the enone *(108)* was alkylated with lithium isopropylamide (LDA)/allyl bromide to *(109)*, the lithium enolate

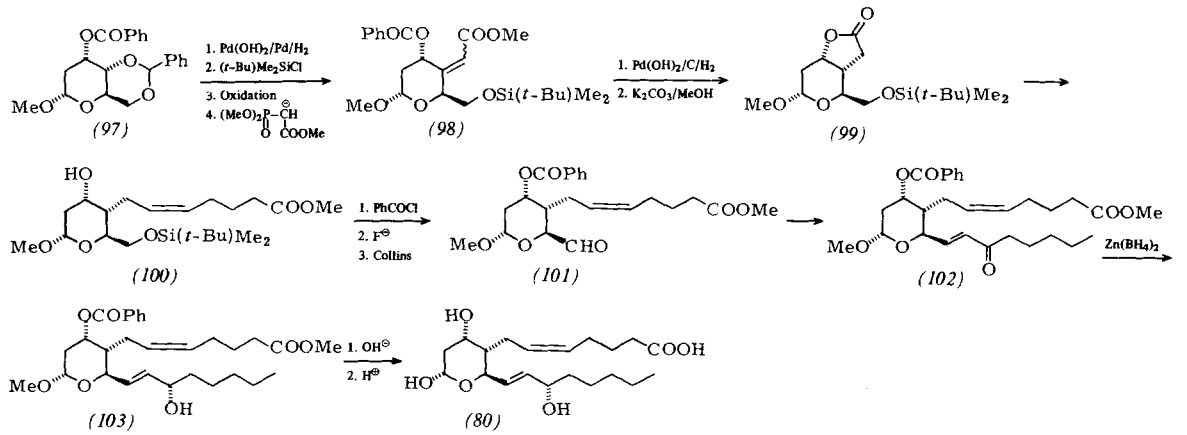

Fig. 12. Synthesis of thromboxane B_2 *(80)* from the sugar derivative *(97)*.

The derivative *(97)*, which is readily accessible from D-glucose, gave, on hydrogenolysis, selective silylation of the primary alcohol with *tert*-butyldiphenylsilyl chloride and oxidation of the secondary alcohol followed by condensation with the anion derived from trimethylphosphonoacetate and potassium *tert*-butoxide, the compound *(98)* as a mixture of geometrical isomers in high overall yield. Hydrogenation of the double bond and removal of the benzoyl groups led to the γ-lactone *(99)*. The remaining pathway followed the well known methodology of *Corey* for the attachment of the side chains.

Corey et al.[58] have also utilized sugar chemistry to produce thromboxane B_2 *(80)* by a simple and stereocontrolled route. This synthesis starts with the optically active sugar precursor α-methyl-D-glucoside *(104)*, which was converted by a of which was condensed with the aldelyde *(110)* furnishing *(111)*. Depyranylation of this intermediate led to *(112)* which, under acid conditions, cyclized to *(113)*. The protected derivative *(114)*, on reduction with $NaBH_4$, gave a diastereomeric mixture of alcohols from which the lactone *(115)* could be isolated after silver-induced removal of the thioketal function. Reduction with diisobutylaluminum hydride (DIBAH) followed by treatment with boron trifluoride in methanol led to the cyclic acetal *(116)*. Cleavage of the terminal methylene group by sequential exposure to osmium tetroxide/pyridine (to generate the diol) and sodium periodate led to the lactol *(117)*. The final steps of the synthesis involved condensation of *(117)* with the standard Wittig reagent[42] followed by exposure to 85% phosphoric acid/water/tetrahydrofuran

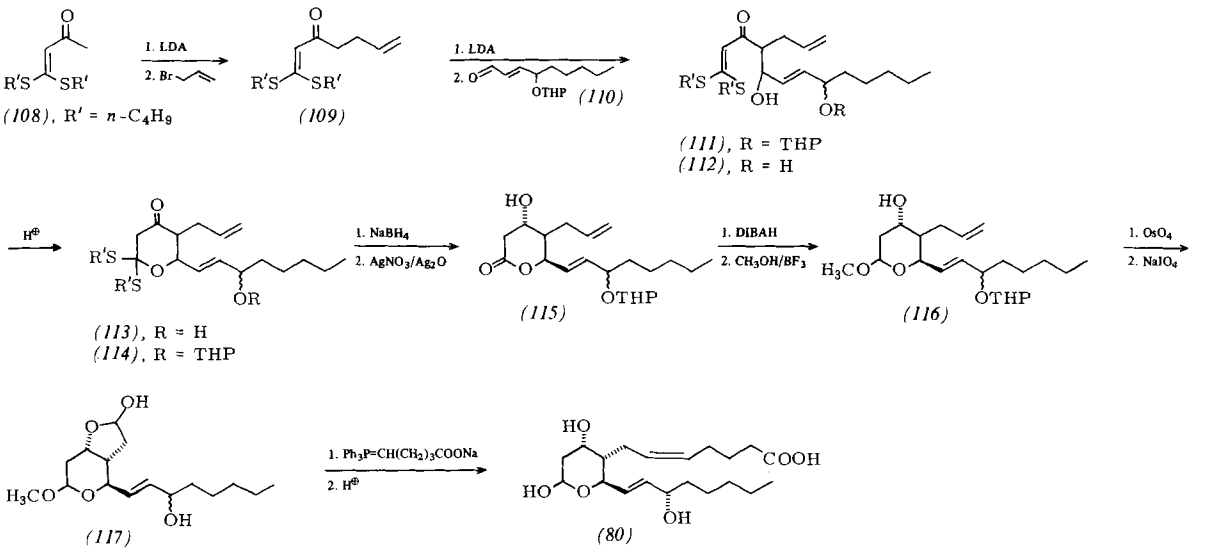

Fig. 13. Total synthesis of thromboxane B_2 *(80)* according to *Corey et al.*

(1:10:10) and chromatographic separation of thromboxane B_2 *(80)* from its 15-epimer. The 15-*epi*-thromboxane B_2 was converted into thromboxane B_2 *(80)* by (a) methyl ester-methyl acetal formation, (b) selective mesylation of the 15-hydroxyl group, (c) potassium hyperoxide/[18]crown-6 treatment to invert the C-15 configuration[37] and, (d) deprotection.

2.3. Prostacyclins

The remarkable role of prostacyclin in biological processes and its very low natural abundance dictated the need for an early chemical synthesis. *Corey* was the first to report a confirmation of the structure of prostacyclin by synthesis[31]. We have developed a simple and highly efficient synthesis[61] of this rather unstable molecule that allows its production in large quantities and in a stable form. Extensive biological investigations are now possible employing these stable basic solutions. The Upjohn group[29a] and *Hayashi*[62] have also synthesized prostacyclin and its (5*E*)-isomer. These syntheses and the syntheses of prostacyclin analogs are discussed in detail below.

The early realization that electrophilic reagents such as phenyl selenium chloride (PhSeCl) and halogens induce facile ring closure of $PGF_{2\alpha}$ derivatives to form, in high efficiency, 5-membered-ring ethers involving the C-9 oxygen and C-6, allowed us[61,63] and others[29a,31,65] to synthesize not only prostacyclin *(118)* but also a number of analogs.

Figure 14 outlines our synthesis of prostacyclin *(118)* and its isomer, (4*E*)-isoprostacyclin *(120)*. Thus, the natural form of prostaglandin $F_{2\alpha}$ methyl ester *(122)* on treatment with PhSeCl[64] in dichloromethane at −78 °C afforded the phenylselenoether *(123)* in 80% yield as a mixture of diastereoisomers. Similarly iodine reacted with *(122)* to form the iodoether *(124)* in 96% yield (mixture of diastereoisomers, in the ratio 90:6). Reaction with bromine produced a similar mixture of bromoethers *(125)*, although in lower yield. These regio- and chemospecific ring closures were expected on steric and proximity grounds. Conversion of the phenylselenoether *(123)* into the corresponding selenoxide with hydrogen peroxide followed by the expected *syn*-elimination away from the oxygen to afford a *trans* double bond, furnished the methyl ester *(121)* (95%) of (4*E*)-isoprostacyclin. Base hydrolysis of *(121)* gave (4*E*)-isoprostacyclin *(120)* in quantitative yield. Elimination of HI from either isomer of the iodoether *(124)*,

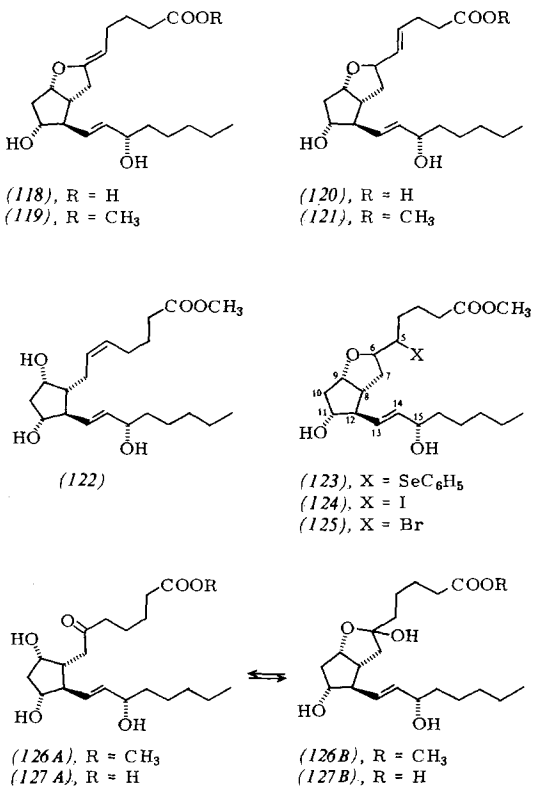

Fig. 14. Synthesis of prostacyclin *(118)* and (4*E*)-isoprostacyclin *(120)*.

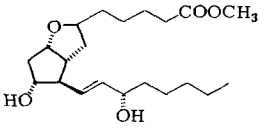
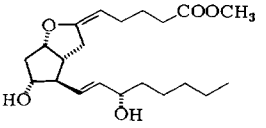


or from a mixture of the two, proceeded smoothly on exposure to sodium methoxide in anhydrous methanol at 75 °C (30 min) to afford prostacyclin methyl ester *(119)* in essentially quantitative yield. The same conversion *(124)* → *(119)* is also realized employing 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in

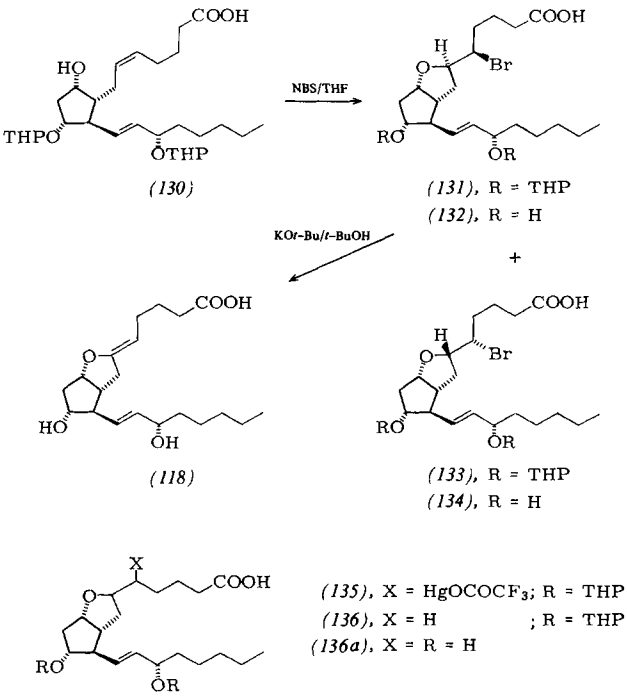
toluene at 110°C (30 min). The ethyl ester of prostacyclin is formed when sodium ethoxide in anhydrous ethanol is used. Use of 95% alcohol as solvent for the above reaction allows the production of prostacyclin *(118)* as its sodium salt. These basic ethanolic solutions of prostacyclin are stable at ambient temperatures for prolonged periods of time and can be directly used for bioassays.



Thus the choice of the electrophilic reagent to induce the cyclization of $PGF_{2\alpha}$ methyl ester to the 5-membered ring ethers could, after elimination, lead selectively and in high overall yield to either prostacyclin *(118)* or (4*E*)-isoprostacyclin *(120)* (two C-6 epimers) by short and simple routes. Furthermore, reductive removal of the phenylseleno (PhSe—) group (or the iodide) with tri-*n*-butyltin hydride leads to the 5,6-dihydroprostacyclin methyl ester *(128)* (two C-6 epimers) in 90% yield[66].

The prostacyclin methyl ester *(119)*, although relatively stable in neutral or basic media, rearranges rapidly under acid conditions to 6-keto-$PGF_{1\alpha}$ methyl ester *(126A)*, in equilibrium with its lactol form *(126B)*. Prostacyclin *(118)* is stable in basic media but shows even higher instability under neutral or acidic conditions than its methyl ester towards formation of 6-keto-$PGF_{1\alpha}$ *(127A)*, in equilibrium with its lactol form *(127B)*. Unlike prostacyclin, (4*E*)-isoprostacyclin *(120)* is stable at ambient temperatures in both basic or acidic media.

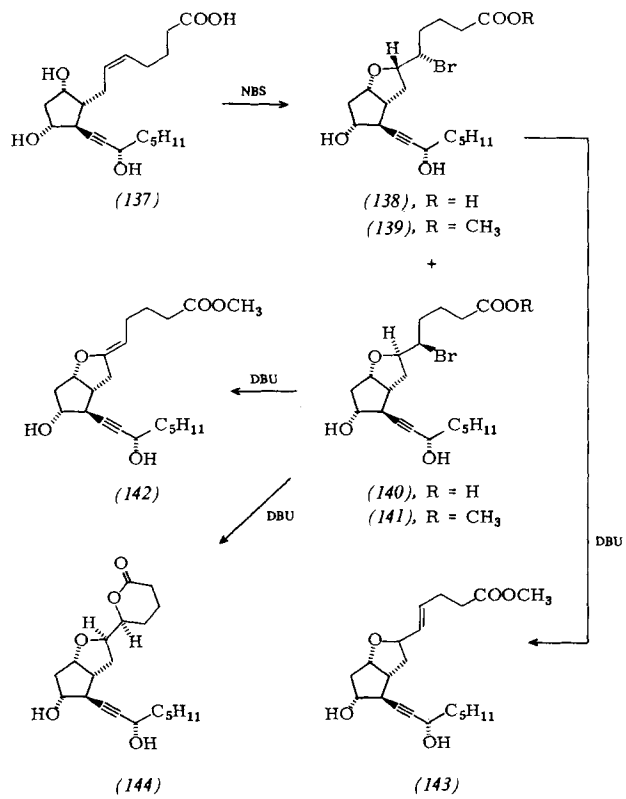
Similar methodology has been employed by Upjohn scientists in their synthesis[29a] of prostacyclin *(118)*. Utilizing the iodoether *(124)* (Fig. 14) they have synthesized prostacyclin methyl ester *(119)* employing 1,5-diazobicyclo[4.3.0]non-5-ene (DBN) or potassium hyperoxide (KO_2) as base, and 5,6-dihydroprostacyclin methyl ester *(128)* utilizing tri-*n*-butyltin hydride to remove the iodine. Starting with 5-*trans*-$PGF_{2\alpha}$



(128)

(129)

methyl ester and following the same methodology the methyl ester *(129)* of the (5*E*)-isomer of prostacyclin was synthesized[29a]. Interestingly, the (5*E*)-isomer *(129)* or the corresponding acid do not show the biological properties of prostacyclin *(118)*. *Corey*[31] and *Hayashi*[62] have also prepared the (5*E*)-isomer of prostacyclin.



Corey's prostacyclin synthesis[31] starts with the 11,15-bis(tetrahydropyranyl) ether of $PGF_{2\alpha}$ *(130)*, which underwent bromoetherification on treatment with *N*-bromosuccinimide (NBS) in tetrahydrofuran (THF) to afford a mixture of the bromoethers *(131)* and *(133)*. This mixture was converted by mild acid treatment into the dihydroxybromoethers *(132)* and *(134)*, which were separated chromatographically (3:1 ratio). Prostacyclin *(118)* was produced from the major isomer *(132)* on exposure to potassium *tert*-butoxide in *tert*-butanol at 45°C and isolated by careful extraction at low temperatures. The bromoether *(134)* did not react under similar conditions and was recovered unchanged. Using the same starting material *(130)* and employing the selenium-based methodology[64], *Corey et al.* obtained the two isomers of (4*E*)-isoprostacyclin *(120)*[63] by the sequence (a) exposure to PhSeCl, (b) depyranylation with mild acid, and (c) oxidation with excess hydrogen peroxide[31].

(130); *(131)*, R = THP; *(132)*, R = H; *(118)*; *(133)*, R = THP; *(134)*, R = H; *(135)*, X = $HgOCOCF_3$; R = THP; *(136)*, X = H; R = THP; *(136a)*, X = R = H

The C-6 epimers *(136a)* of 5,6-dihydroprostacyclin were obtained by *Corey et al.*[31] from *(130)* by sequential treatment with mercury(II) trifluoroacetate [*(130)*→*(135)*], $NaBH_4$ [*(135)*→*(136)*] and acetic acid/tetrahydrofuran/water (3:1:1).

Recently the synthesis of 13,14-dehydroprostacyclin methyl ester *(142)* was reported by *Fried* and *Barton*[65]. Treatment of 13,14-dehydro-$PGF_{2\alpha}$ *(137)* with *N*-bromosuccinimide led

(137); *(138)*, R = H; *(139)*, R = CH_3; *(142)*; *(140)*, R = H; *(141)*, R = CH_3; *(144)*; *(143)*

to a 1:4 mixture of the cyclic bromoethers *(138)* and *(140)*. The methyl ester *(141)* of the major isomer on treatment with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) furnished 13,14-dehydroprostacyclin methyl ester *(142)* in high yield. Similar treatment of the methyl ester *(139)* of the minor isomer was claimed to yield the (4*E*)-13,14-dehydroisoprostacyclin methyl ester *(143)*. This interesting pathway was suggested to originate from internal base abstraction of one of the C-4 hydrogens by the C-11 hydroxylate anion. The lactone *(144)* is formed from *(140)* on treatment with DBU.

We have recently synthesized several sulfur containing prostacyclins[66], and preliminary investigations indicate interesting biological properties[67] such as high potency and a higher stability than prostacyclin (cf. Addendum).

3. Biological Properties

The great enthusiasm generated in the biological sciences over the unstable prostaglandin endoperoxides, thromboxanes, and prostacyclin has quickly spread into the sector of synthetic chemistry. Several types of prostaglandin endoperoxide analogs, synthetic thromboxane B_2, synthetic prostacyclin, and various prostacyclin analogs have resulted from recent synthetic endeavors. The elegant synthetic work carried out by *Corey*'s group and other groups has produced analogs that are more stable than their natural counterparts, and in some cases more potent. With regards to the prostaglandin endoperoxides, these analogs have facilitated inquiry into the mechanism of endoperoxide-induced platelet aggregation, cardiovascular regulation by endoperoxides, the endoperoxide-induced release of renin and thyroid hormone, and the role of endoperoxides in the inflammatory process. In contrast to the prostaglandin endoperoxides, little if any investigation has probed the physiological role of thromboxane B_2, and the lack of isolated thromboxane A_2 or a stable mimic of it has hampered progress in definitively establishing the role of thromboxane A_2. Temporarily, prostacyclin has overshadowed research in this essential area. In a short span of time, several groups have synthesized this interesting molecule. Also, several more stable but less potent analogs have been synthesized, and prostacyclin has stimulated research dealing with its involvement in blood pressure regulation, shock, lysozomal stabilization, and various types of inflammation. The importance of these prostaglandins in physiology and medicine and the challenge they pose to synthetic chemistry places them in the forefront of chemical and biochemical investigation.

3.1. Naturally Occurring Prostaglandin Endoperoxides and Thromboxanes

Previous studies of the roles of prostaglandins as cellular regulatory agents have now been reexamined in light of the recent discoveries of the unstable prostaglandin intermediates. These short-lived molecules are, in some instances, hundreds of times more potent than the primary prostaglandins. Endoperoxides and thromboxanes have been implicated in such widely divergent processes as smooth muscle contraction[14], platelet aggregation[16], chemotaxis[68-71], inflammation[72], phagocytosis by polymorphonuclear leucocytes[73], the release of renin and thyroid hormone[3], and the induction of spawning in molluscs[74]. These intermediates have been detected in several types of tissues[75, 76]. All these findings have come about within the last five years.

Although the formation of an endoperoxide during prostaglandin biosynthesis was first proposed by *Samuelsson* in 1965[13], the isolation of this intermediate (PGH_2) from sheep vesicular gland homogenates took place eight years later. In the same year (1973) an additional endoperoxide (PGG_2) carrying a hydroperoxy group at the C-15 position was isolated[15, 16]. PGH_2 and PGG_2 are stable for months at $-20\,^{\circ}C$ in dry acetone, but rapidly decompose in aqueous media at $37\,^{\circ}C$. Their effects upon various *in vitro* smooth muscle preparations are considerably greater than those of PGE_2 and $PGF_{2\alpha}$.

Although the addition of arachidonic acid to platelets causes aggregation and prostaglandin formation[77], neither of the endogenously formed primary prostaglandins, PGE_2 and $PGF_{2\alpha}$, cause aggregation. Recent evidence has established that aggregation of human platelets induced by collagen, thrombin, epinephrine, and arachidonic acid is partially mediated through the production of prostaglandin endoperoxides PGG_2 and PGH_2[77, 83]. These platelet stimuli liberate arachidonic acid from the C-2 position of phospholipids by activation of phospholipase A_2[19, 84]. Therefore, the activation of the arachidonate pathway in platelets can be viewed as an amplification system for signals reaching the platelet cell surface.

Since not only endoperoxides, but also thromboxanes are formed during aggregation, either or both acting in concert may cause aggregation when the arachidonate pathway is activated[21, 78]. Thromboxane B_2 is relatively inert in terms of aggregation. At present, it is unknown whether endoperoxides must be converted into thromboxane A_2 for aggregation to occur. It is clear that thromboxane A_2 is a much more potent inducer of platelet aggregation, and inhibitor of PGE_1-stimulated cyclic AMP accumulation than PGH_2[79]. Although several agents have recently been reported as selective thromboxane synthetase inhibitors[80-82], their multiple side effects make interpretations difficult. They are used in relatively large quantities and at these concentrations they also inhibit prostacyclin synthetase. Resolution of this question may hinge upon the development of a stable biological mimic of thromboxane A_2. Although the exact arachidonate pathway intermediate responsible for aggregation is still in doubt, several aggregating agents exert their effects, in part, through the activation of this pathway.

Two products of arachidonate metabolism, namely prostaglandin endoperoxides and thromboxane A_2, also have profound effects upon vascular smooth muscle[85-87]. The endoperoxides PGG_2 and PGH_2 have been reported to contract porcine coronary and rabbit aorta[85], while they cause a transient contraction followed by relaxation in bovine coronary[27]. Recent evidence suggests that the relaxatory effects of these endoperoxides result from prostacyclin production, and that vessel preparations which do not exhibit this relaxatory activity have lost their prostacyclin synthetase activity[27]. Although thromboxane A_2 profoundly contracts all three vessels, none of the above were found to possess thromboxane A_2 synthetase activity[85]. However, human umbilical artery does contain this thromboxane synthetase activity. In addition,

thromboxane A_2 can be synthesized by circulating platelets when they are aggregated by endothelial injury. *Needleman*[85] has suggested, that coronary tone, and possibly spasm, in ischemic myocardial zones may be influenced markedly by the interplay between prostaglandins, endoperoxides, and thromboxanes formed by platelets on the one hand, and endoperoxide products (thromboxane or prostacyclin) synthesized endogeneously in the coronary arteries on the other. Likewise the modulation of vascular tone may be very important in the regulation of blood pressure.

Endoperoxides and thromboxanes may also have a pivotal role in the inflammatory processes[72]. Since the discovery that non-steroidal anti-inflammatory agents (aspirin, indomethacin) are potent inhibitors of prostaglandin synthetase[88-90] primary prostaglandins were thought to mediate the inflammatory process. However, administration of these primary prostaglandins does not fully mimic inflammation[91]. Recently, *Vane*[91] has suggested that endoperoxides and thromboxane A_2 play a major role in inflammation. Furthermore, *Kuehl et al.*[72] have demonstrated that MK-447 (2-aminomethyl-4-*tert*-butyl-6-iodophenol), which accelerates the conversion of PGG_2 into PGH_2, decreases inflammation. In focussing on this endoperoxide it is necessary to consider that PGG_2 itself may not be the active triggering agent in acute inflammation, but merely the precursor of such a substance. Thromboxane A_2 or 15-hydroperoxythromboxane A_2 may be the agents directly responsible. Alternatively, the free radical formed in the metabolism of PGG_2 and tentatively identified as a hydroxy radical[92] may be the inflammatory component liberated in the oxidation of arachidonic acid. In addition MK-447 stimulated overall primary prostaglandin synthesis in ram seminal vesicle microsomes. These observations that both inhibitors and stimulators of primary prostaglandin formation can suppress inflammation, can be interpreted as to implicate a labile prostaglandin intermediate in the inflammatory processes. Also implicated in inflammation is bradykinin, whose generation precedes or accompanies prostaglandin release in inflammatory exudates. By stimulating phospholipase A_2, bradykinin makes available arachidonic acid for prostaglandin precursors. Another interesting observation is that thromboxane B_2 promotes chemotaxis[69,70] of polymorphonuclear leucocytes, important mediators of inflammation.

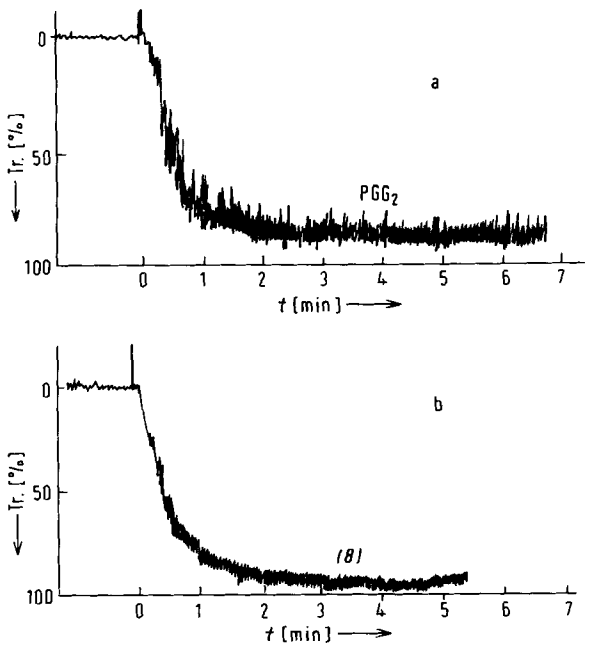
Further investigation is required to elucidate the mechanism of prostaglandin endoperoxide and thromboxane action. An intriguing possibility is that they act as calcium ionophores, transporting calcium across membranes down the calcium concentration gradient. In such a manner, they could cause smooth muscle contraction and platelet aggregation. *Reed*[93] has very recently described the weak ionophore activity of endoperoxides and their analogs in transporting calcium from an aqueous phase to an organic phase and in uncoupling mitochondrial succinate oxidation.

3.2. Prostaglandin Endoperoxide Analogs

Two years prior to the isolation of the prostaglandin endoperoxides (PGH_2 and PGG_2) from sheep vesicular gland homogenates, the first endoperoxide analog was synthesized[45]. This bicyclo[2.2.1]heptene derivative *(47a)* resembles PGH_1, since it lacks the double bond between C-5 and C-6. Biologically, this PGH_1 analog proved to be a weak inhibitor of the isomerase enzyme forming PGE_1 in sheep vesicular gland microsomes[45]; however, it had no effect on the reductase catalyzing the formation of $PGF_{1\alpha}$[45]. At that time, there were several reports on the inhibition of prostaglandin formation by various unsaturated fatty acids and the synthesis of this analog did not stimulate further synthetic endeavors. In light of the minor biological activity this analog displayed, further development of PGH_2 analogs was postponed until the physiological role of prostaglandin endoperoxides was better understood.

The pace of research in this field was markedly accelerated by the discovery of the high potency of the endoperoxides in contracting smooth muscle and aggregating platelets[16]. Almost simultaneously, *Corey*[33] and *Bundy*[38], published their syntheses of the first PGH_2 analogs. Beginning with a PGA_2 skeleton, *Corey* synthesized the 9α,11α-azo-PGH_2 *(8)*, while *Bundy* produced the epoxymethano-PGH_2 analogs *(24)* and *(25)*. At once these analogs had an impact on biological research, facilitating the study of the physiological role of the prostaglandin endoperoxides. These analogs possess very nearly the same molecular geometry as PGH_2, but enjoy greater stability at pH = 7.0 and 37°C. Although there was no assurance *a priori* that these analogs would behave as mimics rather than antagonists of PGH_2, the emerging importance of the endoperoxides made the synthesis of these and other analogs highly desirable. Table 1 shows the various PG endoperoxide analogs synthesized to date.

Since the azo-PGH_2 *(8)* is the most potent and extensively studied endoperoxide analog, its biological properties will be considered in detail. Like the endoperoxides, the azo analog causes rapid and irreversible aggregation of platelets in platelet rich plasma (Fig. 15) and release of ^{14}C-serotonin from prelabeled platelets (Fig. 16). However, the azo compound was



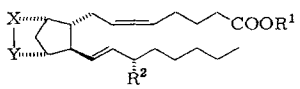


Fig. 15. Platelet aggregation in platelet rich plasma (from the same donor) induced by a) 1 μmol/l PGG_2 and b) 0.1 μmol/l azo-PGH_2. The compounds were added at zero time. Tr = light transmission.

[c] Effects aggregation.

almost eight times more potent than PGG_2 in inducing aggregation (Fig. 17) and six times more active with respect to serotonin release (Fig. 16). Although both compounds cause much faster release than such aggregating agents as ADP, thrombin, and collagen, release induced by the azo compound was not as fast as PGG_2 (Fig. 16). A significant difference between PGG_2 and the azo analog (Fig. 16) as reported, is the continued release of serotonin with the azo analog as opposed to the rapid re-uptake with PGG_2. The reason proposed for this difference is the increased metabolic stability of the azo analog.

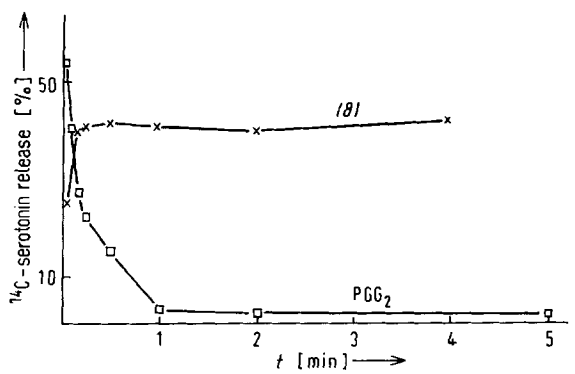

Fig. 16. ^{14}C-serotonin release from prelabeled platelets by PGG_2 (1 μg/ml) (□) and azo-PGH_2 *(8)* (0.2 μg/ml) (×).

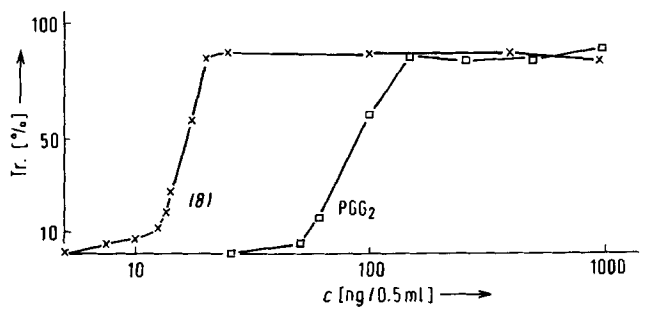

Fig. 17. Dose (log scale)-response in platelet aggregation induced with PGG_2 (□) and azo-PGH_2 *(8)* (×). Tr = light transmission.

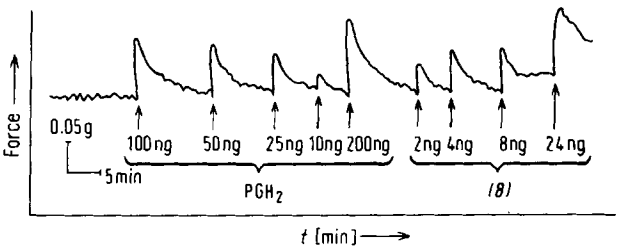

Fig. 18. Contractile effects of PGH_2 and azo-PGH_2 *(8)* on strips of rabbit aorta.

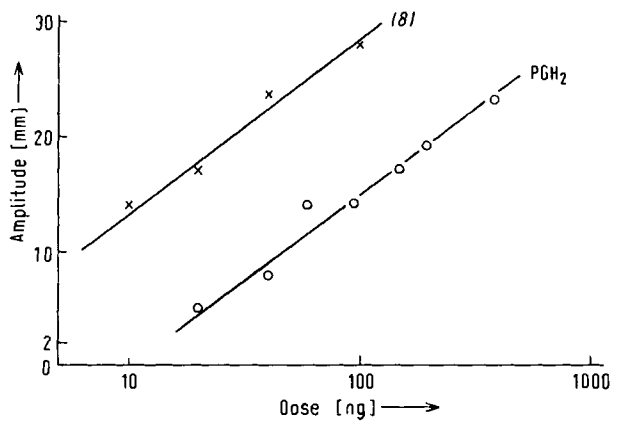

Fig. 19. Dose (log scale)-response of the contractile effect of PGH_2 (○) and azo-PGH_2 *(8)* (×) on strips of rabbit aorta.

Another system which is sensitive to the endoperoxides PGG_2 and PGH_2 as well as the azo analog *(8)*, is the rabbit aorta strip (Fig. 18). The azo analog is, however, seven times more active in contracting this smooth muscle than PGH_2 (Fig. 19) and 1500 times more potent than the primary prostaglandin $F_{2\alpha}$.

The properties of the azo analog are presently being studied with respect to release of renin and thyroid hormone. The azo analog will be of considerable value in studies related to the biological role of the unstable prostaglandin endoperoxides.

Recently, *Malmsten* has reported[94] on the biological activity of the two epoxymethano analogs *(24)* and *(25)* which also mimic the effects of the endoperoxides on platelets and rabbit aorta. The 11α,9α-epoxymethano-15-hydroxyprosta-5,13-dienoic acid *(25)* is 3.7 times more potent than PGG_2 in eliciting contractions of isolated rabbit aorta. This analog induces platelet release reaction, but is less active than the endoperoxide in this respect. Furthermore, the release of ^{14}C-serotonin induced by this analog is inhibited by indomethacin, indicating that endogenous endoperoxide production is required. Interestingly the corresponding 9α,11α-isomer *(24)* was less active than PGG_2 in the test system employed[94].

Several other analogs of PGH_2 (Table 1) have been synthesized and in some cases their biological properties have been determined. For instance, even the bulky acetal endoperoxide analog *(53)* has some activity in aggregating platelets and contracting smooth muscle[47]. The utility of such analogs will become more apparent when the endoperoxide receptor is studied.

The endodisulfide analog of PGH_2 *(59)*[48] is also of special interest, since a dithio linkage is chemically more stable than a peroxide moiety and the molecular geometry of this structure approximates that of PGH_2. This cyclic disulfide *(59)* is reported[48] to be 24 times more potent than PGH_2 in contracting aorta strips, making it the most active smooth muscle contracting analog. Rapid and irreversible aggregation occurs when this disulfide analog is added to washed platelets[48]. Even more interesting is the finding that platelet aggregation occurs when the endotetrasulfide PGH_2 analog *(61)*[49] is added to platelet rich plasma, indicating that the bulky sulfur groups are accommodated by the endoperoxide receptor.

The azo- and epoxymethano-15-deoxy-PGH_2 analogs *(145)* and *(146)*, lacking the oxygen at the C-15 position, were reported[26, 95] to possess significant thromboxane synthetase inhibiting activity although they also inhibit prostacyclin synthesis to some extent.

3.3. Prostacyclin

The discovery late in 1976[1] of a novel prostaglandin which was found to be the most potent inhibitor of platelet aggregation known has not only revolutionized current concepts in thrombosis and hemostasis but has also intensified the pace in one of science's fastest developing fields. This discovery came only one year after the finding that thromboxane A_2 was an extremely effective vasoconstrictor and platelet aggregator, two properties which promote thrombus formation[22]. Since this new prostaglandin, named prostacyclin (PGI_2 *(118)*), has diametrically opposite effects, *Moncada* and *Vane* have proposed that a balance between the activities of these prostaglandins determines thrombosis and hemostasis[25, 27, 28]. Taking into consideration only prostacyclin's vasodilatory and anti-aggregating properties, this local hormone has already earned a position of foremost importance in medicine.

Each year stroke and heart attack claim thousands of lives, and the formation of small clots and thrombi in circulation is a major contributing factor to these deaths. In addition, endothelial injury appears to be a prerequisite for thrombus formation. *Moncada* and *Vane*[2] have shown that prostacyclin is synthesized by human arteries and veins and the enzyme that generates PGI_2 is located in the endothelium, the innermost lining of blood vessels. These investigators suggest that basal prostacyclin formation may be important in maintaining the normal integrity of endothelium by inhibiting platelet adhesion, and that prostacyclin may normally limit thrombus formation. Recent evidence by *Minick et al.*[96] indicates that lipid accumulation is greatest beneath damaged endothelium which is regenerating. This lipid accumulation constitutes one of the initial phases of atherosclerotic plaque formation. Since *Moncada* and *Vane*[27, 28] have demonstrated that lipid hydroperoxides (*e.g.* 15-hydroperoxyarachidonic acid) effectively inhibit prostacyclin synthetase, the presence of these hydroperoxides in atherosclerotic plaques might explain the increased incidences of thrombosis in atherosclerotic patients. Therefore, endothelial injury is necessary for both thrombus and plaque formation, two processes which are central to cardiovascular disease.

Platelets have also been implicated as instrumental agents in the blockage of coronary and cerebral arteries. A growth factor released from platelets as well as low density lipoprotein will lead to increased proliferation of vascular smooth muscle cells and fibromuscular intimal thickening[97–99]. Such thickening will decrease the internal vessel diameter. Stroke or heart attack will occur when such a diseased vessel is contracted by thromboxane A_2 or occluded by a thrombus. Prostacyclin would prevent both events by inhibiting thrombus formation and dilating smooth muscle. Further investigation is required to determine if PGI_2 would also inhibit release of platelet growth factor.

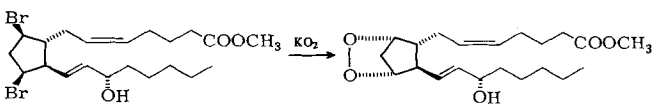
Although the majority of investigations with prostacyclin have been carried out *in vitro*, investigators are beginning to explore the effects of PGI_2 *in vivo*. *P. W. Ramwell*[105] and *A. M. Lefer*[101] have found that systemic infusion of PGI_2 markedly reduces blood pressure in cats, dogs, and rhesus monkeys. The proposed mechanism for this action is a vasodilatory induced decrease in resistance to blood flow of the systemic circulatory system. Prostacyclin may also be useful in the treatment of several types of shock. For example, in hemorrhagic shock, vasoconstriction may severely limit the flow of blood to the gut and kidneys. Replacement of the blood volume lost will easily redilate the gut vessels but flow through the kidney may be impeded for a long period of time. During this interval the kidneys may infarct. In addition, prolonged vasoconstriction in the gut region may release proteases from liver and pancreatic lysozomes. Prostacyclin may attenuate these deliterious effects by maintaining a small amount of blood flow through these areas.

Despite the large amount of physiological work with prostacyclin, relatively little has been done to determine its mode of action. Recently, prostacyclin has been shown to elevate cyclic AMP concentrations in human platelets[102, 103]. This elevation of cyclic AMP inhibits hydrolysis of arachidonic acid from platelet phospholipids, and prevents the production of endoperoxides[104]. Whether inhibition of aggregation is also due to cyclic AMP elevation still remains to be determined.

3.4. Prostacyclin Analogs

In light of the physiological importance of prostacyclin *(118)* and its unstable nature, the design of stable prostacyclin

mimics merits high priority. Up to date, a number of analogs have been reported[31,63,65]: 5,6α- and 5,6β-dihydroprostacyclin [cf. *(128)*]; (4*E*)- and 6-epi(4*E*)-isoprostacyclin [cf. *(120)*]; 13,14-dehydroprostacyclin methyl ester *(142)*. Only the last of these, which closely resembles PGI_2, possesses activity comparable to prostacyclin[65]. All the other analogs are several times less potent than the natural product[105]. Recently, we have synthesized a sulfur analog of prostacyclin[66] which has divergent activities. Its potency in inhibiting platelet aggregation is between two to four times less than the natural product[67]. However, thiaprostacyclin is considerably more stable at neutral pH. In contrast to the vasodilatory effects of prostacyclin, the sulfur-analog is a potent constrictor of isolated cat coronary artery[67]. In this regard, it mimics the endoperoxides (PGG_2 and PGH_2) and thromboxane A_2.

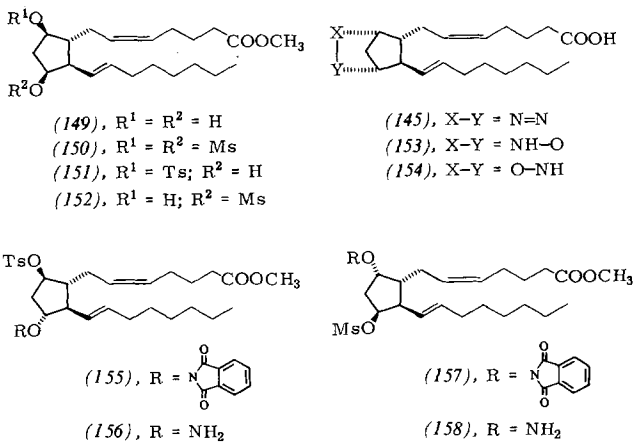


4. Conclusion

Without a doubt, prostaglandin research is one of the most exciting and fastest developing areas in synthetic chemistry, biochemistry, physiology, and medicine. Since the beginning of the prostaglandin era these local hormones have had great potential as therapeutic agents. Today, a number of synthetic prostaglandins are already in use in human and veterinary medicine and many more are currently under clinical investigation. The discovery of the very active unstable prostaglandin endoperoxides, thromboxanes, and most recently, prostacyclin, has significantly augmented interest in them. The optimists are more excited than ever that these developments will lead to the long-sought specific pharmacological agents for the treatment of a wide spectrum of diseases.

It is greatly hoped that this article has gathered together useful information for chemists, biochemists, physiologists, and pharmacologists and that these scientists will use this information as a platform from which they will view the future challenges with excitement and imagination.

5. Addendum



Since the preparation of the original manuscript, a number of significant developments in this area have been reported. This addendum contains some of these results concentrating on the chemistry and is intended to bring the present article up to date at the time of the 1978 Winter Prostaglandin Conference (January, 1978, Sarasota, Florida, USA).

(147) *(148)*

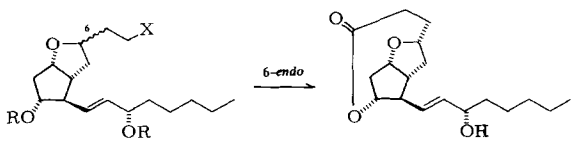
PGH_2 methyl ester *(148)* has been synthesized chemically for the first time by *Johnson et al.*[106] of the Upjohn Company from the dibromide *(147)*. This precursor was obtained from $PGF_{2\alpha}$ methyl ester by a multistep sequence and reacted with potassium hyperoxide in dimethylsulfoxide (DMSO)[37] in the presence of [18]crown-6[37] under carefully controlled conditions to afford the PGH_2 derivative *(148)* in very low yield. Studies on the thermal decomposition of 2,3-dioxabicyclo-[2.2.1]heptane *(70)* have been published[107].

A number of 15-deoxy-PGH_2 analogs with interesting properties have been synthesized. The 9,11-azoprosta-5,13-dienoic acid (15-deoxyazo-PGH_2) *(145)* was prepared (cf. Table 1)[108] from the dimesylate *(150)* following similar methodology to that used in the synthesis of the azo-PGH_2 analog *(8)*[33]. The requisite 9β,11β-dimesylate *(150)* was obtained from $PGF_{2\alpha}$ in a number of steps that included hydrogenolysis of the 15-hydroxy group (Li/neopentyl alcohol/$MeNH_2$) and inversion of the 9- and 11-hydroxy groups (benzoic acid/triphenylphosphine/diethyl azodicarboxylate). The two isomeric 15-deoxy-PGH_2 analogs *(153)* (11,9-epoxyimino) and *(154)* (9,11-epoxyimino) were synthesized[109] from the ester *(149)* as follows: Taking advantage of the different steric environment of the two hydroxy groups, the tosylate *(151)* and the mesylate *(152)* were first prepared. Exposure of *(151)* to triphenylphosphane, *N*-hydroxyphthalimide and diethyl azodicarboxylate afforded the precursor *(155)*. When *(155)* was treated with hydrazine the hydroxylamine derivative *(156)* was formed and cyclized spontaneously to *(153)*, after ester hydrolysis. In a similar manner, *(154)* was obtained from the mesylate *(152)* *via* the intermediates *(157)* and

(149), $R^1 = R^2 = H$
(150), $R^1 = R^2 = Ms$
(151), $R^1 = Ts$; $R^2 = H$
(152), $R^1 = H$; $R^2 = Ms$

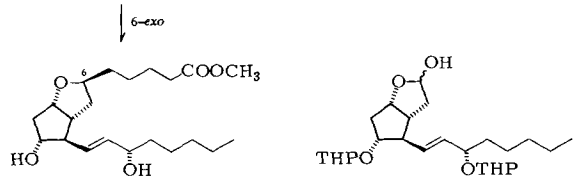
(145), X–Y = N=N
(153), X–Y = NH–O
(154), X–Y = O–NH

(155), R = N-phthalimido
(156), $R = NH_2$



(157), R = N-phthalimido
(158), $R = NH_2$

(158). All three 15-deoxy-PGH_2 analogs *(145)*, *(153)* and *(154)* were stable and showed inhibitory activity towards human platelet thromboxane A_2 synthetase, the most specific one being the 11,9-epoxyimino-PGH_2 analog *(153)*. Since these analogs antagonized the human platelet aggregation induced by endoperoxide PGH_2 or aracidonic acid, the important conclusion that PGH_2 must be converted to thromboxane A_2 in order to induce platelet aggregation was drawn[108].



An intense effort in the prostacyclin area in the last few months resulted in the synthesis of a plethora of interesting analogs.

Nelson[110] provided the first chemical proof of the stereochemistry at C-6 of PGI_1 isomers and formulated a useful empirical "rule" for the assignment of the C-6 configuration of PGI_1 analogs. By a series of steps lactol *(163)* was converted into the two 6-epimeric acids *(160a)* and *(160b)* which were separately subjected to the "double activation" lactonization procedure (dipyridyl disulfide/triphenylphosphane)[111]. Only one acid, the *endo* isomer *(160b)* cyclized to give the lactone *(162)*. The more abundant 6-*exo* isomer *(160a)* was converted into the PGI_1 derivative *(128)* (*via* aldehyde *(161)*) and compared to the PGI_1 isomers previously obtained from a $PGF_{2\alpha}$

precursor[29a]. Thus it was established and generalized that the PGI_1 analogs with the 6-*exo* configuration exhibit an ill-defined quartet centered at about $\delta = 4.4$–4.5 ($J = 6$ Hz) in their ^{1}H-NMR spectra ($CDCl_3$) and are slower moving on silica gel than the corresponding *endo* isomers.

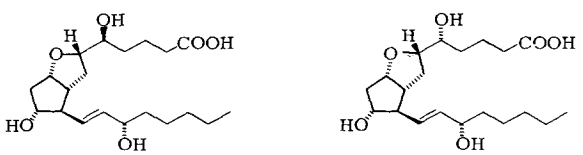
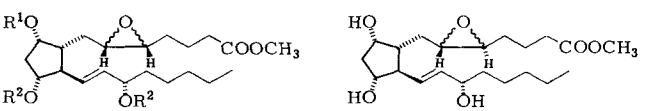
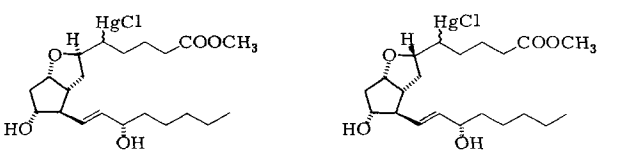
(160a),(160b), X = COOH; R = H
(161), X = CHO; R = H



(128) *(163)*



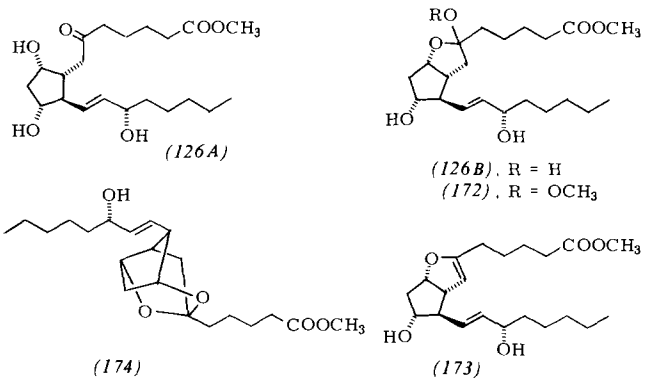
All four possible isomers of 5-hydroxy-PGI_1 [*(164)*—*(167)*] were synthesized. *Sih et al.*[112] prepared the (5*R*,6*R*)- and the (5*S*,6*S*)-isomers *(165)* and *(166)* from the epoxide *(168)*, $R^1 = H$, $R^2 = Si(t\text{-}Bu)Me_2$, by silica gel-promoted cyclic ether formation accompanied by epoxide opening. No PGI_2 was detected when 9-tritiated *(165)* or *(166)* was incubated with dog aortic microsomes suggesting that these 5-hydroxy-PGI_1 analogs are not biosynthetic intermediates in the enzymatic formation of PGI_2 from the endoperoxides PGH_2 or PGG_2.



(164), (5*S*, 6*R*) *(165)*, (5*R*, 6*R*)

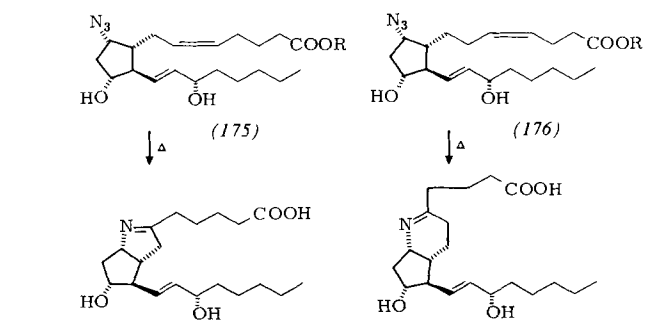
(166), (5*S*, 6*S*) *(167)*, (5*R*, 6*S*)

(168) *(169)*



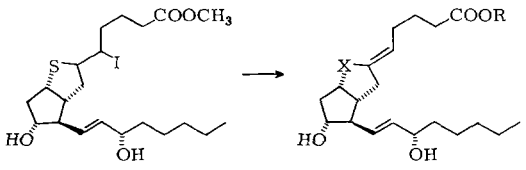
(170a), *(170b)* *(171a)*, *(171b)*

Johnson et al.[113] synthesized the PGI_1 analogs *(164)* and *(167)* in addition to *(165)* and *(166)* by two different methods.



In the first route the *cis*-epoxide *(168)*, $R_1 = R_2 = H$, was utilized to obtain *(165)* and *(166)* and the *trans* epoxide *(169)* to obtain isomers *(164)* and *(167)* by similar methodology to that used by *Sih*[112] (silica gel, ester hydrolysis). In the second route $PGF_{2\alpha}$ methyl ester was treated with mercury(II) acetate followed by sodium chloride to give four diastereomeric cyclic ethers separated into two pairs *(170a)/(170b)* and *(171a)/(171b)*. Sodium borohydride in the presence of oxygen converted *(170a)/(170b)* into *(164)* and *(165)* and *(171a)/(171b)* into *(166)* and *(167)*, respectively.

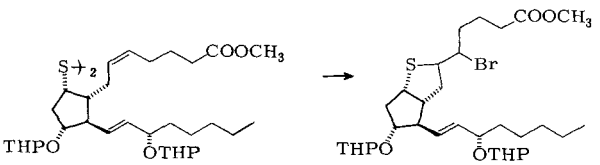
Hayashi et al.[114] recently synthesized two novel isomeric forms of prostacyclin (PGI_2) from 6-oxo-$PGF_{1\alpha}$ *(126A)* $\rightleftharpoons$ *(126B)*. The PGI_2 isomer *(174)* which represents an internally protected form of *(126)* was obtained from *(126)* by stirring with powdered molecular sieves 4A and kiesel gel in dichloromethane. We have also synthesized this compound *(174)* from PGI_2 methyl ester *(119)* and *p*-toluenesulfonic acid in dry benzene at 25°C (80%). The Δ^6-PGI_2 isomer *(173)* was obtained by pyrolysis of the methoxy compound *(172)* (obtained from *(126)* and methanol under acid conditions) in hexamethylphosphoric triamide at 180°C. An alternative procedure[114] for the preparation of *(173)* from *(126)* involved (a) complete trimethylsilation, (b) GC isolation of the major component (260°C), and (c) deprotection of the 11- and 15-hydroxy groups (K_2CO_3/methanol). The internal ketal *(174)* was found to be biologically inactive, whereas the Δ^6-prostacyclin isomer *(173)* showed potent activity (11.7 times as active as PGE_1) as an inhibitor of rat platelet aggregation[114].



(126A) *(126B)*, R = H
(172), R = OCH_3
(174) *(173)*

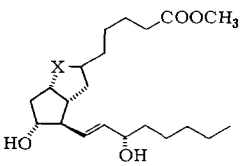
Upjohn scientists have recently reported the nitrogen-containing prostacyclin analogs *(177)* and *(178)*[115] which

(175) *(176)*
(177) *(178)*



showed both high stability and potency in inhibiting platelet aggregation. The synthesis of *(177)* proceeded smoothly from the $PGF_{2\alpha}$-azido derivative *(175)* by an interesting thermolytic process accompanied by the loss of nitrogen. The six-membered ring PGI_2 analog *(178)* was obtained in an analogous manner by thermolysis of *(176)*[115].

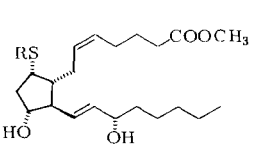
(179)



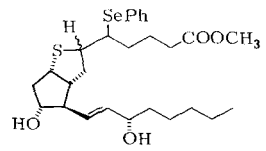
(180), X = S
(181a), *(181b)*, X = SO
(182), X = SO_2

A series of sulfur-containing prostacyclins have been synthesized[116–120]. The thiaprostacyclin *(180)*, R = H[119], a stable and biologically potent analog of PGI_2 having a sulfur-containing ring, was prepared from the cyclic iodothioether *(179)* by base (DBU) elimination followed by ester hydrolysis. The iodide *(179)* was obtained from the thiol *(188)*[119] upon addition of iodine at low temperatures. The desired (5*Z*) geometry in *(180)* was secured by intramolecular *trans* addition to the *cis* double bond of *(188)* followed by *trans* E_2-type elimination of hydrogen iodide from *(179)*. Japanese workers

(183) *(184)*

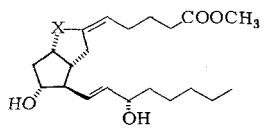


have also prepared the thiaprostacyclin *(180)*[116,117]. *Shibasaki* and *Ikegami*[116] arrived at *(180)* in an elegant manner *via* the bromide *(184)* which was obtained from the disulfide *(183)* and bromine.



(185), X = S
(186a), *(186b)*, X = SO
(187), X = SO_2

The 5,6-dihydrothiaprostacyclin *(185)* has also been prepared[118] by acid treatment of the thiols *(188)* or *(195)*. Controlled oxidation of *(185)* afforded selectively *(186a)*/*(186b)* (two sulfoxide isomers) or *(187)*[118]. Similar acid-catalyzed cyclizations have also been reported by *Shibasaki* and *Ikegami*[116].



Selenium-induced ring closure of *(188)* or its acetate *(189)* led to the phenylselenothioether *(190a)* which upon oxidation followed by *syn*-elimination resulted in the formation of a number of (5*E*)-PGI_2 analogs[120]. Thus, oxidation of *(190a)* with 2.2 equivalents of *m*-chloroperbenzoic acid (78→25 °C) led selectively to a mixture of two sulfoxide isomers, (5*E*)-thiaprostacyclin methyl ester *S*-oxides *(191a)*/*(191b)*, which were separated chromatographically, *(191a)* being the major product. With 2.2 equivalents of *m*-chloroperbenzoic acid (−78→25 °C) and excess hydrogen peroxide (25 °C) the (5*E*)-thiaisoprostacyclin methyl ester *S*,*S*-dioxide *(192)* was formed selectively and in high yield. The (4*E*)-*S*,*S*-dioxide *(193a)* was obtained with its conjugated isomer *(192)* upon oxidation of *(190a)* with excess hydrogen peroxide.

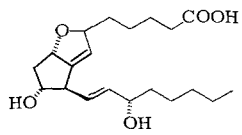
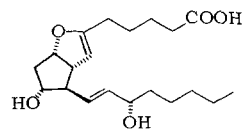
(191a), *(191b)*, X = SO
(192), X = SO_2



(193a), *(193b)*



(194), R = Ac
(195), R = H

Utilizing similar methodology and starting with the 9-acetylthio-5-*trans*-$PGF_{2\alpha}$ derivative *(194)*[118], the cyclic sulfoxides *(181a)* and *(181b)*[120], the cyclic sulfones *(182)*[120] and *(193b)* [6-epimer of *(193a)*][120] were synthesized; *(181a)*, *(181b)* and *(182)* have the same natural (5*Z*) geometry.

(196)

(197)

These stable sulfur-containing prostacyclins show interesting and divergent biological properties. Thus, thiaprostacyclin *(180)*, for example, showed comparable potency to natural prostacyclin in inhibiting platelet aggregation and potent vasoconstricting activity in isolated cat coronary artery, while the sulfones *(182)* and *(193a)* showed antagonistic action against PGI_2 in inhibition of platelet aggregation.

The novel structure *(196)* assigned by *Pace-Asciak* and *Wolfe*[29] to a major prostaglandin biosynthesized from arachidonic acid by rat stomach homogenates has recently been revised to structure *(197)* by *Sih* and *Huang*[121], mainly on the basis of mass spectroscopic evidence [cf. *(173)*].

Several important biological studies involving prostacyclin (PGI_2) have been carried out. The cardiovascular properties of PGI_2 have been studied by *Lefer et al.*[101] by infusing PGI_2 into anesthetized cats. As shown in Figure 20, PGI_2 reduces significantly both the mean arterial blood pressure and the total peripheral resistance without affecting the heart rate. *Vane* has recently reported[122] that PGI_2 infused into anesthetized dogs on kidney machines prevented both platelet loss and microthrombi formation. *Fried*'s compound, 13,14-didehydroprostacyclin methyl ester *(143)* was found to exhibit

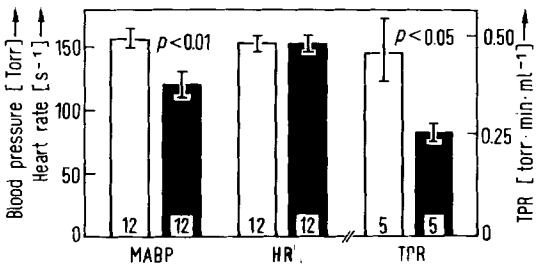


Fig. 20. Hemodynamic response in cats 10 minutes after PGI_2 infusion (2.7×10^{-9} mol·kg^{-1}·min^{-1}, *i.v.*). Open bar heights indicate pre-infusion mean values (control). Solid bars indicate mean values attained 10 minutes after infusion. Numbers within bars indicate the number of cats in which responses were measured. Left two bars represent values of mean arterial blood pressure (MABP) measured by intra-aortic catheters positioned *via* the right common carotid artery. PGI_2 infusion resulted in significantly reduced MABP ($p<0.01$) at 10 minutes compared to pre-infusion control MABP. Middle two bars indicate the heart rate (HR) response to PGI_2 infusion. No significant changes from pre-infusion HR was observed after 10 minutes of PGI_2 infusion. Right two bars represent values for total peripheral resistance (TPR). PGI_2 infusion resulted in significant reduction in TPR ($p<0.05$).

unusual pulmonary vasodilatory activity[1 2 3]. These and other novel biological properties of prostacyclins strongly suggest possible therapeutic uses of these substances.

The authors wish to thank their collaborators R. L. Magolda and W. J. Sipio for their assistance in the research carried out in these laboratories and in the preparation of this article. Many thanks are also due to Professors G. J. Gasic, M. J. Silver, J. B. Smith and A. M. Lefer for their encouragement and helpful comments. One of us (KCN) wishes to express his deep gratitude and appreciation to Professor E. J. Corey of Harvard University for his teachings in organic chemistry during the years 1973—76. Research in our laboratories was assisted by Merck Sharp and Dohme, USA, Ono Pharmaceutical Company, Japan, and the University of Pennsylvania.

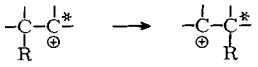
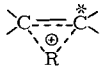
Skeletal Rearrangements of Organoalkali Metal Compounds



By Erling Grovenstein, Jr.[*]

Dedicated to Professor Avery A. Morton on the occasion of his 85th birthday

Organometallic compounds of the alkali metals undergo concerted [1,*n*] sigmatropic migration of aryl, vinyl, carbonyl, alkoxycarbonyl, silyl, germyl, and related groups. Sigmatropic migration of alkyl, benzyl, and hydrogen occur only under special circumstances and then may occur by an alternate fragmentation-recombination pathway. Allyl groups may migrate by the latter process or by a concerted [2,3] sigmatropic reaction. These molecular rearrangements are discussed from the viewpoint of simple molecular orbital theory. By suitable choice of the alkali metal, temperature, ligands of the alkali cation and/or the solvent, considerable control may be exercised over the rate of rearrangement, the relative migratory aptitude of groups, and the mechanistic pathway.



1. Introduction

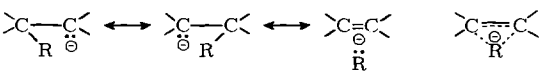
Early progress in the elucidation of the structures of organic compounds was made possible by the general correctness of the *principle of minimum structural change*[1] or of the *non-occurrence of molecular rearrangements* during organic reactions. Nevertheless, *Fittig*'s discovery[2] of the transformation of pinacol into pinacalone by treatment with sulfuric acid preceded the Kekulé formulation of the structure of benzene. The pinacol rearrangement and related rearrangements[3] such as Wagner-Meerwein rearrangements are now considered to proceed *via* carbenium ions [eq. (a)], electron deficient carbon

(a)

atoms, or non-classical ions *(1)*[4]. The details of such rearrangements have fired the imagination of chemists and aroused controversy now for over one hundred years.

(1)

Some time ago it occurred to the author that a related rearrangement of carbanions [eq. (b)] or organometallic compounds of the alkali metals might be of interest. Rearrangements of this type were already known in systems involving hetero atoms—the Stevens and Sommelet rearrangements of quaternary ammonium ions and the Wittig rearrangement



(b)

of ethers; however, the hetero atom in the known examples appears to play an important role since a bond to the hetero atom is broken during rearrangement. This review will be concerned chiefly with systems in which the organic moiety of the organoalkali compound contains only carbon and hydrogen.

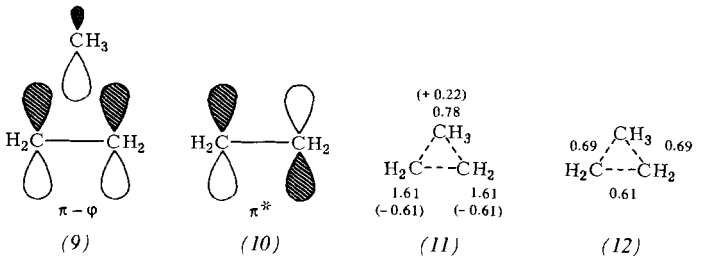
2. Molecular Orbital Considerations for [1,2] Sigmatropic Rearrangements of Carbanions

In terms of the simple qualitative theory of resonance between valence bond structures *(2)*—*(4)* or the equivalent hybrid structure *(5)* for the transition state (or intermediate) in the rearrangement of eq. (b), it is by no means obvious that rearrangements of carbanions (similarly, free radicals) should not be as common as rearrangements of carbenium ions[5]. Hence the application of Hückel molecular orbital (HMO) theory[6] to this problem by *Zimmerman* and *Zweig*[7] in 1961 represented a considerable advance in theory and was prescient of further developments by *Woodward* and *Hoffmann*[8,9].



(2) *(3)* *(4)* *(5)*

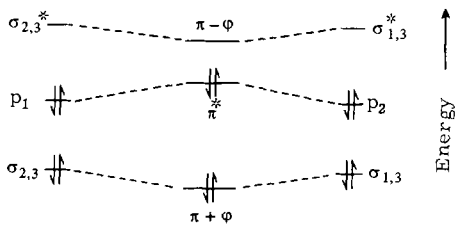
The simplest example is illustrated by calculations upon the *n*-propyl anion which rearranges *via (7)*; the orbitals used in the calculation are shown schematically in terms of the appropriate basis sets. Since the transition state *(7)* has

a symmetrical distribution of atomic nuclei with respect to the plane (represented by the dotted line) which bisects the ethylene and methyl moieties, the allowable molecular orbitals for *(7)* must be either symmetric or antisymmetric with respect to this symmetry element. Hence the only allowed combination of orbitals are the bonding combination $\pi + \varphi$ (where π denotes the contribution from the ethylene π moiety and φ the sp^3

(9) (10) (11) (12)

Electron distribution (Net charge) Bond orders

orbital of the methyl group) and the two antibonding combinations $\pi-\varphi$ *(9)* and π^* *(10)*. The energies and coefficients of these orbitals may be obtained from a detailed HMO calculation; when the parameters of *Zimmerman* and *Zweig*[7] are used the net electron distribution may be calculated as in *(11)* and the bond orders as in *(12)* for the anion. The diagram for molecular orbital following[10] of reaction *(6)*→ *(8)* is given in Figure 1.



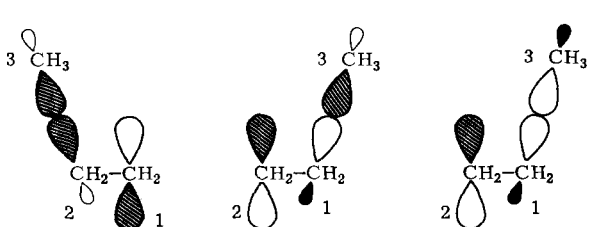


Fig. 1. Energy-molecular orbital diagram for [1,2] sigmatropic rearrangement of methyl in *n*-propyl anion *(6)*.

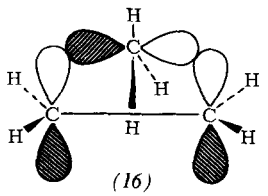
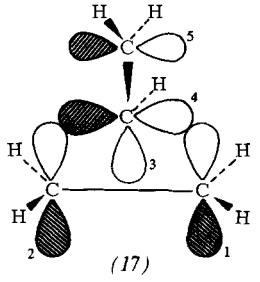
According to this calculation the transition state for methyl migration is some 1.13β units[11] higher in energy than the *n*-propyl anion. The qualitative explanation is that the 1,2-alkyl shift involves electrons moving into the antibonding π^* orbital with consequent weakening of the bond between C-1 and C-2 [see *(12)*[14]]. Hence *Zimmerman* and *Zweig*[7] concluded that "simple alkyl migration of carbanions ... may never be observed except under extreme conditions."



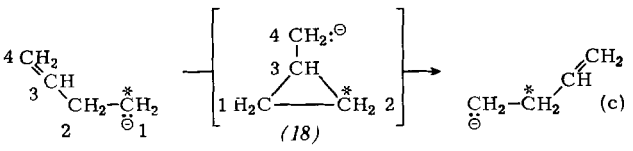
An alternative way of examining the [1,2] sigmatropic shift of methyl in *n*-propyl anion is that while the bonding orbital ($\sigma_{2,3}+p_1$) of the reactant *(6)* correlates with the bonding orbital ($p_2+\sigma_{1,3}$) of the product *(8)*, the other bonding orbital of the reactant *(13)* ($\sigma_{2,3}-p_1$) correlates with the antibonding orbital ($p_2-\sigma^*_{1,3}$) of *(14)* rather than the more stable bonding orbital ($p_2-\sigma_{1,3}$) of *(15)*. (In this approach of *Woodward* and *Hoffmann*[8] the local symmetry of composite atomic orbitals is utilized since the reactant and product do not possess relevant molecular symmetry elements.) This reaction is accordingly said to be symmetry-forbidden by the principle of conservation of orbital symmetry.



(13) (14) (15)

From yet another viewpoint due to *Evans*, *Dewar*, and *Zimmerman*[12] the transition state *(7)* for migration of methyl in *n*-propyl anion consists of a Hückel array of orbitals containing $4n$ or four electrons; hence the transition state is antiaromatic or destabilized relative to *n*-propyl anion. The transition state may be likened to molecules such as cyclobutadiene and cyclopropenyl anion which, as judged sometimes by derivatives, are known to be antiaromatic[13].

Are all [1,2] sigmatropic rearrangements of carbanions forbidden as thermal processes by molecular orbital considerations? The answer to this question by the Woodward-Hoffmann rules is that while suprafacial-suprafacial processes are forbidden, suprafacial-antarafacial processes are allowed [see *(7)*]. As alternatively stated by *Zimmerman*[15], the basis set of orbitals needs to contain one sign inversion since then it would constitute a Möbius array containing four (in general, $4n$) electrons and would be expected to be stable or aromatic. A conformation with such a sign inversion for methyl migration in *n*-propyl anion is shown in *(16)*; however, this conformation, which constitutes an inversion in configuration at the migrating methyl group, has obvious steric difficulties in that two of the hydrogens of the migrating group appear to undergo severe van der Waals repulsions with the carbon atoms of the ethylene moiety. While other conformations

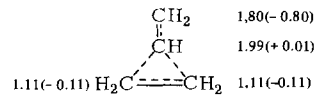


(16)

(17)

for methyl migration may be considered, all which involve one sign inversion in the basis set of orbitals appear to be of high energy content either because of repulsion between nuclei or poor overlap of orbitals.

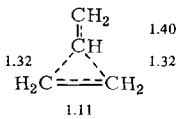
A method of avoiding the steric repulsions in *(16)* is to have for the migrating group an atom of lower coordination number, *e.g.* an sp^2 hybrid atom as in the migration of vinyl or phenyl. The basis set of orbitals for the transition state (or intermediate) for vinyl migration [eq. (c)] is shown



(18)

in *(17)*. An HMO calculation for *(17)* with parameters like those of *Zimmerman* and *Zweig*[7] is summarized in Table 1; apparently this calculation has not appeared elsewhere[16].

Table 1. Molecular orbitals for the transition state (or intermediate) *(17)* for vinyl migration [eq. (c)].

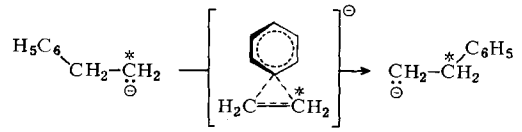


ψ	1	2	3	4	5	Energy [β units]
1	0.552	0.552	0.626	0	0	2.28
2	0.305	−0.305	0	0.784	0.512	1.45
3	0.396	−0.396	0	0.225	−0.798	−0.28
4	0.443	0.443	−0.780	0	0	−1.47
5	0.501	−0.501	0	−0.630	0.319	−1.98

The highest filled molecular orbital for vinyl migration (ψ_3) is of considerably lower energy ($-0.28\,\beta$) than that for methyl migration ($-0.81\,\beta$). The electron distribution for population of the three lowest lying orbitals is as shown in *(19)* while the bond orders[17] are as in *(20)*. Comparison with *(11)*

(19)

Electron distribution (Net charge)



(20)

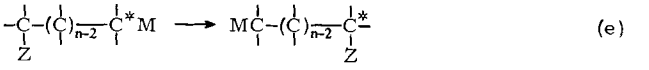
Bond orders

and *(12)* (methyl migration) shows that for vinyl migration most of the net negative charge is on C-4 as in the valence-bond structure *(18)* rather than on C-1 and C-2 as in *(11)*. Also the bond order is greater than unity everywhere in *(20)* rather than less than unity as in *(12)*. Indeed migration of vinyl in the homoallyl anion [eq. (c)] to give *(18)* is now computed to be *exothermal* by $0.67\,\beta$ whereas methyl migration of *n*-propyl anion to *(7)* was computed to be *endothermal* by $1.13\,\beta$. Also correlation of orbitals according to localized symmetries by the molecular orbital following technique now leads to the conclusion that vinyl migration is an allowed process[10]. It should be pointed out that less complete molecular orbital correlations which consider only the highest filled molecular orbital of the reactant (most simply the orbital containing the non-bonding electron pair on C-1) and of the intermediate *(17)* might have led to the conclusion that the reaction was forbidden since a non-bonding orbital of the reactant correlates with an anti-bonding orbital (ψ_3) of the intermediate. Also it is not *a priori* obvious whether *(17)* constitutes a Möbius array ($\varphi_1+\varphi_2+\varphi_4+\varphi_5$) or a Hückel array ($\varphi_1+\varphi_2+\varphi_3$) of orbitals, since in fact it contains both basis sets, or whether the number of electrons belonging to each array is $4n$ or $2+4n$ electrons. To be sure, detailed calculations (Table 1) do reveal that for the ground state two electrons are assigned to the Hückel system and four electrons to the Möbius system as expected for a stable (or "aromatic") transition state or intermediate. More simply still *(17)* might have been regarded as a rather stable structure since at least one reasonably stable valence-bond structure *(18)* may be written for it.

Molecular orbital considerations for phenyl migration [eq. (d)] are similar to those for vinyl migration except that the negative charge in the intermediate or transition state *(21)* is more highly delocalized somewhat at the expense of the conjugated π system of the benzenoid ring. *Zimmerman* and

(d)

(21)



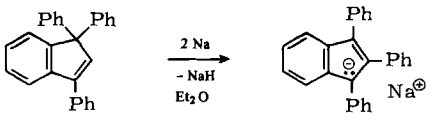
Zweig[7] calculated that migration of phenyl in β-phenylethyl anion to give *(21)* was exothermal by $0.52\,\beta$ units or somewhat less exothermal than vinyl migration as estimated above.

A qualitatively most interesting result of these simple molecular orbital calculations is that they predict[7] that, other factors being equal, [1,2] sigmatropic rearrangements will occur with decreasing ease along the series: carbenium ion > free radical > carbanion since, in general, for free radical and carbanion rearrangements a non-bonding orbital in the reactant is converted into an antibonding orbital in the intermediate or transition state. The antibonding orbital is not occupied for carbenium ions while it is doubly occupied for carbanions. The calculation also suggests that, once a carbanion rearrangement has been identified, the corresponding free radical rearrangement should occur and, with less certainty, *vice versa*.

A chemist who does not believe that molecular orbital theory is the greatest advance in organic chemistry since the introduction of valence-bond (Kekulé) structures might question the conclusions from the present calculations. Indeed most chemists need to be concerned with the approximations involved. Of immediate concern is whether the correct resonance integrals have been chosen; *Phelan*, *Jaffé*, and *Orchin*[18] have repeated many of the present calculations with different resonance (and Coulomb) integrals and obtained different quantitative results although most of the qualitative conclusions are unaffected. Another problem is whether all of the relevant orbitals have been included in the calculations. For example in *(7)* why not consider the σ-bond linking C-1 to C-2 in the basis set of orbitals? Indeed inclusion of this orbital in simple HMO calculations leads to the conclusion that methyl migration in *n*-propyl anion to give the bridged species *(7)* would be exothermal by some $0.21\,\beta$ units; however, one might question whether such a calculation which concentrates yet more charge on atoms C-1 and C-2 (albeit on more orbitals) and which does not take into consideration electron repulsion could represent an improved calculation. A still approximate but more advanced molecular orbital calculation[19,20] (CNDO/2) gives the result that methyl migration in *n*-propyl anion to the bridged species *(7)* should be endothermal by some 24 kcal/mol. In addition to the approximations which are inherent to the calculations themselves, chemists must question any calculations for carbanions which neglect the counterion and the solvent surrounding the ions. Nevertheless molecular orbital calculations have been of considerable heuristic value and on the whole have correlated experimental results as is shown by the following summary on rearrangements of organoalkali compounds.

3. Experimental Results upon [1,*n*] Sigmatropic Rearrangements of Carbanions

In this section [1,*n*] sigmatropic rearrangements of the type



(e)

will be reviewed according to the nature of the migrating group Z (*e.g.*, Z = phenyl, vinyl, or alkyl). The chain of atoms over which Z migrates will normally be a saturated carbon chain but will include in some examples hetero atoms and

multiple bonds. While this survey emphasizes rearrangements of organoalkali compounds, some related rearrangements of Grignard reagents will be included for comparison.

3.1. Migrations of Aryl Groups[21]

The earliest known example of skeletal rearrangement of an organoalkali compound appears to be the rearrangement of 1,1,3-triphenylindene *(22)* by sodium which was discovered, but misinterpreted, by *Schlenk* and *Bergmann*[22] and reinterpreted by *Ziegler* and *Crossman*[23] to involve phenyl migration as shown in equation (f). In a reinvestigation of this reaction *Miller* and *Boyer*[24] suggested that the rearrangement occurs in a radical anion of *(22)*, although rearrangement of the disodium adduct of *(22)* was not excluded by the available

(f)

(22)

evidence. Since rearrangement of a radical anion may be looked upon as rearrangement of a free radical, reaction (f) does not necessarily exemplify rearrangement of a carbanion.

The first example of rearrangement of a simple carbanion [eq. (e), $n=1$] with all carbon skeleton was provided by rearrangement during the reaction of 2-chloro-1,1,1-triphenylethane *(23)* with sodium in ethereal solvents; this reaction was discovered by the author[25], and independently, essentially at the same time, by *Zimmerman* and *Smentowski*[26]. That this reaction involved formation of an intermediate organosodium compound *(24)* prior to rearrangement was demonstrated[25] by carrying out the reaction in dioxane containing

$$\underset{(23)}{Ph_3C{-}CH_2Cl} \xrightarrow[-NaCl]{2\,Na} \underset{(24)}{Ph_3C{-}CH_2Na} \rightarrow Ph_2\overset{\ominus}{C}{-}CH_2Ph \quad (\overset{\oplus}{Na})$$

a little *tert*-amyl alcohol, whereupon the reaction product was primarily 1,1,1-triphenylethane. In contrast, if *tert*-amyl alcohol was added after reaction with sodium, 1,1,2-triphenylethane was the dominant product. Similarly cleavage[27] of the chloride *(23)* or of 2,2,2-triphenylethyltrimethylammonium iodide *(25)* with sodium in liquid ammonia gave

$$Ph_3C{-}CH_2\overset{\oplus}{N}(CH_3)_3\ I^{\ominus} \quad (25)$$

primarily 1,1,1-triphenylethane accompanied by some 11% of 1,1,2-triphenylethane. The 2,2,2-triphenylethyl group in *(25)* cleaves from quaternary nitrogen 10^4 times more readily than methyl or 10^6 times more readily than ethyl[28]. If the relative rates of cleavage of primary, secondary, and tertiary alkyl groups from quaternary nitrogen can be taken as a guide[28] to the mechanism of cleavage, primary alkyl groups cleave directly as carbanions rather than free radicals. Accordingly the cleavage of *(25)* is interpreted as giving initially the 2,2,2-triphenylethyl anion which is largely protonated by ammonia prior to rearrangement. The much more facile cleavage of the 2,2,2-triphenylethyl group as compared with that of ethyl is evidently due to the ability of phenyl groups to stabilize a negative charge upon the triphenylethyl group; it cannot arise from a direct neighboring group participation of phenyl during cleavage (cf. the 4×10^6 anchimeric acceleration[29] in solvolysis with carbenium ion rearrangement of 2,2,2-triphenylethyl brosylate) since most of the final hydrocarbon product is of unrearranged structure. This example does illustrate the conclusion from molecular orbital calculations that, even in a favorable case for rearrangement of carbanions, rearrangements of carbenium ions occur with considerably greater facility than rearrangements of carbanions such that rearrangement of a carbanion may occur in a concerted process with formation of the carbenium ion.

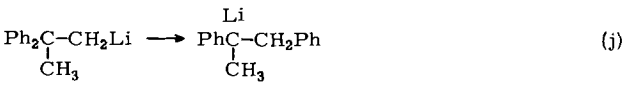
More direct evidence for formation of an organoalkali compound prior to rearrangement is provided by reaction[30] of the chloride *(23)* with lithium metal in tetrahydrofuran (THF) at -65 to -30°C to give 2,2,2-triphenylethyllithium which is comparatively stable at low temperature but rearranges rather readily at 0°C or higher to give 1,1,2-triphenylethyllithium. In contrast potassium[30] in 1,2-dimethoxyethane at -50°C or Cs-K-Na alloy[31,32] in THF at -65°C gives almost instantly rearranged 1,1,2-triphenylethyl-potassium or -cesium. Bis(2,2,2-triphenylethyl)mercury reacts[33] with butyllithium in THF below 0°C to give 2,2,2-triphenylethyllithium which rearranges at higher temperature to 1,1,2-triphenylethyllithium [eq. (g)].

$$(Ph_3C{-}CH_2)_2Hg \xrightarrow{BuLi} Ph_3C{-}CH_2Li \rightarrow LiCPh_2{-}CH_2Ph \quad (g)$$

Also 2,2,2-triphenylethyllithium reacts[34] with excess potassium *tert*-butoxide at -75°C in THF to give complete rearrangement in less than 10 minutes; evidently this rearrangement goes by the process[35] outlined in eq. (h).

$$Ph_3C{-}CH_2Li \xrightarrow{KO\,tBu} Ph_3C{-}CH_2K \rightarrow KCPh_2{-}CH_2Ph \quad (h)$$

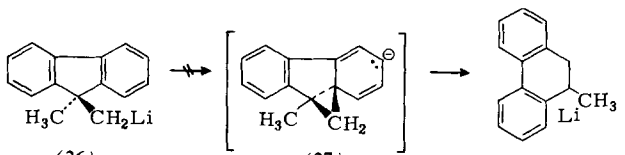
The above summary of experimental work provides compelling evidence that 2,2,2-triphenylethylalkali compounds are rearrangement precursors; however, the circumstance that rearrangement starts and ends with an organoalkali compound does not prove[36] that the rearrangement itself directly occurs in an organoalkali compound or in an anion derived from the organoalkali compound. For example, the rearrangement might occur in an intermediate free radical or methylene. Also the rearrangement might occur by an inter- rather than an intra-molecular process as implied by our previous molecular-orbital considerations. What evidence is available concerning the detailed mechanism of migration of aryl groups in organoalkali compounds?



A possible mechanism for phenyl migration in 2,2,2-triphenylethyllithium would be by an elimination-readdition process [eq. (i)]. As a test for this mechanism 2,2,2-triphenylethyl-

$$Ph_3C{-}CH_2Li \rightarrow Ph_2C{=}CH_2 + PhLi \rightarrow LiCPh_2{-}CH_2Ph \quad (i)$$

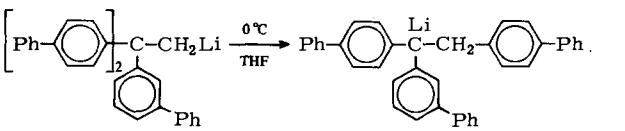
lithium was allowed[37] to undergo rearrangement in the presence of ^{14}C-labeled phenyllithium or in the presence of the much more reactive[38] benzyllithium. There was no detectable incorporation of radioactive phenyl or of benzyl group in the product of rearrangement. While these experiments help establish that rearrangement of 2,2,2-triphenylethyllithium



occurs by an *intramolecular* process, they do not eliminate some subtle modifications of the elimination-readdition process. For example, 2,2,2-triphenylethyllithium may eliminate phenyl anion to give 1,1-diphenylethene; the phenyl anion and 1,1-diphenylethene may exist in a solvent "cage" and recombine before radioactive phenyllithium or benzyllithium can penetrate the "cage".

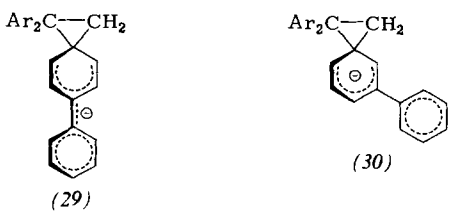
Zimmerman and *Zweig*[7] have reported that 2,2-diphenylpropyllithium, prepared by reaction of lithium metal with 1-chloro-2,2-diphenylpropane or with bis(2,2-diphenylpropyl)-mercury, rearranges at reflux temperature in diethyl ether to give 1-methyl-1.2-diphenylethyllithium [eq. (j)]. In contrast

(j)



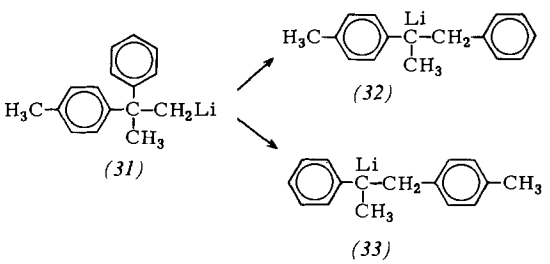
Eisch and *Kovacs*[33] find that the rather similar organolithium compound *(26)* did not rearrange to *(28)*, presumably because rearrangement requires production of the highly strained spiro

(26) *(27)*



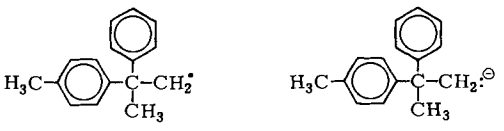
intermediate *(27)*. If aryl migration proceeded by an elimination-readdition process, there is no apparent reason why rearrangement of *(26)* to *(28)* should not have occurred.

Positive evidence in favor of spiro intermediates or transition states during aryl migrations is found[39] in the highly preferential migration of *p*-biphenylyl as opposed to *m*-biphenylyl in 2-*m*-biphenylyl-2,2-bis(*p*-biphenylyl)ethyllithium *(28)*. This



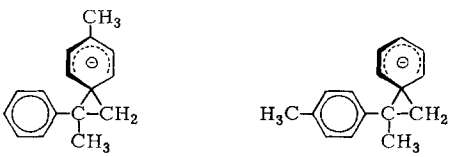
(28) > 98%

result can be explained on the basis that the rearrangement can proceed much more readily *via* the transition state or intermediate *(29)* than *via (30)* because of the more extensive charge delocalization in the *p*-phenyl group of *(29)* compared with that in the *m*-phenyl of *(30)*. Had the organolithium compound rearranged by elimination of a biphenylyl anion or radical little difference in migratory aptitude of *m*- and *p*-biphenylyl groups would have been expected.



(29) *(30)*

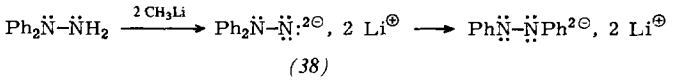
In view of what is expected from molecular orbital considerations for the comparative ease of migration of carbanions *versus* free radicals, what is the evidence that aryl migration occurs in an anion (or organoalkali compound) rather than a free radical? *Zimmerman* and *Zweig*[7] have shown that 2-phenyl-2-*p*-tolylpropyllithium *(31)* rearranges in ethereal solution at reflux temperature with formation of about a 11:1 ratio of the product of phenyl migration *(32)* to the product of *p*-tolyl migration *(33)*. If rearrangement of *(31)*



(31) *(32)* *(33)*

occurred in the intermediate free radical *(34)*, no appreciable selectivity would be expected in the migration of phenyl *versus* *p*-tolyl (in the rearrangement of neophyl radicals[40], the *p*-tolyl

(34) *(35)*

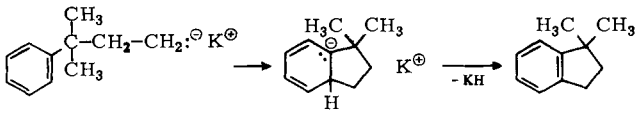


group migrated about 0.7 times as fast as phenyl). If rearrangement occurred in the carbanion *(35)*, *p*-tolyl would be expected to migrate appreciably more slowly than phenyl since the expected intermediate or transition state *(36)* for *p*-tolyl migration should be less stable than that for phenyl migration *(37)* (toluene is reported[41] to be some 19 times more acidic per

(36) *(37)*

methyl hydrogen than *p*-xylene). Hence the relative ease of migration of *p*-tolyl *versus* phenyl in *(31)* argues strongly in favor of this rearrangement being a carbanion rearrangement rather than a free radical rearrangement.

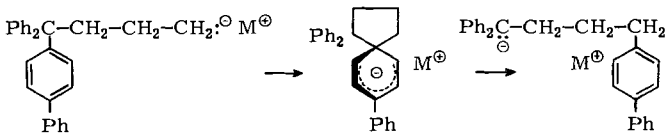
Other examples of [1,2] migrations of aryl groups in organoalkali compounds could be cited[21]. Such rearrangements appear to be a general phenomenon and also occur in various hetero-atom analogs. A notable case is exemplified by the dianion of 1,1-diphenylhydrazine *(38)* which rearranges[42] slowly but quantitatively in diethyl ether at 30°C



(38)

whereas the corresponding monoanion (as lithium salt) does not undergo [1,2] phenyl migration even at 100°C in bis(2-methoxyethyl) ether.

Sigmatropic aryl shifts of order [1,3] should occur in organoalkali compounds in principle but appear never to have been observed because of competing reactions. Thus 3,3,3-triphenylpropyllithium[43] in THF at −40°C undergoes fragmentation [eq. (k)]. In liquid ammonia the 3,3,3-triphenylpropyl anion from cleavage of 3,3,3-triphenylpropyltrimethyl-

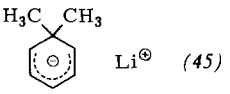


$$Ph_3C{-}CH_2{-}CH_2{-}Li \rightarrow Ph_3CLi + CH_2{=}CH_2 \qquad (k)$$

ammonium iodide with sodium undergoes primarily protonation to 1,1,1-triphenylpropane in addition to a little fragmentation[27]. The 3-methyl-3-phenylbutyl anion *(39)*, formed evidently in reaction of isopropylbenzene at 190°C with potassium-anthracene catalyst under some 30 atmospheres pressure of ethylene, undergoes cyclization to the indan *(41)* in about 50% yield, evidently by way of the intermediate *(40)*[44].

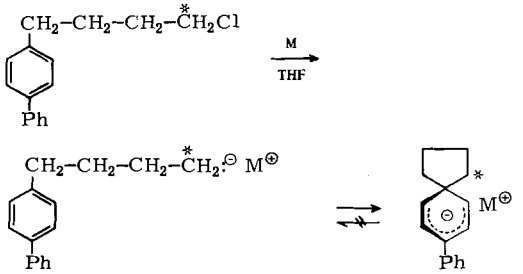
(39) *(40)* *(41)*

Sigmatropic aryl shifts of order [1,4] have been observed in reactions of organoalkali compounds in a number of instances. Whereas 4,4,4-triphenylbutyllithium in THF gave primarily 1,1,1-triphenylbutane but no product of [1,4] rearrangement of phenyl when warmed to 25°C, the corresponding organo-potassium compound gave a low yield of 1,1,4-triphenylbutyl anion from [1,4] migration of phenyl in addition to chiefly 1,1-diphenyl-1,2,3,4-tetrahydronaphthalene (product from *ortho* cyclization of the anion) and a little 1,1,1-triphenylbutane[31]. A high yield of 4-*p*-biphenylyl-1,1-diphenylbutyl anion (product of [1,4] migration of *p*-biphenylyl) was obtained from reaction of 4-chloro-1-*p*-biphenylyl-1,1-diphenylbutane in THF with potassium, cesium, or Cs-K-Na alloy[45]. Since in presence of active proton donors such as *tert*-butyl alcohol, the product was largely unrearranged 1-*p*-biphenylyl-1,1-diphenylbutane (or products derived therefrom), the reaction is believed to proceed by way of 4-*p*-biphenylyl-4,4-diphenylbutylalkali metal compounds *(42)*. Even in a reaction time of two minutes at −75°C it was not possible to detect the suspected spiro intermediate *(43)*



(42) *(43)* *(44)*

which evidently suffers facile ring opening to *(44)*. The relative rate of [1,4] migration of *p*-biphenylyl *versus* protonation of the organoalkali compound *(42)* by solvent was found to increase rapidly along the series: Li ≪ Na ≪ K or Cs. Also [1,4] migration of aryl competes less favorably in competition with protonation than does [1,2] migration. In other work[31] [1,5] migration of phenyl was somewhat less favorable than [1,4] migration in rearrangements of organoalkali compounds in THF.

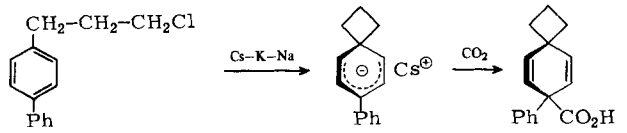


In the forgoing discussion we have considered spiro anions [cf. *(21)*, *(27)*, *(29)*, *(30)*, *(36)*, *(37)*, *(43)*] to be intermediates or transition states for [1,*n*] sigmatropic rearrangements of aryl. Is there any direct evidence bearing on this point? HMO calculations suggest that spiro anions might be stable intermediates in rearrangements of carbanions (see Section 2). The failure to observe such intermediates in all of the forgoing work could be attributed either to inadequate calculations (especially the neglect of solvation and cation-anion interactions) or to the fact that while spiro anions are more stable than the initial anions, they are in all cases so far considered less stable than the open product anions. Both explanations are probably of importance.

The successful preparation[46] of various pentadienyllithiums including 6,6-dimethylcyclohexadienyllithium *(45)* by

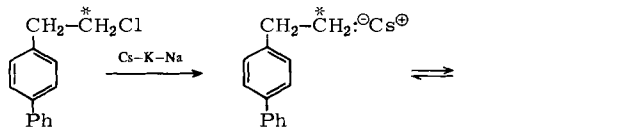
(45)

reaction of 1,4-dienes with *n*-butyllithium in THF encouraged us to attempt the detection of spiro anions in what would otherwise be [1,*n*] sigmatropic migration of aryl groups. While the spiro anion *(43)* was too unstable for detection even at −75°C, we have been able to prepare the related spiro anion *(47)* from reaction[47] of the corresponding chloride with cesium or potassium in THF. Anion *(47)* was characterized both on the basis of its NMR spectrum and from its products of carbonation and protonation. That anion *(46)*



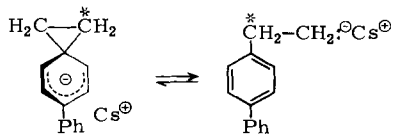
(46) *(47)*

M = K, Cs



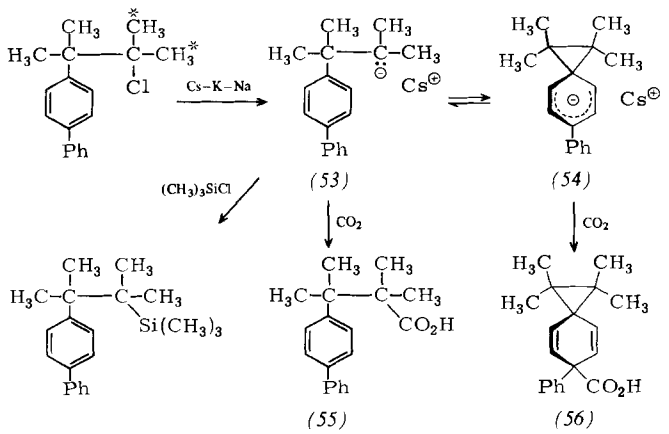
was a precursor of *(47)* was indicated by experiments in which various proton sources were able to "trap" *(46)* as 1-*p*-biphenylylbutane (or derivative) prior to cyclization. Interestingly anion *(47)* once formed did not reopen to *(46)* since deuterium labeling experiments (asterisks) gave no scrambling of the label in products derived from *(46)*. Indeed the anion *(47)* was moderately stable in THF even at 65°C and underwent other reactions such as protonation and polymerization faster than ring opening to regenerate *(46)*. Evidently the geminal phenyl groups of the spiro anion *(43)* greatly accelerate ring opening to give *(44)*; since these phenyl groups also accelerate ring closure[47] of *(42)* more than 240 fold (potassium as counterion), the subtle question of whether *(43)* is best described as an intermediate or transition state is unresolved.

In related experiments 1-*p*-biphenylyl-3-chloropropane was found to react[48] with Cs-K-Na alloy in THF at −75°C for one minute to give after carbonation the spiro acid *(49)* (36% yield); the cleavage product, *p*-biphenylylacetic acid (14%); the α-metalation product, 2-*p*-biphenylylbutanoic acid (3%); and the "normal" non-cyclized product, 4-*p*-biphenylylbutanoic acid (6%). The formation of *(49)* provides good evidence for the presence of the spiro anion *(48)* whose half-life was only some 13 minutes under the reaction conditions.



(48) (49)

In contrast, the reaction[48] of 1-*p*-biphenylyl-2-chloroethane with Cs-K-Na alloy in THF at −75°C for 1 minute before carbonation gave less than 1% (if any) of product expected from the spiro anion *(51)*, even though experiments[49] with the labeled compound 2-*p*-biphenylyl-1-chloro-1,1-dideuterioethane at −65°C suggest that 18 to 44% of spiro anion is formed as judged by the amount of deuterium scrambling in the product *p*-biphenylylethane. Evidently the spiro anion *(51)* is unstable with respect to the open anions *(50)* and *(52)*.



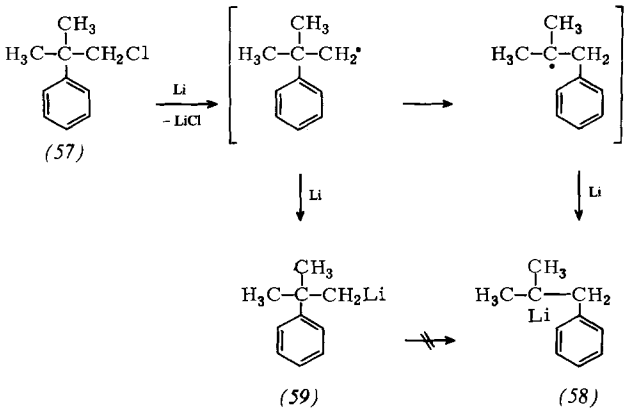
(50)

(51) (52)

Since *Maercker et al.*[50] were able to stabilize the cyclopropylmethyl form of the 3-butenyl Grignard reagent by introduction of two *gem*-dimethyl groups onto the cyclopropyl ring, we[48] undertook a related application of the Thorpe-Ingold effect. Reaction of 2-*p*-biphenylyl-3-chloro-2,3-dimethylbutane with Cs-K-Na alloy in THF at −75°C for one minute gave after carbonation 28% of the spiro acid *(56)* and 7% of 3-*p*-biphenylyl-2,2,3-trimethylbutanoic acid *(55)*. These products are evidently formed according to Scheme 1.

Scheme 1

(53) (54) (55) (56)



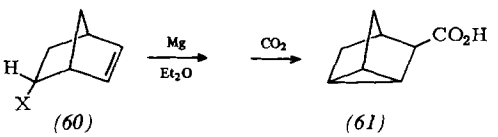
According to the results of carbonation the half-life of *(54)* is about 22 minutes at −75°C in THF. Interestingly, the open anion *(53)* seems to have the *same* half-life[51] as *(54)*. This result can be understood if *(53)* and *(54)* are in mobile equilibrium. Evidence in favor of an equilibrium comes from studies[51] with deuterium-labeled chloride (see asterisks). The resulting carboxylic acid *(55)* showed extensive deuterium label in the methyl groups nearest the biphenylyl group in about the amount expected for equilibration of the position of the label. For a mobile equilibrium *(53)*⇌*(54)*, certain electrophilic reagents may attack one of the isomeric anions more readily than the other; this is the approach used to explain the results of reaction[51] with trimethylsilyl chloride which yielded the normal product but no spiro cyclic derivative. Clearly the equilibrium between *(53)* and *(54)* needs to be studied also by spectroscopic techniques.

While the equilibrium mixture of *(53)* and *(54)* with cesium as counterion contains the anions in a ratio of about 1:4 (if the results of carbonation can be relied upon to supply such information), with lithium as counterion in THF only the open acid *(55)* is obtained upon carbonation. Evidently lithium ion prefers to interact with the localized anion *(53)* since such interaction can lead to the usual covalent organolithium compound. Somewhat similar results were obtained by *Maercker* and *Roberts*[52] in their studies upon cation effects in the cyclopropylmethyl-homoallyl rearrangement.

The work cited here on direct observation of spiro anions from reaction of arylalkyl chlorides with alkali metals, along with work[53] on related heteroatom analogs, establishes spiro anions as plausible intermediates during aryl migrations in organoalkali compounds. To be sure, what is more simply described, by analogy with model compounds, as a transient reaction intermediate may in some cases later be found to be better described as a transition state.

A warning needs to be sounded concerning rearrangements in reaction of alkali metals with alkyl halides: the observed rearrangements are *not* necessarily all rearrangements of organoalkali compounds. For example, reaction[54] of neophyl chloride *(57)* with lithium in THF at −65°C for 30 minutes gives 6% of 1,1-dimethyl-2-phenylethyllithium *(58)* in addition to the normal product 2-methyl-2-phenylpropyllithium *(59)*. The normal product *(59)*, however, does *not* rearrange to *(58)* under the reaction conditions for formation of *(58)*.

If the observed rearranged product came not from rearrangement of an organolithium compound, whence did it come? A reasonable explanation is that reactions of alkyl halides with lithium metal occur by way of intermediate radicals which in part are free enough from the metal surface to rearrange. This conclusion agrees with molecular orbital considerations (see Section 2) which suggest that free radical rear-



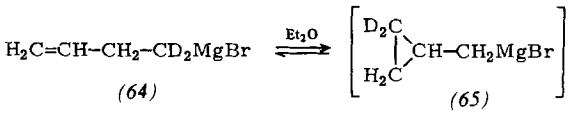
(57) (59) (58)

rangements should occur more readily than rearrangements of carbanions. In the case of reaction[45] of 1-*p*-biphenylyl-4-chloro-1,1-diphenylbutane with lithium metal in THF at −75 °C, the organolithium product contained up to 47% of the rearranged product 4-*p*-biphenylyl-1,1-diphenylbutyllithium [cf. *(44)*]; again the normal product 4-*p*-biphenylyl-4,4-diphenylbutyllithium did not undergo rearrangement under the conditions of its preparation.

Better yields of normal as opposed to rearranged organolithium compounds are obtained[45] by use of homogeneous solutions of lithium dihydrobiphenylylide in THF as reducing agent for alkyl chlorides rather than lithium metal; evidently this lithium carrier more readily donates lithium atoms to intervening free radicals than does lithium metal itself. In our experience molten alkali metals (Na, K, Cs) in ethereal solvents normally react with alkyl halides with little rearrangement prior to formation of organoalkali compounds; this conclusion rests upon "trapping" of intervening organoalkali compounds by proton donors. At least for cesium and Cs-K or Cs-K-Na alloys the efficacy in reducing expected intermediate radicals to organoalkali compounds prior to rearrangement may rest upon the solubility of cesium in tetrahydrofuran (blue solution especially at low temperatures). Potassium is also said[55] to be slightly soluble in tetrahydrofuran although we have never been able to detect the claimed blue color in the purified solvent even at low temperatures; blue solutions[30] of potassium are clearly visible in cold 1,2-dimethoxyethane.

3.2. Migrations of Vinyl Groups

Aryl and vinyl groups frequently display similar behavior in chemical reactions; nevertheless, the discovery of vinyl migration in organometallic compounds of the alkali metals was entirely independent of work upon aryl migrations. Indeed early pertinent work was in the area of Grignard reactions. In 1950, *Roberts, Trumbull, Bennett,* and *Armstrong*[56] noted cyclopropane ring formation during Grignard reactions of *endo*-norbornenyl halides [*(60)* → *(61)*].

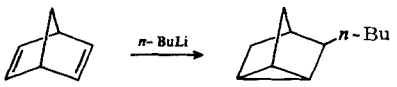


(60) *(61)*

Roberts and *Mazar*[57] observed the reverse reaction of cyclopropylmethyl chloride *(62)* with magnesium to give ring-opened product *(63)*; however, it was not clear at which

(62) *(63)*

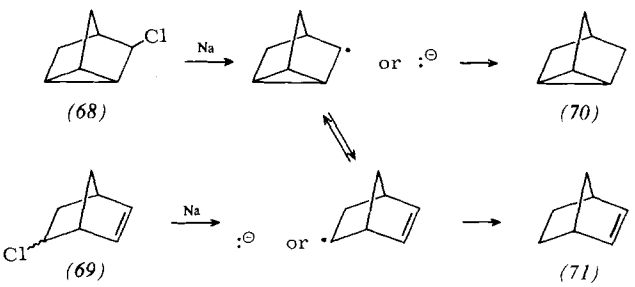
step of the Grignard sequence rearrangement occurred. The full import of these observations became apparent in 1960 when *Silver, Shafer, Norlander, Rüchardt,* and *Roberts*[58] unequivocally demonstrated by NMR spectroscopy (in addition to chemical methods) that labeled homoallyl Grignard reagent *(64) itself* undergoes a [1,2] migration of a vinyl group to give *(66)*. Since the Grignard reagent from *(62)* existed only in the open form according to its NMR spectrum, cyclopropylmethyl Grignard reagent *(65)* was assumed to be the intermediate in the conversion of *(64)* into *(66)*. The reasonableness of this assumption was strengthened by partial "trapping" of cyclopropylmethylmagnesium chloride as cyclopropylmethane during reaction of *(62)* with magnesium in diethyl ether containing benzoic acid; also the magnesium bromide corresponding to *(62)* could be prepared in dimethyl ether at −24 °C and observed to rearrange to 3-butenylmagnesium bromide[59].



(64) *(65)*

$\rightleftharpoons$ $H_2C{=}CH{-}CD_2{-}CH_2MgBr$

(66)

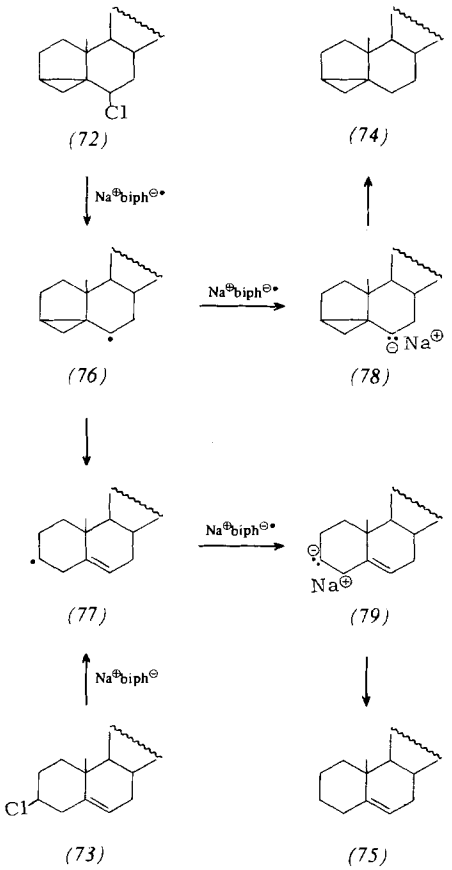


The extension of this work to corresponding organolithium compounds was perhaps implicit in the report of *Wittig* and *Hahn*[60] on the addition of *n*-butyllithium to norbornadiene to give among other products 3-*n*-butylnortricyclene *(67)*.

(67)

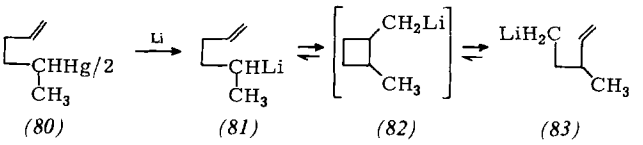
The full demonstration was provided by *Lansbury et al.*[61] who prepared cyclopropylmethyllithium by a lithium-halogen exchange at −70 °C and observed its isomerization to 3-butenyllithium. The isomerization was faster in diethyl ether than in a 10:1 mixture of petroleum ether and diethyl ether; also tetrahydrofuran was more effective than diethyl ether in promoting the isomerization.

Freeman et al.[62] found that the reaction of nortricyclyl chloride *(68)* and of norbornenyl chloride (50% *endo*, 50% *exo*) *(69)* with sodium in decane at 85—90 °C gave about the same mixture of nortricyclene *(70)* and norbornene *(71)* (in ratios of 71:10 and 49:10, respectively). They noted that



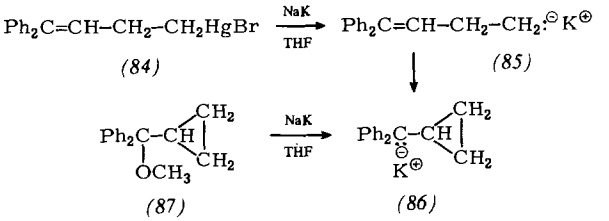
(68) *(70)*

(69) *(71)*



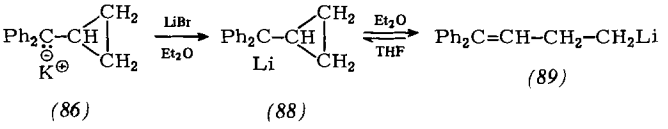
these products could be attributed to an equilibrium between cyclopropylmethyl and homoallyl anions; however, equilibrium between free radical intermediates analogous to the anions remained an alternative mechanistic possibility. That the latter interpretation is perhaps correct is indicated by the work of *Cristol* and *Barbour*[63] upon 3,5-cyclocholestanyl chloride *(72)* and cholesteryl chloride *(73)* with sodium dihydrobiphenylylide in various solvents containing 1,2-dimethoxyethane. While cholesteryl chloride *(73)* gave only 5-choles-

tene *(75)*, *(72)* gave mixtures of 3,5-cyclocholestane *(74)* and 5-cholestene in ratios *(74)*:*(75)* which increased with the effective concentration of sodium dihydrobiphenylylide but were independent of the hydrogen-atom donating ability of the solvent. These results were reasonably interpreted on the basis that intermediate classical radicals were first formed.

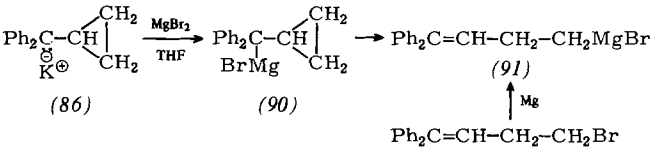


The radical *(76)* either rearranges to *(77)* or undergoes "capture" by sodium dihydrobiphenylylide to give organosodium compound *(78)* which is ultimately protonated prior to appreciable rearrangement to *(79)*. Similar interpretations and results were obtained by *Garst*, *Ayers*, and *Lamb*[64] for the reaction of sodium dihydronaphthylide with 5-hexenyl and cyclopentylmethyl halides; in this case cyclization of the 5-hexenyl radical to the cyclopentylmethyl radical was observed whereas the corresponding anions only underwent protonation. These results suggest that radicals undergo cyclization more readily than carbanions in agreement with the HMO calculations of Section 2. The results taken in comparison with related work upon aryl migration suggest that, relative to corresponding rates of reduction to anions, vinylalkyl radicals undergo cyclization more readily than arylalkyl radicals undergo spirocyclization (however comparisons have never been made under identical experimental conditions); this conclusion is also in agreement with HMO calculations.

The reactions of unsaturated aliphatic halides with alkali metals are frequently complex; in addition to products from rearrangements of intermediate free radicals or carbanions, products from rearrangements of carbenes are sometimes found[65]. Presumably the [1,3] migration of vinyl observed[66] during the cleavage of the mercury compound *(80)* with

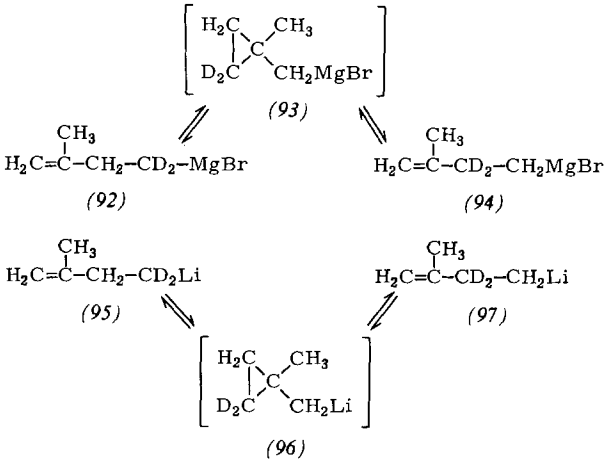


lithium in cyclohexane at reflux temperature occurred in intermediate organolithium compounds [*(81)* → *(83)*]; if so, the compound *(83)* is much more stable than *(81)* since at least 99 % of the C_6 product upon hydrolysis consisted of 3-methyl-1-pentene.



A detailed study of equilibria between the organometallic derivatives of cyclopropylmethyl and homoallyl compounds has been made by *Maercker* and *Roberts*[67]. Reaction of 4,4-diphenyl-3-butenylmercuric bromide *(84)* with Na-K alloy in THF gave only cyclopropyldiphenylmethylpotassium *(86)* according to the products of carbonation. No evidence was found for the open organopotassium compound *(85)* under these conditions.

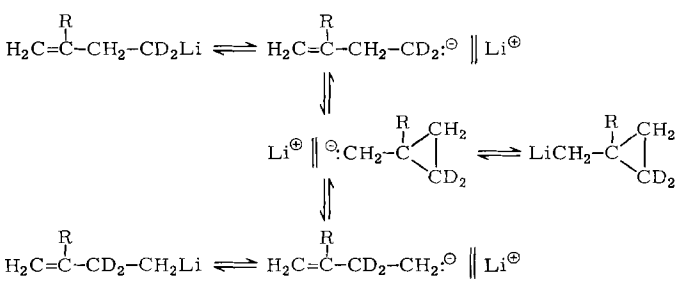
The anion of *(86)* can also be generated by cleavage of the ether *(87)*. The structure of *(86)* is confirmed by its NMR spectrum. Reaction of *(86)* with lithium bromide in diethyl ether resulted in disappearance of the deep-red color of the anion; carbonation affords only diphenylallylacetic acid.

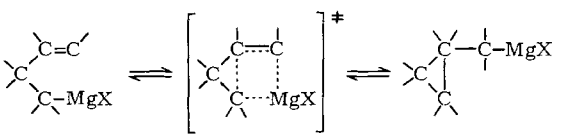


Hence in diethyl ether the open-chain lithium compound *(89)* predominates. Repetition of this experiment with lithium bromide in THF interestingly showed only the presence of *(88)*. In ether: tetrahydrofuran (2:1) the equilibrium mixture contained some 15 parts of *(88)* to 1 part of *(89)*. Reaction of *(86)* with magnesium bromide in THF gave the same Grignard reagent *(91)* as obtained from 4,4-diphenyl-3-butenyl bromide[68]; this Grignard reagent contains more than 99 % of the open form *(91)* in diethyl ether or in tetrahydrofuran.

These results were taken to mean that the open-chain lithium and magnesium compounds are truly covalent species while the cyclic lithium and potassium compounds are ionic species which are solvated. Better solvating solvents, tetrahydrofuran as opposed to diethyl ether, favor the ionic species with lithium as counterion.

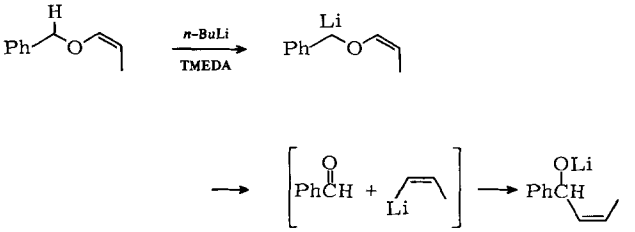
The kinetics of vinyl migration in labeled 3-methyl-3-butenylmagnesium bromide *(92)* has been investigated by *Maercker* and *Weber*[69]. The postulated cyclopropylmethyl intermediates *(93)* and *(96)* could not be detected chemically





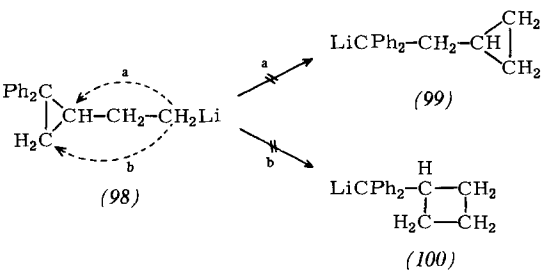
or by NMR spectroscopy. Hence the two phenyl groups of *(88)* must greatly stabilize the ionic intermediate by delocalization of the negative charge. The organolithium compound *(95)* rearranges much faster than the organomagnesium compound *(92)*. The calculated first-order rate constant for rearrangement of the organolithium compound was "largely independent of concentration" and increased with increasing solvating power of the solvent (cyclopentane < ether < THF); also addition of a little *N,N,N',N'*-tetramethylethylenediamine (TMEDA) greatly accelerated rearrangement. In contrast, *(92)* rearranged more readily in diethyl ether than in tetrahydrofuran; the calculated first-order rate constant for rearrangement increased with increasing concentration of *(92)* or of added magnesium bromide.

The kinetics of these rearrangements is complicated by molecular association of Grignard reagents[70] and organolithium compounds[71] in ethereal solvents and by irreversible reactions of organolithium compounds[72] with ethers. The kinetics of rearrangement of the organolithium reagent requires that the transition state of the rate-determining step be more highly solvated than the bulk of the reacting molecules. Within this broad category there are many detailed mechanisms possible within the restricted range of the kinetic studies. The simplest possibility, a slight modification of that of *Maercker* and *Weber*[69], is presented in Scheme 2.

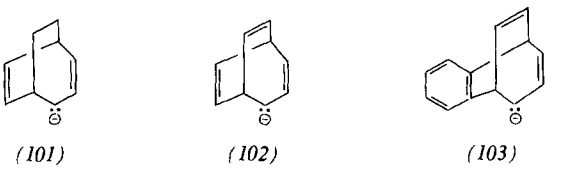


In this mechanism the rearrangement itself is depicted as occurring in a loose or solvent-separated ion pair. In contrast, the rearrangement of Grignard reagents[73a] is generally regarded as occurring by a concerted mechanism.

Scheme 2

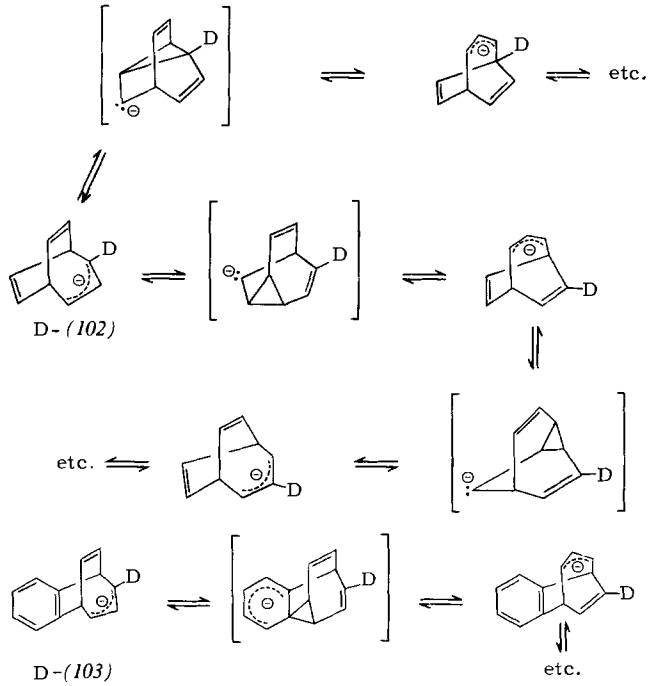


It has also been suggested[73b] for vinyl migrations in Wittig ether rearrangements that the initially formed lithium species cleaves to a vinyllithium derivative and a carbonyl compound, the two fragments then recombining to give the products.

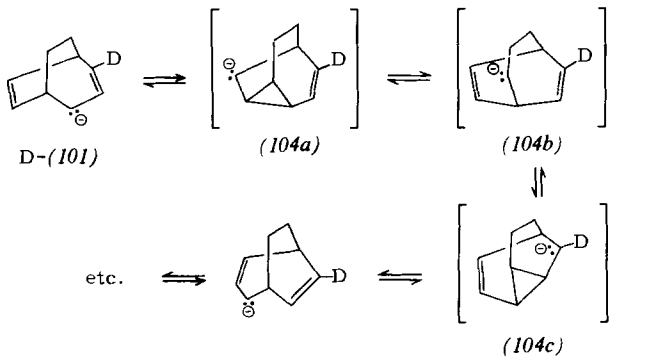


This mechanism accounts for the retention of geometry of the migrating vinyl group.

While cyclopropane rings sometimes behave somewhat like vinyl groups, it is notable that the organolithium compound *(98)* rearranged neither to *(99)* nor to *(100)*.

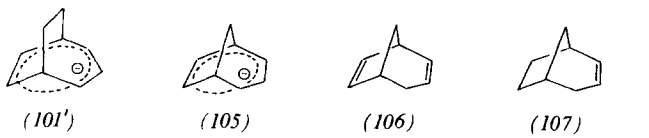


Instead, attempts[74] to force these rearrangements resulted in reaction of *(98)* with the solvent diethyl ether or tetrahydrofuran. What would much facilitate the study of such organoalkali compounds is a solvent which does not react with carbanions (cf. the "magic acid" of carbenium ion chemists).

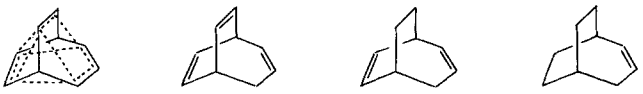


The bicyclic anions *(101)*, *(102)*, and *(103)* can be looked upon as homoallylic anions and hence in principle should

be able to undergo [1,2] vinyl migrations *via* cyclopropylmethyl intermediates. In fact, such rearrangements have been observed in suitably labeled derivatives of *(102)* and *(103)* but not of *(101)*. Thus *Grutzner* and *Winstein*[75] found that 2-deuteriobicyclo[3.2.2]nonatrienylyl anion D-*(102)* (as potassium salt) in an ethereal solvent underwent random scrambling of deuterium over all nine carbon atoms (four non-equivalent positions) of the anion with a half-life of 10 minutes at 28 °C. Similarly for D-*(103)* *Moncur*, *Grutzner*, and *Eisenstadt*[76] found that the deuterium label equilibrated over the seven carbons of the non-benzenoid moiety with a half-life of 1 hour at 32 °C; this seven-carbon scrambling

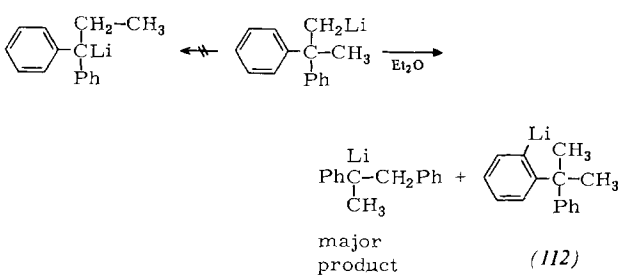


requires phenyl as well as vinyl migration. The deuterium-labeled bicyclo[3.2.2]nonadienyl anion D-*(101)* does *not* undergo analogous deuterium scrambling[76] evidently because this would require intervention of a series of unstable intermediates such as *(104a)*, *(104b)*, and *(104c)*.



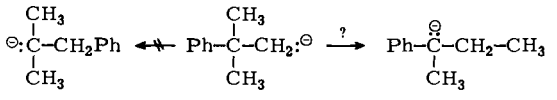
A cyclopropyl substituent evidently does not provide substantial stabilization[77] to an adjacent carbanionic center; the carbanions *(104a)* and *(104c)* and also the secondary carbanion *(104b)* are considerably less stable than the allylic anion *(101)*.

Indeed there is some evidence that the allylic anions *(101)*, *(102)*, and *(103)* are more stable than simple allylic anions. Thus anion *(101)* has been judged to be a bishomocyclopentadienyl anion[78] [see *(101')*] on the basis of both its NMR spectrum and its lifetime in ethereal solvents.



Similar arguments have been presented for the bishomoaromatic character of the lower homolog[79] *(105)*; the corresponding hydrocarbon *(106)* undergoes deuterium exchange with KO-*t*-Bu in dimethyl sulfoxide at 10^4 fold greater rate than *(107)* or cyclohexene. The anion *(102)* has been assigned the structure[75] *(108)* on the basis of its NMR spectrum. More detailed studies[78] upon *(108)* suggest that the major portion of the stabilization is due to bishomoaromatic stabilization (interaction between the allylic anion and *one* double bond); laticyclic interaction with the second double bond provides some 2.5 kcal/mol additional stabilization according

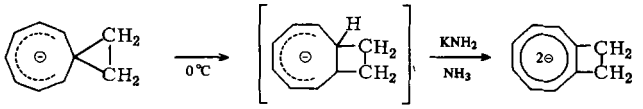
to studies upon the comparative lifetimes of *(101')* and *(108)* in tetrahydrofuran and 1,2-dimethoxyethane. A kinetic study[80] of detritiation of *(109)*, *(110)*, and *(111)* (all labeled with tritium at the allylic CH_2 group) by KO-*t*-Bu in dimethyl sulfoxide shows that *(109)* undergoes detritiation with an activation energy 4.0 ± 0.3 kcal/mol less than *(110)* while *(110)* has an activation energy > 5.6 kcal/mol less than that of *(111)*. While these studies are in agreement with structures such as *(101')* and *(108)* for the anions from detritiation, it was pointed out that the anion from *(111)* is formed less readily than anions from simple olefins and it was suggested that this anion was destabilized by interaction of the allylic moiety with the filled orbitals of the σ-framework. Since quantitative dissection of the observed reactivities into σ and π contributions is not resolved for the anions *(101)*, *(102)*, and *(103)* (if indeed it is resolvable), and because these anions and their related hydrocarbons have peculiar problems involving steric strain, the non-classical structures assigned to these anions must be accepted with some reservation. *Trimitsis* and *Tuncay*[81] have noted that the NMR spectra, in particular the sizable upfield shifts of *ca.* 1—2.5 ppm in the resonance of the protons directly attached to the remote carbon-carbon double bonds, do not necessarily imply that the anions in their ground states have the non-classical structures *(101')*, *(105)*, and *(108)*. It remains to be established whether the orbitals of these molecules, which have suitable symmetries and topologies for mixing and hence by molecular orbital theory must mix[82], do indeed undergo appreciable long range interaction.



3.3. Migrations of Alkyl Groups and Hydrogen

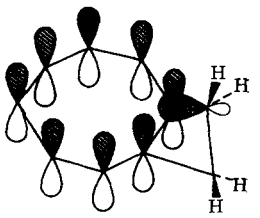
As noted in Section 2, [1,2] migration of alkyl groups in simple carbanions is not expected to occur as a concerted process according to molecular orbital considerations. This negative expectation is in agreement with much useful synthetic

chemistry. It finds confirmation in the careful study of *Zimmerman* and *Zweig*[7] who reported no migration of methyl in rearrangement of 2,2-diphenylpropyllithium to 1-methyl-1,2-diphenylethyllithium; the by-product *(112)* arose by *ortho*-metalation. Also cleavage[7] of bis(2,2-diphenylpropyl)mercury with potassium gave [1,2] migration of phenyl but no [1,2] migration of methyl.



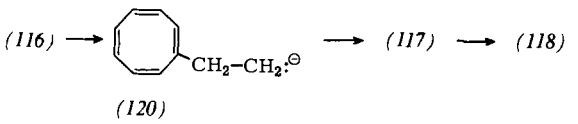
We considered that rearrangement of methyl in 2,2-diphenylpropyllithium might in principle occur but was masked by the more facile migration of phenyl. To test this postulate, reactions of neophyl chloride *(57)* with alkali metals have been studied. The corresponding 2-methyl-2-phenylpropyl anion (neophyl anion) *(113)* would not be expected to undergo phenyl migration since the product *(114)* would be a less stable tertiary anion; on the other hand, the product of methyl migration would be the more stable benzylic anion *(115)*. Reaction of neophyl chloride with lithium in THF

(114) *(113)* *(115)*



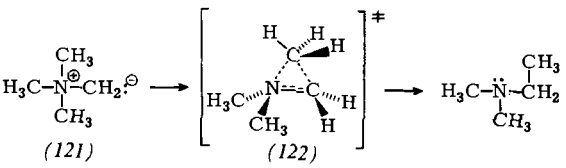
at −65 °C gave a product consisting of 93 % of neophyllithium *(59)* and 6 % of its rearrangement product 1,1-dimethyl-2-phenylethyllithium *(58)* (see Section 3.1); when the reaction mixture was warmed to 4 °C for 4 hours before carbonation, the reaction mixture contained less than 5 % (if any) of the 2-phenylbutane skeleton derived from *(115)*. Attempts to catalyze the rearrangement of neophyllithium with a large excess of *N,N,N',N'*-tetramethylethylenediamine in THF at −20 °C likewise did not give any appreciable products with methyl migration. Reaction of neophyl chloride with Cs-K and Cs-K-Na alloys in THF at −40 to −63 °C gave, upon carbonation, complex mixtures of products containing 1 to 4 % of an acid judged to be 2-methyl-2-phenylbutanoic acid [derived from *(115)*] according to its retention time in gas chromatographic analysis. Thus methyl migration is at most a minor reaction of carbanion *(113)*; additional work will be required to establish if any of the rearrangement product *(115)* arises by *direct intramolecular* methyl migration in *(113)*[83].

Are there any examples of concerted [1,2] migration of alkyl groups in carbanions? In carbanions containing only carbon and hydrogen such rearrangements at present are rare to non-existent. A possible example is provided by the rearrangement[84] of the spirocyclic anion *(116)* (with potas-



(116) *(117)* *(118)*

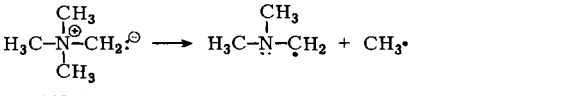
sium as counterion in liquid ammonia solution) to the anion *(118)* evidently by way of *(117)*. The rearrangement of *(116)* to *(117)* while resembling a [1,2] sigmatropic rearrangement may also be looked upon as a [1,8] rearrangement *via* a Hückel array of nine orbitals [see *(119)*] and 10 electrons, a transition state which is expected to be stable or aromatic by analogy with related [1,5]-alkyl shifts in cyclopentadienes[85]. As *Staley et al.*[84] noted, however, non-concerted rearrangements of *(116)* are not excluded by the available



(119)

data. An attractive alternative involves a homoallyl anion *(120)*; in this case the initial rearrangement is but another example of the cyclopropylmethyl-homoallyl anion rearrangement of Section 3.2.

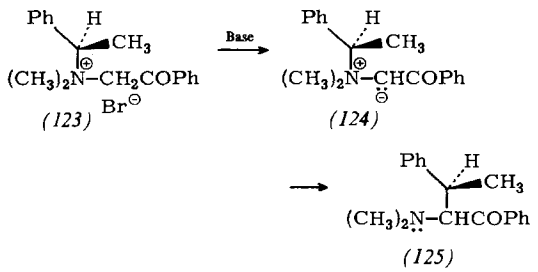
(120)



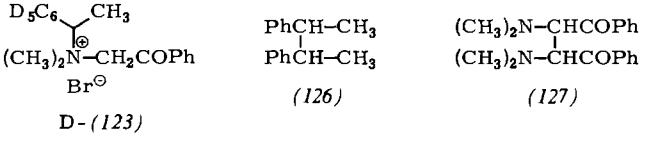
Are there any examples of concerted [1,2] migrations of alkyl groups in carbanions containing hetero atoms? We have answered this question in the affirmative for the Stevens rearrangement[37]; however the question continues to be one which is widely debated. Naive HMO calculations for the rearrangement of a simple ylide *(121)* [eq. (l)], with use of the parameters of *Zimmerman* and *Zweig*[7] but with the Coulomb integral

(121) *(122)* (l)

for nitrogen in *(121)* and *(122)* taken to be $\alpha + 1.5\beta$ rather than simply the value α for carbon, show that the transition state *(122)* is only 0.11β units higher in energy than *(121)*; this result, compared to a value of 1.33β for migration of a methyl group in the *n*-propyl anion (see Section 2), suggested to us[37] that migration of a methyl group in a simple ylide might be a facile concerted process. Qualitatively the difference between rearrangement of methyl in an all-carbon anion and in an anion such as *(121)* containing a heteroatom is that, if the heteroatom is sufficiently more electronegative than carbon, then the transition state will benefit by having more electron density on the more electronegative atom than will the reactant.



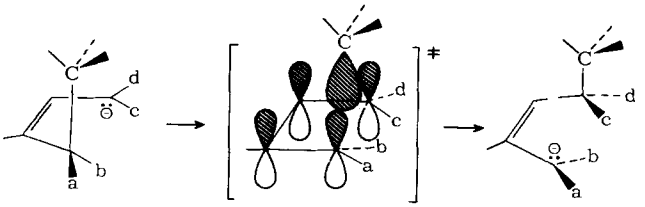
Dewar and *Ramsden*[86] have strengthened this argument by more complete calculations (MINDO/3) for the rearrangement of *(121)*. For rearrangement in the gas phase, the transition state *(122)* is calculated to lie only 4.1 kcal/mol above the reactant *(121)*, while the product *(123)* is 87 kcal/mol more stable than the reactant. Similar calculations also show, however, that in the gas phase the dissociation into radicals [eq. (m)] is exothermal by 10 kcal/mol and occurs without activation energy. The final product *(123)* could, therefore, be formed by combination of the resulting radicals. In practice



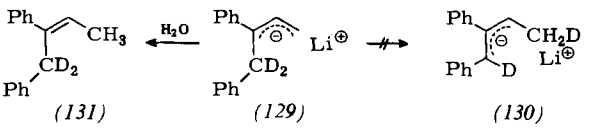
(121) (m)

Stevens rearrangements are carried out in solvents (water, alcohol, ethers) which will solvate polar molecules such as *(121)*. *Dewar* and *Ramsden* note that in the dissociation into radicals most of the solvation energy of *(121)* will be lost but that in formation of the cyclic transition state *(122)*, since this occurs early along the reaction coordinate, much solvation will persist; hence it was thought that the pericyclic path [eq. (l)] could be favored for rearrangement of the ylide in polar solvents. These calculations suggest to the author that the "forbidden" pericyclic mechanism and the radical dissociation mechanism should frequently be competitive processes with the net outcome dependent upon the detailed reaction conditions.

Experimental observations[87] appear to be in accord with this view. For example *Ollis, Closs, et al.*[88] have carefully re-investigated the rearrangement of the salt *(123)*. Treatment of *(123)* with aqueous sodium hydroxide at 0°C gave the

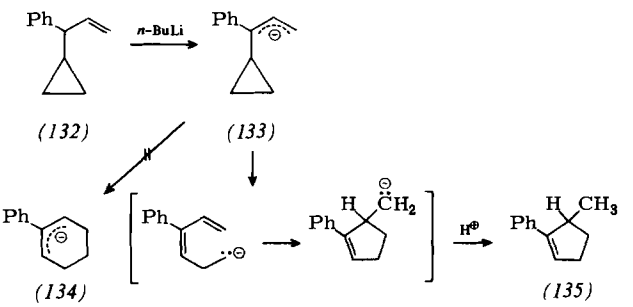


amine *(125)* with 99±1% net retention of configuration at the chiral center of the migrating α-phenylethyl group. The rearrangement was also shown under these conditions to be at least 99% intramolecular by mass spectral examination of the product from an equimolecular mixture of *(123)* (as racemic salt) and its racemic decadeuterio-derivative D-*(123)*. In contrast, in methanolic sodium methoxide at 55°C the salt *(123)* rearranges with 56% net retention and 44±2% racemization and gave intermolecular products to the extent



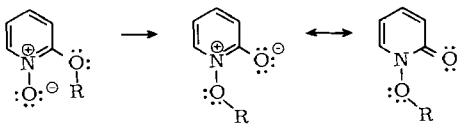
of about 20%. Under the latter conditions, but not under the former, the "escape" products *(126)* and *(127)* were formed, each in 6% yield of mixtures of the two possible diastereomers. A quantitative CIDNP study[89] of the rearrangement of the crystalline ylide *(124)* in $CDCl_3$ gave experimental enhancement factors of only some 25% of that calculated for the radical pair theory assuming freely diffusing radical pairs. These results are in agreement with rearrangement occurring by two competing mechanisms, one a radical pair process and the other a concerted pericyclic process, the latter being the dominant pathway under the conditions studied. Alternatively it may be argued that the entire process occurs by way of radical pairs but that the primary recombination rate is fast relative to the time for a radical to rotate within the pair or the time for a radical to diffuse from the solvent cage.

In a discussion of the related Wittig rearrangement of aralkyl alkyl ethers, *Garst* and *Smith*[90] point out that the distinction between a concerted process and one proceeding by a primary recombination of radicals within a solvent cage is rather ambiguous: one must decide arbitrarily on the degree of interaction between radicals, below which they would be classified as radical pairs and above which as an intermediate state or transition state for the concerted process. Rather than attempting to make such a distinction, *Garst* and *Smith* have suggested that such mechanisms be termed "radical-concerted."



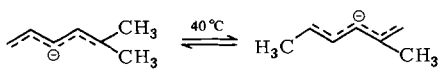
Are there any known examples of concerted [1,*n*] migration of alkyl groups in carbanions when *n* is larger than 2? As has been pointed out previously the rearrangement of *(116)*

may be an example of a [1,8] sigmatropic process. Suprafacial-suprafacial [1,4] sigmatropic rearrangements look especially promising and are allowed processes by orbital symmetry considerations[8]. Such migrations are seen to proceed by way of a transition state *(128)* which constitutes a Hückel array of five orbitals containing 6 electrons and is therefore expected to be "aromatic." *Magid* and *Wilson*[91] noted that the anion *(129)* failed to give *(130)* *via* [1,4] migration of deuterium when the red hexane/THF solution was refluxed overnight; hydrolysis gave *(131)* with an unchanged molecular



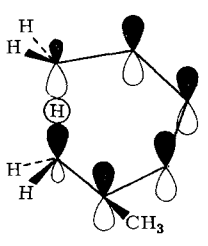
skeleton. The cyclopropyl compound *(132)*, upon reaction with *n*-butyllithium in hexane/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine followed by heating at 60°C for one hour before hydrolysis, gave *(135)*[91], probably by rearrangement to a homoallyl anion as shown, rather than [1,4] migration of

methylene to give *(134)*. These failures show that [1,4] migration is not a ready process in allylic anions. The rearrangement of *(133)* to *(134)*, while it would involve relief of ring strain, would also require loss of delocalization energy [the phenyl group in *(134)* is located on a carbon which is at a nodal position in the highest filled molecular orbital of the allylic anion]. Also in the transition state [see *(128)*] for [1,4] migra-



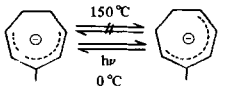
tion, steric interference between groups b and c would be expected to inhibit bringing the ends of the diene moiety close enough for bridging by the migrating group. Perhaps it is the absence of such groups which facilitates rearrangement of 2-alkoxypyridine *N*-oxides along with other beneficial effects of electronegative oxygen atoms.

Schöllkopf and *Hoppe*[92] in a systematic study of the rearrangement of 2-alkoxypyridine *N*-oxides *(136)* to *N*-alkoxy-2-pyridones *(137)* find that the rearrangement is first order and



(136) *(137)*

occurs with apparently complete retention of configuration of the migrating group (R = CHDPh). The rate difference for migration of common alkyl groups (methyl, ethyl, isopropyl, neopentyl) is small (less than ninefold). Unsaturation in the migrating groups facilitates migration; benzyl, allyl, and 2,4-hexadienyl migrate some three, eleven, and one-thousand fold more readily than methyl but the Hammett ρ value for migrating benzyl groups is only *ca.* −0.3. Allyl, propargyl, and 2,4-hexadienyl migrate without "allyl inversion" and cyclopropylmethyl migrates without skeletal rearrangement. The enthalpy of activation is small (5 to 14 kcal/mol) while the entropy of activation is very negative (−43 to −62 cal K^{-1} mol^{-1}). As *Schöllkopf* and *Hoppe* note, these facts agree well with migration of the group R of *(136)* by a concerted suprafacial-suprafacial [1,4] process [see transition state *(128)*]. On the other hand when R is benzhydryl, the product of rearrangement shows a CIDNP signal; rearrangement evidently occurs by a radical-pair process. Some anionic rearrangements of allylammonium salts[93] and allyl ethers[94] also occurs with [1,4] migration of alkyl groups but the mechanisms of these rearrangements have not been clarified.



(138) *(139)*

Thermal isomerizations such as the reaction *(138)* ⇌ *(139)*, involving concerted antarafacial [1,6] migrations of hydrogen, are believed to occur in pentadienyl anions *via* an intramolecular process according to *Bates et al.*[95]. The transition state *(140)* for the proton migration of the lithium salt of *(138)* in THF/hexane evidently is preceded and followed by geometrical isomerization. This transition state is a Möbius array of orbitals (one sign inversion in the basis set) which is popu-

(140)

(141) *(142)*

lated by 8 electrons and hence is expected to be an allowed (or aromatic) transition state[15]. In contrast, the related thermal rearrangement of *(141)* to *(142)*, if a concerted intramolecular process, is constrained so that only a forbidden suprafacial [1,6] proton migration is sterically feasible. In agreement anion *(141)* did not rearrange to *(142)* (or *vice versa*) when heated to 150 °C for 30 minutes; however, the suprafacial [1,6] hydrogen migration occurred upon irradiation at 0 °C with a high-pressure mercury lamp in a quartz apparatus as expected from the theory of conservation of orbital symmetry[8].

3.4. Migration of the Benzyl Group in Competition with Phenyl

Reaction of 1-chloro-2,2,3-triphenylpropane with lithium in THF at −65 °C gives, as expected, 2,2,3-triphenylpropyllithium *(143)*. When the latter is warmed to 0 °C, rearrangement to 1,1,3-triphenylpropyllithium *(144)* occurs readily[96].

$$PhCH_2{-}CPh_2{-}CH_2Cl \xrightarrow{Li} \underset{(143)}{PhCH_2{-}CPh_2{-}CH_2Li}$$

$$\xrightarrow{0\,^\circ C} \underset{(144)}{LiCPh_2{-}CH_2{-}CH_2Ph}$$

This rearrangement has the appearance of a concerted [1,2] sigmatropic migration of the benzyl group; however, experiments[37,97] soon showed that this was not the case. Thus rearrangement of *(143)* in presence of [α-^{14}C]-benzyllithium gave *(144)* labeled with carbon-14. A likely mechanism for this incorporation of external benzyllithium is *via* an elimination-readdition mechanism [eq. (n)]. The rearrangement was

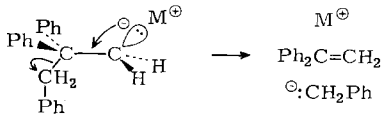
$$\underset{(143)}{PhCH_2{-}CPh_2{-}CH_2Li} \rightarrow PhCH_2Li + Ph_2C{=}CH_2$$

$$\xrightarrow{Ph\,{}^*CH_2Li} \underset{^{14}C\text{-}(144)}{LiCPh_2{-}CH_2{-}{}^*CH_2Ph} \qquad (n)$$

shown to be irreversible; the benzyllithium which became incorporated in the product *(144)* had the same activity as the benzyllithium in the bulk of the solution at the time of the addition. Alternatively a fragmentation of *(143)* into benzyl radical and diphenylethylene radical anion could also account for the results if lithium atom exchange between benzyllithium and benzyl radical is assumed to be rapid. We have always favored the elimination-addition mechanism since in MO theory diphenylethylene radical anion has in its highest occupied molecular orbital (HOMO) an electron which is antibonding whereas benzyl anion has in its HOMO nonbonding electrons. (In contrast, in the Wittig and Stevens rearrangements the corresponding radical anion is stabilized by electronegative oxygen and nitrogen atoms, respectively.) The intermediate diphenylethylene in rearrangement of *(143)* could also be intercepted by isopropyllithium[37].

In opposition to the above results with lithium, reaction[35] of 1-chloro-2,2,3-triphenylpropane with cesium in THF at 65 °C gives organometallic products containing 96 % of [1,2] migration of phenyl rather than benzyl [eq. (o)].

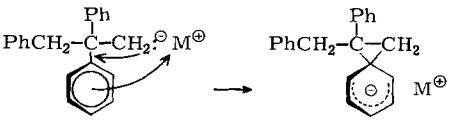
$$PhCH_2{-}CPh_2{-}CH_2Cl \xrightarrow{Cs} [PhCH_2{-}CPh_2{-}CH_2Cs] \longrightarrow PhCH_2{-}\overset{Ph}{\overset{|}{C}}{-}CH_2Ph \quad (Cs^{\oplus}) \qquad (o)$$



A more detailed study of the cation effect was conveniently made by reaction[98] of the unrearranged organolithium compound *(143)* with alkali metal alkoxides in THF according to the metathetical reaction of eq. (p). While the lithium compound *(143)* does not rearrange at an appreciable rate in

$$\underset{(143)}{PhCH_2{-}CPh_2{-}CH_2Li} + MO\text{-}t\text{-}Bu \longrightarrow PhCH_2{-}CPh_2{-}CH_2M + LiO\text{-}t\text{-}Bu \qquad (p)$$

THF at −75 °C, addition of sodium *tert*-butoxide or better potassium and cesium *tert*-butoxides under the same conditions effected ready rearrangement. The rearrangement product with sodium *tert*-butoxide was entirely that of benzyl migration, while with potassium and cesium *tert*-butoxide the ratio of benzyl to phenyl migration was 63:37 and 26:74 respectively. If, however, the potassium and cesium *tert*-butoxides were complexed with 18-crown-6 prior to addition to the lithium reagent, the only rearrangement product was that from benzyl migration.

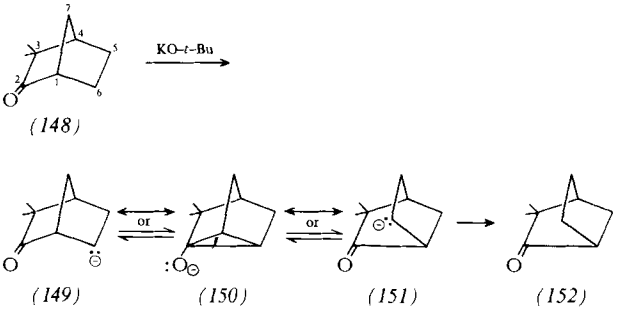


These and other experiments[35] reveal that the following compounds undergo reaction almost exclusively by benzyl migration: 2,2,3-triphenylpropyllithium and -sodium in THF at 0 °C and −75 °C, respectively; 2,2,3-triphenylpropylpotassium and -cesium as 18-crown-6 complexes in THF at −75 °C. The following undergo rearrangement almost exclusively by phenyl migration: 2,2,3-triphenylpropyllithium in diethyl ether at 35 °C; 2,2,3-triphenylpropylpotassium and -cesium in THF at 65 °C. Stated otherwise, benzyl migration is favored by low temperatures, good solvents for solvating cations, coordination of cations by 18-crown-6, and small alkali metal cations; phenyl migration is favored by high temperatures, poorly solvating solvents, absence of good ligands, and large alkali metal cations. The conditions which favor benzyl migration favor loose or separated ion pairs, while those which favor phenyl migration favor tight or contact ion pairs[99]. In terms of the likely mechanisms for migration, it appears that benzyl cleavage [see eq. (n)] occurs in a transition state resembling a loose ion pair while phenyl migration (see Section 3.1) occurs in a transition state resembling a tight ion pair.

These results may be rationalized[35] on the basis that benzyl cleavage occurs in an *anti-periplanar* conformation [see *(145)*] which gives rise to a delocalized benzyl anion separated from the counter cation by a molecule of diphenylethylene. The negative charge is greatly separated from the cation in the

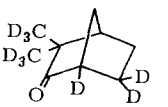
(145)

transition state for this reaction; the electrostatic work required for such charge separation is greatly reduced by solvation of the cation as in a loose ion pair. In contrast, for the transition state [see *(146)*] leading to the spiro anion *(147)*, the alkali metal cation in the tight ion pair may accompany the anionic center during bridging such that no great charge separation is necessary at anytime for the cyclization.



(146) *(147)*

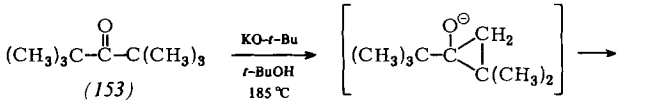
Hence phenyl migration does not benefit as much from solvation of the cation as does benzyl cleavage. Some related solvent effects were observed by *Biellmann* and *Schmitt*[100] in studies of the Stevens rearrangement in competition with the Sommelet-Hauser rearrangement.



3.5. Migration of Carbonyl, Alkoxycarbonyl, *etc.*

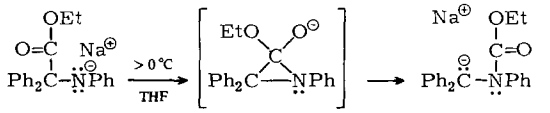
Nickon et al.[101] established that optically active camphenilone *(148)* when heated strongly (*ca.* 185 °C) with potassium *tert*-butoxide in *tert*-butyl alcohol undergoes racemization, evidently by the reaction shown.

(148) *(149)* *(150)* *(151)* *(152)*



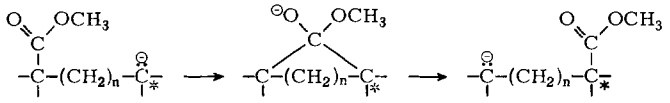
When the reaction was conducted in *t*-BuOD the percentage of racemization and the total percentage of molecules containing deuterium were the same within experimental error. The conclusion was that the intermediate "homoenolate" either had a symmetrical structure [resonance hybrid of the canonical structures *(149)*, *(150)*, and *(151)*] or else if unsymmetrical like *(149)* it rearranged to its enantiomer *(151)* faster than it reverted to ketone. Since the rate of deuterium exchange equals the rate of racemization, the homoenolate ion is the most stable anion which can be formed from ionization of ketone. This fact implies that the homoenolate ion must receive appreciable stabilization by homoconjugation [some resonance interaction between *(149)* and *(150)*] since if only inductive effects were involved the anion at the position (C-1) *alpha* to the carbonyl group would be most acidic (note that mesomeric stabilization of this enolate ion is inhibited by approximate orthogonality of orbitals). Upon prolonged reaction with potassium *tert*-butoxide in *t*-BuOD at 185 °C or better at 250 °C, camphenilone *(148)* exchanged up to nine hydrogens per molecule, the completely deuterated product being D-*(148)* (and enantiomer).

D-*(148)*



This experiment shows that the anion at the bridgehead position C-1 is not much less stable than the homoenolate ion; also ionization of both methyl groups gives homoenolate ions. In contrast, the proton at C-7 and the remote protons at C-4 and C-5 are not ionized. This positional specificity is understandable if the carbanionic center must undergo some orbital interaction with the carbonyl group for stabilization. That *both* protons on C-6 are exchanged shows that protonation of the enolate is not entirely stereospecific even though >94% of the homoenolate [*(149)—(151)*] is thought to be protonated at the *exo* position (the side more remote from the carbonyl).

The racemization of camphenilone *(148)* involves an overall [1,2] migration of the carbonyl group. *Freeman* and *Plonka*[102] generated homoenolate ions by indirect methods and showed that the expected migration of carbonyl group occurred. Recently *Rampersad* and *Stothers*[103] have shown that ionization of the β-hydrogens of di-*tert*-butyl ketone *(153)* and 5,5,7,7-tetramethylundecan-6-one does indeed give skeletal rearrangement.



(153) *(154)*

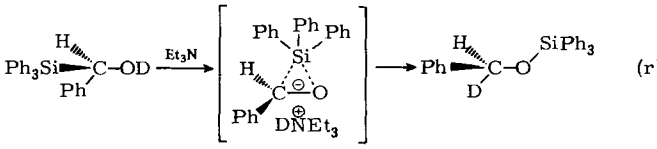
Brooke and *Rutherford*[104] discovered an example of [1,3] migration of a trifluoroacetyl group from nitrogen to carbon. *Smith* and *Simpson*[105] reported an example of [1,2] migration of an ethoxycarbonyl from carbon to nitrogen [*(155)→(156)*]. *Acheson*[106] has suggested that in general

(155) *(156)*

[1,2], [1,3], [1,4], and [1,5] migration of alkoxycarbonyl groups should occur in carbanions such as *(157)→(158)* and cites several possible examples, which, however have not been studied in mechanistic detail. Related rearrangements

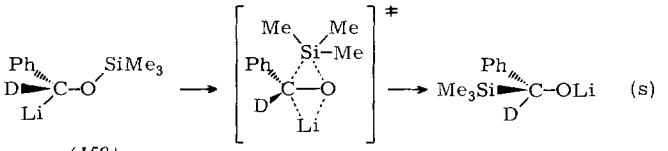
(157) *(158)*

of anions such as of the *N,N*-dimethylthioamide group[107] have also been reported. All of these rearrangements have striking similarity to the migration of vinyl groups (Section 3.2) and can be viewed as related to intramolecular aldol condensations.



3.6. Migration of Silyl, Germyl, and Related Groups

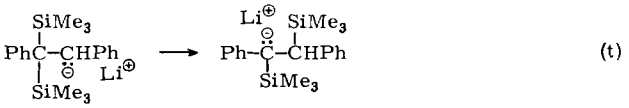
While [1,2] sigmatropic suprafacial shifts of alkyl groups in carbanions are forbidden by orbital symmetry (Section 2) and occur with difficulty, if at all, except when electronegative hetero atoms are present (Section 3.3), similar migrations of silyl groups may occur without symmetry restrictions through a pentacoordinate transition state (or intermediate). An early example was the Brook rearrangement[108] of silylmethanols [eq. (q)] which is promoted by traces of sodium-po-



(q)

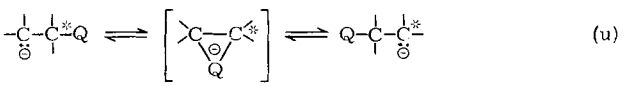
tassium alloy or bases such as pyridine or triethylamine. By use of optically active compounds containing a chiral silicon center, it was shown that the silyl group migrated with retention of configuration. Studies with an asymmetric carbon center[108, 109] showed that a highly stereospecific inversion of configuration occurred at the chiral carbon center during rearrangement [see eq. (r)]. The reverse rearrangement is pro-

(r)



moted by metalation at the benzyl carbon atom with excess *tert*-butyllithium in THF/pentane at −50 °C followed by decomposition with excess acetic acid; again the migration occurs with highly stereospecific inversion[110], evidently according to eq. (s). The abstraction of the proton by *tert*-butyllithium to give *(159)* and the movement of silicon into the bridging position *(160)* may be almost concerted.

(159) *(160)*

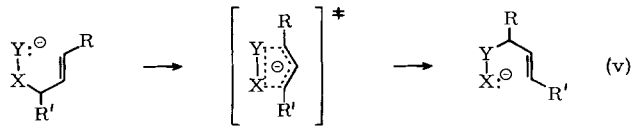


(s)

Many analogous [1,2] and also [1,4] migrations of organosilyl groups to and from various hetero atoms have been discovered by *West et al.*[111]. Similar [1,2], [1,3], and [1,4] shifts of organosilyl groups from carbon to a carbanionic center [*e.g.*, eq. (t)] have been reported by *Eisch* and *Tsai*[112].

(t)

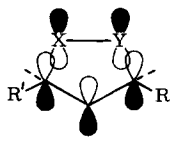
Germanium[110, 113] and phosphonium[114] compounds have been found to undergo related anionic rearrangements with migration of germanium and phosphorus centers. As has been pointed out previously[39], for concerted rearrangements of the type shown in eq. (u), the group Q needs to be unsaturated (vinyl, carbonyl, aryl) or to possess "unsaturated" character because of the presence of vacant d or p



(u)

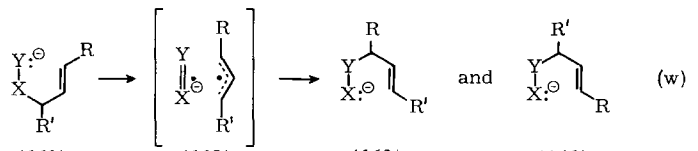
orbitals on the atom Q. It seems likely that many additional examples of such rearrangements will be reported in the future.

4. [2,3] Sigmatropic Rearrangements of Carbanions; Migration of Allyl Groups



The [2,3] sigmatropic rearrangement of ylides and related anionic species [*(161)* → *(163)*] is a process of great facility and widespread occurrence[87, 115]. That this rearrangement

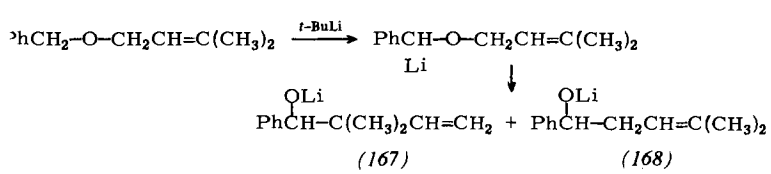
(v)



(161) *(162)* *(163)*

involves an allylic inversion was clearly demonstrated by *Schöllkopf* and *Fellenberger*[116] for allyl migration in the anions of fluorenyl allyl ethers. That the rearrangement occurs suprafacially for both the X-Y and the allylic moiety was demonstrated by *Baldwin* and *Patrick*[115] in studies upon rearrangement of the anion of the benzyl ether of (*S*)-*trans*-3-penten-2-ol. The transition state *(162)* for this concerted rearrangement is shown in terms of the basis set of atomic orbitals in *(164)*. It is notable that this array of orbitals constitutes a Hückel system and, since it contains six π-electrons, is expected to be a stable or "aromatic" transition state.

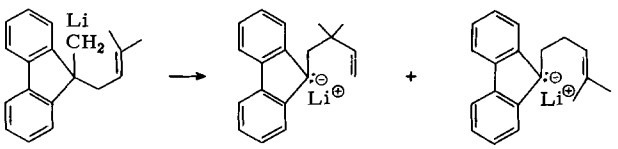
(164)



While the concerted mechanism constitutes the major path in rearrangement of allyl ether anions, and related species, *Baldwin et al.*[117] have suggested that a duality of mechanism exists with minor products being formed with only partial allylic inversion by a non-concerted radical dissociation-recombination process [*(161)* → *(163)* and *(166)*]. The extent of the radical dissociation process increases with temperature.

(w)

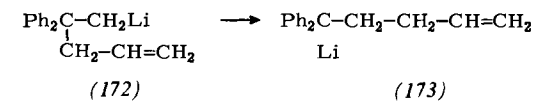
(161) *(165)* *(163)* *(166)*



Thus benzyl 3-methyl-2-butenyl ether with *tert*-butyllithium gives[117] a 95:5 mixture of *(167)* and *(168)* at 25°C and a 98:2 mixture at −10°C. While the rearrangement of *(161)* to *(163)* and *(166)* has been depicted as giving *trans* products, lesser quantities of *cis*-products are also formed[115], presumably by both mechanisms [eqs. (v) and (w)].

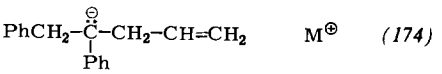
(167) *(168)*

Other examples of the general rearrangement of *(161)* to *(163)* [and sometimes *(166)*] are allyl migration in anions of thio ethers[118], in allylic disulfides[119], in sulfur[120] and nitrogen ylides[121], in *N*-ammonio-amidates[122], in amine oxides[123], and in diazenes[124]. The Sommelet-Hauser rearrangement may be looked upon as a specialized example of the same general process. These rearrangements are closely akin to the Cope and Claisen rearrangements. Are any [2,3] sigmatropic rearrangements known in anions containing only carbon and hydrogen? Two cases have, in fact, been studied.



Baldwin and *Urban*[125] observed that [9-(3-methyl-2-butenyl)-9-fluorenyl]methyllithium *(169)* rearranges in THF to give predominantly the lithium compound *(170)* at −20°C

(169) *(170)* *(171)*

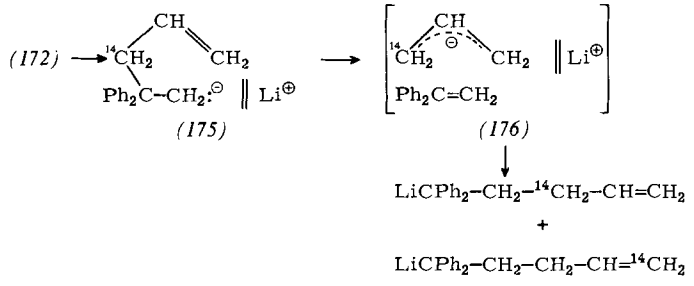


along with *(171)* which was formed in increasing amounts as the temperature was raised. Their interpretation was that *(170)* was formed by an anionic [2,3] sigmatropic rearrangement [eq. (v)] while *(171)* (and an unknown amount of *(170)*) resulted from a radical dissociation-recombination process [eq. (w)].

In related work[126] 2,2-diphenyl-4-pentenyllithium *(172)* was observed to rearrange in THF at −50 to 0°C to give chiefly 1,1-diphenyl-4-pentyllithium *(173)*. With [3-^{14}C]-2,2-diphenyl-4-pentenyllithium, carbon-14 was found in *(173)*

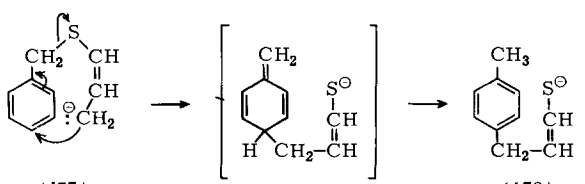
(172) *(173)*

either at the terminal C-5 position (allylic inversion) or scrambled at positions C-3 and C-5. The amount of scrambling increased with increasing temperature, being some 37% at −50°C and 67% at *ca.* 0°C. Potassium and cesium *tert*-butoxides with *(172)* in THF at −75°C induced ready rearrangement to give chiefly 1-benzyl-1-phenyl-3-butenyl anion *(174)*, which is the product of [1,2] migration of phenyl. When, however, the potassium *tert*-butoxide was complexed with 18-crown-6 prior to addition to *(172)* in THF at −75°C,



(174)

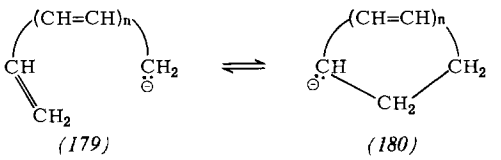
the chief product was 1,1-diphenyl-4-pentenyl anion which was formed with complete inversion of the allyl group according to a tracer study with carbon-14. These results are interpreted to mean that allyl migration occurs in a highly solvated transition state, probably in a loose ion pair either by a [2,3] sigmatropic process (with allylic inversion), favored by low temperatures, or by a dissociation-recombination mechanism (with scrambling of the allylic label); on the other hand, phenyl migration occurs in a more weakly solvated



transition state, likely in a tight ion pair, by a [1,2] sigmatropic process (see Section 3.4).

The details of the dissociation-recombination mechanism are unclear. In an experiment in which the lithium compound *(172)* was mixed with [^{14}C]-allyllithium prior to warming in THF, from −75 to 0 °C to effect rearrangement, the resulting product from allyl migration had picked up only 14% of the maximum possible radioactivity from the allyllithium in the surrounding solution. Yet under these conditions, 67% allylic scrambling and 33% inversion occurs. One possible mechanism is by elimination of allyllithium from a loose ion pair *(175)* derived from *(172)*. Evidently the eliminated

allyllithium is formed initially as a loose ion pair which collapses to ordinary allyllithium at a rate of about 14/67th or 21% of that at which addition occurs to diphenylethylene. The rate of collapse of the loose ion pair is expected to be very fast and hence the rate of addition of the loose ion pair to diphenylethylene must be somewhat faster. In contrast ordinary allyllithium, which evidently exists in THF as a tight ion pair, in which the carbon-metal bond is partially localized or covalent, adds to diphenylethylene comparatively slowly. If the collapse of the loose ion pair of allyllithium occurs nearly at the diffusion-controlled rate, then the intermediates *(176)* need to be described as existing within a solvent cage. The loose ion pair must then add to diphenylethylene at about the diffusion-controlled rate, a process which is perhaps facilitated by having the diphenylethylene as a ligand of the lithium cation. The mechanistic complexities here are somewhat analogous to those described (see Section 3.3) for the Stevens rearrangement; indeed a radical dissociation process [eq. (w)] is not excluded by the available data.



Are there any sigmatropic rearrangements of carbanions of order higher than [2,3]? The question probably should be answered in the affirmative since *Fráter* and *Schmid*[127] have reported [5,5] sigmatropic shifts to occur with allylic inversion in rearrangements of 2,4-pentadienyl phenyl ethers. Indeed, *Biellmann* and *Ducep*[118b] have reported the isolation of *(178)* (as methyl thioether) among other rearrangement

products from reaction of benzyl allyl sulfide with *n*-butyllithium. Evidently *(178)* results from a [4,5] sigmatropic rearrangement of *(177)* (*via* a transition state consisting of a Hückel array of nine orbitals containing 10 electrons); however, other mechanisms have not been excluded.

5. Electrocyclic Reactions of Carbanions

The migration of phenyl and vinyl groups in carbanions has been described as involving cyclization followed by ring opening (see Sections 3.1 and 3.2); however, the process under discussion in the present section refers to cyclization of fully conjugated systems and the converse process [*(179)*⇌*(180)*]. Examples are now known for the cases $n=0$ (ring opening), $n=1$ (ring opening and ring closure), and $n=2$ (ring closure).

In most cases so far tested, the geometrical modes of ring opening and closure are in accord with predictions[8] from orbital symmetry ($n=0$ or 2, conrotatory; $n=1$, disrotatory). These reactions have been discussed in detail elsewhere[128].

6. Conclusions

The question of whether or not carbanions undergo molecular rearrangement must be answered in the affirmative even for anions containing only carbon and hydrogen as work of the last twenty years from diverse laboratories has now made abundantly clear.

Most skeletal rearrangements of carbanions belong to the general class of *intramolecular* rearrangements. Such reactions have always fascinated chemists, in part because they represent organic reactions at the simplest possible level of complexity. For intramolecular reactions, chemists no longer need to be concerned about the ordinary requirement of molecular collisions to bring molecules into proper contact. Instead organoalkali compounds must undergo suitable solvation and conformational changes; however, for rearrangement *via* cyclic transition states of small to medium ring size the number of possible conformations is limited and the choice between them can generally be made from stereochemical studies. Hence intramolecular rearrangements frequently occur in transition states of known geometry. Concerted intramolecular rearrangements necessarily involve cyclic transition states. Cyclic structures involving conjugated systems have unique properties, as first recognized by *Kekulé* for benzene. The application of quantum mechanics to the study of such cyclic molecules and related transition states has enjoyed considerable success and nowhere is this more evident than in the study of rearrangements of carbanions.

More complex are rearrangements of organoalkali compounds which do not take place by intramolecular paths. Interestingly many of these appear to be at the borderline between concerted and non-concerted processes; here even the distinction between homolytic and heterolytic cleavage may be blurred.

Chemists should note, however, that simple molecular orbital theory omits the role of the counterion and the solvent. By variation of the alkali metal, the temperature, the ligands of the metal cation and/or the solvent, the chemist is able to exert considerable control over the rate of rearrangement, the relative migratory aptitude of groups, and the mechanism of rearrangement. That carbanion rearrangements do not occur in acyclic saturated anions is of considerable importance in synthetic chemistry. The rapidity and complexity of rearrangements of carbenium ions has severely limited their utility in synthesis.

It is the author's hope that this review may help make syntheses *via* organoalkali compounds more successful by pointing out the general conditions needed to effect rearrangement and the type of rearrangement which may be encountered. Occasionally rearrangement itself may produce structures which are not readily available by other pathways. Surely future workers will uncover yet unsuspected rearrangements of organoalkali compounds.

The author is pleased to acknowledge the many contributions of current and former students and research associates who did most of the work ascribable to the author's laboratory. Financial support from the National Science Foundation for all the recent work is gratefully acknowledged.

Mechanistic and Preparative Aspects of Vinyl Cation Chemistry

By Michael Hanack[*]

Compelling evidence for the intermediacy of vinyl cations has accumulated in recent years. Vinyl cations can be generated by electrophilic additions to alkynes and allenes, and on participation of such functions in solvolysis reactions. Heterolysis of vinyl compounds likewise affords vinyl cations. Syntheses of substituted indenes, cyclobutanones, and cyclopropyl ketones illustrate preparative applications.

1. Introduction

Few areas of organic chemistry have been studied so intensively over a period of 75 years as has the chemistry of carbenium ions. The term carbenium ion was long applied only to those intermediates in which the positively charged carbon atom is linked to three substituents (trisubstituted or saturated carbenium ions) *(1)*.

(1) $-\overset{|}{\underset{|}{C}}-\overset{\oplus}{C}$ $\quad$ $>C=\overset{\oplus}{C}-$ *(2)*

Only comparatively recently have disubstituted carbenium ions, of which the vinyl cation *(2)* is an important representative, been studied in detail; thus in 1969 *W. M. Jones* was at last able to write: "Vinyl cations have finally become acceptable members of the reactive intermediate community"[1].

Apart from vinyl cations, acylium *(3)* and nitrilium ions *(4)* also number among the disubstituted carbenium ions. A further disubstituted carbenium ion, *i.e.* the phenyl cation *(5)*, has so far been unequivocally detected in only few reactions.

$-\overset{\oplus}{C}=\ddot{O} \longleftrightarrow -C\equiv\overset{\oplus}{O}:$ $\qquad$ $-\overset{\oplus}{C}=\ddot{N}-R \longleftrightarrow -C\equiv\overset{\oplus}{N}-R$

(3) $\qquad$ *(4)*

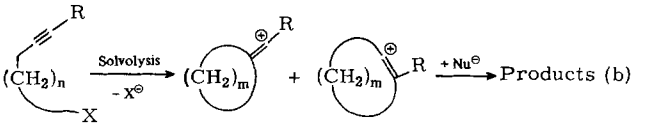
(5)  $\qquad$ $-C\equiv\overset{\oplus}{C}$ *(6)*

The monosubstituted ethynyl cation *(6)* corresponds to the disubstituted vinyl cation *(2)*. Calculations have shown *(6)* to have a particularly high energy; however, experimental evidence has yet to be obtained for its existence[2, 3].

Textbooks often state that vinyl cations *(2)* occur only rarely as intermediates owing to their low stability, but recent studies have revealed a large number of reactions proceeding *via* vinyl cations. In some reactions, vinyl cations qualitatively resemble saturated carbenium ions.

One of the reasons for rejecting vinyl cations as intermediates was considered to be the modest reactivity of vinyl halides in solvolysis reactions, *i.e.* it appeared unlikely that these species could react *via* an S_N1 mechanism. Although it was generally accepted that, *e.g.* electrophilic additions to a double and a triple bond should proceed according to the same mechanism, vinyl cations were formulated only reluctantly as intermediates in electrophilic additions.

The chemistry of vinyl cations has now come very much to the fore. This is partly a result of more accurate mechanistic studies on electrophilic additions to acetylenes and allenes. However, the observation that vinyl cations can also be generated under certain conditions by simple solvolysis reactions led to a breakthrough in the chemistry of these intermediates. Subsequent developments in vinyl cation chemistry also led to interesting preparative applications.



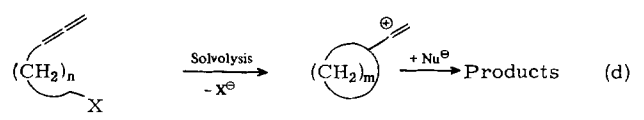
Direct detection of vinyl cations by ^{1}H- and ^{13}C-NMR spectroscopy has also been attempted[4].

Vinyl cations occur as intermediates in electrophilic additions and in solvolysis reactions which proceed with neighboring group participation. These include electrophilic additions to CC triple bonds [eq. (a)],

$$R-C\equiv C-R' + E^{\oplus} \longrightarrow \underset{R}{\overset{E}{}}C=\overset{\oplus}{C}-R' \xrightarrow{+Nu^{\ominus}} \text{Products} \qquad \text{(a)}$$

$E^{\oplus}$ = e.g. $H^{\oplus}$, carbenium ions; $Nu^{\ominus}$ = e.g. halide

solvolysis reactions involving these bonds [eq. (b)],



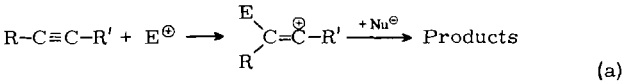
R = H, Alkyl, Aryl; $X^{\ominus}$ = Halide, Sulfonate

electrophilic additions to allenes [eq. (c)],

$$>C=C=C< + E^{\oplus} \longrightarrow >C=\overset{\oplus}{C}-\underset{E}{C}< \longrightarrow \text{Products} \qquad \text{(c)}$$

and solvolysis reactions involving this group [eq. (d)].

Heterolysis of vinyl compounds [eq. (e)] likewise leads to vinyl cations. Among the special reactions, mention should be made of photochemical processes.



$$>C=\underset{X}{C}< \longrightarrow >C=\overset{\oplus}{C}- + X^{\ominus} \qquad \text{(e)}$$

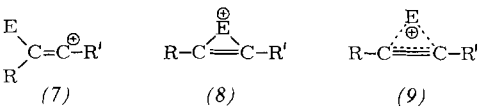
In the present article, examples of these reactions for generating vinyl cations will be considered from a present-day mechanistic vantage point and preparative applications will be described. Comprehensive surveys of vinyl cation chemistry have been published[5], and reviews have appeared on such detailed aspects as the chemistry of stabilized vinyl cations[6] or solvolyses of α-arylvinyl derivatives[7].

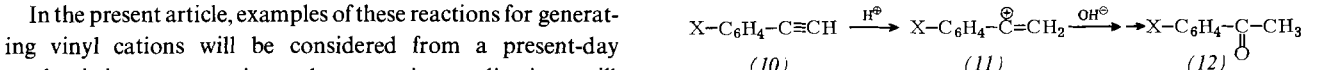


2. Electrophilic Additions and Solvolyses Proceeding with Neighboring Group Participation

2.1. Electrophilic Additions to CC Triple Bonds

$E^{\oplus}$ = e.g. $H^{\oplus}$, carbenium ions; $Nu^{\ominus}$ = e.g. halide (a)

Like electrophilic additions to CC double bonds, additions to CC triple bonds can also proceed stepwise, as shown in eq. (a) (Ad_E2 mechanism). The linear vinyl cation *(7)* formed transiently in the slow step is attacked from both sides by nucleophile $Nu^{\ominus}$, yielding the products in a non-stereospecific reaction. This simple addition scheme, however, is of limited validity and applies only to simple acetylenes[8,9,17]. Subsequent studies have shown that the direction of nucleophilic attack on the vinyl cation *(7)* depends upon the relative size and upon the electronic character of the β-substituents R and E[10–12]. Owing to ion-pair formation on addition, the *cis* isomer can predominate. The intermediate cation is not necessarily an open vinyl cation. Depending upon the structure of the acetylene and the attacking electrophile, an "onium" cation *(8)* (σ bridged) or a π-bridged cation *(9)* may also act as intermediate. Attack of *(9)* by nucleophile would preferentially yield the *trans* product.—Electrophilic addition to acetylenes may also follow an Ad_E3 mechanism, instead of the Ad_E2 mechanism.

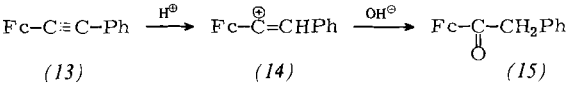


(7) *(8)* *(9)*

The most thoroughly studied electrophile is the proton; however, other species such as carbenium ions may also be involved. Among all electrophilic additions to alkynes, addition of $H^{\oplus}$ shows the greatest variation; its mechanism is a function of the reaction conditions. In the case of highly polar, strongly acidic, but only weakly nucleophilic acids such as trifluoroacetic acid, a vinyl cation is formed preferentially as intermediate; with less polar and more strongly nucleophilic reactants, *e.g.* acetic acid, other addition mechanisms prevail[5c]. Arylacetylenes can react *via* different mechanisms from alkylacetylenes. Some examples are presented in Section 2.1.1.

2.1.1. Addition of Acids to Aryl- and Alkyl-acetylenes

Acid-catalyzed hydration of variously substituted arylacetylenes *(10)* gives the vinyl cation *(11)* as intermediate stabilized by the α-aryl substituent (Markovnikov orientation)[13]. Aryl methyl ketones *(12)* are obtained quantitatively as the sole products. Kinetic studies, especially the large solvent isotope effects measured, demonstrate protonation of the triple bond in the rate-determining step.

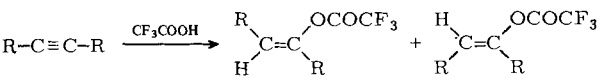


(10) *(11)* *(12)*

X = H, *m*- and *p*-halogen, *m*- and *p*-CH_3, CH_3O

Phenylacetylene reacts with HCl in glacial acetic acid at 25 °C to give α-chlorostyrene and acetophenone in the ratio of 12:1. Detailed mechanistic studies showed that under these conditions the addition proceeds exclusively by an Ad_E2 mechanism, *i.e. via* a vinyl cation[14]. Under different reaction conditions, the effect of solvent and added catalysts can cause the Ad_E3 mechanism to predominate. Thus, for instance, addition of HCl to deuterated phenylacetylene in CH_2Cl_2 with $ZnCl_2$ as catalyst gives mainly *syn* addition products[11,15].

The stabilizing effect of α-substituents on the intermediate vinyl cation is apparent from the acid-catalyzed hydration

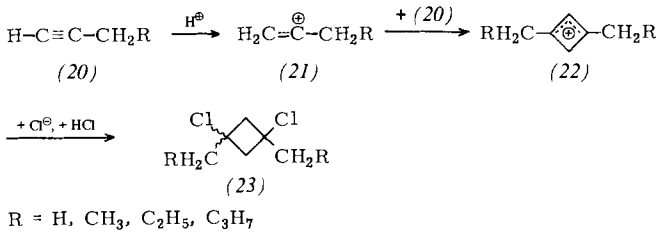


(13) *(14)* *(15)*

of ferrocenyl-phenylacetylene *(13)*[16]. Benzyl ferrocenyl ketone *(15)* is formed quantitatively, thus demonstrating the greater stability of the α-ferrocenylvinyl cation *(14)* as against the analogous α-phenylvinyl cation. Accordingly, the acid-catalyzed hydration of *(16)* is 10^5 times faster than that of *(17)*; protonation of the triple bond is the rate-determining step of this reaction.

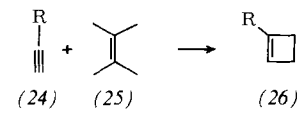
(16) Fc—C≡CH Ph—C≡CH *(17)*

Detailed studies on the kinetics and products of addition of carboxylic acids, especially trifluoroacetic acid, to alkylacetylenes convincingly demonstrate the intermediacy of vinyl cations in these reactions. Thus 3-hexyne *(18a)* reacts non-stereospecifically with trifluoroacetic acid to form the vinyl trifluoroacetates (*Z*)-*(19a)* and (*E*)-*(19a)*, in the approximate ratio of 1:1, together with other products[17]. This result, along with specific substituent effects, was considered to constitute proof for the formation of vinyl cations on addition of trifluoroacetic acid. Other dialkylacetylenes, *e.g.* 2-butyne



(18a), R = C_2H_5 (*Z*)-*(19)* (*E*)-*(19)*

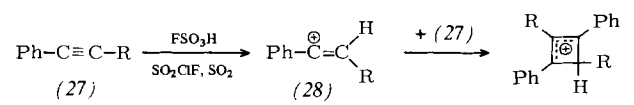
(18b), R = CH_3



(18b), preferentially afford the (*Z*) isomer (*Z*)-*(19b)* on addition of trifluoroacetic acid. This is explained in terms of attraction between the β-methyl group in the intermediate vinyl cation and the attacking nucleophile[18].

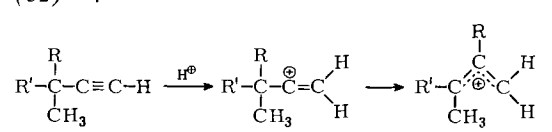
Addition of anhydrous HCl and HBr to alkylacetylenes *(20)* in the liquid phase leads to interesting $[{}_{\pi}2_s + {}_{\pi}2_a]$ cycloaddition reactions, product formation being formulated *via* the vinyl cation *(21)*[19]. Reaction of *(21)* with the alkyne *(20)* gives the stereoisomeric cyclodimers *(23)* in good yields, presumably *via* the resonance-stabilized 1,3-disubstituted cyclobutenyl cation *(22)*. The normal mono- and di-adducts to the triple bond are also obtained. It recently also proved possible to prepare 1,3-dialkyl-1,3-dichlorocyclobutanes *(23)* contain-

R = H, CH_3, C_2H_5, C_3H_7



ing two different alkyl groups by reaction of mixtures of two alkynes[19c]. Alkylating cycloadditions proceeding *via* a vinyl cation intermediate also occur during the reaction of gaseous HCl with propene and propyne in the molar ratio 2:1:1[20]. In the presence of Lewis acids, 1-alkynes *(24)* react with alkenes *(25)* by cycloaddition to give cyclobutenes *(26)*. The catalytic effect of Lewis acids is probably due to complexation of the alkyne which leads to polarization in the sense of a vinyl cation[21].

(24) *(25)* *(26)*

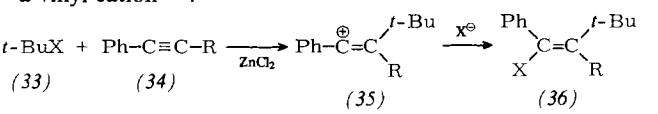


R = Alkyl

A detailed study of the addition of fluorosulfuric acid to alkynes in SO_2ClF at $-120\,°C$ or in SO_2 at $-78\,°C$ furnished the following picture[22]: terminal alkynes such as 1-butyne or 1-hexyne give solvent-separated ion pairs which react preferentially by *syn* addition to give vinyl fluorosulfates. In aryl-substituted alkynes *(27)*, stabilization *via* the adjacent aryl group leads to the vinyl cation *(28)*, which does not exist as an ion pair. The species *(28)* reacts with a second molecule of alkyne *(27)* to give cyclobutenyl cations *(29)*, which thus become readily accessible[23].

R = Ph, CH_3, *t*-Bu

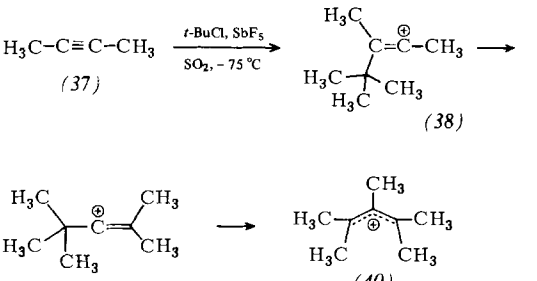
Protonation of alkynes, *e.g. (30)*, with magic acid (FSO_3H—SbF_5) in SO_2ClF or SO_2 at $-78\,°C$ leads merely to oligomers; *i.e.* the intermediate vinyl cation *(31)* is insufficiently stable to be detected under these conditions. At higher temperatures, *e.g.* $-20\,°C$, it rearranges to the allyl cation *(32)*[24].



R = H, Alkyl; R' = Alkyl

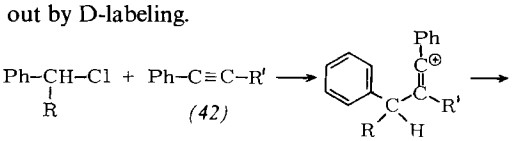
2.1.2. Addition of Carbenium Ions

An Ad_E2 mechanism, *i.e.* vinyl cation formation, has also been demonstrated on addition of *tert*-butyl halides *(33)* to phenylacetylenes *(34)*[12, 15, 25].

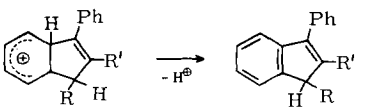


The *tert*-butyl cation formed by the action of the Lewis acid on *(33)* serves as electrophilic reagent. A linear vinyl cation *(35)* is formed as intermediate; it is preferentially attacked from the least hindered side by the nucleophile $X^{\ominus}$, giving products *(36)* with a high degree of stereoselectivity.

The same additions to mono- and di-substituted alkylacetylenes do not proceed in such a clear-cut fashion. The reaction products can also arise by pathways other than that involving a vinyl cation[26].



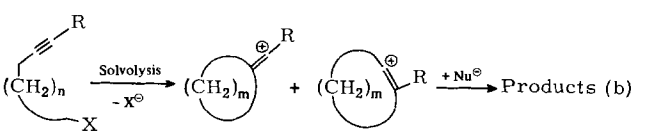
X = Cl, Br; R = Alkyl



Addition of *tert*-butyl cation to 2-butyne *(37)* leads to an interesting rearrangement which was interpreted as a double 1,2-methyl shift[27]: the initially formed vinyl cation *(38)* undergoes a methyl shift across the double bond to give the

vinyl cation *(39)* which affords the allyl cation by a second methyl shift towards the double bond. Cation *(40)* was detected by NMR spectroscopy; a 1,3-methyl shift was ruled out by D-labeling.

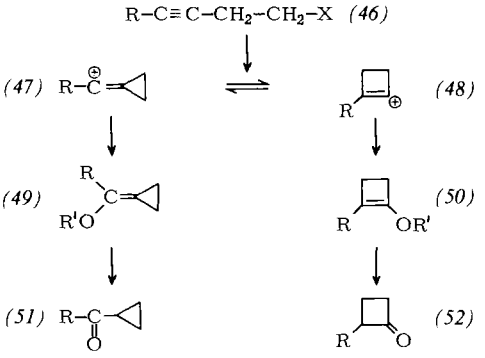
(41a), R = Ph
(41b), R = H



R' = Ph, CH_3

(44) *(45)*

Reaction of diphenylmethyl chloride *(41a)* and benzyl chloride *(41b)* with phenylacetylenes *(42)* in the presence of $AlCl_3$ (in CH_2Cl_2) illustrates the preparative utility of the addition of carbenium ions to triple bonds[28]. Substituted indenes *(45)* are obtained. The initially formed vinyl cation *(43)* cyclizes to *(44)*, yielding *(45)* on proton loss. Compound *(45)* is accompanied by the normal products of addition to the triple bond.



2.2. Participation of CC Triple Bonds in Solvolyses

R = H, Alkyl, Aryl; $X^{\ominus}$ = Halide, Sulfonate

Reactions of carbenium ions involving participation of CC double bonds have been known for several decades; the result-

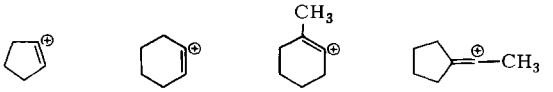
ing cyclizations and kinetic effects have been established by a wealth of experimental material[29]. We first employed the CC triple bond as neighboring group in 1965 [see eq. (b)][30]: solvolysis of reactive homopropargyl derivatives *(46)* in solvents of high ionizing power and low nucleophilicity gives cyclopropyl ketones *(51)* and cyclobutanones *(52)*. In-depth mechanistic studies showed that the stabilized vinyl cations *(47)* and *(48)* are formed as intermediates, and react *via* the enol ethers *(49)* and *(50)* to give the ketones *(51)* and *(52)*[31].

(a), R = H; *(b)*, R = Alkyl; *(c)*, R = Aryl;
(d), R = Cyclopropyl
X = –O–SO₂–⟨⟩–CH₃(OTs), –O–SO₂–CF₃(OTf)

The product pattern obtained from this "homopropargyl rearrangement" depends upon the substituent R in *(46)*. Compounds *(46a)*, R=H, and *(46b)*, R=alkyl, give mainly the four-membered rings *(50a)* and *(52a)*, and *(50b)* and *(52b)*. In compounds *(46c)*, R=aryl, and *(46d)*, R=cyclopropyl, the stabilizing effect of these substituents on the intermediate cyclopropylidenemethyl cation *(47c)* and *(47d)* favors the three-membered ring derivatives *(49c)* and *(51c)*, and *(49d)* and *(51d)*, respectively[31].

The homopropargyl rearrangement is of preparative significance as a facile method for the synthesis of cyclobutanones, as will be illustrated by an example. The readily accessible compound 3-butynyl triflate *(46a)*, X=OTf, is heated to 50 °C in trifluoroacetic acid for 24 h; essentially pure cyclobutanone *(52a)* (yield 60 %) arises owing to the greater stability of *(48a)* compared with the primary vinyl cation *(47a)*[32]. 2-Alkylcyclobutanones *(52b)* are readily obtained in similar manner in high yield starting from *(46b)*[31a, 32]. The relatively high stability of cyclobutenyl cations *(48)* endows the homopropargyl rearrangement with considerable scope for the synthesis of cyclobutanones. Thus, starting from the corresponding homopropargyl derivatives, disubstituted cyclobutanones *(53)* and, *e.g.*, also condensed cyclobutanones *(54)* are accessible[31a, 33].

R = Alkyl

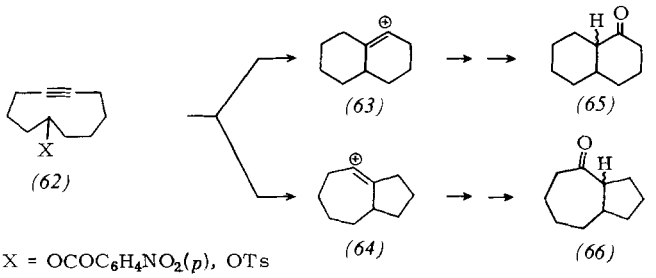


Cyclization reactions involving more distant triple bonds are also feasible. Table 1 lists the solvolysis products of some acyclic alkynyl triflates, showing how they depend upon the position of the triple bond relative to the functional carbon atom[34].

Table 1. Solvolysis of alkynyl triflates *(55)*—*(57)* in anhydrous trifluoroethanol.

R–C≡C–$(CH_2)_n$–CH_2–OSO_2CF_3 ⟶ cyclic products?
(55)—*(57)*

Cpd.	R	*n*	Cyclic products [%]
(55a)	H	2	0
(55b)	CH_3	2	0
(56a)	H	3	50 (Six-membered rings, *e.g.* 1-cyclohexenyl trifluoroethyl ether)
(56b)	CH_3	3	15 (Six-membered rings) 72 (Five-membered rings)
(57)	H	4	22 (Seven-membered rings)

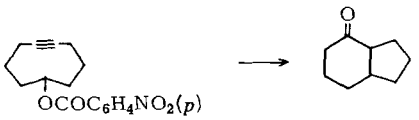


The triflates *(55a)* and *(55b)* solvolyze without cyclizing. Participation of the triple bond would lead to a cyclopentenyl cation *(58)*, whose formation in solvolysis reactions is unlikely. However, the triflate *(56a)* affords six-membered ring derivatives *via* the cyclohexenyl cation *(59)*; *(56b)* solvolyzes to give a mixture of six- and five-membered ring compounds formed from the vinyl cations *(60)* and *(61)*. The greater

(58) *(59)* *(60)* *(61)*

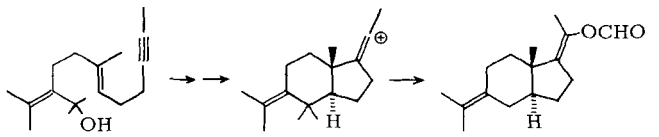
stability of the linear vinyl cation *(61)* compared to the cyclic vinyl cation *(60)* leads to preferential formation of products derived from *(61)*. Compound *(57)* still solvolyzes with participation of the triple bond; however, only 22 % of seven-membered ring derivatives are formed owing to the length of the chain[35].

Transannular participation of a triple bond in medium-sized rings was first observed by us on solvolysis of 5-cyclodecynyl derivatives *(62)*[36]. These esters *(62)* also rearrange on solvol-



X = $OCOC_6H_4NO_2(p)$, OTs

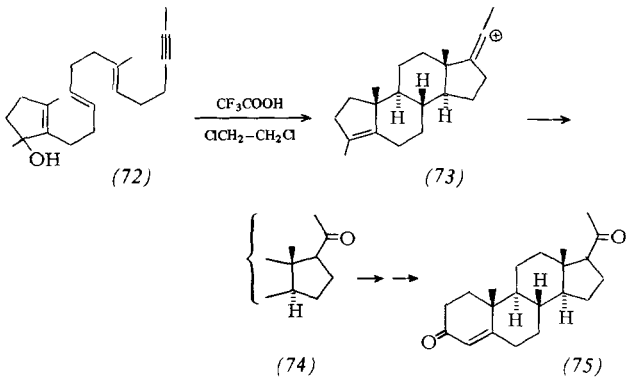
ysis in comparatively nucleophilic solvents, *e.g.* in ethanol/water mixtures, to give mainly *cis*- and *trans*-1-decalone *(65)* while bicyclo[5.3.0]decan-2-one *(66)* is formed only in small quantities. The predominant formation of *(65)* is explained by the greater stability of the vinyl cation *(63)* compared with *(64)*[37].



The proclivity of the triple bond to participate increases drastically in the 5-cyclononynyl derivative *(67)*; it solvolyzes 100 times as fast as *(62)* in 75 % aqueous ethanol, rearranging quantitatively to *cis*-4-hydrindanone *(68)* in spite of the pronounced nucleophilic nature of the solvent[38].

Syntheses of steroids and triterpenes by biomimetic cyclizations[39] have recently also been performed with systems involving triple-bond participation and vinyl cation interme-

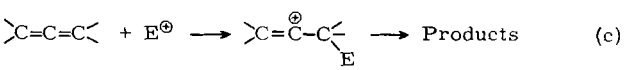
(67) (68)



diates. Thus, treatment of the dienynol *(69)* with formic acid in pentane gives the enol formate *(71)* in 90% yield[40].

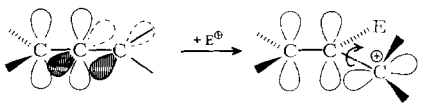
(69) (70) (71)

The acid attacks the tertiary OH group of *(69)*; the resulting carbenium ion cyclizes with participation of the double bond giving a new carbenium ion *via* formation of a six-membered ring. This ion is then transformed, with triple-bond participation, into the linear vinyl cation *(70)*.



In the preparation of DL-progesterone *(75)*, the trienynol *(72)* is converted into the vinyl cation *(73)* in the final cyclization step involving the triple bond; *(73)* affords the ketone *(74)*[40]. Progesterone *(75)* can be obtained from *(74)* in two further steps.

(72) (73) (74) (75)



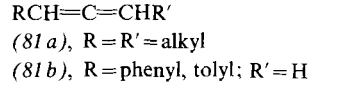
Other comparable cyclization reactions in which vinyl cations are formed have provided an entry to testosterone benzoate[41], and also to longifolene[42]. The high stereospecificity of the cyclization reaction has also been exploited for asymmetric syntheses[39].

2.3. Electrophilic Additions to Allenes

(c)

The cumulated double bonds of allenes permit electrophilic additions to follow various pathways. Additions to allene itself and to substituted allenes may proceed differently: addition to allene can give a vinyl cation, according to eq. (c), which has added the electrophile at the terminal carbon atom. In contrast, attack at the central carbon atom of the allene *(76)* would lead to a carbenium ion *(77)* which is formally an allyl cation and therefore appears preferentially. The carbenium ion *(77)*, however, is not a resonance-stabilized allyl cation. After attack of the electrophile $E^{\oplus}$ on the central carbon atom, a vacant p orbital is oriented perpendicularly on the remaining double bond as shown in *(77)*. Resonance

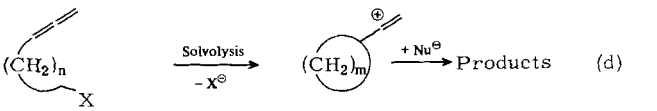
(76) (77)



stabilization can only occur after a 90° rotation about the single bond in *(77)*. Additions to unsubstituted allene therefore proceed exclusively according to eq. (c)[43]. Thus acid-catalyzed hydration of allene gives only acetone, and addition of HCl and HBr to allene leads to the same products, including the cyclobutane derivatives, as are obtained on reaction of propyne with HCl under the same conditions. This suggests formation of the vinyl cation [eq. (c)][44-46].

Electrophilic addition is not so clear-cut with substituted allenes; intermediate formation of vinyl cations depends upon the number and nature of substituents and upon the electrophile. This situation is illustrated by a few examples of reactions between allenes and HCl: 1,2-butadiene *(78)* reacts at −78 °C with HCl with intermediate formation of the vinyl cation *(79)*[46], giving exclusively (*Z*)- and (*E*)-2-chloro-2-

(78) (79) (80)

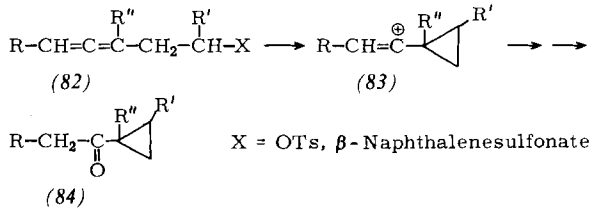


butene *(80)*. In contrast, only partial protonation of the terminal carbon atom occurs on reaction of 1,3-dialkyl-allenes *(81a)*. The ratio of terminal to central carbon protonation depends upon the reaction conditions[47]. Tetramethylallene no longer forms vinyl cation intermediates but, as expected, reacts *via* protonation of the central carbon atom to give a tertiary carbenium ion[48].

(81a), R = R′ = alkyl
(81b), R = phenyl, tolyl; R′ = H

Addition of HCl to arylallenes *(81b)* in glacial acetic acid also proceeds *via* protonation of the central carbon atom to form the more stable benzyl cation[49].

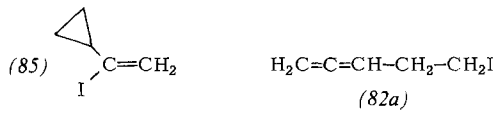
2.4. Participation of Allenic Groups in Solvolyses



(d)

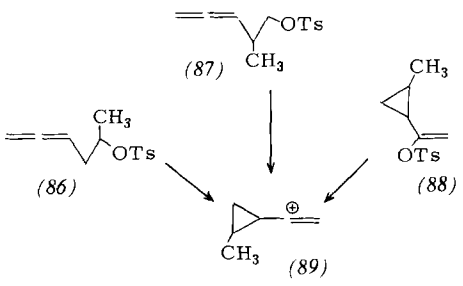
Equation (d) shows the participation of allenic groups in the generation of a carbenium ion. This reaction was first observed by us[50], and independently also by *Bertrand* and *Santelli*[51], in the solvolysis of homoallenyl derivatives *(82)*. Thus *(82)*, R = H, CH_3; R′ = R″ = H, gives mainly alkyl cyclopropyl ketones *(84)* in various solvents. Preferred cyclization to the ketones was rationalized in terms of intermediate formation of the stabilized cyclopropylvinyl cation *(83)*, owing to participation of the allenic bond in the solvolysis of *(82)*.

This reaction is known as homoallenyl rearrangement because of its resemblance to the homoallyl rearrangement.



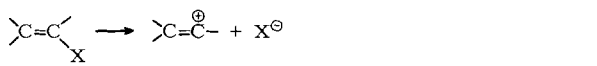
Subsequent systematic studies on the homoallenyl rearrangement showed that product formation depends upon the structure of the homoallenyl compound. While an alkyl attached to the functional carbon atom in *(82)*, R′ = alkyl,

(82) *(83)* *(84)*



R″ = H, still leads to solvolysis products, among which the cyclopropyl alkyl ketone *(84)* predominates, doubly substituted homoallenyl derivatives *(82)*, R′ = R″ = alkyl, solvolyze preferentially to give cyclobutane derivatives[52]. Homoallenyl rearrangement to cyclopropyl ketones *(84)* has also been utilized preparatively[53].

The kinetics and products of solvolysis of cyclopropylvinyl derivatives (halides and tosylates) and isomeric homoallenyl derivatives led to the conclusion that stabilized cyclopropylvinyl cations are the initial intermediates in the solvolysis of homoallenyl derivatives. Thus cyclopropylvinyl iodide *(85)* and the isomeric homoallenyl iodide *(82a)* react under the

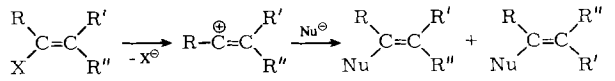


(85) *(82a)*

same conditions to give the same solvolysis products, which contain more than 65% of cyclopropyl derivatives[54]. Solvolysis of the tosylates *(86)*, *(87)*, and *(88)* in acetic acid gives products of very similar composition and stereochemistry whose formation is best explained by way of the cyclopropylvinyl cation *(89)*[55].

Participation of more distant allenic groups in solvolysis reactions also leads to cyclic products, which are not obtained, however, *via* vinyl cations as intermediates[56].

3. Formation of Vinyl Cations by Heterolysis

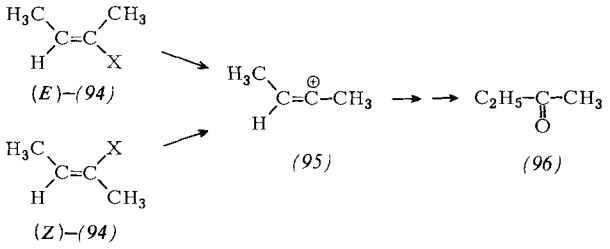


(e)

The reluctance of vinyl halides to undergo S_N1 reactions has a twofold explanation: it is attributed partly to the comparative instability of vinyl cations and partly to the ground state stabilization of vinyl halides. Stabilization of the ground state is a consequence of the higher s character of the carbon-halogen bond in vinyl halides (sp^2) compared with alkyl halides (sp^3)[57,58].

Solvolytic generation of vinyl cations [see eq. (e)] is feasible only if one of the following conditions is fulfilled: 1) Especially good leaving groups must be used for solvolysis, *e.g.* the "super-leaving groups" trifluoromethanesulfonate (triflate)[59] or the even more reactive nonafluorobutanesulfonate (nonaflate)[59]. 2) On use of leaving groups less prone to undergo S_N1 reactions, *e.g.* halides, then vinyl cations will only be formed if they are stabilized by a neighboring group with electron-donating ability.

In any case, it is necessary to establish that solvolysis of the vinyl compounds *(90)* investigated do actually proceed *via* vinyl cations. The pertinent mechanistic criteria can be briefly summarized as follows[60]: if a vinyl cation is formed in the rate-determining step of the solvolysis of *(90)* then the solvolysis must obey first-order kinetics. The rate of solvolysis is independent of solvent pH and of the concentration of added base, but dependent upon the ionizing strength of the solvent. The Winstein-Grunwald *m* value[61] should lie between 0.5 and 1.0. If the solvolysis is performed in deuterated solvents, then only a very slight solvent isotope effect, if any,



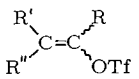
(90) *(91)* *(92)* *(93)*

is to be expected. Moreover, effects characteristic of carbenium ion mechanisms, such as salt effects, ion-pair formation, and phenomena of internal return have been observed. The linear geometry of the intermediate vinyl cation *(91)* suggests that the reaction products *(92)* and *(93)* are formed in equal quantities. Finally, the formation of rearranged products is a good mechanistic criterion for the course of the solvolysis reaction *via* vinyl cations.

Alternatively, the solvolysis products can be formed by, say, addition-elimination mechanisms; the initial step may comprise electrophilic addition of solvent, or possibly a nucleophilic addition of solvent to the double bond[60]. On solvolysis of a vinyl sulfonate, the product can also arise by nucleophilic attack of the solvent on the sulfonyloxy sulfur atom. If R′ or R″ = H in the vinyl derivative *(90)*, concerted β elimination often yields the alkyne.

3.1. Solvolysis of Simple Vinyl Derivatives with Particularly Good Leaving Groups

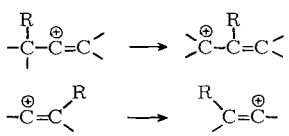
On replacement of halide as leaving group by the tosyloxy group, which has been thoroughly studied in the chemistry of saturated carbenium ions, intermediate formation of a vinyl cation can be accomplished by solvolysis of simple alkyl-substituted vinyl derivatives. Thus, for example, (*E*)-1-methyl-1-propenyl tosylate (*E*)-*(94)*, X = OTs, is solvolyzed in 50% aqueous methanol *via* the vinyl cation *(95)* to give a mixture of 2-butyne and 2-butanone *(96)*; in other solvents, such as acetic acid or formic acid, another mechanism is operative[62].



(E)-(94) (95) (96)

(Z)-(94)

The search for an even better leaving group led to the triflates[63] and nonaflates[59] which react some 10^4 times faster than tosylates. Acyclic secondary alkyl-substituted vinyl triflates and nonaflates solvolyze with few exceptions *via* intermediate vinyl cation formation: thus the vinyl triflates *(E)-(94)* and *(Z)-(94)*, X = OTf, react in ethanol/water mixtures, even at relatively low temperatures (76 °C), considerably faster than the tosylates *via (95)* to give the products [*e.g.* ketone *(96)*[64]].

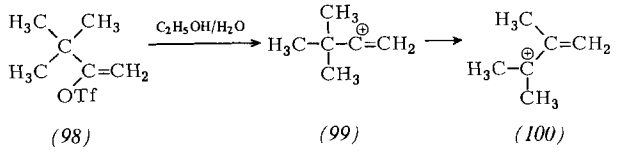


Systematic studies on the solvolysis reactions of the triflates *(97)* in solvents of various ionizing strengths and nucleophilicity revealed a pronounced carbenium ion character and no indication of a S_N2 reaction. The triflates *(97)* can solvolyze *via* ion-pair formation. This can lead to preferential formation of one stereoisomer in spite of expected formation of a linear vinyl cation intermediate[65].

(E)–, *(Z)*-*(97)*

R = CH_3, *i*-Pr, *t*-Bu; R′ = H, CH_3; R″ = H, CH_3

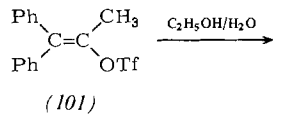
As in the solvolysis to give saturated carbenium ions, the solvolysis of vinyl derivatives is accompanied by rearrangements which can serve as evidence for an intermediate vinyl cation (see Section 3). Both rearrangements towards the double bond [eq. (f)] and rearrangements across the double bond are possible [eq. (g)].



(f)

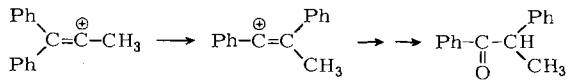
(g)

The driving force of the rearrangements is the formation of more stable carbenium ions. The rearrangements can involve shifts of alkyl and aryl groups; hydride shifts have also been observed. A few typical examples have been selected from the wealth of known rearrangements:



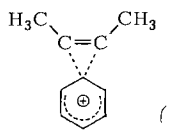
The vinyl triflate *(98)* solvolyzes in aqueous ethanol to give the vinyl cation *(99)*, which affords the saturated carbenium ion *(100)* by migration of a methyl group towards the double bond. The solvolysis products result mainly from *(100)* and only to a slight extent from the vinyl cation *(99)*[66].

Rearrangement across the double bond was observed on solvolysis of the vinyl triflate *(101)*. The initially formed vinyl cation *(102)* undergoes a phenyl shift, giving the vinyl cation *(103)* almost quantitatively. The positive charge in *(103)* is stabilized by the neighboring phenyl group; the ketone *(104)* is obtained on reaction with the solvent[67]. The β-aryl

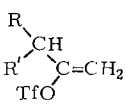


(98) *(99)* *(100)*

group participates in the rearrangement; under certain structural conditions, vinylenebenzonium ions *(105)* may be formed which correspond to the benzonium ions of saturated carbenium ion chemistry[68].

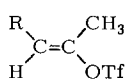


(101)



(102) *(103)* *(104)*

Hydride shifts towards the double bond have been found in the solvolysis reactions of the vinyl triflate *(106)*, and across the double bond in those of the vinyl triflates *(107)*.

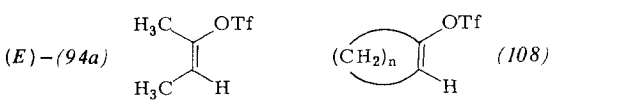


(105)

These processes afford a more stable carbenium ion and a more stable vinyl cation, respectively[69].

(106)

R = R′ = CH_3;

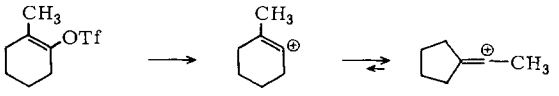


(E)–, *(Z)*-*(107)*

R = Ph, Cyclopropyl

Cyclic vinyl triflates also solvolyze with formation of vinyl cations. Table 2 shows examples of solvolysis rates as a function of ring size[70]. The cyclic vinyl triflates *(108)* solvolyze faster with increasing ring size, reaching a maximum rate with the nine-membered ring. The comparatively low reaction rate of 1-cyclohexenyl triflate is attributed to the impossibility of achieving the linear geometry required in the transition

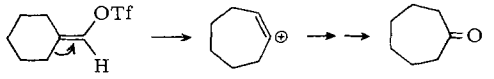
Table 2. Rates of solvolysis of 1-cycloalkenyl triflates *(108)* in 50 % aqueous ethanol at 75 °C and of *(E)*-1-methyl-1-propenyl triflate *(E)-(94a)* [70].



(E)-*(94a)* *(108)*

Cpd.	*n*	k [s^{-1}]	k_{rel}
(E)-(94a)		1.7×10^{-4}	1
(108)	4	1.2×10^{-8}	7.1×10^{-5}
(108)	5	4.2×10^{-5}	2.5×10^{-1}
(108)	6	4.5×10^{-4}	2.6
(108)	7	2.3×10^{-2}	135
(108)	8	3.3×10^{-3}	19
(108)	9	1.1×10^{-2}	65
(108)	10	6.8×10^{-3}	40

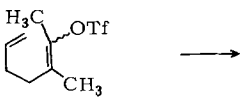
state for a vinyl cation with a ring of this size. In contrast, the 1-cyclooctenyl cation and cyclic vinyl cations having even more ring members can adopt a linear geometry as in the vinyl cation arising from (*E*)-*(94a)*. That the reaction rates of the cyclic vinyl triflates with more than eight ring members are higher than that of (*E*)-*(94a)* is probably due to a reduction of the *I*-strain in the transition state on formation of the vinyl cation. Qualitative comparison with the rates of solvolysis of 1-methylcycloalkyl chlorides appears in order[71]: a maximum rate of solvolysis was also found in the range of medium ring size which could be correlated with the strain energy of the medium-sized rings.



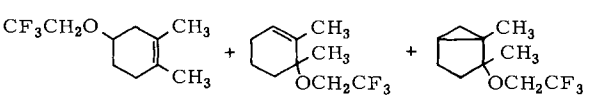
Rearrangements typical of a vinyl cation mechanism are again found in the solvolysis of cyclic vinyl triflates: 2-methyl-1-cyclohexenyl triflate *(109)* gives mainly the ring-contracted cyclopentyl methyl ketone on solvolysis in aqueous trifluoroethanol, the initially formed cyclic vinyl cation rearranging to the more stable linear vinyl cation *(110)*[72].

Cyclic vinyl cations are more stable than primary linear vinyl cations, as demonstrated by the solvolysis of the vinyl triflate *(111)* in aqueous trifluoroethanol: cycloheptanone

(109) *(110)*



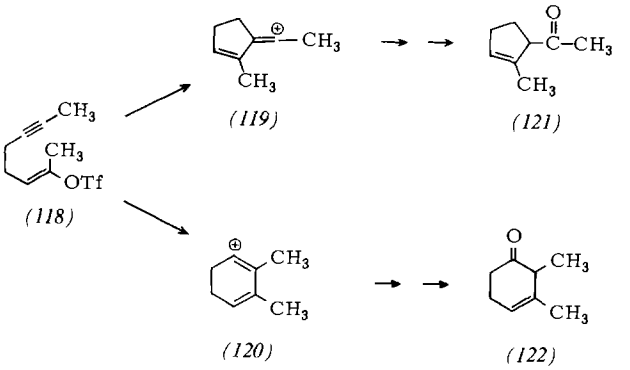
(113) is formed almost quantitatively *via* the cycloheptenyl cation *(112)*. Rearrangement to the cyclic vinyl cation *(112)* proceeds *via* a concerted ionization-alkyl shift without formation of a primary vinyl cation[73].



(111) *(112)* *(113)*

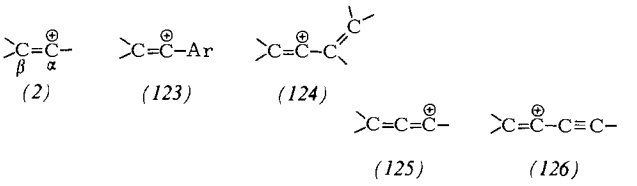
In contrast to cyclohexenyl triflate *(108)*, $n=4$, cyclopentenyl triflate fails to react by a vinyl cation mechanism in solvents of high ionizing strength, *e.g.* trifluoroethanol[74]. A cyclopentenyl cation *(58)* would be highly strained; it appears that the deviations from linear geometry no longer permit solvolytic generation of this intermediate.

The reactions of simple vinyl triflates described thus far are qualitatively reminiscent of the behavior of saturated carbenium ions. Two other reactions typical of saturated carbenium ion were also observed on solvolysis of vinyl triflates: thus solvolysis of the (*Z*)- and (*E*)-dienyl triflates *(114)* in trifluoroethanol gives not only acyclic products but also 20 to 35 % of the cyclic trifluoroethyl ethers *(115)*, *(116)*, and *(117)*, respectively, by participation of the double bond and formation of homoallyl-, allyl-, and cyclopropylmethyl cations[75].



(*E*)–, (*Z*)–*(114)*

(115) *(116)* *(117)*



The enynyl triflate *(118)* solvolyzes in solvents of various ionizing strength with participation of the triple bond *via* the linear vinyl cation *(119)* giving mainly the ketone *(121)*. The cyclic vinyl cation *(120)* is only formed in minor amounts, as indicated by the low yields of ketone *(122)*[76].

(118) *(119)* *(120)* *(121)* *(122)*

3.2. Stabilized Vinyl Cations

Vinyl cations *(2)* are disubstituted carbenium ions. Stabilizing *C*-located substituents can be linked to C_α and C_β. Substituents on C_α give secondary vinyl cations. If C_β is formally part of the substituent group then especially stabilized cations are obtained, *e.g.* the allenyl cation *(125)* or the cyclopropylidenemethyl cation *(128)*.

(2) *(123)* *(124)* *(125)* *(126)*

Any substituents of proven efficacy in the case of saturated carbenium ions can be used to stabilize vinyl cations. Use of the aryl group as substituent gives the vinyl cation *(123)*.

(127) *(128)*

The stabilized cation *(124)* is obtained with a vinyl group. The effect of a neighboring triple bond in *(126)* has not yet been examined.

Vinyl cations are stabilized particularly well by nonclassical interaction with a cyclopropyl group as in *(127)* and *(128)*. The favorable geometry for overlapping of the orbitals involved confers a particularly high stability upon cyclopropylidenemethyl cations *(128)*.

With the exception of *(126)*, the vinyl cations *(123)* to *(128)* have been detected as intermediates in solvolysis reactions of the corresponding vinyl halides. Owing to the stabilizing neighboring groups, halide suffices as leaving group for the solvolytic generation of these vinyl cations (for a survey, see ref. [6]).

Other reactions involving intermediate formation of a vinyl cation by heterolytic bond rupture cannot be dealt with here; they are only of minor importance compared with the solvolyses of vinyl perfluoroalkylsulfonates described. For example, an attempt has been made to produce vinyl cations *via* dia-

zonium ions. A detailed account will be found in the reviews cited[5].

4. Generation of Vinyl Cations by Special Reactions

In this connection, mention should be made of, *e.g.*, photochemical reactions of vinyl iodides in which vinyl cations have been postulated as intermediates[77]. The reader is referred to the literature regarding this and a series of other reactions proceeding *via* vinyl cations[78].

Support of our own experimental work cited in this article by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Volkswagen-Stiftung is gratefully acknowledged. Particular thanks are due to my co-workers who have pursued these studies with such great dedication.
