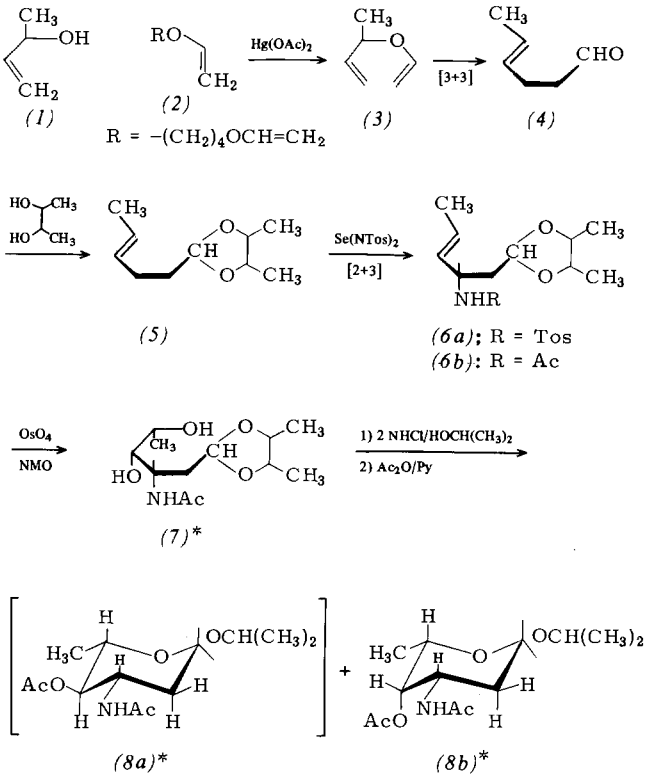
An Effective Synthetic Principle for Amino Sugars of the Daunosamine Type[**]

By *Ingolf Dyong* and *Reihard Wiemann*[*]

Daunosamine (3-amino-2,3,6-trideoxy-L-*lyxo*-hexose) and its configurational isomers are of considerable interest as glycons of anthracyclines showing antineoplastic activity: among other things, adriamycin *(1a)* retains its antitumor activity on inversion at C-4 of the carbohydrate while almost completely losing its toxicity towards myocardial cells[1].



(1a)

(a): R^1 = H, R^2 = OH: Daunosamine (L-*lyxo*)
(b): R^1 = OH, R^2 = H: Acosamine (L-*arabino*)

Attempts to find powerful syntheses of daunosamine[2], acosamine[3a], ristosamine (L-*ribo*)[3b], and the *xylo* isomer so far leave much to be desired. Synthesis from methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose[4] is currently regarded as the best entry to daunosamine. In order to produce antibiotic models of the daunomycin type we have sought a new route to daunosamine.

A combination of sigmatropic rearrangement of an allyl vinyl ether, allylic amination of the resulting 4-hexanal, and subsequent *cis*-hydroxylation proved to be a promising approach.

3-Buten-2-ol *(1)* reacts according to the transetherification procedure of *Watanabe* and *Conlon*[5] with 1,4-bis(vinyloxy)butane *(2)*/mercury acetate to give the allyl vinyl ether *(3)*[6]. Claisen rearrangement of this product gives the *trans*-4-hexenal *(4)*, which is allowed to react without isolation with *rac*-2,3-butanediol in the presence of *p*-toluenesulfonic acid to form the acetal *(5)*. The reaction sequence *(1)*→*(5)* (overall yield 65%) gives up to 70 g of *(5)*. Allylic amination of 10-g portions of the acetal *(5)* with selenium/chloramine T at room temperature in methylene chloride[7] leads to 4-tosylamino-DL-*glycero*-acetal *(6a)* (m.p. 70—72°C, yield 60%) along with a little of the 6-tosylamino derivative (*ca.* 10%). Removal of the toluenesulfonyl group with sodium in liquid ammonia and *N*-acetylation with acetic anhydride/methanol gives the 4-acetylamino-acetal *(6b)* (syrup, yield 80%). *cis*-Hydroxylation of *(6b)* with catalytic amounts of osmium tetroxide in the presence of *N*-methylmorpholine *N*-oxide (NMO)[8] leads to a mixture of DL-*lyxo*/*xylo* configurated amino diols *(7)* (yield 96%), preferential formation of the *lyxo* isomer being expected for steric reasons. The protecting group in *(7)* can be removed with 2 N HCl. Removal of the acid by repeated evaporation with 2-propanol and acetylation afford the *N*,*O*-acetylated isopropyl glycoside *(8a, b)* (yield 70%), of which the DL-*lyxo* epimer (isopropyl 3-*N*-acetyl-4-*O*-acetyl-DL-daunosaminide) *(8b)* crystallizes immediately from ethyl acetate/light petroleum (m.p. 148—151°C; ^{1}H-NMR (100 MHz, $CDCl_3$): δ=4.99, dd (4-H), $^3J_{3',4'}$=4 Hz; δ=3.8, dq (5-H), $^3J_{4',5'}$=2 Hz[9]). The mass spectrometric fragmentation of *(8b)* corresponds to the pattern reported for methyl 3-*N*-acetyl-4-*O*-acetyl-L-daunosaminide by *Vigevani et al.*[10].

(1) *(2)* *(3)* *(4)* *(5)* *(6a)*; R = Tos *(6b)*: R = Ac *(7)**

*(8a)** *(8b)**

* Only the L forms are shown for *(7)* and *(8)*

Experiments using dimethyl L-(+)-tartrate as protecting group have shown that enantiomeric resolution is possible after allylic amination. However, acetalization proceeds better with 2,3-butanediol so that the reaction sequence *(3)*→*(7)* using optically active diols should provide the basis of a particularly effective synthesis of D- or L-daunosamine.

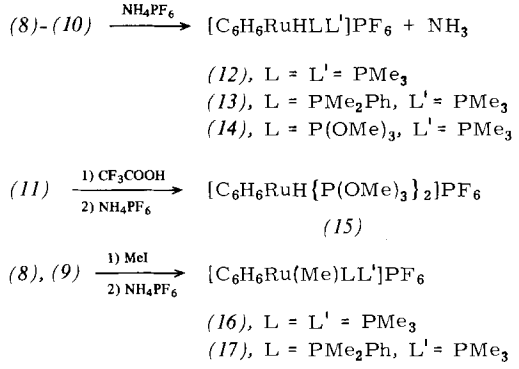
A New Type of Ruthenium(0) Complex with a Half-Sandwich Structure: $C_6H_6RuL_2$[1]

By *Helmut Werner* and *Rainer Werner*[*]

Ruthenium(0) complexes of the type $C_6H_6RuL_2$ with L = CO, PR_3, $P(OR)_3$, *etc.*, were formerly unknown[2]. HMO calculations by *Albright* and *Hoffmann*[3] predict the bonding in $C_6H_6ML_2$ (M = Fe[4], Ru, Os) and $C_5H_5M'L_2$ (M' = Co, Rh, Ir) to be very similar. The cyclopentadienyl complexes $C_5H_5M'L_2$—and particularly those with L = PMe_3—are *strong Lewis bases*; they react with Lewis acids such as H^+, CH_3^+, CH_3CO^+, $ZnCl_2$, $HgCl_2$, $SnCl_4$, *etc.* extremely readily *via* addition and formation of stable M—H, M—C, or M-metal bonds[5].

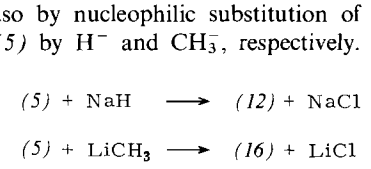
We have now prepared benzeneruthenium(0) complexes with tertiary *phosphanes* and *phosphites* as ligands in a completely different way from that used in the synthesis of $C_5H_5M'(PMe_3)_2$ (M' = Co, Rh)[5] and $C_5H_5M'[P(OMe)_3]_2$ (M' = Co, Rh)[6]:

The successful synthesis of *(8)*—*(11)* depends upon the use of sodium dihydronaphthylide (in tetrahydrofuran) as reducing agent; it permits transformation of the readily accessible neutral compounds *(2)*—*(4)*, as well as the product cations $[C_6H_6RuLL'Cl]^+$, into the desired ruthenium(0) complexes.



Compounds *(8)*—*(11)* are orange solids which melt at low temperatures; their ^{1}H-NMR data are compiled in Table 1. They are extremely sensitive to air and readily soluble in apolar (benzene, hexane) and in polar aprotic solvents (ether, THF).

Table 1. ^{1}H-NMR data of C_6H_6RuLL' *(8)*—*(11)* in C_6D_6 (δ values, rel. to int. TMS; J in Hz).



Com-plex	C_6H_6 [a]	L	L'
(8)	5.10 [J_{PH} = 1.1]	1.29 vt	(=L)
(9)	4.99 t [J_{PH} = $J_{P'H}$ = 1.1]	Me: 1.47 d [J_{PH} = 6.8] Ph: 7.0—7.5 m	1.01 d [J_{PH} = 7.6]
(10)	5.11 dd [J_{PH} = 0.75; $J_{P'H}$ = 1.1]	3.45 d [J_{PH} = 12.0]	1.25 d [J_{PH} = 8.2]
(11)	5.26 t [J_{PH} = 0.8]	3.47 vt	(=L)

[a] P = phosphorus atom of L, P' = phosphorus atom of L'.

The reactions of *(8)*—*(11)* with proton donors and methyl iodide confirm the strongly basic character of the central atom in C_6H_6RuLL'. While *(8)*, *(9)*, and *(10)* react with NH_4PF_6 to form the corresponding highly stable salts of the hydridoruthenium cations $[C_6H_6RuHLL']^+$ *(12)*—*(14)*, the formation of *(15)* from *(11)* requires the use of CF_3COOH. This provides a qualitative demonstration—as for the cyclopentadienyl complexes $C_5H_5M'L_2$—that the Lewis basicity of M in $C_6H_6ML_2$ (and C_6H_6MLL') is critically dependent upon the *donor/acceptor strength* of L (or L and L').

The preparation of *(12)* and *(16)* is possible not only starting from *(8)* but also by nucleophilic substitution of the chloride ligands in *(5)* by H^- and CH_3^-, respectively.

Compound *(12)* does not undergo elimination of H_2 to form *(8)* on treatment with an excess of NaH (in THF). On the contrary, the reaction of $[C_5H_5CoH(PMe_3)_2]PF_6$ with NaH yields the neutral complex $C_5H_5Co(PMe_3)_2$.

Procedure

Preparation of *(8)* from *(2)*: To a stirred suspension of *(2)* (0.5 mmol) in THF (2 ml) at −78 °C are simultaneously added dropwise PMe_3 (1 equiv.) and sodium dihydronaphthylide (2 equiv.), both as solutions in THF. The dark-brown reaction solution is evaporated to dryness at −20 °C, the residue is extracted with pentane (10 ml), and the pentane solution filtered through a cooled frit. Repeated fractional crystallization from pentane at −78 °C affords *(8)* as orange crystals (yield 70%). Compound *(11)* can be prepared from *(4)* (which like *(2)* is preparable from *(1)* and L in THF, 4 h, 50 °C) in analogous manner.

Preparation of *(8)* from *(5)*: To a stirred suspension of *(5)* (0.5 mmol) in THF (2 ml) at −78 °C is added sodium dihydronaphthylide (2 equiv.) as a solution in THF (2.5 ml). The reaction mixture is worked up as in the preparation of *(8)* from *(2)*. The synthesis of *(9)* from *(6)*, and that of *(10)* from *(7)*, can be accomplished in similar manner.

K_2Te_3: The First Binary Alkali-Metal Polytelluride with Te_3^{2-} Ions[**]

By *Brigitte Eisenmann* and *Herbert Schäfer*[*]

The only compound in the K/Te system to have been structurally characterized is K_2Te[1,2], although polytellurides were predicted some time ago by *Klemm et al.*[2] on the basis of magnetic studies performed on this system. While examining Zintl phases possessing aggregate anionic partial structures we have synthesized the compound K_2Te_3 from the elements and isolated it as single crystals. The compound crystallizes in the form of metallic gray prisms which are usually highly distorted.

The structure of this, the first binary alkali metal polytelluride was determined from four-circle diffractometer data obtained for a single-crystalline fragment (Stoe Stadi IV, $Mo_{K\alpha}$, 700 reflections, $R = 0.099$). K_2Te_3 forms orthorhombic crystals, space group Pnma with $a = 1593.8(5)$, $b = 1009.7(5)$, $c = 468.6(3)$ pm [K at 8*d* with $x = 0.3776(6)$, $y = 0.0303(13)$, $z = 0.2892(20)$; Te^1 at 4*c* with $x = 0.4815(2)$, $y = 1/4$, $z = 0.8152(7)$; Te^2 at 4*c* with $x = 0.2594(2)$, $y = 1/4$, $z = 0.7020(8)$; Te^3 at 4*c* with $x = 0.1223(2)$, $y = 1/4$, $z = 0.3267(7)$].

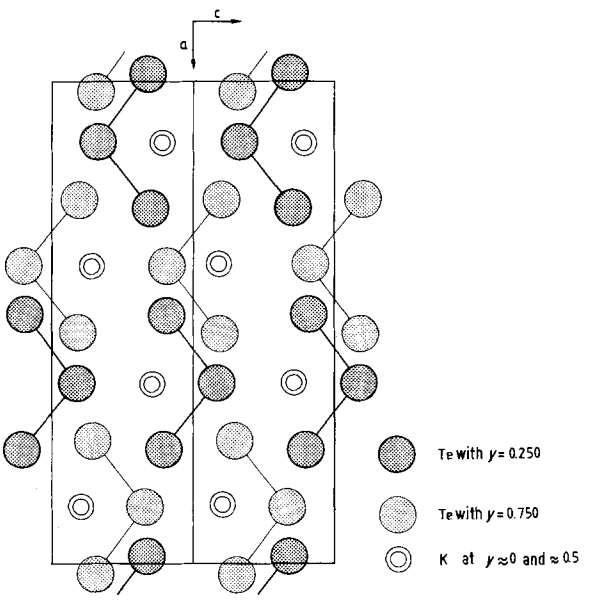

Fig. 1. Projection of atomic arrangement in K_2Te_3 onto the *a*, *c* plane.

The anionic components of this structure are bent Te_3 chain fragments (Fig. 1) arranged in planes $\perp b$ at $y = 0.25$ and $y = 0.75$. The Te—Te distances within such groups are 280.2 and 280.5 pm and are thus shorter than in α-tellurium 283.4 pm), while the bond angle is slightly greater than that in α-tellurium (103.2°). The closest contact between the Te atoms of neighboring Te_3 groups is 357.9 pm (the helical chains in α-tellurium are 349.4 pm apart). The K atoms have eight Te neighbors at distances of 349.5 to 400.6 pm; a strongly distorted four-sided antiprism is found as coordination polyhedron.

Comparison of the compound K_2Te_3 with the cryptate $(C_{18}H_{36}N_2O_6K)_2Te_3$[3] proves interesting. The latter also contains a bent Te_3^{2-} ion which, however, is far less symmetrical with regard to bond lengths. The existence and structure of K_2Te_3 demonstrate that polyanionic systems in the 6th Main Group are not limited to selenides and sulfides, and that the occurrence of Te_3^{2-} ions is not dependent upon the presence of cryptate cations as counterions.

Procedure

A stoichiometric mixture of potassium and tellurium was sealed in carefully baked out quartz ampoules in a dry, oxygen-free atmosphere. The ampoules were placed in iron tubes which were sealed by welding, slowly heated to *ca.* 600 °C within 4 h, and annealed at 250 °C for 12 h [analysis of selected single crystals: Te 82.9 (calc. 83.04) %; K 16.1 (calc. 16.96) %].

Selectivity in Reactions between Metal Phenoxides and Isoprene. Facile Synthesis of 2,2-Dimethylchromans[**]

By *Luciana Bolzoni, Giovanni Casiraghi, Giuseppe Casnati*, and *Giovanni Sartori*[*]

Among the isoprenylating agents, isoprene is a simple, readily available and economic chemical; however, the regiochemical control in reactions involving phenol or its simple derivatives is still an unsolved problem[1,2]. By way of contrast we have found that direct chromanation of phenols *(1)* with isoprene under unusual Friedel-Crafts conditions provides

[a] Ether = diethyl ether, TMEDA = tetramethylethylenediamine, Crown = Dibenzo[18]crown-6. [b] Determined by GLC analyses (Se 30, 5% on chromosorb W, *ca.* 3.2 mm × 2.4 m, 120°C). ND = Not detected. [c] 0.3 mol $(PhO)_3Al$. [d] 1 mole of additive per mole of PhOM.

a general highly selective synthesis of 2,2-dimethylchromans *(2)* (see Table 1). Thus, reaction of a 1:1:1 mixture of phenol, potassium phenoxide and $AlCl_3$ with isoprene in benzene at room temperature affords 2,2-dimethylchroman *(2a)* in 63—65% yield, along with trace amounts (<1%) of *p*-isopentenylphenol. Some 30% of phenol remains unreacted; other constituents of the product include *o*-isopentenylphenol (traces) and 6-isopentenyl-2,2-dimethylchroman (2–3%).

Iron(III) and tin(IV) chlorides are less effective catalysts than aluminum chloride (Table 2, No. 2 and 3). The optimum molar ratio of phenol to phenoxide and $AlCl_3$ is nearly 1:1:1. If one of these three reagents is removed, the yield is drastically reduced (Nos. 4—6). Furthermore, it is worth noting that the use of sodium, lithium, or aluminum phenoxides instead of potassium phenoxide causes a remarkable lack of specificity (Nos. 7—9). Finally, the reaction fails completely when ether solvents or cation coordinating or complexing additives are used (Nos. 10—12).

This is not the first example of variable orientation and dependence of yields upon reaction conditions in processes involving complexes between phenols and Lewis acids or metal phenoxides[7], but the latitude in the choice of substrate as well as the excellent substrate and positional selectivity make this reaction unique and capable of further development in its scope. For example, it has been used for the synthesis of 2-methyl-2-(4-methyl-3-pentenyl)chroman from phenol and myrcene; b.p. 90°C/0.01 torr (bulb-tube distillation), yield *ca.* 60%.

Procedure

A slurry of phenol *(1a)* (0.1 mol), potassium phenoxide (0.1 mol)[3] and $AlCl_3$ (0.1 mol) in benzene is refluxed with stirring for 10 min. The resulting colorless solution is cooled to/or below 20°C and a solution of isoprene (0.2 mol) in benzene is added at a uniform rate (*ca.* 0.04 mol h^{-1}). After the addition is complete, the mixture is allowed to stand, usually overnight, then diluted with a saturated NH_4Cl-water solution and extracted with ether. Solvent removal and chromatography of the residue on a short column of silica gel (100 g) with hexane affords *(2a)* in 63—65% yield (90—93% based on unrecovered phenol).—This procedure is of wide applicability and can be extended without modification to a variety of substituted mono and polyhydric phenols.

Synthesis and Structure of the Ylide Complex $[(Ph_3P{-}C_5H_4)Co(CO)_2]^+[Co(CO)_4]^-$. Its Use in the Cyclotrimerization of Alkynes[**]

By *Norman L. Holy, Norman C. Baenziger*, and *R. M. Flynn*[*]

We wish to report the formation of a new[1] ylide metal-carbonyl complex *(3)* formed by combining octacarbonyldicobalt *(2)* with triphenylphosphoniocyclopentadienide *(1)* in tetrahydrofuran, under nitrogen (see *Experimental*). The complex *(3)* was characterized by a crystallographic structure analysis as $[(Ph_3P{-}C_5H_4)Co(CO)_2]^+[Co(CO)_4]^-$ [2].

(1) *(2)* *(3)*

The anion $[Co(CO)_4]^-$ is a nearly regular tetrahedron, with bond angles ranging from 107.0(3)° to 112.6(3)° (average 109.5°). The Co—C_{CO} distances are 1.751(7), 1.756(9), 1.752(8), and 1.746(8) Å. The cation (Figure 1) has a π bonded ylide

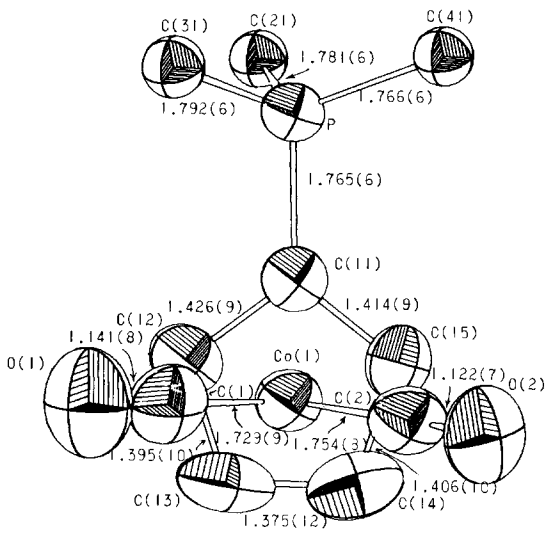

Fig. 1. Structure of the cation $[(Ph_3P{-}C_5H_4)Co(CO)_2]^+$ (ORTEP diagram).

group and two carbonyl groups attached to the Co atom; Co—C_{CO} = 1.729(9), 1.754(8) Å; OC—Co—CO angle = 94.5(3)°. The C—C distances in the cyclopentadienide ring are not significantly changed from those in the uncomplexed ylide *(1)*. In contrast, the P—C^1 bond is significantly longer than in *(1)*. The Co—Co distance is 5.231 Å, and there are no groups bridging the two cobalt atoms. The structure of *(3)* bears similarity to that reported recently for $(Me_2S{-}C_5H_4Cr(CO)_3$ [3].

Because of the analogy of the isolated salt *(3)* to $CpCo(CO)_2$, we wished to establish if there were chemical similarities between the two complexes; this was tested by determining whether *(3)* would cyclotrimerize alkynes[4]. We found that 4-octyne was converted into hexa-*n*-propylbenzene, both by *(3)* (see *Experimental*) and by *(3)* generated *in situ* [*(1)* + *(2)*, 30 minutes' stirring, addition of 4-octyne]. Tolane was converted into hexaphenylbenzene in 96 % yield; no other tolane-derived products were detected.

Experimental

Synthesis of *(3)*: All steps must be carried out in a drybox; the THF and petroleum ether should not contain water or dissolved oxygen.—To a solution of 1.63 g (5.0 mmol) of *(1)* in 200 ml of dry, deoxygenated THF was added 1.50 g (4.4 mmol) of *(2)*. A deep-red color formed immediately and bubbles were evolved. After stirring at room temperature for 0.5 h, dry, deoxygenated petroleum ether was added to precipitate out 1.73 g (65 %) of yellow-red crystals, m. p. 110—115 °C. After recrystallization three times from THF-petroleum ether, 0.84 g of *(3)* was recovered as yellow crystals having m. p. 120—122 °C; IR (KBr): 2109, 2082, 1890 cm^{-1}.

Cyclotrimerization: To a solution of 0.628 g (1.00 mmol) of *(3)* in 25 ml of dry, deoxygenated THF was added 3.30 g (30.0 mmol) of 4-octyne. After refluxing under nitrogen for three days the solvent was stripped off and the products were chromatographed on a neutral alumina column (2 cm × 35 cm). 2.08 g (63 %) hexa-*n*-propylbenzene, m. p. 94—98 °C, was eluted with petroleum ether. No other octyne-derived products were found, though other products are present—68 % of the alkyne is converted. After recrystallization from benzene the melting point of the cyclotrimerization product increased to 100—101 °C.

Electrophilic Amination of "Carbanions" with *N,N*-Dialkyl-*O*-arylsulfonylhydroxylamines[**][1]

By *Gernot Boche, Nava Mayer, Michael Bernheim,* and *Konrad Wagner*[*]

Although there are numerous examples for the amination of nucleophiles with X—NR_2 (X = anionic leaving group, R = H)[2], only isolated reports have been published about the reaction of "carbanions" (more precisely organometallic compounds R'M)[3]. We have performed a study of the electrophilic amination of R'M *(3)* with the *N,N*-dialkyl-*O*-arylsulfonylhydroxylamines *(1a)*, *(1b)*, *(2a)*, and *(2b)* to form the tertiary amines *(4)* (see Table 1).

(1a), R = CH_3; *(1b)*, R = C_2H_5 *(2a)*, R = CH_3; *(2b)*, R = C_2H_5

(3) *(4)*

The amination reagents *(1a)*, *(1b)*, *(2a)*, and *(2b)* were synthesized in 60—90% yield by reaction of the corresponding arylsulfonyl chloride with the corresponding dimethyl- or diethyl-hydroxylamine (or hydroxylamine hydrochloride) and triethylamine in dichloromethane at −20 to −10°C[4]. No differences in amination readiness could be detected between *(1a)*, *(1b)*, *(2a)*, and *(2b)*.

We gave preference to the synthesis of amines *(4)* which are accessible only under drastic conditions, if at all, by nucleophilic substitution [*(4cb)*, *(4da)*, *(4fa)*, *(4ga)*, *(4la)*] and whose organometallic precursors R'M *(3)* are relatively easy to obtain and "stable". Amines of bicyclo[1.1.0]butanes were hitherto inaccessible, even by degradation reactions. Reaction *(3g)* → *(4ga)* opens up a general route to amines of strained ring systems.

Procedures

N,N-Dimethyl-*O*-mesitylsulfonylhydroxylamine *(1a)*: *N,N*-Dimethylhydroxylamine hydrochloride (5.0 g, 51 mmol) is suspended in CH_2Cl_2 (40 ml) at −10°C. Triethylamine (11 g, 110 mmol) is added with stirring, followed, over a period of 90 min, by a solution of mesitylsulfonyl chloride (9.8 g, 45 mmol) in CH_2Cl_2 (40 ml). After another hour at −10°C, the reaction mixture is shaken with ice-water (100 ml), the organic phase separated off, and the aqueous phase washed with ether (2 × 50 ml). After drying the ether phase with $MgSO_4$ and removal of solvent under reduced pressure at 0°C compound *(1a)* precipitates as colorless crystals. Recrystallization from ether leads to 9.3 g (85%) of *(1a)*, m.p. 101—102°C, ^{1}H-NMR ($CDCl_3$): δ = 2.28 (s; *p*-CH_3), 2.60 (s; *o*-CH_3 and NMe_2), 6.87 (s; *m*-H).

N,N-Dimethyl-*cis,trans*-2,3-diphenylcyclopropylamine *(4fa)*: An ether solution of *(3f)* (70 ml, 6.1 mmol) is added at −10°C to a suspension of *(1a)* (1.50 g, 6.1 mmol) in THF (20 ml); the mixture is allowed to warm to 25°C and stirred for 15 h. Workup as usual for amines (2 N HCl, 2 N NaOH) and recrystallization from ether/pentane affords *(4fa)* (790 mg, 47%) as colorless crystals (m.p. 66—68°C).

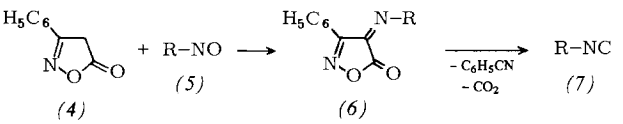
Synthesis of Aryl and Heteroaryl Isocyanides from Nitroso Compounds[**]

By *Curt Wentrup, Uschi Stutz*, and *Hans-Joachim Wollweber*[*]

We recently described the synthesis of aryl- and heteroarylacetylenes *(2)*[1] by thermal decomposition of 4-arylmethylideneisoxazol-5(4*H*)-ones *(1a)*, as well as the generation and rearrangement of isocyanoamines *(3)*[2] from the correspond-

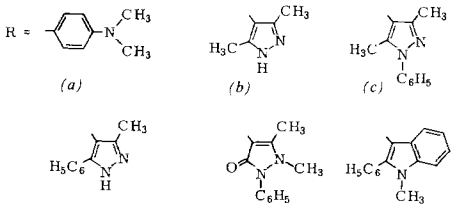


(1a), Z = CH
(1b), Z = NNH

R–C≡CH *(2)*

R–NH–NC *(3)*

ing hydrazones *(1b)*. We now wish to report a preparation of hitherto unknown classes of heteroaryl isocyanides, which is useful also for the production of otherwise difficultly accessible aryl isocyanides.



3-Phenyl-4-(*p*-dimethylaminophenyl)iminoisoxazol-5(4*H*)-one *(6a)* is readily obtained by condensation of *N,N*-dimethyl-4-nitrosoaniline *(5a)* with 3-phenylisoxazol-5(4*H*)-one *(4)* in ethanol solution[3]. *(6a)* decomposes at its melting point (165°C) with formation of benzonitrile, CO_2, and 4-isocyano-*N,N*-dimethylaniline *(7a)*. The isocyanide *(7a)* is obtained

(4) + R–NO *(5)* → *(6)* → (−C_6H_5CN, −CO_2) R–NC *(7)*

in near-quantitative yield when *(6a)* is allowed to decompose in a sublimation apparatus under high vacuum at 130—140°C, or by gas-phase pyrolysis of *(6a)* at 150°C. For preparative purposes, *(6a)* is conveniently decomposed in toluene solution at 90°C (30 h). Distillation of the solvent and benzonitrile, and sublimation of the residue at 60°C *in vacuo* affords the isocyanide *(7a)* in analytical purity[4] and 94% yield (see Table 1) [^{1}H-NMR ($CDCl_3$): $\delta = 2.9$ (s, 6H), 6.6 (d, $J = 9$ Hz, 2H), 7.2 (d, $J = 9$ Hz, 2H)].

f	54	155	100	92	99	2120

[a] Based on nitroso compound *(5)*.
[b] Decomposition of *(6)* in toluene solution.

(7a) was previously known[5,6] only in admixture with the isomeric nitrile *(8a)*, and it was stated[5] that *(7a)* was so unstable that it could only be identified by infrared spectroscopy. Quite on the contrary, we find that *(7a)* is thermally stable. Gas-phase pyrolysis above *ca.* 350°C forms a mixture of *(7a)* and *(8a)*, and at 800°C only the nitrile *(8a)* is obtained.

R–NC $\xrightarrow{\Delta}$ R–CN
(7) *(8)*

In a similar manner, the pyrazole and indole derivatives *(6b)*—*(6f)* decompose in toluene solution with formation of the corresponding isocyanides *(7b)*—*(7f)* in yields over 90% (Table 1)[4]. Gas-phase pyrolysis above *ca.* 500°C affords the isomeric nitriles *(8b)*—*(8f)*. Compounds *(7b)*—*(7f)* are the first reported isocyanides of the pyrazole and indole series. Indeed, heterocyclic chemistry is almost devoid of isocyanides[7]. Thus, the high yields and the extremely simple experimental procedure endows the present method with considerable scope as a synthesis of aryl- and heteroaryl isocyanides, as well as the isomeric nitriles.

Experimental

Synthesis of *(6f)*: A suspension of 1-methyl-3-nitroso-2-phenylindole *(5f)* (0.75 g, 3.2 mmol) in ethanol (40 ml) was added to a warm, saturated solution of *(4)* (0.52 g, 3.2 mmol) in ethanol (25 ml). After addition of three drops of piperidine the color of the solution changed from green to red-violet. The mixture was heated for 15 min on a water-bath, and then allowed to crystallize at 0°C. The dark brown-violet crystals of *(6f)* were recrystallized from ethanol/benzene (1 : 1); yield 0.645 g.

Synthesis of *(7f)*: A solution of *(6f)* (100 mg, 0.26 mmol) in toluene (30 ml) was heated at 100°C for 20 h. The solvent

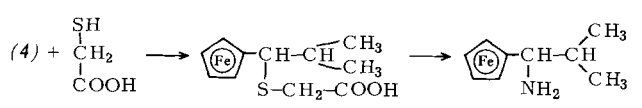
Direct Formation of the α-Ferrocenylisobutyl Cation from Ferrocene and Isobutyraldehyde[**]



By *Rudolf Herrmann* and *Ivar Ugi*[*]

We suspected that ferrocene *(1)* can undergo electrophilic substitution by isobutyraldehyde *(2)* in trifluoroacetic acid (TFA) to form *(3)*, which equilibrates with *(4)*. Evidence favoring this idea comes from (a) the formation of highly stable α-ferrocenylalkyl cations from α-ferrocenylalkanols in TFA[1], (b) the enhancement of electrophilic reactivity of carbonyl compounds by *O*-protonation[2], and (c) the role played by the α-ferrocenylisobutyl cation *(4)*[4] in the chemistry of α-ferrocenylisobutylamine *(7)*[3]. Compound *(7)* is the asymmetrically inducing chiral reference system for peptide syntheses by stereoselective four-component condensation[4].

(1) *(2)* *(3)* *(4)*

Joint dissolution of *(1)* and *(2)* in TFA (each in a concentration of 1 mol/l) leads within a few minutes to the formation of considerable amounts of *(4)*, according to the ^{1}H-NMR spectrum[5].

(5) *(6)* *(7)*

Treatment of the reaction mixture after 30 min at 20 °C with an excess of thioglycolic acid *(5)*[6,7] affords up to 60% of *S*-(α-ferrocenylisobutyl)thioglycolic acid *(6)* while 35% of ferrocene *(1)* can be recovered. After 3 h, the yield of *(6)* increases to 80% and ferrocene can no longer be isolated.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

This reaction is of preparative importance because *(6)* can readily be converted into *(7)*; previous syntheses[3] were much more complicated.

Procedure

Synthesis of *(6)*: Compounds *(1)* (1.86 mmol) and *(2)* (1.8 ml, 20 mmol) are dissolved in TFA (10 ml) and stirred at room temperature for 3 h. Compound *(5)* is added (5 ml, 70 mmol), stirring continued for 15 min, and the mixture slowly neutralized with saturated $NaHCO_3$ solution until the greenish brown color turns to orange. The mixture is treated with 10% caustic soda (100 ml) and CH_2Cl_2 (100 ml). The phases are separated, the organic phase is extracted one more with 10% caustic soda (100 ml) and twice with water (2 × 100 ml) and the combined aqueous solutions are finally extracted twice with CH_2Cl_2. The aqueous phase is acidified with sulfuric acid until incipient precipitation of *(6)* gives rise to a yellowish white turbidity. After extracting three times with CH_2Cl_2, the combined extracts are dried with sodium sulfate, and the solvent removed under reduced pressure. Compound *(6)* is obtained as a red oil which slowly crystallizes. It is recrystallized from ether and cyclohexane; yield 2.65 g (80%), m.p. 82 °C.

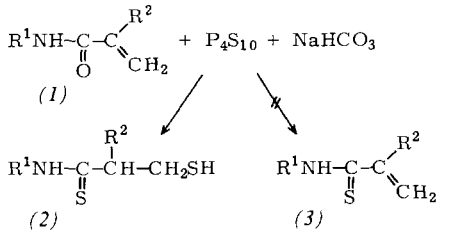
Hydrosulfuration-Thionation of Unsaturated Amides[**]

By *Howard Alper, Janie K. Currie*, and *Rajeev Sachdeva*[*]

In 1973, *Scheeren et al.*[1] reported that carbonyl compounds could be converted into the corresponding thiocarbonyls by the use of tetraphosphorus decasulfide and sodium bicarbonate in acetonitrile or ether solvents. We have found this method to be a very useful one for the synthesis of aromatic and aliphatic thioketones[2]. However, when we applied this procedure to unsaturated amides, an interesting reaction occurred to give a saturated thioamide.



α,β-Unsaturated amides *(1)*, prepared by treatment of an aromatic amine with acryloyl or methacryloyl chloride, react with P_4S_{10} and $NaHCO_3$ in acetonitrile to give the β-mercaptoalkyl thioamides *(2)* in 31—56% yields (Table 1). None

followed by loss of H_2S, and then fragmentation of the olefin to give the isothiocyanate radical ion.

The transformation of *(1)* to *(2)* may proceed *via* Michael addition of SH^- to the unsaturated amide, followed by conversion of the carbonyl into the thiocarbonyl function. Alternatively, compound *(3)* may be formed first, with subsequent Michael addition of SH^- to give *(2)*.

The reaction described above enables one to functionalize a thioamide with a thiol group, the latter serving as a useful entry to other functionalities, and to heterocycles, *via* appropriate reactions[3].

Procedure

Synthesis of *(2)*: To a stirred acetonitrile (80 ml) solution of the amide *(1)* (5—10 mmol) was added P_4S_{10} (1.5 equiv.) followed by $NaHCO_3$ (6.0 equiv.). The reaction mixture was stirred at 70°C for 1—2 h (or 30°C overnight), concentrated *in vacuo*, and ether was added to the residue. The ether solution was washed several times with water, dried ($MgSO_4$), and evaporated to give crude *(2)*. Pure *(2)* was obtained by silica gel chromatography using 5:1 benzene/ether as the eluant.

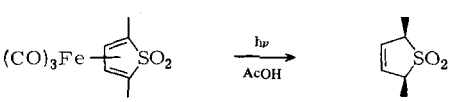
Regioselective Hydrogenation and Carbonylation of Functionalized Dienes on Photocleavage from Their Tricarbonyliron Complexes[**]

By *Michel Franck-Neumann, Daniel Martina*, and *Francis Brion*[*]

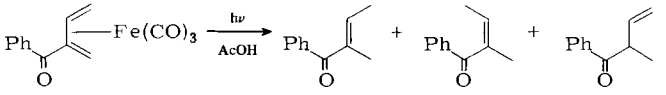
Dienes can usually be oxidatively cleaved from their tricarbonyliron complexes without undergoing any change in structure—however, in certain cases the formation of undesirable by-products takes place[1]. But a change in structure can be preparatively advantageous, if it proceeds in a defined manner. We have now found that tricarbonyliron complexes of 1,3-dienes which are substituted by electron-withdrawing groups in the 1-position are converted regiospecifically into β,γ-unsaturated compounds on photolysis in acetic acid. Thus, for example, the complexes of aliphatic dienones *(1)*, diene esters *(3)*, or cyclic dienones *(5)* are cleanly converted, respectively, into the β,γ-unsaturated carbonyl compounds *(2)*, *(4)*, and *(6)* which can be isolated in good yields.



(1) *(2)*, 80%

(3) *(E)*-*(4)*, 98% *(5)* *(6)*, 90%

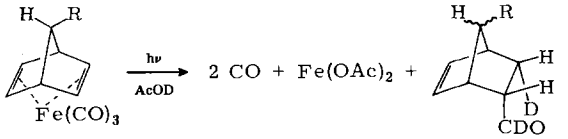
Also the complexed diene *(7)* containing a sulfonyl group is converted specifically into a dihydrothiophene. Only the *cis*-dimethyl isomer *(8)*[2] is formed. The two hydrogen atoms are therefore added from the same side.



(7) *(8)*, 75%

[*] Prof. Dr. M. Franck-Neumann, Dr. D. Martina, F. Brion
Equipe de Recherche Associé au CNRS n° 687
Institut de Chimie de l'Université Louis Pasteur
1, rue Blaise Pascal, F-67000 Strasbourg (France)

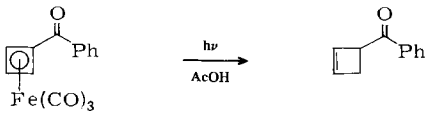
[**] This work was supported by the Centre National de la Recherche Scientifique (ATP n° 2238).



Diene complexes which are substituted in the 2-position, or do not bear electron-withdrawing substituents, react less specifically[3]. For example, the complex *(9)* yields a mixture of the isomeric enones *(10)*, *(11)*, and *(12)*, with the 1,4-addition of hydrogen strongly predominating.

(9) *(10)* *(11)* *(12)*

5 : 4 : 1



In the case of norbornadiene complexes these reductive photocleavages[4] can be accompanied by carbonylation. Thus, the complexes *(13)*, which do not contain any electron-withdrawing groups on the unsaturated system[5], are converted stereospecifically into *endo*-norbornenecarbaldehydes *(14)*[6], a reaction corresponding to a hydroformylation. Both addition processes thus proceed stereospecifically on the metal side.

(13a), R = H
(13b), R = O*t*Bu

(14a), R = H, 80%
(14b), R = O*t*Bu, 80% (2 isomers)

The preparative utility of these photocleavage reactions would seem to lie mainly in the synthesis of β,γ-unsaturated esters and ketones whose preparation *via* alternative routes presents difficulties. As example we might mention the cyclobutadiene complex *(15)*, which behaves as a 1-benzoyl-1,3-diene complex on photocleavage in acetic acid and gives exclusively 2-cyclobutenyl phenyl ketone *(16)*.

(15) *(16)*, 85%

Procedure

(15)[7] (594 mg, 2 mmol) is dissolved in 100 ml acetic acid. The solution, through which nitrogen is passed, is irradiated with a 125 W high-pressure mercury-vapor lamp until elimination of CO is complete (*ca.* 440 ml in 30 min). After addition of 150 ml water the solution is extracted four times with pentane (total volume 200 ml). The combined extracts are washed with water, 10% sodium hydrogen carbonate solution, once again with water, and then dried over magnesium sulfate. After removal of solvent the residual liquid is filtered over 10 g SiO_2; 263 mg (85%) analytically pure *(16)* is obtained as an almost colorless liquid; IR: ν(C=O): 1685 cm^{-1}, ν(C=C): 1580 cm^{-1}; ^{1}H-NMR ($CDCl_3$): 2.90 (2H, d, $J \approx 3.5$ Hz), 4.51 (1H, t, $J \approx 3.5$ Hz), 6.23 (2H, s), 7.40—8.05 (5H, m).

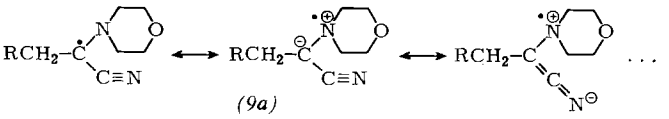
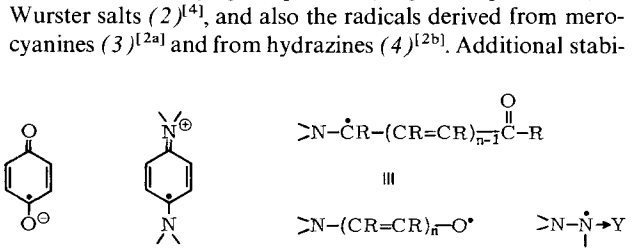
Stabilization of Radicals by "Capto-Dative" Substitution – *C—C* Addition to Radicophilic Olefins

By *Lucien Stella, Zdenek Janousek, Robert Merényi*, and *Heinz Günter Viehe*[*][**]



Dedicated to Professor Horst Böhme on the occasion of his 70th birthday

Whereas carbanions are stabilized by electron acceptors and carbocations by electron donors, radicals are stabilized by simultaneous substitution with a donor and an acceptor group ("capto-dative substitution"[1]).



X = Donor, Y = Acceptor

Although this effect has already been discussed[2], it has hardly been utilized. It is evident from the resonance structures of the radical *(9a)*, and has been confirmed by *ab initio* calculations[3].

(9a)

Many of the known persistent radicals have capto-dative substituents in *vinylogous* positions, *e.g.* semiquinones *(1)*, Wurster salts *(2)*[4], and also the radicals derived from merocyanines *(3)*[2a] and from hydrazines *(4)*[2b]. Additional stabi-

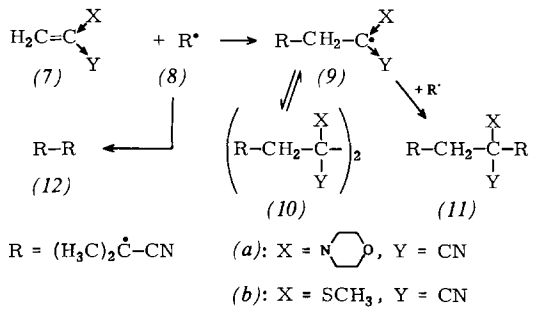
[+] To whom correspondence should be addressed.
[++] New address: Laboratoire de Chimie Organique B, Université d'Aix-Marseille, Rue Henri Poincaré, F-13397 Marseille Cédex 4 (France)

[**] We thank *A. R. Katritzky, G. Smets, J. M. Tedder, J. C. Walton*, and *P. Gouverneur* for valuable discussions.



lization often comes from the presence of further aromatic substituents[5].

Our interest centers on radicals with *directly* capto-dative substituted carbon atoms, *i.e.* very simple systems without olefinic resonance or particular steric stabilization. Among such species only the radicals *(5)* and *(6)* are known[6].

(5) *(6)*

We have now found that 1,1-capto-dative substituted olefins *(7)*[7] do not polymerize with isobutyronitrile radicals *(8)*, but instead undergo addition to form radicals of type *(9)* which are stable in the hot reaction mixture and either dimerize to *(10)* on cooling or react with *(8)* to form the bis-adduct *(11)*.

R = $(H_3C)_2\dot{C}$–CN *(a)*: X = , Y = CN

(b): X = SCH_3, Y = CN

Table 1. Properties of the products *(10)* and *(11)*.

	M.p. [°C]	M_r	^{1}H-NMR: δ in $CDCl_3$
(11a)	152	274	1.55, 1.63, and 1.65 (3H, 3H, and 6H, s), 1.94 and 2.61 (2H, AB system, J = 15.2 Hz), 3.21 (4H, m), 3.8 (4H, m)
(11b)	96	235	1.57, 1.60, 1.62, and 1.64 (each 3H, s), 1.95 and 2.24 (2H, AB system, J = 15 Hz), 2.55 (3H, s)
(10b)	152—153	334	1.59 and 1.65 (each 6H, s), 2.43 and 2.45 (4H, AB system, J = 15 Hz), 2.73 (6H, s)
(10b')	166—167	334	1.58 and 1.64 (each 6H, s), 2.11 and 2.33 (4H, AB system, J = 15 Hz), 2.68 (6H, s)

Thus, under the conditions given in the *Procedure*, *(7a)* furnishes only *(11a)* in 70% yield, whereas *(7b)* affords 18% of *(11b)* together with 51% of the monoadduct dimer *(10b)* as a mixture of the *meso* and DL form. The radicophilic nature of the olefins *(7)* is so pronounced that they act as polymerization inhibitors[8].

The ESR spectra recorded in the hot [mixture of olefin and azoisobutyronitrile, *(9a)*: 90°C, *(9b)*: 120°C, in chlorobenzene, or for *(9b)* from the dimers *(10b)* and *(10b')* at the same temperature] are in accord with the proposed structures (Table 2).

Table 2. The g values and hyperfine coupling constants determined by ESR spectroscopy for radicals *(9)*.

	g	a_N [G]		a_H [G]	
		—CN	—NR_2	—CH_2— (chain)	—NCH_2— (ring) —SCH_3
(9a)	2.0032	2.94	7.9	10.12	7.12
(9b)	2.0056	2.75	—	9.14	3.68

On heating to 100°C in chlorobenzene solution, the racemate *(10b')*[9] gives a 4:1 equilibrium mixture with the *meso* form *(10b)*.

Procedure

2-Azoisobutyronitrile (50 mmol) and olefin *(7)* (100 mmol) are dissolved in dry benzene (80 ml) in a 120-ml ampoule, which is then degassed in three freeze-thaw cycles and sealed under vacuum. It is subsequently heated to 75—80°C in an oil-bath for 15 h. The solvent is evaporated off and the dimer *(12)* extracted with light petroleum (b.p. 60 to 90°C). The bis-adduct *(11)* can then be extracted with diethyl ether. The insoluble residue in the case of *(7b)* consists of the *meso* form *(10b)* and the DL form *(10b')* of the dimer of *(9)*. After recrystallization from benzene/cyclohexane (4:1), large crystals of *(10b')* can be gleaned from the powder-like precipitate of *(10b)*.

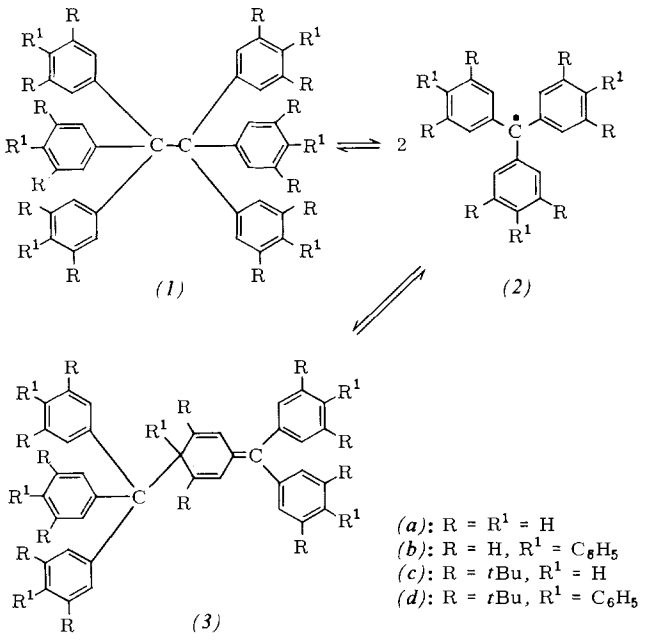
Hexakis(2,6-di-*tert*-butyl-4-biphenylyl)ethane—The First Unbridged Hexaarylethane[**]

By *Martin Stein, Werner Winter*, and *Anton Rieker*[*]

Ever since *Gomberg*'s first attempt to synthesize hexaphenylethane *(1a)* some 80 years ago under the guidance of *V. Meyer* in Heidelberg, this molecule has fascinated generations of chemists[1], and has still remained elusive. The dimer of triphenylmethyl *(2a)*, for decades regarded as *(1a)*, was shown as late as 1968 to be the methylenecyclohexadiene derivative *(3a)* (Jacobson-Nauta structure)[2,3].



The reason for the dimerization of triphenylmethyl to *(3a)* probably lies in the steric hindrance between the hydrogen atoms *ortho* to the benzyl C-atom in structure *(1)*. When two, four, or all six *ortho* positions in *(2)* are bridged directly

(c): R = tBu, R¹ = H
(d): R = tBu, R¹ = C₆H₅

or *via* intermediate units the hexaarylethanes are stable, *e.g.* *(4)*[3a], *(5)*[4], or *(6)*[5] (for further examples cf.[6]).

(4) (5) (6)

According to calculations by *Mislow et al.*[6], hexaphenylethane *(1a)* ought to be capable of existing with a central CC bond length of 164 pm and suitably intermeshed phenyl rings (point group D_3). Two routes would appear particularly promising for the synthesis of *(1a)* or a derivative thereof: 1) Synthesis of one or more phenyl rings in a molecule already containing the central CC bond. 2) Steric hindering of formation of the Jacobson-Nauta structure by incorporation of bulky groups R^1 and/or R; *(2)* must then either be persistent as the monomer—or dimerize (kinetically controlled) to *(1)*, which should be isolable if the dissociation equilibrium is established slowly.

In connection with our studies on the structure of twisted π-electron systems[7a] and on the reason for the monomeric character of the Schlenk radical *(2b)*[7b], we chose the second route.

According to *Berndt et al.*[8] the initially synthesized radical *(2c)*[7a,8] is monomeric in the solid state. However, on evaporating a solution of *(2c)* in cyclohexane colorless crystals of a dimer are obtained which on redissolution afford a yellow solution of *(2c)* (ESR spectrum). The concentration of radicals in a solution of *(2c)* obtained on warming the dimer in benzene decreases to a constant value over the course of 6 days (degree of dissociation *ca.* 55 % for an initial concentration of dimer of 8.13×10^{-3} mol/l). Evaporation of this solution affords red crystals which still contain benzene and *(2c)*.

Because of the high degree of dissociation and the sensitivity of the radical towards traces of oxygen no definite proof of the structure of *(1c)* can be obtained with ^{1}H-NMR, ^{13}C-NMR, and mass spectroscopy, though the length of time required for equilibration would indicate the ethane structure[2].

The radical *(2d)*[7a,9] also dimerizes. The dimer is much more sparingly soluble than dimeric *(2c)* and it dissociates much more slowly to the radical; for a 1.6×10^{-3} M solution of the dimer in benzene the equilibrium degree of dissociation is *ca.* 63 %. The mass spectrum (field desorption technique) shows only the signal of the radical *(2d)*; the IR spectrum (KBr), on comparison with that of the corresponding triarylmethanol, the triarylmethyl chloride, and the triarylmethyl peroxide, indicates the ethane structure *(1d)*. Because of the sparing solubility of the dimer in all common solvents, ^{1}H- and ^{13}C-NMR spectroscopy were here also of little help in deciding between the structures *(1d)* and *(3d)*. On the other hand, the dimer of the radical *(2d)* enriched with 90 atom-% ^{13}C in the benzyl position ($a_{^{13}C} = 2.31$ mT), shows, in hexadeuteriobenzene, in addition to the three signals of the solvent only *one* further signal at $\delta = 70.7$ (the shift value appears plausible for the benzyl carbon of a trityl group[3a]). In order to keep the content of monomeric radical *(2d)* in the solution as low as possible the dimer was brought into solution without warming. The ^{13}C-NMR spectrum is consistent only with structure *(1d)*; for *(3d)* two signals at $\delta = 62$—65 and 135—140 would be expected[3a].

The dimer of the radical *(2d)* could be obtained as colorless crystals (m.p. 276 °C) suitable for X-ray structural analysis after seven months of isothermal concentration of a benzene solution in absence of air. Structural analysis[10] showed that this species is in fact a hexaphenylethane derivative *(1d)*.

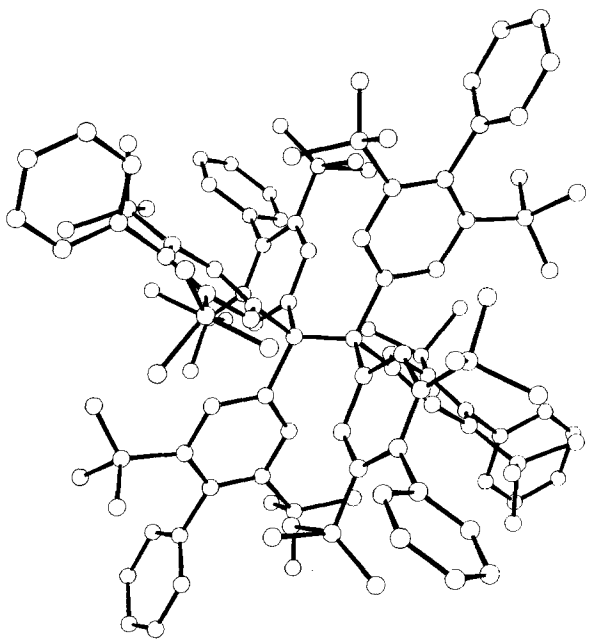

Fig. 1. Molecular structure of *(1d)* in the crystal.

In *(1d)* the heterochiral trityl propellers are staggered (point group S_6). This finding is contradictory to the force field calculations recently carried out by *Mislow et al.*[6], according to which the ground state of the D_3 conformation with homochiral trityl propellers in *(1a)* ought to be *ca.* 10.7 kJ/mol more stable than the ground state of the S_6 conformation. The central CC bond lengths [147(2) pm] and the C_{ethane}—C_{phenyl} bond lengths [average 165(3) pm] likewise differ markedly from the values calculated for *(1a)* (163.6 and 157.6 pm)[6]. Presumably, the *tert*-butyl groups are responsible for this effect.

The high melting point and slow dissociation of *(1d)* in solvents such as petroleum ether or benzene at room tempera-

ture would suggest that the unsubstituted hexaphenylethane *(1a)* should also by synthesizable.

[10] Monoclinic, $P2_1/c$; $a=1385$, $b=1586$, $c=2670$ pm, $\beta=114.95°$; $Z=2$. Intensity measurement: Nonius-CAD 4; the crystals employed contained 4 molecules of solvent benzene per unit cell and effloresced at room temperature; the measurements were therefore carried out at $-130°C$. The phase determination could only be accomplished using "negative quartets" (we thank Dr. *E. Hädicke*, Ludwigshafen, for use of his version of the XCSD-SHELX program by *G. M. Sheldrick*, Cambridge). Refinement: $R=0.13$ for 1480 reflections with $I>2.7\sigma(I)$, isotropic temperature factors, benzene rings as rigid groups. Due to the poor quality of the crystals, the bond lengths quoted in the text are to be regarded as preliminary values.

β-Cyclodextrin Dodecahydrate: Crowding of Water Molecules within a Hydrophobic Cavity

By *Klaus Lindner* and *Wolfram Saenger*[*]

The inclusion of guest molecules in the cyclodextrin cavity[1] has been the object of thermodynamic[2, 3], kinetic[2], theoretical[4], and X-ray structural[5a] studies, especially with α-CD and β-CD, the cyclohexa- and heptaamyloses. Hydrophobic, van der Waals and dipole interactions, and release of conformational strain and hydrogen bonding[5b] energy have all been discussed as driving forces of complex formation. The latter were proposed on the basis of a comparative X-ray crystal study of the "empty" α-CD hexahydrate and α-CD guest complexes[5]. In order to examine the mechanistic conclusions for the larger β-CD, we have now performed an X-ray structural investigation on its hydrate form.

β-CD crystallizes from water as chunky prisms, space group monoclinic $P2_1$ and cell constants $a=21.29$, $b=10.33$, $c=15.10$ Å, $\beta=112.4°$. Cell volume and crystal density (1.453 g/cm³) indicate that the asymmetric unit consists of β-CD· dodecahydrate. The crystal structure was solved with the aid of an isomorphous derivative[6] β-CD·2HI·8H_2O. Present refinement has reached $R=8.3$ % for 6426 X-ray data for the HI complex and $R=7.1$ % for 5036 data for the dodecahydrate.

In both the dodecahydrate and in the 2HI·8H_2O complex, β-CD adopts an almost "round" shape, similar to that in the complexes with other guests[7]. All glucoses are in the C1 chair conformation and arranged such that a ring of hydrogen bonds O(2)···O(3) is formed between adjacent glucoses. The only significant differences between the various β-CD complexes are in the orientations of the C(6)—O(6) bonds which are generally turned "away" from the center of β-CD with torsion angles O(5)—C(5)—C(6)—O(6) corresponding to (−)*gauche*. In the 12H_2O complex, three C(6)—O(6) bonds are rotated "inwards" [(+)*gauche*] to participate in hydrogen bonding with included water molecules (cf. Fig. 1).

Compared with α-CD, the van der Waals cavity diameter is increased from 5.0 Å in α-CD to 6.7 Å in β-CD. The O(4) atoms lie on a circle of radius 4.3 Å in α-CD but 5.1 Å in β-CD and the angles at O(4) are decreased by 2°, relative to α-CD. The change of ring size is accompanied by a slight conformational change of the glucoses, C(4) deviating by 0.70 Å from the C(2), C(3), C(5), O(5) glucose plane in β-CD, but 0.63 Å in α-CD[5a].

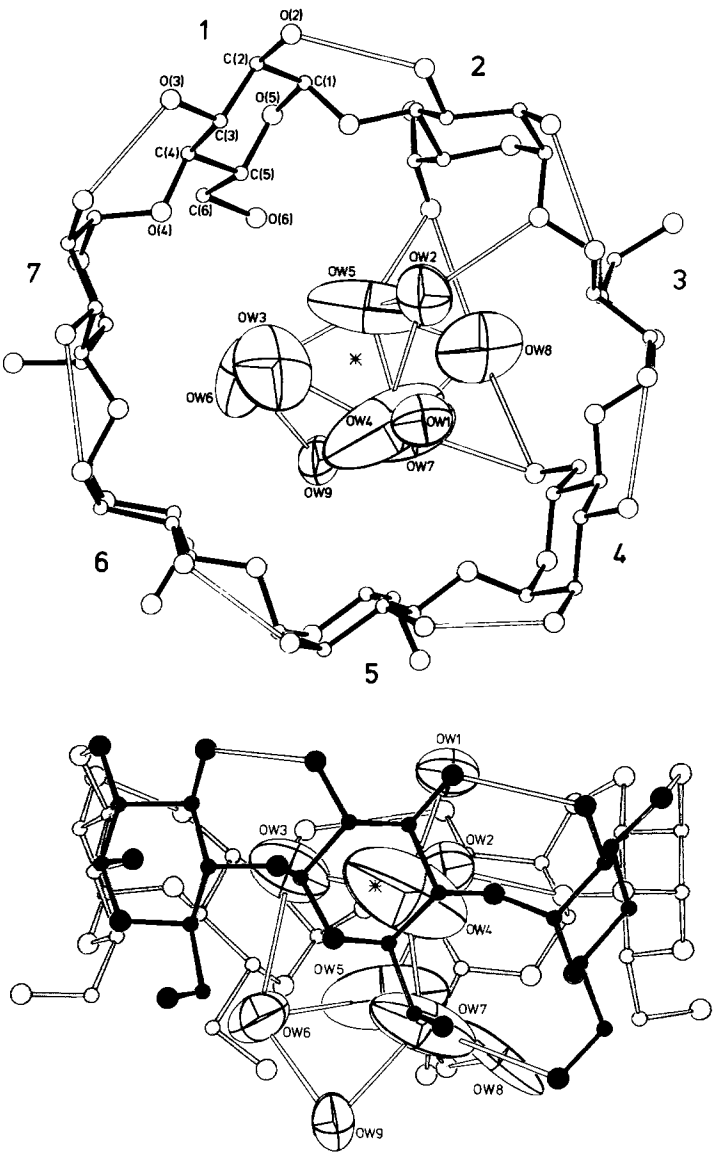

Fig. 1. Above: structure of β-cyclodextrin dodecahydrate from the O(2), O(3) side, water molecules within the cavity are drawn with their 50 % probability ellipsoids, water outside the cavity is omitted except OW9. Hydrogen bonding distances are indicated by open lines. The center of the ring formed by the seven O(4) atoms is marked by an asterik. Occupancies for water are 100 % for OW1, OW3; 89 % for OW4; 85 % for OW6; 73 % for OW5; 68 % for OW7, OW8; 61 % for OW2. The atom numbering scheme for glucose unit 1 is shown. In the text, *e.g.* O(3)2 refers to atom O(3) of glucose 2. O(6)2 is twofold disordered.

Below: The β-CD molecule viewed from the side, glucose unit 5 in front. Parts of the β-CD ring closer to the viewer are shaded more heavily than parts in the back. OW9 is already "outside" the cavity.

[*] Prof. Dr. W. Saenger, Dipl.-Phys. K. Lindner
Abteilung Chemie, Max-Planck-Institut für experimentelle Medizin
Hermann-Rein-Strasse 3, D-3400 Göttingen (Germany)

The β-CD cavity is filled by 6.5 water molecules distributed statistically over eight sites (Fig. 1). The remaining 5.5 water molecules of the dodecahydrate are spread over eight sites between β-CD molecules. Because no water hydrogen atoms could be located, the assignment of hydrogen bonds must be based on distance criteria. One of the O···O distances, (OW5···OW8, 2.32 Å) indicates that both sites cannot be occupied simultaneously. All other O···O contacts between oxygen atoms within the cavity (2.6 Å to 3.0 Å) satisfy the generally accepted distance criteria, The OW2···O(4)3 distance of 2.98 Å may possibly indicate the first observed hydrogen bond to glycosidic oxygen in saccharide crystal structures. All other OW···O(4) contacts exceed 3.3 Å.

The water molecules near O(2), O(3), and near the O(6) rims are also in contact with hydroxyl groups of adjacent β-CD molecules, establishing a hydrophilic surface of the β-CD• water complex. The usual tetrahedral arrangement of hydrogen bonding donor and acceptor groups around water molecules is only verified for OW1, with O···OW1···O angles in the range 91° to 141° deviating significantly from the ideal 107°. Tetrahedra around OW2 and OW4 are even more distorted and OW3 has only three neighbors at suitable distances. The remaining four water sites within the cavity have five neighbors each, with O···OW···O angles from 50° to 166°.

In the "empty" α-CD•6 H_2O, two water molecules are located within the cavity[5b,8]. They are at fixed, fully occupied positions and hydrogen bonded with each other and with two O(6) hydroxyl groups. The α-CD ring is strongly deformed by rotation of one glucose unit into a nearly vertical position relative to the other five, and the ring of O(2)···O(3) hydrogen bonds is disrupted. In all other complexes, the α-CD molecule is "round" and the ring of O(2)···O(3) hydrogen bonds is fully established. This conformational change between "empty" and "full" α-CD has led to the proposal of an "induced fit"-like mechanism[5b].

The larger β-CD molecule exists in β-CD•12 H_2O in a "round" structure and no conformational change except rotation of C(6)—O(6) bonds is observed upon complex formation with other guests. Thus an "induced fit" type mechanism can be ruled out for β-CD.

Hence we infer that the driving force of complex formation is provided mainly by hydrophobic forces and by van der Waals interactions between guest molecules and the interior of the β-CD cavity. "Activated water" may also come into play because the coordination of the water molecules entrapped within the β-CD cavity is by no means "ideal" and some hydrogen bonding energy might be gained by expulsion of these water molecules. Further, entropy terms will be appreciable if the eight water molecules are expelled.

Mixed Carboxylic-Dichlorophosphoric Anhydrides—Reactive Intermediates in Acyl Chloride Synthesis with $POCl_3$[**]

By *Franz Effenberger, Gerd König*, and *Herbert Klenk*[*]

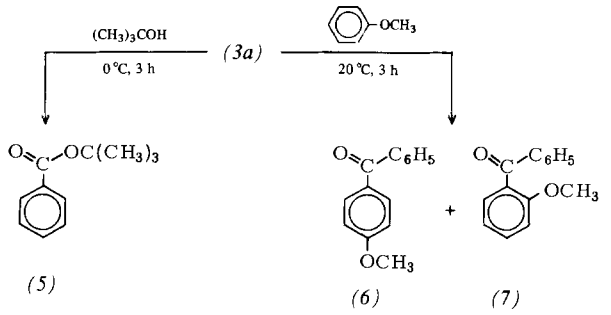
The intermediacy of mixed anhydrides *(3)*, X = Cl, has been proposed[1] in the preparation of acyl chlorides from salts of carboxylic acids and phosphoryl chloride. Acyl dichlorophosphates have likewise been advanced as the actual acylating agents in the "phosphoryl chloride method" developed by *Th. Wieland et al.* for the acylation of amino acids[2]. That no such intermediates *(3)* have yet been isolated or directly identified, is probably due to instantaneous reaction of the mixed anhydrides with nucleophiles still present in the mixture (carboxylate) or being formed in the course of the reaction (chloride).

We have now succeeded in preparing compounds *(3)* by reaction of carboxylic anhydrides *(1)* with dichloro- *(2a)* or difluorophosphoric anhydride *(2b)*. They are characterized by definite boiling points and correct elemental analyses; their structure is confirmed by ^{31}P- and ^{13}C-NMR spectra [*e.g. (3a)*: ^{31}P- (85 % H_3PO_4, ext.) $\delta = +1.66$; ^{13}C-NMR ($CDCl_3$) benzoyl carbon $\delta = 158.3$, $^2J_{O=C\ -O-P} = -11.5$ Hz].

In the case of anhydrides containing aliphatic acyl moieties, *e.g. (3e)* and *(3f)*, secondary processes such as ketene formation or condensation reactions prevent product isolation; however, these compounds can be prepared in dichloromethane solution. The NMR spectra provide unequivocal proof of both the presence and the structure of compounds *(3)*.

(1) *(2a)*, X = Cl; *(2b)*, X = F *(3)* 2 $[R-C\equiv O^{\oplus}\ PO_2X_2^{\ominus}]$ *(4)*

	R	X	Yield [%]	B.p. [°C/torr]
(3a)	C_6H_5	Cl	61	$77/10^{-3}$
(3b)	C_6H_5	F	80	$52/10^{-2}$
(3c)	p-$CH_3C_6H_4$	Cl	60	$97/10^{-3}$
(3d)	p-$CH_3C_6H_4$	F	75	$54/10^{-3}$
(3e)	CH_3	Cl	≈60 [a]	—
(3f)	CH_3	F	≈90 [a]	—



[a] Determined spectroscopically in CH_2Cl_2 solution.

Neither ^{31}P- nor ^{13}C-NMR shows any evidence of dissociation of the anhydrides *(3)* into acylium ions *(4)* which might be expected from the high leaving tendency of the dihalophosphate anion[3]. The IR spectrum also displays only a C=O vibration at 1780 cm^{-1} and no band at higher frequencies that could be attributed to stretching of the acylium function.

As expected, the anhydrides *(3)* are highly reactive. Unlike the corresponding acyl chlorides, they form esters of tertiary alcohols under mild conditions [*e.g. (5)*, 68 %]; with arenes, aryl ketones are produced *without* any Friedel-Crafts catalyst [*e.g. (6)* and *(7)*, 73 % (93:7)].

Institut für Organische Chemie der Universität
Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

As we were able to establish by ^{31}P-NMR and by chemical reactions, the formation of acyl chlorides from carboxylic acids and $POCl_3$ proceeds *via* acyl dichlorophosphates *(3)*. When benzoic acid, triethylamine, and $POCl_3$ are reacted in dichloromethane/ether at $-65\,^{\circ}C$, triethylammonium hydrochloride is precipitated. The presence of *(3a)* in the filtrate is demonstrated by the ^{31}P-NMR spectrum which remains unchanged upon admixture of authentic *(3a)*.

If the solution is warmed to 60 °C, benzoyl chloride and benzoic anhydride are formed; addition of alkali chlorides increases the percentage of acyl chloride. Apart from these two compounds, *tert*-butyl benzoate *(5)* is formed in the presence of *tert*-butanol at room temperature; benzoyl fluoride is produced upon addition of sodium fluoride and catalytic amounts of crown ether. Under these conditions, neither benzoyl chloride nor benzoic anhydride react with *tert*-butanol or NaF. Leaving group in each case is the dichlorophosphate ion, $Cl_2P(O)O^{\ominus}$.

R = C_6H_5

The above evidence definitely establishes the acyl dichlorophosphates *(3)* as true intermediates in the acyl chloride synthesis with $POCl_3$; at the same time, the high acylating potential of the mixed anhydrides *(3)* is demonstrated.

Procedure

Synthesis of *(3a)*: *(2a)*[4] (9.80 g, 38.8 mmol) and benzoic anhydride *(1)*, R = C_6H_5, (8.78 g, 38.8 mmol), are heated to 95 °C for 8 h, with strict exclusion of moisture. Fractional distillation of the reaction mixture yields 1.7 g (17%) of *(2a)*, b. p. 30 °C/10^{-3} torr, and 11.3 g (61%) of *(3a)*, b. p. 77 °C/10^{-3} torr.

Novel Mode of Formation of *cis,trans*-1,5-Cyclooctadiene[**]

By *Hans-Dieter Martin, Bernd Heiser*, and *Michael Kunze*[*]

Highly strained, *trans*-configurated double bonds in eight-membered rings are usually generated by elimination[1a], olefin inversion[1b], electrocyclic ring-opening[1c], cycloreversion[1d], or thermolysis[1e]. Previously, the *cis,trans*-isomerization of *cis*-configurated double bonds has been used as photochemical method[2]. We report here on photochemical and thermal fragmentations of the cyclic azo compound *(1)*[3], which lead in partly satisfactory yields to *cis,trans*-1,5-cyclooctadiene *(5)*.

A detailed study of *(1)* was promoted by the previous finding that *(5)* is a major product of the thermally induced valence isomerization of the tricyclooctanes *(2)* and *(3)*[1e]; a diradicaloid *(4)* was postulated as product-determining intermediate having three possible conformations *(4a)*—*(4c)* fulfilling all the necessary geometrical requisites for stereoelectronically favorable cleavage. A consequence of this hypothesis was the search for further suitable precursors for *(4)* and thus also for *(5)*. From the preparative standpoint the fragmentation of 7,8-diazatricyclo[4.2.2.$0^{2,5}$]dec-7-ene *(1)* appeared the most suitable approach[3].

As expected, irradiation of *(1)* (λ_{max} = 384 nm, ε = 164) in pentane does in fact afford *(5)* as main product. In ether[3] the yield of *(5)* is considerably lower (see Table 1).

On separation of the products slight losses are incurred on account of the high sensitivity of *(5)*. Compound *(5)* was converted directly in the photolyzate with hexachlorocyclopentadiene.

Thermolysis of the tricyclic compound *(2)* under conditions (A) likewise leads to *(5)* as a major product. Under conditions

[a] In some cases the product mixture contains small amounts of *trans*-1,2-divinylcyclobutane and 4-vinylcyclohexene. The composition of the product mixture was determined gas-chromatographically directly after the photolysis or thermolysis.

(B) the thermolability of *(5)* and the isomerization to *(7)* become strikingly manifest. Also the thermolysis of *(5)* itself (conditions B) yields predominantly *(7)*. The thermolysis of *(1)* is worth noting. The formation of considerable amounts of *(5)* expected *a priori* is not observed; the main product is the *cis,cis*-diene *(7)*. This indicates that the thermal fragmentation of *(1)* *via* the diradicaloid *(4)* to the *cis,trans*-diene *(5)*—in contrast to the photochemical decomposition—takes place only to a minor extent, and that the concerted $[\sigma_s+\sigma_s+\sigma_s]$ fragmentation to *(7)* is the dominant reaction. This is in agreement with experiments[5] which demonstrate the ability of the cyclobutane ring to participate in the process,

and also reconcilable with the positive activation entropy of this process[6]. The supposition that *(1)* lies on the borderline between concerted and diradical decomposition[5] is thus confirmed.

Procedure

A solution of *(1)* (1.00 g, 7.35 mmol) in anhydrous and olefin-free pentane (40 ml) is irradiated (150 W Hg high-pressure lamp, Duran) for 6 h at −10 °C. The conversion of *(1)* amounts to 50 % (decrease in extinction of the $n_-\pi^*$ transition at 384 nm). After addition of 500 mg (1.85 mmol) hexachlorocyclopentadiene, the volatile components are removed in a water-pump vacuum and the residue is distilled at 135—145 °C/0.001 torr in a bulb-to-bulb apparatus; yield of adduct $C_{13}H_{12}Cl_6$[4] 360 mg (52 %); ^{1}H-NMR (60 MHz, CCl_4): $\delta = 1.80$—2.45 (m, 8H, CH_2), 2.50—2.75 (m, 1H, CH), 2.75—2.90 (m, 1H, CH), 5.65 (m, 2H, olefinic).

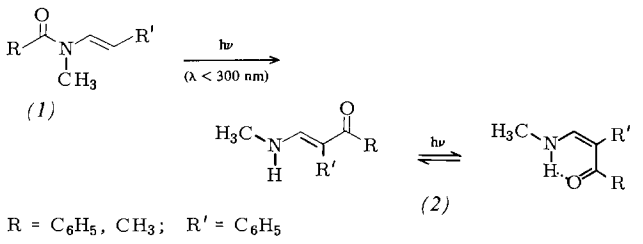
ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

Asymmetric syntheses are surveyed by *D. Valentine, Jr.*, and *J. W. Scott* with regard to preparative utility. Only those syntheses are considered in which the chiral molecules are generated exclusively by chemical reagents and the enantiomeric ratio is at least 3 : 1. Enamines and *N*-substituted imines, olefins without heteroatoms at the double bond, and carbonyl compounds serve as starting materials. [Asymmetric Synthesis. Synthesis *1978*, 329—356; 333 references]

[Rd 33 IE]

Reactions of CF_3-substituted arenes with nucleophilic reagents have been compiled by *Y. Kobayashi* and *I. Kumadaki*. The CF_3 group attached to aromatic compounds was formerly regarded as a very stable substituent, but it has meanwhile been found that CF_3 moieties present on quinolines, indoles, benzofurans, and benzene derivatives can undergo numerous reactions with nucleophiles. For instance, 2-(trifluoromethyl)-



indole *(1)* gives the product *(2)* in an S_N1 reaction with $NaOC_2H_5$ in ethanol. Although benzotrifluoride is not attacked under these conditions, it can be degraded to *p*-aminobenzonitrile by $NaNH_2$ in ammonia after introduction of a *p*-amino group. [Reactions of Aromatic Trifluoromethyl Compounds with Nucleophilic Reagents. Acc. Chem. Res. *11*, 197—204 (1978); 20 references]

[Rd 31 IE]

The insoluble acid salts of tetravalent metals are surveyed by *G. Alberti*. Inorganic ion exchangers of this kind are of potential interest on account of their pronounced resistance to high temperatures and to radiation. The prototype $Zr(HPO_4)_2 \cdot H_2O$ crystallizes in a layer structure (interlayer distance 7.56 Å). The structure contains cavities interconnected by openings of maximum diameter 2.64 Å. In contrast to the zeolites the interlayer distance can be increased, *e.g.* by replacing a proton by sodium; in the resulting product $ZrHPO_4 \cdot NaPO_4 \cdot 5H_2O$ it is 7.6 to 11.8 Å. If Na^+ is now replaced by H^+, a new form arises containing $5—7 H_2O$ and having an interlayer distance of 10.4 Å in which the windows between the cavities are also enlarged, permitting exchange of large cations. [Syntheses, Crystalline Structure, and Ion-Exchange Properties of Insoluble Acid Salts of Tetravalent Metals and Their Salt Forms. Acc. Chem. Res. *11*, 163—170 (1978); 80 references]

[Rd 30 IE]

The photochemistry of enamides is examined by *G. R. Lenz*. Although rather unreactive in the ground state, enamides (*N*-acylenamines) give rise to a plethora of reactions in the excited state. Thus, simple enamides such as *(1)* rearrange photochemically to vinylogous amides *(2)*. Dienamides undergo photocyclization to complicated heterocycles, *e.g.* with benzylisoquinoline or indole alkaloid skeletons; these reactions can facilitate the synthesis of natural products. [The

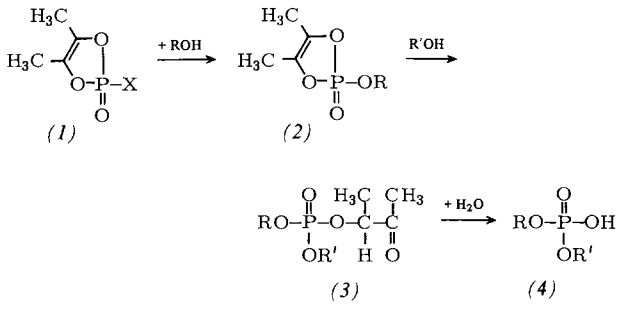
Photochemistry of Enamides. Synthesis *1978*, 489–518; 143 references]

[Rd 34 IE]

The linkage between teichoic acid and peptidoglycan in bacterial cell walls is dealt with in an article by *J. Coley, E. Tarelli, A. R. Archibald*, and *J. Baddiley*. Although teichoic acid can be extracted from cell wall specimens and thus separated from totally insoluble peptidoglycan, the interaction between both cell wall components is not of a purely electrostatic nature but also involves covalent bonding. The acid-labile *N*-acetylglucosamine-1-phosphate bond and an alkali-labile phosphodiester bond between the alcohol and the sugar component were recognized as covalent bonds participating in the linking. The presence of the same type of or similar linkage sites in cell walls of otherwise quite different structure would suggest that various species use the same mechanism for the linkage of both cell wall components. [The Linkage between Teichoic Acid and Peptidoglycan in Bacterial Cell walls. FEBS Lett. *88*, 1—9 (1978); 37 references]

[Rd 27 IE]



Metal-induced rearrangements and insertions into vinylcyclopropanes and related compounds are described by *S. Sarel*. Vinylcyclopropanes can undergo four types of reaction with carbonyliron compounds (a—d). $Fe(CO)_5$ was found to be

an effective "homodienophile", and vinyl- and divinylcyclopropanes were recognized as a new source of 4 and 6 π electrons suitable for coordination to metals. [Metal-Induced Rearrangements and Insertions in Cyclopropyl Olefins. Acc. Chem. Res. *11*, 204—211 (1978); 44 references]

[Rd 32 IE]

Phosphorylation by means of cyclic enediol phosphates, *(1)*, X = *e.g.* Cl, is the title of a review by *F. Ramirez* and *J. F. Marecek*. The synthesis of phosphoric diesters of type *(4)* from the alcohols ROH and R′OH and the enediol phosphate *(1)* has the advantage that the cyclic phosphates are very reactive, that the reaction step *(2)* → *(3)* is effectively catalyzed by, *e.g.*, imidazole or triethylamine, and that the formation of symmetrical diesters by transesterification is suppressed.

The pyrophosphate derived from *(1)* is suitable for the synthesis of, *e.g.*, deoxyribooligonucleotides and phospholipids. [Phosphorylation by Means of Cyclic Enediol Phosphates. Acc. Chem. Res. *11*, 239—245 (1978); 47 references]

[Rd 35 IE]

Transport durch biologische Membranen. (Transport Across Biological Membranes.) By *M. Höfer*. Verlag Chemie GmbH, Weinheim—New York, 1977. 1st edit., ix, 128 pp., 49 figs., 6 tables, paperback, DM 44.00.

The author has given a condensed account—long outstanding in German—of the current knowledge of transport of molecules across biological membranes, permitting the reader to gain a quick access to this already very extensive field.

The work deals mainly with the kinetic and theoretical aspects of membrane transport, which reflects the trend in transport research so far. The structure of the membrane is considered a black box, and the concentrations of ions or metabolites, or changes in these, are measured on both sides of the membrane. Only in the last few years has one started to isolate the molecular components making up the transport system.

The transport across biological membranes is treated in five chapters: 1. Structure and function of biological membranes, 2. The transport function of biological membranes (*e.g.* basic laws, diffusion of ions, and carrier-based transport), 3. Kinetics of catalyzed transport (*e.g.* transport kinetics under equilibrium conditions, kinetics of counter-transport, carrier-based transport and diffusion, and inhibition of transport processes), 4. Active transport processes (*e.g.* the phosphotransferase system in bacteria, sodium pumps, chemiosmotic theory, kinetics of active carrier-based transport), and 5. Molecular foundations of carrier-based transport (*e.g.* carrier molecules, problems of carrier isolation, ionophores, and reconstitution of transport systems). The derivation of kinetic equations and the necessary mathematics are described in detail in an appendix.

The book is mainly oriented at kinetics, therefore some of the experimental problems are not discussed: how to isolate membrane vesicles, how to find out whether these are open or closed, and the question of whether the isolation alters the permeation characteristics of eukaryotic membranes. Similarly, when discussing the current membrane models, the author restricts his presentation to the polymer membrane model, for which not much experimental evidence exists. *Singer* and *Nicolson*'s fluid mosaic model, now accepted by most research workers, is not presented, and literature references for it are also missing.

To sum up, the book gives a condensed and well-organized account of the broad subject of membrane transport and gives the experimental examples which are known up till now. The main emphasis is on kinetics and mathematical treatment. The book makes it possible to gain a quick introduction to the problems of transport across bio-membranes, and it is to be welcomed.

G. Brunner [NB 424 IE]

Basis-Römpp. Taschen-Lexikon der Chemie, ihrer Randgebiete und Hilfswissenschaften (Pocket Dictionary of Chemistry and Related Fields). By *O.-A. Neumüller*. Franckh'sche Verlagshandlung, Stuttgart, 1977. 1st edit., vol. 1: A—L, vol. 2: M—Z, altogether 768 pp., numerous figures, boards, DM 39.50.

Certainly not everybody who needs the big six-volume Römpp for his work has it, either because of the cost or because of the very space it takes up. It was therefore an obvious and sensible idea to produce a "distillate" from the complete version. The result is the Basis-Römpp, which consists of a selection of the entries found in the well-established Chemie-Lexikon. The entries selected for the pocket edition relate to important fundamental concepts of chemistry, classes of compounds like aldehydes, nucleic acids, and metals, types of reactions, measurement methods and methods of investigation, and laws. The entries have the same text as in the parent work, so there is no loss of quality—only the literature at the end of the entries has been omitted to save space. This version does not give *e.g.* commercial products, trivial names, and single compounds. The elements are mentioned only under the heading of the Periodic System and are not discussed where they should come in an alphabetical arrangement. This means that they are not covered, and they may be missed by some non-chemists—*e.g.* medics, biologists and physicists—who are among those for whom the book is intended; chemists at universities and in industry can overlook this, because they will find suffucient information on the elements in other reference books. Of course, we cannot ask for everything when the price is so low. As a handy reference book the Basis Römpp certainly achieves its objective; those who want to know more are referred to the sources taken over from the big Römpp.

C. Weiske [NB 423 IE]

Comprehensive Biochemistry. Vol. 25: Regulatory Functions—Mechanisms of Hormone Action. Edited by *M. Florkin* and *E. H. Stotz*. Elsevier/North Holland Biomedical Press, Amsterdam, 1975. 1st edit., 199 pp., 22 figs., 12 tables, bound, Dfl. 40.00.

When reviewing a book published three years ago one can either mention what has happened since to make the book obsolete or to treat it as a document. In the second case the book under discussion ought to be compared with volume 24. The new volume treats the mechanisms of hormone action and the characteristics and functions of adenylate-cyclases, both under the general heading of "biochemical regulation". The subject is divided into compartments by the cell membrane, being concerned with what happens on the two sides of the cell membrane and in it. Both chapters therefore deal with very topical subjects and, as always when a subject has a future, the work has its own noncooperative evolutionary mechanisms and corresponding non-linear publication kinetics.

In the first chapter *P. Karlson, B. Doenecke*, and *C. E. Sekeris* discuss—on the basis of over 400 references, covering the field up to 1974—the interactions of steroid, thyroid, and peptide hormones with components of the cytoplasm and the nucleus, particularly with chromatin. Adenylate-cyclase systems are thus deliberately treated separately in the next chapter. The authors first cite the experimental observations and then weigh up the merits and the shortcomings of the various interpretations, hypotheses, and theories—and mostly reject them. The most likely interpretation is that the signal substances are bound on a chromatic protein, and this initiates the transcription by RNA polymerase B. The chapter is distinguished by exemplary clarity and critical systematization and is a good, stimulating contribution to a handbook.

E. W. Sutherland made the very important discovery that cyclo-AMP is a secondary messenger, which takes the cell-spe-

cific information coming from catecholamines and hydrophilic hormones and picked up by the membrane receptors, conveys it to protein-kinases by a subcellular mechanism, and regulates enzymatic activities by the modification of enzymes. This feature separates these classes of hormones from the above-mentioned steroid hormones, which have a direct action. In the description of the adenylate-cyclase system, *T. Braun* and *L. Birnbaumer* discuss in detail how the reaction of a hormone with its exo-membrane receptor leads to the activation of the cyclase (mentioning 200 references up to 1973). Despite new data about details, this explanation is basically still valid. However, we have since come much closer to the characterization of the specific receptors and modification reactions. The authors are commendably selective and have refrained from using the very convincing cyclo-AMP-sensitive biological process as a supporting model. In all, this chapter leaves little to desire even after three years, so that the present volume maintains the standard we have come to expect of this series[*]. Unfortunately, the readers should be warned that the series is slow in reaching completion and that many supplementary volumes are still to come.

L. Jaenicke [NB 428 IE]

Developments in Food Carbohydrate—1. Edited by *G. G. Birch* and *R. S. Shallenberger*. Applied Science Publishers Ltd., London, 1977. 1st edit., x, 189 pp., 58 figs., 51 tables, bound, $ 25.00.

This first volume in a series of concise monographs on recent developments and advances in topical areas of carbohydrate research in the field of nutrition science contains ten contributions, most of which were originally given as papers at an ACS Symposium by the Division of Carbohydrate Chemistry and Agricultural Food Chemistry. They deal with new theoretical and practical data on the structure and properties of sugars and polysaccharides, metabolic and biochemical relationships, biological functions, analyses, and points of technology and nutrition physiology.

More specifically, *G. Birch*'s contribution deals with the chemistry and properties of glucose syrups (19 pages), and *M. Seidman*'s with the particularly topical subject of the technological development of fructose manufacture (24 pages). *S. Arnott* describes investigations of the states of order in gel-forming polysaccharides by the X-ray crystallographic analysis of oriented fiber structures (18 pages). The next two contributions deal with the occurrence, biosynthesis, and functions of heptuloses (by *E. A. McComb* and *V. V. Rendig*, 16 pages) and with the raw materials and the method used in lactose production (by *T. A. Nickerson*, 14 pages). Special topics are covered by the next sections: nonenzymatic browning in orange juices (*P. Shaw*, *J. Tatum*, and *R. Berry*, 22 pages), the effect of carbohydrates on intestinal transport and enzymatic activities in rats (*S. Reiser*, 28 pages), the solubilities of starch fractions in the cooking of rice (*R. J. Priestley*, 16 pages), the connection between food quality and carbohydrate dehydration reactions (*M. S. Feather*, 16 pages), and the production of biscuits with a reduced risk of causing caries (*T. Grenby* and *J. Bull*, 16 pages).

The contributions are written by competent writers, contain a large number of literature references, and provide what must certainly be a large circle of interested people with useful information and ideas.

Extraction with Supercritical Gases—A Foreword

By Günther Wilke[*]

A comparative study of the diverse operations of chemical synthesis and analysis quickly reveals the paramount importance of separation steps. Any synthesis affords mixtures, and the desired product usually has to be separated from by-products and auxiliary materials—whether it is formed *in vitro* or *in vivo*. Analysis is based primarily on separations. These trivial statements would suggest that during the development of chemistry the fundamental methods of separation have long been recognized and mastered. It is therefore all the more astonishing that the first symposium on a novel method of separation, *viz.* extraction with supercritical gases[**], was held this year. In simplified terms, this new method is characterized by the following features:

1) Relatively involatile materials can be dissolved by supercritical gases—sometimes even selectively—to form a charged supercritical phase.

2) Phenomena of distillation and extraction are utilized simultaneously, *i.e.* enhancement of vapor pressure and phase separation both play a role.

3) The properties of the extracting agent, and especially its density, can be varied within wide limits by means of pressure and temperature.

4) Separation of the dissolved substances can be accomplished either by reducing the pressure (at constant temperature) or by raising the temperature (at constant pressure).

The first observations that solids such as metal halides are soluble in ethanol or tetrachloromethane under conditions above the critical point (C_2H_5OH: $T_c = 243\,°C$, $P_c = 63$ atm; CCl_4: $T_c = 283\,°C$, $P_c = 45$ atm) date back to 1879[1]. It was also known at an early date that hydrocarbons are entrained in highly compressed natural gas during the winning of petroleum[2]. Even purely academic studies on well-defined multicomponent systems, *e.g.* the methane/*n*-decane system, have long been available[3]. It appears, however, that no chemical engineering applications were initially considered apart from technically impractical proposals[4] and a process corresponding to liquid-liquid extraction which happens to employ a supercritical gas[5].

As is so often the case, it was a simple and, in fact, misinterpreted observation that initiated the development of new separation process. In view of discussions on research-planning it seems appropriate to retrace the course of such developments and to demonstrate on the basis of the known motivations that it is in general the careful observation of the unexpected which marks the beginning of significant new advances in knowledge and not theoretical predictions. However, only the correct conclusions drawn from the observation lead ultimately to success. Although this is trivial, it is a far from trivial matter to draw such conclusions.

The route leading from the chance individual observation to the now imminent industrial commercialization of separation with supercritical gases is described in the first of the following essays. *Zosel* began his fundamental studies as early as 1962 at the Max-Planck-Institut für Kohlenforschung and has since developed a general industrial process[6]. In 1970 he discovered the decaffeination of green coffee with the pharmacologically completely acceptable carbon dioxide[7] which is to come on stream this year. *Vitzthum* and *Hubert* investigated other applications to the isolation of natural products and these too have already attracted industrial interest.

That the physicochemical principles underlying the novel method are highly sophisticated, although the process was developed with a fair degree of intuition, follows from the

[*] Prof. Dr. G. Wilke
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr (Germany)

[**] This symposium was held on 5 and 6 June, 1978, at "Haus der Technik", Essen, an external department of the Technische Hochschule Aachen. Joint chairmen were *G. M. Schneider* (Bochum), *E. Stahl* (Saarbrücken), and *G. Wilke* (Mülheim-Ruhr).

contribution by *Schneider*. The study of binary mixtures of polar components such as water or ammonia with nonpolar substances such as hydrocarbons in the critical range is also based on physicochemical measurement (*Lentz* and *Franck*). The extractability of natural products in particular can be assessed with great facility and speed by using supercritical gases in the elegant chromatographic microanalysis developed by *Stahl*. Practical possibilities and the theoretical basis of chromatography with supercritical gases are discussed by *Klesper* who was responsible for the first application of such systems to gas chromatography[8].

Peter and *Brunner* have studied the separation of relatively involatile substances with compressed gases in a countercurrent process and have already made calculations for a large-scale plant. The approach to the design of such plants is discussed by *Eggers*; the high-pressure systems necessarily involve a certain degree of sophistication.

It is no coincidence that all the authors of the progress reports published in this issue come from West Germany, since it is here that the separation process was discovered and developed. For the sake of completeness, however, it should be mentioned that the extraction of coal with supercritical solvents such as toluene ($T_c = 320\,°C$, $P_c = 41.6$ atm) has been studied in Great Britain since about 1970 with the support of the National Coal Board[9]. Under these extreme conditions (350 °C) up to about 30 % of the coal can be extracted. The solvent-free extract contains more hydrogen than the coal (6.9 % instead of 4.9 %) and could be used in the production of hydrocarbon oils and as a chemical raw material. The economics of the process appear somewhat questionable.

Numerous scientists from abroad also attended the Essen symposium and a general summary might be: the separation of substances with supercritical gases will probably find numerous further applications in the years to come.

Separation with Supercritical Gases: Practical Applications[**]

By K. Zosel[*]

Extraction with supercritical gases combines, to a certain extent, the characteristics of both distillation and extraction; the term "destraction" is therefore proposed for this method of separation. The principles of the method are illustrated in this article by a series of color photographs comparing extraction and destraction. Of the practical uses of this new method may be mentioned the separation of cod-liver oil into 50 fractions, each differing in saponification value and iodine number, by means of supercritical ethane and, in particular, the decaffeination of raw coffee with supercritical carbon dioxide.

1. Introduction

Development of the technique of separating substances using supercritical gases first began in the early 60's[1], though certain fundamental principles had already been known for more than 80 years[2] and experimental results seemingly anticipating the potential of this new principle were first reported in the 50's[3]. What really initiated the development of this new method of separation? It is instructive to follow the progress of this development in connection with research-planning and to show by reconstructing the course of events that, in general, it is the careful observation of an unexpected, and hence presumably seldom theoretically predictable behavior, which initiates significant new trends.

In the early 1950's *Ziegler* and *Gellert*[4] discovered the so-called "Aufbau" reaction of triethylaluminum with ethylene under pressure at *ca.* 100 °C—a reaction which today forms the basis of the large-scale preparation of long-chain primary alcohols *(1)* for conversion into biodegradable detergents.

$$\text{al-}C_2H_5 + x\,C_2H_4 \longrightarrow \text{al-}(C_2H_4)_x\text{-}C_2H_5 \xrightarrow{1/2\,O_2}$$

$$\text{al-O-}(C_2H_4)\text{-}C_2H_5 \xrightarrow[-\text{alOH}]{H_2O} HO\text{-}(C_2H_4)_x\text{-}C_2H_5 \qquad (1)$$

Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr (Germany)

[**] Based on a lecture delivered at the Symposium on "Extraction with Supercritical Gases", June 5, 1978 in Essen (Germany).

This reaction was carried out on a laboratory scale as follows: a 200 ml autoclave was charged with *ca.* 10 ml of triethylaluminum (b.p. 194 °C/760 torr) and filled with ethylene at room temperature. Under these conditions the ethylene is 10—15 °C above its critical temperature ($T_c = +9$ °C). In this temperature range the compressibility of ethylene is particularly high, so the pressure cannot be used as a guide for the amount in the autoclave: this was determined by weighing. In one case it was found that the autoclave was overfull, and heating to 100 °C would have resulted in too high a pressure. It seemed inadvisable to simply vent the autoclave since it was feared that traces of the spontaneously inflammable triethylaluminum might be carried over and ignite the gas. The gas was therefore vented through a cold trap, where condensation of $Al(Et)_3$ was indeed observed. It was assumed that this had been carried over either in the form of droplets or that it had crept up the sides of the autoclave. This phenomenon did not receive further attention.

A systematic investigation of the ability of pressurized ethylene to transport high-boiling material was first undertaken in 1962 as the result of a difference of opinion with a licensee concerning the quality of the product of the "Aufbau" reaction. The product prepared by the licensee contained large quantities of α-olefins which were virtually absent from our product obtained under the same conditions. The α-olefins *(2)* are produced in a side reaction in which, at 100–120 °C, the trialkylaluminum undergoes cleavage to give dialkylaluminum hydride and an α-olefin[5].

$$\text{al-CH}_2\text{-CH}_2\text{-R} \longrightarrow \text{alH} + \text{CH}_2\text{=CH-R} \qquad (2)$$

al = 1/3 Al

The controversial results arose from differences in the experimental procedures. In our experiments the α-olefins formed were removed from the reactor by the supercritical ethylene and hence separated from the "Aufbau" product. This effect could not be associated with the partial pressure of the α-olefin since this was far too low. The procedure used by the licensee, however, did not lead to this separation. It was very quickly realized that a general principle had been discovered for the separation of substances.

2. Phenomenological Considerations

Distillation and extraction are among the most important separation procedures. Whereas separation by distillation is based upon the different vapor pressures of the components, separation by extraction is based on those properties of the material which determine the intermolecular interaction with the molecules of the extraction agent. Both of these effects are, to a certain extent, united in the general process described above for the separation with the help of supercritical gases, and for this reason the expression *destraction*[*] is proposed.

It has been known for some time that liquified gases can be used as solvents, *i.e.* as extraction agents, in liquid-liquid extraction. One of the most important technical applications is in the deasphalting of petroleum with propane[6]. The characteristic differences between an extraction of this type and destraction can be convincingly illustrated using this process as an example.

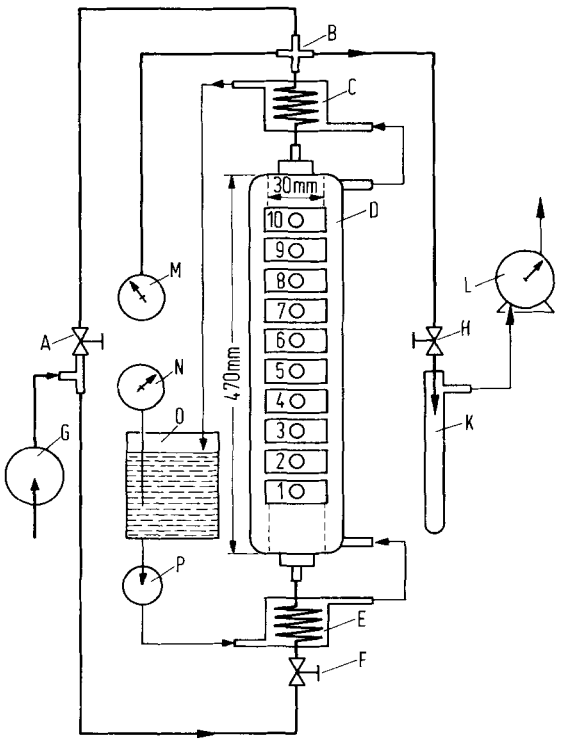

Fig. 1. Thermostated custom-built autoclave (schematic) C, D, E, O, P = pumps, A, F = inlet valves, H = outlet valve for product and gas, G = reservoir for product and gas, L = gas meter for measuring volume of decompressed gas, M = manometer, N = thermometer, B = splitter, *1–10* = glass windows.

A schematic diagram of the apparatus used for this experiment is shown in Figure 1. A custom-built autoclave consisting of a thermostated vertical pressure vessel furnished with 10 glass windows at the front and the rear was used, thus enabling processes occurring inside the autoclave to be observed directly. The autoclave has a volume of *ca.* 450 ml.

The series of pictures in Figure 2 illustrate a typical propane extraction of the top-residue of a petroleum distillation. The extraction conditions in Figures 2a and 2b correspond exactly to those used by *Zhuse*[3] (*i.e.* 105 °C, 8° above T_c, 100 atm, $\rho \approx 0.379\ g\,cm^{-1}$[**]). As mentioned in the introduction, these conditions seem, at a first glance, to have anticipated the principle of destraction.

Fig. 2. Photographs of part of the autoclave shown schematically in Fig. 1 (windows 1—10, manometer M, thermometer N, receiver K) during treatment of petroleum top-residues with propane. a), b) Extraction under the conditions used by *Zhuse* [3]: 105 °C (8° above T_c), 100 atm, $\rho \approx 0.37\ g\,cm^{-3}$. c), d) Destraction at 140 °C (43° above T_c), 100 atm, $\rho \approx 0.29\ g\,cm^{-3}$ (see color plate, p. 705).

Initially the top-residue meniscus appears in the second window (Fig. 2a above, left). Propane is fed in, dissolves, and the level of the meniscus rises (windows 2—9). On reaching a particular composition (with the meniscus in window 9 Fig. 2a below, right) a sudden demixing occurs and a second

[*] From the Latin *destillare* and *extrahere*.

[**] In the following discussion the density of the pure gases as taken from tables are cited. It should be noted that these are not the densities of the loaded phase.

meniscus forms, *i.e.* at this stage the following phases are present: a dark liquid (windows 1—4), a red liquid (windows 4—9), and a practically colorless gas phase (windows 9 and 10, Fig. 2b above, left). Removal of gas at constant pressure through valve H (additional propane is fed in through valve F) causes the second meniscus to rise further (Fig. 2b, above right) until finally a dark, extracted oil is carried over into K. This is accompanied by a fall in the level of the meniscus of the dark phase (window 5 to window 3).

Figures 2c and 2d show the situation at 140 °C (43° above T_c) and 100 atm ($\rho \approx 0.29\,g\,cm^{-3}$). The initial behavior in Figure 2c, in which a liquid and a gas phase are observed, is similar to that Figure 2a, and the dark phase rises from window 2 to window 5.

The basic difference between extraction and destraction becomes clear in the stages which follow: a light, transparent loaded supercritical gas phase is formed in addition to the liquid phase (windows 5—10) *without* the formation of a second liquid phase (Fig. 2d). The removal of this gas phase through the valve H leads to the isolation of pale yellow destracted oil in K. There is a basic difference between the phase behavior and the selectivity in the two cases, which makes itself apparent in the color of the transported product. Both systems also show a characteristic difference in their response to slight decompression: gas bubbles are formed (particularly in the upper phase) in the system having two liquid phases (Fig. 2b), *i.e.* boiling occurs, whereas in the second system (Fig. 2d) turbidity in the gas phase is observed as a result of phase separation, thus indicating that a true supercritical phase has been generated. The top-residue destraction will be discussed in more detail in Section 4. A number of characteristic phenomena will now be discussed. If ethylene is bubbled through paraffin oil at room temperature (23 °C, *i.e.* 14 °C above T_c) and atmospheric pressure ($\rho \approx 0.0013\,g\,cm^{-3}$) 100 g of ethylene transport *ca.* 0.1 g of oil. On raising the pressure, the amount of oil transported per 100 g of ethylene hardly changes until the critical pressure ($P_c = 50$ atm, $\rho \approx 0.22\,g\,cm^{-3}$) is reached; at this point a dramatic increase in the amount of oil transported is observed, and at 200 atm ($\rho \approx 0.4\,g\,cm^{-3}$) 100 g of ethylene transport *ca.* 25 g of paraffin oil. At 200 atm and 70 °C ($\rho \approx 0.32\,g\,cm^{-3}$) the value falls to *ca.* 7 g. These effects can be interpreted to a first approximation as follows: The amount transported at atmospheric pressure corresponds roughly to that expected from the partial pressure of the paraffin oil. As the pressure rises, the solubility of ethylene in the oil increases and is accompanied, at most, by an insignificant increase in the partial pressure as a result of changes in the intermolecular forces. At and just above the critical pressure, the density of the gas increases dramatically as a result of the increased compressibility (as mentioned in the introduction, the pressure in this case says little about the degree of packing, *i.e.* the density). The high density gas is now able to take up large quantities of oil and a loaded supercritical gas phase is formed. Raising the temperature from 23 °C to 70 °C at constant pressure (200 atm) leads to a decrease both in density and in the ability of the gas to transport oil. If, however, the temperature is increased while keeping the density constant (by increasing the pressure) then the ability of the gas to take up oil also increases. The large increase in the density above the critical pressure is also accompanied by a dramatic increase in the solubility of the gas in the liquid phase. This facilitates transfer of the oil into the supercritical gas phase.

3. Fractionation

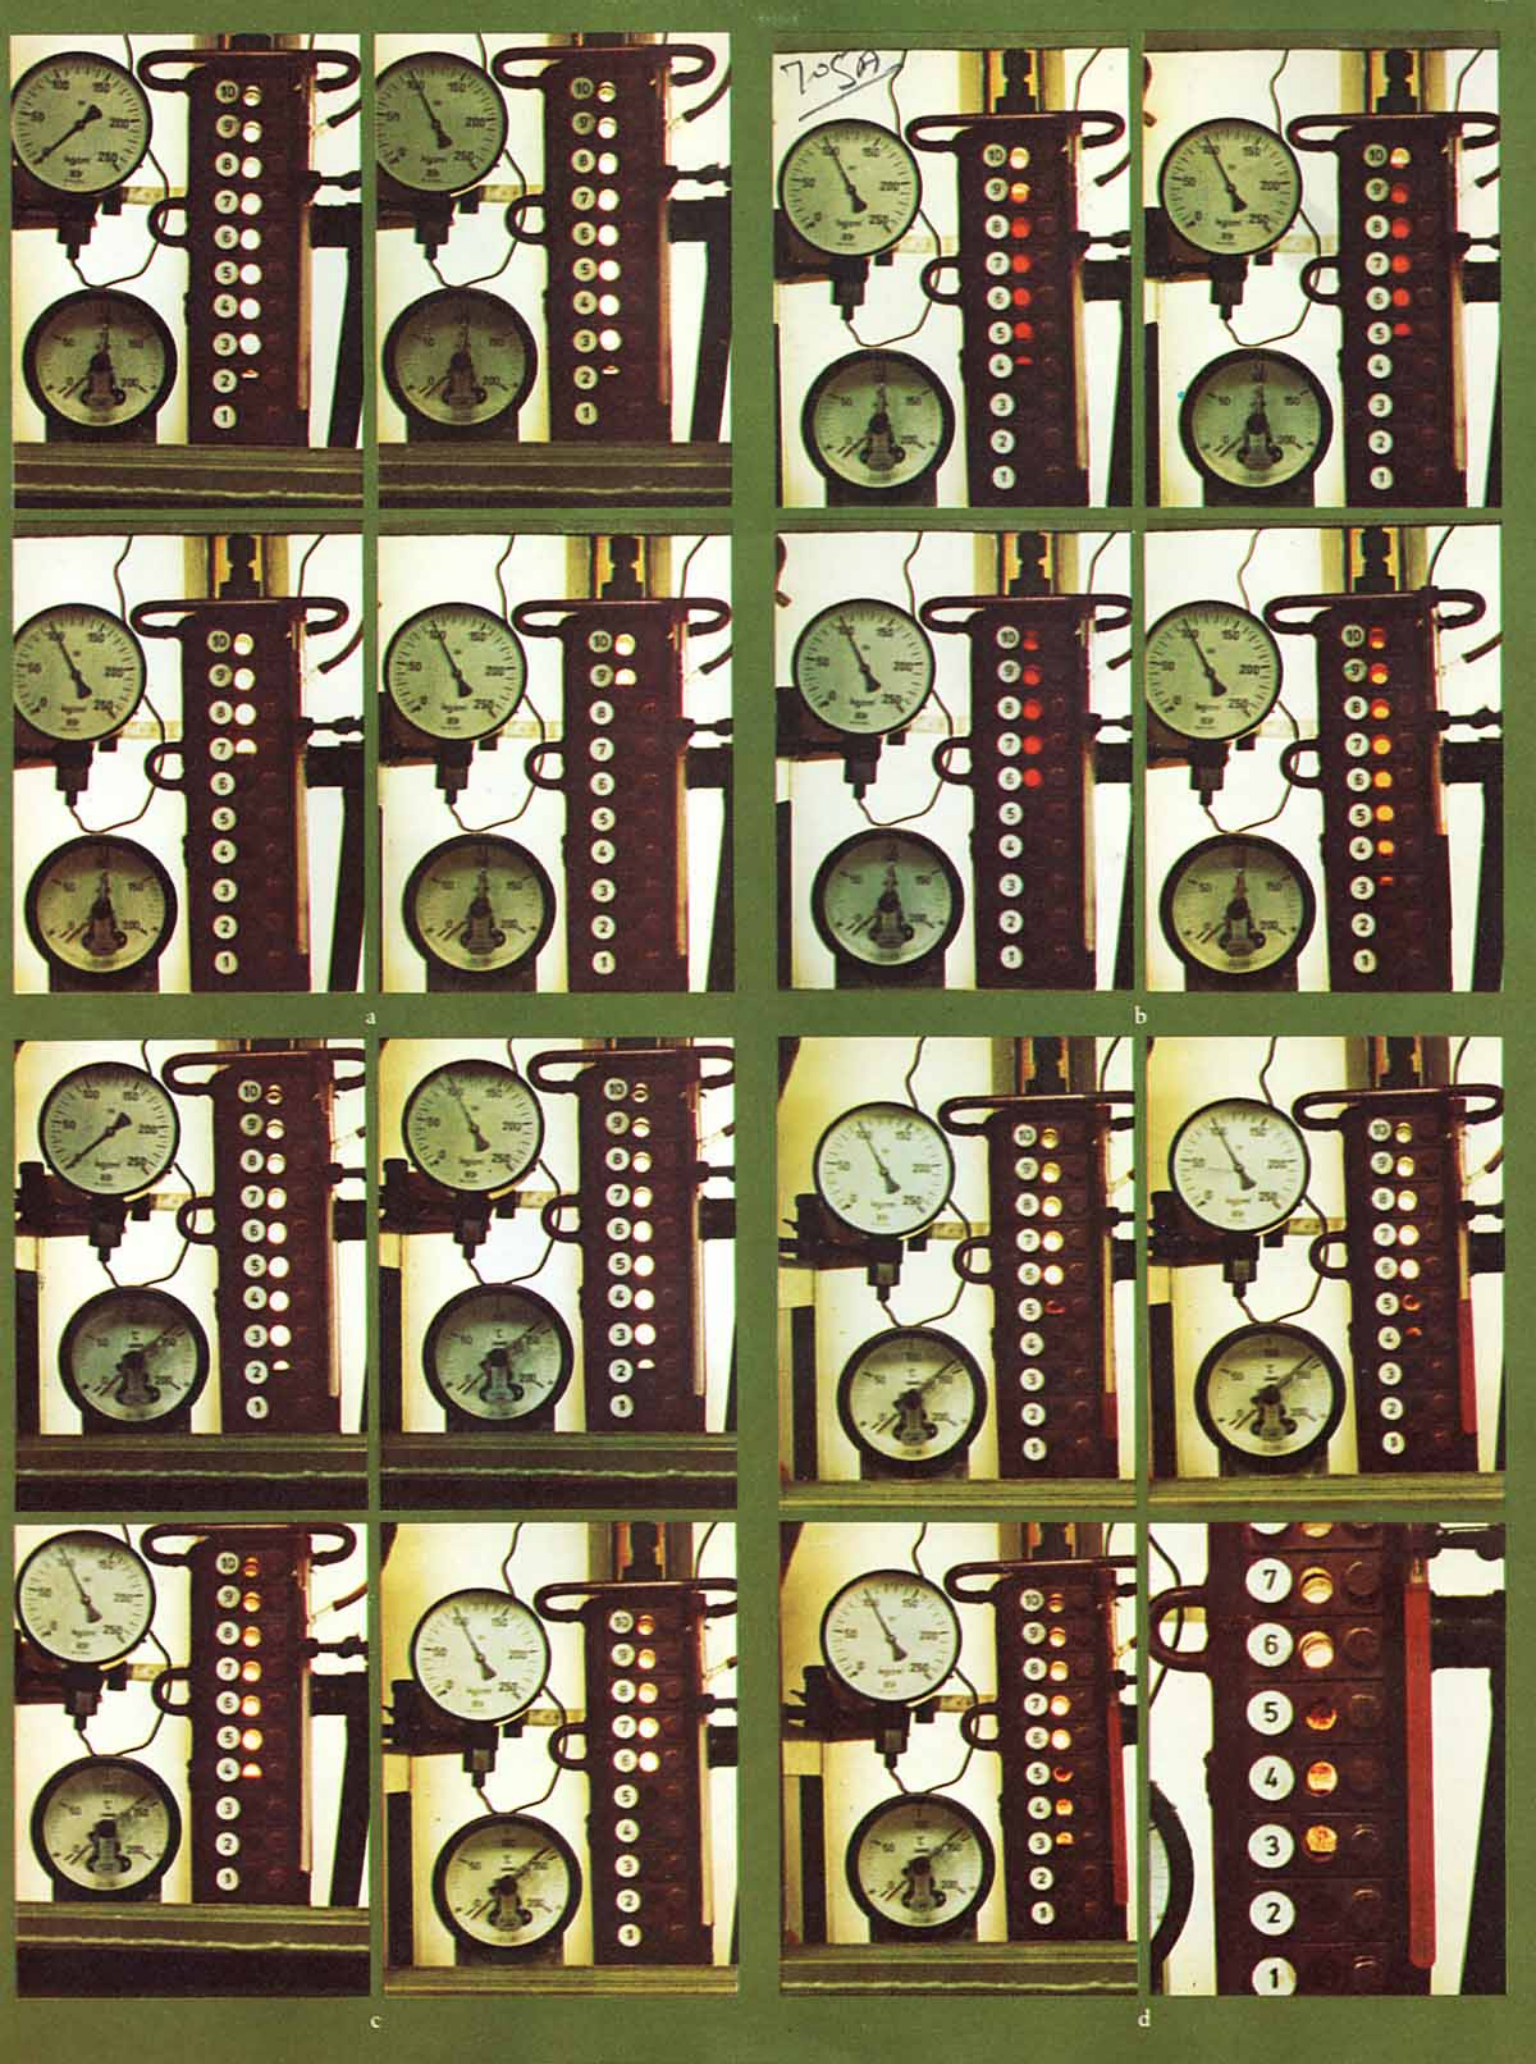
The observation that an increase in temperature at constant pressure is accompanied by a decrease in density and hence in the ability to transport material, forms the basis of an important application: mixtures of high boiling material, which are not amenable to fractional distillation, can be separated. This principle is illustrated in the series of pictures shown in Figure 3.

Fig. 3. Photographs of part of the autoclave shown schematically in Fig. 1 (modified; windows 1—10 (not numbered), manometer M, thermometer N, variable temperature finger) during treatment of a mixture of α-olefins (C_{14}—C_{20}) with supercritical ethylene. a)—f) see text (see color plate, p. 708).

The autoclave shown in Figures 1 and 2 has been fitted with a variable temperature finger and is charged at 25 °C (16 °C above T_c for ethylene) with 100 ml of a mixture of high boiling α-olefins (C_{14}—C_{20}) (Fig. 3a, the meniscus can be seen in the third window). On pressurizing with ethylene, the gas dissolves in the liquid and the level of the meniscus rises. At the critical pressure (*ca.* 50 atm, $\rho \approx 0.22\,g\,cm^{-3}$) a fog forms above the meniscus which is now in the 4th window (Fig. 3b)[*].

The fog disappears on raising the pressure and at *ca.* 70 atm ($\rho \approx 0.24\,g\,cm^{-3}$), the volume of the liquid has increased threefold (Fig. 3c, meniscus in window 6).

Product is now removed from the supercritical phase at constant pressure and depressurized. The olefin mixture is collected and the level of the meniscus falls (Fig. 3d).



Formation of a fog is also observed if the pressure is suddenly decreased by a few atmospheres (Fig. 3e, window 6—9). The liquid droplets that are formed fall back into the liquid phase.

Condensation of the olefin mixture present in the supercritical phase can also be brought about at constant pressure by increasing the temperature of the finger to 35 °C, *i.e.* 10° above the temperature of the rest of the system. Droplets form on the tip of the finger and then fall through the supercritical phase back into the liquid phase (Fig. 3f). The result is vigorous refluxing.

This phenomenon has been exploited to effect a fractionation. The apparatus (Fig. 4), which consists of a still (25 l), a column and a heated finger, was charged with a mixture of α-olefins (traces C_{14}, 21 C_{16}, 21 C_{18}, and 71 C_{20}), and fractionated with ethane ($T_c = 32$ °C, $P_c = 48$ atm) at 45 °C and an initial pressure of 60 atm ($\rho \approx 0.2\,g\,cm^{-3}$) with a finger temperature of 85 °C ($\rho \approx 0.08\,g\,cm^{-3}$). The supercritical ethane-olefin phase passes through the column, which is filled with copper rings, and reaches the hot finger where refluxing

[*] The same effect is observed in lecture demonstrations for the transition of CO_2 from the liquid to the supercritical condition by warming a thick-walled, sealed glass tube filled with CO_2.

Figure caption to the color plate on facing page (Fig. 2). is on p. 703.

occurs. The supercritical gas is bled off and partially depressurized to 30 atm ($\rho \approx 0.03$—$0.04\,g\,cm^{-3}$). The product separates out and is collected (60 ml/h). The gas is then repressurized. The pressure is slowly increased during the destraction from 60 atm to 110 atm ($\rho \approx 0.35\,g\,cm^{-3}$). (Increasing the pressure in a destraction is analogous to raising the temperature during a distillation.) A GC-analysis of the various fractions shows that a successful separation has been accomplished; *e.g.* a fraction containing *ca.* 25% of the C_{16}-olefin has a purity of 95.5%.

Since the components and the gas are aliphatic hydrocarbons this separation is based primarily on the differences in vapor pressure of the components and thus resembles a distillation *i.e.* the components are taken up into the gas phase in the order of their increasing boiling points. This effect can be overlapped by a separation according to the class of compound in those cases in which certain components in the mixture have, for example, little affinity for the supercritical gas while others are taken up preferentially. Distillation and extraction then combine together as destraction.

According to our experience effective destraction can be obtained in a temperature range of 10 to 100°C above the critical temperature of the gas being used and in a pressure range of 50—300 atm. Gases which are particularly effective are those whose critical temperatures are neither extremely high nor extremely low. We have obtained satisfactory results with the following gases: ethane (T_c 32°C, P_c 48 atm), ethylene (T_c 9°C, P_c 50 atm), propane (T_c 97°C, P_c 42 atm), propene (T_c 92°C, P_c 46 atm), CO_2 (T_c 31°C, P_c 73 atm) and NH_3 (T_c 132°C, P_c 111 atm). NO and N_2O can also be used but care must be taken since explosions can occur, particularly in the latter case. Destraction will be the method of choice in cases where separation can otherwise only be carried out by vacuum distillation or particularly where even this is ineffective due to decomposition of the material at the distillation temperature. The process should be of particular interest to the oil industry and to the food industry.

4. Practical Applications

The destraction of top-residues which we have mentioned in the introduction to illustrate the principles involved, has been run as a continuous process in a pilot plant. The flow sheet is shown in Figure 5.

The starting material is stored in a 750 l reservoir at 95°C from where it is pumped through a measuring vessel into a T-piece and mixed with propane at 130 atm. The propane is preheated in a horizontal heat exchanger. The mixture enters a tilted destractor which is kept at 140°C where it separates into a supercritical gas phase and destracted top residue. The former is removed at the top of the packed bed while the latter is collected in a separator and, after decompression in a degasser, is removed as asphalt. The loaded supercritical gas phase is partially depressurized to 125 atm, whereby a small quantity of destract separates out and is recirculated. The main destract is isolated by reducing the pressure to 30 atm followed by degassing at 0.3 atm. The gas liberated at various stages is recompressed, passed through the heat exchanger and recirculated. It is obvious that all the tubing must be heated and well insulated. 75% of the starting material is isolated as destract—the remainder is asphalt and contains most of the vanadium. Additional vanadium separates out during the pressure drop from 130 atm to 125 atm.

A liquid-liquid extraction using propane at 70°C was carried out for comparison and in order to demonstrate the particular advantages of destraction. In this case also, 75% of the starting material could be separated. The products, however, differ significantly in important analytical data: the destract has a much lower vanadium content (0.15 ppm compared to 2.4 ppm in the extract) and a more favorable Conradson number (1.3 compared to 2.0). The Conradson number is a measure of the amount of involatile material present. The low vanadium value is particularly significant should the product be used as fuel to drive a gas-turbine, since vanadium as V_2O_5 is highly corrosive.

Even more impressive is the fractionation of cod-liver oil. The separation was carried out in an apparatus similar to that used to separate the C_{16}–C_{20} α-olefins (Fig. 4). 20 kg of starting material were separated into 50 fractions using supercritical ethane at 100—160 atm with a still temperature of 27°C, a column temperature of 50°C and a finger temperature of 90°C. The fractions were characterized by their saponification values and iodine numbers. (The first is associated with the molecular weight and the second with the degree of unsaturation of the fraction.) The correlation between these values for the various fractions is shown in Figure 6.

The curve is made up of 50 points corresponding to the fractions and is related to a distillation curve. It is almost unnecessary to mention that fractionation of components having such high molecular weights as the triglycerides is impossible using conventional distillation techniques.

This last example shows that destraction can be carried out at relatively low temperatures which predestinates the method for the separation of thermally labile substances. It is for this reason that destraction has received considerable attention in the last few years from the food industries, for it is possible, for example, to remove fats and oils from vegetable

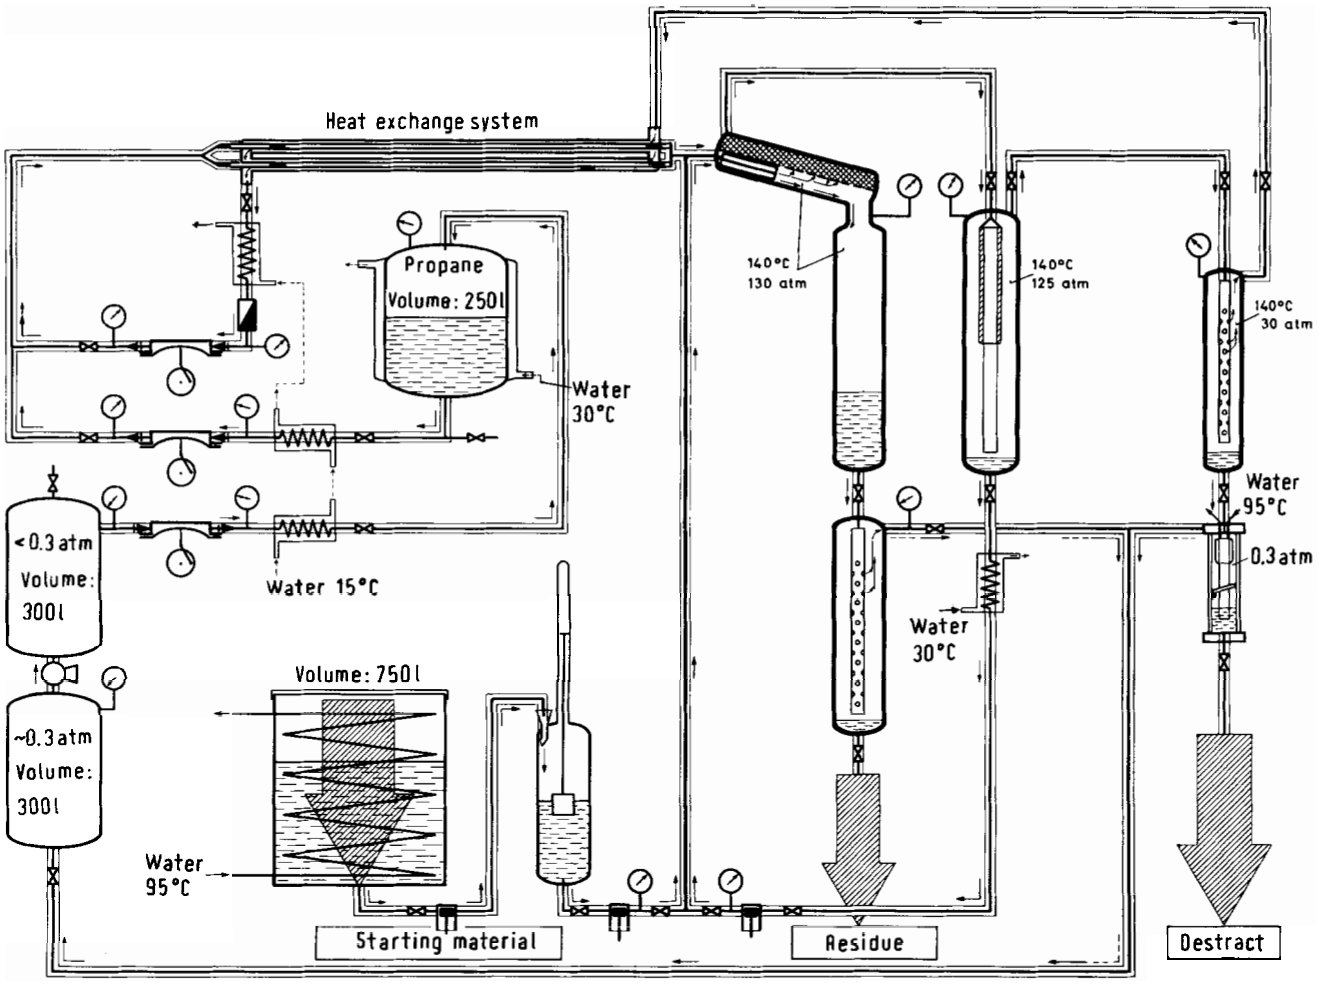

Fig. 5. Flow sheet of a pilot plant for continuous destraction of petroleum top-residues with propane.

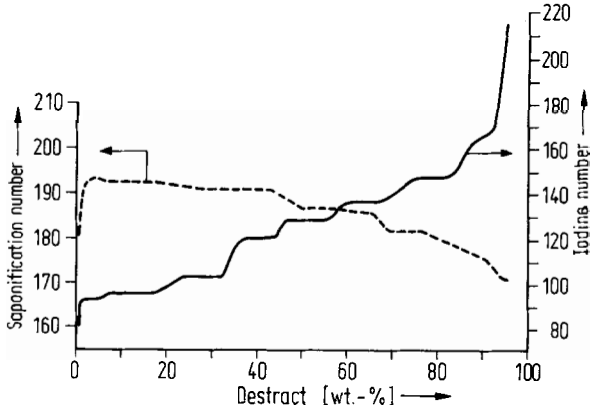
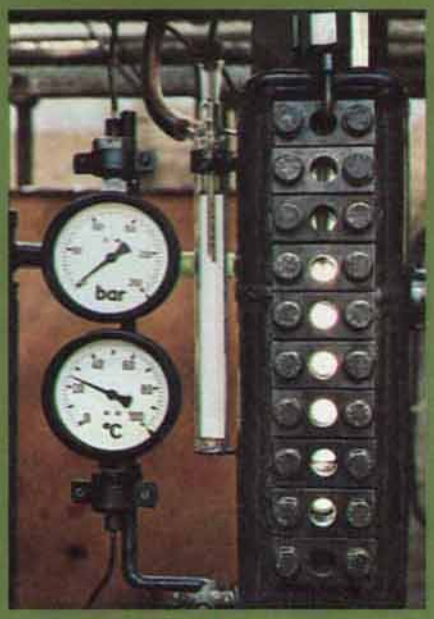
and animal matter under mild conditions without the necessity of a final step in which solvent is removed. A variation of the procedure is to extract the desired product under subcritical conditions, *i. e.* using a liquid gas, and then separate the extract into its components under supercritical conditions. It has proved possible to remove cocoa butter from cocoa beans, soybean oil from soybeans as well as the essential oils from spices. In addition alkaloids can be removed from plants, *e.g.* nicotine from tocacco.





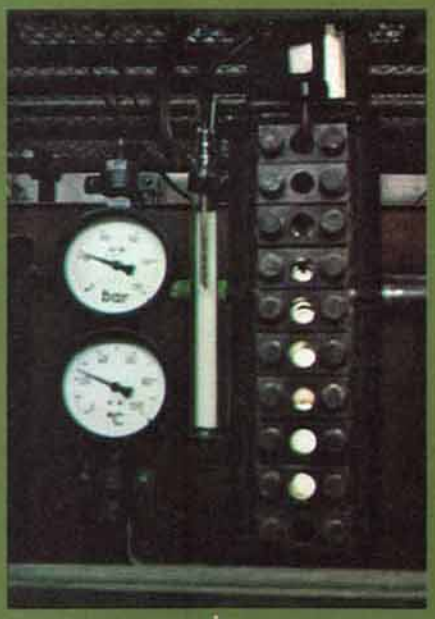


Fig. 6. Fractional destraction of cod-liver oil using the apparatus shown in Figure 4.

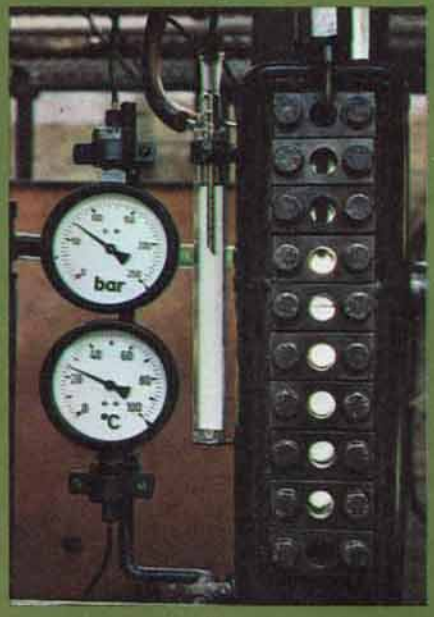
In conclusion, the decaffeination of coffee should be described since this is a process which is due shortly to go into commercial operation. In this process green coffee beans having a certain water content are treated with supercritical carbon dioxide. It seems obvious that CO_2 is physiologically unproblematic; nevertheless, we have carried out an experiment with radioactive CO_2 in order to show that during the destraction no substances are formed which remain in the coffee bean. No radioactivity could be detected in the destracted coffee. CO_2 can be regarded as the optimal solution for all problems which can arise in the conventional decaffeination with solvents. Of still greater interest seems to be the fact that the caffeine is selectively removed by the supercritical CO_2, *i. e.* no substances are lost which contribute to the aroma formed on roasting. Decaffeinated coffee and untreated coffee should then differ only in their pharmacological effect.



The decaffeination can be carried out in three ways (Fig. 7). In the first variation, presoaked green coffee beans are treated in a pressure vessel with CO_2 at 160—220 atm ($\rho \approx 0.4$—$0.65\,g\,cm^{-3}$), the CO_2 being continuously recycled (Fig. 7a). The caffeine diffuses out of the beans into the supercritical CO_2 and is then carried out of the pressure vessel into a washing tower where it is washed out with water at 70—90 °C. After 10 hours (at 90 °C) all of the caffeine is in the wash water which is then degassed and the caffeine recovered by distillation. The caffeine content in the bean is decreased

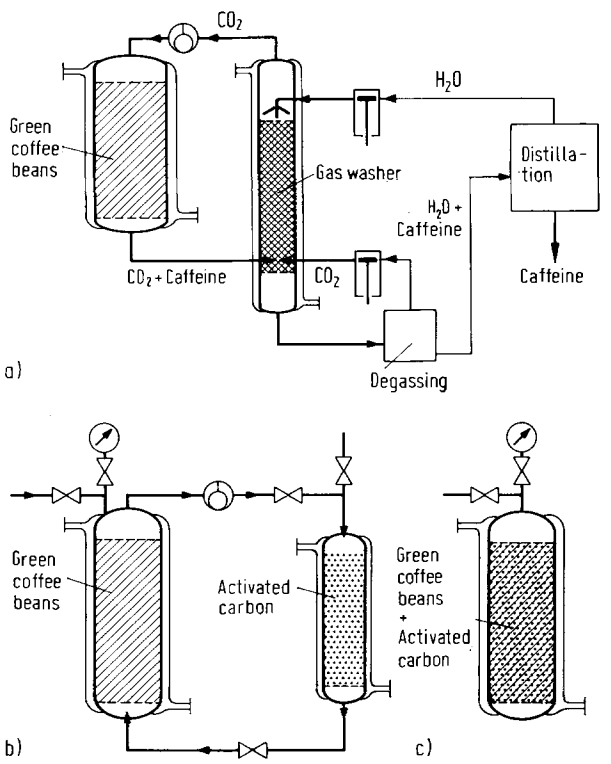

Fig. 7. Decaffeination of green coffee beans with supercritical CO_2. a) 70—90°C, 160—200 atm, $\rho \approx 0.4$—$0.65\,g\,cm^{-3}$. The caffeine is removed from the CO_2 by washing with water.
b) Same conditions as in a). The caffeine is removed from the CO_2 by adsorption on activated charcoal.
c) 90°C, 220 atm. The caffeine is removed from the CO_2, without recycling, by adsorption on activated charcoal admixed with the coffee beans.

from an initial value lying between 3 % and 0.7 % to a value as low as 0.02 %, *i.e.* lower than that stipulated (0.08 %). 3—5 l of wash water are needed to treat 1 kg of raw coffee.

The separation can be carried out with the help of active charcoal instead of water (Fig. 7b). However, in this case the caffeine must then be extracted from the charcoal.

A third variation (Fig. 7c) has certain advantages. The pressure vessel is charged with a mixture of coffee beans and active charcoal pellets whose diameter is such that they fill the space between the beans, *i.e.* the packing situation for the beans is practically identical to that in the absence of active charcoal. One kilogram of active charcoal is sufficient for 3 kg of coffee. A CO_2 pressure of 220 atm at 90°C is used. The caffeine in the supercritical CO_2 diffuses directly into the active charcoal without the need for recycling the gas. The required degree of decaffeination is reached after 5 hours. The mixture is then separated into its components by passing over a vibrating sieve.

The decaffeination of green coffee illustrates well the advantages associated with destraction and it can be anticipated that many other separation problems can be solved using this technique.

Figure caption to the color plate on facing page (Fig. 3) is on p. 704.

5. Summary

In conclusion let us summarize the most important characteristics of the destraction procedure:

1. Destraction is a pressure technique, necessarily requiring special investments.
2. High-boiling material can be separated with supercritical gases, whereby a loaded supercritical phase is formed. The method is particularly suitable for the isolation of thermally labile substances.
3. The ability of a supercritical gas phase to take up high-boiling material increases with increasing density or, at constant density, with increasing temperature.
4. The material taken up can be recovered by decreasing the density of the supercritical phase, either by reducing the pressure at constant temperature or by raising the temperature at constant pressure.
5. This effect can be used in fractionation.
6. In certain cases it is advantageous to carry out the extraction with liquid gas followed by a separation under supercritical conditions.
7. After separation of the destraction agent and destract, only recompression of the gas is needed. Solvent distillation as required in a conventional extraction is not necessary.
8. Substances belonging to the same chemical class are taken up into the supercritical phase in the order of their increasing boiling points (*e.g.* olefins in ethylene).
9. The separation according to boiling points can be overlapped by a separation according to the class of compound whereby the selective affinity to the supercritical gas is the controlling factor (*e.g.* caffeine in CO_2).

Fluid Extraction of Hops, Spices, and Tobacco with Supercritical Gases[**]

By Peter Hubert and Otto G. Vitzthum[*]

This report provides an introduction to the principal methods of extraction with supercritical gases, illustrated by the processing of some natural products with carbon dioxide. The combination of pressure and temperature as process parameters makes it possible to vary the solvent power of the medium within certain ranges as desired without having to change the composition of the solvent, as would be necessary in conventional solvent extraction. The problem-free handling of carbon dioxide and also of the products obtained open up possibilities whose development has only just started.

1. Introduction

Extraction with organic solvents is a well-established method of selective separation of specific constituents from food and semi-luxury products. Extractants with a low boiling point such as ethyl acetate, methanol, dichloromethane, *etc.* are suitable on the one hand for isolating valuable constituents from such products as hops, spices, and oil seeds, and on the other hand for removing or reducing the level of less desirable accompanying substances (nicotine, caffeine). The extracts, such as those obtained from hops and spices, have a number of advantages over the starting material:

- the constituents are better utilized
- the products have a longer shelf-life
- greater uniformity is achieved because of the possibilities of standardization
- the products are sterile.

The solvents used for this purpose must meet the requirements of foodstuffs legislation, which can vary from country to country. The main requirements are as follows:

- a high degree of purity
- chemical stability
- considerable inertness, *i.e.* the extraction agent or traces of impurities present in it must not react chemically with the food constituents
- a low boiling point to facilitate removal of the solvent residue from the treated product
- freedom from toxic effects.

In recent years national and international bodies (Fremdstoffkommission der Deutschen Forschungsgemeinschaft; Food and Drug Administration (FDA), USA; EC Codex Committee; FAO/WHO, Geneva) have increasingly emphasized the importance of complying with such criteria.

2. Extraction with Supercritical Systems

2.1. Applications and Properties of Compressed Gases

The fact that compressed gases can dissolve solids was first demonstrated experimentally by *Hannay* and *Hogarth*[1] in 1879, who dissolved potassium iodide in supercritical ethanol and reprecipitated the salt by reducing the pressure.

Over the years there has been much discussion of the part played by the dissolving effects of supercritical gases in natural processes, for example the influence of methane in the production of crude oil[2] or the influence of water on rock formation in geological processes[3]. Only recently, however, has industrial exploitation of this phenomenon been proposed, for example for removing asphaltenes from crude oil[4], for the extraction of coal[5,6], and for the separation of mixtures of substances[7–11]. A number of authors have described the use of supercritical gases as carriers in supercritical fluid chromatography (SFC)[12–15] and also recently in combination with thin-layer chromatography[16]. In the early seventies advances were made in the solvent extraction of foods as a result of the introduction of separation with supercritical carbon dioxide. This meant that for the first time natural products such as coffee, tobacco, tea, cocoa, hops, spices, and oil seeds could be extracted without the use of organic solvents[17–26]. We shall not deal here in detail with the physicochemical principles of the solvent effects obtained with supercritical gases; for further information the reader is referred to relevant publications[9,27–36].

2.2. Methods of Processing Natural Products with Supercritical Carbon Dioxide

To assess the dissolving power of a supercritical gas it is necessary to determine the phase equilibria with the substances to be dissolved. However, on its own this does not provide sufficient information for estimating the extractability from vegetable material, since apart from the solubility the way in which the substance to be extracted is bound to the vegetable matrix has a considerable influence. For example, the strength of the binding of nicotine in raw tobacco varies: whereas some of it can be removed very easily by extraction, the rest is probably present as a complex salt with tobacco constituents such as chlorogenic acid, citric acid, *etc.* and is more difficult to extract.

For natural products that can be subjected to only moderate heating it is possible to use gases with appropriate critical temperatures, such as CO_2, as the extraction agents. This is generally the case when supercritical extraction can be carried out at about 10—80°C above T_c; 100°C above T_c should not be much exceeded. A selection of suitable gases has been given by *Stahl et al.*[16].

[*] Dr. O. G. Vitzthum, P. Hubert
HAG AG
Hagstrasse, D-2800 Bremen

[**] Based on a paper presented at the symposium "Extraction with Supercritical Gases", held at Essen on June 5, 1978.

Russian authors in particular have used liquid carbon dioxide to obtain extracts of natural products. The processing of tobacco has been described[37], as has the production of extracts from hops[38,39] and spices[40].

Extraction with supercritical in contrast to liquid CO_2 generally offers the following advantages: the substances to be extracted are much more soluble, and there is a wider range of possible operating temperatures. Density and dielectric constants can be changed by varying the pressure. Figure 1 shows how these two properties vary as a function of the pressure of carbon dioxide at 50 °C. It can be seen that the greatest changes take place between about 70 and 150 bar, and that both parameters increase only slightly above about 300 bar.

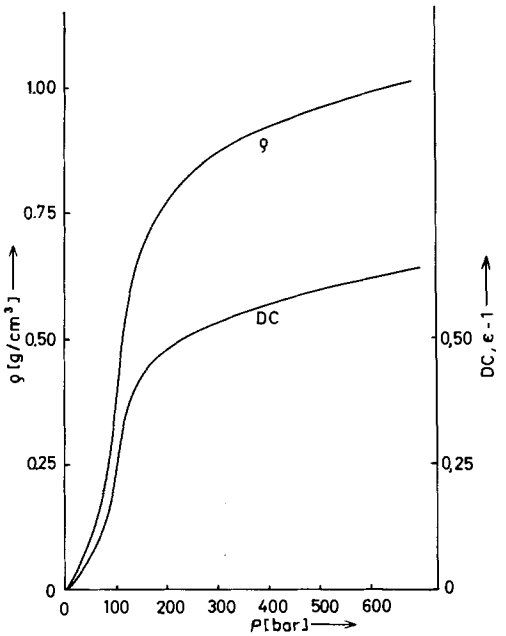

Fig. 1. Density and dielectric constant of CO_2 as a function of pressure (50 °C).

As the density increases, *i.e.* with increasing pressure, the solubility of less volatile components in the gas generally increases. According to our own measurements, the extraction rate, which also depends on the temperature-dependent diffusion of the constituents within the plant material, is at least 2.5 times as high with supercritical CO_2 as with liquid CO_2. The influence of the temperature can vary, depending on the pressure range. For example, Figure 2 shows that increasing the temperature at higher pressures results in an increased solubility of naphthalene in compressed ethylene, while at lower pressures such an increase in temperature reduces the solubility. Hence specific dissolution or separation effects can be achieved by selecting suitable combinations of pressure and temperature.

The method and apparatus used must be adapted to the raw material and to the purpose of the process. In one case the aim may be to obtain an extract and the remaining vegetable matrix or carrier substance may be either of no value (spices) or subjected to a further treatment with water (hops), while in another case it is the carrier substance that is wanted (tobacco) while the extracts are of secondary interest. The principle of extraction with supercritical gases is shown schematically in Figures 3 and 4 in the case of extract recovery and in Figure 5 in the case of recovery of the carrier substance.

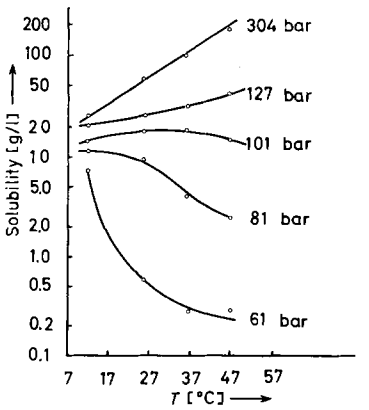

Fig. 2. Solubility of naphthalene in compressed ethylene as a function of temperature.

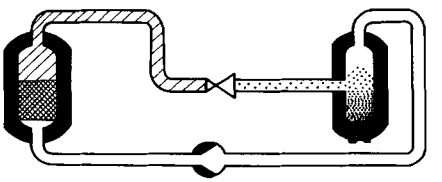

Fig. 3. High-pressure extraction with extract separation by variation of the pressure. Left, extraction stage; right, separation stage.

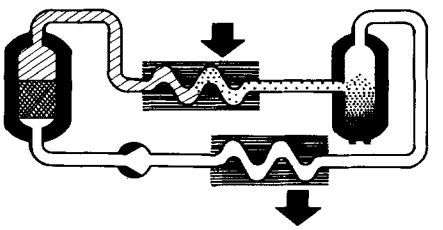

Fig. 4. High-pressure extraction with extract separation by variation of the temperature. Left, extraction stage; right, separation stage.

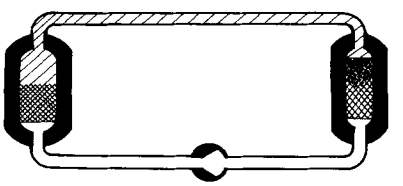

Fig. 5. High-pressure extraction with extract separation by adsorption. Left, extraction stage; right, adsorption.

In the extraction step the soluble constituents are solved by the compressed supercritical gas. The homogeneous phase, regarded as a solution, is decompressed as it passes through the throttle valve into the separation vessel (Fig. 3), with the result that the density of the gas decreases and the extract/solvent mixture separates into its component parts. The gas is then compressed again and returned to the extraction step. Separation can also be achieved by changing the temperature of the supercritical solution (Fig. 4). Figure 5 shows a process in which the dissolved extract is adsorbed onto suitable sorbents. This process, which can be run isobarically and isothermally in the whole circulation, is generally used when it is the carrier substance that is required (tobacco, tea, coffee).

2.3. Process Parameters in Extraction and Separation

Extraction pressures in the range of 80—300 bar are generally necessary to achieve adequate densities. This pressure range has so far been investigated most frequently. The occurrence of further dissolution phenomena at higher pressures cannot be excluded, but their use would probably be rejected for economic reasons. The preferred temperature range for extractions with CO_2 is about 35—80 °C.

There are several possible combinations of extraction and separation conditions that can be used to obtain hop and spice extracts[22, 23]. If we denote the extraction pressure by P_1 and the separation pressure by P_2, with corresponding temperatures T_1 and T_2, the different cases listed in Table 1 can be distinguished.

Table 1. Extraction with supercritical gases. Adjustment of the parameters for extraction (subscript 1) and separation (subscript 2).

Case 1:	$P_1 > P_c > P_2$ $T_1 > T_c > T_2$
Case 2:	$P_1 > P_c > P_2$ $T_1 \geqq T_2 > T_c$
Case 3:	$P_1 > P_2 > P_c$ $T_1 \geqq T_2 > T_c$
Case 4:	$P_1 = P_2 > P_c$ $T_1 \leqq T_2 > T_c$

In case 1 the supercritical gas phase is decompressed to a subcritical pressure and a subcritical temperature. Given these thermodynamic conditions, depending on P_1 and T_1 between 10 and 100% of liquid CO_2 will be found in the separation vessel together with the previously dissolved extract. Providing this extract is not also partly soluble in liquid CO_2, it will be deposited as a further phase. The CO_2 vapor in equilibrium with its liquid phase, and whose density is approximately 0.2 kg/l, has virtually no dissolving properties; to maintain the extraction circulation, it is drawn up by the feed pump, compressed again, and tempered. The method used in the case 1 means therefore that the liquid CO_2 in the separation vessel must be continuously evaporated, necessitating the supply of heat.

Since it is generally unnecessary to reduce the separation pressure and temperature to below their critical values in order to achieve separation (it is sufficient to adjust the density to a suitably low value), for practical purposes cases 2 and 3 are more realistic. Here P_2 is reduced either to below the critical pressure (case 2) or to a value between the extraction pressure and the critical pressure (case 3), while in both cases the separation temperatures are between the extraction temperature and the critical temperature. This also means that drier extracts are obtained. In general, if suitable pressure/temperature combinations are selected it is possible to achieve fractionation effects during the separation, using a multistage pressure cascade for example. Thus, it would appear to be possible in the case of pepper, for example, to obtain fractions enriched with essential oils or the hot flavor components. This also applies to hop extracts. However, it is also possible to achieve similar fractionation effects during the actual extraction with the aid of pressure/temperature programs. In case 4 the separation temperature depends on the pressure. Figure 2 illustrates the different effects of temperature on the solubility of naphthalene in ethylene. According to this, the temperature must be reduced when the pressure is high and raised when the pressure is low. Although case 4 would be of value because of the isobaric method of operation, it remains to be shown whether it is suitable for practical application, since the separation may not be as complete in this case as it is in cases 1—3 and the maximum thermal load that the extracts can withstand limits the rise of the temperature.

3. Properties of Carbon Dioxide as an Extraction Agent and Its Assessment from the Point of View of Food Regulations

The advantages of carbon dioxide, which is unobjectionable from the health point of view, over organic solvents make it appear an ideal extraction agent. It is ubiquitous in nature, *e.g.* in the air and mineral waters. It is what the plants breathe, and is produced when organic substances ferment. It is formed in many manufacturing processes in the food industry, *e.g.* in the production of beer and wine, in the baking of bread, *etc.*, and remains in these food products. Moreover, it is also used in artificially carbonating mineral waters. Being an "inert" gas, even in the supercritical state, CO_2 does not react in any way with the food constituents[41]. This is also the reason for its universal use for quick-freezing foods in the liquid and solid state. Even under the previous Federal German food legislation, CO_2 was not regarded as a foreign substance, and this classification has been retained in more recent legislation. Hence, together with air, nitrogen, and distilled or demineralized water, CO_2 is expressly excluded from the prohibition of additives. Table 2 suggests purity specifications for CO_2 used for extraction purposes.

Table 2. Specification for carbon dioxide for extraction purposes. Determination methods cf. [a—d].

Odor	neither burnt nor pungent	
Color	colorless	
CO_2 content	minimum 99.9 vol-%, measured in the liquid or gas phase	[a, b]
PH_3, H_2S and reducing organic substances	not detectable in 100 l (STP) of the gas	[a—c]
Foreign acids, *e.g.* SO_2, HCl	not detectable in 100 l (STP) of the gas	[a—c]
Carbon monoxide	<2 vol.-ppm	[c, d]
Oxidizable constituents	max. 1 vol.-ppm	[a]
Evaporation residue	max. 1 vol.-ppm	[a]

[d] Analysenmethoden HAG AG, Bremen. Vorschrift No. 081/2/01 (1976).

In addition to its solvent properties, CO_2 has the advantages of being neither flammable nor toxic, not maintaining combustion, and also not exerting a corrosive effect in combination with moisture on the materials used in processing natural products (stainless steel or plastics). It is also inexpensive and readily available in large quantities and high purity.

For all these reasons natural products have so far been processed predominantly with CO_2.

4. Production of Extracts with Supercritical Carbon Dioxide

4.1. Hop Processing

Hops have been used to make beer for some two thousand years. The use of hop extracts by the brewing industry is a more recent development, and is increasing in the interests of rationalization.

The valuable constituents of the hop resins are the soft resins which contain an α-acid fraction (mixture of several humulones) and a β-acid fraction (mixture of several lupulones). It is specifically the α-acids which, after isomerization in the brewing process, give beer its characteristic bitter taste. The structures of humulone and lupulone are shown in Figure 6.

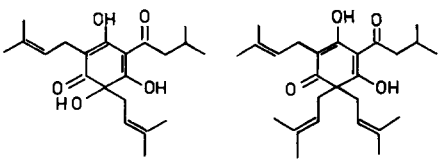

Fig. 6. Soft resin components of hops. Left, humulone; right, lupulone.

Conventional hop extraction generally employs dichloromethane, which has to be evaporated off after the resins have been extracted. The resulting extract is a pasty, dark-green to black-green mass, which is not permitted to contain more than 2.2 % solvent residue (CH_2Cl_2)[42].

To produce hop extract with supercritical CO_2 commercial hop pellets with a bulk density of approximately 0.65 kg/l were extracted under the conditions of case 3 (Table 1) without any further preparation. An olive-green, pasty extract with an intensive aroma of hops was obtained. The pellets had disintegrated into a powder, which was easily shaken out of the extraction vessel. Table 3 gives various analytical results.

Table 3. Hop analysis, CO_2 extraction.

	Pellets before CO_2 extraction	Pellets after CO_2 extraction	CO_2 extract	Degree of extraction	Extract, commercial
Water content [%]	6.0	5.4	7.0		8.0
Total resins [%]	30.3	4.3	90.0	89.9	88.5
Soft resins [%]	26.6	1.3	84.8	96.5	82.0
α-Acids [%]	12.6	0.2	41.2	98.9	39.5
β-Acids [%]	14.0	1.1	43.6	94.4	42.5
Hard resins [%]	3.7	3.0	5.2		6.5

It can be seen that the extent of extraction of the α-acids, almost 99 %, is above the required minimum of 95 %. The analyzed extract was obtained by single-stage pressure reduction (cf. Fig. 3). Extract separation by releasing the pressure in several stages is currently being investigated, this giving a choice of green or yellow extracts of different compositions.

4.2. Processing of Spices

The important constituents of spices are their aroma and flavor components. For industrial use, spices as such have a number of disadvantages, which, together with the trend toward rationalization in the food industry, have led to spice extracts or oleoresins being used. The advantages of these were mentioned in the introduction. The best extract or best oleoresin is a preparation that has aroma, flavor, hotness, *i. e.* all the organoleptic factors of the spice, and after dilution reconstitutes fully the organoleptic characteristics of the starting material[43]. The applications extend throughout the food industry. As there are so many spices, and the list of spice constituents[44] is steadily growing as a result of the refinement of analytical techniques, we shall not deal in detail with this subject. We shall consider only black pepper, nutmeg, and chilies, which can also be extracted with supercritical CO_2. Figure 7 shows the main constituent (98 %[43]) of the hot

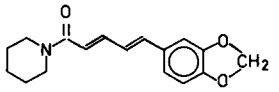

Fig. 7. Piperine, the main component of the hot principle of pepper.

principle of pepper, *i. e.* piperine. Other components are piperettine, piperoline A and B, and piperanine, which have similar structures.

The most important constituent of capsicum spices is a mixture of several amides, the capsaicine alkaloids, whose main components are capsaicine and dihydrocapsaicine[45] (Fig. 8).

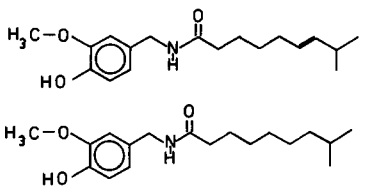

Fig. 8. Main components of the hot principle of capsicum. Top, capsaicine; bottom, dihydrocapsaicine.

The results of spice extraction with supercritical CO_2 are described for pepper, nutmeg, and chilies. A few analytical results are compared in Table 4 with values for the commercial extracts.

Table 4. Spice analysis, CO_2 extraction.

	Material before CO_2 extraction	Material after CO_2 extraction	CO_2 extracted	Degree of extraction	Extract, commercial (usually CH_2Cl_2)
	Pepper				
Piperine [%]	10.1	0.3	44.0	97.7	41.2
Essential oil [%]	3.5	<0.1	12.7	81.1	15.0
Water [%]	9.3	6.2	7.0		0.2
Color of extract			yellow		olive green
	Nutmeg				
Essential oil [%]	7.4	<0.1	19.0	99.0	20.0
Hexane-soluble matter [%]	46.0	1.7	100	98.0	100
Water [%]	4.9	4.4	1.6		0.1
Color of extract			whitish yellow		yellowish-brown
	Chilies				
Capsaicine [%]	0.86	0.03	4.9	97.0	4.7
Water [%]	3.2	1.8	1.3		0.1
Color of extract			red		red

Ground black pepper was extracted under the conditions of case 1 (Table 1). The extract obtained was yellow and pasty and had a very strong smell of pepper. The degree of extraction of piperine was almost 98 %, *i. e.* above the minimum required yield of 95 %, and the piperine content of the extract (44 %) was roughly the same as that of the commercial product (Table 4). The extraction of ground nutmegs under the conditions of case 3 yielded a pale yellow nutmeg butter with a pronounced nutmeg aroma. The degree of extraction was 98 %. The extraction of ground chilies under the conditions of case 1 gave a red oil, the degree of extraction, calculated for capsaicine, being 97 %.

5. Obtaining the Carrier Material: Processing of Tobacco with Supercritical Carbon Dioxide

The greater part of tobacco produced nowadays goes into cigarettes, and the trend toward mild tobacco has risen steadily over the last twenty years. The term "mild" is used here in particular to describe a material whose smoke contains relatively little nicotine and condensate when it is burnt. Tobaccos of this type with a good aroma and a low nicotine content are not available in unlimited quantities, and because of the concern about damage to health that may be caused by nicotine, attempts have already been made to remove this constituent from tobacco[46–51]. Since tobacco treated with organic solvents, for example, often acquires a rubbery structure, special processes have been suggested to avoid this effect, which is extremely disadvantageous to further processing.

In the meantime interest has also grown in other potentially harmful substances such as may appear in smoke condensates.

The primary aim of processing raw tobacco with supercritical CO_2 is to reduce the nicotine content to the desired levels with the minimum loss of aroma. This was found to have the side effect of a certain expansion of the tobacco. It is also possible to obtain a raw tobacco aroma equivalent to that obtained with the method described for extract separation, to transfer aroma from one tobacco to another, or even to impregnate a neutral matrix with the tobacco aroma.

5.1. Preparation of the Material for Extraction

In principle raw tobacco in any form can be used, including leaf ribs and tobacco dust. Apart from conditioning (moistening or drying), the tobacco requires no further preparation. The additives commonly used in tobacco preparation, such as moisture-retainers, sauces, flavors, binders, *etc.* are not added until the tobacco has been treated by the described method.

5.2. Single-Stage and Multistage Processing

The presence of water is essential in the extraction of nicotine. However, at the normal moisture content of tobacco (*ca.* 10—13 %), supercritical CO_2 extracts insufficient nicotine, or none at all, but removes the aroma instead. It should nevertheless be mentioned at this point that tobaccos of different origins behave very differently (Fig. 9), this also applying in all other stages of the process.

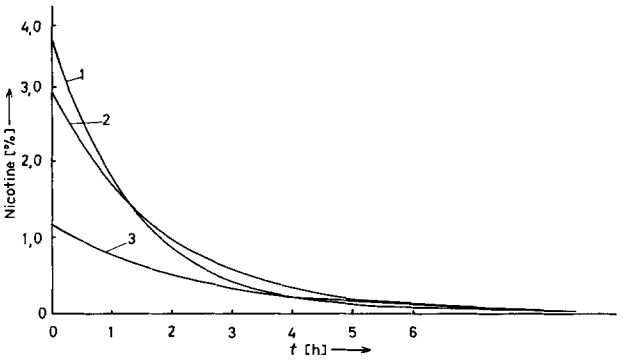

Fig. 9. Residual nicotine content as a function of processing time for three tobaccos of different origins: 1, Burley; 2, Virginia; 3, Orient.

In the single-stage process the moisture content of the tobacco is increased up to 25 %, in special cases even higher, and a stream of supercritical gas is passed through the material. The pressures are approximately 300 bar, and the temperatures are between the T_c of the gas and about 100 °C. The dissolved nicotine is separated by reducing the pressure or by changing the temperature (cf. Section 2.2) or is bound by adsorption onto suitable sorbents[18]. After drying the tobacco is immediately ready for further processing. A multistage process[19] may prove suitable for tobaccos for which the single-stage method has a detrimental effect on aroma. Figure 10 shows a block diagram of a three-stage process as a section of a continuous production process.

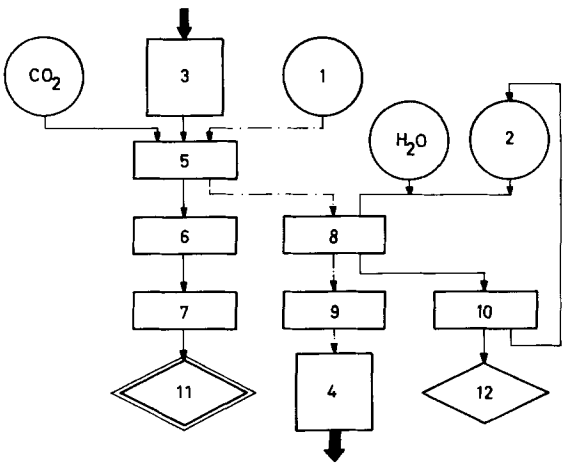

Fig. 10. Multistage extraction of nicotine from tobacco with supercritical CO_2. 1, Tobacco (starting material); 2, nicotine adsorbent; 3, nicotine-reduced tobacco from preceding cycle; 4, nicotine-reduced tobacco produced from 1 in the process shown for the next cycle; 5, transfer of aroma from 1 to 3; 6, aroma distribution; 7, conditioning; 8, removal of nicotine from the (dearomatized) batch produced from 1 with supercritical CO_2; 9, drying; 10, regeneration of the adsorbent; 11, nicotine-reduced, re-aromatized tobacco (finished product); 12, nicotine (by-product).

The arrow at the top indicates the intake of a previously denicotinized batch, the arrow at the bottom discharge of the nicotine-reduced batch produced in the section shown to the next cycle. In the first stage the aroma is removed from the fresh material. (As a rule, less nicotine will be extracted the drier the tobacco.) The aroma could be isolated as an extract in the same way as described for hop and spice extraction. In the present case, the aroma is used to impregnate a previously denicotinized batch, *i. e.* the aroma-carrying gas stream is allowed to expand in the nicotine-reduced batch.

The de-aromatized tobacco is moistened for the second stage and the nicotine is then removed in an isobaric and isothermal recycling operation. Selective sorbents are used for the nicotine. Regeneration of these sorbents affords nicotine as a by-product. The third stage of the process involves a homogeneous distribution of the transferred aroma in the bulk by repeated dissolution and reprecipitation. The rearomatized tobacco can then, after conditioning if necessary, be used directly for further processing.

5.3. Quality Characteristics of the Treated Tobacco

When the treated tobacco is discharged from the extraction vessel, a certain expansion of its fibers is observed as a result of the removal of gas residue from the vegetable tissue. This effect is dependent on the moisture content, the temperature, and several other parameters and can be controlled within certain limits. The external appearance of the product remains unchanged or may change only slightly to a lighter or darker color, this again depending on the origin and the treatment process. Table 5 shows the results of analysis of smoke from

Table 5. Results of smoke analysis performed on cigarettes made from untreated tobacco and tobacco treated by the three-stage process.

		Untreated tobacco	Treated tobacco
Length of cigarette	[mm]	84.0	84.0
Length of filter	[mm]	20.0	20.0
Length of total stub	[mm]	28.0	28.0
Diameter	[mm]	8.03	8.06
Effective sample weight	[mg]	1126	1070
Cigarette paper	[mg]	46	42
Filter and wrapping	[mg]	162	162
Quantity of burnt tobacco	[mg]	803	758
Air-flow resistance of cigarette	[torr]	8.5	8.6
Air-flow resistance of filter	[torr]	4.7	4.7

Physicochemical Principles of Extraction with Supercritical Gases[**]

By Gerhard M. Schneider[*]

The present review considers some physicochemical properties of fluid mixtures that are of importance for fluid extraction and supercritical fluid chromatography (SFC). Firstly, the important types of phase diagrams are treated, the occurrence of solid phases also being considered in some simple cases. Specific examples are given of mixtures of a highly volatile component I (*e.g.* CO_2, C_2H_6) with a relatively involatile component II (*e.g.* squalane) of very different molecular size, shape, structure, and/or polarity, and it is shown how the rather complicated types of phase diagrams can be calculated and correlated. The importance of fluid mixtures extends far beyond the fields of science and technology reviewed.

1. Introduction

As shown in other papers presented at the Symposium "Extraction with Supercritical Gases", fluid extraction and supercritical fluid chromatography (SFC) have already found interesting and important applications. This review considers some physicochemical properties of fluid mixtures pertaining to these new methods of separation; the main emphasis will be placed on phase equilibria and transport properties.

2. Phase Equilibria of Fluid Mixtures

Fluid mixtures may exhibit very different and complicated types of phase behavior. The historical development and present knowledge in this field have been described in several books[1-3] and review articles[4-7] giving extensive references to the relevant literature. This article is concerned mainly with recent publications, which also provide access to less recent work.

Our discussion of the phase-theoretical principles will start from the well-known phase diagram of carbon dioxide, which is still by far the most important solvent in fluid extraction. The situation encountered here and with the fluid mixtures discussed below is also typical for other supercritical extractants such as ethane, ethylene, N_2O, *etc.*

2.1. Phase Diagram of Pure Carbon Dioxide

Figure 1 shows the $p(T)$ phase diagram of pure carbon dioxide: s is a solid, l a liquid, and g a gaseous phase. Curves where two phases coexist are dotted. The vapor pressure curve lg starts at the triple point Tr [$T_{tr}=(216.58\pm0.01)$ K, $p_{tr}=(5.185\pm0.005)$ bar[8]] and ends at the critical point CP [$T_c=(304.20\pm0.05)$ K, $p_c=(73.858\pm0.05)$ bar, $\rho_c=(0.468\pm0.005)$ g·cm^{-3}[8]]. The melting pressure curve ls starts at the triple point and rises steeply with increasing temperatures and pressures [$(dT/dp)^{ls}_{tr}=46.55$ bar·K^{-1}[8]]; a temperature of 40°C on the melting pressure curve is reached at about 7 kbar. The sublimation pressure curve gs is of no significance for the present problems.

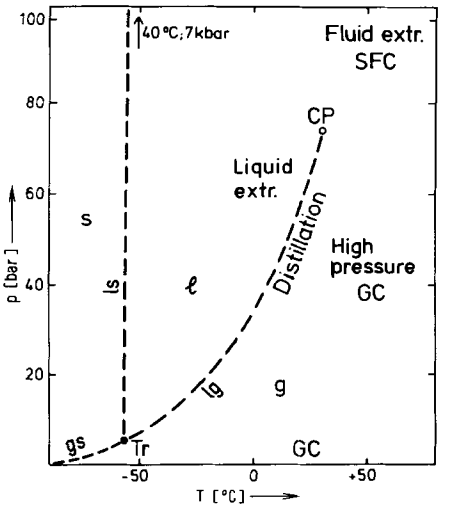

Fig. 1. $p(T)$ phase diagram of pure carbon dioxide [g = gas, l = liquid, s = solid; CP = critical point (here lg), Tr = triple point (here gls)].

In Figure 1 the approximate ranges are additionally marked where separation processes can be effected. Distillation will normally be possible near the vapor pressure curve lg. For liquid extraction the liquid range l must be reached. In gas chromatography (GC) carbon dioxide is used as a mobile phase in the gaseous region g at temperatures above ambient and at pressures up to some 10^1 bar. Fluid extraction and supercritical fluid chromatography, however, are limited to the supercritical region above T_c and p_c.

2.2. Phase Behavior of Fluid Binary Systems

In the following, the principal types of phase behavior will be discussed that may be encountered with mixtures of CO_2 or similar gases mainly with organic substances. Recent phase theoretical investigations have shown that the different types can be easily classified according to the shape of their critical curves[1,5-7]. The following discussion also follows this approach (see[9]).

Figure 2a shows the pTx surface for the liquid-gas phase equilibria of a binary system in the simplest case. The dotted lines are the vapor pressure curves of the pure components I and II respectively; here and in the following diagrams

[*] Prof. Dr. Gerhard M. Schneider

[**] Based on a paper read at the symposium "Extraction with Supercritical Gases" at Essen on June 6, 1978.—At the 6th AIRAPT International High Pressure Conference, July 25—29, 1977, at Boulder, Colorado (USA), there were three sessions on "Fluid Phase Equilibria and Separation Processes at High Pressure".

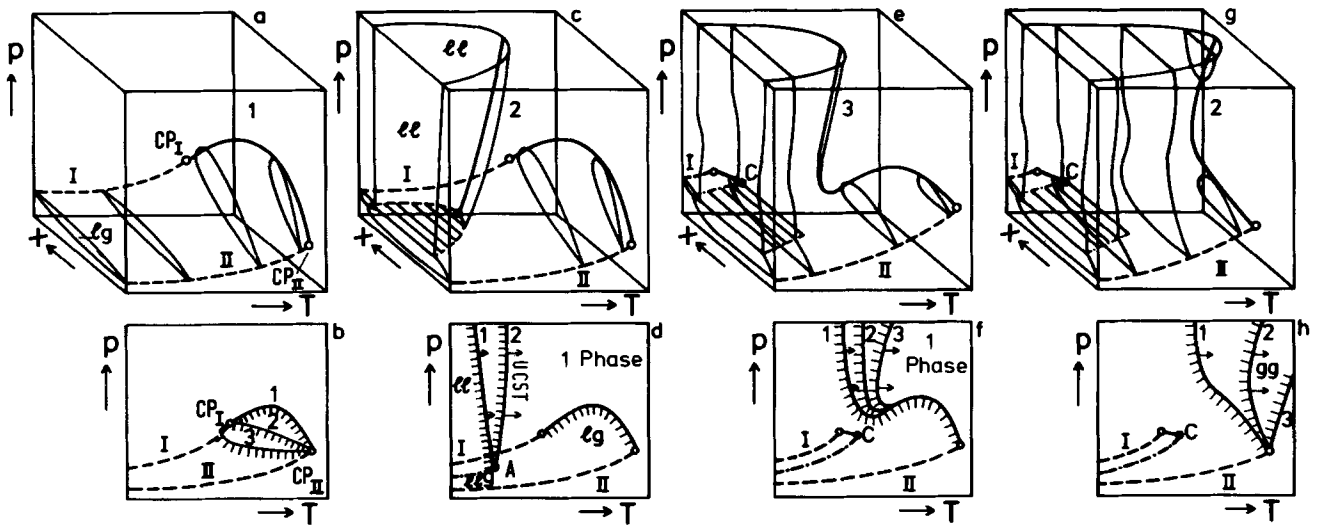

Fig. 2. Fluid phase equilibria in binary systems: pTx surfaces (a, c, e, g) and $p(T)$ projections ("$p(T)$ diagrams") (b, d, f, h) (schematic; for details and examples see text): ——— = vapor pressure curve of pure component; ——— = critical curve, ——— = $p(x)$ isotherm, –·–·– = three-phase line llg, UCST = upper critical solution temperature, A, C = critical endpoint). x = mole fraction = $n_I/(n_I + n_{II}) = 1 - n_{II}/(n_I + n_{II})$.

component I corresponds to carbon dioxide or a similar highly volatile substance, and component II is an organic compound. The vapor pressure curves end at the critical points CP_I and CP_{II} of the pure components I and II respectively. Some binary $p(x)$ isotherms are also schematically presented. For $T < T_c(CO_2)$ they have the well-known spindle-like shape. Homogeneous liquid states occur above, and homogeneous gaseous states below each $p(x)$ isotherm. Coexisting phases are connected by an horizontal line, called a connode. For $T > T_c(CO_2)$, the $p(x)$ isotherms no longer run to the side of pure component I but form characteristic loops. At the maximum of each isothermal $p(x)$ loop the connode degenerates to a point, the critical point CP of the $p(x)$ section at the given temperature; here the liquid and gaseous phases become identical. The curve that connects the critical points of all isotherms is the binary critical curve. The types and shapes of different sections through the pTx surface (*e.g.* of $T(x)$ isobars or of $p(T)$ curves for x = const (called isopleths)) are discussed in the literature (*e.g.* [10, 11]). Numerous examples are presented by *Hicks* and *Young* [12].

Type 1 in Figure 2b corresponds to the $p(T)$ projection of the schematic three-dimensional phase diagram in Figure 2a; such a projection is usually called a $p(T)$ diagram of the binary system considered. For type 2 the critical curve is monotonous between CP_I and CP_{II}, and type 3 exhibits a temperature minimum on the critical line. Here, as well as in the following figures, heterogeneous regions are marked by hatching. At conditions of temperature and pressure beyond the critical line the components are miscible in all proportions. For fluid extraction this means that, beyond this curve, substances can be dissolved completely in the supercritical solvent whereas for reprecipitation heterogeneous regions have to be entered.

In Figures 2c and 2d, separation into two liquid phases is also considered. For the types given the critical curve lg is not interrupted and runs through the usual pressure maximum. At temperatures far below the critical temperature of pure component I, liquid-liquid immiscibility is also found. The branch of the critical curve ll that starts at the critical endpoint A corresponds to upper critical solution temperatures (UCST) that may rise slightly with increasing pressure (type 2, for details see Figure 4) or decline (type 1).

The lower the mutual miscibility of components I and II the more the branch ll of the critical curve that has to be attributed to liquid-liquid equilibria will be shifted to higher temperatures. It can eventually penetrate the temperature and pressure range of the critical phenomena liquid-gas and merge continuously with the critical curve lg such as shown in Figure 2e and 2f. Here the branch of the critical curve at high pressures can exhibit different shapes: It may run to lower temperatures and higher pressures (type 1 in Figure 2f), or (within the limits of experimental error) vertically to higher pressures (type 2 in Figure 2f), or it can bend back again and assume a positive slope at high pressures (type 3 in Figure 2f); this type is represented three-dimensionally in Figure 2e (for details see Figure 5).

For further decreasing mutual miscibility of the components critical $p(T)$ curves without any pressure maximum or minimum as in Figures 2g and 2h will be obtained. Here the branch starting at CP_{II} can exhibit different shapes:

1) It may start from CP_{II} with a negative slope and become steeper and steeper with increasing pressure without reaching, however, any temperature minimum within the experimental range (type 1 in Figure 2h), or
2) it may run through a temperature minimum (type 2 in Figure 2h, three-dimensionally represented in Figure 2g; gas-gas equilibrium of the 2nd kind), or
3) it may start from CP_{II} with a positive slope and proceed directly to increasing temperatures and pressures (type 3 in Figure 2h; gas-gas equilibrium of the 1st kind).

Two important modifications of the phase behavior as shown in Figures 2c—h are discussed in Figure 3. In Figures 3a and 3b the branch of the critical curve that starts from the critical endpoint A on the three-phase line llg has to be attributed to upper critical solution temperatures (UCST) for liquid-liquid equilibria whereas that starting from B first corresponds to lower critical solution temperatures (LCST) and then merges continuously into the critical curve lg. With

increasing mutual miscibility (*e.g.* for smaller differences of components I and II in size, shape, and/or polarity) the branch starting at A is shifted to lower temperatures and may disappear completely below the crystallization surface, whereas on the branch starting from B the liquid-liquid critical phenomena will disappear until finally a phase diagram of the simple type 2a or 2b results. With *decreasing* mutual miscibility in comparison with Figures 3a and 3b types 3, 2′, 2, 1′, and 1 in Figure 3d will be successively obtained that resemble the corresponding types in Figures 2e through 2h.

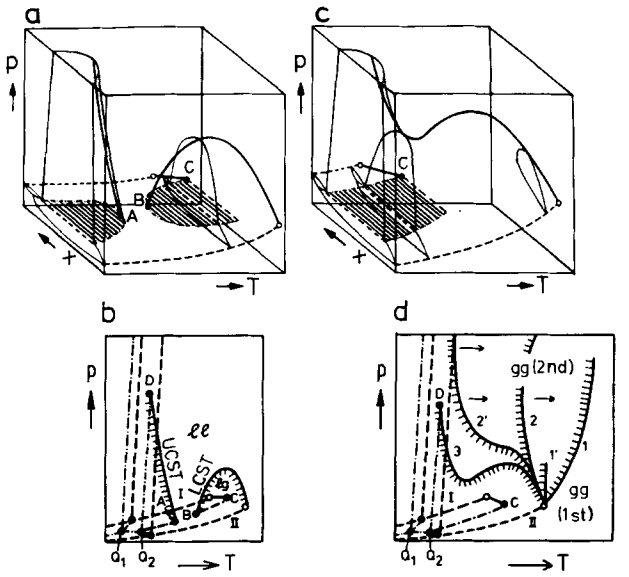

Fig. 3. Fluid phase equilibria in binary systems: Supplements to Figure 2 (schematic; for details and examples see text; for symbols see Figure 2; A, B, C, D = critical endpoint; Q = quadruple point; LCST = lower critical solution temperature).

Figures 2 and 3 show that for fluid binary mixtures of components differing more and more in size, shape, structure, and/or polarity a whole pattern of different types of phase behavior and critical curves has to be considered. They also demonstrate that there are continuous transitions between liquid-gas, liquid-liquid, and gas-gas equilibria. For a detailed discussion and many examples see [1, 3–7, 9, 10–12].

2.3. Detailed Treatment of Types of Diagram of Significance for Fluid Extraction

Figure 4a shows the schematic $p(T)$ diagram of a binary system according to Figure 2c on a larger scale (= type 2 in Fig. 2d). This type is found for mixtures of CO_2 with octane, decane, or dodecane[7, 13] as well as with 2-hexanol or 2-octanol[9] (see Figures 11 and 12). The branch of the critical curve lying between CP_I and CP_{II} corresponds to liquid-gas (lg) critical phenomena whereas the branch ll starting from A has to be attributed to upper critical solution temperatures for liquid-liquid equilibria as a function of pressure. Some characteristic $p(x)$ isotherms are schematically represented in Figures 4b—4d.

In the homogeneous region beyond the critical curves the substances I and II are completely miscible in all proportions, *e.g.* at point G in Figure 4a. Under these conditions low-volatile substances can be completely dissolved by the supercritical

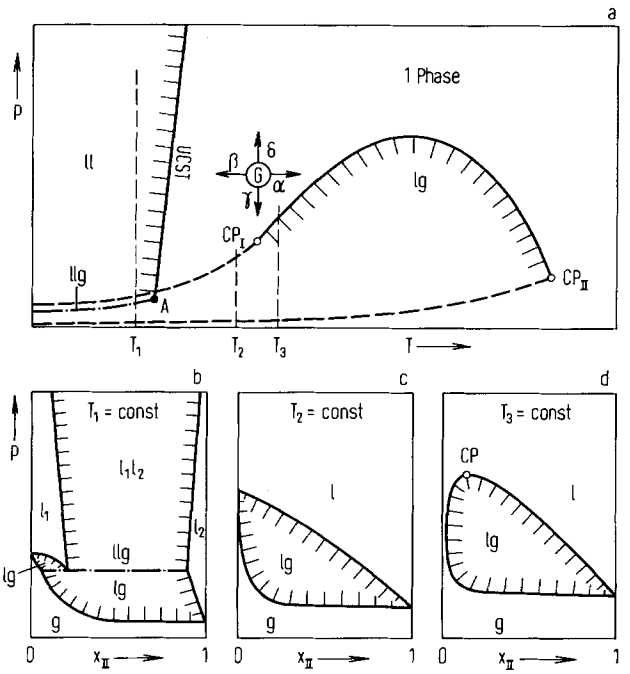

Fig. 4. $p(T)$ diagram (a) and selected $p(x)$ isotherms (b—d) for binary systems of the type CO_2 + octane, CO_2 + decane, CO_2 + dodecane, CO_2 + 2-octanol (schematic; see text; for symbols see Figures 2 and 3).

highly compressed gas I. Here reprecipitation (*e.g.* for the separation of the dissolved substance from the extractant) is possible by a temperature increase (case α), by a (usually large) temperature decrease (case β), by a pressure decrease (case γ) and (exceptionally) by a (usually pronounced) pressure increase (case δ). Moreover, for precipitation the types shown in Figures 2 and 3 differ characteristically: Phase separation with decreasing pressure at constant temperature is possible in all cases except for type 3 in Figure 2h and type 1 in Figure 3d whereas separation with increasing temperature at constant pressure is limited to suitable regions of the types 2a—f, 3a—c and type 3 in Figure 3d.

Figure 5a shows the schematic $p(T)$ phase diagram of a binary system according to Figure 2e on a larger scale; this type is found for CO_2 + hexadecane[13] (Figures 11 and 12) and CO_2 + 2,6,10,15,19,23-hexamethyltetracosane (squalane)[14] (see Figures 8, 11, 12, 14). Precipitation (*e.g.* starting from point G in Figure 5a) is again possible with increasing temperature (case α), decreasing temperature (case β), decreasing pressure (case γ), and (strongly) increasing pressure (case δ).

Some characteristic isothermal $p(x)$ sections for $T > T_{c(I)}$ are shown in Figures 5b—5d. For the isotherm at $T = \text{const} = T_1$ in Figure 5b the two-phase region at pressures below the three-phase line llg corresponds to liquid-gas equilibria; here the branch a on the right represents the solubility of the supercritical component I in the liquid component II and the branch b on the left that of the liquid component II in the supercritical component I. At pressures above the three-phase line the two-phase liquid-gas region occurring at high contents of component I vanishes at the binary critical point CP; additionally a liquid-liquid miscibility gap ll is found. The isotherm corresponding to Figure 5c is situated at such a high temperature T_2 that the three-phase line llg is no

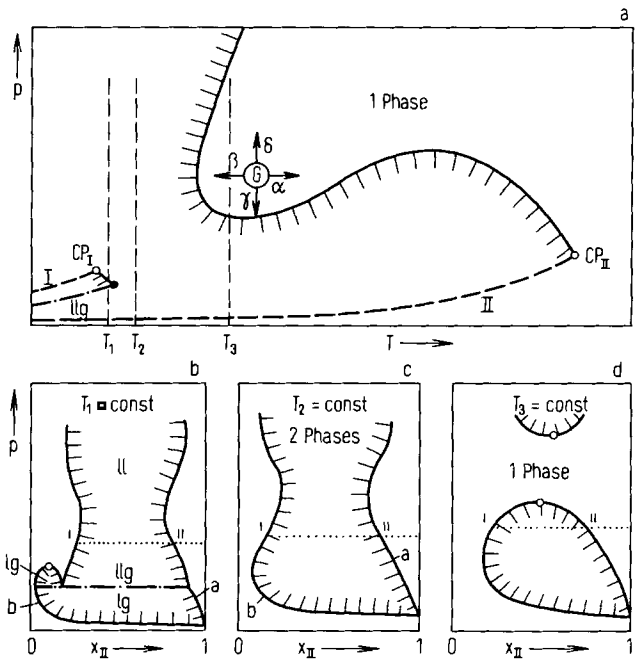

Fig. 5. $p(T)$ diagram (a) and selected $p(x)$ isotherms (b—d) for binary systems of the type CO_2 + hexadecane, CO_2 + squalane, CO_2 + 2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene (squalene) (schematic; see text; for symbols see Figures 2 and 3).

longer cut and liquid-liquid and liquid-gas equilibria can no longer be distinguished. The isotherm in Figure 5d consists of two completely separated two-phase regions.

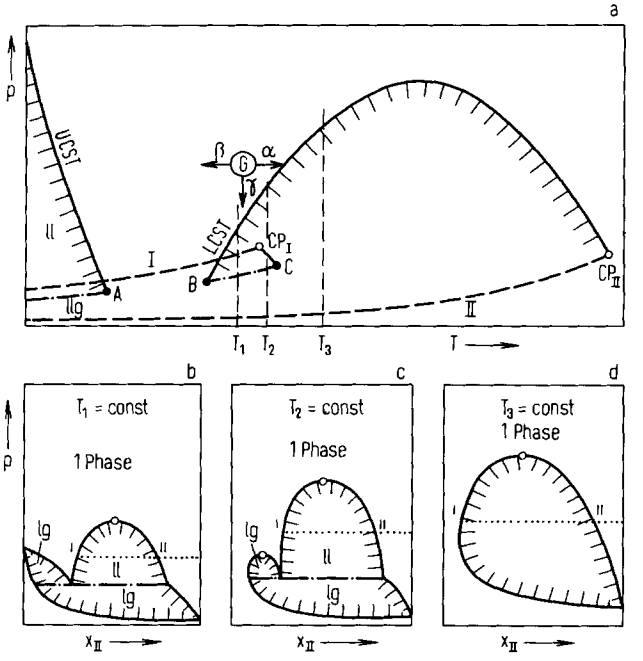

Fig. 6. $p(T)$ diagram (a) and selected $p(x)$ isotherms (b—d) for binary systems of the type CO_2 + nitrobenzene, C_2H_6 + squalane (schematic; see text; for symbols see Figures 2 and 3).

Figure 6 shows the schematic $p(T)$ diagram of binary systems according to Figures 3a and 3b with upper (UCST) and lower (LCST) critical solution temperatures. This type is found for binary mixtures of CO_2 with nitrobenzene, 2-nitrophenol, or 1,4-dichlorobenzene, of C_2H_6 with squalane (see Figure 14) or 1,3,5-trichlorobenzene, of CH_4 with 1-hexene or 3,3-dimethylpentane, as well as for solutions of polymers or oligomers in low-molecular solvents[1, 7]. Precipitation (*e.g.* starting from point G in Figure 6a) is possible with increasing (case α) or decreasing (case β) temperature and decreasing pressure (case γ). Some characteristic $p(x)$ isotherms are represented in Figures 6b—6d. As in Figure 5b the two-phase regions in Figures 6b and 6c below and above the three-phase line correspond to liquid-gas and liquid-liquid equilibria respectively. For the $p(x)$ isotherm at $T = \text{const} = T_3$ in Figure 6d liquid-gas and liquid-liquid equilibria are no longer distinguishable.

For the discussion of problems in fluid extraction and SFC $p(c)$ isotherms (where c = concentration, *e.g.* in $g \cdot cm^{-3}$) would be more suitable than $p(x)$ isotherms such as given in Figures 4b—4d, 5b—5d, 6b—6d, 7b, 7d, and 7e. Since hardly any pVT data for coexisting phases are available, the calculation of concentrations is impossible in most cases and thus $p(c)$ isotherms are known for a few systems of interest only (such as in Figures 9b, 9c, and 10).

According to Figures 4, 5, and 6 unusual $T(x)$ isobars and consequently an extraordinary temperature dependence of solubilities at constant pressure have to be expected, *e.g.* for systems of the type 5a a maximum solubility should be found with increasing temperature at low pressures (say below the pressure minimum of the critical curve) whereas at much higher pressures only a solubility increase with rising temperature should be possible. Such a temperature dependence is already known, *e.g.*, for the solubility of naphthalene in supercritical ethylene[76].

The solubility phenomena described by *Zosel*[15] can qualitatively be explained from Figures 5b and 5c or 6b and 6c. For a constant pressure above the three-phase line, CO_2 is first dissolved in the liquid under test until the mole fraction x_2'' is reached. With further addition of CO_2 phase separation into two phases with the mole fractions x_2' and x_2'' is found, phase ′ being taken from the high pressure vessel until all phase ″ is transformed into phase ′. For the types in Figures 5b, 6b, and 6c the three-phase line llg is reached with decreasing pressure and gas bubbles such as mentioned by *Zosel* appear; for the types in Figures 5c, 5d, and 6d, however, (transient) turbidity is observed because of additional phase separation along the equilibrium curves, the latter runs being effected in the ranges of temperature and pressure recommended for fluid extraction by *Zosel. Zhuze et al.*[16] have probably been concerned mainly with diagrams according to Figures 5b, 6b, and 6c that will also correspond to the well-known process for production of bitumen from petroleum residues by selective precipitation with propane.

2.4. Occurrence of Solid Phases

Up to now mixtures have been considered that consist of fluid phases only. For fluid extraction, the dissolution of solid substances by a supercritical fluid phase, however, is of considerable importance, *e.g.* for most of the separations described by *Stahl*[17].

The phase relationships are schematically represented in Figure 7 for a case where the critical fluid phase behavior corresponds to the simple type of Figure 2a. For the solid phases complete immiscibility of the components is assumed. In Figure 7a the triple point temperature $T_{tr(II)}$ of pure com-

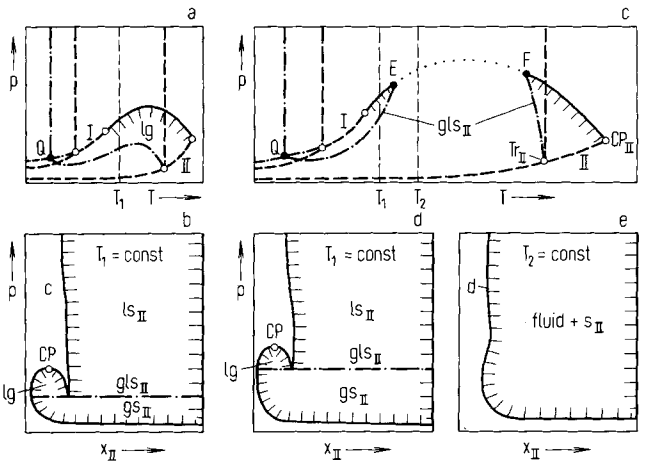

Fig. 7. $p(T)$ diagram (a; c) and selected $p(x)$ isotherms (b; d and e) for binary systems with occurrence of solid phases in the supercritical region lg in simple cases (schematically; see text; for symbols see Fig. 2).

ponent II (here the organic substance to be extracted) is higher than the critical temperature $T_{c(I)}$ of pure component I (here the supercritical solvent, *e.g.* CO_2). In Figure 7b a typical $p(x)$ isotherm slightly above $T_{c(I)}$ is shown. For pressures above the three-phase line gls_{II} the solubility of solid II in the fluid phase is given by curve c (*e.g.* C_2H_6 + 1,4-dichlorobenzene).

In Figure 7c the three-phase line gls_{II} runs to pressures high enough for it to cut the critical line lg twice at the critical endpoints E and F. Figures 7d and 7e show two characteristic $p(x)$ isotherms. Whereas the diagrams 7b and 7d are very similar, the three-phase line gls_{II} is no longer cut in Figure 7e and the solubility of solid component II in the fluid phase is given by curve d. Examples for the latter type are CO_2 + diphenylamine, C_2H_6 + naphthalene, CH_4 + naphthalene, binary mixtures of C_2H_4 with diphenyl, naphthalene, anthracene, hexachloroethane, *etc.* (for references, see [18]) as well as $H_2O + SiO_2$ [19]. It will probably occur rather often in the systems investigated by *Stahl*[17].

A more complicated critical behavior in the fluid phase (*e.g.*, as in Figures 2c—2h) can also be considered. The most important types have been discussed by *Zernike*[10], *Rowlinson*[1], and *Schneider*[7] and two types of interest for fluid extraction are represented in the $p(T)$ diagrams given in Figures 3b (*e.g.*, CH_4 + 1-hexene) and 3d (*e.g.*, CH_4 + methylcyclopentane) (for references and details, see [7]). Similar diagrams are also important for the solubility of inorganic compounds in supercritical water (see *Franck*[20], *Horvath*[21]).

2.5. Ternary Systems

For the simultaneous extraction of two components A and B with CO_2 the phase diagram of the ternary system A + B + CO_2 is of interest, especially when the concentrations of A and B are relatively high. Extensive data exist for $T < T_c(CO_2)$ [38]. From the sparse experimental material available for $T > T_c(CO_2)$, only measurements on the ternary systems CO_2 + heptane + methanol[39], $CO_2 + H_2O$ + acetic acid[39], $CO_2 + H_2O$ + acetone[39], CO_2 + acetone + glycerides[40], CO_2 + *n*-butylbenzene + 2-methylnaphthalene[74] will be mentioned here. Additional data exist for other supercritical solvents, *e.g.* C_2H_4 + quinoline + 2,4-xylenol, C_2H_4 + quinoline + dodecane[73] (for references to earlier work, see [40,74]).

3. Data for Selected Systems

3.1. Experimental Procedure

Two principal methods are used for determination of fluid phase equilibria at high pressure.

1) The analytical method:

The temperature, pressure, and concentration in the heterogeneous region are set at chosen values and the compositions of the coexisting phases are determined (mostly for an aliquot sample). The method is generally difficult and tedious, but multicomponent systems can also be investigated.

2) The synthetic method:

The autoclave is filled with a mixture of known composition in the homogeneous region. The temperature and/or pressure are then varied until a second phase appears. Thus parts of $p(T)$ curves for x = const ("isopleths")—or in rare cases the whole curve—can be determined. Phase separation is mostly detected visually but other methods can also be used[22, 75]. Normally this method is quick and simple and simultaneous pVT measurements are possible; for systems with more than two components, however, the connodes cannot be determined.

These and other methods are discussed in detail in recent review articles by *Schneider*[22] and *Young*[23] where many references are given and where the most important experimental set-ups from the literature are described.

3.2. Discussion of Selected Systems

Figures 8a and 8b give data for the system CO_2 + squalane that have been determined in a simple apparatus by *Liphard*[14] according to the synthetic method. This substance is well-suited for a phase-theoretical discussion of the foundations of fluid-extraction. Squalane is an alkane which is liquid at room temperature and has a relatively high molecular mass; it is synthesized by hydrogenation of the natural product squalene and being a well-known stationary phase in GC it is readily available. Figure 8a shows some isopleths between 6.9 and 72.8 wt % $C_{30}H_{62}$ and Figure 8b some pressure (composition) isotherms that have been interpolated from the isopleths in Figure 8a; the upper and lower abscissa show the mole fraction x and the content of the hydrocarbon in wt % respectively. The type of phase behavior has been discussed in detail above (see Figures 2e, 2f, and 5).

For fluid extraction, a knowledge of concentrations in $g \cdot cm^{-3}$ is more informative than mole or mass fractions. For calculating the concentrations c of the equilibrating phases additional pVT data would be necessary. Unfortunately there is a great lack of such data for all systems that are of interest for fluid extraction. One of the few examples known is presented in Figure 9 (measurements by *Reamer* and *Sage*[24]). Here the pressure (composition) isotherm at 37.8 °C for CO_2 + decane is plotted three times: as a function of mole fraction x (Figure 9a), of concentration c of the hydrocarbon in $g \cdot cm^{-3}$ (Figure 9b), as well as of $\log c$ (Figure 9c)[25]. Point A corresponds to the concentration of the decane in

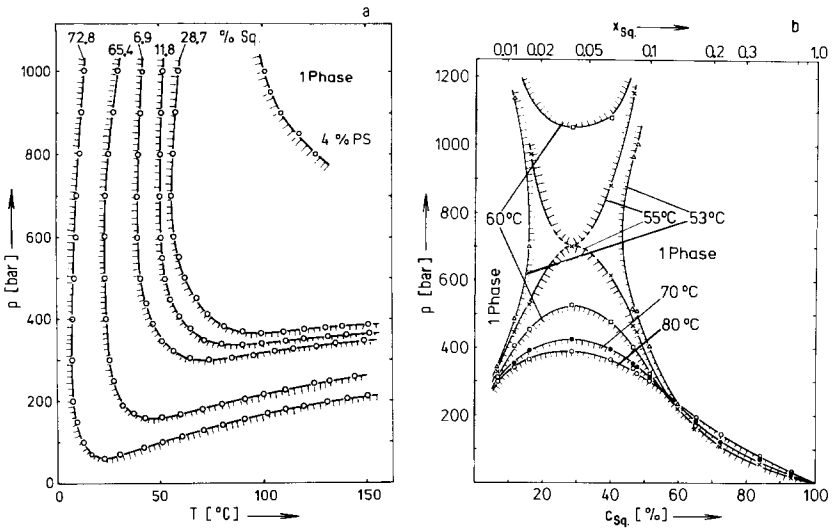

Fig. 8. Fluid phase equilibria in the system CO_2 + squalane (sq.). a) $p(T)$ isopleths, b) $p(c)$ or $p(x)$ isotherms (concentrations in weight percent), PS = polystyrene 600 (for comparison) (according to [14]).

the gas phase before adding CO_2 (that is to the concentration that results from the vapor pressure of pure decane in the gaseous phase) and point B to the concentration in $g \cdot cm^{-3}$ in pure liquid decane. In Figures 9b and 9c the branch on

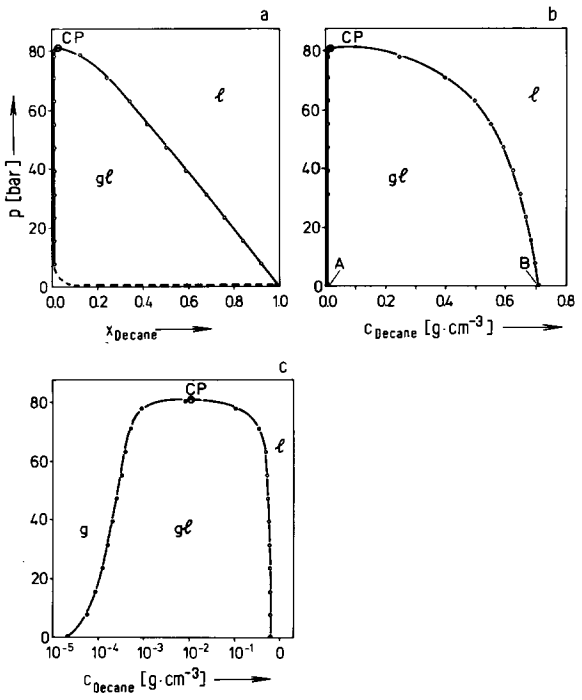

Fig. 9. Pressure (composition) isotherms of CO_2 + decane at 37.8 °C (according to *Reamer* and *Sage*[24]). a) $p(x)$ isotherm, b) $p(c)$ isotherm, c) $p(_{10}\log c)$ isotherm (see [25]).

the left gives the concentration of decane in the gaseous phase; it is increased by a factor of about 10^3 when raising the partial pressure of CO_2 from 0 to about 75 bar. Figure 9c demonstrates the high increase in decane concentration that can be obtained with increasing carbon dioxide pressures. Here the very rapid increase in the immediate neighborhood of the binary critical point CP of the isotherm is especially remarkable; for $p > p_c$ decane and CO_2 are even miscible in all proportions resulting in an infinitely high solubility of decane in CO_2.

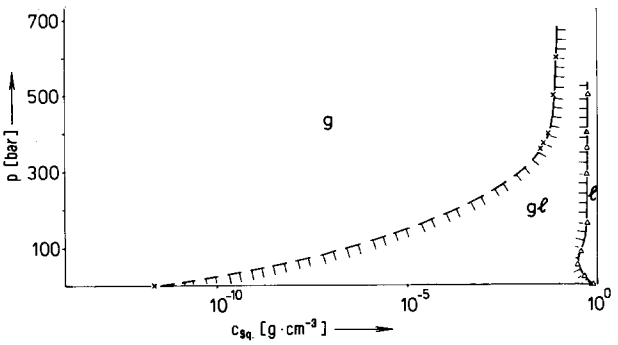

Fig. 10. $p(c)$ isotherm of CO_2 + squalane (sq.) at 40 °C (according to [14]).

This effect is even much more pronounced for the system CO_2 + squalane[14] in Figure 10: the squalane concentration in the gaseous phase is increased by a factor of about 10^{10} on raising the CO_2 pressure from 0 to about 400 bar; for the isotherm given, however, the mutual miscibility does not become complete as the pressure of CO_2 increases further but on the contrary a decrease of mutual miscibility is found.

Figures 9c and 10 demonstrate the rapidly increasing solvent power of highly compressed carbon dioxide and other fluids with increasing pressures, as is extensively exploited in fluid extraction. The short part of the isopleth for 4 wt % of polystyrene in CO_2 shown in Figure 8a demonstrates that relatively low-molecular material can be extracted with supercritical CO_2 from a polymeric substance.

In Figure 11 the $p(T)$ projections of the phase diagrams for binary mixtures of CO_2 with some normal alkanes of very different chain length (between 1 and 30 carbon atoms) are presented[13, 14]. The critical $p(T)$ curves (thick solid lines) have a very different shape and correspond to many of the types schematically given in Figure 2, *e.g.* to type 1 in Figure 2b (methane + CO_2, CO_2 + butane, CO_2 + pentane, CO_2 + octane (lg), CO_2 + decane (lg), CO_2 + undecane (lg)), to type 2 in Figure 2b (CO_2 + propane), to type 3 in Figure 2b (CO_2 + ethane; exhibition of critical azeotropy), to the type in Figure 2c (CO_2 + octane (lg and ll), CO_2 + undecane (lg and ll)) and to the type in Figure 2e (CO_2 + hexadecane,

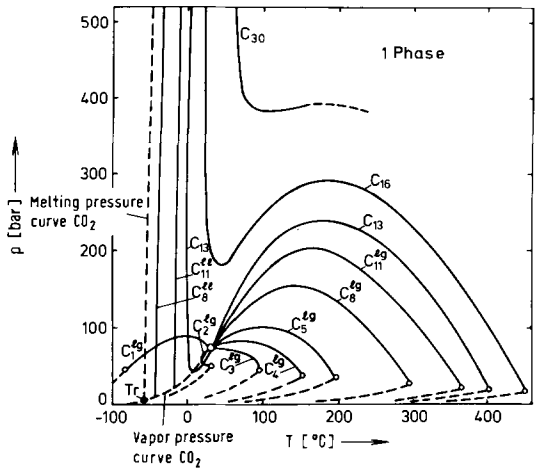

Fig. 11. $p(T)$ diagrams of CO_2 + n-alkanes ($C_n = n$-C_nH_{2n+2} for $n = 1$ to 16; C_{30} = squalane; for details and references see text; cf. [7]).

CO_2 + squalane). The critical $p(T)$ curves of the two last-mentioned systems run through temperature minima and thus resemble those of systems with gas-gas equilibria of the 2nd kind (see type 2 in Figure 2h). For a detailed discussion and numerous references, see [7].

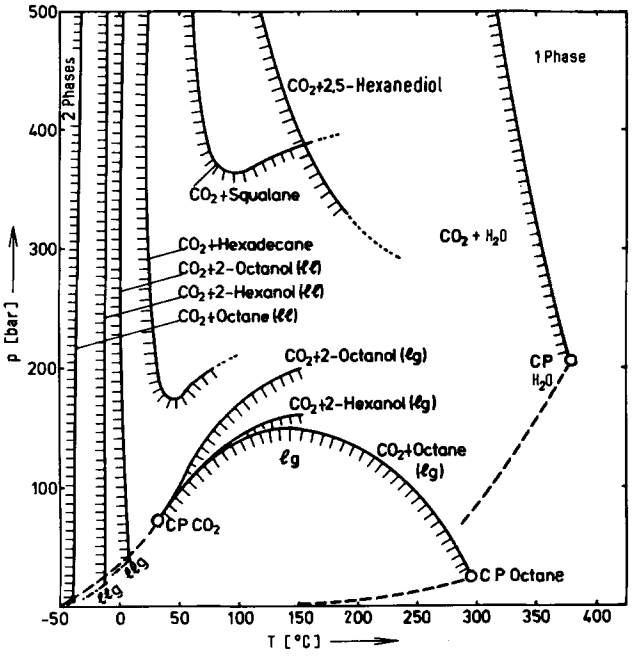

Fig. 12. $p(T)$ diagrams for binary mixtures of CO_2 with alkanes, alkanols, and water (for details and references, see text; cf. [7]).

In Figure 12 some curves already given in Figure 11 and also parts of the critical $p(T)$ curves of the systems CO_2 + 2-hexanol (lg and ll)[9], CO_2 + 2-octanol (lg and ll)[9], and CO_2 + 2,5-hexanediol[9] as well as of CO_2 + water[26] are plotted. Whereas the phase behavior of CO_2 + 2-hexanol and CO_2 + 2-octanol corresponds to the type in Figure 2d (such as CO_2 + octane, *etc.*), the system CO_2 + water belongs to type 2 in Figure 2h (with gas-gas equilibria of the 2nd kind), and CO_2 + 2,5-hexanediol has to be attributed to an intermediate type.

In Figure 13 the critical $p(T)$ curves of some binary C_2H_6 systems are given where the low-volatile component II is varied systematically[9]. Whereas C_2H_6 + methanol belongs to type 2 in Figure 2f and C_2H_6 + water[27] to type 2 in Figure 2h (corresponding to a gas-gas equilibrium of the

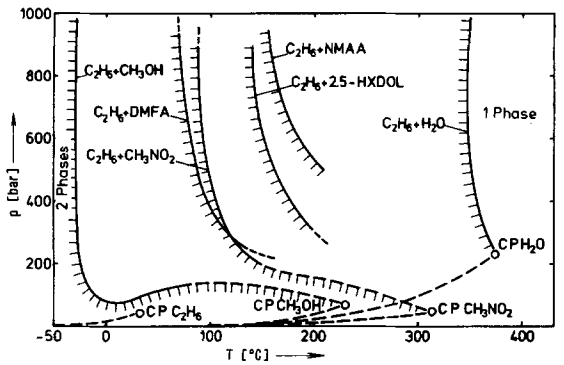

Fig. 13. $p(T)$ diagrams for binary mixtures of C_2H_6 with organic compounds (DMFA = dimethylformamide; NMAA = *N*-methylacetamide; 2,5-HXDOL = 2,5-hexanediol; for details and references, see text; cf. [9]).

2nd kind) all other systems show intermediate types of phase behavior (*e.g.*, C_2H_6 + nitromethane corresponds to type 1 of Figure 2h).

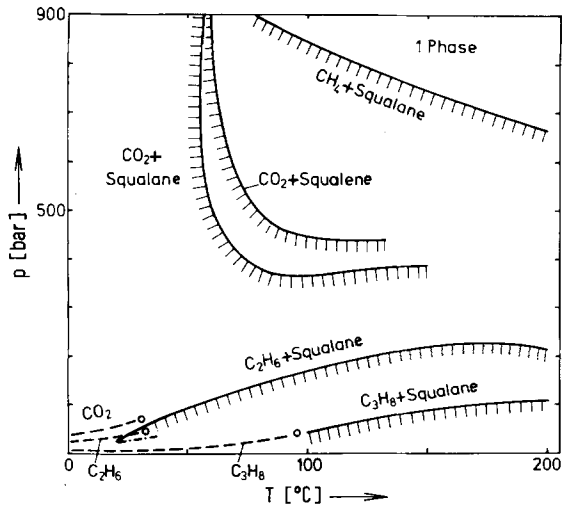

Fig. 14. $p(T)$ diagrams of binary mixtures of squalane with CH_4, C_2H_6, C_3H_8, and CO_2 and for CO_2 + squalene (for details and references, see text).

In Figure 14 the critical $p(T)$ curves for binary mixtures of squalane (component II) with methane, carbon dioxide, ethane, or propane (component I) as well as the critical $p(T)$ curve of CO_2 + squalene are presented; here, in contrast to Figures 11—13, the high-volatility component I is varied. Whereas the CH_4 + squalane system[28,29] exhibits a critical curve of type 2′ in Figure 3d (or type 1 in Figure 2h), the systems CO_2 + squalane[14] and CO_2 + squalene[28] correspond to type 3 in Figure 2f with a temperature minimum on the critical curve. For C_2H_6 + squalane type 3a and 3b was found[30,31,29]; here the part of the miscilitity gap that corresponds to upper critical solution temperatures (UCST) is situated at temperatures below the crystallization surface and can only be reached in undercooled melts[29]. The system C_3H_8 + squalane belongs to the simple type of Figure 2b[28].

Figures 11—14 demonstrate the very different types of phase diagrams for mixtures of CO_2 or ethane with organic substances of different molecular size, shape, structure, and/or polarity. Very similar phenomena have also been found for

binary mixtures of ethylene[9], methane[7, 32], or inert gases[33, 34], and even of water[4, 7, 35, 36] or ammonia[37] in a wide temperature range between about 100 and 700 K but in a comparable pressure range up to some kbar (for a review, see [7]). Figures 11—14 thus demonstrate the diversity and complexity of phase behavior in mixtures that are of importance for fluid extraction. This complexity makes predictions difficult and at least some informative measurements are recommended. Furthermore it follows from Figures 12 and 13 (for similar plots see [7, 9]) that supercritical gases (*e.g.* CO_2 or C_2H_6) are not all "super-solvents" for nearly all substances but, on the contrary, relatively poor solvents (*e.g.* in comparison with many liquids). Depending on pressure and temperature they have, however, a very selective and highly pressure-dependent solvent power for substances of medium molecular mass and relatively low polarity such as found for some important natural products (for a systematic discussion of this point, see *Stahl*[17]). This variable but limited solvent power is an important advantage and without it no selective extraction (*e.g.* of caffeine from coffee or of nicotine from tobacco[15]) would be possible.

3.3. Applications in Supercritical Fluid Chromatography (SFC)

The increasing solvent power of carbon dioxide for organic substances with increasing pressure can be easily demonstrated in SFC experiments. In this relatively new chromatographic technique highly compressed fluid phases mostly at temperatures somewhat above their critical temperatures are used as mobile phases especially for the separation of substances with a very low volatility and/or too low a thermal stability to allow a normal GC separation. The influence of varying the pressure of the mobile phase is shown in Figure 15 where SFC chromatograms for the migration of hexadecane with CO_2 as a mobile phase at 40 °C and different pressures are given according to measurements of *van Wasen*[41]. A pressure increase from 73 to 87 bar raises the migration rate of the organic compound in the column by a factor of about 10.

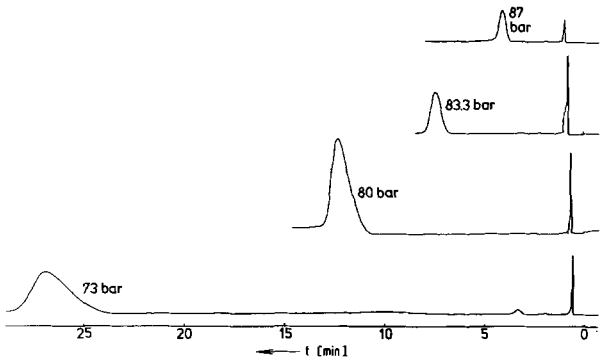

Fig. 15. Supercritical fluid chromatography (SFC) with supercritical CO_2 as mobile phase: retention times of hexadecane at different pressures of CO_2 (according to [41]); CO_2, 40 °C, 0.5 dm^3 (NTP)·min^{-1}; stationary phase: Carbowax 400 (chemically bonded on Porasil C); column length 2 m, diameter 1.4 mm; sample size 0.2 µl).

Some physicochemical properties can be derived from SFC experiments: *e.g.* the capacity ratio k_i of a component i that can be calculated from equation (1) with the retention time t^0 of an inert substance and the retention time t_i^r of the substance i under test

$$k_i = \frac{c_i^{stat}}{c_i^{mob}} \cdot \frac{V^{stat}}{V^{mob}} = K_i \frac{V^{stat}}{V^{mob}} = \frac{t_i^r - t^0}{t^0} \quad (1)$$

The capacity ratio k_i is proportional to the partition coefficient K_i and thus characteristic for the elementary separation effect; V^{stat} and V^{mob} are the volumes of the stationary and the mobile phases in the column respectively.

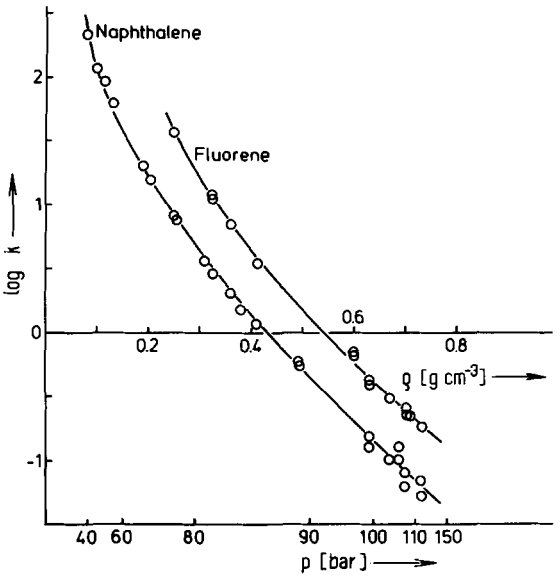

Fig. 16. Supercritical fluid chromatography (SFC) with supercritical CO_2 as a mobile phase: Density and pressure dependence of the capacity ratio k for naphthalene and fluorene (according to [41]); 40 °C, 0.7 dm^3 (NTP) · min^{-1}; stationary phase 3.1 g Perisorb A.

In Figure 16 the logarithms of some experimental k-values are plotted against the density ρ (linear abscissa) and the pressure p of supercritical carbon dioxide at 40 °C as a mobile phase for SFC experiments on naphthalene and fluorene according to *van Wasen*[41]. It follows that with a density increase from 0.1 to 0.8 g·cm^{-3} the capacity ratio k_i and the partition coefficient K_i decline by a factor of about 10^4, corresponding to an enormous increase of the concentration in the mobile phase. As is usually found, the plot of $\log k_i$ *versus* $\rho(CO_2)$ better approaches a straight line than does that *versus* $p(CO_2)$[42]. However, this analogy between solvent power and density should not be over-interpreted since a decrease of solubility with increasing density is also frequently found (*e.g.* for type 2 in Figure 2d, for type 3 in Figure 2f, for types 2 and 3 in Figure 2h).

Figure 16 demonstrates the large change in solvent power of supercritical CO_2 and other fluids as a function of density and pressure such as used in fluid extraction and SFC. In comparison with normal GC, SFC is advantageous for the separation of thermally labile and/or low-volatility substances because of the lower separation temperatures and the use of pressure programs (instead of temperature programs as in GC). In comparison to HPLC, SFC will in general be less effective for analytical purposes but it may have considerable advantages for preparative applications mainly because of easy reprecipitation of the separated pure substances from the mobile phase (*e.g.* by decreasing pressure or freezing out). For a detailed discussion of SFC see *Klesper*[43], *Gouw* and *Jentoft*[44], *Bartmann* and *Schneider*[25]).

4. Calculation of Phase Equilibria in Fluid Mixtures

Because of the important applications mentioned above, methods for the calculation and correlation of the thermodynamic properties of fluid mixtures at high pressures (*e.g.* the phase diagrams) are of increasing interest; this fact is demonstrated by an increasing number of publications in this field in recent years.

The calculation methods start with the fact that the conditions for phase equilibria and for critical points are essentially the same for all types of two-phase equilibrium in fluid mixtures: namely liquid-gas, liquid-liquid, and gas-gas. In a binary mixture, two phases (′ and ″) are in equilibrium if the following equations hold

$$p' = p'' \tag{2}$$

$$T' = T'' \tag{3}$$

$$G'_m - x'_i \cdot (\partial G_m/\partial x_i)'_{p,T} = G''_m - x''_i \cdot (\partial G_m/\partial x_i)''_{p,T} \tag{4}$$

with $i=1$ and 2, or condition (4a) that is equivalent to (4)

$$\mu'_i = \mu''_i \tag{4a}$$

G_m is the molar Gibbs energy and μ_i the chemical potential of component i in the mixture.

A binary critical point is defined by

$$(\partial^2 G_m/\partial x_i^2)_c = 0 \tag{5}$$

$$(\partial^3 G_m/\partial x_i^3)_c = 0 \tag{6}$$

From the phase equilibrium conditions (2), (3), and (4) or (4a) the phase diagram and from conditions (5) and (6) the binary critical curve can be calculated. In most cases, however, the more complicated corresponding conditions for the molar Helmholtz energy A_m (instead of the molar Gibbs energy G_m) have to be used.

G_m or A_m can be obtained:

a) from an equation of state that is often a modified version of the Redlich-Kwong or the van der Waals equation using sometimes rather sophisticated combining rules for the parameters,

b) from theories of mixtures starting from models with the use of different combining rules for the potential parameters in the mixture, or

c) for liquid-gas and liquid-liquid equilibria up to moderately high pressures using equations for the excess functions in the liquid phase (*e.g. Porter, van Laar, Wilson*, NRTL, UNIQUAC, *Flory-Huggins* and others or using group contributions, *e.g.* ASOG and UNIFAC[2,45,46]).

Such calculations require not only a good representation of the phase equilibria but also of *pVT* data and caloric properties. Much of this field has recently been reviewed by *Prausnitz*[47,48]. Calculations and references have been given by *Schneider*[7], *Deiters et al.*[49], *Deiters*[72], *McGlashan et al.*[50], *Twu et al.*[51], *Young et al.*[52], *Peter et al.*[53,55], *Huron et al.*[54], *Smith et al.*[77], and others. The reader is referred to the literature for details; for a review, see [45].

Only two examples are presented in Figure 17 where, for $C_2H_4+CH_3NO_2$ (Figure 17a) and C_2H_6+dimethylformamide (DMFA) (Figure 17b), the critical $p(T)$ curve calculated by *Deiters et al.*[49] from the Redlich-Kwong equation is compared with measurements of *Alwani*[9]. Figures 17a and 17b show that even systems belonging to type 1 in Figure 2f (Figure 17a) or to type 1 in Figure 2h (Figure 17b) can be calculated in good agreement with experimental data. Considerable progress can be expected in this field within the next few years.

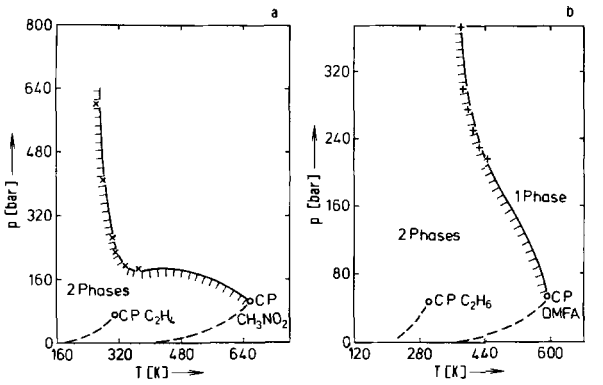

Fig. 17. $p(T)$ diagrams for a) C_2H_4 + nitromethane and b) C_2H_6 + dimethylformamide (DMFA): Comparison of experimental (×) [9] and calculated values (–) [49].

5. Selected Physicochemical Properties

Besides phase equilibria (see Sections 2—4), some other physicochemical properties (*e.g. pVT* data, viscosities, diffusion coefficients, *etc.*) are also of fundamental importance for a separation process such as fluid extraction. Since there is a great lack of experimental data in this field, some remarks concerning the most important properties only will be given in the following.

5.1. *pVT* Data and Dielectric Constant

Figure 18 shows some $p(\rho)$ isotherms for pure carbon dioxide at subcritical and supercritical conditions; here reduced vari-

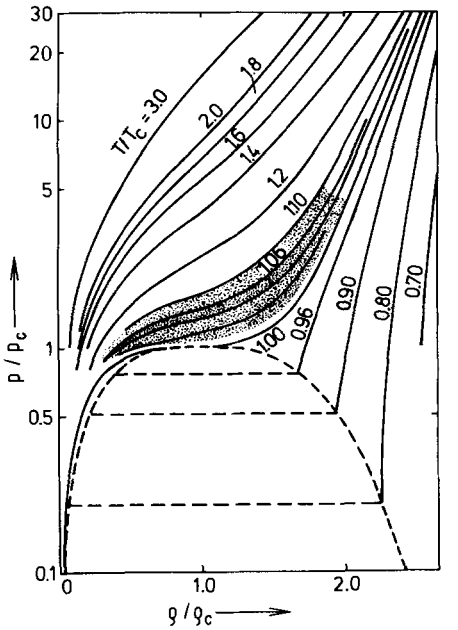

Fig. 18. $p(\rho)$ isotherms for pure carbon dioxide. p_c, T_c, and ρ_c are critical data; region of interest for fluid extraction is dotted.

ables are used and the region that is of interest for fluid extraction is shown dotted. For $T > T_c(CO_2)$ the density increases rapidly with rising pressure and at the critical point CP $(\partial\rho/\partial p)_T = \infty$[1].

In Figure 19 the density ρ and the static dielectric constant ε for carbon dioxide[8, 56] and argon[57, 58] are compared with respect to their dependence on pressure. In Figure 19a, ε is plotted against pressure up to 2000 bar; $\varepsilon(CO_2)$ increases from 1 to about 1.8 (322.9 K) and ε(Ar) from 1 to 1.4 (298 K). This effect also provides evidence for the greater solvent power of supercritical carbon dioxide for low-volatility compounds at elevated pressure.

For substances without permanent dipole moments ρ and ε are related according to the Clausius-Mosotti equation [eq. (7)]

$$P_M \equiv \frac{\varepsilon - 1}{\varepsilon + 2} \cdot \frac{M_r}{\rho} = \frac{1}{3 \cdot \varepsilon_0} \cdot N_L \alpha \qquad (7)$$

Numerous literature data demonstrate that, up to moderately high pressures, the molar polarization P_M defined by equation (7) is essentially independent of pressure. A constant value of the polarizability α follows from this finding; thus α is practically uninfluenced within the pressure range that is relevant for fluid extraction.

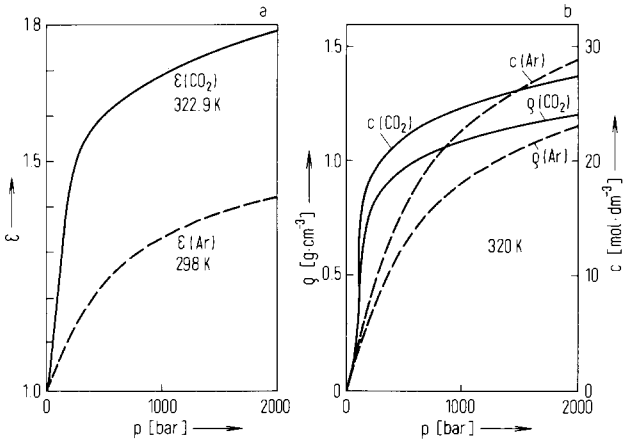

Fig. 19. Comparison of the pressure dependence of density ρ, concentration c, and (static) dielectric constant ε for pure CO_2 and Ar (see [8, 56, 58, 72]).

In Figure 19b the density ρ and the concentration c are plotted against pressure p at 320 K for carbon dioxide[8, 72] and argon[57, 72]. For carbon dioxide both isotherms rise steeper than those for argon at the beginning but they then turn off and at about 1450 bar the $c(p)$ isotherms of the two substances intersect, whereas for the two corresponding $\rho(p)$ isotherms an intersection point can be extrapolated at about 2900 bar. In spite of similar densities, however, the solubility of organic substances in compressed argon is normally smaller than that in carbon dioxide by several orders of magnitude and can already widely be understood in view of the vapor pressure increase of a condensed substance under high inert gas pressures only ("Poynting effect"; see [2]). Thus Figure 19b demonstrates that the solvent power of supercritical fluid phases cannot exclusively be explained from their density increase.

5.2. Transport Properties

For very small concentrations of substance II to be purified the transport properties of the pure solvent gas (component I) will give some information about the orders of magnitude involved. In Figure 20 the density ρ, the viscosity η and the product $D_{11} \cdot \rho$ (where D_{11} = self-diffusion coefficient) of pure carbon dioxide are plotted against pressure up to 500 bar and at 40 °C (that is about 9 K above T_c) according to data taken from the literature (for references, see [25]).

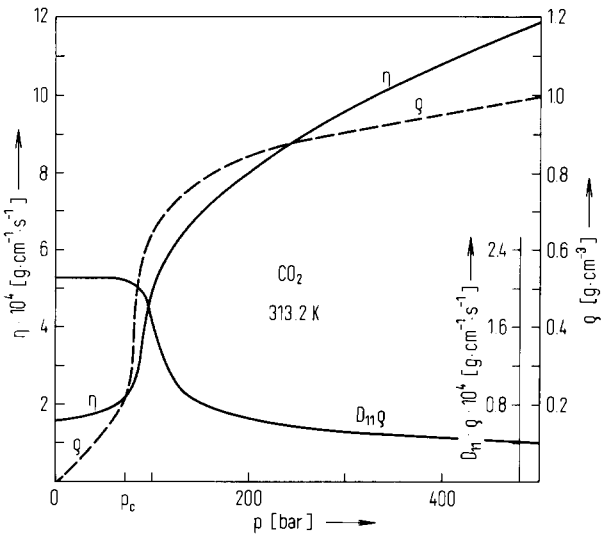

Fig. 20. Density ρ, viscosity η, and $D_{11} \cdot \rho$ for pure CO_2 as a function of pressure at 40 °C (according to literature data [25]; D_{11} = self-diffusion coefficient).

In agreement with simple kinetic theory, η and $D_{11} \cdot \rho$ remain essentially constant up to about 80 bar. As the pressure rises further, an increase of η and a decrease of $D_{11} \cdot \rho$ are found. At 400 bar the following ratios are obtained $\eta(400\,\text{bar})/\eta(1\,\text{bar}) \approx 7$ and $D_{11}(400\,\text{bar})/D_{11}(1\,\text{bar}) \approx 4 \times 10^{-4}$. Thus fluid extraction can profit from relatively low viscosities in the gaseous phase as well as from diffusion coefficients that are considerably higher than the usual values for liquids ($D_{11} < 10^{-5}\,\text{cm}^2 \cdot \text{s}^{-1}$).

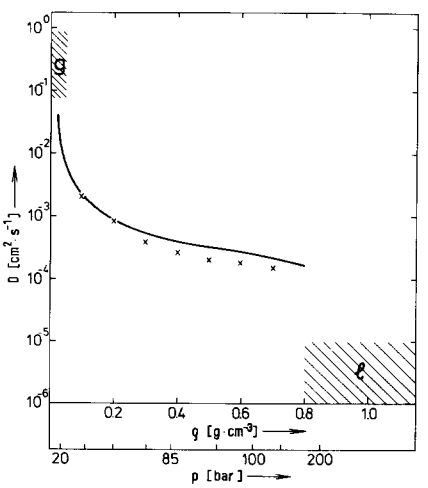

Fig. 21. Self-diffusion coefficient D_{11} of CO_2 at 42 °C (according to [71]) and binary diffusion coefficient D_{12} of benzene in CO_2 at 40 °C (×) [41] as a function of density ρ or pressure p.

The same tendency can be deduced from the rare literature data for the binary diffusion coefficients D_{12} in such mixtures at high pressure. Figure 21 shows D_{12} values for benzene in carbon dioxide at 40 °C as a function of density and pressure as determined with the aid of a chromatographic method by *van Wasen*[41]. A density and pressure dependence similar to that for D_{11} of pure carbon dioxide is obtained. The D_{12} values are smaller than those in a normal gaseous phase at 1 bar by about 2 to 3 orders of magnitude; they are, however, still about 1.5 orders of magnitude above those in normal liquids. Qualitatively similar results on D_{12} of butane in compressed argon were obtained by *Giddings et al.*[59], and for that of naphthalene in compressed carbon dioxide by *Vinkler et al.*[81].

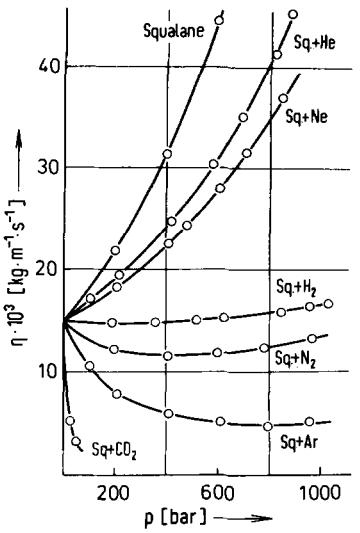

Fig. 22. Pressure dependence of the viscosity η of squalane (sq.), pure and saturated with various gases (according to [60]).

Favorable transport properties can also be estimated for the phase rich in component II. In Figure 22 the viscosity of squalane (pure and saturated with various gases such as helium, neon, hydrogen, nitrogen, argon, and carbon dioxide) at 40 °C and up to 1000 bar is plotted according to measurements of *Kuss et al.*[60]. It is seen that the increase of viscosity with rising pressure becomes considerably smaller for a liquid when gases are dissolved in it, and because of their high solubility even a decrease of viscosity is found for squalane saturated with nitrogen, argon, and carbon dioxide. Since D should be proportional to $1/\eta$ far away from critical states, relatively high diffusion coefficients can also be expected. Therefore the phase rich in component II again shows relatively low viscosities and high diffusion coefficients which are both favorable for separation methods such as fluid extraction or SFC. This is an additional advantage of these methods over liquid extraction and HPLC.

6. Outlook

Fluid mixtures, especially in the critical and supercritical region, are becoming increasingly important in many fields. Characteristic for the situation is the recent foundation of a journal entitled "Fluid Phase Equilibria". (For the recent literature, see [61].)

Fluid aqueous mixtures at high pressures are of fundamental interest in geology and mineralogy, *e.g.* in the formation and migration of minerals, gases, or petroleum in the mantle of the earth, for research on volcanos and geysers, for hydrothermal synthesis, *etc.* The solubilities of many inorganic substances in supercritical water have been measured (for a review, see [21, 62]).

In astronomy and space research, fluid phase equilibria of mixtures (*e.g.* also gas-gas equilibria) play an important role in the atmospheres of some planets[63].

In chemistry highly compressed supercritical gases are of increasing importance as reaction media of continuously variable density, dielectric constant, and solvent power; here the supercritical gas can be solvent as well as reactant, *e.g.* C_2H_4 (especially in the synthesis of polyethylene), NH_3[64], CO_2[65], Cl_2[66], F_2[68]. They are also of interest for some industrial high pressure syntheses, *e.g.* of ammonia, methanol, acetic acid, polyethylene, as well as in the oxo synthesis and in the Fischer-Tropsch process[67].

Fluid phase equilibria at high pressures are of fundamental importance in the petroleum and natural gas industry, *e.g.* for the exploitation of wells, for separation and purification methods (also under cryogenic conditions), or for the storage and transport of products.

Direct applications have already been implemented in fluid extraction and supercritical fluid chromatography treated in the present issue of this Journal. Extraction of coal with supercritical toluene appears promising[78–80]. A patent has already been granted for a method for desalination of sea water with isopropylbenzene which utilizes gas-gas equilibria[69]. Supercritical water has been considered as an extractant for aromatic hydrocarbons from mixtures with straight-chained and branched alkanes[70]. For the exploitation of mineral springs and the production of carbonated beverages, phase equilibria of the kind discussed in Sections 2—4 are of fundamental interest[*]. Moreover, supercritical carbon dioxide is a very mild drying agent, *e.g.* for tissue sections.

Since there will certainly be further applications in the near future, it seems worthwhile to stimulate interest in the physicochemical properties of fluid mixtures at high pressures. These properties are largely unknown up to now and really merit extensive investigation, particularly since the ranges of temperatures and pressures involved in such studies are already accessible owing to rapid developments in experimental high pressure techniques.

Phase Equilibria and Critical Curves of Binary Ammonia–Hydrocarbon Mixtures[**]

By Harro Lentz and Ernst Ulrich Franck[*]

Liquid or dense supercritical ammonia has been suggested as an extraction fluid. It is indeed a good solvent for very different classes of compounds, as can be seen from phase diagrams. Such diagrams for binary systems of ammonia and hydrocarbons are presented and discussed on the basis of their critical curves. Apparatus and methods for the measurement of phase equilibria and equation of state data of fluid mixtures at high pressure are described.

1. Introduction

Ammonia is one of the compounds suggested as a mobile phase for extraction and chromatographic processes[1]. It is a good solvent, particularly for nitrogen-containing compounds, and has a convenient critical point ($T_c = 132.24$ °C, $P_c = 113.53$ bar, $V_c = 72.8$ cm^3 mol^{-1}). Evaluation of possible applications as extractant requires a knowledge of phase equilibria, critical phenomena, and thermodynamic functions of binary systems of ammonia and selected, typical hydrocarbons. Experimental results of this kind as well as methods and equipment will be described here.

Ammonia–nitrogen[2,3] was the first system for which vapor–liquid equilibria and the critical behavior were investigated experimentally up to high pressures. Measurements on ammonia–argon[4,5] and ammonia–helium[6] were published later. These systems have discontinuous critical curves, while the ammonia–water system has a continuous critical curve[7]. An exhaustive study of the phase equilibria in the ammonia–carbon dioxide system has so far been precluded by chemical interaction[8].

Phase equilibria and critical phenomena are known for the following ammonia–hydrocarbon mixtures: NH_3–methane[9,10], NH_3–ethane[11–13], NH_3–*n*-butane[14], NH_3–2,2,4-trimethylpentane[15], NH_3–cyclohexane[16], NH_3–*o*-xylene[17], and NH_3–acetylene (in part)[18]. Very recently studies have been made on NH_3–ethylene[19], NH_3-propylene[20], NH_3–benzene[21] and NH_3–*trans*-decalin[22].

2. Apparatus and Methods

Phase equilibria have been determined using both the "analytical" and the "synthetic" method.

In the analytical method, samples taken from the coexisting phases are analyzed. A one-liter stainless steel vessel is suitable for equilibration up to pressures of about 200 bar. The contents are stirred magnetically and the internal temperature measured by two miniature sheathed thermocouples. Pressure is generated by a hydraulic pump and measured by precision Heise-Bourdon gauges. Several other designs of apparatus for the analytical method have been described for higher pressures[23–25].

In the synthetic method, a mixture of known composition is filled into the vessel and the disappearance of phases observed. Apparatus for this method is less common. However, the method permits simultaneous determination of volumes and hence of molar concentrations which are of value, for example, in chromatographic applications.

Figure 1 shows a one-window equilibrium cell for measurements to 3 kbar and 500 °C[26]. The sample is located between a window of colorless synthetic sapphire and a movable piston. The sample volume can easily be changed and measured by moving the piston and determining its position. At the rear of the piston is a pressurizing fluid, which may be water, and which serves to determine the sample pressure, because both pressures are very nearly equal. Attached to the piston is a thin steel rod with a magnetic tip, reaching into the nonmagnetic high pressure capillary through which the pressurizing fluid is fed into the vessel. The position of the tip is determined from outside by an inductive bridge with a pair of coils on a straight rule with a vernier scale. The front of the piston carries a platinum mirror which facilitates visual observation of the whole sample through the sapphire window. The front part of the autoclave, containing the window, can be separated from the main body. Sealing is achieved by means of a double cone and a left-hand and a right-hand thread. High pressure cell, piston, and the sealing double cone are made from a high-strength nonmagnetic nickel alloy (DEW ATS 340). A small magnetic stirrer within the sample space can therefore be agitated from the outside. Close to the window, two holes and high pressure connections serve for sample introduction and to accommodate a sheathed thermocouple. The autoclave is surrounded by a resistance heater divided into several sections, so that a uniform temperature can be produced in the sample space and—if necessary—a lower temperature can also be ensured at the rear O-ring of the long piston.

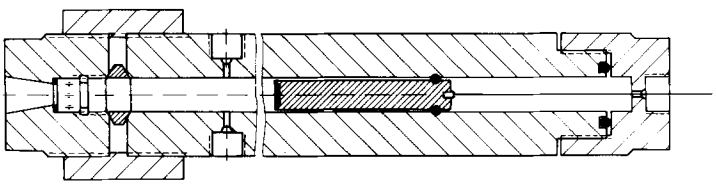

Fig. 1. High pressure cell for measurement of phase equilibria, and *P,V,T*-data at high pressures and temperatures. Left-hand side: removable part with sapphire window. Right-hand side: main body of the cell with movable piston (see text).

[**] Based on a paper presented at the symposium on "Extraction with Supercritical Gases" held at Essen on June 6, 1978.

Ammonia and hydrocarbon are introduced from reservoirs into the high pressure cell and the amounts transferred are determined by weighing.

At constant volume, *i.e.* at constant position of the piston, the temperature is raised slowly and the temperature and pressure values are recorded. Phase transitions are indicated as break points of the isochoric curves thus obtained, and can be verified by visual observation through the sapphire window. The pressure is generated by means of a spindle press filled with the pressurizing fluid, and it is measured by precision Bourdon gauges or strain gauge pressure transducers. In the region of homogeneous behavior of the mixture, *P,V,T*-data could also be determined in this way with relative ease. This had been done previously with acetonitrile[27], benzene[28], *n*-pentane[29], and with the binary mixtures water-argon[30] and water-xenon[31].

Another type of apparatus shown in Figure 2 is simpler since it does not need any additional high pressure equipment. It can be used up to 150°C and 2 kbar, and permits phase observations as well as volume determinations (Hofer Hochdruck GmbH, Mülheim-Ruhr). The lower part is an optical cell with two sapphire windows of 10 mm diameter and O-ring packings. Pressure is generated with a hand-operated piston in the upper part and is measured with a small strain gauge transducer. The position of the piston, and hence the sample volume are directly measurable. The temperature is adjusted by means of a thermostated heating jacket. A thermocouple is located inside the sample space or within a bore close to the sapphire window. Liquids can be filled into the cell directly while gases can be fed in *via* a valve replacing the blind closure shown on the left-hand side of Figure 2. Melting pressure curves[32] as well as the liquid-liquid phase separation of the system ammonia-ethylene have been determined with a cell of this design.

3. Results

The shape and position of the critical curve contain essential information on the phase behavior of a binary system. Such curves may simply connect continuously the two critical points of the pure components. If both components have very different properties, the critical curve may be broken. The lower branch begins at the critical point of the low-boiling partner and may find a "lower critical end point" on a three-phase curve (liquid-liquid-gas). The upper branch of the curve starts at the higher critical point and proceeds to higher temperatures and pressures. It may exhibit extreme values of pressure.

Figure 3 shows a number of gas-liquid critical curves of binary ammonia–hydrocarbon systems. With the exception of ammonia–methane, all systems show continuous curves. Temperature minima and—very probably azeotropy up to the critical region—occur for ammonia in combination with ethane, propylene, butane, and 2,2,4-trimethylpentane. Pressure maxima have been found for ammonia together with cyclic compounds and with ethylene and 2,2,4-trimethylpentane. The curve of the last-named system appears to have a pressure minimum as well. Ammonia–ethylene, ammonia–*n*-butane and ammonia–2,2,4-trimethylpentane show inflection points. The critical curve for ammonia–methane has a temperature minimum at 44°C, 1080 bar, and 29.0 $cm^3 mol^{-1}$. The mixture

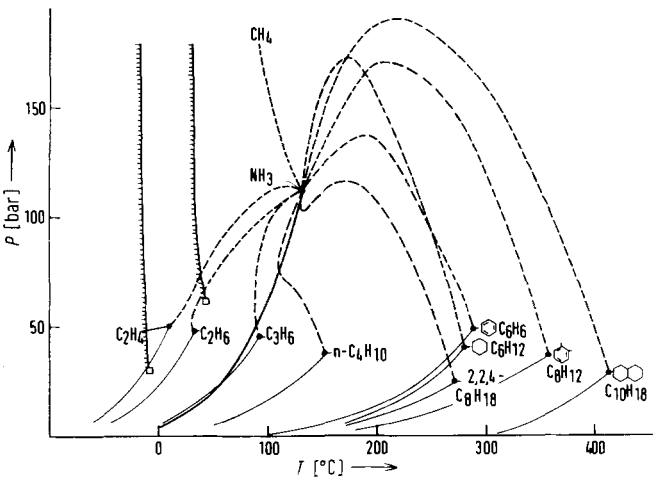

Fig. 3. Projection of critical curves on the pressure-temperature plane for binary ammonia–hydrocarbon mixtures. Liquid-vapor critical curves are dashed, liquid-liquid critical curves have horizontal marks, vapor pressure curves are shown as solid lines.

contains 44.5 mol percent methane at this point. Liquid-liquid critical curves for systems of this kind have so far only be determined for ammonia with ethane and ethylene (see Fig. 3).

The points on the critical curves are the locations of the maxima and minima of the equilibria isotherms and isobars on the phase interface in *P,T,x*-space. Figure 4 gives a set of such isotherms for ammonia–*trans*-decalin. Above 300°C chemical reactions impede the measurements, particularly in the liquid phase. Thus some isotherms had to be partly estimated (dashed curves in Fig. 4)[22].

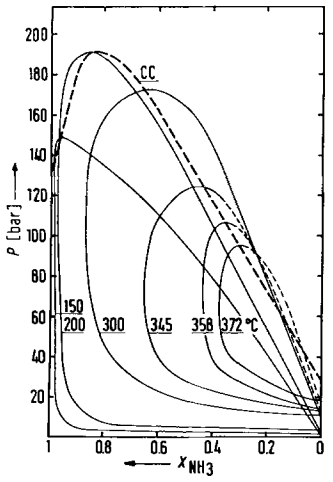

Fig. 4. Equilibrium isotherms for the ammonia–*trans*-decalin system. CC is the critical curve.

4. Discussion

The phase equilibria of several hydrocarbons have been investigated in combination with ammonia and with water. The critical temperature and pressure of water (374.15 °C, 221.3 bar, 57.4 cm^3 mol^{-1}) are considerably higher than those of ammonia. Accordingly, the phase diagrams for aqueous systems often differ in character from those of the ammonia systems. Ethane, butane, and benzene in aqueous systems have discontinuous critical curves. Figure 5 compares the phase behavior of methane[9, 10, 33, 34], ethane[11–13, 35], and benzene[21, 36, 37] in combination with ammonia and with water. A liquid-liquid miscibility gap is expected for ammonia–benzene but has not yet been verified experimentally.

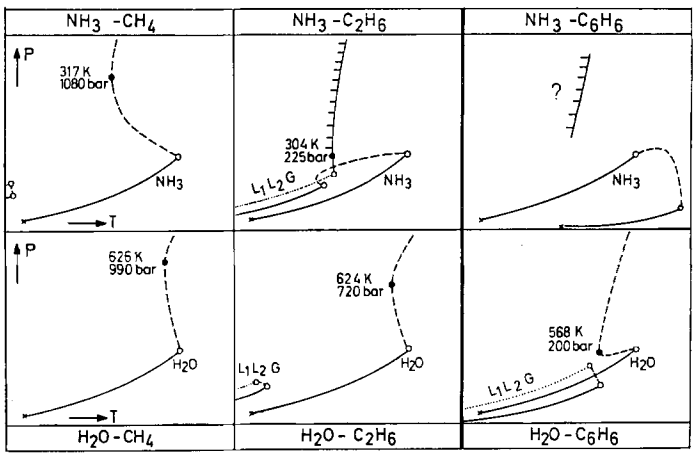

Fig. 5. Comparison of the phase behavior of binary systems with water or ammonia as polar component. Three-phase lines are dotted. Other curves are drawn as in Fig. 3.

The existing theoretical methods of describing and predicting the phase behavior of mixtures with polar components are still unsatisfactory. It appears, however, that data for ternary systems can be derived with reasonable dependability from a knowledge of the three relevant binary systems. Thus it is hoped that the results presented here might provide a useful contribution to the future application of ammonia for supercritical extraction purposes.

A Quick Method for the Microanalytical Evaluation of the Dissolving Power of Supercritical Gases[**]

New analytical methods (12)

By Egon Stahl, Winfried Schilz, Erwin Schütz, and Eberhard Willing[*]

A new method of microextraction with supercritical gases involving direct coupling with thin-layer chromatography enables the solubility behavior of a large number of natural products to be investigated in pressure gradients of up to 400 bar. The results are summarized in general rules that enable the extractability to be predicted on the basis of the chemical structure. The substances that can be satisfactorily extracted in supercritical carbon dioxide and nitrous oxide are preferably lipophilic. The extracting capacity of the two gases was compared using alkaloids. In the case of polar compounds such as sugars and amino acids the solubility is so low even at pressures of 2500 bar (less than 10 μg/Nl) that application is not practicable. Quantitative tests of the solubility behavior of model substances in supercritical gases provide a basis for the technical application of the method.

1. Introduction

We were interested in new methods of separation for "solvent-free" microextraction of natural products and their direct transfer to a thin-layer chromatogram (TLC). Although solvent-free direct transfer is possible with the TAS process[1] and the thermofractography[2] described by us earlier, the action of heat is required in these cases. The temperatures needed for extraction are between 100 and 250 °C, so that the thermal stress on the substances is equivalent to that usual in gas chromatography. Since the transport is assisted by a carrier gas, the process can be regarded as carrier gas distillation on a microscale. We wanted to find a milder solvent-free method for the extraction of non-volatile and thermolabile natural products.

The inspiration came from fluid chromatography (cf. p. 738), which makes use of the fact that many substances that cannot be chromatographed under the normal conditions of gas chromatography despite the high temperature, because their vapor pressure is too low, can be transported at a relatively low temperature in supercritical gases. Our task was therefore to perform extraction with supercritical gases on a microscale, using TLC as the "detector".

Table 1. Physical data for a number of possible extractant gases.

Gas	At 1 bar B.p. [°C]	T_c [°C]	P_c [bar]	ρ_c [g/ml]	DC at 1 bar, 0 °C [ε − 1]
Carbon dioxide	− 78 (subl.)	31.3	73	0.448	0.0011
Nitrous oxide	− 89	36.5	71	0.457	0.00113
Ethylene	−103.7	9.5	50	0.20	0.0018
Chlorotrifluoromethane	− 81.4	28.8	39	0.58	0.0015
Trifluoromethane	− 82.2	25.9	46.9	0.516	—

The principal gases suitable for such extraction on account of their favorable critical parameters are carbon dioxide, nitrous oxide, ethylene, and special freons (Table 1).

The most attractive of these is carbon dioxide, which is easy to handle, ecologically unobjectionable, and reasonably priced. It can be seen from Figure 1 that the density and DC values rise steeply between 70 and 200 bar and reach values similar to those for liquids. This provides further explanation for the fact that several supercritical gases exhibit considerable solvent power above a certain pressure and can therefore be used in place of the usual solvents.

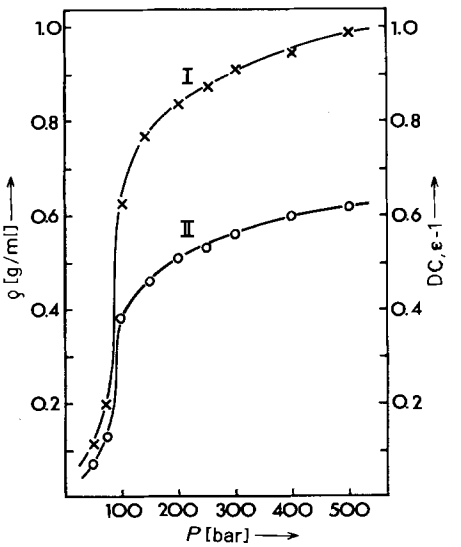

Fig. 1. Dependence of the density ρ(I) and the dielectric constant (II) of carbon dioxide at 40 °C on pressure.

The results that can be obtained are therefore of general interest. Basic research is important because it is difficult to gain access to some of the information obtained so far on extraction with supercritical gases, mainly because it is set out in patent applications or patents[3,4]. For this reason it was necessary to construct an installation for the microscale process so as to be able to test a large number of pure substances and more complex samples in a rational manner.

2. Apparatus for and Function of Coupled Microextraction-TLC

The gas is taken from a commercial pressurized cylinder and its pressure is reduced to the desired preliminary level of 40—60 bar (Fig. 2).

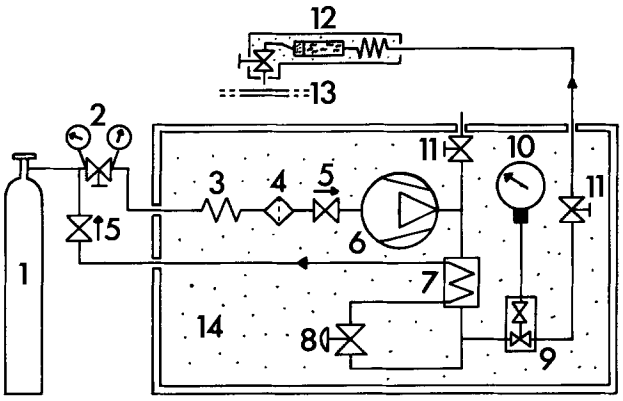

Fig. 2. Schematic layout of the apparatus for direct coupling of fluid extraction with thin-layer chromatography: 1) gas cylinder, 2) pressure-reducing valve, 3) preheating column, 4) filter, 5) check valve, 6) diaphragm compressor, 7) heat exchanger, 8) back-pressure regulator, 9) attenuators, 10) precision pressure gauge, 11) shut-off valve, 12) microautoclave for extraction, 13) TLC plate, 14) thermostatically-controlled container.

It is then compressed with the aid of an electrically driven diaphragm compressor to the desired pressure (70—400 bar). A back-pressure regulator accurate to within about 1 bar enables the pressure to be adjusted exactly; this is controlled by a precision pressure gauge. The compressor unit and the microautoclave are kept at a temperature of *e.g.* 40 °C with the aid of thermostats. The supercritical gas flows into the microautoclave, which has a capacity of 2 ml and contains the samples to be extracted. The outlet from the autoclave is closed by a miniature shut-off valve. When this valve is opened the supercritical gas charged with the substance flows out through a very fine capillary (internal diameter 50 µm), being decompressed in the process. The emerging stream of gas impinges on a TLC plate arranged horizontally 1—5 mm from the outlet. The plate is moved to and fro and collects the precipitating extracted substances as a starting band. As a rule we begin the extraction of a sample at 70 bar and allow 1 Nl (normal liter) of gas to pass through. The pressure is then raised in stages, generally of 10 or 20 bar, the TLC plate is shifted accordingly, the sample is again extracted with 1 Nl of gas, and so on. Figure 3 shows the apparatus for direct coupling of fluid extraction with TLC (FE-TLC); Figure 4 shows the microautoclave with the TLC plate fixed on a sliding support, the control unit, and the gas exhaust device.

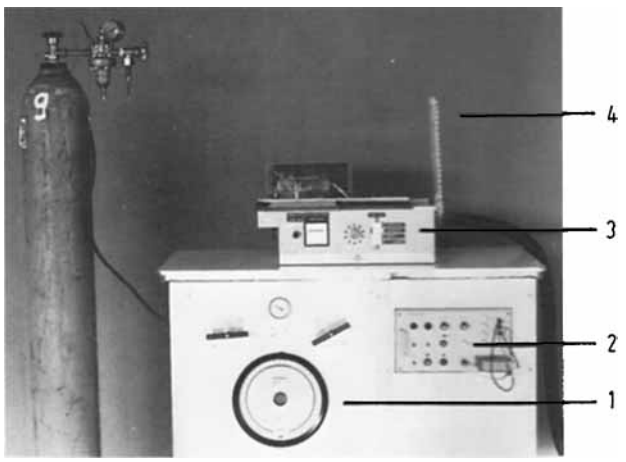

Fig. 3. Front view of the apparatus for direct coupling of fluid extraction with TLC (FE-TLC): 1) compressor station, 2) pressure control unit, 3) microautoclave with collecting device, 4) soap-bubble flowmeter.

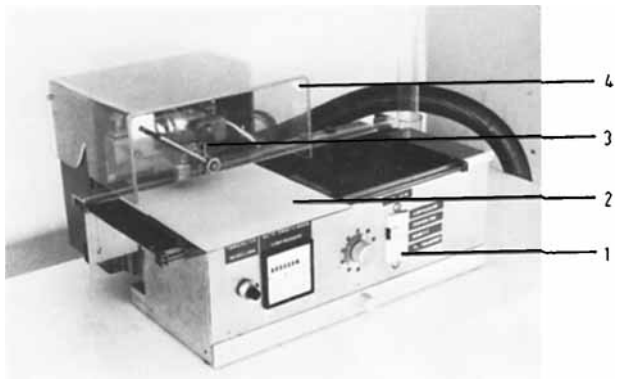

Fig. 4. Microautoclave with TLC collecting device: 1) control switches, 2) carrier slide with TLC plate, 3) microautoclave with shut-off valve, 4) perspex hood with exhaust device.

When the chromatogram has been developed it is possible to see the pressure at which the substance was extracted. It is also possible to tell from the varying intensity of the zones whether the quantity of substance extracted increases or decreases with increasing pressure.

The arrangement shown in Figures 2—4[5, 6] is suitable for use at up to a maximum of 400 bar. At higher pressures the emerging jet of gas damages the chromatographic layer and in addition the rebound effect is so great that only a small part of the extracted substances is collected. Another arrangement was therefore developed, which enables the substances to be collected quantitatively in both the lower and the higher pressure range (up to over 2000 bar). The apparatus is based on the same principle, except that instead of the TLC plate a collecting funnel filled with quartz wool is attached to the capillary tube. After the gas has been decompressed the substances precipitate in this collecting funnel and are extracted with a solvent; they can then be quantitatively determined directly, or applied onto a TLC plate, chromatographed in the usual manner, and then determined quantitatively.

3. Extraction of Difficultly Volatile Substances with Supercritical Gases

3.1. Study with Model Substances in the Pressure Range of up to 400 bar

As no information is yet available about the preconditions a substance must fulfil to be extracted with supercritical carbon dioxide, we first tested pure substances from several groups of natural products[6] (Table 2).

The compounds selected differed in respect of both their relative molecular weight and the number and nature of their functional groups. They ranged from nonpolar hydrocarbons to strongly polar substances. Evaluation of the results showed that a surprisingly large number of different types of substances

Table 2. Model substances extracted directly from quartz wool with supercritical carbon dioxide at 40 °C.

can be extracted with carbon dioxide in the lower pressure range alone. Consideration of the individual groups of substances, *e.g.* the aromatic hydrocarbons, phenols, aromatic carboxylic acids, pyrones, and lipids, is highly informative (Table 2). It is immediately evident that the extractability falls sharply in the pressure range up to 400 bar as the number of C-atoms increases and particularly following the introduction of polar functional groups. One can see here the possibilities for fractionating extraction of complex samples in a pressure gradient.

The findings obtained so far with model substances can be summarized under the following *rules of thumb*:

a) Hydrocarbons and other typically lipophilic organic compounds of relatively low polarity, e.g. esters, ethers, lactones, and epoxides, can be extracted in the lower pressure range, i.e. 70—100 bar.

b) The introduction of strongly polar functional groups (e.g. —OH, —COOH) makes the extraction more difficult. In the range of benzene derivatives, substances with three phenolic hydroxyls are still capable of extraction, as are compounds with one carboxyl and two hydroxyl groups. Substances in this range that cannot be extracted are those with one carboxyl and three or more hydroxyl groups.

c) More strongly polar substances, e.g. sugars and amino acids, cannot be extracted in the range up to 400 bar.

d) Fractionation occurs in the pressure gradient when there are greater differences in the commencement of boiling or sublimation, i.e. in the volatility, and/or marked differences in the polarity of the substances (DC value). The fractionation effects are most marked in the range where there is a sharp rise in the density and dielectric constant of fluid carbon dioxide (Fig. 1).

With these general rules it is now possible to estimate the extractability of the different substances.

3.2. Study of Complex Mixtures in the Pressure Range of up to 400 bar

3.2.1. Extraction of Lipophilic, Non-basic Substances

In continuation of the above fundamental studies we extracted a series of complex mixtures with supercritical gases.

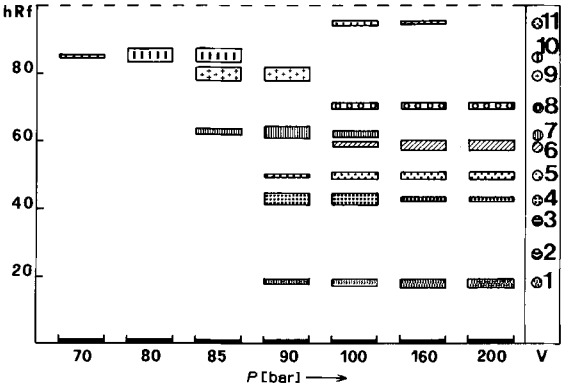

Fig. 5. FE-TLC of a mixture of eleven dyes extracted with carbon dioxide at 40 °C: 1) Fat Orange, 2) Indophenol, 3) Ceres Black, 4) Sudan Red, 5) Sudan Blue, 6) Ceres Red, 7) Ceres Orange, 8) Ceres Green, 9) Sudan Yellow G, 10) Sudan Yellow liquid, 11) Sudan Orange. The fractionating effect was assessed on the basis of the zone width. Plate coating: silica gel 60 F_{254}, dichloromethane, 1 × 15 cm, CS. Detection: observation in daylight.

The resulting fluid extraction thin-layer chromatograms (FE-TLC) provide immediate valuable information on extractability in the respective pressure ranges. They show the increase or decrease in the quantity and the fractionation effects that can be achieved. For example, in Figure 5—the FE-TLC of a mixture of eleven dyes—fractionation of several dyes in the pressure range of 70—100 bar is clearly visible.

The extraction of biological substances present in plant material provided basic confirmation of the results obtained with the model substances, although the fact that the substances are present in the plant material as salts, hydrogen-bonded, or even microencapsulated constitutes a disadvantage for the extraction process. It can be seen from Figure 6 that the terpene hydrocarbons were extracted from camomile flowers at about 70 bar, as were the sesquiterpene alcohol bisabolol and the coumarin herniarin.

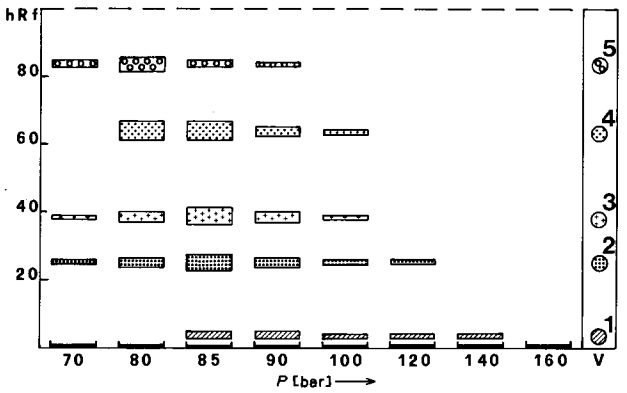

Fig. 6. FE-TLC of 50 mg of camomile flowers extracted with carbon dioxide at 40 °C. 1) matricin, 2) herniarin, 3) bisabolol, 4) "ene-yne dicycloethers", 5) terpene hydrocarbons. Plate coating: silica gel F_{254}, chloroform-benzene (75 + 25), 2 × 12 cm, CS. Detection: a) UV_{365} (herniarin, blue fluorescence); b) EP reagent [7], 10 min 110 °C (matricin, green-blue).

Extraction of the "ene-yne dicycloethers" begins at 80 bar, and the proazulene matricin is extracted at about 85 bar.

An example of the extraction of plant material containing fatty oils with supercritical carbon dioxide is provided by the FE-TLC of sunflower seed that was impregnated with 0.5 % of squalene (Fig. 7). The extraction of squalene begins

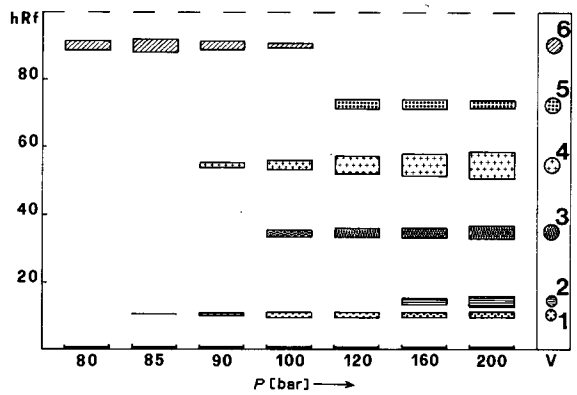

Fig. 7. FE-TLC of 80 mg of sunflower seeds (with 0.5 % of squalene added) extracted with carbon dioxide at 40 °C. 1) sterols, 2) diglycerides, 3) triglycerides with epoxy acids, 4) triglycerides, 5) steryl esters, 6) squalene. Plate coating: silica gel 60 F_{254}, petroleum ether (b. p. = 40—60 °C)—diethylether—acetic acid (70 + 30 + 1), 1 × 10 cm, CS. Detection: acetic anhydride-sulfuric acid reagent [7], heated for 10 min, then UV_{365} (fluorescence).

above 80 bar. At 85 bar the squalene zone is already strongly formed and a weak sterol zone can be seen for the first time. The triglycerides, the main constituents, appear above 90 bar; the triglyceride zone increases steadily with increasing pressure. Extraction of the steryl esters begins at 120 bar, and the diglycerides become visible on the FE-TLC above 160 bar. From a practical point of view, separation of the triglycerides from the other constituents would be possible only below 90 bar; this is also evident from other examples of plant material extraction (Table 3).

Table 3. Microextractions of plant material by the new coupled FE-TLC method.

[a] The "ene-yne dicycloethers" are a mixture of *cis*- and *trans*-spiroethers.

3.2.2. Extraction of Alkaloids

Special attention was also paid to alkaloids and the plant material they are obtained from. These represent a fairly heterogeneous class of natural products as far as the relative molecular weight and polarity are concerned. Here again we found definite correlations between the extractability of alkaloids and their constitution. As shown by Table 4, in addition to carbon dioxide we tried nitrous oxide in these tests. For alkaloids with relatively polar functional groups, such as hydroxyl groups, supercritical carbon dioxide is a poor extractant; supercritical nitrous oxide yields much better results.

with carbon dioxide, fluid nitrous oxide is also the better extraction gas for relatively nonpolar alkaloids. Apart from the polarity of the alkaloids, their extractability is affected by their melting and boiling points. These correlations are also evident from Table 5, which lists some data on the fluid extraction of several alkaloids from plant material.

Here, however, salt formation, hydrogen bonding, and the diffusion effects necessary for extraction inhibit the course of the process.

That fluid nitrous oxide gives better extraction of alkaloids, particularly in the lower pressure range, could well be due

Table 4. Alkaloid model substances, extracted directly from quartz wool with supercritical carbon dioxide or nitrous oxide at 40°C. The polarity of the alkaloids increases from top to bottom within each group.

Alkaloid	Rel. molecular weight	Functional groups	M.p. [°C]	Commencement of FE [bar] CO_2	N_2O

	Ajmaline	—	80

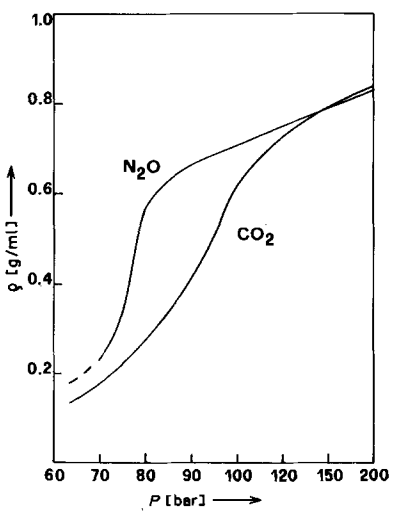

Fig. 8. Pressure dependences of the densities of supercritical carbon dioxide and nitrous oxide at 40°C.

to the fact that under these conditions nitrous oxide has a higher density than carbon dioxide (Fig. 8).

Compared with fluid carbon dioxide, it is better able to solvate the alkaloids in the fluid extraction process. Furthermore, unlike nitrous oxide, carbon dioxide is known to have no dipole moment, and therefore cannot interact with polar groups in the alkaloids. The basic character of the alkaloids does not appear to have any marked influence on their extractability with fluid carbon dioxide and nitrous oxide. Alkaloids with roughly the same basicity, such as morphine and codeine, are extracted to different degrees because of their different polarity. The behavior of the neutral colchicine also shows that the basicity is of minor importance where extraction is concerned.

A vivid example of the possibilities of fluid extraction is provided by the FE-TLC of opium. The plant material was extracted in this instance with supercritical nitrous oxide at 40°C. It is evident from the extent of the individual zones (Fig. 9) that the alkaloids papaverine and narcotine are extracted particularly easily. These are followed by thebaine, which exhibits good extractability at only about 120 bar. The extraction of codeine is less good and that of morphine is worst. In view of the new trend of extracting thebaine from *Papaver bracteatum*, the results of the fluid extraction are of particular interest.

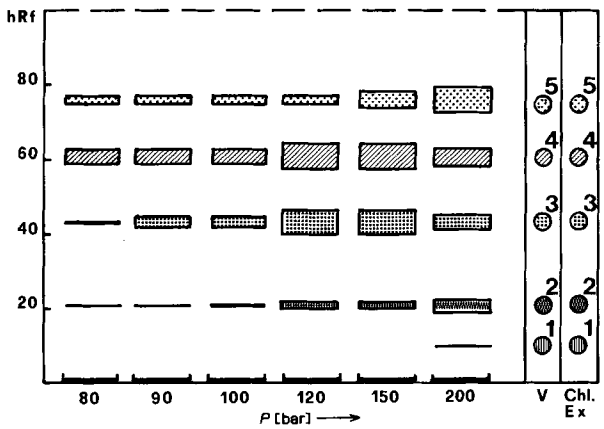

Fig. 9. FE-TLC of 100 mg of crude opium extracted with nitrous oxide at 40°C. 1) Morphine, 2) codeine, 3) thebaine, 4) papaverine, 5) narcotine. Plate coating: silica gel 60 F_{254}, toluene-acetone-ethanol-2.5% ammonia solution (45 + 45 + 7 + 3), 1 × 10 cm, CS. Detection: Dragendorff reagent, modified after *Puech* [8], dark-brown zones.

If supercritical carbon dioxide is used, on the other hand, codeine and morphine are not extracted at all until at least 200 bar. The other three alkaloids are also far less soluble. Further details about the extractability of alkaloids from areca, china, colchicum, conium, ephedra, ipecacuanha, nicotiana, rauwolfia, tropa, and vinca are given in the original paper[9].

4. Quantitative Study of the Solubility Behavior of Model Substances in Supercritical Gases

Exact determination of the solubility of selected substances as a function of pressure is important for further development of the general rules based on the qualitative tests. In addition, knowledge of the solubility of the substances to be extracted is required if the yields of plant material extraction processes with supercritical gases are to be calculated.

Figure 10 shows the relationship between solubility and pressure for three aromatic carboxylic acids and for 1,8-dihydroxyanthraquinone between 80 and 200 bar. Benzoic acid, the most lipophilic compound of this group, can be detected qualitatively already below 70 bar.

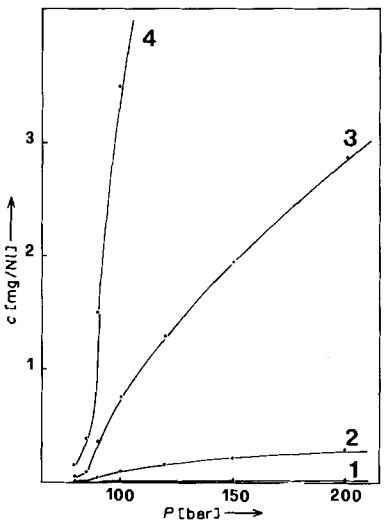

Fig. 10. Pressure dependences of the solubility of a number of solids in supercritical carbon dioxide at 40°C. 1) *p*-Hydroxybenzoic acid, 2) 1,8-dihydroxyanthraquinone, 3) salicylic acid, 4) benzoic acid.

The concentration in the gas does not rise very markedly until the level of 85 bar has been reached; at 100 bar it is about 3.5 mg/Nl, while at 150 bar it is already about 9 mg/Nl. This represents a 10^4- to 10^5-fold increase over the quantity expected solely on the basis of the vapor pressure calculated from the ideal gas equation.

The slope of the solubility curve declines again between 90 and 100 bar with increasing pressure. Salicylic acid, which is rather more polar because of the OH-group *ortho* to the carboxyl group, has a lower solubility. Its concentration in the gas at 150 bar is 2 mg/Nl. If, on the other hand, the hydroxyl group is *para* to the carboxyl group, as in *p*-hydroxybenzoic acid, the solubility is strongly reduced, namely to only about ~10 μg/Nl at 150 bar.

5. Extractability of Polar Natural Products in the Range of up to 2500 bar

Giddings et al. succeeded in dissolving and chromatographing sugars and amino acids, among other substances, with supercritical carbon dioxide at high pressures, *i.e.* above 100 bar in this context[10]. On the basis of model calculations with modified Hildebrand's solubility parameter, these authors concluded that supercritical carbon dioxide and isopropanol have comparable dissolving power at comparable density. To assess the extractability of polar natural products at pressures in excess of 2000 bar we carried out quantitative solubility determinations in this pressure range with supercritical carbon dioxide and nitrous oxide[11]. We found the solubility of amino acids, sugars, and other polar natural products in supercritical carbon dioxide at over 2000 bar to be less than 10 μg/Nl,

i.e. $< 1 : 200000$. These substances are at least 500 times more soluble in isopropanol.

The pressure-dependent solubility of various substances in supercritical gases at 40 °C is shown in Figure 11. The anthraquinone glycoside frangulin A was extracted with supercritical carbon dioxide and supercritical nitrous oxide, while the corresponding aglycone, emodin, was extracted with supercritical carbon dioxide.

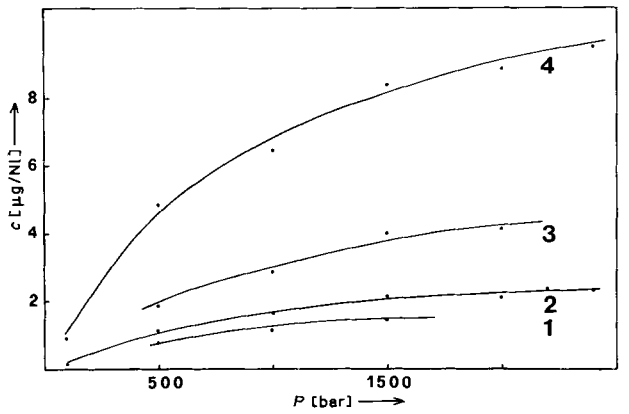

Fig. 11. Pressure dependence of the solubility of a number of substances in supercritical gases at 40 °C. 1) Frangulin A in nitrous oxide, 2) frangulin A in carbon dioxide, 3) aesculetin in carbon dioxide, 4) emodin in carbon dioxide.

These two substances differ considerably in polarity and, as was to be expected, their solubility curves were different; the more strongly polar frangulin A is less soluble than emodin. Both solubility curves have the same characteristics as the curves for sugars, amino acids, and even for example the more soluble *p*-hydroxybenzoic acid; the solubility of the latter at 2000 bar is about 40 µg/Nl.

Frangulin A is about 35 % less soluble in supercritical nitrous oxide than in carbon dioxide under the same conditions. Generally, the higher the polarity (and the lower the volatility) of the substances, the flatter are the curves. A number of polar natural products that could not be extracted and detected with the direct FE-TLC coupling with supercritical carbon dioxide up to 400 bar were also investigated. Only the solubility of aesculetin (cf. also Table 2) could be determined quantitatively (Fig. 11). On the other hand, the solubility of gallic acid and 2,6-dihydroxyanthraquinone, for example, was so low in supercritical carbon dioxide even at 2500 bar that the quantities extracted were insufficient for quantitative determination. The concentrations in compressed carbon dioxide were below 0.1 µg/Nl.

All the solid natural products tested exhibit the same characteristic sigmoid form of the solubility curve in the lower pressure range above 80 bar. The turning point is at about 90 bar; as the pressure increases, the slope becomes less steep. This course of the curve continues for all the substances tested until over 2000 bar. On the whole, the solubility curves resemble the density isotherms at 40 °C in their pressure dependence (cf. Fig. 1). This dependence of the solubility on the density of the gas is probably due to the fact that at higher densities more particles are available for solvation. As the density increases so too does the polarity (DC value), which is frequently cited for the solubility. The relationship is explained by the Clausius-Mosotti equation[12]. However, there is no linear relationship between the gas density and the dissolving power. If the logarithm of the substance concentration (for a wide variety of substances) in the compressed gas is plotted against the logarithm of the gas density, a direct proportionality is found in a pressure range of roughly 80 bar to 2000 bar (and higher). A few examples are shown in Figure 12.

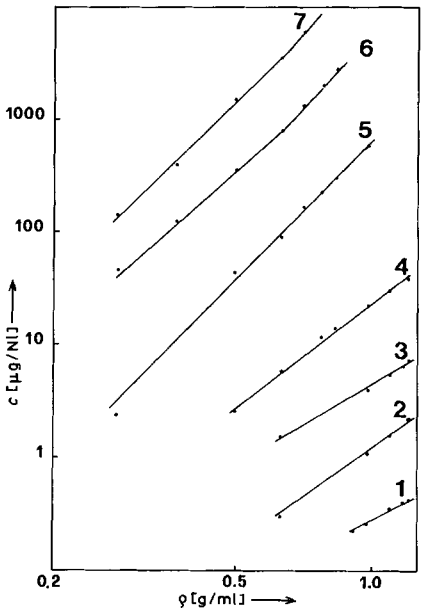

Fig. 12. Dependence of the solubility of a number of substances in carbon dioxide at 40 °C on the (pressure-dependent) density of the carbon dioxide. 1) Glycine, 2) frangulin, 3) emodin, 4) *p*-hydroxybenzoic acid, 5) 1,8-dihydroxyanthraquinone, 6) salicylic acid, 7) benzoic acid.

The solubility curves can be described by the simple straight-line equation:

$$\ln c = m \times \ln \rho + \text{const.}$$

The constants and the factor m contain characteristic quantities of the substance properties. The solubility of polar substances in supercritical carbon dioxide and nitrous oxide has proved to be so low that the expenditure necessary for an industrial extraction plant working at up to 2000 bar and higher cannot be justified. The situation is still less favorable in the case of extraction from plant material.

6. Discussion of the Results and Future Prospects

Summarizing the experience gained with our microscale methods for practical application, it can be said that fluid extraction with carbon dioxide will be largely restricted to lipophilic natural products. It is of particular interest that the gas densities are easily variable between 0.2 and 0.9 g/ml in the lower pressure range slightly above the critical temperature. This easily effected fourfold increase in density results in a sharp enhancement of the dissolving power and can be achieved in the region of the critical temperature by relatively small increases in pressure. Furthermore, by the reverse process it is also possible to achieve fractionating separation and hence a further concentration of specific substances. We made use of this effect, for example, to obtain camomile extracts

with a high concentration of matricin[13]. In order to evaluate extraction tests it will be particularly important to determine the solubilities quantitatively, and this too is possible with our method. In our view, solubilities of at least 1:500 to 1:1000 are needed if the fluid extraction process is to be applied on a technical scale.

A further problem that will continually arise is the presence of the material in complex samples. In this respect extractability can be hindered even mechanically by a type of microencapsulation. Furthermore, salts or strong hydrogen bonds may also be present. Some of these obstacles may be eliminated by suitable additives to the material for extraction. In this connection we are thinking, for example, of moistening the material and, if necessary, of adding ammonia. Also worth investigating is the influence of auxiliaries which, when mixed with the extraction gas, increase the dissolving power, *i.e.* improve the extractability. Greater attention will also be paid in future to competitive phenomena such as occur, for example, when the plant material is moistened. With the microextraction methods at our disposal it is relatively simple to investigate the extraction properties of other supercritical gases, ethylene and certain freons undoubtedly being of prime interest in this context.

New analytical methods (13)

Chromatography with Supercritical Fluids

By E. Klesper[*]

Chromatography with supercritical fluids unites the features of both gas chromatography and liquid chromatography, yet retains special characteristics of its own. The diffusion coefficient and particularly the viscosity of fluid phases may approach values for low-pressure gases, while the solvent power may be similar to that of liquids. However, with supercritical fluids it is possible to control chromatographic separations very effectively by pressure programming, since the solubility increases with increasing density. Temperature programming, on the other hand, can have the opposite effect to that in gas- or liquid-chromatography since the density decreases with increasing temperature at a given pressure. Supercritical fluid chromatography is primarily of interest for the separation of higher molecular weight compounds. The efficiency of this method of separation is demonstrated on several homologous series. Thus, a styrene oligomer with nominal $M_w = 2200$ can be resolved by a pressure and temperature program into 40 species.

1. Introduction

Substances of higher molecular weight do not have sufficiently high a vapor pressure to be able to be chromatographed with low-pressure gases as the mobile phase. However, if the gas pressure is increased considerably, *e.g.* to within the range of the critical pressure the mobile phase may assume sufficient "solvent power" to induce migration of even very high molecular weight substances on chromatographic columns. The temperature of the system is so chosen as to avoid liquefaction at a given pressure, *i.e.* it is generally kept above the critical temperature. The permanent gases frequently employed in gas chromatography, such as N_2, He, and Ar, develop only moderate "solvent power" at elevated pressures. Low-boiling solvents, however, including for instance CO_2, pentane, and isopropanol, which are thermally stable and unreactive with substrate and stationary phase, may be suitable solvents in the fluid state.

The "solvent power", of dense gases, particularly of solvents above their critical temperature, has long been recognized[1, 2] and has been reviewed on a number of occasions[3, 4]. Compressed gases, however, have been utilized only relatively recently for chromatographic separations[5–8], as in fact they have been for extraction purposes, or as reaction media.

Previous work in supercritical fluid chromatography has been carried out with low-boiling solvents above their critical temperature[9, 10], as well as with permanent gases[11, 12]. As a substrate, a wide variety of low vapor pressure compounds

Institut für makromolekulare Chemie der Universität
Stefan-Meier-Str. 31, D-7800 Freiburg (Germany)

[**] Based on a lecture delivered at the Symposium "Extraction with Supercritical Gases", June 6, 1978 in Essen (Germany).

have been studied, *e.g.* polycyclic arenes[13], higher *n*-alkanes[6], phthalates[14], cyclopentadienylmetal complexes[15], pentanedionatometal complexes[16], and numerous substances of biochemical interest, including *e.g.* porphyrins[17], sugars, amino acids and proteins[9]. In addition, oligosiloxanes[18] and oligostyrenes[19-21] have also been investigated.

Different modes of chromatographic separation have been reported, namely fluid-solid[13], fluid-liquid[14], and chromatography on gels[22]; a reprecipitation-redissolution mode of separation has also been proposed[20, 23]. Several apparatus for fluid chromatography have been described, relatively simple designs at first[5, 6], followed by devices of higher capabilities[8, 9, 14, 24, 25], including those which allow temperature and pressure programming[18, 23, 26]. Detectors suitable for supercritical fluid chromatography have also been a matter of important concern[27].

The basic principles of supercritical fluid chromatography have been investigated by several groups. Thus, solubilization in compressed gases has been studied and discussed[9, 28, 29] and a series of pertinent phase diagrams have been determined[30-34]. Other investigations have been concerned with pressure induced equilibrium shifts[35], nonideality in dense gases[12], capacity ratios[6, 36], and modified van Deemter equations applied to supercritical fluid chromatography[28, 37, 38].

2. Supercritical Fluids

Table 1 lists some of the low-boiling substances which may be expected, in their supercritical dense state, to dissolve specific classes of compounds, including those of relatively high molecular weight[10, 26]. Others may be added[9], and still others may be considered, such as dimethylether, trimethylamine and tetrahydrofuran.

Table 1. Properties of some compounds which may be suitable for chromatography with supercritical fluid phases.

	B.p. [°C] at 1 atm	Critical data T_c [°C]	P_c [atm]	ρ_c [g/cm³]

Dichlorofluoromethane	8.9	178.5	51.0	0.522
Trichlorofluoromethane	23.7	196.6	41.7	0.554
1,2-Dichlorotetrafluoroethane	3.5	146.1	35.5	0.582
Chlorotrifluoromethane	−81.4	28.8	39.0	0.58
Nitrous oxide	−89	36.5	71.4	0.457
Diethyl ether	34.6	193.6	36.3	0.267
Ethyl methyl ether	7.6	164.7	43.4	0.272

As an approximation, the solvent power of a solvent may be assessed by the solubility parameter $\delta = \sqrt{\Delta H/V}$, where ΔH is the heat of vaporization and V the molar volume[39]. Proceeding to a supercritical dense gas, the solubility parameter may be written

$$\delta = 1.25\, P_c^{0.5}(\rho_{r,g}/\rho_{r,l}) \quad (1)$$

where P_c is the critical pressure, $\rho_{r,g}$ the reduced density of the gas, and $\rho_{r,l}$ the reduced density of the liquid of a given mobile phase[7, 39]. If it is presupposed that the solubility parameters of the fluid and the solute should be about equal for good solubility, one may estimate which supercritical dense gas and which density $\rho_{r,g}$ would be suitable for a given substrate. However, the usual qualifications[7, 39] for the validity of the solubility parameter concept will probably also apply for dense gases. In particular, specific solvent effects for polar and hydrogen bonding solvents can be of considerable importance.

An increase in the density of the supercritical mobile phase results in a higher solubility parameter; higher δ values are usually needed for substances of high molecular weight. However, it is the lower density of the supercritical fluids as mobile phase, compared with the density of liquids below their boiling points, which forms the basis for a potentially higher chromatographic efficiency of fluids. This prediction is supported by the typical properties of low-pressure gases, liquids and supercritical fluids[10] given in Table 2.

Table 2. Physical properties of gases, liquids, and supercritical fluids [10].

Property	Symbol	Units	Gas	Liquid	Supercritical fluid phase
Density	ρ	[g/cm³]	10^{-3}	1	0.3
Diffusivity	D	[cm²/s]	10^{-1}	5×10^{-6}	10^{-3}
Dynamic viscosity	η	[g cm^{-1} s^{-1}]	10^{-4}	10^{-2}	10^{-4}

The data are only approximate, but they demonstrate that the diffusivity of a fluid is between that of a gas and a liquid, while the viscosity more closely approximates that of a gas. Since the diffusivity and viscosity, as well as the packing geometry, govern the radial mass transport of the mobile phase in columns, correspondingly small theoretical plate heights (HETP) should be attainable. It is assumed, of course, that the diffusivity of the substrate shows almost similar behavior to that of the fluid. The low viscosity with increasing density also leads to higher Reynolds numbers $R_{e,p} = (d_p \bar{v} \rho)/\eta$ than in the case of liquids. The Reynolds number $R_{e,p}$ is related to the particle size d_p, $\bar{v}$ is the average linear velocity of the mobile phase, ρ the density and η the dynamic viscosity[38]. In the case of fluids the ratio ρ/η may exceed 10^3 s cm^{-2}, while in the case of liquids and gases it is one and two orders of magnitude lower, respectively. Reynolds numbers above 10 lead to turbulence in packed beds, increasing further the radial mass transport and relaxing flow profiles.

It should be pointed out that it is not actually the density of a fluid which is intimately connected to dissolution power, viscosity, and diffusivity, but the free volume of the fluid,

combined with molecular geometry and specific interactions between fluid and substrate. It appears that the free volume should be kept as high as is compatible with the necessary dissolution power. Besides the solubility and free volume, the temperature is also of importance in fluid chromatography, since the decomposition temperature of the substrate may not be exceeded. Also, an operating temperature well above the critical temperature might be of advantage; the isotherms in the pressure-density diagram (Fig. 1) show very high compressibilities near the critical temperature, indicating a similarity to the liquid state. Raising the temperature will decrease η and increase D. Furthermore, an operative advantage is lost in this region of high compressibility, since a pressure programming, aimed at a steady and increasingly slower rise in density, is made difficult.

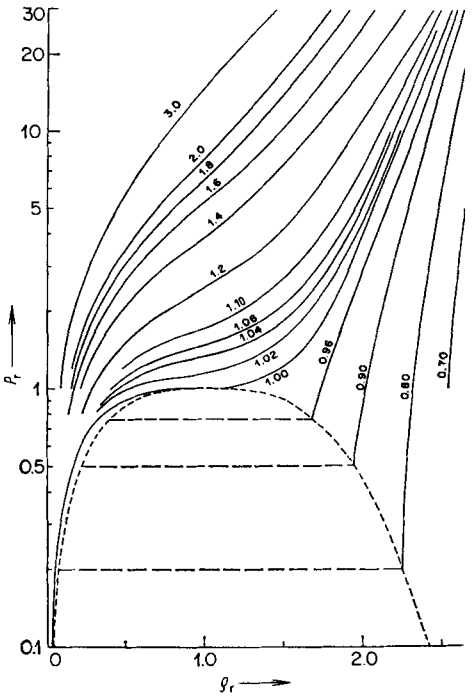

Fig. 1. Plot of reduced pressure P_r *versus* reduced density ρ_r, with reduced temperature T_r as parameter. Two phase region bordered by dashed curve (after [7]).

3. Instrumentation

An obstacle to the development of supercritical fluid chromatography was the lack of an apparatus allowing independent control and programming of the instrumental parameters for the separation, *i.e.* pressure, temperature, flow rate, and composition of the mobile phase. Furthermore, a detector was required which could operate at elevated pressures and which, if possible, was also insensitive to pressure changes. The latter is particularly important with pressure programming. The apparatus shown in Fig. 2 has been constructed bearing these objectives in mind[120, 23]. The characteristic design feature is a pressure cascade of three levels. Each pressure level is controlled by an electronic feedback loop system.

The feedback loop (13) (see Fig. 2) allows the programming of pressure for the chromatographic column (6) while the column oven (4) may be simultaneously and independently temperature programmed with (11). During any pressure and temperature changes for the column, the feedback loop (12)

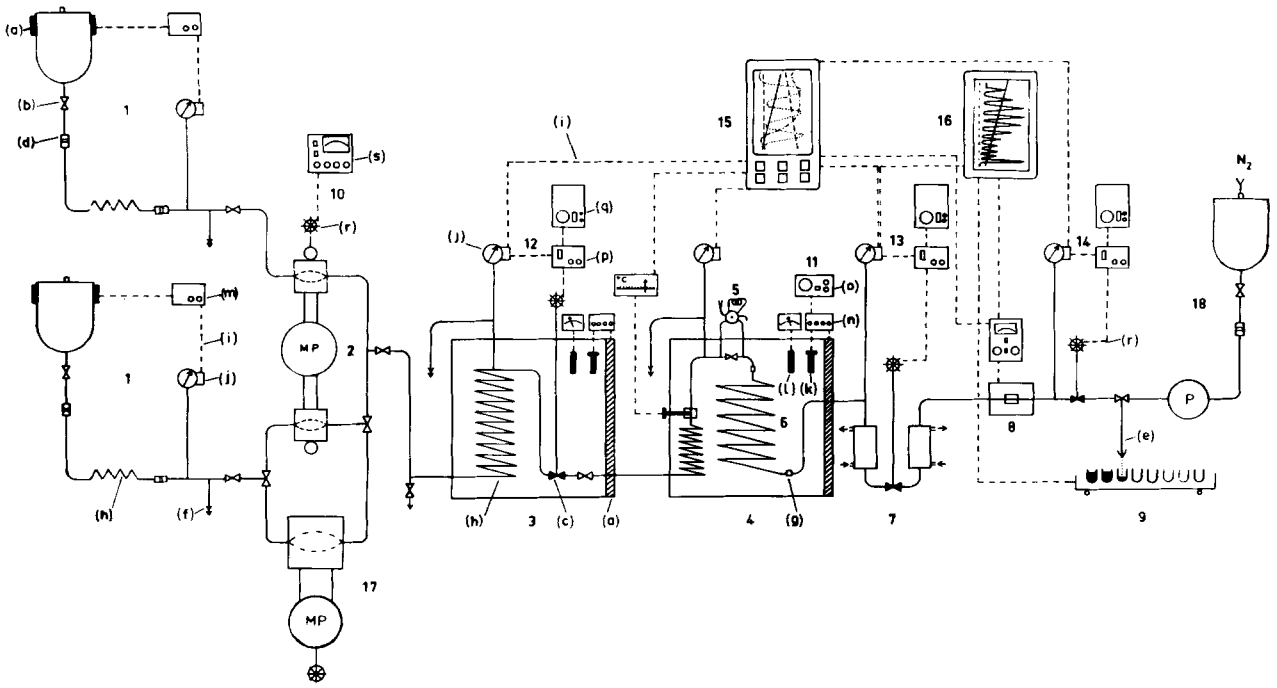

Fig. 2. Supercritical fluid chromatograph. Sections of the apparatus which are marked by numerals are explained in the text. Key to symbols: (a) heating element; (b) shut off valve; (c) metering valve; (d) sintered metal filter; (e) exit; (f) exit with safety head containing a burst disc; (g) column connection; (h) coil of tubing; (i) electrical connection; (j) manometer device; (k) thermoelement; (l) mechanical mercury manometer; (m) relay for heating current; (n) temperature controller; (o) temperature programmer; (p) controller of feedback loop; (q) programmer of feed back loop; (r) stepping motor for controlling either the feed rate of a pump or driving the shaft of a metering valve; (s) programmer for feed rate.

keeps the pressure of the supply unit (1, 2, 3) at a constant and higher level, easing programming of feed rate and of composition of the mobile phase (10). In the supply unit, a double-headed membrane pump (2), capable of 500 bar, allows solvents to be fed from two tanks (1) simultaneously and to enter the oven (3) together. In oven (3) a constant supercritical temperature is maintained; pulsations are smoothed out by the buffering volume of a large diameter coil. An extra pump (17) allows pressures of up to 3000 bar to be reached.

The supercritical mobile phase from oven (3) enters oven (4) and first passes through a temperature conditioning coil and a sample injection device (5) before entering the chromatographic column (6). The eluate from the column is liquified again by passage through two heat exchangers (7), then passes through the UV-detector (8) and, in cases when the boiling point of the mobile phase is below room temperature, is taken up by an auxiliary solvent system (18) before finally being collected in the fraction collector (9). The detector unit (7, 8) is kept at a constant pressure by the feedback loop (14), the pressure being kept sufficiently high to exceed the vapor pressure of the now liquid mobile phase at room temperature. The detector recordings and column pressure recordings are traced out by recorder (16), while those of the temperature of the column oven (4) and the mobile phase itself, as well as those of other operating parameters, are monitored by recorder (15).

4. Separations

With the chromatograph described in Section 3, oligostyrenes *(1)* prepared by anionic initiators and having an average molecular weight $\bar{M}_w = 900$ were separated on porous silica with 90% *n*-pentane/10% methanol (v/v) as mobile phase. The chromatogram obtained is shown in Figure 3.

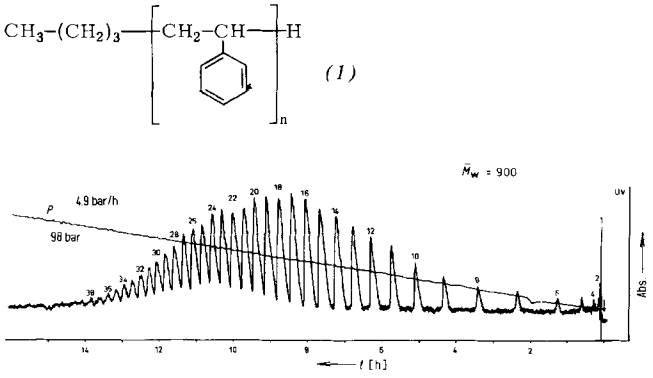

Fig. 3. Chromatogram of styrene oligomer (1) of nominal $\bar{M}_w = 900$. Mobile phase is 90% *n*-pentane and 10% methanol (v/v), feed rate: 1.9 ml/min (NTP), stationary phase: Porasil A (porous silica, Water Associates) particle diameter: 37—75 µm, pore size: < 100 Å. Sample size: 20 mg in 100 µl cyclohexane solution. $T = 235$ °C. The number of peaks corresponds to the degree of oligomerization (after [23]).

The time of sample injection is marked by an arrow. The sloping line *P* represents the column exit pressure, which is programmed with the feedback loop at the column exit [(13) in Fig. 2]. The pressure rises linearly at a rate of 4.9 bar/h, starting at 25 bar and reaching 98 bar after 15 h. The temperature is kept constant at 235 °C, well above the estimated critical temperature of the mixture [T_c(mixture) ≈ 207 °C; T_c(pentane) = 196.6 °C; T_c(methanol) = 240 °C]. The pressure drop of $\Delta P = 300$ bar over the 2 mm-ID column is considerable, due to the small particle size of the packing. As shown in Figure 3 the oligomeric species up to a degree of oligomerization of $n = 38$ were separated. With an oligostyrene of $\bar{M}_w = 2200$, peaks up to $n = 50$ could even be resolved. A smooth increase in pressure during the chromatographic runs is, however, essential for good resolution.

Without any increase in pressure—whether continuous or in steps—only a part of the oligomers may be eluted and resolved[23]. Even changing the speed of the pressure program affects the separation profoundly, as is demonstrated in Figure 4.

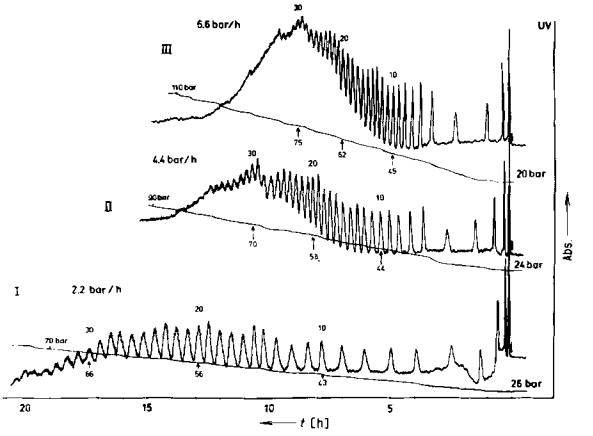

Fig. 4. Chromatograms of styrene oligomer *(1)* of nominal $\bar{M}_w = 2200$. Linear pressure program with differing rates of increase in pressure. Pressure drop over column: 25 bar. Mobile phase: 95% *n*-pentane/5% methanol (v/v), stationary phase: Porasil A, sample size: 40 mg in 100 µl cyclohexane solution, column: 6 m × 3 mm, $T = 220$ °C. Trace III: 6.6 bar/h increase, 2.6 ml/min; trace II: 4.4 bar/h increase, 3.0 ml/min; trace I: 2.2 bar/h increase, 3.2 ml/min. The number of peaks corresponds to the degree of oligomerization. The numbers below the arrows indicate the elution pressure for peaks 10, 20 and 30 (after [23]).

Increasing the pressure at a rate of 6.6 bar/h leads to far inferior resolution than when the increase in pressure is programmed at 2.2 bar/h, while at 4.4 bar/h an intermediate resolution is achieved. Naturally, improved resolution is coupled with a decrease in unresolved "background". A similar effect on pressure programming has also been observed with oligosiloxanes[18]. Comparing the pressures (Fig. 4) at which the same peak is eluted, and noting that the flow rates do not differ greatly, it would appear that the elution pressure is more important than elution volume. For comparison the elution pressures for peaks 10, 20, and 30 have been marked on the curves of the pressure programs. An analogous result is obtained when the pressure program is kept unchanged and the flow rate is varied. Elution pressure determines elution time more than elution volume.

Besides pressure, the temperature also has a major influence on the separation of the styrene oligomers on porous silica with *n*-pentane/methanol. From Figure 5 it can be seen that the resolution decreases rapidly with decreasing temperature as soon the temperature falls below T_c.

The pressures, even at the start of the chromatograms, are high enough to maintain the mobile phase in the liquid, rather than in the vapor state. If, however, temperatures

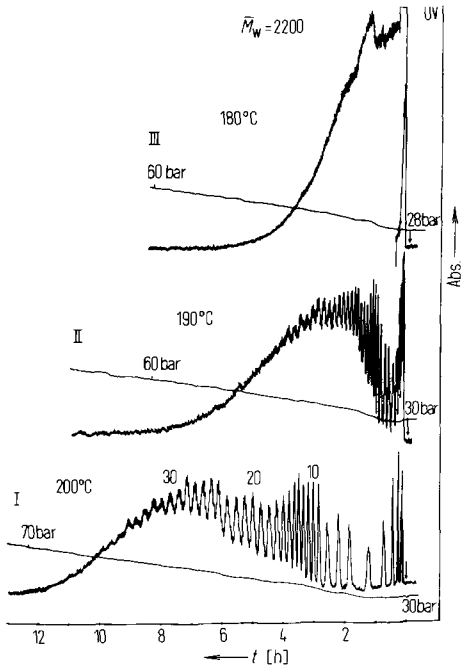

Fig. 5. Chromatograms at different temperatures below or near T_{cr}: at 180, 190 and 200°C. Similar pressure programs with 3.3 bar/h increase. Mobile phase: 95% *n*-pentane, 5% methanol, flow rates: 2.8 ml/min (trace III) 3.0 ml/min (trace II), and 2.8 ml/min (trace I): Other conditions as in Fig. 4 (after [23]).

approach T_c and then are raised above T_c, the resolution increases progressively, as shown in Figure 6. It may be concluded, therefore, that for best resolution the operating temperature should well exceed the critical temperature.

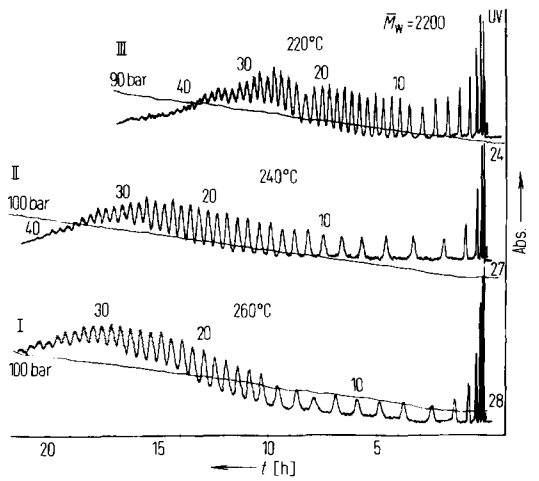

Fig. 6. Chromatograms at different temperatures above T_c: at 220, 240 and 260°C. Pressure program as in Fig. 5. Mobile phase: 95% *n*-pentane, 5% methanol. Flow rates: 2.75 ml/min (trace III), 3.0 ml/min (trace II) and 3.3 ml/min (trace I). Other conditions as in Fig. 4 (after [23]).

Since, for higher degrees of oligomerization, better resolution with simultaneous disappearance of unresolved background is desirable, a temperature program has been carried out simultaneously with the normal pressure program. For the chromatogram in Figure 7 the temperature first reaches 220°C only after 13 peaks have been eluted, thus reserving the higher temperatures up to 260°C for the higher oligomeric species. The resolution of the latter peaks appears to be better than in isothermal chromatograms. An increase in temperature at constant pressure reduces the density. This may lead to a slower increase in solubility with a given pressure program.

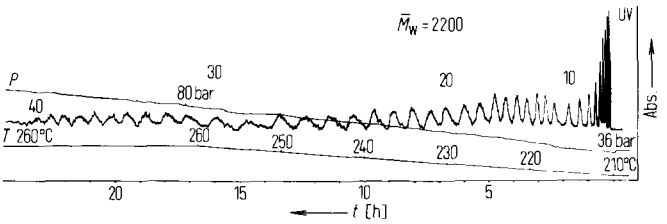

Fig. 7. Chromatogram with combined pressure and temperature program. Mobile phase: 95% *n*-pentane, 5% methanol at a flow rate of 4.2 ml/min. Pressure program starting at 36 bar and increasing linearly with 2.2 bar/h. Temperature program starting at 210°C and increasing linearly with 3°C/h up to 260°C. Other conditions as in Fig. 4 (after [23]).

A change in the composition of the mobile phase, by varying the amount of methanol, also has a large influence on the separation. Pure *n*-pentane without methanol shows smaller retention times and inferior resolution than *n*-pentane with 5% methanol (Fig. 8). It can be concluded, therefore, that adsorption on silica gel is not the dominant mechanism of this separation, for retention times should be decreased on addition of methanol on account of competitive adsorption and non-solubility of oligostyrenes in the methanol which is adsorbed on the surface. On using 10% methanol, the retention times are further increased, possibly because of the decrease in solubility power of the mobile phase. Consideration of this result, together with the fact there is always a pressure drop over the column, would suggest the mechanism of separation to be a reprecipitation-redissolution process for the zones of substrates migrating down the column. The pressure drop and the low initial pressure at the column exit lead to precipitation of the injected oligostyrenes. The pressure program then slowly raises the solubility, moving different oligomeric species by continuous reprecipitation-redissolution with different speeds down the column. In this connection, the experimental finding of a rather sharp threshold pressure of solubility for numerous substances is of interest, *i.e.* on exceeding a certain

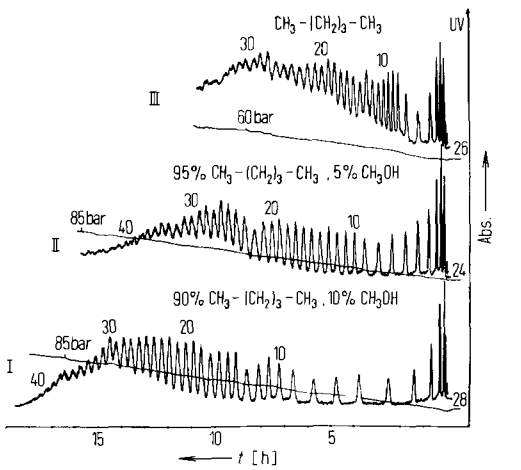

Fig. 8. Chromatograms, with variation of the methanol content of the mobile phase. Rate of pressure increase 3.3 bar/h. Trace III: 100% *n*-pentane, 3.1 ml/min; trace II: 95% *n*-pentane/5% methanol, 2.75 ml/min; trace I: 90% *n*-pentane/10% methanol, 3.1 ml/min. Other conditions as in Fig. 4 (after [23].

pressure, the substances become soluble in the supercritical phase[9]. This type of behavior is also reflected in the capacity ratios k' of columns which probably function by fluid-liquid partition[34]. The capacity ratio is defined by

$$k' = \frac{c''}{c'} \cdot \frac{V''}{V'} = K \cdot \frac{V''}{V'} \qquad (2)$$

where c'' and c' are the concentrations of substrate in the stationary ('') and the mobile phase ('), V'', V' the volumes of these phases and K the partition coefficient. The data for 4 higher molecular weight hydrocarbons are shown in Figure 9[36].

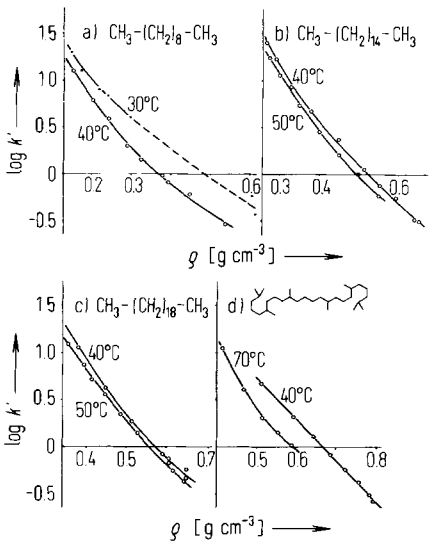

Fig. 9. Density and temperature dependence of capacity ratio k' for hydrocarbons in CO_2. Stationary phase: chemically bonded Carbowax 400 on silica gel (Durapak, 100—200 mesh, Waters Associates). Column dimensions: 2 m × 1.4 mm ID, flow rate: 0.5 $dm^3\,min^{-1}$ (NTP), sample size: 0.2 mm^3, no pressure program (after [36]).

Changing the density of the supercritical CO_2 by 0.01 g/cm^3, *i.e.* by changing the pressure by only about 2 bar, alters the capacity ratio k' by up to one order of magnitude. Hence, a relatively small increase in pressure, if in a critical range, will suffice to start movement of a substrate zone on a chromatographic column.

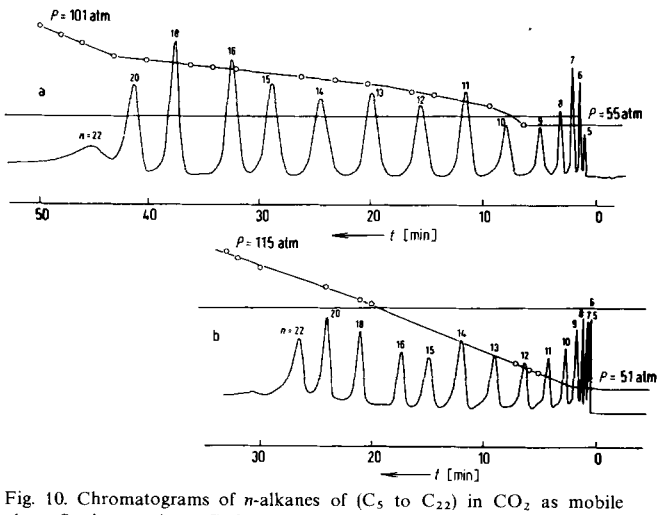

Fig. 10. Chromatograms of *n*-alkanes of (C_5 to C_{22}) in CO_2 as mobile phase. Stationary phase: Carbowax 400 bonded on porous silica gel (Porasil C). a) 40 °C, 1 l/min (NTP), slow pressure program; (b) 50 °C, 2 l/min (NTP), fast pressure program. Column: 3 m × 1.7 mm I D (after [28]).

A number of other homologous series, besides oligostyrenes, have been used as test cases for studying resolution in supercritical fluid chromatography. Figure 10 shows two chromatograms of a series of *n*-alkanes from C_5 up to C_{22} with CO_2 as the mobile phase and pressure programming. The homologous species are well separated, even with increased flow and enhanced rate of increase of pressure (Fig. 10b). Satisfactory separations have also been achieved without a pressure program, *e.g.* with a homologous series of di-*n*-alkyl phthalates[14] using isopropanol as the mobile phase (Fig. 11). If

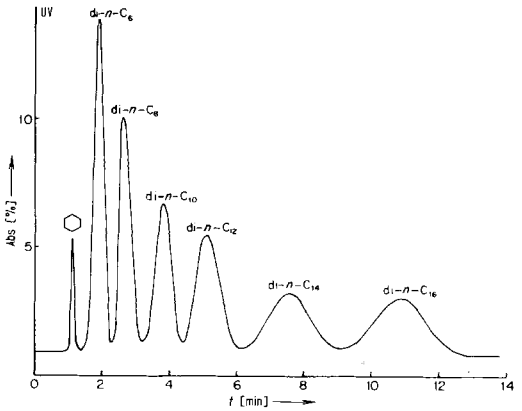

Fig. 11. Chromatogram of di-*n*-alkyl phthalates in isopropanol as mobile phase. Stationary phase: alkathene (10 wt-%) on Sil-O-Cel (firebrick), 50/70 mesh. $T = 245\,°C$, $P = 49.5$ bar. Column: 2 m × 6 mm ID (after [14]).

the members of the series with an odd number of C-atoms in the alcohol component (di-*n*-C_9, di-*n*-C_{11}...) had also been present, the resolution would naturally have been less satisfactory. However, a pressure program may be assumed to have improved the resolution and the peak width of the higher members of the series.

5. Basic Considerations

The usefulness of supercritical fluid chromatography, like that of other chromatographic techniques, depends on the resolution R. Hence, probably the most important single equation in chromatography is

$$R = \frac{1}{4} \cdot \frac{\alpha - 1}{\alpha} \cdot \frac{k'_2}{1 + k'_2} \cdot \sqrt{N} \qquad (3)$$

which links R with other fundamental chromatographic parameters

$$\alpha = \frac{k'_2}{k'_1} = \frac{K_2}{K_1}; \quad k'_2 > k'_1 \qquad (4)$$

where the subscripts 1 and 2 refer to two different compounds whose resolution is in question, and k' and K are the capacity ratios and partition coefficients, respectively [Eq. (2)]. The number of theoretical plates N is given by $N = L/H$, where L = column length and H = height of a theoretical plate. The second term $(\alpha - 1)/\alpha$ requires that $\alpha > 1$. This must be achieved by proper choice of mobile fluid and stationary phase, otherwise no resolution is obtainable even with a high number of theoretical plates. The third term $k'_2/(1 + k'_2)$ changes very

little at $k'_2 > 20$. However, in fluid chromatography k' might become rather small if the pressure is raised too high.

Homologous series are suitable test cases to determine whether $\alpha > 1$ can be achieved, since neighboring members become progressively closer in physical properties on proceeding to higher members of the series. In Figure 12 the k' values of propane, *n*-butane, and *p*-pentane, as measured on a silica/squalane column with CO_2 as the mobile phase, are given as a function of pressure[6].

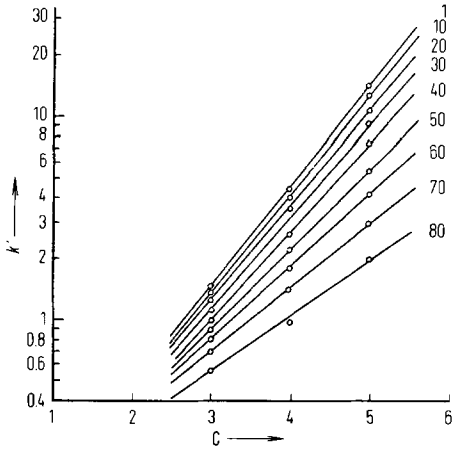

Fig. 12. Capacity ratios k' of *n*-alkanes with 3, 4 and 5 carbon atoms in CO_2 as mobile phase, plotted with the pressure P_{CO_2} (in kp/cm²) as parameter. Stationary phase: squalane on Sil-O-Cel, 50/70 mesh. $T = 40$ °C. Column: 1 m × 6 mm ID (after [6]).

The graph shows that the differences in k' between neighboring species are considerable in an isobaric operation and that they are still sufficient to enable separation of these compounds on using an upward pressure program of reasonable rate. Analogous conclusions can be drawn for isobaric runs from the measured capacity ratios of the *n*-paraffins up to C_{13} (Fig. 13)[40].

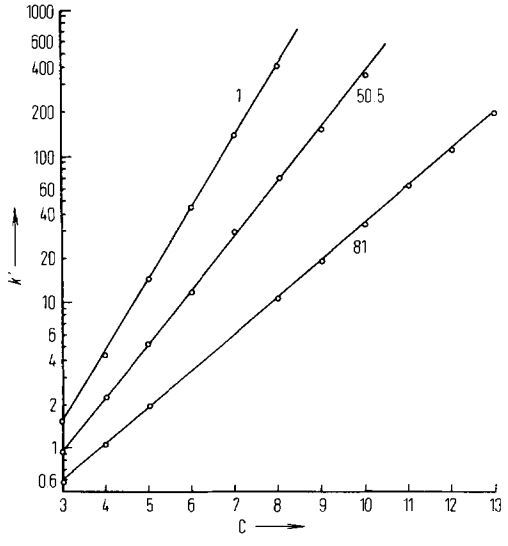

Fig. 13. Capacity ratios k' of *n*-alkanes with 3 to 13 carbon atoms in CO_2 as mobile phase at 40 °C, plotted with pressure P_{CO_2} (in kp/cm²) as parameter. Stationary phase: 23 wt-% squalane on Sil-O-Cel. 50/70 mesh. (after [40]).

If $R = 1$ suffices one obtains from Eq. 3 and values for $(\alpha - 1)/\alpha$ between 0.50 and 0.70 and for $k'_2/(1 + k'_2)$ between 0.5 and 0.9 a value for N which is between 50 and 300 theoretical plates. This number of plates is not difficult to achieve with column lengths of 2 or 3 m (cf. Figs. 15 and 16).

Measuring the k' values for a series of di-*n*-alkyl phthalates using different combinations of stationary and mobile phases indicated favorable α-values when a nonpolar stationary phase (Alkathene, a low molecular weight polyethylene) was employed in conjunction with a polar mobile phase (isopropanol) at 245 °C between 30 and 49.5 bar[14]. In contrast, on using a polar stationary phase (polyethylene glycol 6000) in conjunction with a nonpolar mobile phase (*n*-pentane) at 213 °C and pressures between 35 and 44.9 bar, smaller α-values were obtained. On investigating the latter combination of phases, the temperature dependence of k' at 35 bar revealed, however, a strong variation of α with temperature (Fig. 14)[14].

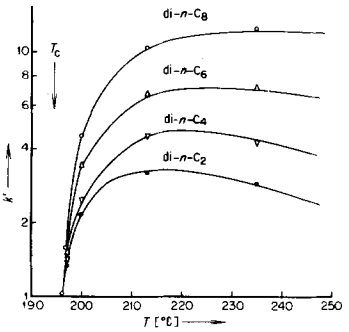

Fig. 14. Capacity ratios k' of di-*n*-alkyl phthalates with 12—24 carbon atoms plotted as function of temperature. Stationary phase: polyethylene glycol 6000 (≈23 wt-%) on Sil-O-Cel, mobile phase: *n*-pentane at 35 kp/cm² (after [14]).

A similar series of measurements at constant density instead of at constant pressure is called for in order to determine whether this is in part an effect of temperature and not primarily of a change of density with temperature.

The number of theoretical plates, N, is inversely proportional to the plate height H. Therefore the peak-broadening mechanisms which oppose resolution might be discussed in terms of H. In Figure 15 a plot of H *vs* the average interstitial linear velocity of the mobile phase, $\bar{v}$, is shown for CO_2 as the mobile phase and *N*-pentane as the substrate[38]. The plate heights are seen to increase strongly with $\bar{v}$ and with pressure. The increase with pressure, however, becomes smaller above 30 bar. Customarily, H is expressed in the form of the van Deemter equation:

$$H = A + \frac{B}{\bar{v}} + C\bar{v} \qquad (5)$$

By extrapolation of the high velocity part of the curves to $\bar{v} = 0$ it is likely that $A > 0$. On the other hand, A is not the major contributor to H at higher $\bar{v}$. The same holds true for $B/\bar{v}$, which in gas chromatography gives rise to a minimum in the curve, small remainders of which are seen in the 5 and 10 bar curves. Hence, it is the term $C\bar{v}$ which renders the largest contribution to H at already moderate $\bar{v}$.

Equation 5 may be written in full as[41,42]:

$$H = 2\lambda d_p + \frac{2\gamma D_m}{\bar{v}} + \left\{ 2\frac{k'_2}{(1+k'_2)^2} t_s + \frac{\omega \cdot d_p^2}{D_m} \right\} \bar{v} \qquad (6)$$

where λ = packing correction factor (≈ 0.5), d_p = particle diameter, γ = tortuosity factor (≈ 0.7), D_m = solute diffusion coefficient in the mobile phase, t_s = mean residence time of the solute molecule in the stationary phase, after leaving and re-entering the mobile phase, and ω = a flow path dependent term.

The first term (A) in Eq. (6) accounts for the longitudinal convective mixing as a cause of peak-broadening. This mixing is due to the interstitial flow pattern and is velocity independent. The second term $B/\bar{v}$ describes the longitudinal diffusion as a cause of peak broadening. Since the relative magnitude of D_m is small and $\bar{v}$ is usually relatively large, the second term can probably be neglected in many cases, a view which is supported by Figure 15. The third term ($C\bar{v}$) consists of

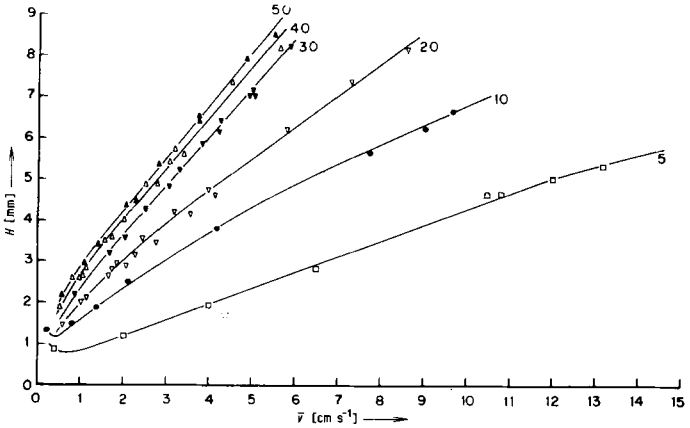

Fig. 15. Plate height H as a function of the velocity $\bar{v}$ of the fluid phase CO_2 at 40 °C, plotted with P_{CO_2} (in kp/cm^2) as parameter. Stationary phase: squalane on Sil-O-Cel, 50/70 mesh. Substrate: n-pentane (after [38]).

two additive components. The first accounts for nonequilibrium in radial transport of the substrate between mobile and stationary phase. It becomes small when k' is large as well as when t_s is small, *i.e.* when there is a high rate of solute transfer from and to the stationary phase. For these conditions, a pressure as small as possible and a temperature as high as possible, together with as thin a layer of stationary liquid as possible on the carrier particle may be of advantage. The second component of C may be looked upon as due to the hindered diffusive and convective radial transport of the substrate in the

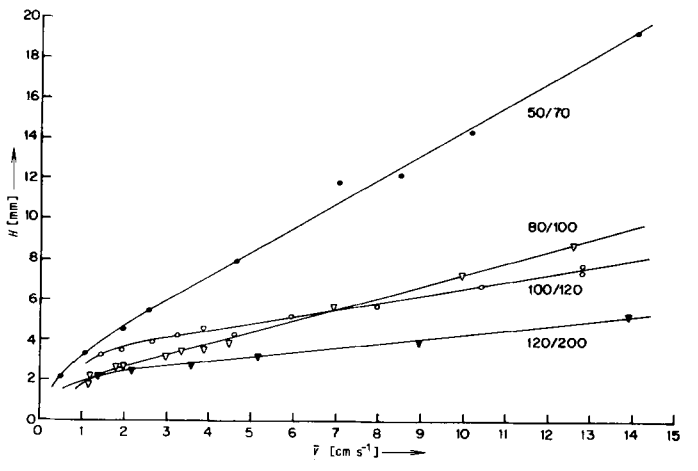

Fig. 16. Plate height H as a function of the velocity $\bar{v}$ of the fluid phase CO_2 at 40 °C and 57 kp/cm^2, plotted with the particle diameter d_p (in mesh) as parameter. Stationary phase: squalane on Sil-O-Cel. Substrate: n-pentane (after [38]).

mobile phase between the different velocity regimes within the interstitial flow pattern. Here a small particle size, higher temperature, and probably turbulent flow is of advantage. The high diffusion coefficients and the low viscosities previously discussed are important for both components of C, because they will lead to a decrease in t_s and ω.

It has been shown[38] by changing the particle diameter d_p that the second component of C is in fact the most important at higher pressures and velocities, at least for porous particles. In Figure 16 it is shown that a reduction in d_p, with other conditions being kept equal, leads to a large decrease in H. With the smallest particle diameter, other contributions to H are negligible, apart from the contribution of the A-term[38].

6. Outlook

A glance at the literature reveals an ever-increasing interest in the technique of chromatographic separation with supercritical fluid phases and in the development and design of more sophisticated, yet reliable and easily manipulated equipment, as are available commercially for gas- and liquid chromatography. Essential requirements are apparatus which enable automatic pressure control and programming as well as the usual temperature programming presently employed in gas-chromatography.

Research effort is also being directed to investigations on the influence of the type of mobile phase on dissolution and other relevant chromatographic parameters, *e.g.* in the series propane to hexane. It is to be expected that the mobile phase plays a more significant role in chromatography with supercritical fluid phases than in, say, gas-chromatographic separations. In this connection the possibilities arising from high Reynolds numbers and thus turbulent flow ought to be checked regarding their practical utility for increasing the efficiency of separation. Moreover, no investigations have, as yet, been performed with composition gradients of binary mobile phases.

Conventional stationary phases as used in gas and liquid chromatography, and newly developed ones including bound phases and porous layer beads should be examined more thoroughly with regard to their performance in fluid chromatography. Apart from conclusions based on analogies, it is not yet apparent which stationary phases are best suited for chromatography with supercritical fluid phases. Particle size and interparticle volume should, however, be considerably smaller than for gas chromatography.

The effects of pressure gradients along the separating column represent a methodological characteristic of fluid chromatography. No such pronounced effect of pressure gradient on the solvent power and other properties of the mobile phase is observed in gas- or liquid chromatography. This feature of chromatography with supercritical fluid phases should be explored for improving separations.

A recent development will also be utilized, *viz.* selective extraction with fluid phases, followed by normal thin-layer chromatography for identification and further resolution[43].

We are grateful to the Arbeitsgemeinschaft Industrieller Forschungsvereinigungen for financial support.

The Separation of Nonvolatile Substances by Means of Compressed Gases in Countercurrent Processes[**]

By Siegfried Peter and Gerd Brunner[*]

Mixtures of nonvolatile and heat-sensitive substances can be separated by means of compressed gases in countercurrent processes. Moreover, such separations can be carried out at lower temperatures than in vacuum distillation. Addition of an entrainer enables alteration of the relative volatilities of the components. That such a method of separation is feasible on a large scale is illustrated using as example the separation of monoglycerides from a mixture of oleic glycerides at *e.g.* 110°C/135 bar. Propane is used as compressed gas, and acetone as entrainer.

1. Introduction

It has been known since the work of *Hannay* and *Hogarth*[1] in 1879 that compressed gases dissolve substances of low volatility. In industry it was the unfavorable aspects of this phenomenon that first manifested themselves. During the development of high-pressure hydrogenation it was observed, for example, that lubricating oil dissolved in the compressed gas led to diminished lubricating efficiency. Furthermore, the dissolved oil caused problems in subsequent processes. The use of increased operating pressures in power stations led to dissolution of salts in high-pressure steam. These salts precipitate on the turbine blades as the high-pressure steam expands. During the production and processing of oil it proved necessary to carry out detailed investigations on retrograde and anomalous vaporization, both experimentally as well as theoretically.

It is understandable, therefore, that the first proposals to utilize the phenomenon of solubilization in compressed gases as the basis of a separating process came from the petroleum industry. *Messmore*[2] in 1943 was perhaps the first to propose the use of supercritical hydrocarbons at high pressures for the deasphalting of oil. In 1955 *Zhuze* and *Kapelyushnikov*[3] described a process for removing resin from crude oils by means of supercritical propane at high pressures. In 1958 *Zhuze, Jushkevic* and *Gekker*[4] patented a process for the extraction of lanolin from wool grease. In the past two decades several separation processes involving the use of compressed gases have been proposed, *e.g.* the removal of caffeine from

raw coffee by *Zosel*[5] in 1964, the production of spice extracts by *Vitzthum* and *Hubert*[6] in 1972, and the extraction of coal by *Whitehead* and *Williams*[7] in 1975.

The efficiency of a separation with compressed gases as solvent can be increased considerably in multistage countercurrent processes. *Zosel*[8] suggested such a procedure using conditions under which solubilization in the compressed gas decreases with increasing temperature, while *Ellis*[9] has discussed a process involving refluxing part of the nonvolatile material separated from the gas stream.

The efficiency of a multistage process can be increased still further by using an entrainer. The solubility can be increased and the nonvolatile substances can be removed from the compressed gas without expansion and recompression[10].

It will be shown, using as example the separation of the monoglycerides from a mixture of oleic acid glycerides, that a countercurrent process using compressed gases is technically feasible. In addition the economic aspects of the process will be discussed.

2. Physical Principles

For selection of suitable operating conditions, the phase equilibria of the relevant systems have to be known as a function of pressure, temperature and concentration of the different components. Under suitable conditions the concentration of the nonvolatile components can be increased by a factor of more than 10^{10} over that expected from vapor pressure data. Results obtained during investigation of the solubility of oleic acid in supercritical ethylene, are shown in Figure 1. The relative increase in concentration (= apparent increase in vapor pressure) of oleic acid is plotted against density on a logarithmic scale; some isobars and isotherms are shown. The relative increase in concentration of oleic acid increases with increasing density of the compressed gas up to a value of 10^9, approaching the critical point. The effect is primarily due to interaction forces between the molecules of oleic acid and those of the ethylene.

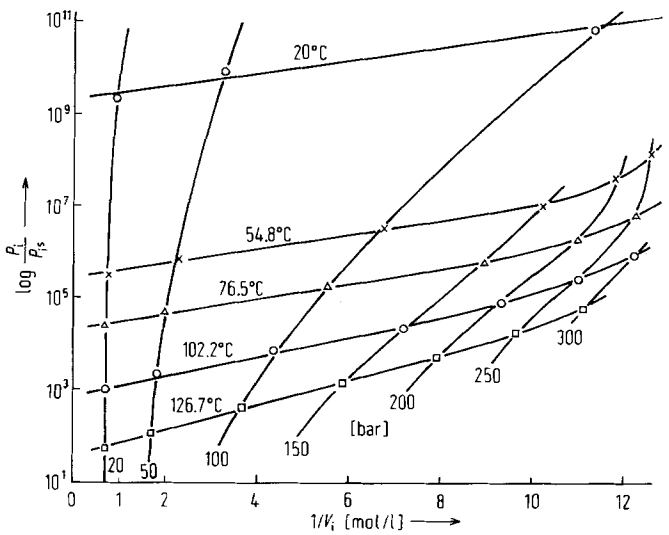

Fig. 1. Relative increase in concentration (P_i/P_{i^0}) of oleic acid in the gas phase as a function of density of the compressed gas in the system oleic acid/ethylene.

The effect of temperature on the solubility of a substance in a compressed gas changes with pressure. This can be seen from Figure 2, which shows the solubility of naphthalene in compressed ethylene as a function of temperature at different pressures as recorded by *Tsekhanskaya*, *Yomtev* and *Mashkina*[11]. Slightly above the critical temperature of the compressed gas, a rise of temperature at moderate pressures results in a decrease of solubility of the difficultly volatile component. At high pressures, a rise in temperature causes an increase in the solubility. This behavior can be understood, if the density of the compressed gas is considered as decisive for the solubility of the nonvolatile component in the gaseous phase.

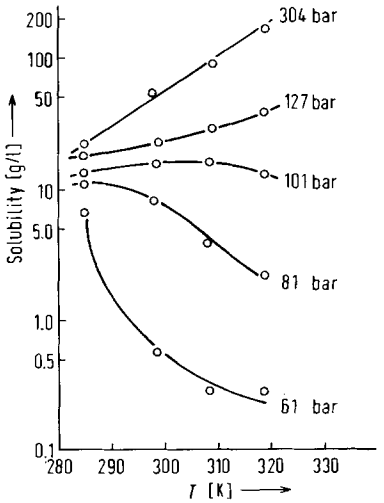

Fig. 2. Solubility of naphthalene in compressed ethylene *vs.* temperature at various pressures.

A rise in temperature at constant pressure leads, on the one hand, to a decrease in density of the compressed gas, and, on the other, to an exponential increase in the vapor pressure of the nonvolatile components. Figure 3 shows,

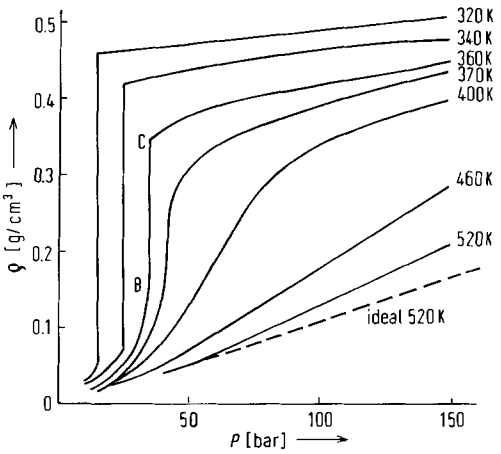

Fig. 3. Density of propane as a function of temperature and pressure. B = dew point, C = boiling point.

as example, the change in density of propane as a function of pressure and temperature. Slightly above the critical temperature, the density of the compressed gas at moderate pressures is lowered by a temperature rise to such an extent that the concentration of nonvolatile components in the gaseous phase decreases considerably. At high pressures the decrease of density caused by the temperature rise is so small that

the increase in vapor pressure leads to a higher concentration of the nonvolatile components in the gaseous phase.

In most cases, the relative volatilities of the components to be separated are only slightly influenced by the compressed gas. Hence, for mixtures of substances with small relative volatilities it is recommended that an entrainer be employed. The function of the entrainer is to increase the solubility of the nonvolatile components in the compressed gas as well as to facilitate their separation from the circulating gas at constant pressure. In such a way costs of recompression can be avoided. Furthermore, the entrainer can also increase the separation factor of the nonvolatile components.

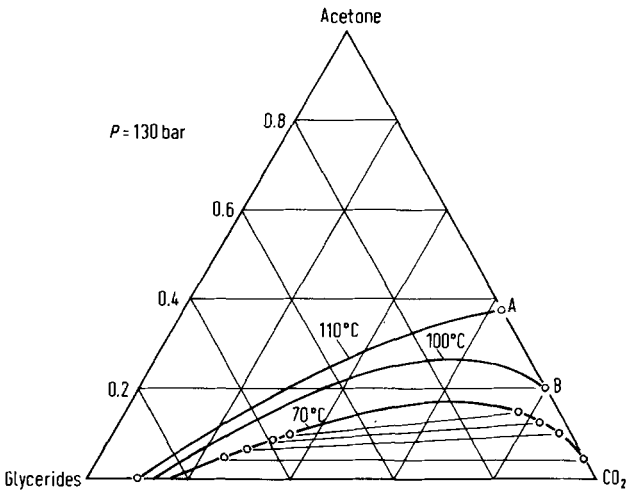

Fig. 4. Phase equilibria of the quasiternary system CO_2—acetone—glycerides of oleic acid at 130 bar and 70, 100 and 110°C. A, B see text.

Figure 4 shows the phase equilibria of the quasiternary system CO_2—acetone—oleic glycerides at a pressure of 130 bar and 70, 100 and 110°C. In the quasiternary system the content of glycerides in the gaseous phase is appreciably higher than that in the quasibinary system CO_2—oleic glycerides. In the temperature range over which the ternary system was examined, the glyceride content of the gaseous phase at constant pressure increases with decreasing temperature.

At 100°C and 70°C the binary system CO_2—acetone is supercritical at 130 bar. Under these conditions, only the system CO_2—oleic glycerides shows a miscibility gap. Figure 4 shows, moreover, that an appreciable enrichment of glycerides in the compressed gas is possible in the region near the critical point. At 130 bar and 110°C the binary system CO_2—acetone is subcritical. The miscibility gap is marked by points A and B on the diagram. At constant pressure and higher temperatures, the ability of the gaseous phase to take up components of low volatility is poor.

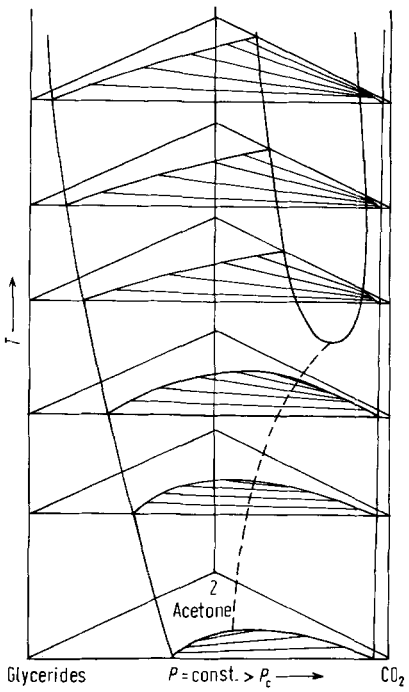

Fig. 5. Three-dimensional plot of the phase equilibria in the system CO_2—acetone—glycerides of oleic acid.

The phase equilibria of the system CO_2—acetone—oleic glycerides are shown in Figure 5 on a three-dimensional plot as a function of temperature and pressure.

Some experimental results of the phase equilibria in the quasiternary system CO_2—acetone—oleic glycerides are listed in Table 1. The concentration of glycerides in the gaseous phase is given as a function of the acetone content. In the last column the separation factor between mono- and diglyceride is shown. It can be seem that the separation factor decreases with increasing amount of entrainer—on approaching the critical point the separation tends towards unity.

Table 1. Phase equilibria in the system oleic triglycerides (1)—oleic diglycerides (2)—oleic monoglycerides (3)—glycerol (4)—acetone (5)—CO_2 (6). T = 69.6°C; P 132.5 bar. α_{32} = separation factor monoglyceride/diglyceride.

	Liquid phase			Gaseous phase

1	79.1	—	20.9	0.4	—	99.6	—
2	66.3	5.5	28.2	0.3	4.2	95.5	>100
3	57.5	7.7	34.8	2.7	10.0	87.3	30
4	51.1	9.6	39.3	4.3	12.4	83.3	3
5	45.8	11.1	43.1	8.9	14.8	76.3	1.4

3. Apparatus and Process

As described above, phase equilibria make it possible to separate nonvolatile substances at relatively low temperatures.

The process will be discussed with the aid of a schematic diagram of the apparatus used in the investigations (Figure 6). The apparatus consists of two columns, the first of which is used for the separation of the nonvolatile substances and the second is used for the separation of the nonvolatile components from the circulating gas.

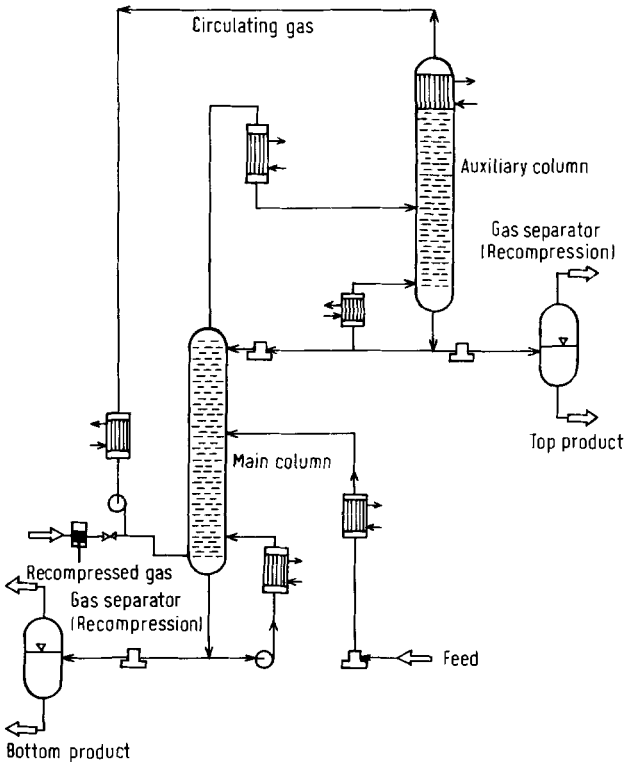

Fig. 6. Flow diagram of apparatus for the countercurrent separation of nonvolatile substances by means of compressed gases.

The mixture to be separated is fed together with the entrainer into the middle section of the main column. The stream of compressed gas leaving the top of the rectifying section of the main column is fed into the lower section of the auxiliary column. At the top of this column the gas stream flows through a heat exchanger, where part of the entrainer condenses. This refluxes countercurrently to the circulating gas and strips it of nonvolatile components. A heat exchanger at the bottom of the auxiliary column heats the mixture of nonvolatile substances and entrainer when required. The product withdrawn from the bottom of the auxiliary column is split into top product and reflux for the main column. The circulating gas, which consists of compressed gas with a certain proportion of entrainer, and which has, to a large extent, been freed of nonvolatile components, leaves the auxiliary column at the top and is returned to the bottom of the main column by means of a circulating pump. It is thus, possible to omit expansion and recompression of the circulating gas. At the bottom of the main column the nonvolatile substances dissolve in the gas phase. Here, the bottom product is also withdrawn.

It follows from Figure 4 that the binary system of compressed gas and entrainer in the main column must be under supercritical conditions in order to achieve a high concentration of nonvolatile substances in the gas phase. In the second column operating conditions have to be chosen under which the binary system, gas and entrainer, is subcritical. Under such conditions a fraction of the entrainer condenses and washes out the nonvolatile components from the circulating gas. The entrainer should have a boiling point lower than the decomposition temperature of the nonvolatile components, or it should be removable by extraction.

For the experimental investigations an apparatus made of strainless steel (1.4571) was employed. The bubble-cap columns have an internal diameter of 65 mm and are designed for an operating pressure of 150 bar at 120 °C. The main column contains 51 plates, the second column 34 plates.

4. Experimental Results

The separation of glycerides was investigated experimentally at a pressure of 135 bar and a bottom temperature of 80 °C in the main column. The temperature at the top of the auxiliary column was 110 °C. It should not fall below 100 °C, as the mixture acetone—CO_2 would then consist of only one phase. The content of nonvolatile substances in the circulating phase in the auxiliary column could be lowered to about 0.008 wt-%, 1/500 of the amount in the main column.

Using a reflux ratio of 1.5, under the above given conditions, the monoglyceride concentration in the top product of the main column amounted to 95 % of the total glycerides. A feed of 1.25 kg/h yielded a top product of 0.65 kg/h. With a reflux ratio of 2, the top product contained practically no diglycerides. This can be seen from the gas chromatograms of feed and top product shown in Figure 7.

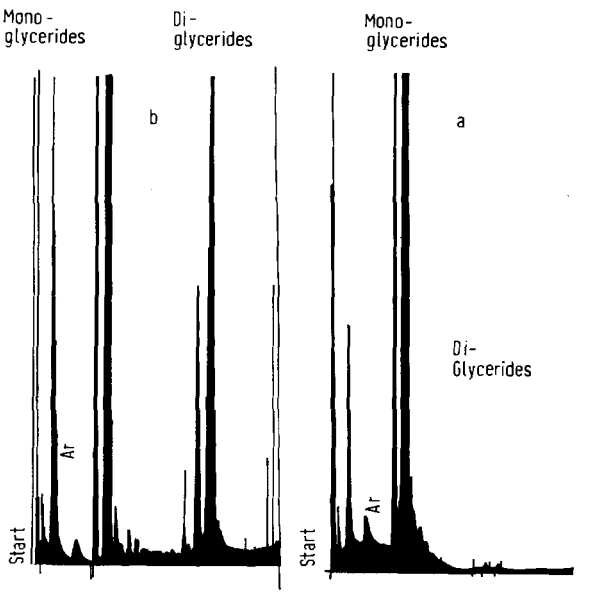

Fig. 7. Gas chromatograms of glycerides: a) top product and b) feed.

5. Economic Aspects

The results of the experiments described above on the separation of monoglyceride from a mixture of glycerides could be used as a basis for the estimation of investment and operating costs of a plant for the separation of substances by means of compressed gases in a countercurrent process. The costs were estimated according to a method described by *Kölbel* and *Schulze*[13]. The costs of the individual items of equipment

were determined using the September 1977 price index, published in the journal "Chemische Industrie"[14]. The results of the cost estimation for separating a mixture of glycerides containing 45 wt.-% monoglycerides are listed in Table 2.

Table 2. Cost estimation for the separation of glycerides. Method: see [13]. Price index: September 1977 [14]. Throughput 250 g m^{-2} sec^{-1} nonvolatile components. Operating conditions: 135 bar; 110°C; oleic glycerides with *ca.* 10 wt-% acetone as entrainer and propane as compressed gas.

Product	[t/a]	5000	15000	30000
Column diameter	[m]	1.56	2.70	3.83
Total cost of plant	[DM]	8500000	13100000	20800000
Depreciation 10 %	[DM]	850000	1310000	2080000
Capital risk 1 %	[DM]	85000	131000	208000
Calculated interest	[DM]	374000	576400	915200
Energy costs	[DM]	25000	30000	50000
Payroll	[DM]	250000	250000	250000
Overheads	[DM]	125000	125000	125000
Maintenance	[DM]	425000	655000	1040000
Total costs	[DM]	2134000	3077000	4668000
Processing costs	[DM/kg]	0.43	0.20	0.15

If the process is carried out at lower pressures, the reduction in costs is considerable (Table 3). An investigation revealed that this reduction in the operating pressure is possible with suitably chosen supercritical component and entrainer.

Table 3. Comparative costs at different operating pressures. Processing costs in DM/kg top product.

Size of plant (Amount of product)	5000 t/a	15000 t/a	30000 t/a
Operating pressure [bar]	Processing costs [DM/kg]	[DM/kg]	[DM/kg]
135	0.43	0.20	0.15
95	0.35	0.16	0.12
80	0.31	0.15	0.11

In Tables 2 and 3 only the costs for the high-pressure distillation have been considered. The costs for separation of the product streams from the entrainer have not been taken into consideration.

6. Discussion of Results

The choice of entrainer will depend not only on thermodynamic considerations but also, *inter alia*, on its physiological effects and price.

For the selected operating conditions the densities of the two phases differ by a factor of 3—8, a difference which is considerably higher than in an extraction process. The ratio of the phase densities for a given pressure and temperature depends mainly on the entrainer concentration.

The proportion of nonvolatile components in the gaseous phase increases with increasing concentration of entrainer, but the separation factor decreases. It is therefore necessary to choose a favorable mode of operation between two competing conditions: a large concentration of entrainer leads to a high concentration of nonvolatile components in the gaseous phase, but because of poor separation per stage, a large number of stages is necessary; a low concentration of entrainer leads to a low concentration of nonvolatile components; however, only a few stages are then required.

As in rectification, the separation in the present process improves with increasing reflux ratio. For a given product stream, a higher reflux ratio requires a larger column diameter. As this results in a considerable increase in price of the pressure vessels, it would be preferable to choose tall, slim columns with relatively low reflux ratios rather than short columns of large diameter.

In general, mixtures of nonvolatile and heat-sensitive substances can be handled in this process, at temperatures far lower than those encountered in vacuum distillation. The method described here appears particularly suitable for the processing of materials which are easily oxidized—at such elevated pressures there is no danger of oxygen entering the equipment.

Since the relative volatilities of components can be altered by addition of entrainer, the new process not only provides an alternative to vacuum and molecular distillation, but also enables the advantages of extractive distillation to be exploited for the separation of mixtures of slightly volatile compounds.

The authors wish to thank the Fonds der Chemischen Industrie and the Max-Buchner-Forschungsstiftung for support of this work.

Large-Scale Industrial Plant for Extraction with Supercritical Gases[**]

By R. Eggers[*]

Criteria for the design and construction of plant for obtaining carrier material or extracts are discussed for the example of the extraction of natural products with supercritical carbon dioxide. The parameters to be established and the course of the process in a large-scale plant are indicated. Plant engineering and optimization must be attuned to specific process-technological and construction problems.

1. Introduction

In order to exploit the phenomenon of good solubility of difficultly volatile substances in compressed supercritical gases, increasing attention has been devoted to the planning of processes and equipment and the design of suitable large-scale plant.

High-pressure extraction with carbon dioxide represents a potential method for the separation of thermally unstable materials such as natural products. The resulting advantages cannot be attained by classical separation processes. The design and construction of such plant for the extraction of natural products with supercritical CO_2 will be reviewed below with due emphasis on the important features.

2. Plant Design Criteria

The concept of a plant for high-pressure (HP) extraction of natural products must be based upon the desired aim of production with due consideration of the starting materials. Two fundamental possibilities should in principle be distinguished:

a) *Carrier material separation.* This is the situation where the starting material constitutes the final product after the removal of certain components by an extraction process. Examples are the production of decaffeinated coffee and of nicotine-free tobacco.

b) *Extract material separation.* Here the carrier material is regarded as a virtually valueless matrix from which the extract is obtained, for example hop extract, cocoa butter, and extracts of spices.

In order to provide a numerical basis for the plant dimensions and for detailed design of the structural components, it is necessary that a number of process data be known or determined:

a) Output capacity;

b) The mode of operation of the plant (continuous production or occasional shutdowns);

c) The bulk density of the material to be extracted;

d) The mass ratio of CO_2 and the material to be extracted;

e) The extraction time.

If the above-listed data are known or specified, it becomes possible to calculate the required extraction volumes and hence the size of the vessels and pipe cross-sections.

The operating pressures and temperatures are further fundamental parameters for the design of an extraction plant with the use of supercritical gases. Apart from process-technological data (such as the required input and output of energy) the above fundamental parameters also determine the plant design characteristics. One problem that should not be underestimated is the precise knowledge of the material properties of the solvent, the starting material, and the extract which, in many cases because of the absence of literature data, can only be obtained by laboratory determinations.

Pressure drops may be calculated on the basis of models, but if the starting material is unusual with regard to shape or consistency they must be determined in preliminary experiments.

3. Process Description

Products dissolved in a supercritical gas may be separated out by pressure reduction and/or by changing the temperature[1-4]. Separation by changes in temperature will not be discussed here, because this entails the loss of important constituents in the case of thermolabile natural products.

Plant for separating solute from solvent by pressure reduction is, in principle, characterized by the following main stages:

1) Extractor vessel in the extraction stage;
2) Pressure reduction at a throttle;
3) Demixing container in the separation stage;
4) Pressure increase in a pump or a compressor.

The principal course of events in a one-stage process is described in greater detail below. It may be readily followed by means of Figures 1 and 2 and by referring to a block diagram and the associated flow chart.

Preparation of the material to be extracted. The material may be comminuted (chopped or ground) or it may be treated by swelling with steam or water.

Charging of the plant. The quantity of solvent required for the extraction is determined precisely by the pressure and temperature conditions.

Heating to the extraction temperature. Heating is carried out isochorically by pumping the solvent through the steam-heated heat exchanger W1 using the pump P2 until the desired process conditions—supercritical pressure and supercritical temperature—have been attained in the extraction vessel A.

Extraction. The supercritical gas extracts the soluble components from the carrier material and is recycled *via* the throttle, the separator vessel B, the heat exchanger W2, the pumps P3 and P1, and the heat exchanger W1. The pressure reduction causes a precipitation of the extracted material in

[**] From a paper given at the Symposium on "Extraction with Supercritical Gases", held at Essen on 5th June 1978.

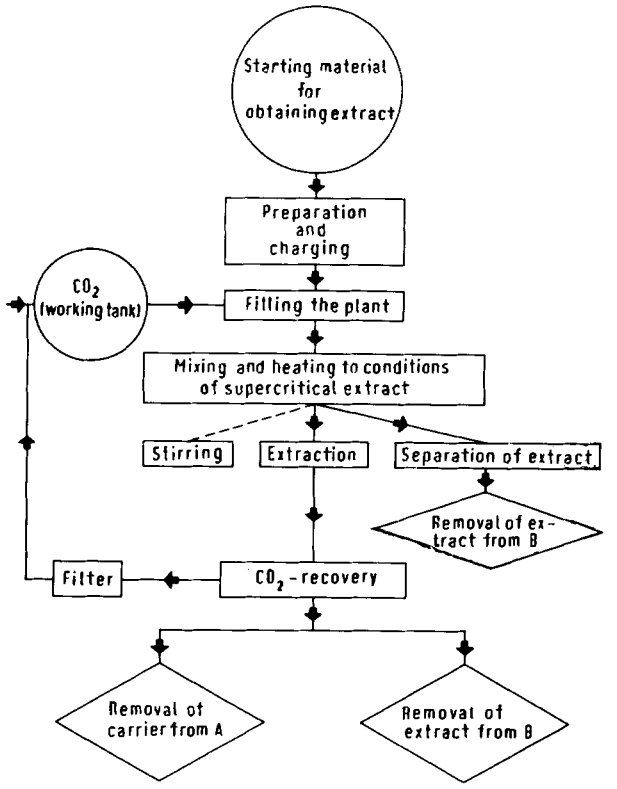

Fig. 1. Block diagram for extraction using supercritical CO_2 with the aim of extract isolation.

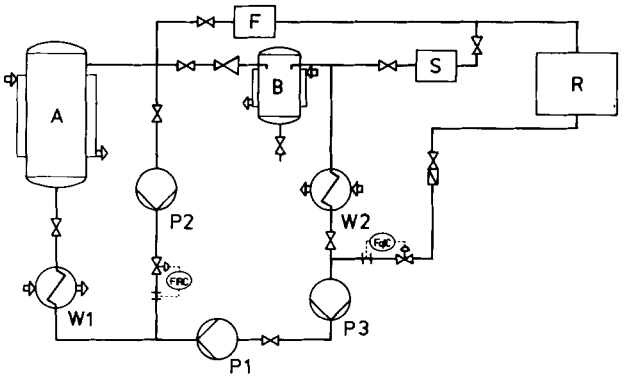

Fig. 2. Flow chart for obtaining the extract using supercritical CO_2. A, extraction vessel; B, demixing vessel; F, filter; S, sorption vessel; R, CO_2-recovery with working tank; P1, pressure build-up pump; P2, mixing pump; P3, preliminary pressure pump; W1, heater; W2, condenser; FRIC, mass flow governor; FqIC, quantity governor.

the separator vessel, from where it may be continuously removed by means of a bottom outlet. The medium must be completely liquefied in the condenser W2, so that suction can be applied from the liquid gas pump P1 and to make its circulation possible. The pressure rise to the extraction pressure in P1 is followed by raising the temperature to the extraction temperature in the heat exchanger W1. This completes the cycle.

Provision is made during extraction for periods of stirring the charge to prevent the formation of channels through which the supercritical gas could pass freely in the carrier material, since this would lead to local limitation of mass transfer.

Recovery. The solvent is returned to the working vessel from the extraction system *via* filter F, in order to prevent any contamination of the contents of this vessel with the extracted material. Finally the extraction residue is removed from the vessel A and the extract from the vessel B.

4. Thermodynamic Aspects

In order to obtain the thermodynamic data for a given step of the process it is particularly useful to have a phase diagram for the solvent used in the extraction. Many diagrams are available for CO_2, but they do not agree in all respects[5–8]. Temperature-entropy (T,s) diagrams are particularly suitable, because in these diagrams the heat energy supplied and removed in reversible processes is represented by areas.

In order to illustrate the course of events in a T,s diagram (Fig. 3), let us consider the extraction/demixing cycle, using representative values for the phase data.

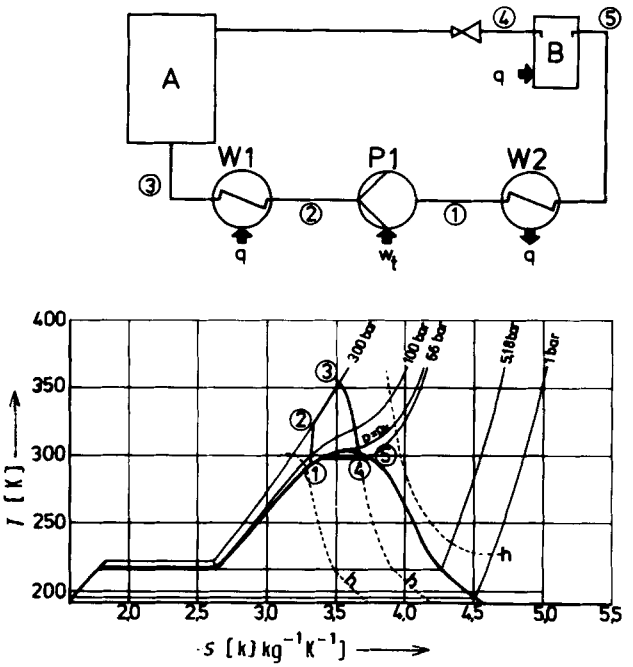

Fig. 3. Flow chart and phase diagram for a single-step cyclic extraction and demixing process. ①—②, compression in P1; ②—③, heating up in W1 under constant pressure; ③—④, adiabatic pressure release; ④—⑤, evaporation of the liquid fraction; ⑤—①, condensation and supercooling in W2 under constant pressure; q, heat flow; w_t, power supply; h, enthalpy.

The path from point 3 to point 4 corresponds to the adiabatic pressure release in the demixing vessel, the extract then separating out and undergoing precipitation. At point 4 the CO_2 is present as a wet vapor. The liquid fraction is evaporated by supplying heat, so that only the vapor without the extract is removed from B (point 5). This vapor is condensed in heat exchanger W2 and the liquid phase is supercooled (point 1). The solvent must then be compressed to the extraction pressure in pump P1 (point 1 to point 2). The solvent is finally heated at a constant pressure to the extraction temperature by supplying heat to W1 (point 2 to point 3).

It must also be established to what extent the process data would be modified if data for the charged phases actually present were to be used rather than those for pure CO_2. The thermodynamic consideration has the advantage that the solvation energies of the components that pass into solution are negligibly small compared with the enthalpy of the flowing medium.

5. Plant Technology and Optimization

Although the basic plant concept varies according to the starting material, it is possible to specify certain components and combinations of equipment common to all designs and for which the following characteristics are important:

- vessel design for high pressures (100 to 300 bar), with an allowance for an increasing stress
- compliance with the requirements of foodstuffs legislation, *i.e.* corrosion-resistant internal surfaces and surfaces that are easy to clean or decontaminate
- temperatures generally not exceeding 100 °C
- the bulk density of the starting material is sometimes extremely low.

The vessel-filling devices must be adapted to the widely varying properties of the natural materials under consideration. Granular material is relatively simple to handle, but loose bulk material, which can be compacted only with difficulty, presents certain problems. It will be necessary to examine possible designs for continuous operation in the latter case. Pretreatment such as grinding may be recommended if the material suffers no detrimental effects. Materials requiring special care are suitably placed in baskets that can be prepared in individual batches; this is generally appropriate for all natural products in which the leaf or the fiber structure must be preserved unchanged.

The design of closures is determined by the method of charging and discharging. Granular materials may be fed in or removed through the top or bottom of the vessel using a small funnel; in the case of baskets it must be possible to fully open the vessels. In such cases it is particularly necessary to provide for fast closure; there are comparatively few examples of the latter with the required dimensions in high-pressure vessel technology. One such design is shown in Figure 4.

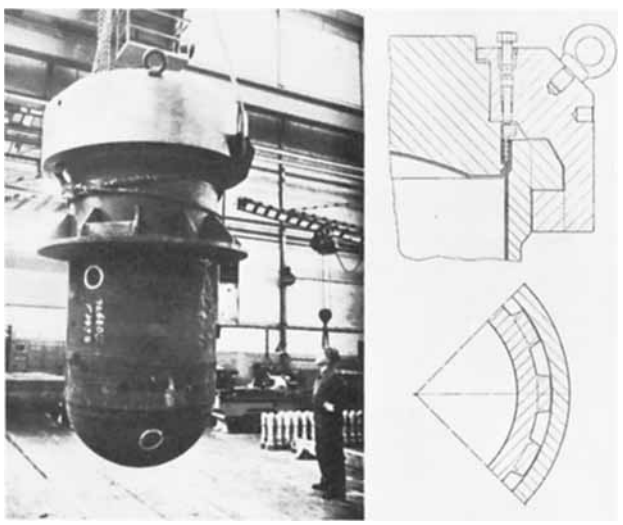

Fig. 4. A quick method of closure for a high-pressure vessel.

Pipe sections in which there is a risk of extract separation along the internal surface require the provision of external heating, for example by means of electric heating mantles.

The degree of automation of the plant is important. The following settings must be suitably selected and controlled in a plant in which the extraction is carried out with supercritical gases: quantities, mass flows, temperatures, pressure, and charge levels.

For the construction of a production plant the optimum working conditions must be known; these are determined on a pilot plant. Such a pilot plant must permit maximum possible variation of the operating conditions, in order to provide adequate data on the yield and quality of extract, and on the extraction times.

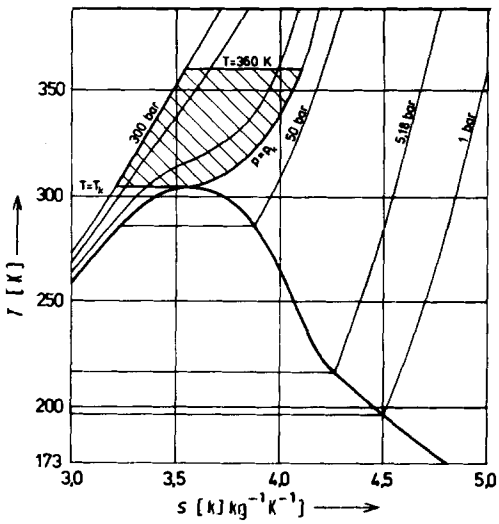

Fig. 5. Phase range for the extraction of natural products with supercritical CO_2.

The T,s diagram for CO_2 (see the shaded area within the supercritical region of Figure 5) clearly demonstrates the need for an extensive operating range of a pilot plant for the extraction of natural products in order to permit optimization of the operating conditions in the final production plant. Having thus determined the operating conditions and times for the individual process steps, it becomes possible to plot the course of the pressure and temperature *versus* time; an example of

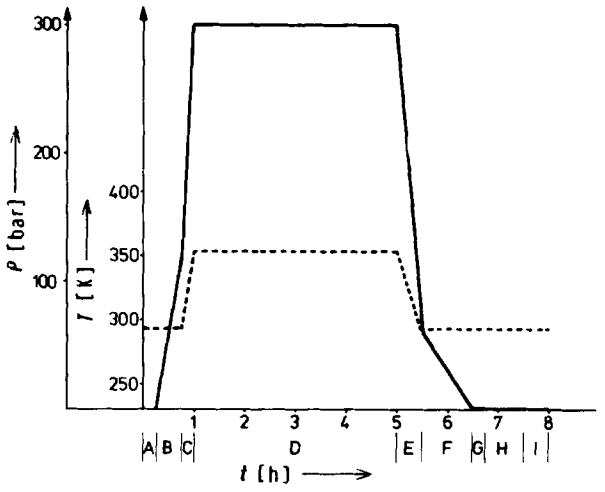

Fig. 6. Pressure (—) and temperature (----) in the extraction vessel as a function of time. A, charging of the extraction vessel; B, filling the plant with solvent; C, heating up to extraction conditions; D, removal of the extract and separation; E, venting down to tank pressure; F, evacuation to residual pressure; G, venting of the residual gas; H, removal of carrier material and extract; I, regeneration of the adsorbant.

this is given in Figure 6 for the single-step extraction process that has already been discussed.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Thermal Degradation of Cellulose and Chitin in Supercritical Acetone

By *Peter Köll* and *Jürgen Metzger*[*]

In the thermal degradation of polysaccharides rapid removal of the primary products from the reaction zone is a decisive prerequisite for the use of this reaction on a preparative or industrial scale as regards obtaining a high-yield uniform product pattern. Customary pyrolysis methods lead, particularly on a large-scale, to secondary reactions accompanied by strong carbonization. This cannot be entirely avoided, even if the reaction is carried out *in vacuo*; moreover, the pyrolysis is then rendered difficult by the poor transfer of heat.

To overcome this problem, we have for the first time exploited the good dissolution properties of compressed gases in the supercritical state[1] in a flow apparatus. With this method we have been able to detect—to our knowledge for the first time—the primary product of the thermal degradation of chitin[2], namely 2-acetamido-1,6-anhydro-2-deoxy-β-D-glucopyranose[3], an important amino sugar used as starting substance for the synthesis of physiologically active oligosaccharides[4], and to isolate it on a preparative scale. Furthermore, cellulose could be degraded to the extent of 98%.

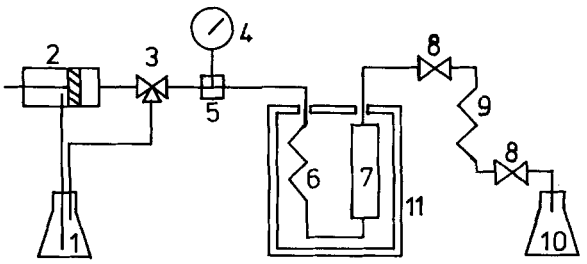

Fig. 1. Schematic diagram of the apparatus. 1) Solvent reservoir; 2) high-pressure pump for up to 500 bar (HPLC pump); 3) excess-pressure valve; 4) manometer for up to 600 bar; 5) T-piece; 6) pre-heater capillary (diameter 1.6 mm); 7) reactor (V = 50 ml), 8) valve; 9) heat exchanger (1.6 mm-diameter capillary); 10) collector; 11) GC furnace.

The apparatus used (Fig. 1) was largely made up of HPLC equipment; a GC furnace was used for heating. Acetone (T_c = 508.5 K, P_c = 47 bar) proved to be especially suitable as aprotic solvent. In a typical experiment, 18 g of microcrystalline cellulose (Merck; dry weight 17.1 g) was transferred to a preparative HPLC column and treated at a pressure of 250 bar with acetone at an average flowrate of 4.5 ml/min. The temperature was slowly increased from 250°C at the beginning of the experiment to 340°C at completion of the degradation (after 10 h). There remained an extraction residue of only 0.36 g (2.1 %). Concentration of the acetone solution *in vacuo* gave 18.3 g of a dark syrup, which was shown by thin-layer chromatography to consist mainly of low molecular products. The mass balance exceeded 100 %, since small amounts of difficultly volatile condensation products of acetone are also formed during the reaction. However, since evolution of gases during the reaction is very slight, it can be assumed that approximately 98 % of the cellulose is in fact liquefied. The main products could be identified, in particular, as anhydrosugars by comparison with authentic materials. The following amounts (based on consumed cellulose) were determined by quantitative gas chromatography of the acetates (Carlo Erba Fractovap 2300, column 2 m XE60, T = 473 K, injection block 523 K, 20 ml He/min, triacetyl-1,6-anhydrogalactofuranose as internal standard):
38.8 % 1,6-anhydro-β-D-glucopyranose ("glucosan"), 4.3 % 1,6-anhydro-β-D-glucofuranose, 4.0 % 1,4:3,6-dianhydro-α-D-glucopyranose, *ca.* 1 % 1,6-anhydro-3,4-dideoxy-β-D-glycero-hex-3-enopyranos-2-ulose.

The yield of glucosan can be regarded as excellent when compared with the yields obtained on vacuum pyrolysis[5]. The cellulose is extraordinarily gently degraded by acetone,

despite the high temperature. Thus, according to diffractometer measurements the residue still has the crystallinity of the starting cellulose even after 50 % degradation. Nor do scanning electron photomicrographs show any serious changes in the structure at this stage of the degradation.

Chitin (Fluka, techn., ash content 5 %; 15.0 g) was degraded in the same way as cellulose in the temperature range 250—340 °C at 250 bar by acetone at a flow rate of 5.0 ml/min over 7.5 h. The residue amounted to 2.3 g (15.3 %). Concentration of the acetone solution by evaporation afforded 16.4 g of a mobile black oil, which was shown by combined GC/MS to contain acetamide and diacetamide. Additional thin-layer chromatography showed the presence of 1,6-anhydro-3,4-dideoxy-β-D-glycero-hex-3-eno-pyranos-2-ulose. Partition of the syrup between water and chloroform afforded 4.1 g of water-soluble product and 12.3 g of chloroform extract. The main sugar component 2-acetamido-1,6-anhydro-2-deoxy-β-D-glucopyranose[3] could be recovered from the water-soluble product in 5.6 % overall yield (0.8 g) by chromatographic separation on a silica gel column using acetone as eluent. The actual amount of this sugar in the pyrolysate is higher; but, further recovery by crystallization is rendered difficult by the degree of contamination with acetamide. However, in view of the ready accessibility of the starting material and the relative ease with which the reaction and isolation can be carried out, the yield is nevertheless preparatively acceptable.

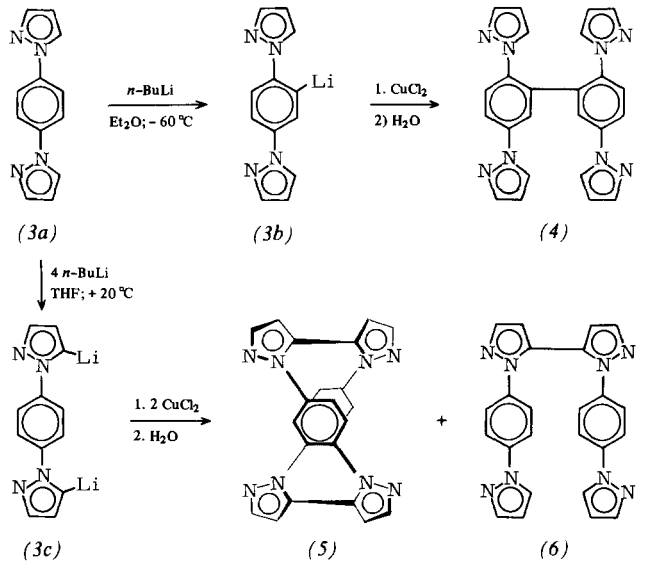
Heterocyclohexaaromatic Compound with Face-to-Face Arrangement of Two Benzene Rings[**]



By *Thomas Kauffmann* and *Herbert Lexy*[*]

We previously reported the synthesis of the first heterocyclohexaaromatic compounds 4,6,4‴,6‴-tetraazahexa-*m*-phenylene *(1)*[1a] and 4,6,4′,6′,4‴,6‴,4⁗,6⁗-octaazahexa-*m*-phenylene[1b]. The ring members in these macrocycles are arranged in the form of a wreath, without their individual planes being twisted[1c]. Since compounds *(2a)*[2] and *(2b)*[3] are known, it was expected that cyclohexaaromatic compounds in which two rings lie one on top of the other, *i.e.* face-to-face[4], could also be synthesized. We have now been able to prepare the first compound of this type by the reaction sequence *(3a)* → *(3c)* → *(5)*.

(1) *(2a)* *(2b)*

The starting compound 1,4-phenylenedi(1-pyrazole) *(3a)*, previously only accessible in low yields by a ring-forming synthesis[5], could be obtained in 79 % yield from *p*-dibromobenzene and pyrazole by ring linkage. On treatment with 1 mol *n*-butyllithium in ether at −60 °C, *(3a)* was preferentially lithiated (kinetic control) at the benzene ring to give *(3b)*, which on reaction with $CuCl_2$ was converted mainly into *(4)* (28 %; m.p. 208—212 °C). In contrast, treatment of *(3a)* with 4 mol *n*-butyllithium in THF at +20 °C afforded almost quantitative yields of *(3c)*[6], whose coupling with $CuCl_2$ in the temperature range −70 to +20 °C gave the desired product *(5)* in the astonishingly good yield of 43 %. *(6)* was formed as by-product (5 %; m.p. 238—243 °C). The structures have been confirmed by elemental analysis, MS and ^{1}H-NMR data, and the melting points given are corrected.

(3a) *(3b)* *(4)* *(3c)* *(5)* *(6)*

According to the Stuart-Briegleb model the benzene rings of *(5)* are oriented face-to-face. The resulting interaction between their orbitals is revealed in the ^{1}H-NMR spectra ($CDCl_3$) by an upfield shift of the proton signals (s, $\delta = 6.97$) compared to *(3a)* ($\delta = 7.80$). This corresponds to the behavior observed in [2.2]paracyclophane[7], in *(2a)*[2], and in other strained phanes, and can be explained in terms of an anisotropic effect of the neighboring benzene ring[8]. Since the phenylene protons of *(5)* appear in the ^{1}H-NMR spectrum as a sharp singlet, despite different chemical environments, it may be assumed that *(5)* and its mirror image undergo fast interconversion. No splitting of the singlet could be observed at −80 °C [in ethanol/$CDCl_3$ (1 : 3)][9]; the temperature could not be lowered any further because of the sparing solubility of *(5)*.

Experimental

Synthesis of *(3a)*: A mixture of 1,4-dibromobenzene (2.36 g, 10.0 mmol), pyrazole (6.80 g, 100.0 mmol), K_2CO_3 (16.0 g,

[**] Heterocyclopolyaromatics, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft (Ka 144/30) and the Fonds der Chemischen Industrie.—Part 6: *Th. Kauffmann, B. Greving, R. Kriegesmann, A. Mitschker, A. Woltermann,* Chem. Ber. *111,* 1330 (1978).

120.0 mmol), and CuI (5.00 g) in nitrobenzene (20 ml) is heated under reflux for 3 h. The volatile components are distilled off at 0.2 torr (bath temp. 100 °C) and the residue chromatographed on a silica gel column with dichloromethane. The third fraction eluted contains 1.64 g (79 %) of pure *(3a)*, m.p. 182 °C (Ref. [5]: 180 °C).

Synthesis of *(5)*: A stirred solution of *n*-BuLi (4.0 mmol) in ether (5 ml) is treated dropwise within 15 min at 25 °C with a solution of *(3a)* (210 mg, 1.0 mmol) in 20 ml THF. Stirring is continued for a further 30 min, whereupon a yellow precipitate separates out. The mixture is cooled to −70 °C, treated with 670 mg (5.0 mmol) of extremely dry $CuCl_2$, and then allowed to warm to room temperature within 12 h. After protolysis with 5 ml methanol, complexation of the copper salt with 100 ml conc. ammonia, and extraction several times with hot chloroform, the dried extract is concentrated by evaporation and the residue chromatographed on a silica gel column with dichloromethane/methanol (100:1). Recrystallization of the third fraction from chloroform affords 90 mg (43 %) *(5)* as colorless crystals which sublime at 300 °C/0.02 torr and decompose between 420 and 450 °C.

[2.2.2.2](1,2,4,5)Cyclophane Quinhydrone—A Donor-Acceptor Cyclophane with an Extremely Short Transannular Distance[1]

By *Heinz A. Staab* and *Volker Schwendemann*[*]

[2.2.2.2](1,2,4,5)Cyclophane[2] has extremely short distances of 2.69 Å between the four pairs of bridged carbon atoms of the aromatic rings[3]. The intramolecular quinhydrone *(1)* of this cyclophane was therefore of particular interest for our studies on the influence of distance and orientation on donor-acceptor interaction in cyclophane quinhydrones[1].

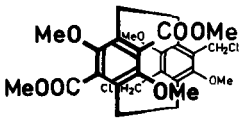
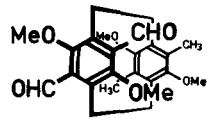
(5)

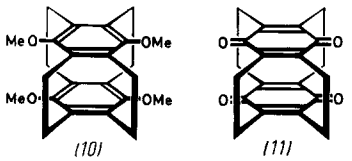


(6)



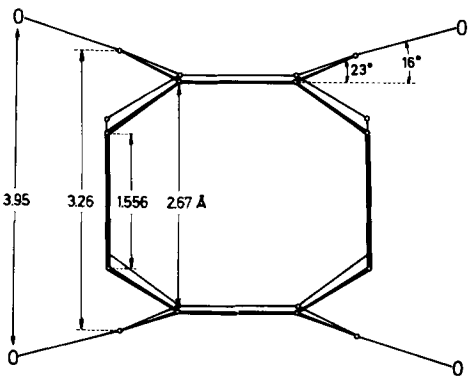
The mixture of *(5)* and *(6)*, like the pure stereoisomers *(5)* and *(6)*, on irradiation in trimethyl phosphite[6] (600-W Hg high-pressure lamp, 6 h), gave only one of the two possible 4,7,12,15-tetramethoxy-5,8-dimethoxycarbonyl[2.2]paracyclophanes, *viz.* *(7)*[5] (m.p. 168 °C, 68 % yield), which has the four methoxy groups in the desired pseudogeminal position and the more bulky methoxy carbonyl groups opposite the unsubstituted C atoms of the adjacent ring.

(7)



(8)

(9)



Subsequent synthetic steps were performed according to the preparation of the unsubstituted [2.2.2.2](1,2,4,5)cyclophane[2] with a number of modifications required by the special steric situation in the highly substituted [2.2]paracyclophane: chloromethylation of *(7)* (chloromethyl methyl ether, aluminum chloride) gave the bis(chloromethyl) compound *(8)*[5] (dec. >235 °C, 52 %) whose reduction with diisobutylaluminum hydride (boiling ether, 4 h) and subsequent oxidation with active manganese dioxide (ether, 50 h, 20 °C) led to 4,7-diformyl-12,15-dimethyl-5,8,13,16-tetramethoxy[2.2]paracyclophane *(9)*[5] (yellow needles, dec. >235 °C, 28 % yield); the bis(tosylhydrazone) of *(9)* underwent a carbenoid insertion reaction (sodium methoxide, tetrahydrofuran, 24 h irradiation with a 300-W daylight lamp, 29 %) to give tetramethoxy-[2.2.2.2](1,2,4,5)cyclophane *(10)*[5]: colorless prisms, m.p. 309—310 °C (dec.); MS, M^+ calc. for $C_{24}H_{28}O_4$ 380.1987, exp. 380.1985; ^{1}H-NMR (80 MHz, $CDCl_3$): $\delta = 3.388$ (12H, CH_3O), AA'BB' (16H) with $\delta_A = 3.216$, $\delta_B = 2.724$, $J_{AB} = -13.0$, $J_{AA'} = 11.0$, $J_{AB'} = 3.6$, $J_{BB'} = 11.0$ Hz. The electron-rich cyclo-

phane *(10)* can be oxidized by lead(IV) acetate in trifluoroacetic acid to a radical cation, for which the splitting of the ESR signals corresponds to equivalent coupling of the radical electron with the protons of both cyclophane halves[7].

(10) *(11)*

Demethylation with methylmagnesium iodide[4], which has proved of value for synthesis of cyclophane quinones, proceeded with surprising ease (20 min, 180 °C) in spite of the potential difficulties envisaged at high temperatures owing to the considerable ring strain in *(10)*[8]. After oxidation with silver(I) oxide (acetone, 20 °C) we obtained the bisquinone *(11)*[5] in 42 % yield: yellow needles, dec. >305 °C; MS, M^+ calc. for $C_{20}H_{16}O_4$ 320.1049, exp. 320.1050; ^{1}H-NMR (80 MHz, $CDCl_3$) AA'BB' with $\delta_A = 3.007$, $\delta_B = 2.548$, $J_{AB} = -13.1$, $J_{AA'} = 11.4$, $J_{AB'} = 3.7$, $J_{BB'} = 11.4$ Hz. In contrast to other paracyclophane bisquinones with pseudogeminal orientation of the quinone units[9], double intramolecular cycloaddition of the two pairs of quinonoid C=C double bonds could not be accomplished photochemically in spite of their parallel arrangement and short distance. This might be connected with the strong boatlike deformation of the quinone units: X-ray structure analysis of *(11)*[10] shows the interplanar distances between the planes formed by the four bridged ring C atoms each to be 2.67 Å; the C—C(=O)—C planes deviate outwards from this plane by 23°:

Relatively stable radical anions are obtained from *(11)* by treatment with potassium *tert*-butoxide in dimethyl sulfoxide. The ESR spectrum shows the expected coupling of two groups of eight equivalent protons ($a_1 = 1.40$, $a_2 = 0.505$ G) expected for equivalence of the two cyclophane halves.

Catalytic hydrogenation of *(11)* (1 equiv. of hydrogen, 10 % Pd on activated charcoal, dioxane, 15 min, 20 °C) gave the quinhydrone *(1)*: black-violet microcrystals (from dioxane), dec. >300 °C, 60 % yield; MS, M^+ calc. for $C_{20}H_{18}O_4$ 322.1209, exp. 322.1205. In the ^{1}H-NMR spectrum (360 MHz, D_6-DMSO, 80 °C), ABCD multiplets ($\delta \approx 3.2$, 2.9, 2.6, 2.3) are observed for the four groups of four equivalent protons of the methylene bridges, together with the OH absorption at $\delta = 7.81$; on raising the temperature (to 140 °C) no evidence was found for fast exchange of oxidation states between the two halves of the molecule, as has been deduced for the pseudogeminal [2.2]paracyclophane quinhydrone[4].

Between 650 and 350 nm, the UV/VIS spectrum of *(1)* shows a broad intense charge transfer absorption at $\lambda_{max} = 491$ nm ($\varepsilon = 1280$, in methanol). The great similarity in line shape and position to the CT absorption of pseudogeminal [2.2]paracyclophane quinhydrone ($\lambda_{max} = 492$ nm, $\varepsilon = 1600$, in methanol)[4] appears surprising in view of the shorter transannular distances and the completely rigid mutual fixation of the donor and acceptor by fourfold bridging.

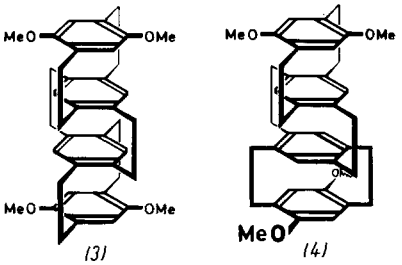
Indirect Donor-Acceptor Interactions in Quinhydrones of Quadruple-Layered [2.2]Paracyclophanes[1]

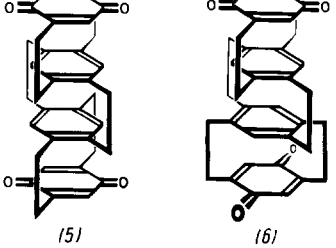
By *Heinz A. Staab* and *Udo Zapf* [*]

We have recently demonstrated for intramolecular quinhydrones of the triple-layered [2.2]paracyclophane system[2] that typical charge-transfer (CT) absorptions can also be observed when the donor and the acceptor are not in direct spatial contact but are separated by an aromatic π-electron system intercalated between the donor and acceptor moieties. Higher members of this class of compounds having additional aromatic π-electron systems inserted parallel between the donor and the acceptor are of interest in order to determine the range of indirect charge transfer of this kind. We now report the synthesis and spectroscopic properties of the intramolecular quinhydrones *(1)* and *(2)* having the donor and acceptor moieties in the external positions of a quadruple-layered [2.2]paracyclophane.



(1) *(2)*

pseudo-*ortho*-4,7-Dimethoxy-12-methyl-15-trimethylammoniomethyl[2.2]paracyclophane bromide[2] can be trans-



[*] Prof. Dr. H. A. Staab, Dipl.-Chem. U. Zapf
Abteilung Organische Chemie, Max-Planck-Institut für medizinische Forschung
Jahnstrasse 29, D-6900 Heidelberg 1 (Germany)

formed in 20 % yield by 1,6-Hofmann elimination (conversion into the hydroxide with silver oxide/water; 12 hours' heating in boiling xylene with a water separator, addition of phenothiazine) into a mixture of diastereomeric quadruple-layered tetramethoxy[2.2]paracyclophanes *(3)* and *(4)* (ratio of 1:2). The diastereomers could be separated by repeated fractional crystallization from toluene/acetone (2:3): *(3)*[3] forms colorless platelets (from acetone), dec. >265°C; MS, M^+ calc. for $C_{40}H_{44}O_4$ 588.3239, exp. 588.3243; mass spectrometric fragmentation corresponds to the [2.2]paracyclophane structure: $m/e = 588$ (M^+, 80 %), 424 (40 %), 294 (100 %); ^{1}H-NMR (80 MHz, C_6D_6): $\delta = 2.1$—3.6 (m, 24H), 3.31 (s, 12H), 5.45 (s, 4H), 5.53 (s, 4H). *(4)*[3] is obtained from its acetone solution as colorless needles of m.p. 263—265°C (dec.); MS, M^+ exp. 588.3243, $m/e = 588$ (M^+, 100%), 424 (46%), 294 (97%); ^{1}H-NMR (80 MHz, C_6H_6): $\delta = 2.1$—3.6 (m, 24H), 3.28 (s, 12H), 5.46 (s, 4H), 5.68 (s, 4H). Assignment of *(3)* and *(4)*, and hence also that of the derived compounds *(5)*/*(1)* and *(6)*/*(2)*, is based on the crystal structure of *(3)*, which requires a molecular center of symmetry for this diastereomer[4].

(3) *(4)*

Demethylation of *(3)* and *(4)* was accomplished with methylmagnesium iodide[5] (5 equiv., 3h, 130—140°C, under nitrogen). After oxidation with silver(I) oxide (acetone, 1 h), chromatography (silica gel plates, chloroform) gave three fractions: $R_F \approx 0.57$, 50—70 % of the colorless compounds *(3)* and *(4)* recovered; $R_F \approx 0.44$, 4—8 % yield (*ca.* 15 % based on reacted *(3)* and *(4)*) of the red quinhydrone dimethyl ethers *(1)* and *(2)*; $R_F \approx 0.31$, 4—8 % yield of the orange-red bisquinones *(5)* and *(6)*: light red crystals (from ethanol), dec. 270°C; ^{1}H-NMR (80 MHz, C_6D_6) for *(5)*, $\delta = 1.3$—3.1 (m, 24H), 5.36 (s, 4H), 5.42 (s, 4H); for *(6)*, $\delta = 1.4$—3.1 (m, 24H), 5.35 (s, 4H), 5.48 (s, 4H). The UV/VIS spectra show intense longwave absorption bands [*(5)*, $\lambda_{max} = 415$ nm ($\varepsilon = 4960$); *(6)*, $\lambda_{max} = 417$ nm ($\varepsilon = 5010$), in chloroform] which are to be interpreted as CT absorptions of the donor-acceptor partial systems in *(5)* and *(6)*[6].

(5) *(6)*

The intramolecular quinhydrones *(1)* and *(2)* were further purified by chromatography on alumina from toluene and recrystallization. *(1)*[3], dark-red platelets (from methylcyclohexane), dec. >270°C; MS, M^+ calc. for $C_{38}H_{38}O_4$ 558.2770, exp. 558.2769; ^{1}H-NMR (80 MHz, C_6D_6) $\delta = 1.4$—3.5 (m, 24H), 3.28 (s, 6H), 5.41 (s, 4H), 5.47 (s, 4H).—*(2)*[3], dark-red crystals (from *n*-hexane), dec. >270°C; MS, M^+ exp. 558.2768; ^{1}H-NMR (80 MHz, C_6D_6) $\delta = 1.4$—3.55 (m, 24H), 3.27 (s, 6H), 5.38 (s, 2H), 5.43 (s, 2H), 5.57 (s, 2H), 5.61 (s, 2H).

The UV/VIS spectra of *(1)* and *(2)* show an intense CT absorption in the 350 to 550 nm range [*(1)*, $\lambda_{max} = 447$ nm ($\varepsilon = 2500$); *(2)*, $\lambda_{max} = 450$ nm ($\varepsilon = 2490$)]; their concentration independence (examined between about 7×10^{-4} and 8×10^{-6} M) confirms their intramolecular character. Not only are the intensities of the CT bands of *(1)* and *(2)* higher in comparison with the corresponding triple-layered [2.2]paracyclophane quinhydrones[2], but they also show a distinct bathochromic shift, indicating overall enhancement of the donor strength of the π-electron system interacting with the acceptor *p*-benzoquinone moiety in *(1)* and *(2)*. As in the case of the "triple-decker" quinhydrones[2], there is no evidence in the stereomeric pair *(1)*/*(2)* for any dependence of the CT band on the mutual orientation of the donor and acceptor units of the kind observed for simple [2.2]- and [3.3]paracyclophane quinhydrones[5, 7].

A Novel Photochemical Synthesis of Propellanes[**]

By *Gerd Kaupp* and *Michael Stark*[*]

Hitherto, the photochemical syntheses of propellanes[1] utilized intramolecular [2+2]-[1, 2], [4+2]-[1] and [4+4]-cycloadditions[3] or trapping reactions of doubly-bridged electronically excited conjugated alkenes with simple alkenes[1, 4]. We have now been able to trap electronically excited acyclic chromophores with bicyclic alkenes to give propellanes.

Mechanistic findings with [2+2]-photocycloadditions of *trans*-stilbene *(1)* and diphenylacetylene *(5)*[5] suggested that *(1*)* and *(5*)* are more effectively trapped by bicycloalkenes with doubly-bridged double bonds to give propellanes than by simple cycloalkenes to give bicyclic [2+2]-adducts. Thus, in the readily accessible tetrahydroindene *(2)*[6] the (electron-rich) central double bond ought to preferably react with *(1*)* or *(5*)*. Since molecular models indicate that steric hindrance of the chemically productive collision of these partners is not excessive, propellane formation ought also to compete with the substituting additions[7] favored here [to give *(4)* and *(7)*, respectively]. These predictions could in fact be confirmed by the ready syntheses of *(3)* and *(6)* (Table 1).

(10) [c]	85	7.25—6.95 (10H, m), 5.9—5.55 (4H, m), 2.35 (4H, br. AB, J=16 Hz, $\Delta\nu_{1/2}$ ca. 9 Hz), 2.08 (4H, br. BA, $\Delta\nu_{1/2}$=3.5 Hz)	226, 268 (sh), 275, 283 (sh), 294 (sh), 310 (sh), 332 (sh)

[a] ^{13}C-NMR (90.5 MHz, $CDCl_3$): δ=141.5, 140.6 (quart. arom. C), 129.4, 127.4 (olefin. C), 128.1, 128.0, 127.8, 127.0 (*o*-, *m*-arom. C), 125.9, 125.7 (*p*-arom. C), 50.8, 49.4 (bridgehead-C), 46.9, 45.3 (benzyl. C), 41.7, 37.2, 35.1, 30.3, 24.9 (allyl. and aliph. C). [b] Fluorescence (cyclohexane): λ_{max}^{corr}=380 nm, Φ_{fl}=0.60. [c] Fluorescence (cyclohexane): λ_{max}^{corr}=380 nm.

Selective irradiation ($\lambda > 290$ nm) of *(1)* dissolved in *(2)* affords 56 % of the [4.3.2]propellane *(3)* and 21 % of a diastereomeric mixture of *(4a)* and *(4b)*, together with traces of 1,2-diphenylethane and higher molecular weight material[8].

Correspondingly, irradiation of *(5)* in *(2)* (almost selective excitation, λ=253.7 nm) affords mainly the [4.3.2]propellane *(6)* (41 %), together with (*Z*)-*(7)*, (*E*)-*(7)*, unreacted *(5)*, three unknown products (none of which showed fluorescence in the visible range), and photolysis products of *(5)*[8, 9].

(9) *(10)* *(11)* *(12)*

The utility of this versatile method for the synthesis of substituted propellanes having different numbers of double bonds is not restricted to tetrahydroindene. Thus, reaction of 1,4,5,8-tetrahydronaphthalene with *(1*)* or *(5*)* affords the [4.4.2]propellanes *(9)* (35%) and *(10)* (37%) (Table 1). However, "electron-poor" doubly bridged alkenes apparently do not react with *(1*)* and *(5*)* to give propellanes. For example, reaction of 3,4,5,6-tetrahydrophthalic anhydride with *(1*)* leads to the spirooxetanes *(11)* (40%; m.p. 143 °C) and *(12)* (13%; m.p. 154 °C)[10].

Experimental

trans-10,11-Diphenyltricyclo[4.3.2.0^{1,6}]undec-3-ene *(3)*: A solution of *(1)* (2.0 g, 11.1 mmol) in *(2)* (50 g, 0.42 mol) is irradiated under N_2 at 25 °C for 12 h with a mercury high-pressure lamp (Hanau, Q 81) using a pyrex filter. After removal of excess *(2)* by distillation the residue is chromatographed on 200 g SiO_2 with cyclohexane as eluent. Initially, 1.89 g (56 %) *(3)* with 40 mg (2 %) 1,2-diphenylethane is eluted [crystallization from ethanol (5 ml) furnishes 1.78 g (53%) *(3)*, m.p. 76 °C] and finally 690 mg (21 %) of a 3:2 mixture of the diastereomers *(4a)*, *(4b)* [^{1}H-NMR analysis[10]; separation by preparative thin-layer chromatography on SiO_2 with cyclohexane]. The mixture of diastereomers is heated under reflux with 550 mg (2.4 mmol) DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone) in 30 ml benzene for 3 h under N_2. After filtration over 30 g SiO_2 with cyclohexane, *(8)* is purified by preparative thin-layer chromatography (SiO_2/cyclohexane) and short-path distillation (5×10^{-4} torr; bath temp. 100 °C); yield 0.52 g (75%).

10,11-Diphenyltricyclo[4.3.2.0^{1,6}]undeca-3,10-diene *(6)*: A solution of *(5)* (2.0 g, 11.1 mmol) in *(2)* (20 g, 0.17 mol) is irradiated in a quartz tube for 4 d with eight mercury low-pressure lamps (253.7 nm) in a Rayonet reactor at 30 to 35 °C (after 2 d the solution is transferred to a fresh quartz tube because of deposition of polymeric products). The excess of *(2)* is removed by distillation at 40 °C under vacuum and the oily residue is chromatographed on 200 g SiO_2 with cyclohexane. On treatment of the residue of the first eluate (300 ml after 700 ml forerun) with ethanol (10 ml) at −20 °C, there separates out 1.13 g (34%) of *(6)* (m.p. 79 °C). According to gas chromatographic analysis (1% SE 30, 2m, 210 °C) the mother liquor and the second eluate (500 ml) contain 0.23 g (7%) *(6)*, 0.60 g (18%) (*Z*)-*(7)*, 0.30 g (9%) (*E*)-*(7)*, 0.26 g (13%) *(5)*, and three other compounds (together, *ca.* 5%). (*Z*)-*(7)* and (*E*)-*(7)* were separated from the mixture for ^{1}H-NMR analysis[10] by preparative thin-layer chromatography (SiO_2/cyclohexane). For isolation of *(8)* the mixture is treated, as above, with DDQ and then hydrogenated catalytically with PtO_2 in ethyl acetate; yield after preparative TLC = 0.48 g.

Simple Template Synthesis of Zinc Tetrabenzporphyrin[**]

By *Arnd Vogler* and *Horst Kunkely*[*]

Although tetrabenzoporphyrin (TBP) and some of its metal complexes had already been synthesized some 40 years ago by *Helberger et al.* and *Linstead et al.*[1], very little is known about its chemical and physical properties[2]. The main reasons for this are that the previously published methods for the synthesis of TBP are extremely complicated and the yields are very low[2]. The few investigations so far carried out on TBP have been concerned almost exclusively with the unusual optical properties[2] of this pigment. ZnTBF, for example, exhibits three different luminescences. A study of the redox behavior of TBP complexes could make an important contribution to our understanding of electron transfer by metalloporphyrins (*e.g.* cytochromes) in biological systems. The redox potentials of porphyrins could hitherto be altered essentially only by varying the central metal and additional axial ligands[3]. The greatly expanded π-electron system of TBF should allow reductions and oxidations at comparatively low potentials.

We report here on a single-step template synthesis of ZnTBP, which enables a detailed investigation of TBP and its metal complexes. The synthesis involves heating a solution of commercially available 2-acetylbenzoic acid ("acetophenone-2-carboxylic acid") *(1)* and zinc acetate in aqueous ammonia in the presence of a molecular sieve; the stoichiometry is as shown in the following scheme:

The two electrons required for the reduction could originate from the acetate ion or from decomposition products of excess acid *(1)*. The readily purifiable crude ZnTBP contains no tetrabenzoazaporphyrins which often occur as by-products in the previously described syntheses and which are difficult to separate. ZnTBP was identified by elemental analysis and by IR and UV/VIS spectra[2]. The electron absorption spectrum[2] is especially valuable for detecting the presence of impurities. Demetalation of ZnTBP leads to the protonated form $TBPH_2$[4] which can be used as starting material for the preparation of other complexes[5].

Procedure

To a solution of 20 g of *(1)* (Ega/Aldrich), 30 g zinc acetate, and 1 g sodium hydroxide in 130 ml conc. ammonia in a 2 l flask is added 10 g of molecular sieve (4 Å, Merck) and the mixture rapidly heated under a stream of nitrogen. Rapid heating is achieved by transferring the flask and contents to a fully pre-heated mantle (G2/2). Within a short time an almost black residue is obtained whose temperature reaches about 400 °C. After about 1.5 h the residue is allowed to cool, with continued passage of N_2, and then extracted several times each with 100 ml of hot pyridine. The combined extracts are cooled, treated with 2 l ether, allowed to stand for 1 h, and filtered. The dark-green filtrate is concentrated to about 30 ml in a rotating evaporator and then treated with 150 ml ether. This solution is chromatographed on Al_2O_3 (neutral), using a 20 % solution of pyridine in ether as eluent. The tailings, which contain impurities (absorption bands at 460 nm), are discarded. The eluate is concentrated to 10 ml by evaporation, treated with 100 ml methanol, and then allowed to stand for *ca.* 12 h at −20 °C. The precipitate—shiny, dark violet crystals—is filtered off, washed with ice-cold methanol, then with petroleum ether, and finally dried; yield 2.9 g (17 %).

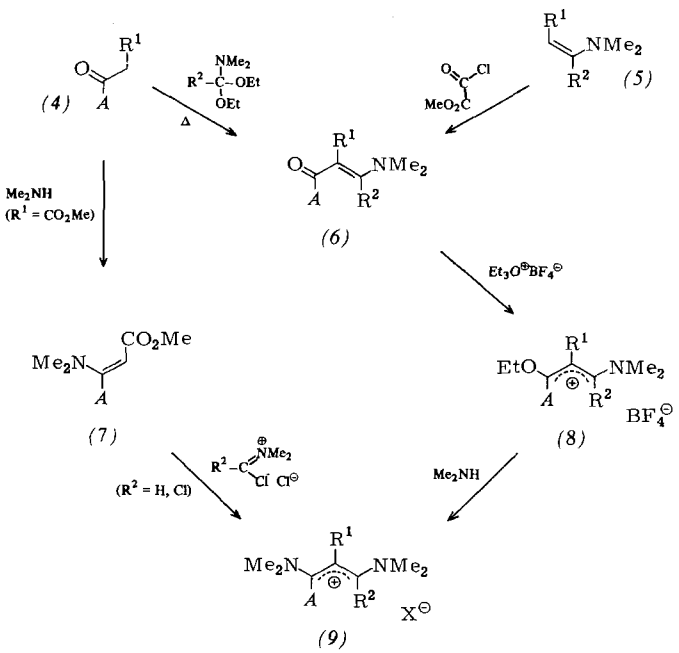
Acceptor-Substituted Allyl Cations as Ambifunctional Electrophiles[1]

By *Rudolf Gompper* and *Rainer Sobotta*[*]

In continuation of our studies on the influence of substituents on the reactions of ambifunctional anions, we have applied the allopolarization principle[2] to allyl cations. On

[*] Prof. Dr. R. Gompper, Dipl.-Chem. R. Sobotta
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

the basis of the charge distribution (HMO model), 1-donor substituted cations are accordingly expected to react preferentially at C-1 with nucleophiles (this is substantiated by several examples), whereas 1-acceptor substituted cations *(2)* should



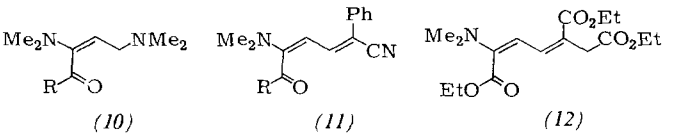
(1) *(2)* *(3)*

$1^{\oplus}_1 > 1^{\oplus}_3$ $1^{\oplus}_3 > 1^{\oplus}_1$

react at C-3. The reactions of *(2)* did not appear to be a very promising field of study because the simple salts of these cations are probably unstable. We therefore turned our attention to the allyl cations *(3)* having a charge distribution corresponding to that of *(2)*; their stability is expected to resemble that of *(1)*.

Salts of type *(9)* containing the partial structure *(3)* can be obtained from *(4)* or *(5)* *via* reactions known from the chemistry of vinamidinium salts[3], β-aminovinyl ketones[4], and enamines[5]: reactions of *(4)* with amide acetals to give

Scheme 1. Synthesis of compounds *(6)* and *(9)*.



(6) (only the action of DMF acetal on several 1,2-propanediones was previously known[6]) or of *(5)* with oxalic ester chloride to give *(6)*, of *(6)* with triethyloxonium tetrafluoroborate to form *(8)*, and then with dimethylamine to form *(9)*, and of *(7)* with amidoyl chlorides which likewise gives *(9)* (see Scheme 1 and Table 1).

Table 1. 1-Acceptor substituted β-aminovinyl ketones *(6)* and vinamidinium salts *(9)*, X = ClO_4.

	A	R^1	R^2	*(6)* M.p. [°C] B.p. [°C/torr]	*(9)* M.p. [°C]

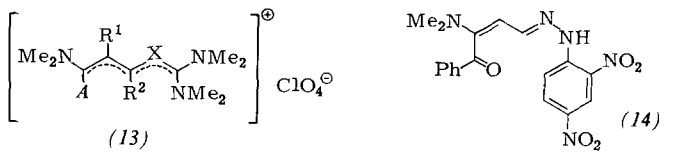
m	COPh	Ph	H	oil [6]	—
n	$CH(OMe)_2$	H	H	150/0.1	90—92



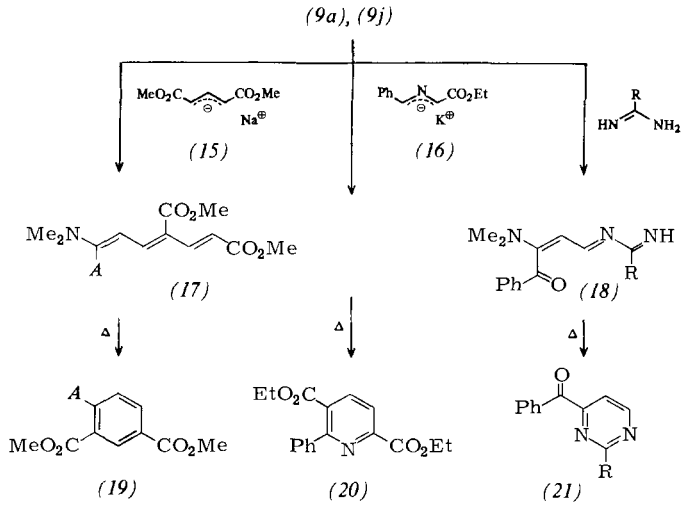
[a] R_2N = Morpholino.

The salts *(9)* are resistant to hydrolysis at room temperature. Reactions of *(9a)* and *(9j)* with $NaBH_4$ in ethanol, leading to *(10a)* (colorless oil) and *(10b)* (yellow oil), demonstrate the expected relationship between the regioselectivity and charge distribution in compounds of type *(2)*. The formation of *(11a)* and *(11b)* from *(9a)* and *(9j)*, respectively, and benzyl cyanide (Na ethoxide in ethanol), of *(12)* from *(9a)* and diethyl succinate (NaH, THF), of *(14)* from *(9j)* and 2,4-dinitrophenylhydrazine, and of *(13a)*—*(13d)* from *(9a)*, *(9h)*, *(9i)*, and *(9j)*, respectively, on heating with 1,1-bis(dimethylamino)ethylene in DMSO, DMF, or dichloromethane, as well as that of *(13e)* and *(13f)* from *(9a)* and *(9i)*, respectively, and tetramethylguanidine could also be subject to thermodynamic control (see Scheme 2 and Table 2).

(10) *(11)* *(12)*

(a), R = OEt; *(b)*, R = Ph

(13) *(14)*

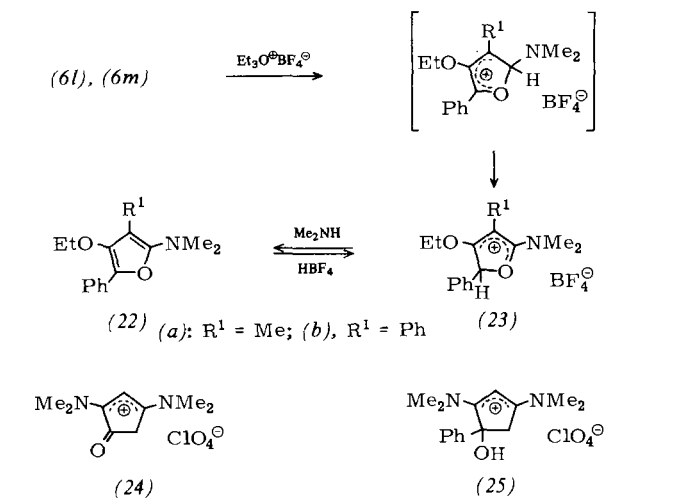


Scheme 2. Open chain reaction products of compounds *(9)*. *(10a)*, b.p. 115°C/0.1 torr. ^{1}H-NMR ($CDCl_3$): $\delta = 1.36$ (t, 3H), 2.26 (s, 6H), 2.63 (s, 6H), 3.03 (d, 2H), 4.30 (q, 2H), 4.70 (t, 1H); *(10b)*, b.p. 150°C/0.1 torr; *(11a)*, m.p. 64—66°C; *(11b)*, m.p. 138—139°C; *(12)*, b.p. 190°C/0.1 torr; *(13)* see Table 2; *(14)*, m.p. 163—165°C.

Table 2. Acceptor-substituted salts *(13)*.

	A	R^1	R^2	X	*(13)*, m.p. [°C]
a	CO_2Et	H	H	CH	128—132
b	CO_2Me	CO_2Me	H	CH	124—126
c	CO_2Me	CO_2Me	NMe_2	CH	164—167
d	COPh	H	H	CH	173—175
e	CO_2Et	H	H	N	55—56
f	CO_2Me	CO_2Me	NMe_2	N	145—147

The preparative significance of the salts *(9)* is further demonstrated by reactions resembling the aromatic synthesis described by *Jutz*[3c] which lead to (hetero)aromatic carboxylic acids and ketones: reaction of *(9a)* and *(9j)* with *(15)* initially gives the hexatrienes *(17a)* and *(17b)*, respectively, which are transformed into the benzenecarboxylic esters *(19a)* and *(19b)* on heating in xylene. The primary product obtained upon the action of *(16)*[7] on *(9a)* affords the pyridinedicarboxylic ester *(20)* on bulb-to-bulb distillation. Compound *(9a)* reacts with amidines to form *(18a)* and *(18b)*, from which the pyrimidines *(21a)* and *(21b)* result on heating (see Scheme 3).



The action of triethyloxonium tetrafluoroborate on *(6l)* and *(6m)* does not give the salts of the allyl cations *(8l)* and *(8m)*, respectively, but instead the furanium salts *(23a)* and *(23b)*, which form the furans *(22a)* (49%, orange-yellow

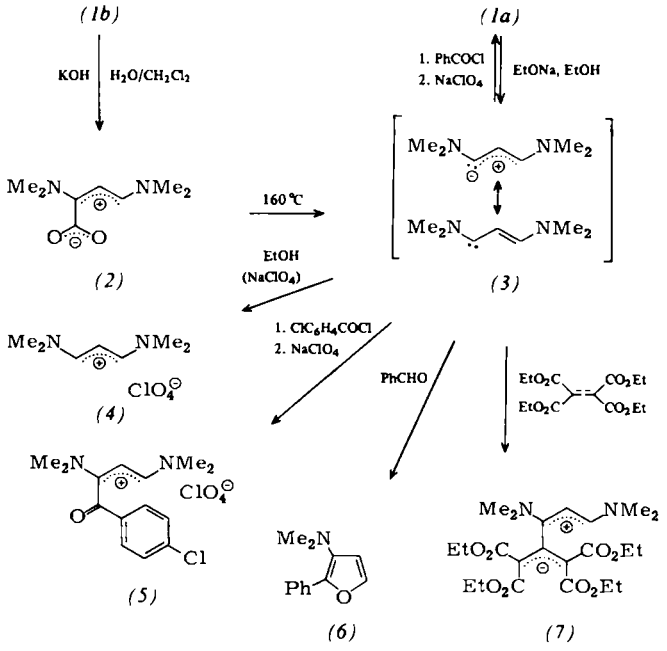
1,3-Bis(dimethylamino)vinylcarbene[1]

By *Rudolf Gompper* and *Rainer Sobotta*[*]

In compliance with the charge distribution in the allyl system, 1-acceptor substituted vinamidinium salts *(1)* preferentially react with nucleophiles at C-3[1]. However, the ambifunctional character of *(1)* also embraces the acceptor group

(1a), R^1 = R^2 = H; *A* = COPh
(1b), R^1 = R^2 = H; *A* = CO_2Et



A: treatment of *(1a)* with Na ethoxide in ethanol leads exclusively to the salt *(4)* together with ethyl benzoate. The simplest explanation of this behavior invokes the intermediacy of the nucleophilic carbene *(3)*, which undergoes subsequent protonation. Analogous eliminations of acyl groups have been observed with 2-acyl-1-methylpyridinium salts[3]; the decarboxylation of 1-methylpyridinium-2-carboxylate[4] should also be mentioned in this context.

A detailed study of the reactions of the nucleophilic vinylcarbene *(3)* is facilitated by the possibility of generating the species from the zwitterion *(2)*, which is accessible by alkaline hydrolysis of *(1b)* (81%; colorless crystals; see Scheme 1).

Heating of *(2)* with an excess of benzoyl chloride or 4-chlorobenzoyl chloride to 160°C affords *(1a)*, or *(5)*, respectively, in 65—70% yield. Similar reaction with benzaldehyde gives the furan *(6)*.

The reaction of *(2)* with tetraethyl allenetetracarboxylate, leading to the zwitterion *(7)* (32%; yellow needles), is remarkable. The formation of *(7)* demonstrates that cyclopropanes do not necessarily result on reaction of carbenes with olefins (for further examples, see ref. [5]).

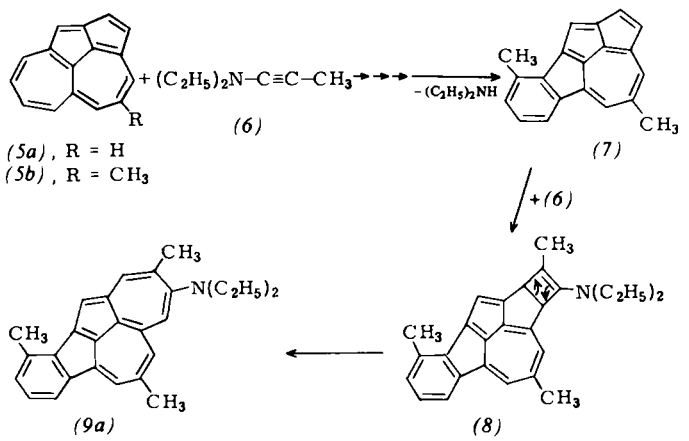
Synthesis of Penta- and Hexacyclic Conjugated Hydrocarbons by Cycloaddition Reactions[**]

By *Klaus Hafner, Hans Dieter Diesel*, and *Winfried Richarz*[*]



Cycloaddition reactions of bi- and tricyclically conjugated hydrocarbons such as pentalenes, azulenes, and aceheptylenes with electron-poor and electron-rich alkynes recently opened up an unexpectedly facile entry to cyclically conjugated systems[1]. On examining the scope and limitations of this synthetic approach we obtained, among other compounds, for the first time, the penta- and hexacyclic polyenes *(4)*, *(9a)*, and *(10)*.

By analogy with the dipolar cycloaddition of dimethyl acetylenedicarboxylate and aceheptylene leading to dimethyl 1,2-dicyclopenta[*ef,kl*]heptalenedicarboxylate[1c], the 2,3-ethano-bridged derivative of aceheptylene, 1,2-dihydropentaleno-[6.1.2-*def*]heptalene *(1)*[2], also reacts with the electron-poor alkyne *(2)* *via peri*-annelation of a five-membered ring to give 30% of the dihydropentaleno[6.1.2-*fgh*]aceheptylene derivative *(3)*[3] (yellow-brown rods, m.p. 176 °C). On dehydrogenation with 2,3-dichloro-5,6-dicyanoquinone (DDQ), *(3)* yields the first completely conjugated nonbenzenoid pentacyclic compound having an 18π-electron system, the ester *(4)*,

in 92% yield as brown rods of m.p. 164—165 °C. All attempts to synthesize *(4)* directly by cycloaddition of *(2)* and pentaleno[6.1.2-*def*]heptalene *(5a)*[2] have been unsuccessful so far.

In contrast, reaction of the methyl derivative *(5b)*[4] with *N,N*-diethyl-1-propynylamine *(6)* for 90 min in refluxing xylene affords the thermally stable pentacyclic 1,2-benzopentaleno[6.1.2-*def*]heptalene derivative *(9a)* in 34% yield (based on conversion of *(5b)*) as brown needles of m.p. 188 °C. Like aceheptylene[1c], *(5b)* is expected to initially undergo a dipolar cycloaddition with *(6)*. Two consecutive valence isomeriza-

tions and subsequent elimination of diethylamine lead to the pentacyclic hydrocarbon *(7)*. Like cyclopent[*cd*]azulene[1b], this product immediately combines in another formal [2+2] cycloaddition with a further mole of *(6)* to give *(8)*, which by valence isomerization finally yields *(9a)*. Even on reaction of *(5b)* with less than one equivalent of *(6)*, compound *(7)* could not be isolated. In accordance with quantum-chemical calculations[5] on the dicyclopent[*cd,ij*]azulene system present in *(7)*, this compound exhibits a pronounced reactivity towards cycloaddition partners, mainly at the double bond in the unsubstituted five-membered ring.

Like *(5b)*, but unlike *(9a)*, the hydrocarbon *(9b)*[6] also reacts with *(6)* in a dipolar cycloaddition at the unsubstituted seven-membered ring. Thereby trimethyldibenzo[4,5;7,8]dicyclopent[*cd,ij*]azulene *(10)* is formed (grayish blue platelets; m.p. 224—225 °C; <10 % yield) in a reaction sequence analogous to the formation of *(7)*. Compound *(10)* is the first fully conjugated thermally stable derivative of the hitherto unknown dicyclopent[*cd,ij*]azulene, which presumably has a high ring strain.

The major product formed besides *(10)*, however, is the ketone *(15)* (greenish yellow needles, m.p. 290 °C; yield 56 %), which is only sparingly soluble in organic solvents. This points to a primary attack of *(6)* on *(9b)* with formation of the resonance-stabilized dipole *(11)*. Subsequent cyclization gives the cyclobutene derivative *(12)*, and valence isomerization of *(12)* *via* the thermally unstable cyclononaazulene derivative *(13)* forms the enamine *(14)*, which yields *(15)* on hydrolysis.

Richarz*, Dissertation, Technische Hochschule Darmstadt 1977).

2,3-Dioxa-7-thiabicyclo[2.2.1]heptane: A New Heterobicyclic System Possessing the Thiaozonide Structure[**]

By *Waldemar Adam* and *Henny J. Eggelte*[*]

To the best of our knowledge thiaozonides possessing the 2,3-dioxa-7-thiabicyclo[2.2.1]heptane structure *(3)* are unknown. The only related substance of this type to have been described[1] is the rather labile and therefore difficult to characterize diphenylacenaphthylene derivative *(8)*.

We now wish to report that thiaozonides *(3a)* and *(3b)* can be prepared in good yields, isolated, and characterized. We have also found that oxidation of electron-rich thiophenes *(1)* with singlet oxygen affords the postulated highly reactive thiophene endoperoxides *(2)*, and that peracid oxidation of the thiaozonides *(3)* leads to 1,4-diones *(6)* by sulfur dioxide elimination, presumably *via* the unusual sulfones *(7)*.

(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)*

(8)

(a), R = CH_3; *(b)*, R = $C(CH_3)_3$

Alkyl-substituted thiophenes *(1)* undergo photosensitized reaction with singlet oxygen to afford 2-butene-1,4-dione derivatives *(4)* and sulfenes *(5)*[2], which presumably arise from the labile, intermediary thiophene endoperoxides *(2)* by thermal loss of sulfur or rearrangement, respectively. If the endoperoxides *(2)* really are reaction intermediates in the photooxygenation of thiophenes *(1)*, then it should be possible to reductively trap them with diazene, as recently demonstrated for the unstable endoperoxides of cyclopentadiene[3a], spirocycloheptadiene[3b], fulvene[3c], and α-pyrone[3d].

Indeed, photooxygenation of 2,5-dimethylthiophene *(1a)* in CH_2Cl_2 at −78 °C with tetraphenylporphyrin as sensitizer, followed by diazene reduction of *(2a)*[4] in CH_2Cl_2 at −78 °C[3a], gave a 46% overall yield of thiaozonide *(3a)* after silica gel chromatography at −20 °C and elution with CH_2Cl_2[5]. This compound is thermally unstable and rapidly decomposes at room temperature to 2,5-hexanedione *(6a)*. The same diketone was obtained in essentially quantitative yield by triphenylphosphane desulfurization of *(3a)*[6], confirming the thiaozonide structure *(3)*.

In an analogous manner, 2,5-di-*tert*-butylthiophene *(1b)* was converted into the thiaozonide *(3b)* by diazene reduction of the unstable *(2b)*[4]. Compound *(3b)* was isolated by silica gel column chromatography at −20 °C with CH_2Cl_2 as eluant and could be purified by low temperature recrystallization from pentane. *(3b)* is more stable than *(3a)*, but also decomposes rapidly to 2,2,7,7-tetramethyl-3,6-octanedione *(6b)* at room temperature. The diketone *(6b)* was also obtained in essentially quantitative yield by catalytic hydrogenation over Pd/C, thus confirming the thiaozonide structure *(3)*.

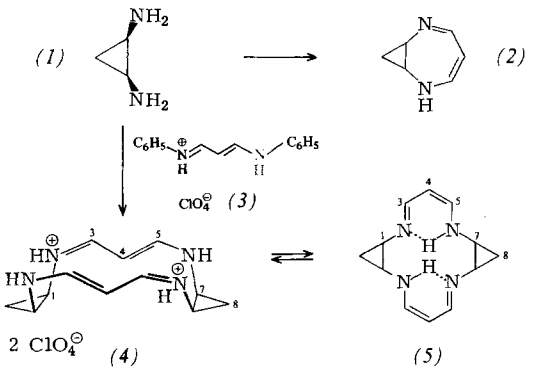
Synthesis and Stereochemical Consequences of Protonation of a Bishomodihydrotetraaza[14]annulene: A New Macrocyclic Complex Ligand[**]

By *Helmut Quast, Josef Stawitz, Karl Peters*, and *Hans Georg von Schnering*[*]



Unsaturated fourteen-membered heterocycles having two[1] or four[2] nitrogen atoms are sometimes formed with surprising ease instead of azepines or diazepines despite the absence of transition metal ions acting as template. Derivatives of tetraaza[14]annulenes are of interest because of their ability to complex transition metal ions[3]. On preparation of the diazahomotropilidene *(2)* from *cis*-1,2-cyclopropanediamine *(1)*[4] we observed the formation of bishomodihydrotetraaza[14]annulene *(5)*. This compound exhibits a drastic change of structure on protonation hitherto known only for corresponding acyclic compounds such as the base underlying the perchlorate *(3)*[5]. Moreover, *(5)* also warrants attention as

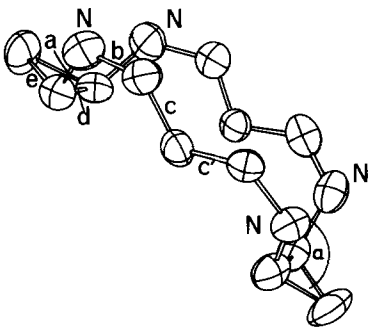
[+] To whom correspondence should be addressed.

a new complex ligand and, because of its periphery of 16 atoms, as a potential precursor of porphinoid systems[6].

Reaction of the dihydrochloride of *(1)*, malondialdehyde dianil perchlorate *(3)*, and sodium acetate in methanol gives a product whose hot aqueous solution precipitates a colorless diperchlorate *(4)* on addition of sodium perchlorate. Treatment of *(4)* with sodium methoxide in methanol gives the base *(5)* as pale yellow needles of m.p. 147—149°C, which exhibit recrystallization at *ca.* 155°C (without any change in the IR spectrum) and a second m.p. at 185°C.

The gross structure of the diperchlorate *(4)* and the free base *(5)* follows from elemental analysis, IR[7], and ^{1}H-NMR spectra (Table 1), and from the mass spectrum of *(5)*. The broadened NH band of *(5)* is independent of concentration. This finding and the downfield shift of the *N*-protons[2c, 5] suggest intramolecular hydrogen bonding.

The ^{1}H-NMR spectra of *(4)* and *(5)* each contain just *one* ABX_2 spectrum for the cyclopropane protons and just *one* AX_2 spectrum for the methine protons, and thus assign a symmetry to the two compounds that may (as always) also be due to fast dynamic processes. The small coupling constants of the methine protons of *(5)* prove the cisoid configuration of the N2—C3—C4—C5—N6 and N10—C11—C12—C13—N14 units[5] expected from intramolecular hydrogen bonds. On the other hand, the methine protons of *(4)* exhibit almost the same coupling constant as in *(3)*[5] and other *trans*-configurated trimethine cyanines[8]. While this confirms the transoid configuration of the corresponding systems in *(4)* no further information is available from the NMR spectrum about the other bonds of the fourteen-membered ring or about the relative arrangement of the cyclopropane rings.



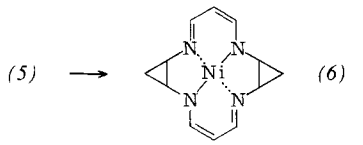


Fig. 1. Structure of the diperchlorate *(4)*. The compound forms monoclinic crystals of space group $P2_1/n$ (No. 14); $a = 1154.2$, $b = 1716.9$, $c = 915.1$ pm, $\beta = 101.19°$, $Z = 4$; Syntex $P\bar{1}$ four-circle diffractometer; scintillation counter; MoKα radiation; $2\theta \leq 55°$; 2642 *hkl* with $I > 2\sigma(I)$; $R_{aniso} = 0.084$ (H atoms isotropic); site disorder in one of the $ClO_4^\ominus$ ions. Average bond lengths: $a = 143.1$, $b = 131.9$, $c = 137.9$, $d = 151.7$, and $e = 149.2$ pm. The individual distances deviate from the average values by at most 5 pm. Bond angles and torsional angles: $a/b = 123.7$, $b/c = 124.6$, $c/c' = 118.6$, $a/d = 120.1$, $a/e = 117.5°$; $a/b/c = 1.0$ and $b/c/c' = 8.6°$.

charge delocalization. The three-membered rings are inclined to the plane formed by the neighboring bonds *a* by $\alpha = 106.1°$.

Brief heating of *(5)* with nickel(II) acetate tetrahydrate in ethanol to 70°C affords a nickel complex as a green powder that is readily soluble in nonpolar solvents such as toluene; its mass spectrum ($m/e = 272$, 100%, M^+) and ^{1}H-NMR spectrum (Table 1) indicate structure *(6)*. Solutions of *(6)* are air-sensitive and on standing they deposit an insoluble bluish-black substance which is presumably polymeric[2a].

Procedure

(1)·2HCl (1.45 g, 10 mmol), sodium acetate (1.66 g, 20 mmol), and *(3)* (3.22 g, 10 mmol) were stirred together in methanol (500 ml) at 25°C for 3 d. The residue obtained on evaporation in vacuum was digested with ether (200 ml) and washed with ethanol (12 ml). Compound *(4)* was obtained as colorless crystals (m.p. 309—312°C; yield 676 mg, 32%) from aqueous solution (charcoal) by addition of sodium perchlorate.

Table 1. ^{1}H-NMR data (90 MHz) of the diperchlorate *(4)* in [D]trifluoroacetic acid and of the base *(5)* and the nickel complex *(6)* in [D]chloroform. Only one set of equivalent protons is listed. The values of the ABX_2 spectrum of the cyclopropane protons were optimized with the aid of the LAOCOON III computer program.

Decamethyl-1λ³,4λ³-diphospha-2,3,5,6,7-pentastannabicyclo[2.2.1]heptane, a Bicyclic Compound Rich in Tin[**]

By *Bernd Mathiasch* and *Martin Dräger*[*]

Dimethylstannane *(1)* reacts with chalcogens to give chalcogen hydrides and compounds containing tin-chalcogen bonds; in the presence of catalytically active bases, hydrogen and compounds containing tin-tin bonds are formed (cf. [1]).

We have now found that base-catalyzed reaction of *(1)* with white phosphorus affords hydrogen, phosphane, and 2,2,3,3,5,5,6,6,7,7-decamethyl-1λ³,4λ³-diphospha-2,3,5,6,7-pentastannabicyclo[2.2.1]heptane (pentakis(dimethyltin) diphosphide) *(2)* in 62% yield:

$$5(CH_3)_2SnH_2 + P_4 \xrightarrow[Et_2O/295\,K]{DMF} 2H_2 + 2PH_3 + [(CH_3)_2Sn]_5P_2$$
(1) *(2)*

In the absence of organic bases (dimethylformamide, pyridine) mainly the already well-known hexakis(dimethyltin) tetraphosphide *(3)* is formed[2]:

$$6(CH_3)_2SnH_2 + 2P_4 \xrightarrow[Et_2O/295\,K]{} 4PH_3 + [(CH_3)_2Sn]_6P_4$$
(1) *(3)*

Organotin hydrides containing tin-tin bonds react under these conditions to give heterocycles still more rich in tin; *e.g.* tetramethyldistannane *(3)* reacts with white phosphorus to give hexakis(dimethyltin) diphosphide *(5)*[3]:

$$3(CH_3)_4Sn_2H_2 + P_4 \xrightarrow[Et_2O/273\,K]{} 2PH_3 + [(CH_3)_2Sn]_6P_2$$
(4) *(5)*

On recrystallization from benzene, *(2)* forms colorless, strongly refracting crystals which decompose only slowly at room temperature, but rapidly with discoloration at temperatures above 400 K. An X-ray structure[4] of *(2)* showed the molecule to have ideal C_{2v} symmetry with measured bond lengths within 2σ (Fig. 1).

[*] Prof. Dr. M. Dräger, Dr. B. Mathiasch
Institut für Anorganische Chemie und Analytische Chemie der Universität Johann-Joachim-Becher-Weg 24, D-6500 Mainz (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

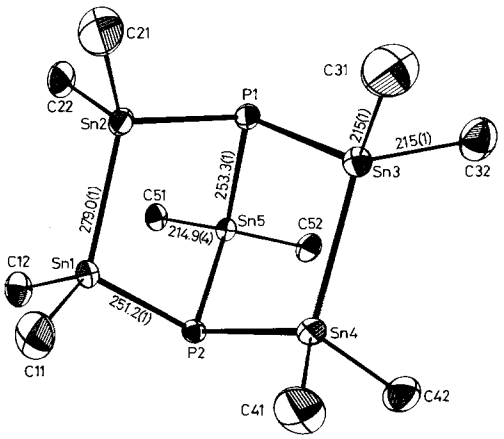

Fig. 1. Molecular structure of *(2)*, with bond lengths in pm. The torsion angles about the tin-tin bonds, like the corresponding angles in norbornane [5] are 0°. Representative bond angles and torsion angles [°]:

Sn1—Sn2—P1	106.8(1)	P2—Sn1—Sn2—P1	0.1(3)
Sn2—P1—Sn3	102.2(1)	Sn1—Sn2—P1—Sn3	68.1(1)
Sn2—P1—Sn5	93.7(1)	Sn1—Sn2—P1—Sn5	26.5(1)
P1—Sn5—P2	113.6(1)	Sn2—P1—Sn5—P2	51.2(1)
C11—Sn1—C12	107.3(2)		
C51—Sn5—C52	111.7(2)		

As shown by the ^1H- and ^{13}C-NMR spectra, the rigid bicyclic skeletal structure of *(2)* is retained in solution. Three types of methyl groups can be distinguished, both by their chemical shift[6] as well as by their couplings to ^{31}P and $^{117/119}Sn$.

The extent of the ^3J(PSnCH) and the ^2J(PSnC) coupling is strongly dependent upon the position of the coupling groups (nuclei) in relation to the non-bonding orbital on the phosphorus atom (Table 1), whose direction was determined by two methods[7].

Table 1. Torsion angles/coupling constants [7] (cf. text).

Torsion angle	[°]	41	61	76
^2J(PSnC)	[Hz]	10.3	8.4	5.9
^3J(PSnCH)	[Hz]	3.3	2.1	1.5
$^2J(^{119}$SnCH)	[Hz]	49.7	45.4	47.4
$^1J(^{119}$SnC)	[Hz]	205		200

Experimental

A mixture of *(1)* (3.6 g, 24 mmol) in 50 ml ether/0.5 ml dimethylformamide and 0.6 g (19 mmol) of white phosphorus is gently stirred for 12 h at room temperature in an Ar-filled flask furnished with a rubber balloon. Dissolution of the phosphorus is accompanied by precipitation of needle-shaped colorless crystals. The reaction mixture is allowed to warm to *ca.* 300 K, filtered under argon, and the residue recrystallized from dichloromethane. On cooling to 240 K the filtrate yields a further fraction of *(2)*; total yield 2.4 g (62%).

(*Z*)-5-Decenyl Acetate, a Sex Attractant for the Male Turnip Moth *Agrotis segetum* (Lepidoptera)[**]

By *Hans Jürgen Bestmann, Otto Vostrowsky, Karl-Heinz Koschatzky, Hans Platz, Thorolf Brosche, Iwan Kantardjiew, Marlies Rheinwald*, and *Werner Knauf*[*]

The turnip moth *Agrotis* (=*Scotia*) *segetum* (Noctuidae, Lepidoptera) is an ubiquitous grain pest, which up to the present time has proved very difficult to control. An electroantennogram screening (EAG screening)[1,2] with *ca.* 100 unsaturated aldehydes, alcohols, and their acetates on the antennas of the male species of the insects showed that (*Z*)-5-decenyl acetate *(7)* caused the greatest excitation. We still found EAG responses on loading the stimulus source with as little as 10^{-5} µg of *(7)*. As expected[2,3] (*Z*)-7-dodecenyl acetate also exhibits high EAG activity.

We have synthesized *(7)* according to Scheme 1.

Scheme 1.

The phosphonium salt *(1)*, obtainable from 4-pentenyl bromide and triphenylphosphane, is converted by the silazide method[4] into the ylide *(2)*, which reacts with pentanal *(3)* at -78 °C in a (*Z*)-stereoselective Wittig reaction to give 1,(*Z*)-5-decadiene *(4)*, b.p. 55—57 °C/14 torr, yield 62%. Hydroboration of *(4)* with 9-borabicyclo[3.3.1]nonane *(5)* (9-BBN) and subsequent oxidation with H_2O_2 affords the alcohol *(6)*, b.p. 114—115 °C/14 torr, yield 82%, which on acetylation gives the acetate *(7)*, b.p. 105—107 °C/16 torr, yield 87%.

In order to identify the natural pheromone the abdominal tips with sex glands were excised from 500 females and together extracted with hexane. The pheromone extract was filtered and separated chromatographically on a silica gel column (0.06—0.2 mm, 30 × 1.5 cm) with an eluent system of increasing polarity (pentane/diethyl ether/methanol) into 17 fractions, the physiological activity of which was determined by means of the EAG test. The active fractions were combined, concentrated in a stream of nitrogen and analyzed by capillary gas chromatography synchronously with a flame ionization detector and EAG detector[5]. The EAG detector showed a physiologically active compound having the retention time of (*Z*)-5-decenyl acetate *(7)*. Cochromatography of synthetic *(7)* gave retention times identical with those of the contents of the gland substances.

Proof of the presence of *(7)* in the sex glands of the females was provided by an analysis of the extract by coupled capillary gas chromatography—mass spectroscopy. 17 ions[6] were inferred from the mass spectrum of synthetic *(7)*. All these ions could be determined simultaneously in the chromatogram of the extract, precisely at the previously determined retention time of *(7)*. For further proof of the structure, the pheromone extract was separated gas chromatographically on a packed column; fractions were collected at minute intervals in cooled glass capillaries. Once again, according to the EAG test the activity was found in the fraction having the retention time of synthetic *(7)*.

Synthetic (*Z*)-5-decenyl acetate *(7)* was transferred to a multistep single-tube olfactometer[7], monitored with an automatic television camera fitted with time scanning and magnetic tape printout, and its efficacy as an attractant for male turnip moths was checked. *(7)* proved to have a luring effect up to attractant loadings of 10^{-6} µg, whereas above 10^{-3} µg an inhibiting effect was observed.

Trapping of the male species in open wind-socks was still recorded at a loading of 5×10^{-4} µg of *(7)*; more than 0.5 µg of *(7)* has an inhibiting effect.

Thus, (*Z*)-5-decenyl acetate *(7)* has been identified for the first time as a sex attractant for Lepidoptera. It is more effective than any of the previously reported butterfly pheromone components.

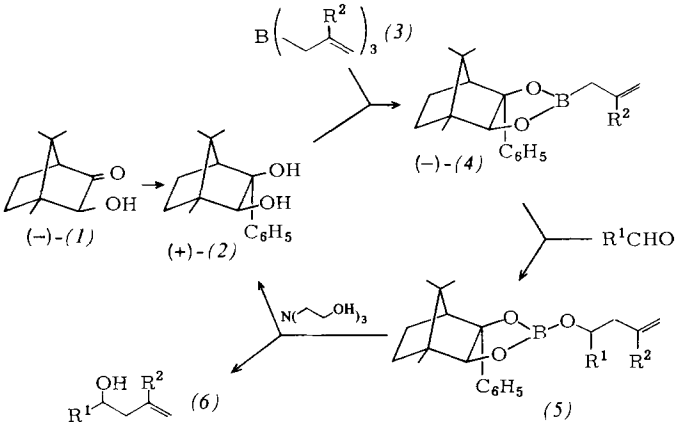
Enantioselective Synthesis of Homoallyl Alcohols *via* Chiral Allylboronic Esters

By *Thomas Herold* and *Reinhard W. Hoffmann*[*]



We report on the enantioselective synthesis of secondary homoallyl alcohols of type *(6)* by a modification of the

[*] Dipl.-Chem. T. Herold, Prof. Dr. R. W. Hoffmann
Fachbereich Chemie der Universität
Lahnberge, Postfach 1929
D-3550 Marburg 1 (Germany)

known[1] addition of allylboronic esters to aldehydes. This procedure improves upon and supplements existing methods[2] for the enantioselective conversion of aldehydes into secondary alcohols.

We used the glycol *(2)* [obtained from (+)-camphor *via* the ketol *(1)*[3] and its reaction with phenyllithium in ether] as chiral matrix. Reaction of equimolar amounts of the allylboranes *(3)*[1] and *(2)* (THF, 30 min, 50 °C) yielded more than 95 % of the allylboronic esters (−)-*(4)* after vacuum distillation. A 2 M solution of *(4)* reacted (*n*-hexane, 1 h at −40 °C, 12 h at 25 °C) with an equivalent amount of an aldehyde to give the borates *(5)*, from which the alcohols *(6)* were obtained directly by cleavage with 1.2 equiv. of triethanolamine (2 h, 25 °C) (Table 1).

Except in the case of *(6f)*, the alcohols *(6)* were purified by vacuum distillation; the chiral glycol (+)-*(2)* was recovered in approximately 80 % yield by chromatography on silica gel with CH_2Cl_2. The whole sequence *(2)* → *(6)* can also be effected in a one-pot process without isolation of intermediates.

Table 1. Enantiomeric excesses and yields in the synthesis of the alcohols *(6)*.

	R^1	R^2	$[\alpha]_D^{20}$	*c* solv. [a]	e.e. [%] [b]	Yield [%] [c]

(6i)	*n*-Pr	Me	+23.08	2.60 E	65 (*R*)	84
(6j)	*i*-Pr	Me	− 1.40	8.46 E	76 (*S*)	87
(6k)	*t*-Bu	Me	− 3.10	8.39 E	70 (*S*)	92

[a] Solvents: E = diethyl ether, B = benzene, D = dichloromethane. [b] The enantiomeric excess of the alcohols *(6)* was determined in most cases by ^{19}F-NMR spectroscopy according to *Mosher* [4]. [c] Isolated yields of *(6)* based on (−)-*(4)*.

The enantiomeric excesses are surprisingly constant for various aldehydes with a (sp^3-C)—CHO structure. With benzaldehyde, however, and other aldehydes with a (sp^2-C)—CHO structure the values range from 24 to 54 %.

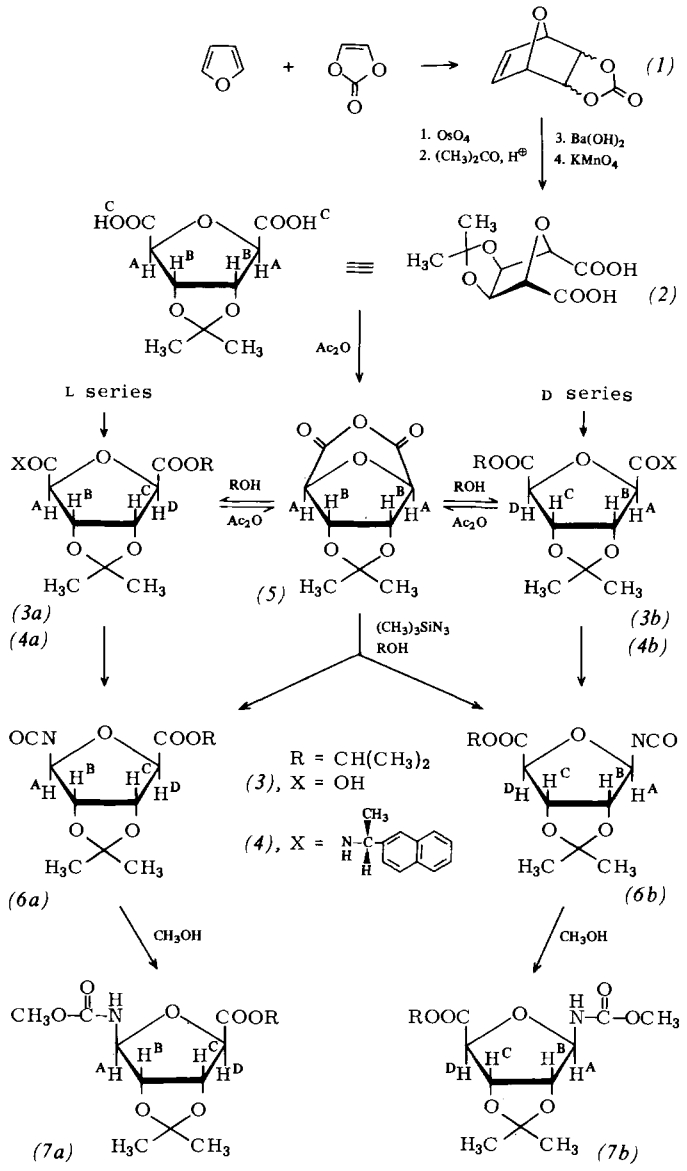
Functional Derivatives of D- and L-Ribose by Optical Resolution with Recycling[**]

By *Richard R. Schmidt* and *Albrecht Lieberknecht*[*]



Starting from furan and the readily accessible vinylene carbonate[1] we have developed a chirally economic synthesis[2] of the functional D- and L-riburonic acid derivatives *(6a)* and *(6b)*[3]. These compounds are valuable intermediates for the synthesis of biologically important nucleosides and nucleoside uronic acids[4] and sugar-amino acid conjugates[5].

Five straightforward reaction steps without isolation of intermediates transform the *meso*-Diels-Alder adduct *(1)*[1] (mixture of diastereomers) into the cyclic *meso*-anhydride *(5)* (purified by distillation) in 40 % overall yield (Table 1). Compound *(1)* is specifically transformed by osmium tetroxide into the *exo,exo*-dihydroxy derivative, which is subsequently isopropylidenated at the hydroxy groups; removal of the carbonate protecting group by barium hydroxide and oxidation by potassium permanganate converts the mixture of diastereomers into the sterically uniform *meso*-1,5-anhydroallaric acid *(2)* which contains the principal configurational components of D- and L-ribose[6]; reaction with acetic anhydride gives the *meso*-anhydride *(5)*, which assumes a key role in the further synthesis.

Reaction of *(5)* with trimethylsilyl azide quantitatively yields a racemate of the ribofuranosyl isocyanates *(6a)* and *(6b)*. This reaction removes the *meso* structure of *(5)* and irreversibly generates a mixture of enantiomers which reacts with methanol to give the enantiomeric urethanes *(7a)* and *(7b)*.

[**] *De-novo* Synthesis of Sugars, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 1: *R. R. Schmidt, R. Angerbauer*, Angew. Chem. *89*, 822 (1977); Angew. Chem. Int. Ed. Engl. *17*, 783 (1977).

A chirally economic synthesis is characterized by recycling of the undesired isomer. To this end the *meso* structure of *(5)* must be reversibly effaced. This is accomplished by alcoholysis with isopropanol. The enantiomeric dicarboxylic monoesters *(3a)* and *(3b)* fulfill all the requirements of this concept for directed asymmetric synthesis (Table 1):

- Optical resolution of *(3a)* and *(3b)* is possible with brucine. The course of resolution was monitored chromatographically by means of the diastereomeric (*R*)-1-(β-naphthyl)-ethylamides *(4a)* and *(4b)*[8] which also permit assignment of configuration[7]. No racemization was observed under the conditions of resolution and isolation of the monoester *(3a, b)*.
- After prior activation of the carboxyl group of *(3b)* with chloroformic ester, β-D-ribofuranosyl isocyanate *(6b)* can be produced stereospecifically *in situ* from *(3b)* with trimethylsilyl azide[9].
- The *meso*-anhydride *(5)* is conveniently regenerated from the monoester *(3a, b)* with acetic anhydride.

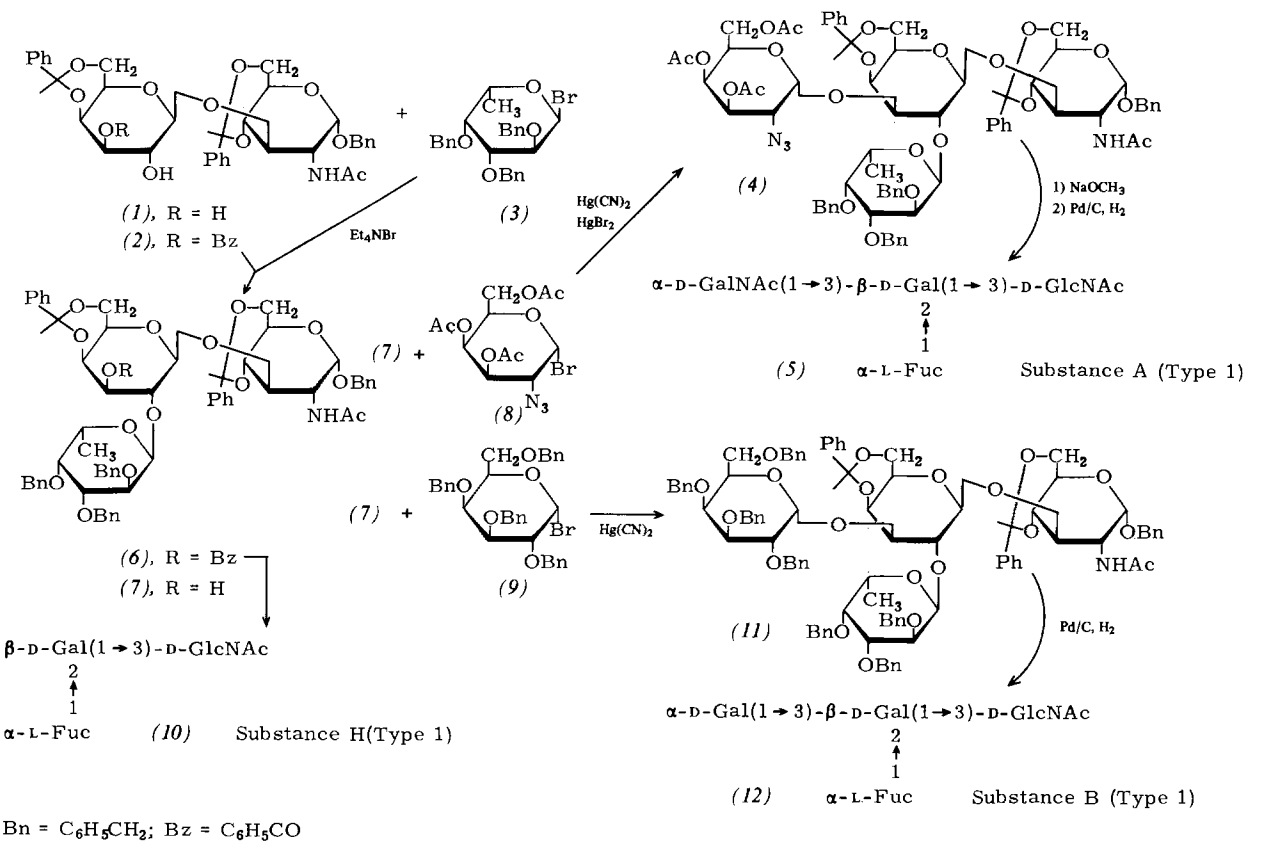
Synthesis of the Tetrasaccharide Chains of the Determinants of Blood Group Substances A and B[**]

By *Hans Paulsen* and *Čeněk Kolář*[*]

The terminal carbohydrate chain of blood group substances of the AB0 system represent the determinant structure of the antigen responsible for the high immunological specificity of these glycoproteins[1]. After having developed a new stereoselective method for the preparation of α-glycosidically linked 2-amino-2-deoxy-D-galactose[2], we have now succeeded in synthesizing the terminal carbohydrate chains of the blood group substances A, B, and H.



As starting substance we used the readily accessible disaccharide benzyl-2-acetamido-3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside[3], which after selective cleavage of the *O*-acetyl groups and subsequent reaction with benzaldehyde affords the bis-(benzylidene) compound *(1)*. *(1)* can be selectively benzoylated at the OH group on C-3 to give *(2)*[4]. The fucose residue can then be linked to the remaining 2'-OH group of *(2)* by reaction with the bromide *(3)* to give *(6)* in 82% yield. On halide ion catalysis this reaction affords only the α-L product[5]. The 3'-OH group can be released again by selective alkaline hydrolysis with formation of *(7)*. Complete deblocking by hydrogenation affords the chain *(10)* of the H substance (Type 1)[5] ($[\alpha]_D^{20} = -15.4°$) in 74% yield based on *(7)*.

The trisaccharide *(7)* can react directly with the α-bromide *(8)*, and, in the presence of $Hg(CN)_2/HgBr_2$, yields the α-D-linked tetrasaccharide *(4)* in 63% yield. The inversion technique generally used by us[2,6] [conversion of *(8)* into the β-chloride and subsequent transformation into the α-glycoside] is unnecessary in this reaction. The tetrasaccharide chain *(5)* of the blood group substance A (Type 1) ($[\alpha]_D^{20} = 53.8°$) can be obtained in 77% yield (based on *(4)*) from *(4)* by deblocking with sodium methoxide and hydrogenolytic cleavage.

The blood group substance B can be obtained in the same way from the trisaccharide *(7)*. The galactosyl bromide *(9)* reacts with *(7)* in the presence of $Hg(CN)_2$[7] also to give the α-D-linked tetrasaccharide *(11)* (in 73% yield). The tetrasaccharide chain *(12)* of the blood group substance B (type 1) ($[\alpha]_D^{20} = 33.3°$) is obtainable from *(11)* in a deblocking step by hydrogenolytic cleavage with Pd/C in glacial acetic acid (yield 82% based on *(11)*).

Direct Synthesis of Metal-Free 1,8-Dihydrotetraaza-[14]annulenes Utilizing the Metal-Template Effect[**]

By *Gerhold Mühmel* and *Eberhard Breitmaier*[*]

Metal chelates of type *(5)*, M = Ni, are formed by cyclocondensation of enediamines *(1)* and 3-ethoxyacroleins *(2)* in the presence of nickel(II) ions[1]. This synthesis, giving yields of about 90 %, is facilitated by the favorable arrangement of two enediamine groups in complex *(3)* and by the stability of the resulting macrocyclic metal chelate (metal-template effect[2]). However, the metal-free macroheterocycle *(4)* is often preparable in only poor yield from *(5)*.

During our experiments concerned with the preparation of metal chelates 6,13-dialkyl-1,8-dihydro-1,4,8,11-tetraaza[14]-annulene-2,3,9,10-tetracarbonitriles by the reaction sequence *(1)* → *(3)* → *(5)* we found that the metal-free macroheterocycles *(4)* are formed directly if the metal ion M^{n+} has an ionic radius[3] significantly smaller or larger than 70 pm. Thus we obtained complexes of type *(5)* with Ni^{2+} (r = 69 pm), Co^{2+}, Cu^{2+} (both with r = 72 pm), Fe^{2+}, and Zn^{2+} (both with r = 74 pm). On the other hand, Mg^{2+} having r = 66 pm and Mn^{2+} having r = 80 pm already afford the macroheterocycle *(4)*. In view of the expected selectivity of the ligands *(4)* this finding initially appears trivial. It is however of preparative significance that the yields of *(4)* obtained by the

sequence *(1)* → *(3)* → *(4)* in a one-pot reaction in the presence of certain metal ions are considerably higher than when the same reaction is conducted without metal ions (see Table 1). Of decisive importance for the effective synthesis of *(4)* is the low selectivity of this ligand for the (oversize or undersize) metal ion. To our knowledge this variant of metal-template synthesis has not been employed previously.

Table 1. Template effect of metal ions on the yield of *(4)*. Reactions performed in ethanol.

[**] This work was supported by the Ministerium für Forschung und Wissenschaft des Landes Nordrhein-Westfalen.

Procedure

Synthesis of *(4e)*: Compound *(1)* (4.32 g, 40 mmol) and $Cr_2(SO_4)_3 \cdot 18H_2O$ (7.16 g, 10 mmol) are dissolved in anhydrous ethanol (50 ml) and heated for 30 min under argon. After brief cooling, a solution of *(2e)* (6.24 g, 40 mmol) in anhydrous ethanol (10 ml) is added and the mixture is heated under reflux for an additional 11 h. After cooling the crude product is filtered off under suction, washed thoroughly with methanol, and dried. Further purification is accomplished by extraction for 16 h with toluene, in which *(4e)* dissolves with an intense green color when hot. On cooling a sample of *(4e)* is obtained (4.9 g, 61 %) which proves to be pure on thin-layer chromatography.

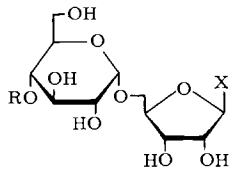
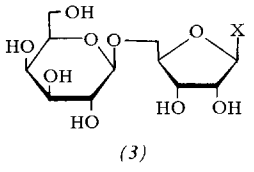
Synthesis of 5′-*O*-Glycosyl-*ribo*-nucleosides[**]



By *Frieder W. Lichtenthaler, Yuzuru Sanemitsu*, and *Toshihiro Nohara*[*]

Certain bacteria, such as *Brevibacterium ammoniagenes*[1] and *Bacillus sp. No. 102*[2], have the potential for elaborating 5′-*O*-hexosylated nucleosides of type *(1)*—*(3)*, a novel group of bacterial metabolites that can vary in the nucleobase (hypoxanthine and guanine), in the hexose portion [glucose *(1a)*, *(1b)*; maltose *(2a)*, *(2b)*; and galactose *(3a)*], and in the configuration of the intersaccharide bond (α- and β-linkage). Analogs with adenine and uracil as the aglycon, *i.e. (1c)*[3], *(3c)*[4], and *(3d)*[5], have also been obtained yet by the action of bacterial enzyme preparations on maltose and *o*-nitrophenyl α-D-galactoside and the respective *ribo*-nucleoside.



The unknown biological role of these glycosylnucleosides prompted us to embark on their chemical synthesis[6], which

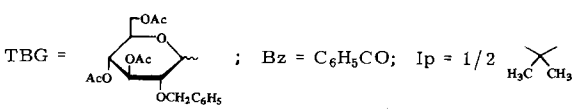
we have now completed for β-D-galactosyluridine *(3d)* and the 5′-*O*-α-D-glucosides of inosine *(1a)*, adenosine *(1c)*, and uridine *(1d)* *via* glycosylation of the respective 2′,3′-*O*-isopropylidene-nucleosides. This synthetic approach, however, is seriously impaired by fission of the *N*-glycosidic bond in purine nucleosides on glycosylation with mercuric salt type catalysts (sugar exchange reaction[7,8]), and particularly by the various nucleophilic sites of similar reactivity, whereby glycosylation can occur at the sugar hydroxyl group, at several nitrogen functions of the heterocycle as well as on oxygen in those nucleobases that contain a carboxamide function[9]. These difficulties were eventually overcome by using suitable 2′,3′-*O*-isopropylidenenucleosides protected in the heterocyclic moiety, such as the O^6-glycosylated inosine *(6)* and the N^6,N^6-bis(benzoyl)adenosine *(14)*, in which 5′-*O*-glycosylations with 2-*O*-benzylacetobromoglucose *(4)* can be effected by silver carbonate in chloroform at 60 °C.

Accordingly, on reaction of isopropylidene-inosine *(5)* with halogenose *(4)* and silver carbonate in chloroform at ambient temperature the imidoyl glucoside *(6)* is formed exclusively, which on heating (3 d, 60 °C) with an excess of *(4)* is converted into the bis(glucoside) *(7)*. In *(7)*, the imidoyl glucoside linkage is readily cleaved by treatment with 80% aqueous acetic acid (3 h, 25 °C) to give *(8)* as an approximate 3:1 mixture of α- and β-anomers. When performing the three steps *(5)* → *(6)* → *(7)* → *(8)* in one continuous operation the overall yield of *(8)* amounted to 39%. Silica gel separation of the anomers is readily effected after deacetonation[10a] to give the α-disaccharide *(9)* and its β-anomer *(10)*. For preparation of the unblocked glucosyl-inosines, *(9)* and *(10)* were first converted *via* hydrogenolysis[10b] and acetylation into their highly crystalline hexaacetates *(11)* and *(24)*. De-*O*-acetylation of *(24)*[10c] gave the 5′-*O*-(β-D-glucosyl)inosine *(25)*, which was readily hydrolyzed upon digestion with β-glucosidase, yet was unaffected by α-glucosidase treatment. Similarly, *(11)* was converted into 5′-*O*-(α-D-glucosyl)inosine *(1a)*, which was identical with the product derived from *Bacillus sp. No. 102*[11] on the basis of IR, rotation, and TLC behavior, as well as its stability towards β-glucosidase[10d] *versus* prompt hydrolysis on exposure to α-glucosidase.



For the synthesis of adenosine glycosides the N^6,N^6-bis(benzoyl) derivative *(14)* [prepared from 2′,3′-*O*-isopropylidene-5′-*O*-trityladenosine[12] by exhaustive benzoylation to give *(13)* and subsequent detritylation with 1% trifluoroacetic acid in dichloromethane] was subjected to silver carbonate-induced glycosylation with *(4)* (3 d, 60 °C in $CHCl_3$) to yield *(15)* as an approximately 5:1 mixture of α- and β-anomers. Removal of the minor product by silica gel chromatography was effected at the triacetate stage *(16)* (generated on acid treatment and subsequent hydrogenolysis[10a,b]) and afforded 58% [based on *(15)*] of the pure α-anomer *(16)*. Acetylation gave the hexaacetate *(17)*, deacetylation[10c] the 5′-*O*-(α-D-glucosyl)-adenosine *(1c)*, readily characterized by UV, ^{1}H-NMR, and MS data. On the basis of the scarce data available for the

A. niger derived *(1c)*—R_F-values relative to adenosine, hydrolysis with α-glucosidase, and stability towards β-glucosidase[3]—synthetic and natural product were identical.

Synthetic access to 5′-*O*-glycosyluridines proved to be more simple, since pyrimidine nucleosides are unable to undergo the sugar exchange reaction *via* 1,5-anhydroribose formation[7, 8], and hence allow the use of Königs-Knorr type catalysts for inducing *O*-substitution at the sugar portion. Thus, mercuric cyanide induced reaction of 2′,3′-*O*-isopropylideneuridine *(18)* with acetobromoglucose in nitromethane (3 h, 55 °C) afforded the 5′-*O*-β-glucoside *(20)* with only small amounts of the N^3,$O^{5'}$-bis-glucoside being detectable by TLC. Deacetonation[10a] gave a crystalline tetraacetate *(21)*, which was converted into 5′-*O*-(β-D-glucosyl)uridine β-*(1d)* by deacetylation. When using *(4)* for glycosylation of *(18)* under these conditions, an approximately 2:1 mixture of *(19)* and its β-anomer was obtained, which is readily separable on silica gel. Sequential deblocking[10] of *(19)* then afforded 5′-*O*-(α-D-glucosyl)uridine *(1d)*, which exhibited a positive optical rotation (Table 1) as opposed to the negative value for the β-anomer β-*(1d)*. Thus, the configuration of the intersaccharide bond in 5′-*O*-hexosylnucleosides may already be deduced from rotational data.

[a] Values for combustion analysis, molecular weights (MS-FD spectra), as well as UV, ^{1}H-, and ^{13}C-NMR data are in accord with the structures and configurations assigned. [b] Overall yields from *(5)* are 19 % for *(9)* and 5 % for *(10)*. [c] Softening at 145—155 °C. [d] Reactant: 2′,3′-*O*-isopropylidene-5′-*O*-trityladenosine [12]. [e] Overall yield for the steps *(14)* → *(15)* → *(16)* → *(17)*.

In similar fashion, 5′-*O*-(β-galactosyl)uridine *(3d)* was synthesized in an overall yield of 43 % by mercuric cyanide catalyzed glycosylation of *(18)* with acetobromogalactose and subsequent deblocking of *(22)*. Acetylation afforded the hexaacetate *(23)*, whose crystal form (rhombic prisms), m.p., and NMR data [1′-H at δ = 6.31 as 6 Hz-d, 1″-H at δ = 4.58 as 7 Hz-d (in $CDCl_3$)] were in good agreement with those reported for the product resulting from the action of β-D-galactosidase on *o*-nitrophenyl α-D-galactoside and uridine and subsequent acetylation[5].

The problem of a specific chemical synthesis of 5′-*O*-glycosylated purine and pyrimidine nucleosides thus appears to be solved, permitting the preparation of specifically labeled compounds of this type for unraveling their biological role. The first indications of their function come from strong inhibition of maltodextrin phosphorylase by inosine β-glucoside *(25)* [$K_i = 2 \times 10^{-4}$ mol/l at 30 °C for polysaccharide biosynthesis and 3.8×10^{-4} mol/l for maltodextrin degradation] which is competitive with glucose 1-phosphate and maltodextrin whereas the α-anomer *(1a)*, like inosine, exhibits no significant effector property[13]. Compound *(25)* is therefore a specific active site inhibitor, suggesting a role as regulator of the activity of phosphorylases or other enzymes of reserve carbohydrate metabolism.

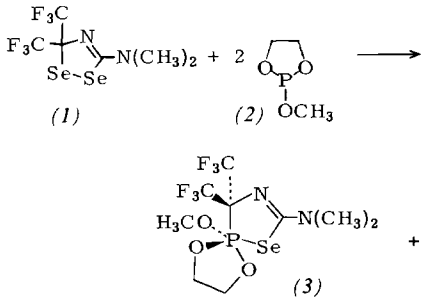
Synthesis of a Δ^4-1,4,2λ^5-Selenazaphospholine, the First Selenophosphorane[**]



By *Klaus Burger, Ralph Ottlinger, Albin Frank*, and *Ulrich Schubert*[*]

Selenophosphoranes have been discussed as intermediates in the hydrolysis of selenophosphoric acid *O,O*-diesters[1], in the stereospecific deoxygenation of oxiranes with triphenylphosphane or tri-*n*-butylphosphane selenide[2], and in the oxidation of trivalent phosphorus with dimethylselenium oxide[3], though demonstration of their actual existence has not been reported in the literature so far.

We have now been able to prepare, to our knowledge, the first selenophosphorane by reaction of 5,5-bis(trifluoromethyl)-Δ^3-1,2,4-diselenazoline *(1)*[4] with 2-methoxy-1,3,2-dioxaphospholane *(2)* at −30 °C. The product turned out to be sensitive to hydrolysis and thermolabile.

The spectroscopic data[5] are consistent with the structure of a Δ^4-1,4,2λ^5-selenazaphospholine *(3)*. The $^5J_{PH}$ coupling of 1.5 Hz demonstrates the presence of the structural unit P—SeCNC—H. The magnetic non-equivalence of the two trifluoromethyl groups indicated by the ^{19}F-NMR spectrum discounts involvement of irregular isomerization processes *via* open-chain dipolar species.

The downfield position of the ^{31}P-NMR signal ($\delta = -26.1$)[6] finds a parallel in the thiophosphorane series, for which δ-values up to -18 have been reported[7], and thus appears to be a chalcogen effect.

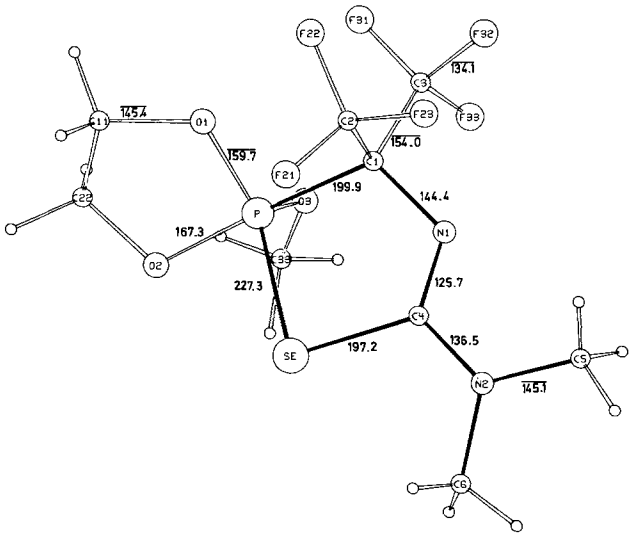

Fig. 1. Structure of compound *(3)*. Bond lengths in pm. Bond angles: C1—P—O1 87°, C1—P—O3 91°, C1—P—Se 89°, O2—P—O1 91°, O2—P—O3 99°, O2—P—Se 83°, O1—P—O3 112°, O1—P—Se 135°, O3—P—Se 111°, C1—P—O2 168°; P—Se—C4 89.9°; all other angles have the usual values.

Final confirmation of the proposed structure *(3)* was provided by an X-ray structural analysis[8] (Fig. 1). The selenazaphospholine ring skeleton is almost planar (max. deviation C1, 20 pm); the dimethylamino moiety deviates only slightly from a coplanar arrangement. The selenium atom assumes an equatorial position in the slightly distorted trigonal-bipyramidal coordination sphere of the phosphorus in which both ring systems are placed apical/equatorial. The observed P—Se bond length of 227.3(2) pm corresponds very well to the single-bond length calculated from covalent radii.

Experimental:

A solution of *(2)* (0.30 g, 2.5 mmol) in 5 ml anhydrous hexane is added dropwise under nitrogen at -30°C to a solution of *(1)*[4] (0.38 g, 1 mmol) in 5 ml of anhydrous hexane. A precipitate consisting of *(3)* and *(4)* crystallizes out, with concomitant decoloration of the reaction solution. Recrystallization of this precipitate three times from chloroform affords analytically pure 7-dimethylamino-5-methoxy-9,9-bis(trifluoromethyl)-1,4-dioxa-6-selena-8-aza-5λ^5-phosphaspiro-[4.4]non-7-ene *(3)*; yield 0.30 g (69%), m.p. 102 °C (dec.).

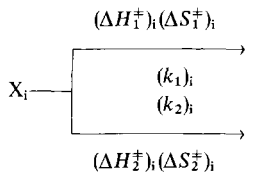
Scope of Application of the Isoselective Relationship

By *Otto Exner* and *Bernd Giese*[*]



Linear relationships between activation enthalpies $\Delta H^{\neq}$ and activation entropies $\Delta S^{\neq}$ of a reaction series, the isokinetic relationships (IKR), have important applications in organic chemistry[1a], biochemistry[1b], and catalysis[1c]. Since $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are interdependent, a statistically correct treatment of the IKR with the independent variables T (reaction temperature) and $\lg k$ (reactivity) must be carried out[2]. The IKR then describes a family of Arrhenius lines intersecting in a point with the coordinates β^{-1} (β = isokinetic temperature) and y (reactivity at the isokinetic temperature) [Eq. (1)][2].

$$X_i \xrightarrow[k_i]{\Delta H_i^{\neq}\,\Delta S_i^{\neq}} \text{Products}$$

$$\lg k_{ij} = y + b_i(T_j^{-1} - \beta^{-1}) \qquad (1)$$

The subscript i signifies the reaction (*e.g.* that of the molecules X_i) and j the reaction temperature. The collection of *selectivity values* for molecules X_i of the same type of structure which fall within a small temperature range, the isoselective temperature β_{is}, has led to the concept of the isoselective relationship (ISR)[3], in which the differences in activation enthalpies $\Delta H_2^{\neq} - \Delta H_1^{\neq}$ are linearly related to the differences in activation entropies $\Delta S_2^{\neq} - \Delta S_1^{\neq}$. If the isoselective temperature does not fall in the range of measurement the validity of the ISR according to Eq. (2) can be checked analogously to Eq. (1).

[+] Author to whom correspondence should be addressed.

$$\lg\left(\frac{k_1}{k_2}\right)_{ij} = y + b_i(T_j^{-1} - \beta_{is}^{-1}) \qquad (2)$$

Whether isoselective relationships have the same scope of application as isokinetic relationships will be examined here using reaction series in which isokinetic relationships are valid in accordance with Eqs. (3a) and (3b).

$$(\lg k_1)_{ij} = y_1 + (b_1)_i(T_j^{-1} - \beta_1^{-1}) \qquad (3a)$$

$$(\lg k_2)_{ij} = y_2 + (b_2)_i(T_j^{-1} - \beta_2^{-1}) \qquad (3b)$$

The reactivity relationships (3a) and (3b) can be transformed by subtraction into the selectivity relationship (4).

$$\lg\left(\frac{k_1}{k_2}\right)_{ij} = y_1 - y_2 - (b_1)_i\beta_1^{-1} + (b_2)_i\beta_2^{-1} + [(b_1)_i - (b_2)_i]\,T_j^{-1} \qquad (4)$$

Eq. (4) corresponds to Eq. (2) and thus affords a relationship between the independent variables $\lg k_1/k_2$ and T (validity of the ISR) if

a) the slopes b_1 and b_2 and thus the activation enthalpies $\Delta H_1^{\neq}$ and $\Delta H_2^{\neq}$ are linearly related to each other [Eq. (5), α and c are constants]

$$(\Delta H_2^{\neq})_i = \alpha(\Delta H_1^{\neq})_i + c \qquad (5)$$

in this case the isoselective temperature $(\beta_{is})_{calc}$ can be calculated according to Eq. (6)[4]:

$$(\beta_{is})_{calc} = \frac{(\alpha - 1)\cdot\beta_1\cdot\beta_2}{\alpha\beta_1 - \beta_2} \qquad (6)$$

and/or b) if the isokinetic temperatures are equal in magnitude [Eq. (7)].

$$\beta_1 = \beta_2 = \beta_{is}$$

For seven pairs of reaction series we have calculated the isoselective temperatures from the isokinetic temperatures β_1 and β_2 using Eq. (6). In Table 1 these are compared with the isoselective temperatures β_{is} obtained applying the previously developed statistical method[2] to the isoselective relationship [Eq. (2)].

As in the discussion of isokinetic relationships[2], for assessment of the isoselective relationships the standard differences $s_{o,is}$ (calculated with assumption that the ISR is valid) and $(s_{oo})_{is}$ (calculated without additional assumption of the validity of the ISR) must be compared with each other. If $s_{o,is}$ is smaller or of similar magnitude to $(s_{oo})_{is}$ and the statistical ψ value is smaller than 0.1[11a] the existence of the ISR can be deduced from the experiments. The data given in Table 1 show that of the seven series of reactions for which the isokinetic relationships have been demonstrated, the isoselective relationship applies to only three (A, B, and G). In the case of the reaction series A and B, Eq. (5) is fulfilled very accurately, so that β_{is} is given by Eq. (6). However, also in the case of the reaction series for which the validity of the ISR cannot be deduced, Eq. (5) can be approximately applied. The mathematical analysis of reactivities thus indicates limited validity of the ISR compared to the IKR. The reason for this is that the changes in the selectivities within the small temperature range in which the reactivities could be measured are too small. A decision on the validity of the ISR should then be carried out experimentally by selective measurements which are usually possible over much greater temperature ranges than corresponding reactivity determinations.

Synthesis of Carbocyclic Carbene Complexes by Metal-Induced Diazocyclopentadiene Fragmentation[1]

By *Wolfgang A. Herrmann, Johann Plank, Manfred L. Ziegler,* and *Klaus Weidenhammer*[*]

η^1- and η^5-Halocyclopentadienyl-metal complexes which are otherwise accessible only by multistep reactions, if at all, can be prepared from diazocyclopentadiene *(1)*[2] in a reaction involving halogen transfer from the metal to the carbon atom which originally carried the N_2 substituent[3]. On attempted preparation of cyclopentadienylidene complexes by metal-induced fragmentation of *(1)*, by analogy with earlier work on acyclic diazoalkanes[3], we observed formation of a transition-metal stabilized oligocyclic carbene for the first time:

(2a), R = H
(2b), R = CH_3

(1)

(3a, b)

The action of an excess of diazocyclopentadiene *(1)* on tetrahydrofuran solutions of the manganese complexes *(2a)* and *(2b)* at 10 to 25 °C leads, by way of slow evolution of nitrogen and black coloration of the reaction mixture, to the diamagnetic compounds *(3a)* and *(3b)*, respectively, which were shown by complete elemental analysis, osmometric molecular-weight determination, and IR and mass spectra to be dimers of the expected carbene derivatives $(\eta^5\text{-}RC_5H_4)Mn(CO)_2(\sigma\text{-}C_5H_4)$. Since the NMR spectra did not permit unequivocal determination of structure we have performed an X-ray structure analysis on *(3b)*[4]. The surprising result of this study was that the molecular units dimerize by a [2+2]cycloaddition of the cyclopentadienylidene systems. The novel tricyclic $C_{10}H_8$ dicarbene formed in this way spans two $(\eta^5\text{-}RC_5H_4)Mn(CO)_2$ units, the *anti* configuration of the bridging ligand giving rise to the centrosymmetry of the molecule. The planar central four-membered ring (±0.004 pm) makes angles of 110.3° with the best planes (±1 pm) of the two annelated five-membered rings.

The remarkably high thermal stability of the complexes *(3a)* and *(3b)* is due to conjugation of the manganese-carbene bonds with the vinylic double bonds in the bridging ligand system. This conjugation is manifested in the short Mn—C(carbene) distances of 187.8(8) pm[5] and the significant shortening of the C(1)—C(5) and C(1′)—C(5′) distances relative to those of typical single bonds.

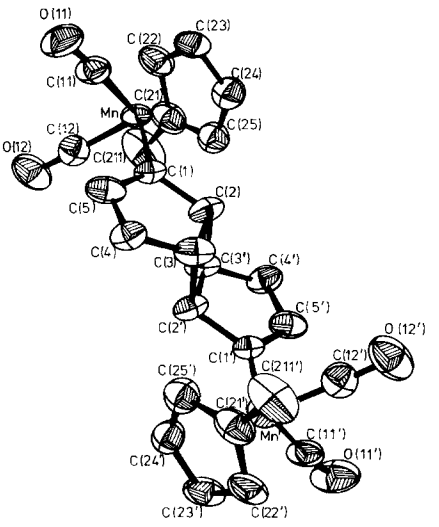

Fig. 1. ORTEP plot of the dinuclear manganese complex *(3b)* having a tricyclic dicarbene bridge. The thermal ellipsoids correspond to a probability of 50 %.

Bond lengths [pm]		Angles [°]	
C(1)—C(2)	153.0(14)	C(1)—C(5)—C(4)	112.5(1.0)
C(1)—C(5)	146.0(15)	C(2)—C(3)—C(4)	103.4(8)
C(2)—C(3)	157.4(13)	C(3)—C(4)—C(5)	111.2(9)
C(2)—C(3′)	159.6(13)	C(3)—C(2)—C(3′)	88.3(6)
C(3)—C(4)	153.0(17)	Mn—C(1)—C(5)	126.8(7)
C(4)—C(5)	136.7(14)		
Mn—C(1)	187.8(8)		

Procedure[6]:

$(\eta^5\text{-}RC_5H_4)Mn(CO)_3$ (10 mmol, 2.04 and 2.18 g, respectively) is dissolved in THF (200 ml) and irradiated in a Pyrex immersion well apparatus at 10 °C until evolution of gas ceases (Hg high-pressure lamp, TQ 150/Z1). A 0.1 M solution of *(1)* in benzene (100 ml) is added dropwise to the resulting solution of *(2a)* or *(2b)*. After 12 hours' stirring at 25 °C the dark brown oily crude product is chromatographed on 60 × 2.4 cm SiO_2 (Merck, 0.063—0.200 mm, activity II—III, 15 °C), the dicarbene complex *(3a)* or *(3b)* being eluted with benzene as a dark brown zone that is slightly air-sensitive. After evaporation *in vacuo* the eluate is stirred with *n*-pentane (50 ml), the precipitated dark brown powder is filtered over a G 3 frit, washed twice with *n*-pentane (2 × 10 ml), and crystallized from dichloromethane/diethyl ether (2:1) at −35 °C. The product forms black air-stable crystals which are soluble in benzene and polar organic solvents. Yield 504 mg of *(3a)* (21 %) and 508 mg of *(3b)* (20 %).—IR: νCO [$CHCl_3$; cm^{-1}] *(3a)* 1965 vs, 1900 vs; *(3b)*: 1963 vs, 1897 vs; νC=C [KBr; cm^{-1}]: *(3a)* 1517 m, *(3b)* 1520 m.

A Cyclotetra(azadithiane)—The First Twelve-Membered Sulfur-Nitrogen Ring[**]

By *Bernt Krebs, Michael Hein, Manfred Diehl*, and *Herbert W. Roesky*[*]

The largest previously reported sulfur-nitrogen ring[1] containing sulfur atoms of coordination number 2 is the ten-membered S_5N_5 cation[2]. It is clear that large SN rings such as this can be synthesized only in the form of their cations or carrying electron-attracting substituents; otherwise strong transannular interactions favor the formation of smaller rings. We have now found that the trifluoromethanesulfonyl group is suitable as electron-attracting substituent for this purpose. Thus, the diaminodisulfane *(1)*, prepared from S_2Cl_2 and $CF_3SO_2N(SnMe_3)_2$ reacts with further dichlorodisulfane in dichloromethane to give the novel S_8N_4 ring *(2)*:

$$2\,CF_3SO_2N[Sn(CH_3)_3]_2 + S_2Cl_2 \xrightarrow[-2(CH_3)_3SnCl]{}$$

(1)

$$2\,(1) + 2\,S_2Cl_2 \xrightarrow[-4(CH_3)_3SnCl]{} S_8N_4(SO_2CF_3)_4$$

(2)

The mass spectrum of *(2)* contains the molecular ion at $m/e = 844$ (rel. int. 1 %) and the fragment NS_2^+ at $m/e = 78$ (100 %). In the ^{19}F-NMR spectrum only one signal is observed at $\delta = 79.2$ ($CFCl_3$ ext.). An X-ray structural analysis of *(2)* [monoclinic, space group $C2/c\text{-}C_{2h}^6$; $a = 16.715(3)$, $b = 7.377(2)$, $c = 22.420(4)$ Å, $\beta = 104.39(3)°$; $Z = 4$; $R = 3.8\,\%$] shows that the twelve-membered ring has a chair configuration (molecular symmetry $C_i\text{-}\bar{1}$) and contains four S—N—S units coupled *via* S—S bonds (2.006—2.009(1) Å). In this configuration interaction of the lone pairs is smallest. The S—N bond lengths are 1.724—1.732(3) Å in the ring and those between the N-atoms and sulfonyl groups 1.650—1.657(3) Å. The dihedral angles NSS/SSN have values of 91.3 and 94.1°.

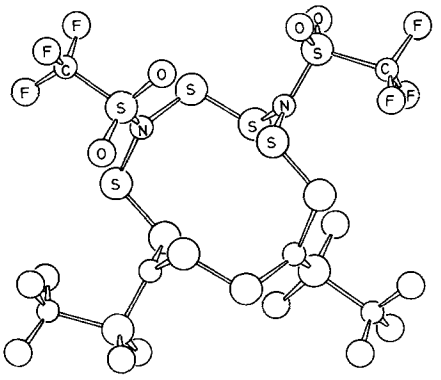

Fig. 1. Structure of the fourfold CF_3SO_2-substituted cyclotetra(azadithiane) derivative *(2)* in the crystal.

Experimental

A solution of S_2Cl_2 (1.35 g, 0.01 mol) in CH_2Cl_2 (20 ml) is added slowly with stirring to a suspension of $CF_3SO_2N(SnMe_3)_2$ (4.75 g, 0.01 mol) in 30 ml CH_2Cl_2. Compound *(1)* precipitates out, but is redissolved on further addition of S_2Cl_2. On completion of addition of S_2Cl_2 the reaction mixture is stirred for *ca.* 12 h, whereupon a product mixture $(CF_3SO_2NS_2)_n$ precipitates. The solvent and any Me_3SnCl are removed under vacuum and the residue washed with benzene. Ring compounds having $n < 4$ are then removed by sublimation at 140 °C/0.01 torr. Extraction of the remaining residue with CH_2Cl_2 and recrystallization from CH_2Cl_2 yields 0.68 g (32 %) 3,6,9,12-tetrakis(trifluoromethanesulfonyl)cyclotetra(azadithiane) *(2)*, m. p. 213—215 °C (decomp.).

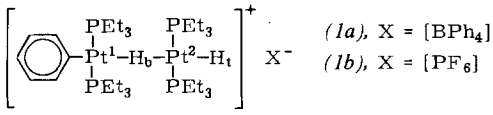
A New Cationic Mono-Hydride-Bridged Binuclear Platinum(II) Dihydride[**]

By *Gustav Bracher, David M. Grove, Luigi M. Venanzi, Fiorella Bachechi, Pasquale Mura*, and *Luigi Zambonelli*[*]



There have recently been reports of various types of dinuclear platinum hydrides[1–3]. In all instances where a monohydride-bridge has been postulated bidentate donor ligands have also been present and it has been suggested that such ligands may to a large extent influence the formation of such compounds[2].

During the reaction of *trans*-$[PtH(NO_3)(Et_3P)_2]$ with $Na[BPh_4]$, which was reported to give $[PtPh_2(Et_3P)_2]$[4], we noticed the formation of a new complex which was isolated and characterized by NMR as having the schematic structure *(1a)*. To facilitate interpretation of the aromatic region of the ^{1}H-NMR spectrum of the cationic species, the $[BPh_4]^-$ ion was exchanged with $[PF_6]^-$ to afford *(1b)*. Both *(1a)* and *(1b)* are white air-stable solids which decompose only slowly in solution.

The hydride region of the ^{1}H-NMR spectrum of *(1b)* shows two complex multiplets with associated ^{195}Pt satellites [$(CD_3)_2CO$, 360 MHz: $\delta H_t = -11.45$, $^1J_{HPt(2)} = 1148$ Hz, $^3J_{HPt(1)} = 108$ Hz; $\delta H_b = -9.46$, $^1J_{HPt(1)} \simeq {}^1J_{HPt(2)} \simeq 500$ Hz]. The satellite structure of the two sets of signals in the ^{31}P-NMR spectrum [$(CD_3)_2CO$: $\delta = 19.0$, $^1J_{PPt} = 2591$ Hz, $^3J_{PPt} = 12$ Hz; $\delta = 8.2$, $^1J_{PPt} = 2629$ Hz, $^3J_{PPt} = 13$ Hz] provides further evidence for the binuclear structure. This was uniquely verified by a ^{195}Pt-NMR study on *(1b)* which revealed two sets of resonances ($J_{PtPt} = 366$ Hz). Interestingly, although both a bridging and terminal hydride are present in the same molecule, there is no spectroscopic evidence for a hydride-exchange process on the NMR time scale at room temperature.

(1a), X = $[BPh_4]$
(1b), X = $[PF_6]$

To date there has only been one reported X-ray crystallographic determination of a binuclear platinum hydride[3] and this fact coupled with the completely novel nature of our complex prompted us to undertake such a study on *(1a)*[5]. The overall molecular geometry of the cation, with some relevant bond lengths and interbond angles, is shown in Figure 1.

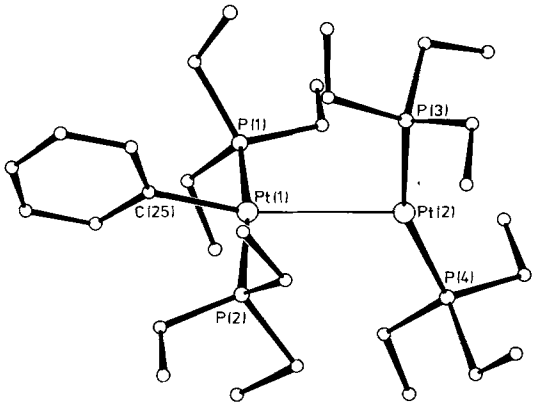

Fig. 1. Molecular Structure of $[Pt_2H_2(C_6H_5)\{P(C_2H_5)_3\}_4]^+$. Bond lengths: Pt1—Pt2 3.09, Pt1—P1 2.29, Pt1—P2 2.31, Pt1—C25 2.02, Pt2—P3 2.26, Pt2—P4 2.30 Å; Interbond angles: P1—Pt1—Pt2 93.7, P1—Pt1—P2 169.4, P1—Pt1—C25 87.8, P2—Pt1—Pt2 93.0, P2—Pt1—C25 87.9, C25—Pt1—Pt2 164.3, Pt1—Pt2—P3 91.1, Pt1—Pt2—P4 112.0, P3—Pt2—P4 156.8°; Torsion angles: P1—Pt1—Pt2—P3 87.4, P1—Pt1—Pt2—P4 −90.4, P2—Pt1—Pt2—P3 −100.6, P2—Pt1—Pt2—P4 81.6°.

Although the two hydride atoms, indicated by the spectroscopic data, have not been located at the present stage of refinement, their positions may be inferred from the X-ray data. On this basis the bridging hydride H_b lies approximately *trans* to C(25) and the terminal hydride H_t is then situated on Pt(2) approximately *trans* to H_b. The large Pt—Pt separation (3.09 Å) is consistent with a *single* hydride-bridge[3, 6] and the C(25)Pt(1)Pt(2) angle of 164.3°, probably the most important structural feature, indicates that H_b is not collinear with the two metal centers. This geometrical arrangement appears to be characteristic of compounds containing the M—H—M moiety[6]. It is also noteworthy that the plane containing P(3), Pt(2) and P(4) makes an angle of *ca.* 85° with the approximate coordination plane of Pt(1).

Compound *(1)* on addition of chloride ion undergoes a simple reversible cleavage reaction,

$$\underset{(1)}{[Pt_2H_2(Ph)(Et_3P)_4]^+} + Cl^- \rightleftharpoons \underset{(2)}{trans\text{-}[PtHCl(Et_3P)_2]} + \underset{(3)}{trans\text{-}[PtH(Ph)(Et_3P)_2]}$$

as evidenced by ^{31}P and ^{1}H-NMR spectral studies. The complex *(3)* was assigned the structure shown on the basis of its NMR data [^{31}P-NMR, $(CD_3)_2CO$: $\delta = 17.3$, $^1J_{PPt} = 2796$ Hz; ^{1}H-NMR (hydride), $(CD_3)_2CO$, 360 MHz: $\delta_H = -7.05$, $^1J_{HPt} = 648$ Hz, $^2J_{HP} = 19$ Hz]. This previously unreported compound is stable in the reaction mixture but attempts at isolating it pure from this mixture (or from the reaction of *trans*-$[PtHCl(Et_3P)_2]$ *(2)* with PhLi where it is also formed) have so far proved unsuccessful. The reactivity of *(1)*, *(3)* and related hydrides is now being investigated.

Experimental

Synthesis of *(1a)*: 500 mg (1 mmol) *trans*-$[PtH(NO_3)(Et_3P)_2]$ and 680 mg (2 mmol) $Na[BPh_4]$ were dissolved in 15 ml MeOH and the solution stirred at room temperature for 16 h. The white precipitate was separated from the yellow solution and recrystallized from $CHCl_3$/MeOH to give *(1a)*. Yield 410 mg (64 %).

Synthesis of *(1b)*: 1.261 g (1 mmol) *(1a)* was dissolved in a minimum of acetone and $NH_4[PF_6]$ added with stirring until no further precipitate of $Li[BPh_4]$ appeared to be formed. The solid was filtered off and further $NH_4[PF_6]$ added to ensure complete removal of $[BPh_4]^-$ ion from the solution. After refiltering, the solution was evaporated to dryness and the complex *(1b)* was extracted with CH_2Cl_2. Concentration of this solution and the addition of MeOH afforded crystalline *(1b)*. Yield 750 mg (70 %).

(1a) with Cl^-. 200 mg of *(1a)* was dissolved in 1 ml of $[D_6]$ acetone and LiCl added until no more would dissolve. The solution was filtered directly into an NMR tube and the product mixture *(2, 3)* measured. After removal of the solvent *in vacuo* and extraction with $CHCl_3$ (to separate LiCl) *(1a)* was retrieved almost quantitatively.

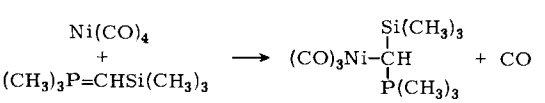
Trimethylphosphoranediyl- and -arsoranediylmethyl-(trimethylsiloxy)carbene Complexes by 1,3-Silyl Shift[**]

By *Wolfgang Malisch, Herbert Blau,* and *Siegfried Voran*[*]

Transition metal coordinated CO ligands are usually attacked by carbanionic nucleophiles at the carbon atom[1]. In the case of phosphorus ylides there is only indirect evidence of such an attack, since the primary metalcarbonyl-ylide adduct is immediately deprotonated by further ylide to give the acyl metalate[2].

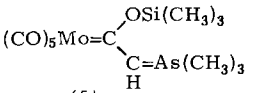
We have now found that reaction with the silyl-substituted ylide $(CH_3)_3P{=}CHSi(CH_3)_3$ takes a very different course: On starting with hexacarbonyl compounds of chromium, molybdenum and tungsten, *neutral* carbene-pentacarbonyl-metal complexes of type *(2)*, whose carbene carbon atom bears a trimethylphosphoranediylmethyl- and a trimethylsiloxy-group as substituents, are formed *directly* and *quantitatively.*



(a), M = Cr; *(b)*, M = Mo; *(c)*, M = W

In accord with this mode of product formation—to be regarded formally as addition of the ylide fragments $(CH_3)_3P{=}CH$ and $Si(CH_3)_3$ to a CO ligand—the zwitterionic adduct *(1)* generated by initial carbanion attack is not stabilized, as in other cases, by transylidation, but by transfer of the silyl group to the negatively charged acyl oxygen. The 1,3-silyl shift leading to regeneration of the ylide function proceeds so rapidly that *(1)* is neither isolable under the reaction conditions (10 °C) nor detectable by NMR spectroscopy at low temperatures (−30 °C)[3]. Accordingly the carbon bound silyl group in *(1)* displays extraordinary mobility, due to the possibility of formation of the stable Si—O bond[4].

The pale-yellow, readily crystallizable carbene complexes *(2)* are stable under N_2, but rapidly decompose in solution to, *inter alia*, $M(CO)_6$ and hexamethyldisiloxane. The composition and structure of the complexes have been confirmed by analytical and spectroscopic findings. The ^{1}H-NMR and ^{13}C-NMR spectra show, respectively, the signal of the ylide proton and of the carbene carbon as doublets with characteristic splitting ($^2J_{HCP}$ = 34 Hz; $^2J_{CCP}$ = 10 Hz) at lowest field (δH = 4.7; δC = 250). The presence of the C—O, P—C, and Si—O bonds follows from the position of the stretching absorptions at 1062 (vs), 968 (s), and 752 (m) cm^{-1}. The pentacarbonyl structure is proved from the νCO bands, which indicate both high steric demand and high σ-donor/π-acceptor ratio for the ylide carbene ligand (5 IR-active νCO, low wavelengths).



While, analogously to the $M(CO_6)$ reaction, $Fe(CO)_5$ and the silyl ylide afford the complex $(CO)_4FeC[OSi(CH_3)_3]$—$CH{=}P(CH_3)_3$ *(3)*, which is trigonal bipyramidal configurated and bears the carbene ligands in the axial position [local C_{3v} symmetry; νCO: 2020 (s) $A_1^{(2)}$, 1939 (s) $A_1^{(1)}$, 1908 (vs) E][5], $Ni(CO)_4$ affords the *ylide complex (4).*

(4)

This different mode of reaction is rationalized in terms of the high exchange activity of $Ni(CO)_4$[6] and low electrophilicity of its CO ligands[7].

The direct conversion of complex-bound carbon monoxide into a ylide carbene ligand according to the simple principle of silyl-ylide addition/1,3-silyl shift presented here also occurs with $(CH_3)_3As{=}CHSi(CH_3)_3$. On reaction with $Mo(CO)_6$ in benzene at 25 °C we obtained the first (arsenic ylide)carbenemetal complex *(5)*, m.p. 71—73 °C, which exhibits the same spectral characteristics as *(2b)*. Moreover, its ^{1}H-NMR spectrum (in benzene) recorded at room temperature demonstrates the existence of two isomers attributable to hindered rotation about the $C_{carbene}$—C_{ylide} bond.

(5)

Procedure

All operations must be carried out under N_2 using oxygen-free solvents.

A solution of $(CH_3)_3P{=}CHSi(CH_3)_3$[8] (0.85 g, 5.2 mmol) in benzene (10 ml) is added dropwise at 10 °C to a suspension of $Cr(CO)_6$ (1.15 g, 5.2 mmol) in benzene (20 ml). After 30 minutes' stirring the clear yellow solution is concentrated by evaporation to 10 ml and *(2a)* is precipitated by addition of 20 ml pentane; recrystallization from benzene/pentane (1 : 2) at −15 °C affords pale yellow crystals, m.p. 91—93 °C, yield 1.71 g (86 %).—*(2b)*: m.p. 112—114 °C (88 %); *(2c)*: m.p. 118—120 °C (84 %).

Using the same procedure, reaction of $Fe(CO)_5$ (0.39 g, 2.0 mmol) with $(CH_3)_3P{=}CHSi(CH_3)_3$ (0.32 g, 2.0 mmol) affords pale-pink crystalline *(3)*; yield 0.65 g (91 %), m.p. 42—44 °C.

Spectroscopic data of (2a): ^{1}H-NMR (in C_6D_6, TMS int.): δCH$_3$P = 0.6 (d, 9H), $^2J_{HCP}$ = 13.4 Hz; δCH$_3$Si = 0.44 (s, 9H); δCH=P = 4.78 (d, 1H), $^2J_{HCP}$ = 34.2 Hz.—^{13}C{^{1}H}-NMR (in C_6D_6, TMS int.): δCH$_3$P = 11.3, J_{CP} 57.3 Hz; δCH$_3$Si = 2.1; δC_{ylide} = 94.7, J_{CP} = 67.6 Hz; δCO_{cis} = 211.6; δCO_{trans} = 222.0; δ$C_{carbene}$ = 250.9, $^2J_{CCP}$ = 10 Hz.—^{31}P{^{1}H}-NMR (in C_6D_6, H_3PO_4 ext.): δ = −11.8.—IR (ν_{CO} in C_6H_6): 2035 (w) $A_1^{(2)}$, 1951 (vw) B_1, 1915 (s) E, 1902 (s) E, 1897 (m) $A_1^{(1)}$ cm^{-1}.

Dichlorocarbene Complexes of Iron(II)-Porphyrins—Crystal and Molecular Structure of Fe(TPP)(CCl_2)(H_2O)

By *Daniel Mansuy, Marc Lange, J. C. Chottard, J. F. Bartoli, Bernard Chevrier*, and *Raymond Weiss*[*]

We recently reported that the reaction of *meso*-tetraphenylporphyrinatoiron(II) (Fe(TPP)) with carbon tetrachloride in the presence of an excess of reducing agent leads to the formation of a complex, for which we proposed the dichlorocarbene complex structure Fe(TPP)(CCl_2) on the basis of elemental analysis, and spectral data[1]. Since it was the first example of a dihalogenated carbene complex of a transition metal and the first isolated carbene complex of a metalloporphyrin, the latter point bringing valuable evidence in favor of the formation of such a CCl_2 complex of hepatic cytochrome P 450, after carbon tetrachloride metabolization[2], it appeared to us most important to prove the Fe—CCl_2 structure. We have now carried out an X-ray structure analysis, which, despite low accuracy due to crystal disorder, unequivocally confirms the proposed structure.

Single crystals for X-ray examination were obtained by slow evaporation, under argon, from a chloroform/DMF/H_2O solution of the solid previously obtained and described as Fe(TPP)(CCl_2)[1]. The compound crystallizes with a water molecule completing the coordination of the metal and with two molecules of dimethylformamide present as uncomplexed solvent of crystallization.

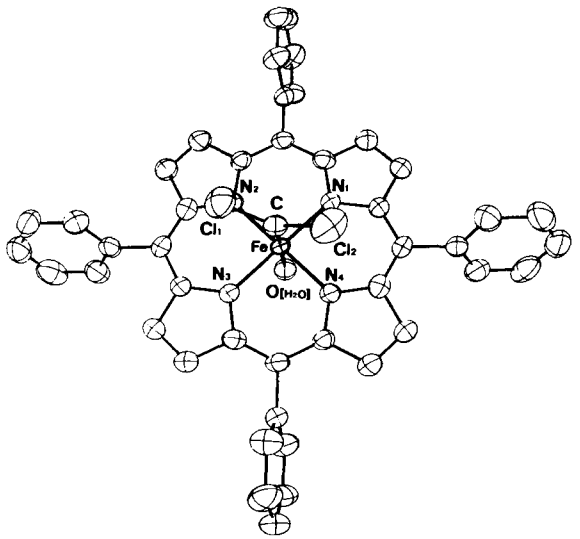

Fig. 1. Crystal structure of Fe(TPP)(CCl_2)(H_2O)·2 DMF (solvate molecule not shown). Crystal data: triclinic P1 or $P\bar{1}$: $a = 11.969(8)$, $b = 10.521(7)$, $c = 10.163(7)$ Å; $\alpha = 101.48(8)$, $\beta = 106.20(8)$, $\gamma = 107.52(8)°$; $U = 1114.6$ Å^3; $Z = 1$; $\rho_{calcd} = 1.364$, $\rho_{obsd} = 1.36$ g·cm^3 (by flotation in aqueous zinc chloride solution); MoKα radiation; 3105 independent reflections with $I > 3\sigma(I)$; anisotropic refinement; present $R = 0.085$.—Initially the structure was solved in the non-centrosymmetric space group P1. But structure refinement led us to assume that the correct space group is the centrosymmetric $P\bar{1}$. Then the molecule has crystallographically imposed $\bar{1}$ symmetry and hence the CCl_2, O(H_2O) and dimethylformamide groups are disordered. In a first approximation, the disordered groups were included with occupancy factors of 0.5.

Figure 1 is a computer-drawn model, in perspective, of one Fe(TPP)(CCl_2)(H_2O)·2 DMF molecule as it exists in the crystal.

The overall deviations from planarity of the porphyrin core are very small (±0.03 Å). The planes of the phenyl groups are each rotated nearly 10—20° from the perpendicular to the mean plane of the porphyrin core. The iron atom is not significantly displaced from this plane. The averaged length of the equivalent Fe—N bonds (1.984(4) Å) and the distances within the porphyrin core are in good agreement with those reported for the other low-spin iron porphyrins[3]. The Fe—C (1.83(3) Å) and Fe—O(H_2O) bonds (2.13(3) Å) are essentially collinear, the C—Fe—O(H_2O) bond angle being 177.1(1.5)°[4]. The sum of the angles at the coordinated carbon is 359.2(1.0)° (sp^2 type). The C—Cl bond distances are 1.76(3) Å and the plane defined by the Fe, C, Cl_1 and Cl_2 atoms is practically perpendicular to the mean plane of the porphyrin core (87.6°). The coordinated water molecule forms hydrogen bonds to the oxygen atoms of both dimethylformamide solvate molecules (O...O distances of about 2.7—2.8 Å).

The crystallization of Fe(TPP)(CCl_2)[1] in anhydrous noncoordinating solvents (chloroform or benzene and hexane) leads to the pentacoordinated complex Fe(TPP)(CCl_2) *(1)*, while in the presence of a ligand L the hexacoordinated complexes Fe(TPP)(CCl_2)(L) *(2)* are formed. In solution, *(1)* and *(2)* are in equilibrium:

$$\underset{(1)}{\text{Fe(TPP)(CCl}_2\text{)}} + \text{L} \rightleftharpoons \underset{(2)}{\text{Fe(TPP)(CCl}_2\text{)(L)}}$$

(a), L = CH_3OH; *(b)*, L = C_2H_5OH; *(c)*, L = THF; *(d)*, L = pyridine; *(e)*, L = *N*-methylimidazole

The IR spectrum (KBr pellet or Nujol mull) of *(1)* exhibits a band at 872 cm^{-1}. This band, which is absent in the IR spectrum of Fe(TPP)($py)_2$ or Fe(TPP)(CO)(py), and which is shifted to 841 cm^{-1} in the spectrum of the Fe(TPP)($^{13}CCl_2$) complex (prepared with 95% enriched $^{13}CCl_4$), is assigned to a C—Cl stretching vibration. In the spectra of the crystalline complexes *(2a)*, *(2b)* and *(2c)* the νC—Cl band is shifted to 863 cm^{-1}. Upon heating to 100 °C/10^{-2} torr or upon recrystallization from chloroform/hexane, the complexes *(2)* are transformed into complex *(1)*. This accords with coordination of L on the iron atom *trans* to the carbene ligand[5]. This coordination is supported by the ^{1}H-NMR spectrum of *(2b)* in $CDCl_3$ solution, which evidences the one to one ratio of porphyrin and ethanol. At 34 °C, the signals of free ethanol appear; lowering the temperature to −65 °C shifts the methylene quartet and methyl triplet upfield by about $\Delta\delta \approx 1$ and 0.6 ppm[6]. Further addition of excess ethanol causes a downfield shift of the signals. These data are indicative of a rapid exchange, on the NMR time scale, between coordinated and free ethanol, the equilibrium being almost totally displaced to the left at 34 °C, when established from pure complex *(2b)*, but progressively driven to the right upon cooling.

The existence of the equilibrium is further supported by the IR spectra of *(1)* in solution, a νC—Cl vibration being observed at 872 cm^{-1} in benzene and at 863 cm^{-1} in 90:10 benzene/ethanol mixture [*(1)* → *(2)*]. The progressive addition of a ligand L to a benzene solution of complex *(1)* can be followed by visible spectroscopy. For instance, there is a gradual transformation, with isosbestic points at 413, 496 and 535 nm, of the characteristic spectrum of complex *(1)* into that of complex *(2b)* (λ = 419 and 538 nm) upon addition of ethanol.

The affinity of ethanol ($K_1 = 41$ mol^{-1} at 25 °C) and of other alcohols or tetrahydrofuran for complex *(1)* is low ($K_1 \approx$ 3—10 l mol^{-1} at 25°). Nitrogenous ligands have much higher

affinities (pyridine: $K_1 = 3500\,l\,mol^{-1}$[1]; *N*-methylimidazole: $K_1 = 75000\,l\,mol^{-1}$, each at 25 °C)[7].

Though unstable in the presence of good nucleophiles[7], and slowly oxidized in aerated solvents[1], complex *(1)* exhibits a very strong Fe—CCl_2 bond, for, as a solid, it remains unchanged when heated for one hour at 200 °C/10^{-2} torr, and in deaerated 10^{-8} M solutions it does not display any significant dissociation (as shown by visible spectroscopy).

Similar CCl_2 complexes[8] are obtained with the iron(II) complexes of *p*-methyl- and *p*-chloro-TPP, octaethylporphyrin, deuteroporphyrin dimethyl ester[9] and protoporphyrin IX.

[4] As a result of the disorder the errors in the Cl_2C—Fe—$O(H_2O)$ portion of the molecule are large.

[5] A similar influence of a *trans* ligand L on the ν(NO) frequency of Fe(TPP)(NO)(L) complexes has been reported: *W. R. Scheidt*, Acc. Chem. Res. *10*, 339 (1977). Moreover, a shift from 860 to 807 cm^{-1} of the ν(C—Cl) band of Rh—$CCl(NMe_2)$ carbene complexes on going from $[Rh(CO)Cl_3\{CClNMe_2\}]_2$ to $[RhCl_3(PEt_3)_2\{CClNMe_2\}]$ has been described: *A. J. Hartshorn, M. F. Lappert, K. Turner*, J. Chem. Soc. Chem. Commun. *1975*, 929.

[6] Upfield shifts of $\Delta\delta = 4.71$ and 3.13 have been observed for the methylene quartet and methyl triplet in the bonding of EtOH in Ru(TPP)(CO)-EtOH), see *J. J. Bonnet, S. S. Eaton, G. R. Eaton, R. H. Holm, J. A. Ibers*, J. Am. Chem. Soc. *95*, 2141 (1973).

[7] At 27 °C, titration of 10^{-5} M *(1)* with 10^{-5}—10^{-3} M pyridine or *N*-methylimidazole leads only to the complexes *(2d)* and *(2e)*, λ = 423, 504, 544 nm [1] and 427, 547, 590 nm (sh), resp.; isolation at −50 °C from equimolar *(1)* and base *(2d)*, *(2e)*, ν(C—Cl) = 854 cm^{-1}. Primary amines RNH_2 react with *(1)* to give the isocyanides RNC. Other nucleophiles like phosphanes and thiolates also rapidly destroy the Fe—CCl_2 bond.

[8] Characterized by λ (benzene) = 409 ($\varepsilon = 2\cdot10^5$), 525 ($1.5\cdot10^4$), 555 nm (sh); 409 ($2\cdot10^5$), 525 ($1.5\cdot10^4$), 555 nm (sh); 390 ($1.3\cdot10^5$), 524 ($8\cdot10^3$), 553 nm ($1.6\cdot10^4$); 390 ($1.22\cdot10^5$), 521 ($9\cdot10^3$), 549 nm ($1.8\cdot10^4$) [9]; λ (DMF) = 414 ($1.55\cdot10^5$), 537 ($1.55\cdot10^4$), 570 nm ($1.95\cdot10^4$).

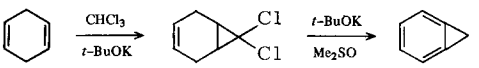
ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.



Applications of pulse radiolysis to chemical research are dealt with in a review article by *J. H. Baxendale* and *M. A. J. Rodgers*. The events which occur in an aqueous solution after the absorption process and before the participation of a dissolved compound in chemical reaction are as follows: ionization by photons or excitation or ionization by fast electrons; ion-molecule reactions with the solvent; thermalization of electrons; solvation of electrons and cations; chemical reactions (after onset of diffusion). In the chemically important final stages the following reactions take place:

$$H_2O \rightarrow H_2O^+ + e^-$$
$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH$$
$$H_2O \rightarrow H + OH$$

The most important reactive species are found to be OH and e^-, which is rapidly hydrated to e^-_{aq}. The topics studied include reduction and oxidation reactions of inorganic compounds, reactions of electrons in liquids, the solution chemistry of radical ions, and reactions of radicals. [Contributions of Pulse Radiolysis to Chemistry. Chem. Soc. Rev. 7, 235—263 (1978); 127 references]

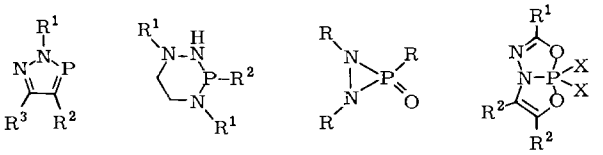
The synthesis and chemistry of cyclopropabenzenes is the topic of a comprehensive report by *W. E. Billups*. The parent compound cyclopropabenzene *(2)* is accessible by several routes, *e.g.* from 1,4-cyclohexadiene *(1)*. Mono- and bis(cyclopropa)naphthalenes have also been synthesized. In the presence of Ag^+, compound *(2)* acts as an excellent benzylation reagent. Butadiene and *(2)* undergo thermal addition *via* ring expan-

(1) *(2)*



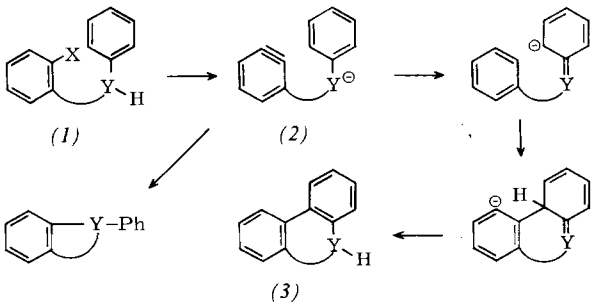
sion to, *e.g.*, 1-vinylindan *(3)*, and Ag^+-catalyzed addition to give *(3)* and pentadienylbenzene. A final decision regarding the extent of double bond localization in *(2)* has yet to be reached. [Synthesis and Chemistry of Benzocyclopropenes. Acc. Chem. Res. *11*, 245—251 (1978); 51 references]

[Rd 36 IE]

The papers presented at the symposium "Chemistry and Flavour" have been collected in a single issue of Chemical Society Reviews. *H. Boelens et al.* report on molecular structure and organoleptic quality, *W. Schlegel* deals with the application of research results to the development of commercial flavors, *K. R. Butterworth* evaluates the safety of natural and synthetic flavors, *W. H. Nightingale* discusses the influence of legislation on flavor chemistry, *J. S. Swan* and *S. M. Burtles* outline the development of flavor in potable spirits, and finally *R. Swindells* deals with the influence of flavor chemistry on consumer acceptence. [Chem. Soc. Rev. 7, 167—218 (1978); total of 87 references]

[Rd 37 IE]

The synthesis and reactions of heterocycles containing a P—N—N linkage are reviewed by *J.-P. Majoral*. The heterocycles are classified according to the number of ligands at the phosphorus atom. Examples of compounds containing di-, tri-, tetra-, and pentacoordinated phosphorus are the heterocycles of type *(1)* to *(4)*. The reactions listed include primarily



(1) *(2)* *(3)* *(4)*

those in which the coordination number of the phosphorus changes and/or a new heterocycle is formed. [Synthesis and Reactions of Heterocyclic Compounds Containing a P—N—N-Linkage. Synthesis *1978*, 557—576; 89 references]

[Rd 41 IE]

The synthesis of polycyclic systems by intramolecular ring closure *via* a benzyne derivative *(2)* generated *in situ* is the subject of a report by *S. V. Kessar*. The synthetic principle of the reaction is illustrated in the scheme; Y is an atom such as C, P, Si or preferably N, which can carry a negative charge; X is *e.g.* Cl. A detailed study has been carried out on the synthesis of phenanthridine, which is obtained from a dihydro precursor of type *(3)*. [A Novel Route to Condensed Polynuclear Systems; Reality and Illusion of Benzyne Intermediacy. Acc. Chem. Res. *11*, 283—288 (1978); 65 references]

[Rd 40 IE]

The lectins have been comprehensively reviewed by *I. J. Goldstein* and *C. E. Hayes*. Lectins are carbohydrate-binding proteins (glycoproteins) which occur in plants and animals; these compounds were previously referred to as *e.g.* agglutinins, hemagglutinins or phytohemagglutinins. An example of the specificity of the lectins is the ability of lima bean extracts to agglutinate exclusively erythrocytes of type A, *i.e.* this lectin can distinguish the blood groups whose determinant groups are carbohydrate chains. The biological function of the lectins is still not absolutely clear. Lectins are used, *e.g.* for blood group determination and for the detection of macromolecules which contain carbohydrates. Membrane-bound carbohydrate-containing structures can be investigated with lectins of defined specificity. [The Lectins: Carbohydrate-binding Proteins of Plants and Animals. Adv. Carbohydr. Chem. Biochem. *35*, 127—340 (1978); 875 references]

BOOK REVIEWS

Grundlagen der Technischen Elektrochemie (Fundamentals of industrial Electrochemistry). By *E. Heitz* and *G. Kreysa*. Verlag Chemie GmbH, Weinheim—New York, 1977. 1st edit., xiv, 290 pp., 69 figs., 20 tables, paperback, DM 48.00.

Since electrochemical methods are now gaining ground in many sectors of chemistry, we must welcome this book, which discusses the electrochemical aspects of industrial chemistry.

This is a guide for experimental work. The first chapter deals with experiments involving the most common measuring techniques. The next chapter is devoted to material, charge, and heat transport. Most of the experiments come under the heading of electrochemical reaction technology. The following chapter covers electrode kinetics, kinetics in electrochemical reactors, separation systems in electrochemical cells, optimization and experimental design, problems of structural materials and corrosion, and model experiments concerning the industrial control of reactions. Finally, a long appendix covers electrochemical and industrial fundamentals, calculation exercises and the results and discussion of experiments.

The individual chapters have a logical structure: the authors first mention the most important relevant literature, explain the basic concepts, and give instructions for useful experiments. The latter are particularly well chosen, for they illustrate equally well the fundamentals and the industrial applications. The authors have incorporated their vast practical experience into the presentation of the experiments. We can only agree with their suggestion that one or another experiment should be included in industrial chemistry or physical chemistry practicals. This manual certainly fills a gap and can be recommended to everyone interested in the application of electrochemical methods.

H. Baumgärtel [NB 425 IE]

Grundlagen der Biochemie I and II (Fundamentals of Biochemistry). By *O. Müller*, Georg Thieme Verlag, Stuttgart, 1977. 1st edit., vol. I: Biochemische Reaktionen (Biochemical Reactions), xiii, 393 pp., 58 figs., 40 tables, paperback, DM 24.80. Vol. II: Stoffwechsel der Organismen (Metabolism of Organisms), x, 345 pp., 115 figs., 78 tables, 1 folding table, paperback, DM 24.80.

A new pocketbook on biochemistry has been published, which is planned for three volumes (the last volume, on metabolic regulation, has not yet appeared) each costing almost DM 25.00. The total price is therefore DM 75.00, which in itself invites comparison with the major standard works. It is ambitious, for it is intended—as the preface says in both volumes—"for students of biochemistry and related subjects such as microbiology, botany, zoology, medicine, pharmacy, agriculture, food chemistry, chemistry, and physics, who want to learn the fundamentals of general biochemistry in a short

time. It is also intended as a self-study aid for chemists and biologists in industry and in schools". Such a textbook could hardly be more ambitious, and it must therefore be judged by like standards. The American textbooks, which are much admired with good reason, set about their task with great enthusiasm and gusto and are aimed at a limited audience—yet they give much to many. They present exemplary science in unpretentious colloquial language; they are admittedly not always right by model-school standards, but they are always stimulating, with suggestions, examples and digressions, give us the feeling that something has finally "clicked", and show things in a different light. We find in them with delight and satisfaction all that makes biochemistry such a fascinating subject: its position between two sciences, encompassing the horizons of both chemistry and biology, and a system of adaptable coordinated hierarchies, which was elaborated by the study of evolution and gives us something to ponder over even in the case of non-biological material. But none claims a "didactic concept" based on "remarkable successes", or "comprehensive treatment" ... "based on the systematic discussion of reaction types", behind which the student finds the usual pushbutton approach of chemical cramming schools. Enthusiasts will miss in these volumes (but also in the American textbooks) explicit references to sophisticated metabolic reactions with ylides, hybrid ions, and organometallic compounds, or to one-electron oxidations, transition states with carbonyl groups, and covalent catalysis, to mention but a few. If such examples are found, they come where they are least expected; we find there also suggestions as to how reaction mechanisms can be deduced from kinetic measurements, isotope-exchange reactions, chiral transformations, *etc.*, as well as ideas of what a preparative chemist can learn from biochemical reactions about catalytic tactics and biomimetic strategy. The author also specifies the function of biochemistry as an intellectual exercise-ground and a means for investigating intermolecular interactions and mechanisms of catalysis, but does not mention it as being a rational basis for molecular pharmacology and a challenge to synthetic chemists. On the other hand, we do find a useful classification of enzymatic reactions according to their course and occurrence, and lists and formulas of memory-taxing substances isolated from cells and tissues. However, there is nothing here that we have not heard quite often before; at this above-average price and with its exorbitant claims, this is not a book that is long overdue.

L. Jaenicke [NB 427 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

High-Resolution, Higher-Order UV/VIS Derivative Spectrophotometry

New analytical methods (14)

By Gerhard Talsky, Lothar Mayring, and Hans Kreuzer[*]

Dedicated to Professor E. O. Fischer on his 60th Birthday

Derivative spectrophotometry has gained increasing importance in the past two years and is currently experiencing vigorous development. Following an introduction the present article provides a review of this extremely effective method. In particular, the advantages of *higher*-order derivative spectrophotometry (HODS method, $n>2$) are discussed on the basis of practical examples from a wide range of analytical fields. The results are achieved with the aid of a newly developed analog computer unit, whereby for the first time readily reproducible, low-noise, on-line spectra can be obtained up to the 7th order and even, in favorable cases, up to the 9th order. In practice it has proved valuable to work with spectra of the 3rd to 5th order; but even higher derivations could be profitable for the separation of strongly superposed signals or for "fingerprinting".

1. Introduction

After the introduction of derivative spectrophotometry by *Hammond* and *Price*[1], *Tannenbauer et al.*[2], *Morrison*[3], and *Giese* and *French*[4], in the early 50's, the differentiation of experimental curves has been applied to many analytical processes. From the very large number of methods and investigations a representative selection may be made here as follows:

UV/VIS absorption spectrophotometry[2, 5–11]
IR and Raman spectrometry[12–16]
NMR spectrometry[17–19]
ESR spectrometry[18–20]
Flame emission and absorption spectrometry[21–25]
Luminescence spectrometry[26]
Atomic and molecular spectroscopy[27]
Gas chromatography[28, 29]
Polarography[30]
Potentiometric titration and other electroanalytical procedures[31–36]
Investigations of reaction kinetics[5, 37–42].

In the past two years derivative spectrophotometry has acquired increasing importance especially in the field of trace analysis[11, 15, 43–45]. It has also begun to be gradually accepted in UV/VIS spectrophotometry and is now undergoing vigorous development.

Unlike gases and vapors, which frequently give many sharp lines in the UV and in the visible part of the spectrum, dissolved substances or liquids usually give less-characteristic spectra with more or less developed maxima and shoulders, which must be ascribed to the overlapping of several terms of electron transitions, such as $n\rightarrow\pi^*$, $\sigma\rightarrow\sigma^*$, and $\pi\rightarrow\pi^*$, and to rotation and translation.

Derivative spectra make it possible to determine flat maxima more precisely and to isolate shoulders and weak signals from an unwanted background.

The current rapid development of derivative spectrophotometry has mainly been due to progress in modern electronics, which has enabled analog differentiation of the signals to

[*] Univ.-Doz. Dr. G. Talsky, Dipl.-Chem. L. Mayring, H. Kreuzer
Lehrstuhl I für Technische Chemie der Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

be carried out relatively simply in on-line operations; however, to the best of our knowledge only the first- or second-order derivatives of fundamental spectra have hitherto been recorded in this way.

The more expensive digital differentiation increasingly makes use of semiconductor storage and microcomputers in off-line operation.

By means of an electronic analog differentiator newly developed by us[46-48] and capable of wide variation, we have investigated systematically whether, and to what extent, *higher* derivatives, in particular, improve the information obtainable from UV/VIS spectra.

2. Theoretical Principles

2.1. Explanations to the Term "Differentiation"

The differentiation of a curve or of its function means, mathematically expressed, determination of the slope of the curve over the whole region.

In spectrophotometry the ratio of the light flux intensity I_0 before entering the sample to that of the light flux I after leaving the sample is determined. According to the Beer-Lambert law the following relationship is obtained:

$$\frac{I}{I_0} = e^{-cd\varepsilon} \tag{1}$$

(c = concentration of the sample [mol/l], d = layer thickness [cm], ε = molar extinction coefficient).

For a constant intensity I_0 over the whole wavelength range, which is achieved technically *e.g.* by an automatically controlled slit or automatic electronic adjustment of the amplification, the first derivative of Eq. (1) is obtained as:

$$\frac{\frac{dI}{d\lambda}}{I} = -cd\frac{d\varepsilon}{d\lambda} \tag{2}$$

The first derivative is directly proportional to the concentration at each wavelength. The sensitivity of the measurement is particularly high in the neighborhood of inflections, since here there are extremum values of $d\varepsilon/d\lambda$.

For the second derivative we find:

$$\frac{\frac{d^2I}{d\lambda^2}}{I} = c^2d^2\left(\frac{d\varepsilon}{d\lambda}\right)^2 - cd\frac{d^2\varepsilon}{d\lambda^2} \tag{3}$$

Direct (linear) proportionality to the concentration then exists only if the first derivative of ε (*i.e.* $d\varepsilon/d\lambda$) is equal to zero. If, additionally, $d^2\varepsilon/d\lambda^2$ (the second derivative of ε) has an extremum value, then the sensitivity is particularly high.

Likewise, for the third derivative:

$$\frac{\frac{d^3I}{d\lambda^3}}{I} = -cd\frac{d^3\varepsilon}{d\lambda^3} + 3c^2d^2\frac{d\varepsilon}{d\lambda}\frac{d^2\varepsilon}{d\lambda^2} + c^3d^3\left(\frac{d\varepsilon}{d\lambda}\right)^3 \tag{4}$$

$d\varepsilon/d\lambda$ must be zero if it is to be linearly proportional to the concentration. Particularly high measurement sensitivity is obtained at shoulders with horizontal tangents to the points of inflection and small radii of curvature.

If, however, the first derivative is not zero, *i.e.* if one is dealing with points not having horizontal tangents, then special nonlinear calibration curves must be prepared.

Equations for still higher derivatives can be set up in similar fashion. For the fourth derivative it should be noted that linear proportionality is achieved only when both $d\varepsilon/d\lambda$ and $d^2\varepsilon/d\lambda^2$ assume values of zero.

$$\frac{\frac{d^4I}{d\lambda^4}}{I} = -cd\frac{d^4\varepsilon}{d\lambda^4} + 4c^2d^2\frac{d\varepsilon}{d\lambda}\frac{d^3\varepsilon}{d\lambda^3} + 3c^2d^2\left(\frac{d^2\varepsilon}{d\lambda^2}\right)^2 - c^4d^4\left(\frac{d\varepsilon}{d\lambda}\right)^4 \tag{5}$$

2.2. Derivations of Analytical Bands

An absorption band, also called an analytical band, can be described by approximation formulas such as the Gauss and Lorentz functions or the Cauchy distribution. According to *Gauss*, the extinction E of the band at wavelength λ is given by:

$$E_\lambda = E_{max}\, e^{-C\lambda^2} \tag{6}$$

(E_{max} = extinction of the absorption maximum, C = const)

and for the half-width s, by which is meant the distance, parallel to the abscissa, between the points of inflection of the curve, we have:

$$s = \sqrt{\frac{2}{C}} \tag{7}$$

The differentiation of a simple analytical band is represented graphically in Figure 1a. The maximum of the fundamental curve in derivatives of odd order corresponds to a passage through zero, and in even-order derivatives it corresponds to an extremum value (alternately minimum and maximum). With increasing order of the derivative the sharpness of the bands increases, while the band width decreases. Inflections on the fundamental curve lead to extrema in the derivatives of odd order and to passages through zero in derivatives of even order, which explains the increase in the number of extrema over that on the fundamental curve. One speaks here of "virtual extrema", since they do not occur on the fundamental curve but are formed from the inflections on differentiation. The result is that the inflections are more readily determined and the spectrum is therefore easier to resolve and, on the other hand, with increasing order simplicity is lost because of the increase in the number of extrema—one maximum produces $n+1$ extrema in the nth derivative.

The advantage of derivative spectrophotometry is thus especially evident on the examination of curves that arise by the overlapping of two or more analytical bands (Gaussian curves):

$$E_{(\lambda)} = E_{1(\lambda_0)} + E_{2(\lambda_0 - \Delta\lambda)} \tag{8}$$

($E_{(\lambda)}$ = superposition, $E_{1(\lambda_0)}$ = absorption bands with maximum at λ_0, $E_{2(\lambda_0-\Delta\lambda)}$ absorption bands whose maximum is shifted from $E_{1(\lambda_0)}$ by $\Delta\lambda$).

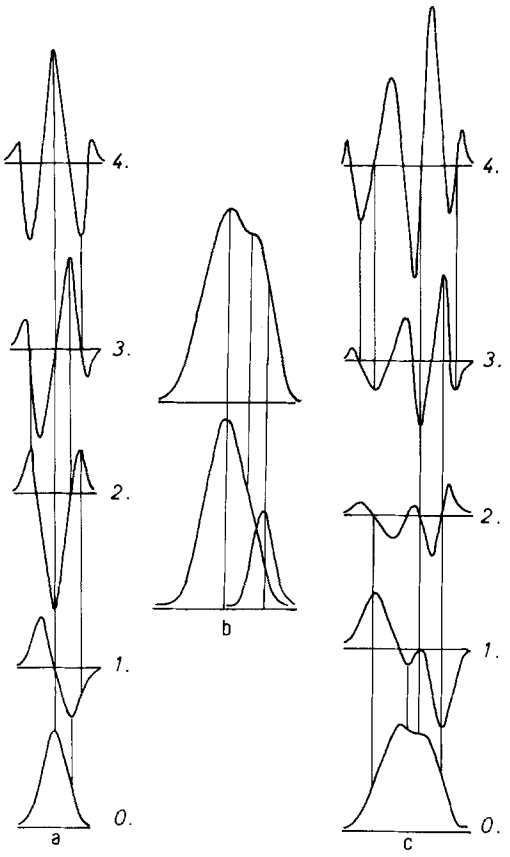

Fig. 1. a) Differentiation of a Gaussian curve (analytical band); fundamental curve and 1st to 4th derivative [$E_\lambda = E_0 \exp(-C\lambda^2)$]; b) superposition of two unequal Gaussian curves [$E_\lambda = E_{1(\lambda_0)} + E_{2(\lambda_0 - \Delta\lambda)}$]; c) Differentiation of two superposed unequal Gaussian curves; fundamental curve and 1st to 4th derivatives.

In cases where there is superposition of two equal Gaussian curves, a third or fourth inflection arises if $\Delta\lambda$ corresponds to at least the half-width.

If, however, bands with *different* ordinates of their maxima overlap, then shoulders are formed even if the separation of the maxima is less than the largest half-width; on further separation of the bands the shoulders are converted into terrace points, this feature being connected with the appearance of a fourth inflection on superposition (Fig. 1b).

If this fundamental curve is differentiated, then in the odd derivatives the terrace point becomes an extremum value (*e.g.* in the third derivative the most intense minimum), whereby a better resolution of the spectrum and also a quantitative determination of both components become possible (Fig. 1c).

2.3. Loss of Information on Differentiation—Increase in Resolution

Any function can be represented approximately by a power series, for example:

$$E_\lambda = c_0 + c_1\lambda + c_2\lambda^2 + c_3\lambda^3 + U_\lambda \tag{9}$$

If this equation is differentiated, the constant c_0 vanishes and the linear term $c_1\lambda$ becomes a constant:

$$E'_\lambda = c_1 + 2c_2\lambda + 3c_3\lambda^2 + U'_\lambda \tag{10}$$

In practice this means that a linear background can be eliminated (Fig. 2).

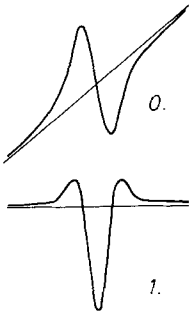

Fig. 2. Elimination of a linear background function ($y = ax$) by differentiation (1st derivative, $dE/d\lambda$).

On the second differentiation of the fundamental function (9)

$$E''_\lambda = 2c_2 + 6c_3\lambda + U''_\lambda \tag{11}$$

the terms $c_0 + c_1\lambda$ vanish, since they become constants, and $c_2\lambda^2$ (*i.e.* a parabolic background function) is converted into a linear function.

Derivatives of higher order also eliminate background functions of higher order and complicated shape:

$$E'''_\lambda = 6c_3 + U'''_\lambda \tag{12}$$

$$E''''_\lambda = \quad U''''_\lambda \tag{13}$$

Resolution is thus improved by the sharpening of signals that is achieved by derivative spectrophotometry. In the case of Lorentzian or Gaussian functions the ratio of the half-width of the primary function to the half-width of the 2nd derivative is 1:0.33, *i.e.* it decreases to a third of its original value. However, if special measures are not taken, noise increases by a factor of $0.33^2/1$, *i.e.* becomes 10 times greater[49]. A derivative order greater than $2n$ ($n = 1, 2, \ldots$) is generally used, since in this case the extremum values correspond to one another[50] (Figs. 3a and 3b).

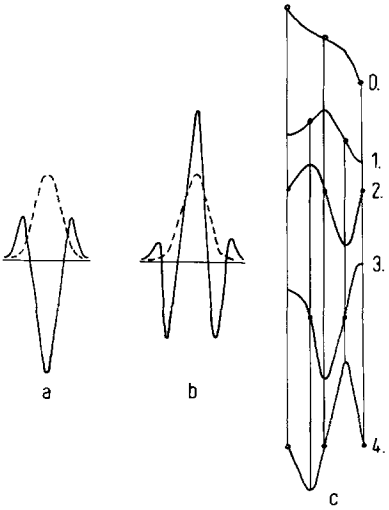

Fig. 3. Sharpening of signals by differentiation of the maxima. a) Fundamental function (---) and the 2nd derivative $d^2E/d\lambda^2$ (—); b) fundamental function (---) and the 4th derivative of $d^4E/d\lambda^4$ (—); c) signal sharpening by differentiation of shoulders; fundamental curve and the 1st to 4th derivatives.

Extreme sharpening of signals can also be observed when shoulders are resolved. Two effects are then produced (Fig. 3c):

a) Conversion of a shoulder into an extremum value in the derivatives of odd order,

b) the signal sharpening shown in Figures 3a and 3b.

Band overlaps may be resolved by a) and the fine structure of the spectra is emphasized by b), which is important for identity and purity tests (fingerprint spectra, see for example Fig. 18). In analysis, and particularly in biochemical analysis, this procedure is in many cases superior to the customary formation of the ratio of absorptions at two wavelengths as a criterion of purity (*e.g.*[11]). In the higher derivatives, however, the spectra become increasingly complex, which can make their evaluation more difficult.

Derivative spectrophotometry cannot increase the amount of information in the spectra—this is determined by the standard of the spectrophotometer—but it can increase the resolution at the cost of loss of the background signals, and can thus considerably improve the detection sensitivity of masked weaker bands or it can even make possible for the first time a qualitative or quantitative determination of these bands.

Further works on the theory of derivative spectrophotometry can be found in [51–60].

2.4. Evaluation of Derivative Spectra for Quantitative Measurements

As stated in Section 2.1, there are certain conditions in which the derivatives of I/I_0 are linearly proportional to the concentration and need not first be converted into extinctions by means of logarithms.

In the *tangent method* a common tangent is drawn to two neighboring maxima or minima and the distance t to the intermediate extremum value is measured parallel to the ordinate (Fig. 4). This method can be applied satisfactorily with a linear background.

The distance p between two extremum values is proportional to the difference between the slopes of the tangents to the inflections on the fundamental curve. This is called the *peak-peak* method and is most often used for quantitative multicomponent analyses. Two examples—p_1 and p_2—are illustrated in Figure 4.

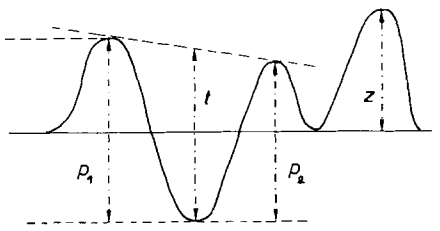

Fig. 4. Evaluation of derivative spectra. Tangent method (t), peak-peak method (p), and peak-zero method (z) (see Text).

The *zero-crossing method (peak-zero method)* is used only in special cases. In this the vertical distance z to the zero line is measured (Fig. 4); the method is suitable for the evaluation of higher derivatives containing signals symmetrical with respect to the abscissa and in cases of undistorted overlapping of individual curves if one of the curves passes through zero at this position.

Finally the ratios between pairs of neighboring peaks ($p_1 : p_2$) can be determined; if these differ, then background interference and, therefore, inferior quality of the sample are indicated (*peak-peak ratio method*) (Fig. 4).

3. Experimental Verification of Derivative Spectra

3.1. Electromechanical Tachometer

Olson and *Alway*[61] have described a method of recording the first derivative. The authors used a recorder with a tachometer generator and a lock-in amplifier followed by a filter. On wavelength scanning the rate of movement of the recorder in the ordinate direction is proportional to the first derivative.

Klein and *Dratz*[62] and *Cook*[63] produced, by a tachometer generator, a 60 Hz signal whose amplitude was proportional to the ordinate component; after amplification by a lock-in amplifier it was rectified, smoothed, and filtered.

3.2. Modulation Processes

In sinusoidal wavelength modulation the main wavelength λ_0 is sinusoidally modulated:

$$\lambda - \lambda_0 = d \cdot \sin \omega t \qquad (14)$$

(λ = auxiliary wavelength, d = vibration range, ω = angular velocity, t = time).

This is achieved *e.g.* by vibrating lattices, quartz plates, mirrors, vibrating exit slits, or optical wobblers[52, 55, 64–68]. Modulation of the wavelength induces a synchronous modulation of the amplitude. If these intensities are expanded in the form of a Taylor series in λ_0 and the powers of the sine functions are expressed as sine and cosine functions of the corresponding multiple angles, then the derivatives can be obtained from the Fourier coefficients of this series. The second derivative is obtained from the second harmonic of the induced intensity. *Hager* and *Anderson*[55] give a complete theoretical description of the sinusoidally modulated derivative spectrometer. The second possibility, namely direct modulation of the amplitude, is used only rarely.

3.3. Two-wavelength Spectrophotometry

This method of differentiation, also an optical one, which dates back to *French*'s investigations[69], was developed further and used by *Saidel*[70] and, especially by *Shibata*[7, 71].

In this method the light is divided between two monochromators and its intensity is measured by two identical photomultipliers. The signals are then directed, after amplification, to a subtraction unit whose output is connected to the Y-input of a recorder; the X-axis of the recorder is driven synchronously with the wavelength scan. If the difference between the wavelength scans is sufficiently small (usually 1–2 nm), the first derivative with respect to the wavelength is obtained. The time constant can be adjusted by altering the wavelength difference (time interval of the scan) of the monochromator. Higher derivatives cannot be obtained directly by this method.

3.4. Derivative Spectrophotometry by Subtraction of Temporally or Spatially Delayed Spectra

Another instrumental arrangement for obtaining the first derivative has been described by *Grum et al.*[72]. The output of the photomultiplier is divided into two equal parts. One signal passes direct to the subtraction unit, the other signal is first delayed in time or space by an electronic or electron-optical circuit.

The output signal from the subtraction unit is passed to the recorder and is directly proportional to the first derivative of the spectrum.

Inoue et al.[73] have developed a technique in which the signal delay is produced by tape recording with two recording heads arranged in tandem. The time constant is given, and can be regulated, by the separation between the recording heads.

Apparatus for the temporal or spatial delay to the spectra described here is relatively easily constructed for the first derivative and affords a differentiation with respect to time. Higher derivatives have not so far been obtained in this way; the cost of this would be relatively high.

3.5. Digital Differentiation

One method requiring expensive apparatus makes use of a numerical calculation of the derivatives by digital computer[74, 75]. The calculation can be effected on-line or off-line[72]. The output signal of the spectrophotometer must first be fed to an analog-digital converter. To increase reproducibility, the signals at each given wavelength are accumulated and smoothed out; the mean value is then calculated (off-line). In other procedures the curves are smoothed by the method of least squares. The differentiation can also be programmed point by point or by the use of Lagrange differentiation polynomials. The wavelength separation in the measurement is usually 0.1–1.0 nm. The spectrum and its derivatives can be interpolated by linear regression.

For the analysis of digitalized spectra *Morrey*[76] used a large computer. To determine the positions of the absorption bands, the second, third, and fourth derivatives were calculated, and from them the signal width and the relative amounts of the components could be obtained.

Butler and *Hopkins*[77–79] investigated pigments in suspensions of mitochondria, chloroplasts, and yeast cells. The background function due to scattered light and other components was eliminated by electronic function simulation or off-line, after digitalization and storage, by pointwise digital differentiation. These authors also carried out empirical computer analyses of the spectra and give examples of derivative spectra of second and fourth orders.

In the past months less expensive and less complicated digital differentiators, generally based on microcomputers, have come onto the market. Hitherto they have usually been designed for giving only the first and second derivatives and provide few possibilities of variation. Recently also, MC differentiators have been offered for derivatives up to the fourth order; there have been no accounts of experience with these modules in the literature, apart from intrafactory reports. As long as the microcomputer has sufficient storage capacity one can in fact carry out differentiations of any desired order by retrieving the fundamental spectrum from storage, differentiating it, storing that result, differentiating this in its turn, and repeating this process n times. However, with increasing order the errors in the approximate solutions become increasingly evident, being shown by slightly jagged curves and an increasing noise level.

3.6. Electronic Analog Differentiation

Analog differentiation by means of electronic differentiation circuits presents a series of advantages over the methods described in Sections 3.1 to 3.5:

- Modification of the optical system is omitted.
- The use of lock-in amplifiers is avoided.
- Feedback on the measuring process is easy to avoid.
- All the advantages of analog data processing (*e.g.* filtering, smoothing) are retained.
- Time constants, filters, attenuation, *etc.* can be easily optimized.
- Higher derivatives can be obtained relatively simply.
- Susceptibility to disturbance is small.
- Costs are relatively low; the cost/performance ratio is good.

Against these advantages must be set some disadvantages:

- The differentiation is not carried out directly with respect to wavelength, but with respect to time. This, however, does not interfere if the wavelength scan is effected at a constant rate.
- The derivative spectra are somewhat delayed with respect to the fundamental spectrum, this being caused by the RC units. This phase shift depends on the differentiation time constant and on the rate of the wavelength scan. The shift of the signals can be taken into account by standardization or calculation[80] (systematic error). A further possibility is to compare the derivative spectra by scanning the fundamental spectrum in the forward and reverse directions, followed by formation of the mean.
- Reproducible and time-constant wavelength scanning is absolutely essential (*e.g.* synchronous operation of wavelength scan and recorder travel by stepping motors or other devices). This can be effected easily with lattice monochromators or—but only with great difficulty—with prism instruments having logarithmic scales.
- The bandwidth of the light must be independent of λ; the method is thus unsuitable for spectrophotometers with automatically adjusted slits.

For derivative luminescence spectrophotometry, *Green* and *O'Haver*[26] have been able to show that the wavelength-modulation technique and electronic analog differentiation give the same signal/noise ratio and that there is no difference for other spectral parameters either[81–83].

4. Electronic On-line Analog Differentiation of Higher Order

Electronic analog differentiation can be achieved in the simplest case by a combination of a condenser C_s and a resistance R_r. This passive constructional unit is preferably

connected to an operation amplifier OP (Fig. 5). The operation amplifier should here be regarded as a "black box". On an

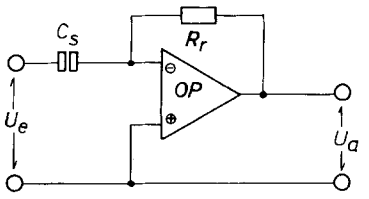

Fig. 5. Basic circuit of an inverting differentiator (U_e input potential, U_a output potential, C_s condenser, R_r feedback resistance, OP operation amplifier).

area of 1—2 m^2 this modern integrated active element takes over the functions of eight to ten transistors and of several resistances and condensers and amplifies the signal after input in equipolar fashion (⊕), *i.e.* with the same sign, or inverted (⊖) (no-load amplification 1000—100000!). The differentiation time constant τ is obtained from:

$$\tau = C_s \cdot R_r \tag{15}$$

and it can thus be adjusted by varying the capacitive component or the ohmic component.

The resolution of the derivative spectrum depends not only on the slit width but also to a large extent on the rate of the wavelength scan S and on τ. The best resolution is thus obtained with a small slit width, slow scan, and small τ. In practice a middle way must be chosen, because if the slit is narrow the noise increases greatly owing to the high amplification and gives a poor zero-line constant, which has a detrimental effect on the reproducibility of the derived spectra. If both S and τ are small, then again only small differences in potential are obtained, as we have:

$$\frac{dE}{d\lambda} \sim \frac{dE}{dt} \sim \frac{dU}{dt} \tag{16}$$

In optimizing the differentiator care must be taken that the resolution A_D of the differentiator is at the most equal to—but is better smaller than—the spectral bandwidth, since otherwise valuable information is lost and the resolution of the spectra becomes worse. On the other hand, in special cases this particular effect can be made useful—to damp down or suppress disturbing signals in the spectrum. The time resolution T of an analytical band amounts, for the first derivative to:

$$T_1 \sim 4\tau_1 = 4RC \text{ [s]} \tag{17}$$

and for the second derivative to:

$$T_2 \sim 8\tau_2 = 8RC \text{ [s]} \tag{18}$$

This gives the resolution of the differentiator:

$$A_D = T \cdot S \text{ [nm]} \tag{19}$$

(S = scan [nm/s])

When the spectral bandwidth B of the apparatus has been adjusted we should have:

$$A_D \leqq B \tag{20}$$

and

$$T < \frac{B}{S} \tag{21}$$

Except in cases of extreme difficulty, spectral bandwidths of 0.5—2 nm, a wavelength scan rate S of 1—5 nm/s, and differentiation time constants τ between 0.1 and 1 s are usually chosen.

While with the fundamental circuit the first or, in the most favorable case, the second derivative is obtained, with higher derivatives the noise becomes so great that the reproducibility—the prerequisite for quantitative evaluation—becomes very unsatisfactory.

By "noise" is understood the, generally higher-frequency, variation of the signal potential around a central value. The following are the principal causes:

a) Noise from the sample, *e.g.* due to temperature gradients, inhomogeneities or scattering.
b) Noise from the optics due to fluctuations of the light source.
c) Noise from the electronics of the spectrophotometer, mostly from the multiplier and amplifiers.
d) Noise from the differentiator unit, mainly the intensification of noise by differentiation.

Since the output voltage of a differentiator is directly proportional to the change in the input voltage with time, the (higher-frequency) noise is amplified in preference to (lower-frequency) signal voltage. The noise level therefore increases exponentially with the order of the derivative. Consequently, in derivative spectrophotometry spectral resolution and noise suppression are two opposing effects, which must be optimized from case to case.

Hitherto it has been possible to obtain only first- and second-order derivative spectra on-line by analog differentiation. We have now developed an instrument for producing higher-order derivative spectra to test how far the resolution of experimental signals is improved by the higher derivatives and up to which order differentiation still remains useful.

The apparatus consists of nine differentiation modules (inverting and noninverting; tandem differentiators); in addition, there are operation amplifiers, impedance transformers, attenuating units, active and passive filters, measuring devices, and potential dividers for matching input and output (cf. also Fig. 7).

The wide variability of the input source resistance, the input time unit, the amplifiers, the ohmic and capacitive members of the differentiators and filters, as well as of the attenuating units enables the instrument to be adjusted optimally for any desired purpose. Experience gained so far has enabled the important principles for such an electronic circuit to be deduced; in addition, a ratio between efficiency in signal resolution and the expenditure involved has been reached that is favorable for practical use.

What basic demands must an analog differentiator satisfy in order to be useful especially for verifying higher derivatives?

In the first place, care must be taken that the input signals are not affected by the differentiator units and that these units do not affect each other. This is done by placing before and between them impedance transformers with a high input and a low output resistance (galvanic separation). The signal is then raised to 5—10 V by means of a linear operation amplifier of, usually, 10 mV to 1 V peak voltage, this having a beneficial effect on the quality of the subsequent differentiation (short dead time). Both inverting and noninverting modules, the time constants of which should be separately variable, are suitable as differentiators. The noise, which has a decisive effect on the quality of the derivatives, especially those of higher order, can be eliminated by several measures:

a) Damping of the differentiator. This can be brought about for example by placing an ohmic resistance in front of the differentiating condenser or by switchable condensers in the feedback (capacity countercoupling).
b) Repeated differentiation with a large time constant τ. If differentiation is performed with large time constants, the signals with small amplitude and frequency are only poorly resolved in the form of small shoulders in the first derivative but, on further—if necessary repeated —differentiation they are transformed into relative extrema. A spectrum is finally obtained that shows no more shoulders and contains little noise. A disadvantage may be the size of the phase shift, which is proportional to the values of τ and the increase in "virtual" derivative bands caused by the higher order of differentiation.
c) Use of electronic filters. The noise can also be eliminated by the pre- or post-inclusion of passive or active (with amplification) selective electronic filters. A "low-pass" permits all signals to pass almost unhindered up to an adjustable limiting frequency, while the unwanted higher- and high-frequency signals are diverted.—A further possibility consists in the integration of the frequency filter in the feedback of the differentiating unit itself, whereby, for example, the low-frequency signals of interest are differentiated preferentially.—Selective frequency filtration is thus an efficient method for noise suppression, particularly when the limiting frequency and the quality of the filter can be varied separately.
d) Elimination of noise by statistics. This procedure is used above all when only small amounts of the sample are available, when the substances have low extinction coefficients, and/or if, owing to the high amplification, a poor signal/noise ratio is obtained in spite of all the measures described above.—The spectrum is drawn by a recorder with a medium intensity of color, at least ten times in exactly the same place. The regions of high line-density appear more intense and can now either be traced manually or photographed with underexposure on film material having a steep gamma. After copying onto hard paper, areas of high line-density stand out predominantly.—Naturally the superimposed curves could be prepared after digitalization by statistical methods, but this would be much more expensive.

How the individual adaptation of the differentiating units to each particular problem already affects the second derivative is shown in Figure 6. In the spectrum of trypsin, for example,

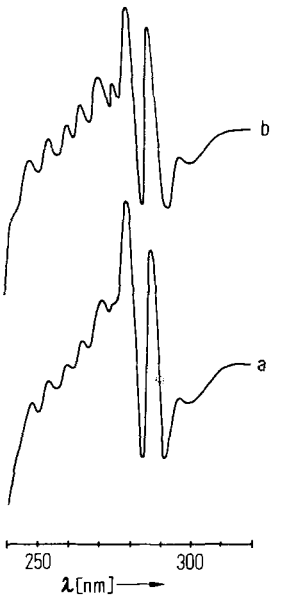

Fig. 6. Comparison of the spectral resolution (bovine trypsin): a) 2nd derivative, obtained by the use of a commercial analog differentiator; concn. 1 g/l, LTH (layer thickness) 1 cm, slit 1 nm, scan rate 1 nm/s, mode 6; b) 2nd derivative, recorded by means of an analog differentiator developed by us; concn. 1 g/l, LTH 1 cm, slit 1 nm, scan rate 1 nm/s.

the weak shoulders at 245 and 275 nm are, in particular, more clearly resolved.

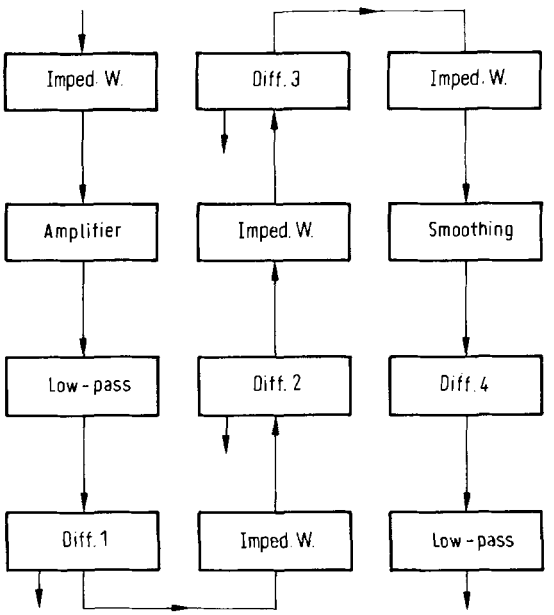

Fig. 7. Block diagram of a differentiator for derivatives up to 4th order.

Finally, it is possible to show by means of a block diagram the preferred construction of a differentiator circuit, in this case for obtaining derivatives up to the fourth order (Fig. 7).

5. Applications of UV/VIS Derivative Spectrophotometry

The following practical examples from the various fields of analysis are designed to demonstrate the wide area of

application of derivative spectrophotometry and, in particular, the capabilities and advantages of *higher*-order derivative spectrophotometry (HODS method; $n > 2$).

specimen. The order chosen should, however, be at least one at which all the shoulders and terraces are converted into bipolar signals. This can usually be attached with the fourth

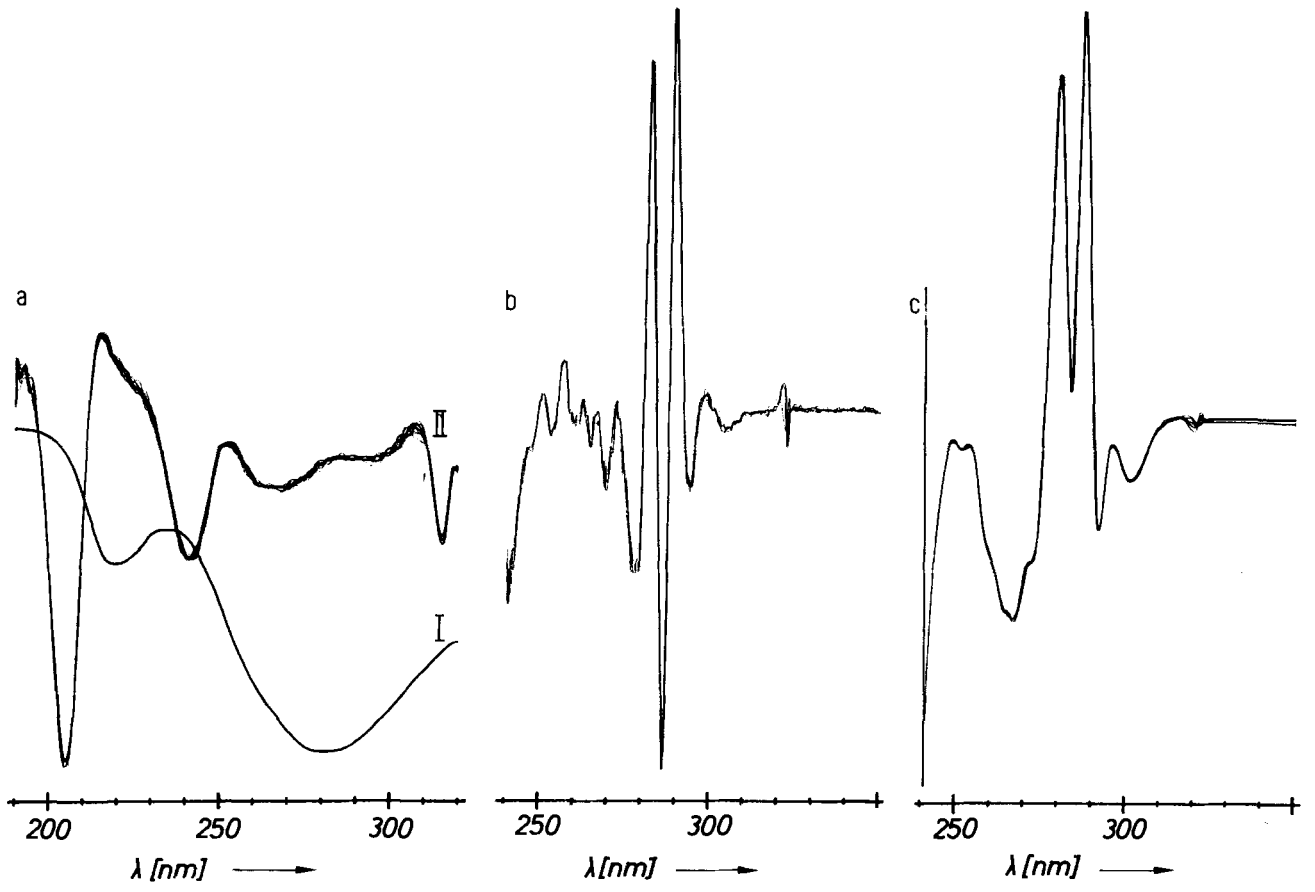

Fig. 8. a) Congo Red, concn. 20 mg/l, LTH 1 cm, slit 1 nm, scan 5 nm/s. I: fundamental spectrum; range 2E; II: 4th derivative, tenfold recording; b) bovine trypsin, concn. 0.5 g/l, LTH 1 cm, slit 1 nm; 4th derivative, sixfold recording, scan 2 nm/s; c) as b), scan 5 nm/s.

Some introductory remarks may first be made about analog differentiation. Figure 8a reproduces an original fourth-order spectrum of the azo-dye Congo Red. The tenfold superposition of recordings of the fourth derivative demonstrates the excellent reproducibility and low noise level; these were achieved by stepwise special adaptation of the apparatus to the problem at hand. The derivatives of spectra with broad maxima and flat flanks can be produced relatively rapidly (scan S about 5 nm/s). With steep and narrow maxima this would lead to reduced resolution, particularly if a large time constant were selected ($\tau \geqq 1$ s); this is shown in Figures 8b and 8c. In Figure 8b a scan of 2 nm/s was chosen. The fine structure of the fourth derivative (trypsin, sixfold superposition) can be well reproduced. However, little of the fine structure is visible in Figure 8c; with a scan rate of 5 nm/s the characteristic bands between 250 and 280 nm are suppressed. A smaller time constant could of course have been chosen, but this is possible only to a limited extent since $dE/d\lambda$ then becomes small, especially in the case of a gentle slope, and the high amplification then necessary increases the noise.

Up to what order is it reasonable to differentiate the fundamental spectrum? This question cannot be answered precisely, because the most favorable order varies from specimen to

or fifth derivative. Still higher derivatives can bring advantages particularly as "fingerprints". Figure 9 shows this for the fundamental spectrum and for the first- to seventh-order derivative spectra of the enzyme ribonuclease A. The fundamental spectrum shows the maximum at about 280 nm that is typical of proteins and a minimum at about 250 nm; shoulders on the flanks are merely hinted at. In the second and third derivatives the fine structure already appears distinctly, and in the fourth derivative it is largely converted into bipolar signals. The fifth to seventh derivatives increasingly sharpen the small maxima. The advantages of higher-order differentiation are increasingly recognizable if in each case the even- and odd-numbered orders are compared with one another. The seventh derivative was recorded 10 times in superposition to demonstrate the excellent reproducibility still shown at such high orders.

While extrema of the fundamental curve are most easily recognized in even-numbered derivatives (see Section 2.2), the inflections are most advantageously resolved in odd-numbered derivatives. It is thus useful to produce spectra of $(2n+1)$-th and $2n$-th order ($n = 0, 1, 2, \ldots$).

In the optimization of the individual steps care must be taken not to exceed the maximal working voltage of the

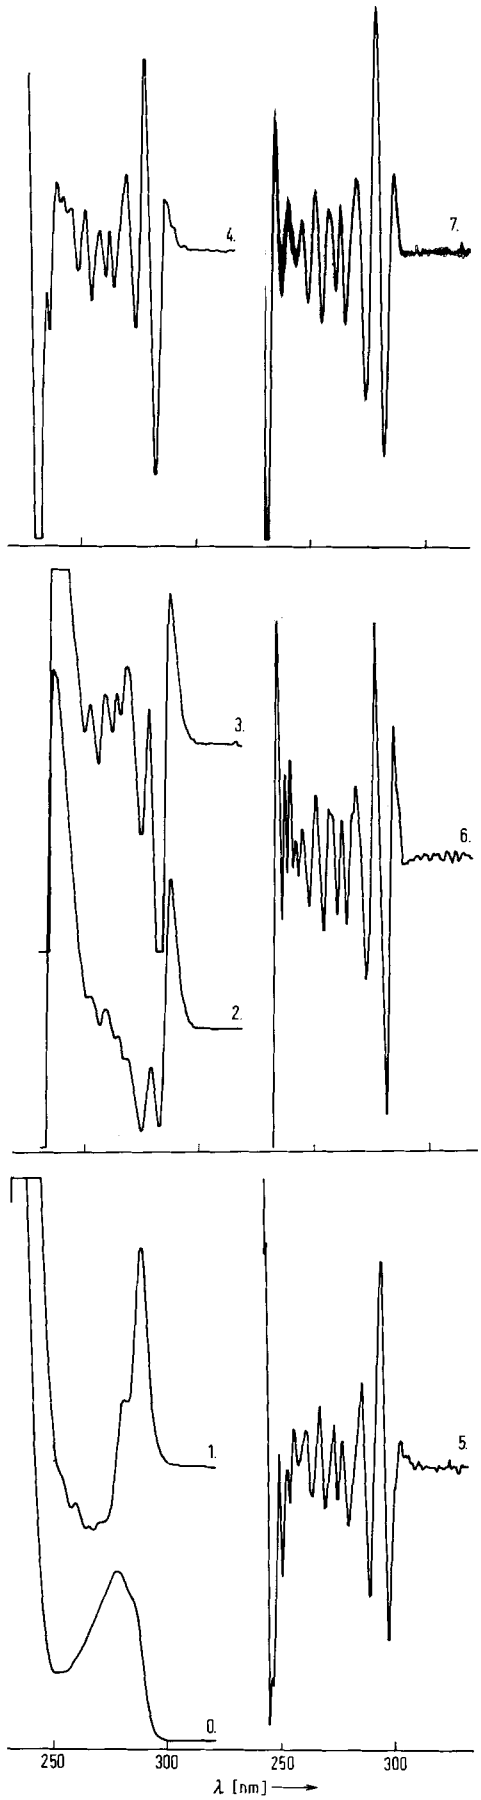

Fig. 9. Ribonuclease A (bovine), concn. 1 g/l, LTH 1 cm, slit 1 nm, scan rate 2 nm/s, range 2*E*; fundamental spectrum and 1st to 7th derivatives. The 7th derivative was recorded tenfold.

IC's used, as otherwise distortion of the spectra and oscillating in the circuit can occur, causing poor reproducibility and severe departure from linearity. When the spectra show flat maxima and poorly developed shoulders it has proved valuable to raise the signal voltage to *ca.* 5—8 V before differentiation. The output from the first stage, which then exhibits a voltage of 10—12 V, is subsequently attenuated to 5—8 V after filtration and is fed to the second stage (differentiation at the same voltage level). If, however, the extrema have steep flanks it is better to raise the input signal only to about 2 V before differentiation; in this case the inputs of the second, third, fourth, and higher stages are raised to 4, 6, 8 V and above (differentiation with rising voltage level).

5.1. Trace Analysis

Purity tests of crude, intermediate, and end products, and the detection of small amounts of impurities in foods, pharmaceuticals, effluents, *etc.* are the subject of much applied analysis. A few examples will be given here.

Ethanol is usually made absolute by ternary rectification with benzene, toluene, or xylene as entraining agents. However, when it is used as raw material for the production of alcoholic drinks, pharmaceutical preparations, extracts, *etc.* no more than traces of such toxic arenes may be present. In the fundamental spectrum of ethanol (layer 1 cm thick) 50 ppm of benzene can just still be determined (±10 %); 10 ppm gives only slight waves (Fig. 10, curve III), and 1 ppm can no longer be detected at all (Fig. 10, curve II). If, however, the spectrum is differentiated several times, the lower detection limit decreases: for the second derivative it is 5 ppm and for the fourth derivative it is reduced at least to 1 ppm (Fig. 10, curve V; mean error of the mean ±5 %), and semiquantitative analysis is still possible even with 100 ppb!

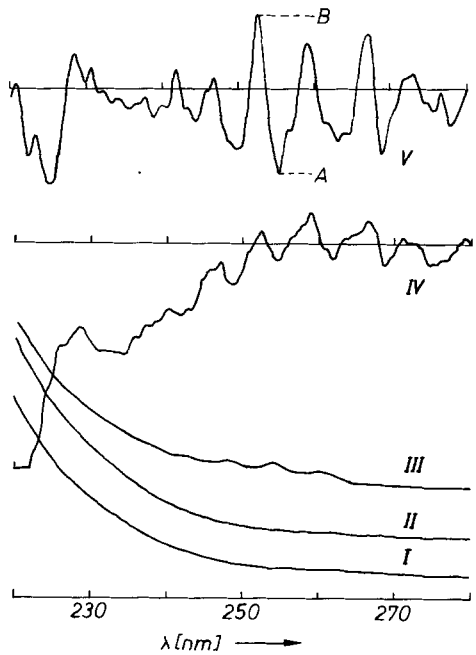

Fig. 10. Quantitative determination of traces of benzene in ethanol. Range 1*E*. LTH 1 cm, slit 1 nm. I: fundamental spectrum of "Uvasol" ethanol; II: fundamental spectrum with 1 ppm of benzene; III: fundamental spectrum with 10 ppm of benzene; IV: 2nd derivative of II (1 ppm of benzene), scan 2 nm/s; V: 4th derivative of II (1 ppm of benzene) scan rate 2 nm/s; $\overline{AB}$ is proportional to the concentration of benzene.

Arenes can similarly be detected in waste gases or waste air. The gases and vapors are drawn through an absorbent liquid such as ethanol, hexane, or cyclohexane and these are then investigated. Alternatively, the procedure described in Section 5.10 for "gases and vapors" is used.

Aniline and phenol are often present in effluents. These compounds can be analyzed very rapidly and simply by derivative spectrophotometry and, if necessary, determined quantitatively and even continuously down to low concentrations (2—5 ppm). Even varying amounts of turbid or colored materials do not usually disturb this analysis, since the background can be eliminated by differentiation.

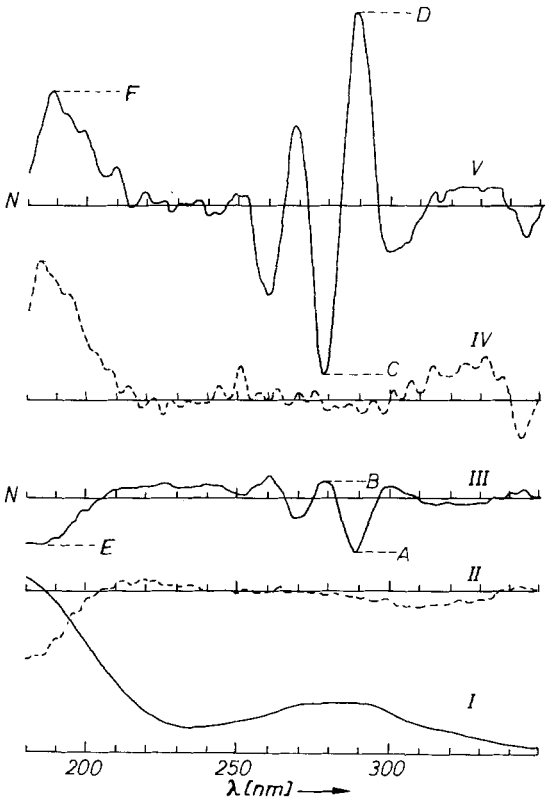

Fig. 11. Quantitative simultaneous determination of aniline and phenol in waste water. LTH 1 cm, slit 1 nm, scan rate 2 nm/s (cf. H_2O). I: fundamental spectrum with 5 ppm contents of aniline and phenol; II: 3rd derivative, 6 ppm of aniline; III: 3rd derivative, 5 ppm contents of aniline ($\overline{EN}$; N = zero line) and phenol ($\overline{AB}$); IV: 4th derivative, 6 ppm of aniline; V: 4th derivative, 5 ppm contents of aniline ($\overline{FN}$) and phenol ($\overline{CD}$).

Figure 11, curve III, shows the third derivative of the spectrum of a mixture of the two substances in a ratio of 1:1 (5 ppm of each) in water. However, they can be determined much more sensitively and simply by means of the fourth derivative (curve V): for instance, 2 ppm of phenol can still be determined with $\pm 5\,\%$ accuracy.

The use of a spectrophotometer with a built-in timer enables effluents to be monitored at predetermined time intervals. A flow-through cell is fed with the effluent *via* a by-pass by means of a peristaltic pump, and the amounts of toxic impurities are determined from the appropriate peak-peak distances in the third or fourth derivatives of the spectra.

Murexide and dithizone are reagents much used in trace analysis for the detection of metal ions; the detection limit lies at 10 to 100 ppm. By higher-order derivative spectrophotometry the sensitivity can be raised by at least one power of ten. The method can also be used with success for other color reactions.

5.2. Dyes

Derivative spectrophotometry can be applied advantageously to tests for identity and purity and to simultaneous quantitative determination of dye mixtures which are important in the manufacture of *e.g.* writing and printing inks and textile dyes, and also of diagnostic agents, pharmaceuticals, cosmetics, and foodstuffs. Of this group we have successfully investigated Congo Red/Cresol Red, Methyl Orange/Acridine Yellow, Rhodamine B, Trypaflavine, Methylene Blue, Brilliant Green, and Quinosol. The third to fifth derivatives were used.

5.3. Isomeric Compounds and Homologous Series

The following systems have been analyzed by HODS:

a) *n*-Propanol/isopropanol (undiluted, fourth derivative).
b) *n*-Butanol/isobutanol (undiluted, fourth derivative).
c) *o*-Xylene/*p*-xylene (1 % in hexane). The fundamental spectra provide little information. However, the *o*- and *p*-compounds can be satisfactorily distinguished in the third-derivative spectrum and can also be determined quantitatively with $\pm 4\,\%$ accuracy in the presence of one another.
d) Methyl, ethyl, and isoamyl acetates (undiluted and in the vapor state, third and fourth derivatives).
e) Benzene in "normal" and "super" gasoline (0.1 % in hexane). The addition of benzene, which increases the octane number, has acquired particular importance from the legal requirement to reduce the lead content of fuels. By means of the third-derivative spectrum (Fig. 12) the benzene contents of "normal" and of "super" gasoline were found to be $2.8 \pm 0.3\,\%$ and $9.8 \pm 0.3\,\%$, respectively, in good agreement with the supplier's specification (2.5—3.5 % and 9.5 to 10.5 %, respectively).

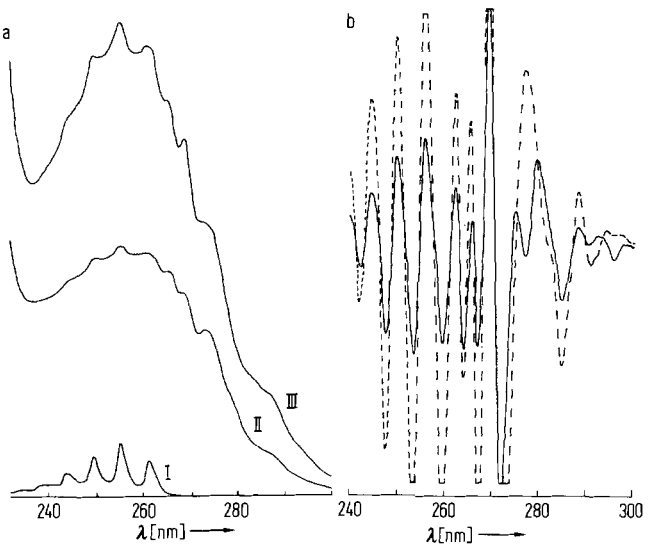

Fig. 12. Benzene in gasoline LTH 1 cm, slit 1 nm, scan rate 2 nm/s (cf. hexane). a) Fundamental spectra; I: 100 ppm of benzene in hexane; II: normal gasoline (0.1 % in hexane); III: super gasoline (0.1 % in hexane); b) 3rd derivatives of II (—) and III (---).

5.4. Foods and Beverages

Derivative spectrophotometry makes it possible, for example, to determine saccharin simply and quantitatively

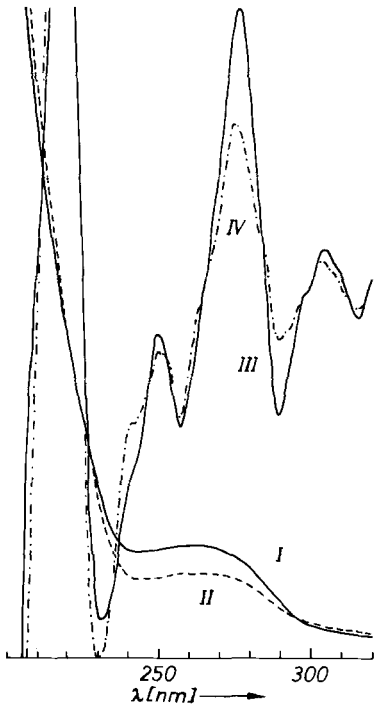

Fig. 13. Characterization of types of beer (0.4% in H_2O, range 2*E*). I: fundamental spectrum of light "Vollbier"; II: fundamental spectrum of "Weizenbier"; III: 4th derivative of I; IV: 4th derivative of II; slit 1 nm, scan rate 5 nm/s, LTH 1 cm.

in fruit juices. By a suitable setting of the differentiator the background due to the slightly turbid fruit juice can be emphasized and then filtered out, yielding the undistorted derivative

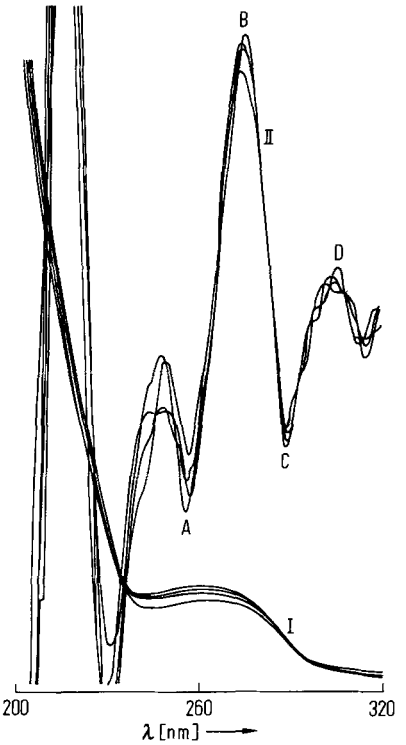

Fig. 14. Characterization of "Vollbier" from various suppliers. I: fundamental spectra (0.4% in H_2O); II: 4th derivative; LTH 1 cm, slit 1 nm, scan rate 5 nm/s. The extrema A, B, C, D, were evaluated.

spectrum. As little as 1 ppm of saccharin can be determined in this way.

Even complicated mixtures such as bottom- and top-fermented beers can be characterized. Whereas up to the third derivative practically no difference can be detected between "Vollbier" (Porter beer) and "Weissbier" (pale beer), this can be done from the fourth derivative spectrum (Fig. 13). It is actually possible to identify the products from several different suppliers (Fig. 14). For this purpose it is useful to establish the ratio $\overline{BC}:\overline{CD}$, this being then multiplied by the factor $\overline{AB}$, which is always typical for each of the two kinds. Under the given experimental conditions these characteristics of all the types of "Weissbier" lie between 25.7 and 31.0, and of "Vollbier" between 33.0 and 37.6.

Similarly, it is possible to examine and determine the protein content of milk types such as untreated cow's milk, uperized milk, and skimmed milk. The HODS method can also be applied *e.g.* to the analysis of unsaturated fatty acids in fats (hexane as solvent).

5.5. Drugs

Cysteamine (2-aminoethanethiol) and vitamin C (ascorbic acid) are used, *inter alia*, for protection against radiation and in the treatment of ketonuria. Both compounds reduce iodine solution. Vitamin C can be determined without interference *e.g.* by the Methylene Blue method, but it is simpler to find the contents of both substances simultaneously from the *fifth*-

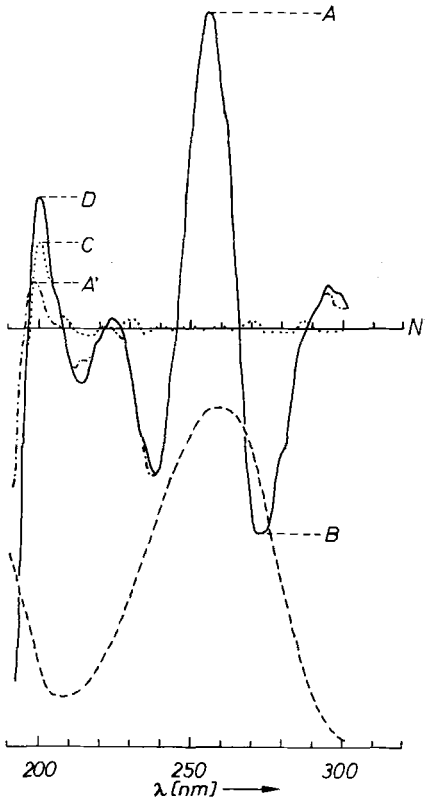

Fig. 15. Simultaneous determination of a mixture of cysteamine (concn. 6 mg/l) and vitamin C (concn. 15 mg/l); LTH 1 cm, slit 1 nm, scan rate 5 nm/s. Fundamental spectrum of the mixture (---); 5th derivative vitamin-C spectrum (-·-·-); 5th derivative cysteamine spectrum (.....); 5th derivative spectrum of the mixture (——). A, A', B, C, D, see text.

derivative spectrum (Fig. 15). Such a high order is necessary here because the cysteine spectrum overlaps a part of the

vitamin C spectrum very unfavorably. However, the objective can be attained by first determining the ratio of $\overline{AB}$ to $\overline{A'N}$ (N = zero line) in the fifth-derivative spectrum of vitamin C, and then recording the fifth derivative of the spectrum of the mixture, calculating the contribution of the vitamin C to the maximum at about 200 nm by means of the ratio determined in the previous experiment and subtracting it ($\overline{DN} - \overline{A'N} = \overline{A'D}$ = cysteamine).

We have also used the HODS method with success in investigations of cortisones, azulenes, plant extracts, and tea infusions.

5.6. Amino Acids

In addition to cysteine which absorbs weakly in the ultraviolet, phenylalanine (Phe), tyrosine (Tyr), and tryptophan (Trp) absorb actively between 200 and 300 nm. Although the individual chromophores can easily be determined, owing to the overlapping of the spectra this cannot be done at all, or only unsatisfactorily, for mixtures of two or three of these amino acids (Fig. 16). It is occasionally possible to determine

Fig. 16. Fundamental spectra of Tyr (---), Trp (-·-·-), and Phe (-···-); concn. 5×10^{-4} mol/l in all cases.

the composition of a binary mixture from the ratio of the extinction coefficients at two wavelengths (*e.g.* for Tyr/Phe at pH 10). The problem can certainly be solved far better by computer analysis of the superposed curves than by means of the extinction ratio, as has been done with success for many other mixtures. *Hirt et al.*[84], *Kienitz*[85], *Neuer*[86], *Lübbers* and *Wodick*[87], *Klabuhn et al.*[88], *Junker* and *Bergmann*[89], and *Fahr et al.*[90] have studied digital multicomponent analysis in detail.

Matsushima et al.[9] have described the investigation of amino acids and native proteins by means of derivative spectrophotometry; they were able by this method to achieve a considerable increase in the sensitivity of the determination of Phe in presence of Tyr and Trp. Further, *Ichikawa*[91] showed that the second derivatives of the spectra of Tyr and Trp do not disturb the characteristic bands in the spectrum of Phe in the 245 to 270 nm region. *Schmitt*[11] draws attention to the broad band at 280 nm, known as the "aromatic peak", which is to be ascribed to Phe, Tyr, and Trp and which shows surprisingly well-developed fine structure in the second derivative spectrum; he also discusses the possibility that the three aromatic amino acids could be determined quantitatively in the presence of one another in unhydrolyzed proteins if the broad maximum were resolved by derivative spectrophotometry.

Our systematic investigations to date have shown that very satisfactory results can be obtained for two-component mixtures within certain molar ratio limits (Table 1).

Table 1. Simultaneous two-component determination of Tyr, Trp, and Phe. Total concentration of the amino acids 5×10^{-4} mol/l.

Molar ratio	Amino acid	pH	Derivative	Max. error [%]
Tyr—Trp				
10:1—2:1	Tyr	7	2nd	96±6
7:1—1:4	Tyr	10	1st	92±5
7:1—1:2	Tyr	10	3rd	105±6
10:1—1:4	Trp	7	1st	106±6
Phe—Tyr				
7:1—1:7	Phe	7	4th	90±4
7:1—1:7	Tyr	7	0th -4th	100±5
Phe—Trp				
4:1—1:4	Phe	7	4th	96.5±4
4:1—1:4	Trp	7	0th—4th	100±5

In the case of three-component mixtures Phe and Trp are best determined from the fourth derivative at pH 7, and Tyr

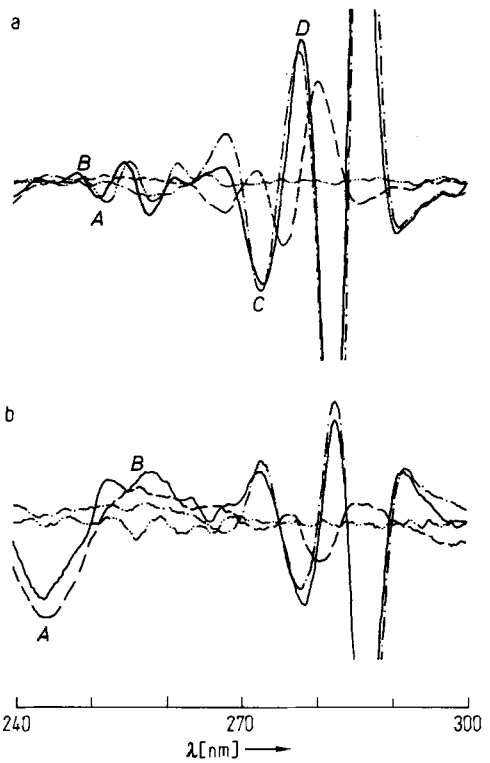

Fig. 17. Simultaneous determination of Phe, Trp, and Tyr (concn. 5×10^{-4} mol/l in all cases). LTH 1 cm, slit 1 nm, scan 2 nm/s range 2*E*; Tyr (---), Trp (-·-·-), Phe (-···-), mixture of Tyr, Trp, and Phe (——); a) 4th derivative, pH 7. $\overline{AB}$ is proportional to the concentration of Phe, $\overline{CD}$ to that of Trp; b) 3rd derivative, pH 10. $\overline{AB}$ is proportional to the concentration of Tyr.

best from the third derivative at pH 10 (total concentration 5×10^{-4} mol/l; Table 2, Figs. 16 and 17). Further experiments

Table 2. Simultaneous three-component determination of Tyr, Trp, and Phe. Total concentration of amino acids 5×10^{-4} mol/l. Molar ratios Tyr:Trp:Phe = 1:1:1, 4:1:1, 1:4:1, 1:1:4, 4:1:4, 4:4:1, or 1:4:4.

Amino acid	pH	Derivation	Max error [%]	
Tyr	10	3rd	Phe:Tyr $\leq$ 4:1	100 ± 10
			Phe:Tyr $\gg$ 4:1	107.5 ± 17.5
Trp	7	1st		112.6 ± 12
		4th		100 ± 10
Phe	7	4th		93 ± 10

are needed to show whether the maximum error of the determination, now $\pm 10\%$, can be reduced.

5.7. Peptides and Proteins

We have also investigated whether Phe, Tyr, and Trp can be determined directly in three-component mixtures of the free amino acids even in unhydrolyzed peptides and proteins. According to our results so far this is not directly possible, at least in aqueous solution. In most cases too low a content is observed if calibration is carried out with the free amino acids. Phe, however, still gives the best values (± 5 to $\pm 10\%$ deviation). Difficulties arise mainly from the differing chemical environment of the chromophore, leading to a shift of the maxima and broadening of the peaks, as well as a change in the ε values. Addition of organic solvents, strongly denaturating substances, or substances which effect uniform solvation and permeation of the molecules (perturbation effect) might lead to more successful results here.

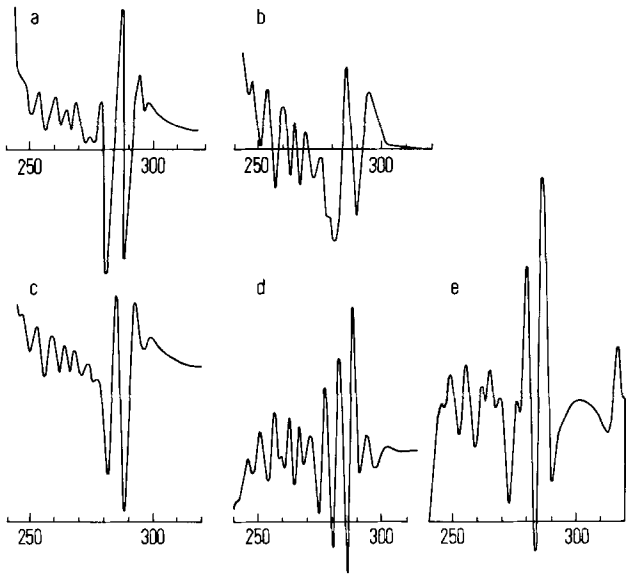

Fig. 18. Examples of "fingerprint spectra", all 3rd derivative, concn. 500 mg/l, LTH 1 cm, slit 1 nm, scan rate 2 nm/s. a) γ-Globulin from bovine serum (inverted); b) catalase (pH 8, inverted); c) fibrinogen (inverted); d) aldolase from rabbit muscle; e) horse heart cytochrome C; numerical values: wavelengths λ in [nm].

Derivative spectrophotometry, particularly of the higher orders, is however very well suited for the provision of "fingerprints" for characterization, purity testing, and identification of proteins with the aid of a spectral catalog. The following small selection of third-derivative spectra may serve as examples: γ-globulin (Fig. 18a), catalase (Fig. 18b), fibrinogen (Fig. 18c), aldolase (Fig. 18d), and cytochrome C (Fig. 18e).

We have also used HODS successfully in the study of protein denaturation (Fig. 19a) and for investigating modified proteins. For example, the acetylation of trypsin can be followed and albumins can be characterized (Fig. 19b). The influence of the solvent on proteins and their structure can also be studied in this way.

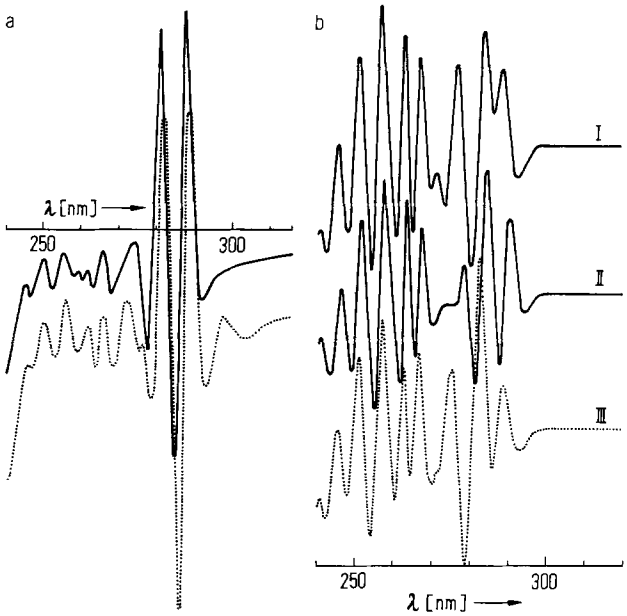

Fig. 19. a) Denaturation of bovine trypsin (concn. 500 mg/l), 3rd derivative; native enzyme (– – –), enzyme denatured in 6 M urea solution (——); LTH 1 cm, slit 1 nm, scan rate 2 nm/s; b) spectra of several albumins (concn. 500 mg/l), 3rd derivative; LTH 1 cm, slit 1 nm, scan rate 2 nm/s; I: bovine albumin, II: hen albumin; III: methylated hen albumin.

5.8. Turbid Solutions, Suspensions, and Emulsions

Turbid solutions and suspended or emulsified solid or liquid materials make spectrophotometric investigations very much more difficult. Because of the scattering that occurs in the UV region in particular, the spectrum of the substance of interest is superimposed on a more or less intense background and, in addition, loses much of its intensity. For example, *Butler* and *Hopkins*[77–79] recommend single-beam instruments for investigating pigments in yeast cells and chloroplasts because of the greater light yield; they eliminate the background by a function simulator[79] or calculate the second and fourth derivatives of the spectrum by an off-line method employing a memory[77, 78].

In our investigations we used a double-beam instrument, the sample and comparison positions of which were immediately in front of the multiplier, whereby it was possible to increase the energy yield considerably for strongly scattering substances.

Depending on the difficulty of the problem we used the third, fourth, or fifth derivative. We studied several types of milk, cream, whey, sour milk, yoghurt and edible curds, and also turbid fruit juices, polysulfides, and kieselgur and bentonite slurries.

5.9. Solids

Higher-order derivative spectrophotometry finds a very interesting and effective application in investigations of highly viscous liquids, gels, and solids.

In the case of solids, for qualitative studies it is sufficient to place the finely powdered sample between two Suprasil plates, in one of which a depression 0.2 mm deep has been cut. It is also advantageous here to use apparatus in which the second sample chamber is immediately in front of the multiplier. A thin layer of paste or highly viscous liquid can be placed directly on a small glass or quartz plate. The same procedure can be used for foils and gels, in which *e.g.* insoluble materials may also be embedded.

Another application is the investigation of paper chromatograms and thin-layer chromatograms. An absorbing position on the foil is found and the derivative spectrum at that point is measured. The unknown compound can then be identified by means of the "fingerprint" and a spectral catalog. Moreover, substances can be enriched by adsorption on a suitable column packing and the solid can then be analyzed as described above.

We have also, as in IR spectroscopy, prepared KBr disks of constant weight (300.0 mg) and compressed them under a constant pressure to ensure constant thickness. The results available so far indicate that the problem of quantification can probably be solved. By standardizing the tableting conditions and averaging several measurements at different tablet positions, we have attempted, for example, to determine the protein content of protein-containing samples directly, without the need for hydrolysis or a determination of the total nitrogen. Figure 20a shows the fundamental spectra of bovine trypsin

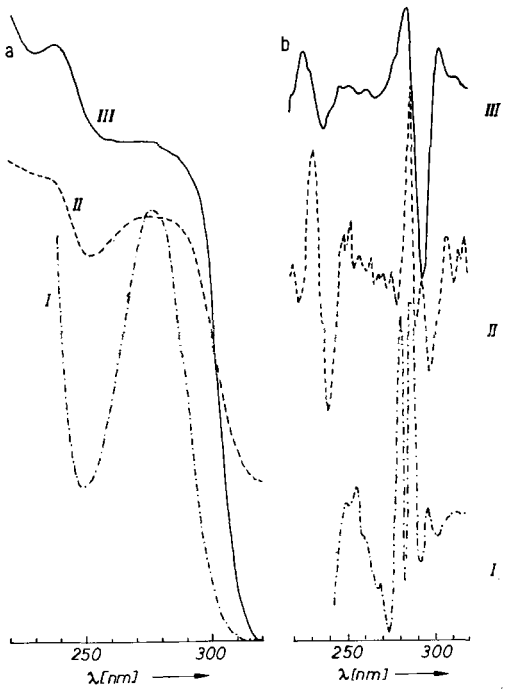

Fig. 20. a) Fundamental spectra of bovine trypsin. I: aqueous solution (concn. 500 mg/l); LTH 1 cm; II: powder, LTH 0.2 mm; III: KBr disk (3 mg of protein in 300 mg of KBr), LTH 0.9 mm; b) 4th derivative of spectra I to III from Fig. 20a. Slit 1 nm, scan rate 2 nm/s.

in aqueous solution, in powder form, and in a KBr disk, all these giving little information; the fourth derivative of the spectra shows the highly differentiated characteristic fingerprints of trypsin (Fig. 20b). We have studied water-insoluble carrier-bound enzymes in the same way.

5.10. Gases and Vapors

Mention should also be made of the application of HODS to the analysis of gases and vapors. For this purpose, for example, a drop of a highly volatile liquid is placed in a tightly closed cell with a ground-in stopper, and is kept in a thermostat at temperatures above *ca.* 20°C; alternatively, the gaseous substances are drawn into the evacuated cell. For continuous investigations the gas or vapor mixture is pumped continuously through a flow-through cell by a peristaltic pump.

Finally, vapors can also be bound to foils coated with an adsorption agent and then be treated as described in Section 5.9.

5.11. Other Fields of Application

We have also applied HODS to the characterization of copolymers and, especially, to the investigation of azopolycarbonates[92]. Preliminary experiments have been encouraging.

Of biopolymers we have studied ribonucleic acids, in addition to the proteins mentioned in Section 5.7.

From the field of clinical chemistry we should mention studies of serum and urine (total porphyrin, proteins, determination of metabolites and traces of drugs).

Since HODS can drastically enhance the sensitivity of many methods of determination, we have been able to use the analog computer with advantage for studying kinetic processes, in particular the kinetics of enzyme reactions and of the thermal decomposition of azo compounds[92].

Finally, mention should also be made of the use of higher-order derivative spectrophotometry for the characterization of column eluates.

For differentiating the elution diagrams themselves we are currently developing an analog differentiator with particularly large differentiation time constants, and this should be useful for processes that occur very slowly.

6. Summary and Prospects

The above examples represent only a small selection from the many diverse possibilities of applying HODS to practical problems. This improved analog on-line analytical technique provides UV/VIS spectrophotometry with a new dimension as regards its ability to provide information, and by relatively simple means it opens new fields of application.

Particular advantages are offered by higher-order derivative spectrophotometry in the following cases: trace analyses, purity testing, quality control, separation of superposed spectra (multicomponent analysis), elimination of background absorption, investigations of turbid solutions and suspensions and of solids, and characterization of individual substances and mixtures.

In addition, derivative spectrophotometry can offer valuable help *e. g.* in the study of reaction kinetics, study of adsorption on surfaces of catalysts or macromolecules, and in the examination of the effects of solvents and chemical surroundings on chromophore groups.

The order of the derivative will vary from [illegible] to case. Optimum conditions are generally reached when all the

shoulders and inflections of a unipolar fundamental spectrum are converted into bipolar maxima and minima. It is then also possible to filter out interfering signals of higher frequency (noise) most successfully, this leading to very good reproducibility and narrow limits of error in spite of high spectral resolution. This is generally achieved with the third, fourth, or fifth derivative. Derivative spectra of still higher order—we have recently checked this up to the ninth order—provide further information only in exceptional cases, since with increasing order the number of extrema and thus the complexity of the spectra increase (which can often be of advantage for fingerprints).

The vigorous development of higher-order derivative spectrophotometry will presumably continue for some time and will lead to new instruments using both the simpler route of on-line analog working and the more expensive method of digital calculations *via* intermediate storage with all their advantages and disadvantages. It is certain that this method, which is so productive of results, will not remain restricted to a few research laboratories but will be increasingly introduced into industrial and teaching laboratories and clinics. From the advantages of higher-order derivative spectrophotometry an expanded range of application can be expected for the otherwise relatively uninformative UV/VIS spectrophotometry, and it will certainly contribute to the solution of many problems that have previously been difficult to deal with.

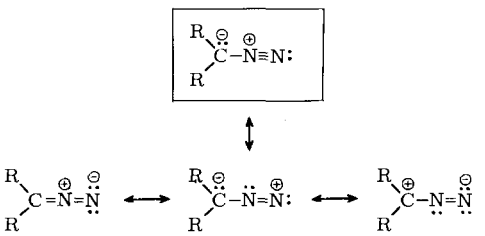
Organometallic Syntheses with Diazoalkanes



By Wolfgang A. Herrmann[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

In recent years, aliphatic diazo compounds have proved to be more and more versatile as reagents in the preparative chemistry of organometallic complexes. As readily accessible compounds, they are not only suitable for the synthesis of known kinds of metal complexes but also open fresh routes to novel complex systems. The comparatively new field of diazoalkane complex chemistry exhibits numerous unexpected and novel reactions, and introduces interesting and promising aspects into the chemistry of carbonylmetal compounds.

1. Introduction

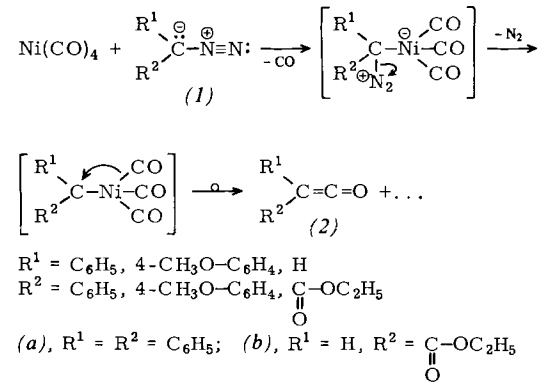
The discovery of diazoalkanes by *Curtius* and *von Pechmann* is one of the pioneering deeds of organic chemistry. Research performed in the past hundred years led not only to the development of powerful new synthetic methods but also prepared the way for mechanistic studies with the aid of carbene chemistry. Thanks to the classical work of *Meerwein*, *Hine*, *Skell*, and *Doering*, aliphatic diazo compounds were to assume a key role. Progress reports by *Huisgen*[1], *Weygand* and *Bestmann*[2], and *Eistert* and *Regitz*[3, 4] paint an impressive picture

of the preparative versatility of diazoalkane chemistry, while *Kirmse* is concerned primarily with mechanistic aspects of the preparation of carbenes from diazo precursors[5]. A recent monograph describes the properties and syntheses of several hundred diazoalkanes[6].

In organometallic complex chemistry, simple aliphatic diazo compounds have been employed with varying degrees of success, especially for the transformation of metal hydrides into the corresponding alkylmetal compounds. On the basis of these isolated cases it was concluded that diazo compounds are unsuitable for organometallic syntheses owing to their susceptibility to catalytic decomposition. Hence attempts to stabilize carbenes by metals ceased all too prematurely. However, there is hardly a better approach to that goal than by catalytic, photochemical, or thermal decomposition of diazoalkanes. Production of transition metal-dinitrogen complexes should also be possible with diazo reagents.

Surveys by *Fischer*[7], *Lappert*[8], and *Cotton*[9] reveal the great importance of transition metal—carbene complexes in organometallic chemistry. Progress reports by *Sellmann*[10] and *Chatt*[11] show that transition metal—dinitrogen complexes constitute a highly topical research field in connection with nitrogen fixation. The synthesis of members of these two classes of compounds was the initial aim of our studies. However, we soon recognized that diazoalkanes readily form many other complex compounds, some containing nitrogen and others containing none. Meanwhile, the synthetic potential of aliphatic diazo compounds has been utilized for producing a variety of ligand systems on transition metal substrates.

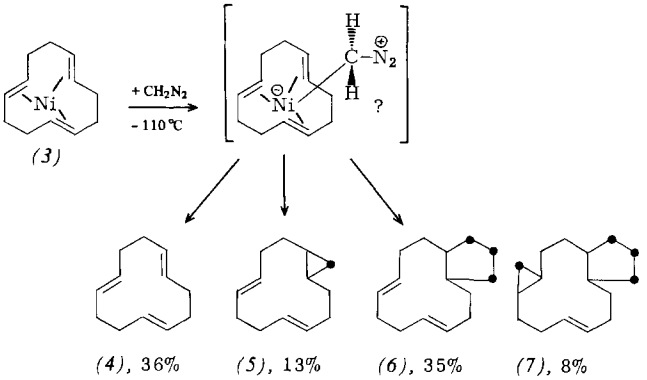
2. Transition Metal—Carbene Complexes from Diazoalkanes



2.1. Historical Background

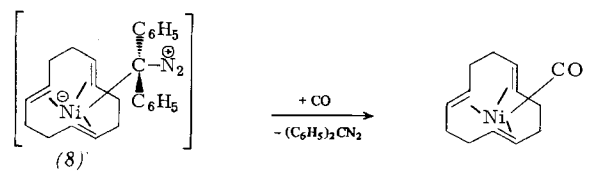
The catalytic action of numerous transition metal substrates on the decomposition of almost all aliphatic diazo compounds has been known since the early days of diazoalkane chemistry. Thus the addition of copper powder or of silver compounds, such as Ag_2O or $[Ag\{N(CH_3)_3\}_2]^+OCOC_6H_5^-$, is still used in the Wolff rearrangement[1, 3, 12]. At a very early stage, carbene complexes were assigned a crucial role in metal-induced diazoalkane reactions[13]. Although many years were to pass before the synthesis and isolation of stable transition metal—carbene complexes from aliphatic diazo compounds was demonstrated[14], there was no lack of experimental results to sustain the hypothesis of unstable diazoalkane—metal or carbene—metal intermediates.

Turning their attention to the question of carbonylation of carbenes, originally raised by *Staudinger*[15], *Rüchardt* and *Schrauzer* were the first to prove the general ability of carbenes to form complexes[16]. These authors examined the action of tetracarbonylnickel on diphenyldiazomethane *(1a)* and some of its homologs and on ethyl diazoacetate *(1b)*; they found that excess $Ni(CO)_4$ in ethanol transforms *(1a)* into diphenylketene *(2a)* in 73% yield. The initial step of the reaction possibly involves a nucleophilic attack on $Ni(CO)_4$ by the diazoalkanes *(1) via* their basic C atom, leading to carbonyl substitution. Subsequent exothermic elimination of nitrogen, which now has the character of an aliphatic diazonium group, apparently yields a highly unstable carbene complex, which decomposes to a ketene *(2)* and a metal carbonyl fragment. Similar reaction steps are also assumed to occur in the carbonylation of olefins and acetylenes.



Although stable nickel—carbene complexes could not be synthesized in this way, *Rüchardt* and *Schrauzer* had already

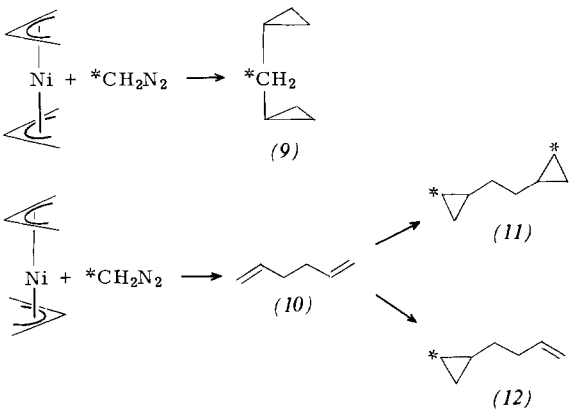
[*] Priv.-Doz. Dr. W. A. Herrmann
Chemisches Institut der Universität
Universitätsstrasse 31, D-8400 Regensburg 1 (Germany)



mentioned that dπ(metal)—pπ(carbene) interactions might have an important function in the stabilization of carbenes[16]. Predictions of bond stabilization in complexes with conjugated carbenes by mesomeric delocalization of the positive charge on the carbene were also confirmed by subsequent organometallic studies. In spite of further evidence[17], carbene carbonylation long remained unconfirmed until the recent successful high-pressure carbonylation of diphenylcarbene—manganese complexes to give diphenylketene derivatives (see Section 2.3)[18]. Carbene carbonylation with subsequent hydrogenolytic degradation of the ketene complexes is a model system for the formation of oxo products in the Fischer-Tropsch synthesis[18a].

Investigations by *Wilke* and his research team showed that all-*trans*-1,5,9-cyclododecatrienenickel, (*t,t,t*-CDT)Ni *(3)*, reacts with excess diazomethane even at −110 °C with vigorous evolution of gas and deposition of nickel[19]. Apart from the free ligand cyclododecatriene *(4)*, new bi- and tricyclic systems could be isolated and quantitatively determined: bicyclo[10.1.0]trideca-4,8-diene *(5)*, bicyclo[10.3.0]pentadeca-4,8-diene *(6)*, and tricyclo[11.3.0.0^{4,6}]hexadec-9-ene *(7)*.

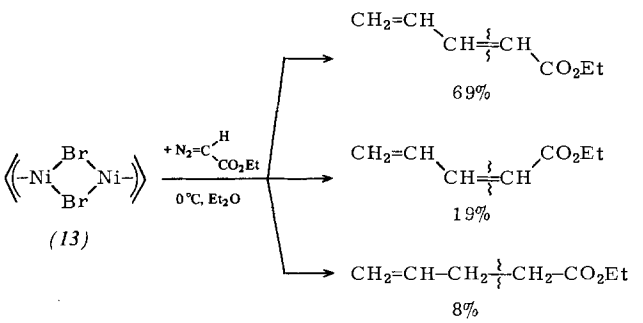
(4), 36% *(5)*, 13% *(6)*, 35% *(7)*, 8%



Formation of multiply methylenated reaction products has not otherwise been observed in diazomethane chemistry. The idea that the reaction is initiated by nucleophilic attack by diazomethane on the free coordination site of the metal center is supported both by the failure of methylenation to occur on use of the coordinatively saturated carbonyl derivative (*t,t,t*-CDT)Ni(CO) and by the formation of a 1:1 adduct *(8)* of (*t,t,t*-CDT)Ni *(3)* and diphenyldiazomethane, which is stable below −30 °C[19-21].

(8)

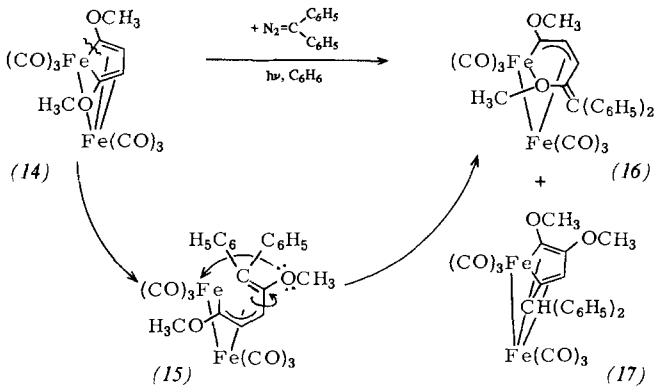
Further studies of the diazomethane reactions of *t,t,c*-, *t,c,c*-, and *c,c,c*-1,5,9-cyclododecatrienenickel led to similar results. The yields of methylene addition products and the yield of the product with annelated five-membered ring decrease sharply along the series given. In the case of the *t,t,c*- and *t,c,c*-isomers, methylene adds stereospecifically to a *trans* double bond[20,21].



Bis(η^3-allyl)nickel displays a pronounced conformational control of reactivity towards diazomethane[22-24]. The *cis* isomer forms exclusively dicyclopropylmethane *(9)*; under the same conditions (−78 °C) the *trans* isomer gives a mixture of 1,5-hexadiene *(10)*, 1,2-dicyclopropylethane *(11)*, and 4-cyclopropyl-1-butene *(12)*. Reaction with [D$_2$]diazomethane furnished proof that the two allyl ligands first undergo linear dimerization—probably in the coordination sphere of the metal—and are then "cyclopropanated". Deuterium-labeling

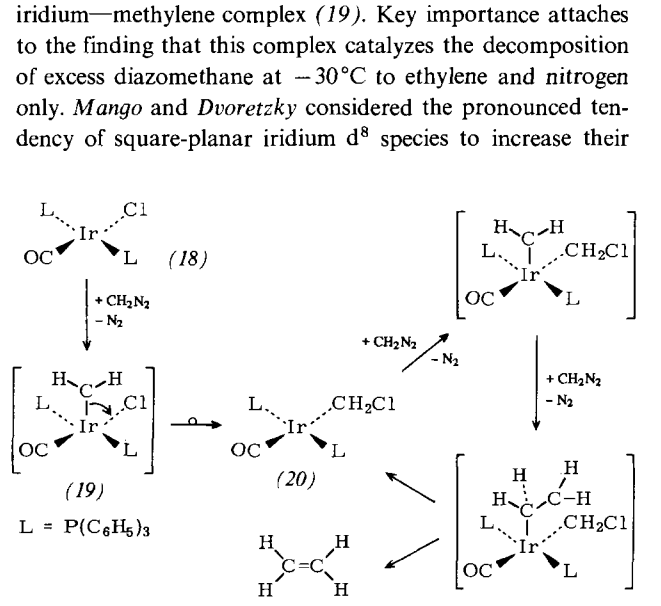
(9) *(10)* *(11)* *(12)*

experiments also showed that the product ratio (GC-MS) *(9)*:Σ*(10)* + *(11)* + *(12)* is in exact agreement with the *cis/trans* ratio of the substrate (η^3-C$_3$H$_5$)$_2$Ni as determined by ^{1}H-NMR spectroscopy in the temperature range examined (−30 to −78 °C). Although this represented the first chemical proof of the existence of *cis/trans* isomers of bis(η^3-allyl)nickel, it provided little information about the nature of the intermediates involved in this interesting sequence of reactions. Primary adducts of diazomethane and unstable carbene complexes will certainly play a role.



Butadiene derivatives are formed on reaction of bis(η^3-allyl-μ-bromo)nickel *(13)* with ethyl diazoacetate[25]. Even at 0 °C, the reaction is so fast that evolution of gas is complete within

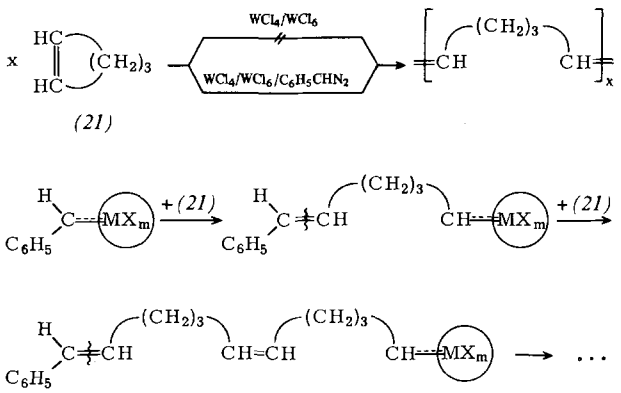
(13)



seconds. A carbenoid 1:1 complex is again proposed as key intermediate: it is assumed to transform into a σ-allyl complex "L$_x$Ni—CH(CO$_2$Et)C$_3$H$_5$" which then undergoes β-elimination.

Carbene insertion into the Fe—C bond has been accomplished with the carbonyliron complex *(14)* without spontaneous decomposition of the primary adduct[26]. The structure (X-ray) of the resulting product *(16)* is compatible with (Fe—C)carbene insertion followed by rotation of the open-chain allyl-ene system *(15)* about the C—C single bond. Formation of the complex *(17)* is less readily understandable.

Among the ferrocene-type sandwich complexes, nickelocene has the greatest catalytic effect on the polymerization of diazomethane and ethyl diazoacetate[27]. Low-molecular products (oligomers, insertion products) are not formed, in contrast to the reactions considered so far. A nickel—methylene complex $(C_5H_5)_2NiCH_2$ is postulated[27] in connection with the formation of polymethylene from diazomethane, a fast reaction even at −78 °C. The rate of polymerization is much higher than with conventional catalysts such as powdered copper or iron-chelate complexes.



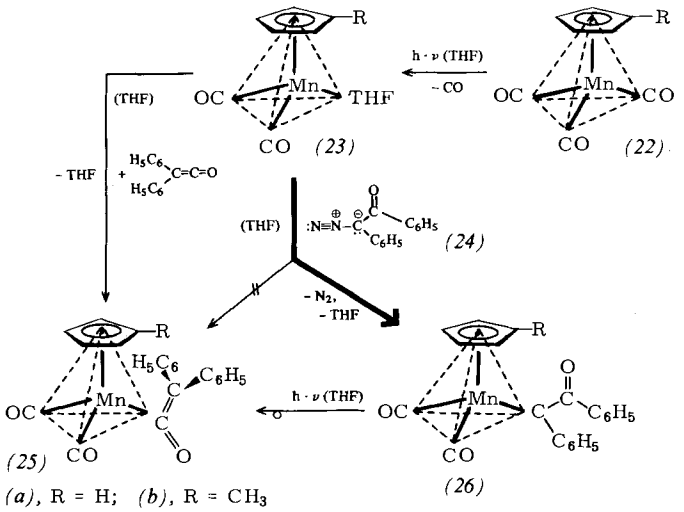
An almost quantitative precipitate of polymethylene is rapidly obtained on treating solutions of diazomethane in benzene or chloroform with catalytic amounts of the Vaska compound *(18)* at room temperature[28]. However, treatment of a diethyl ether suspension of complex *(18)* with diazomethane at −30 °C gives a crystalline air-stable product containing no polymethylene. The compound, which is unstable in solution, proves to be the square-planar carbene insertion product *(20)*; it might be formed *via* the hypothetical five-coordinate iridium—methylene complex *(19)*. Key importance attaches to the finding that this complex catalyzes the decomposition of excess diazomethane at −30 °C to ethylene and nitrogen only. *Mango* and *Dvoretzky* considered the pronounced tendency of square-planar iridium d^8 species to increase their coordination number from four to five without any formal change in oxidation state to justify their proposed mechanism for ethylene formation shown here in simplified terms.

Deuterium-labeling experiments convincingly demonstrate that the initially formed Ir—CH_2Cl group in *(20)* does not participate in methylene dimerization[28]. In this context, the work of *Meerwein* and *Rathjen* should be called to mind: they too could detect only ethylene on $TiCl_4$-catalyzed decomposition of diazomethane[29].

Diazoalkanes were also instrumental in the recent demonstration that olefin metathesis proceeds not by *Calderon*'s four-center mechanism but instead *via* carbene complexes. *Dolgoplosk et al.* attributed an initiator role to several aliphatic diazo compounds in the special case of ring-opening cycloalkene polymerization[30–35]: thus just a few drops of a 0.02 M toluene solution of phenyldiazomethane suffice to polymerize cyclopentene *(21)* or 1,5-cyclooctadiene with WCl_6 (molar ratio 1000:1 or 500:1, respectively) within a few minutes to polyalkenamers of extremely high molecular weight[31,32].

Similar observations have been reported[31] for the heterogeneous system with WCl_4 as catalyst. The failure of ring-opening and polymerization to occur in the absence of phenyldiazomethane demonstrates that the actual catalytic species is a tungsten—phenylcarbene complex formed by decomposition of phenyldiazomethane in the coordination sphere of the metal which initiates reaction with the (π-coordinated) cycloolefin.

The carbene intermediate in polymerization reactions of this kind has not been rigorously established; however, it appears highly likely in view of the results obtained with olefin metathesis in the stricter sense[36–38] and especially the mechanistic studies performed by *Katz et al.*[39].



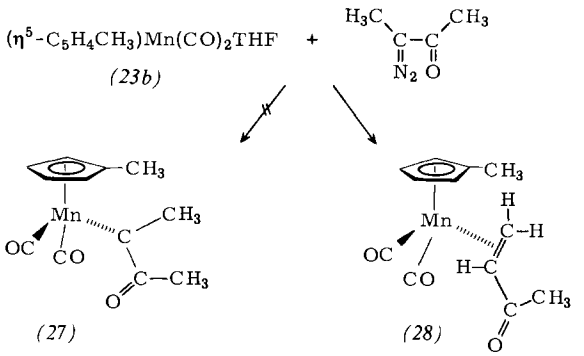
2.2. Statement of Problem

Although the cases cited and other work surveyed in 1973 by *Lappert*[40] suggest that diazo compounds are basically suitable as precursors of transition metal—carbene complexes, the instability of the postulated intermediates long stood in the way of more thorough and synthetically oriented studies. Moreover, it was formerly held, quite justifiably at that time, that only heteratom-stabilized carbene complexes are sufficiently stable to be unequivocally characterized and handled on a preparative scale. Precisely the alkoxy- or bis(alkoxy)diazomethanes required for their synthesis number among the least stable diazoalkanes and cannot be isolated pure.

2.3. Preparative Work

The methodological feature of the synthesis of transition metal—carbene complexes from diazoalkanes is the exchange of a readily replaceable two-electron ligand of the organometallic starting compound for the CRR′ unit of the diazo precursor. The reaction conditions should be as mild as possible to avoid uncontrolled decomposition of the diazoalkane.

The action of, *e. g.* benzoyl(phenyl)diazomethane (azibenzil) *(24)* on the manganese-THF complexes *(23a)* and *(23b)* at room temperature yields the hitherto inaccessible air-stable benzoyl(phenyl)carbene complexes *(26a)* and *(26b)*[14,41].



(a), R = H; *(b)*, R = CH_3

The formation of these two carbene complexes is all the more surprising in view of the fact that Wolff rearrangement of aliphatic diazoketones is usually so fast that the keto carbenes formed as reactive primary fragments[*] can be trapped only under special conditions[4,12,42]. While carbenes generated, *e. g.* photolytically by nitrogen elimination from *ortho*-quinone diazides, can be saved from intramolecular rearrangement by 1,3-dipolar cycloadditions[43], direct trapping of benzoyl(phenyl)carbene has so far proved impossible.

Remarkably, the reaction of azibenzil *(24)* with the manganese-THF complexes *(23)* does not afford coordination compounds *(25)* of diphenylketene. This means that the Wolff rearrangement of the diazoketone is quantitatively stopped after the rate-determining step of nitrogen elimination. The keto carbene, which is, so to speak, conserved in the transition metal complex *(26)*, can nevertheless be induced to undergo intramolecular rearrangement: UV irradiation gives the π-diphenylketene complexes *(25)*[41,44]; X-ray structure analyses are also available for *(25a)* and *(26a)*[45,46].

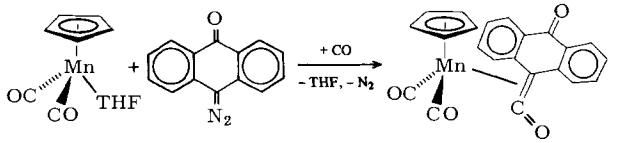
In similar manner, the diarylcarbene complexes of type *(26)*, with R = H, CH_3, and C(*p*-$R^1C_6H_4$)(*p*-$R^2C_6H_4$) in place of the keto carbene (R^1, R^2 = H, CH_3, Cl, NO_2, OCH_3) are formed from diphenyldiazomethane and its derivatives in yields of up to 82 %[41]; ethyl (4-nitrophenyl)diazoacetate gives the corresponding ester—carbene complexes[47].

Complications occur when secondary reactions of the carbene receive catalytic support. Thus intermolecular ketazine formation from diaryldiazomethane derivatives can never be completely suppressed, while intramolecular rearrangements come to the fore with alkyl-substituted α-diazo ketones. For example, the expected acetyl(methyl)carbene complex *(27)* is absent from the reaction products of 3-diazo-2-butanone with complex *(23b)*; instead, the isomeric 3-buten-2-one derivative *(28)* is formed, at least formally, by an H shift within the carbene fragment[41].

The realistic nature of the proposed reaction route is supported by independent work by *Fischer* and *Held*, who likewise obtained only the corresponding π-olefin complexes on attempted synthesis of [alkyl(phenyl)carbene]pentacarbonyltungsten complexes[48]. We cite these examples because the linkage of carbene and olefin complexes is of cardinal importance in current research on olefin metathesis.

Transfer of the diazo nitrogen from diazoalkanes to metal centers has also been accomplished in some cases: reactions of 1,1,1-trifluorodiazoethane and *(23)* give the dinuclear dinitrogen complexes μ-$N_2[(\eta^5\text{-}RC_5H_4)Mn(CO)_2]_2$ of known structure (X-ray); its formation cannot involve free nitrogen liberated catalytically or thermally from the diazoalkane[49]. Initial end-on coordination of the diazoalkane $[RR'C{=}N{=}N \rightarrow ML_x]$ is assumed to be followed by elimination of the carbene which undergoes ready intramolecular stabilization. Ethyl diazoacetate reacts with $[Ru(NH_3)_5H_2O]^{2+}$ in a neutral aqueous medium to give a mixture of $[Ru(NH_3)_5N_2]^{2+}$ and $[(NH_3)_5Ru{-}N{\equiv}N{-}Ru(NH_3)_5]^{4+}$[50].

2.4. Classification of the Diazo Method



Great activity in the field of transition metal—carbene complexes has led to the development of numerous preparative methods based essentially upon four synthetic principles (cf. [7-9,51]): 1) Formation of the carbene ligand at the metal substrate by refunctionalization of an existing metal—carbon bond; 2) exchange of substituents on the (metal—)carbene system; 3) carbene transfer $L_xM{-}CRR' \rightarrow L_yM'{-}CRR'$; 4) introduction of a carbene ligand *via* suitable carbene precursors into a metal substrate.

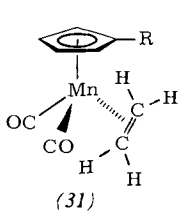
The diazo method considered here belongs to the last-named group. The method exploits the *a priori* most accessible possibility of synthesizing transition metal—carbene complexes; the intact carbene ligand is transferred from an aliphatic diazo compound onto complex substrate. Closely related syntheses of transition metal—methylene complexes are known (cf. Section 4).

[*] Concerning the role of the oxirene intermediate present in equilibrium with the ketocarbene in the photochemical Wolff rearrangement, see [12].

3. Transition Metal—Ketene Complexes from Diazoalkanes

In some cases, metal-induced diazoalkane fragmentation proceeds beyond complexation of the carbenes to η^2-ketene complexes; the product yields increase drastically on working in a CO atmosphere[52]. The reaction of 10-diazoanthrone *(29)* may be cited as an example. Although complete elucida-

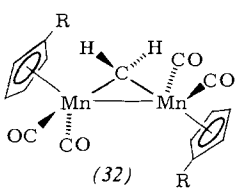
(23a) *(29)* *(30)*



tion of the reaction course must wait for ^{13}CO-labeling studies, it is nevertheless very probable that the η^2-ketene complexes *(30)* are formed by carbonylation of the initially formed metal carbenes with external carbon monoxide. This possibility of reaction points to a new entry to the class of η^2-ketene complexes[51], of which only scattered examples were previously known, especially in those cases where the instability of the free ketenes precludes direct synthesis.

4. Syntheses of Transition Metal—Methylene Complexes

Hundreds of stable transition metal—carbene complexes have been prepared since the discovery of the first representative by *Fischer* and *Maasböl* in 1964. Surprisingly then, there is a comparative lack of knowledge about carbene systems whose central carbon bonds not to just one metal atom but bridge *two* metal-complex fragments. Apart from a few exceptions, compounds of the type μ-$CRR'[ML_x]_2$ have only been isolated in yields below 5% as products of rather unclear reactions[51]. Aliphatic diazo compounds now provide a pathway to numerous highly stable μ-methylene complexes[*] belonging to the carbonyl—manganese, —iron, —cobalt, —rhodium, and —osmium series, which also include the first examples of bridged CH_2 complexes[53,58].



4.1. Incorporation of Methylene into Manganese Complexes

Depending upon the molar ratio of reactants, the reactions of diazomethane with manganese—THF complexes *(23)* give a mixture of the olefin complexes *(31)* and the μ-methylene complexes *(32)*[53]. The *trans* configuration[54,125] deduced

(31)

(a), R = H; *(b)*, R = CH_3

(32)

$(\eta^5\text{-}RC_5H_4)Mn(CO)_2CH_2$

(33)

for the latter from spectroscopic results was confirmed by X-ray structure analyses. Although the π-ethylene complexes are more readily accessible photochemically directly from the tricarbonylmanganese complexes *(22)*, their formation should be noted in this context inasmuch as the thermal decomposition of diazomethane does not[4] lead to ethylene, and the transition metal-catalyzed decomposition of diazomethane does so but rarely[28,29].

Surprisingly, the mononuclear carbene complexes *(33)* expected from the results obtained with diphenyldiazomethane and its *p*-substituted derivatives are not formed. Product analysis supports the proposed intermediacy of the methylene—manganese complex *(33a)*. If it fails to react with another species, then it decomposes on heating to room temperature. However, if an excess of diazomethane is present then it preferentially forms the monomeric ethylene derivative *(31a)*, whereas the carbene species *(33a)* reacts in the presence of the reactive complex substrate *(23a)* to form the μ-methylene complex *(32a)*.

The structural parameters of the prototype compound *(32b)* (Fig. 1) synthesized by the diazo method are characteristic of all transition metal—methylene complexes: the cyclopropane-like Mn—CH_2—Mn skeleton has an angle of 86.9° at the CH_2 bridge[125]; the range between 75 and 90°[63] is typical for analogous compounds. Strikingly, M—CH_2—M and M—CO—M groups always occur together with additional metal—metal bonds. *Hofmann* was able to demonstrate by theoretical calculations (EH procedure) for the first time that μ-methylene complexes are to be regarded electronically as dimetallacyclopropanes and exhibit considerably greater negative charge at the quasi-saturated bridging carbon atom than carbene complexes. The (distorted) tetrahedral configuration of the methylene bridges is in accord with the results of MO calculations[126].

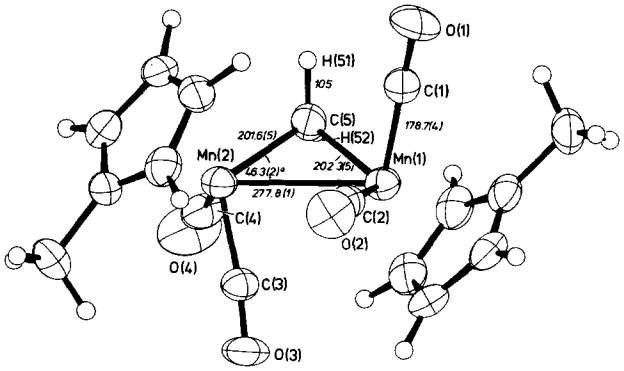


Fig. 1. ORTEP representation of μ-methylene-bis[dicarbonyl(η^5-methylcyclopentadienyl)manganese] *(Mn—Mn) (32b)*. Apart from the hydrogen atoms, the thermal ellipsoids correspond to 50% probability. $R(F)=4.86\%$, $R_w(F)=4.86\%$. Bond lengths in pm.

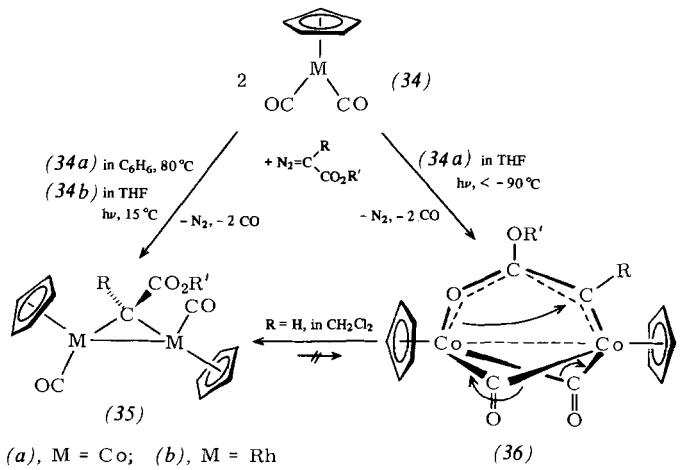
4.2. μ-Methylene—Cobalt and —Rhodium Complexes



Dicarbonyl(η^5-cyclopentadienyl)cobalt *(34a)* and the homologous rhodium compound are further complex components for the preparation of carbene derivatives. Fast exchange of one of the two carbonyl groups for analogous ligands has been established[5] for both compounds by CO

[*] Concerning the problem of carbene/methylene nomenclature, cf. [51].

exchange experiments and by the kinetic data of carbonyl substitution of phosphanes—this is an important prerequisite for the introduction of CRR′ ligands into carbonylmetal compounds by the diazo method.

4.2.1. Complexes of Type *(35)*, M = Co, Rh

As expected, the cobalt complex *(34a)* reacts smoothly with diazoacetic ester and diazomalonic ester reagents in boiling benzene to give the dinuclear complexes *(35a)* with bridging carbene ligands[56]. The rhodium complex *(34b)* can be transformed photochemically into the corresponding derivatives *(35b)*[57]. X-Ray structure analyses on *(35b)* with a methylene and on *(35a)* with a 1,3-dioxoindan-2-ylidene bridge (in place of R—C—CO_2R') show the carbene C atoms to have a strongly distorted tetrahedral configuration[57a, 58, 59].

(a), M = Co; *(b)*, M = Rh

(36) → *(35a)*, R = H, R′ = C_2H_5: $k = (3.80 \pm 0.03) \cdot 10^{-4}\ s^{-1}$ (17.3 ± 2 °C)
$\Delta G^{\neq} = 21.5 \pm 0.5$ kcal K^{-1} mol^{-1}

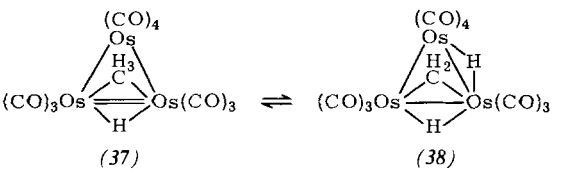
(36) → *(35a)*, R = H, R′ = $C(CH_3)_3$: $k = (5.19 \pm 0.23) \cdot 10^{-4}\ s^{-1}$ (29.3 ± 2 °C)
$\Delta G^{\neq} = 22.3 \pm 0.6$ kcal K^{-1} mol^{-1}

The primary reaction step must be either a) dissociation of *(34)* to give the highly reactive fragments (η^5-C_5H_5)M(CO), whose existence is regarded as definite at least under photolysis conditions in the absence of other reactants[60, 61], or b) a direct nucleophilic attack of the diazo compound on the coordinatively unsaturated complex *(34)*. In neither case is it known at what stage the diazo nitrogen is released.

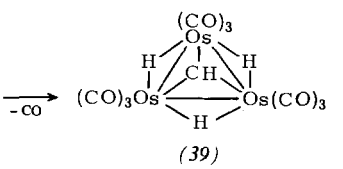
In addition to its synthetic exploitation, this class of compounds has already been the subject of thorough spectroscopic studies. In a detailed mass-spectrometric analysis *Mayer* was able to demonstrate the occurrence of interesting carbene reactions which are unknown for mononuclear carbene complexes[62]. CO exchange phenomena in μ-CH_2[(η^5-C_5H_5)Rh(CO)]$_2$ are presently being studied with the aid of ^{13}C-NMR spectroscopy by *Cotton et al.*, whereas *Bau et al.* are presently performing a neutron diffraction study on the same compound.

The μ-methylene complexes now available in large numbers by the diazo method can be distinguished by their ^{13}C- and ^{1}H-NMR parameters from related complexes L_xM—CH_3 and L_xM—$(CH_2)_n$—ML_x ($n \geq 3$) and from the carbene complexes L_xM—CH_2 (also with R in place of H), as is apparent from a comparison of the typical resonance regions for the methylene and methyl ligands[53, 56–58, 131]:

	$\delta(^{13}C)$	$\tau(^1H)$
L_xM—CH_3	−30... 5	9...11
L_xM—$(CH_2)_n$—ML_x	0... 10	8... 9
μ-$CH_2[ML_x]_2$ (*M*—*M*)	100...190	4... −0.5
L_xM—CH_2	240...370	1... −1



4.2.2. Complexes of Type *(36)*

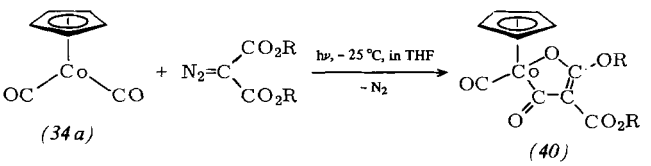


Low-temperature photolysis of diazoacetic ester compounds with the cobalt complex *(34a)* gives both the μ-methylene complexes *(35a)* already described and the isomers *(36)*.

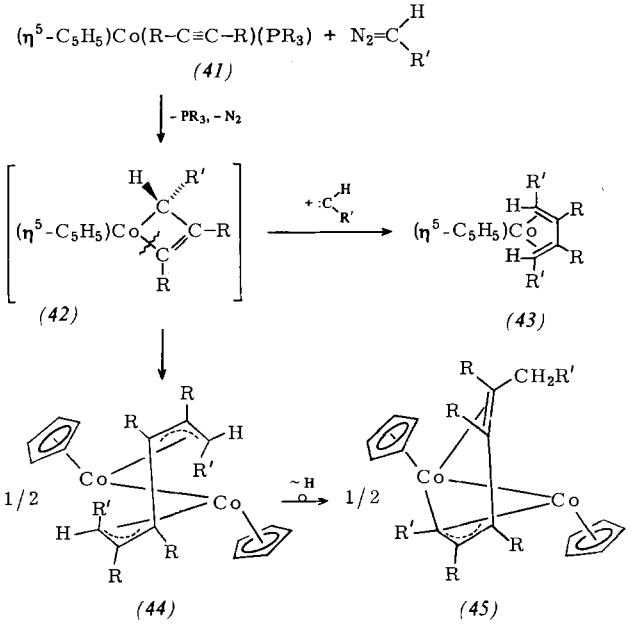
The low-temperature products *(36)* possess two carbonyl bridging ligands as well as a μ-alkoxycarbonylcarbene group, which is attached to both metal centers *via* the carbene carbon *and* the carbonyl function. Most probably, the heat-sensitive products *(36)* are intermediates in the synthesis of complexes *(35a)*, to which they undergo quantitative and irreversible rearrangement with restructuring of the μ-carbene ligand and simultaneous rupture of the carbonyl groups[63]. IR and ^{1}H-NMR kinetic studies show this hitherto unknown type of isomerization to be a first-order reaction. Ligand exchange reactions prove the intramolecular nature of these scrambling processes[63].

4.3. A μ-Methylene—Osmium Cluster

Applying the diazo method to the trinuclear carbonylosmium hydride $H_2Os_3(CO)_{10}$, *Shapley et al.* were recently able to synthesize the cluster molecules *(37)*—*(39)*, of which the μ-methyl derivative *(37)* and the μ-methylene complex *(38)* are in mutual equilibrium. The μ_3-methylidine cluster *(39)*



is formed irreversibly from a mixture of *(37)* and *(38)* in xylene at a temperature of 110 °C[127]. The tautomerism of type M(CH_3) ⇄ HM(CH_2) first detected in this case is of importance in mechanistic interpretation of the reactions of hydrocarbons on metal surfaces and associated chemisorption problems[128].

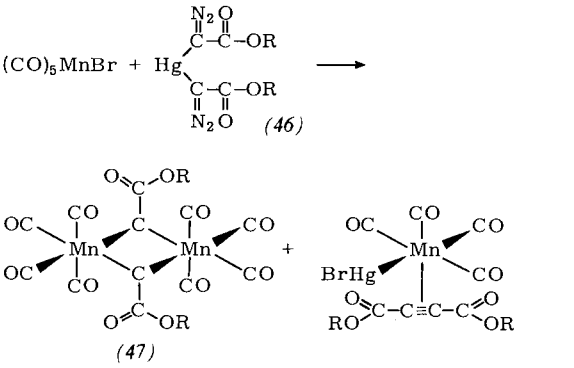


5. Addition of Carbenes to Organometallic Compounds

The bis(alkoxycarbonyl)carbenes formally derived from diazomalonic ester substrates can be added photochemically

to the organometallic component *(34a)* without fragmentation of the latter to give the metallacycle *(40)*: the coordination number of the metal center increases, by coordination of a carbonyl oxygen atom of the carbene unit to the metal and transformation of a M—CO group into a M—acyl function, until it is ultimately in the preferred tetrahedral environment[64,65]. These novel [2+3]-carbene additions should become important in the construction of further five-membered metallacycles.

Reactions of diazoacetic ester derivatives with the acetylene—cobalt complex *(41)* probably proceed both *via* the carbene and *via* metallacyclic intermediates. Formation of the stable end products *(43)*—*(45)* is interpreted in terms of carbene insertions or dimerizing ring opening *via* the common intermediate *(42)*, a 1,6 hydrogen shift of unknown mechanism being invoked to explain formation of *(45)* from the *syn,anti-* and/or *syn,syn* isomer of *(44)*[129]:

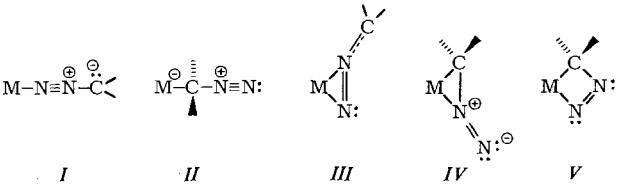


R = C_6H_5; R' = CO_2CH_3, $CO_2C_2H_5$, $CO_2C(CH_3)_3$

6. Organometallic Diazoalkanes; Complexation of Alkoxycarbonylcarbynes as Bridging Ligands in Carbonylmetal Systems

Although *Buchner* synthesized bis(ethoxycarbonyl-α-diazomethyl)mercury *(46a)* as the first metal-containing diazo compound over 80 years ago, metallodiazoalkanes played a very minor role for many decades in the enormous advances of preparative diazoalkane chemistry. Meanwhile, the lithium, silver, mercury, germanium, and tin derivatives are known to be valuable intermediates for the synthesis of homologous diazoalkanes[66]. Moreover, *Lorberth et al.* have very recently developed facile and universally applicable syntheses of a plethora of singly and doubly metalated compounds of type $(L_xM)(R)C{=}N_2$ and $(L_xM)_2C{=}N_2$[67].

Once *Strausz* and *Skell* had found that not only mercury-containing carbenes $R^1(R^2Hg)C$: but also carbynes $R^1{-}\dot{C}$: can occur as intermediates on photolysis of α-mercuriodiazoalkanes[68–72], the scene was set for the first attempts to transfer the carbynes to complex substrates. Starting from the mercury derivatives of diazoacetic esters, it proved possible to prepare, *e.g.*, dinuclear carbonylmanganese complexes *(47)* containing μ-methylidyne ligands[*][74,75].

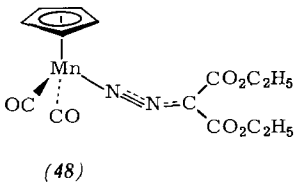


(a), R = C_2H_5; *(b)*, R = $C(CH_3)_3$

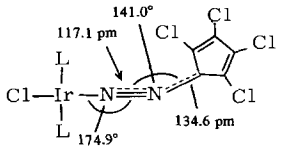
This facile method of carbyne (methylidyne) transfer has so far attracted little attention, and its mechanism has not yet been elucidated. In view of the large number of heterodiazoalkanes now available, it holds promise for the synthesis of other μ-methylidyne or carbyne complexes.

7. Transition Metal—Diazoalkane Complexes

The complexation properties of diazoalkanes is of considerable importance in mechanistic discussions on the reactions of organometallic compounds with diazoalkanes, for in most cases the structurally intact diazo component is most likely initially attached to the metal center. As heterocumulene systems, $RR'C{=}N_2$ molecules possess several "basic" functions capable of coordination. Considering just the possible 1:1 products of heteroatom-free diazoalkanes, five more or less realistic structural models can be enumerated: the diazoalkane can be attached to the metal as a monodentate ligand bonding *via* the terminal N atom *(I)* or *via* the central C atom *(II)* or as a η^2 ligand *via* a π-function [N=N *(III)*, C=N *(IV)*], and possibly also after the manner of a 1,3-cycloadduct *(V)*. Some of these possibilities are considered in a recent review[76].



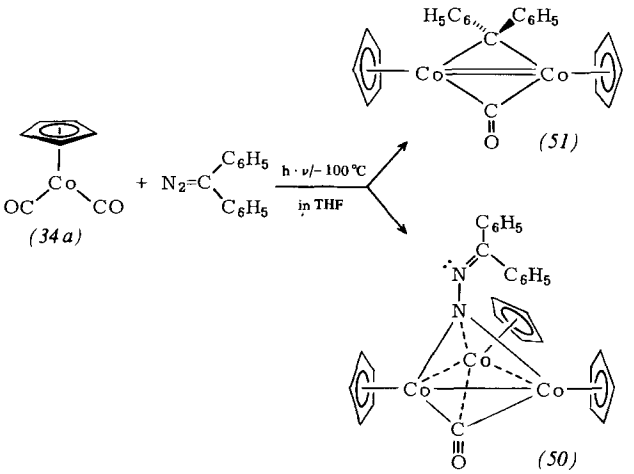
I *II* *III* *IV* *V*



In *type I*, the diazo compound is bonded *via* its terminal nitrogen atom to the central metal. This kind of coordination is less favored, owing to the relatively low energy level of the relevant orbital. Nevertheless, *end-on* attachment of neutral diazo molecules to metal centers has been accomplished in two cases: diethyl diazomalonate is bonded remarkably strongly in the carbonyl manganese complex *(48)*; it can only be displaced by carbon monoxide under high pressure[77]. The analogous compound *(49)*, likewise accessible by direct ligand exchange and which has been examined by X-ray anal-

[*] Concerning carbyne/methylidyne nomenclature, cf. [51]. For a survey of the preparation and properties of carbyne complexes, cf. [73].

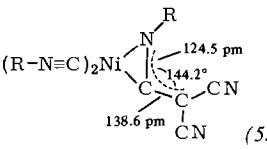
ysis, contains tetrachlorodiazocyclopentadiene as a ligand with a nonlinear skeleton which is replaceable by CO or SO_2[130]. Only slight π backbonding by neutral diazo ligands N_2R, as compared with the formally cationic alkyl- or phenylazo groups N_2R^+, is deduced from the observed bond lengths[130].



(48)

L = $P(C_6H_5)_3$ (49)

In general, however, we have to resort to indirect methods to produce mononuclear diazo complexes; such methods elaborate the complexed diazoalkane system from dinitrogen- or hydrazine complexes. Terminal polycoordination is a special case. It has repeatedly been encountered in the complex chemistry of diazoalkanes and leads to stabilization of cluster fragments: the photoreaction of $Fe(CO)_5$ with diphenyldiazomethane gives not only a dinuclear μ-hydrazido derivative but also a trinuclear organometallic hydrazone[78]. Similarly, diphenyldiazomethane has been introduced into the stable cluster molecule of *(50)* by low temperature photolysis with the cobalt compound *(34a)*; the μ-methylene complex *(51)* is formed at the same time. Hence this reaction provides



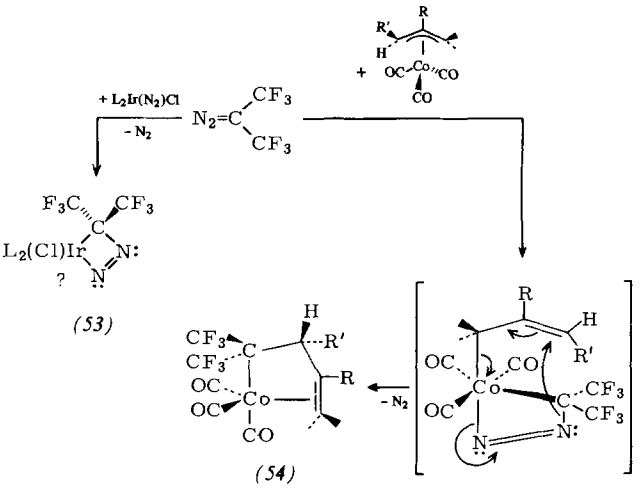
(34a) (51) (50)

the first example of simultaneous stabilization of a diazo compound and the corresponding carbene in a transition metal complex[79]. As in all other cases, the intact diazo molecule can be attached to the metal centers only under extremely mild conditions; thermal reaction gives only the nitrogen-free μ-methylene derivatives *(51)*[79].

Type II is frequently considered for primary adducts (organometal + diazoalkane); it has not yet been verified in stable compounds.

Type III has been achieved by ligand displacement reactions on some zerovalent metal complexes of the nickel group: under mild conditions (−78 to 0 °C) a ligand of "bis(*tert*-butyl isocyanide)nickel" and its palladium homolog, as well as other similar compounds, is replaced by 9-diazofluorene or diphenyldiazomethane[80], resulting in thermally labile diazoalkane derivatives of general composition $L_2M[N_2{=}CCR']$ [M = Ni, Pd; L = $(CH_3)_3C{-}N{\equiv}C$, $P(C_6H_5)_3$]. X-Ray structure analysis confirms the postulated geometry in the case of $[(CH_3)_3C{-}N{\equiv}C]_2Ni$(9-diazofluorene)[81]: the bent diazoalkane skeleton is bonded *unsymmetrically* by its two N atoms to the metal atom as a formally bidentate ligand.

In contrast, the action of dicyanodiazomethane on tetrakis(*tert*-butyl isocyanide)nickel at −10 °C in *n*-hexane solution leads not to the substitution product $[(CH_3)_3C{-}N{\equiv}C]_2Ni$(dicyanodiazomethane) but surprisingly to the ketenimine complex *(52)*—the overall result of addition of the carbene $:C(CN)_2$ to the isocyanide fragment $(CH_3)_3C{-}N{\equiv}C$[82,83].



(52)

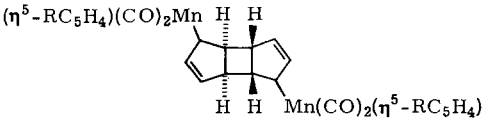
R = $(CH_3)_3C$

Apart from being the first example of a heterocumulene system RR'C=C=X [X = O, N—R] coordinated to the metal by way of its carbon—heteroatom bond, and not the C=C function as in all other species of this kind, compound *(52)* also warrants attention because it apparently also catalyzes formation of ketenimine from isocyanides and diazoalkanes.

No example of π(C=N) coordination as in *type IV* is known. The diazoalkane may be activated for a cleavage of the N=N bond, such as could be operative in the formation of ketimine complexes from diazoalkanes[84].

[1+3] Cycloadducts belong to *type V*. There are no unequivocal examples of this structural type. This kind of coordination was attributed to the product *(53)*, which is thought to possess a diazairidacyclobutene structure with a trigonal-bipyramidal central metal[85].

(53) (54)



R, R' = H, CH_3; L = $P(C_6H_5)_3$

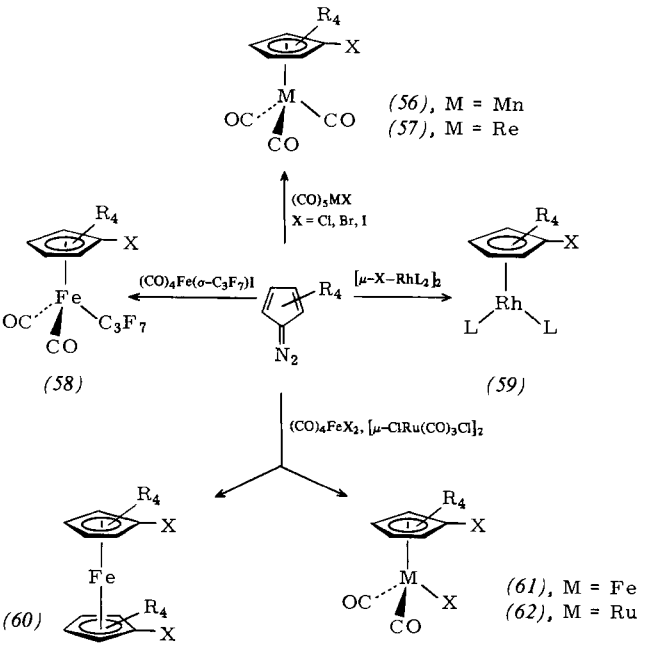
Cycloadducts of this kind are usually not resistant to decomposition by elimination of N_2: thus π-allyl(tricarbonyl)cobalt complexes are transformed by $(CF_3)_2C{=}N_2$ into the carbene addition products *(54)* with refunctionalization of the π-allyl systems. These reactions lead to 3-butenyl systems which are attached to the metal *via* the olefin function and also by alkyl-type bonding as bidentate chelate ligands. In view of the mild reaction conditions, attack by the free carbene on the metal is unlikely. Instead, 1 : 1 adducts are probably formed initially and then rearrange with loss of their four-membered ring structure to give the stable products *(54)*[86].

The behavior of the π-allyl—cobalt compounds also exemplifies the formation of complexed products from the diazoalkanes in the coordination sphere of a metal. A foreign ligand is not essential for the success of this reaction: formation of azine complexes on reaction of nickel, palladium, and platinum complexes with $(CF_3)_2C{=}N_2$ takes place under conditions in which no perfluoroacetone azine is formed from the diazo component[85, 87, 88]. An initial 1,3-dipolar addition of $(CF_3)_2C{=}N_2$ to the complex core L_2M is assumed to occur. Opening of the four-membered M—N—N—C heterocycle and attack of a further diazo molecule explains formation of the stable final product. The pronounced dipole character indeed appears to play a dominant role, for no well-defined metal complexes could be isolated with trimethylsilyldiazomethane[87, 88].

8. Organometallic Syntheses with Diazocyclopentadienes and Diazoindene

The successful synthesis of new carbene and methylene complexes from diazoalkanes called for studies on cyclic diazo compounds. This field appears all the more attractive because the complex stabilization of carbocyclic carbenes is still a topical problem of organometallic chemistry. Should it not be possible to synthesize cyclopentadienylidene complexes from diazocyclopentadienes? Only partial successes have hith-

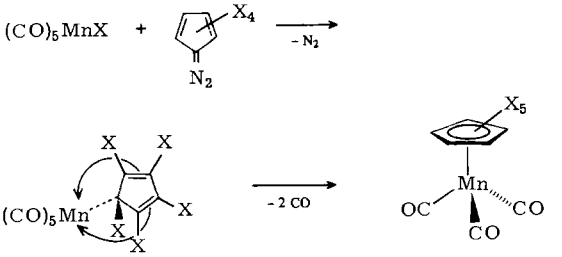
(55), R = H, CH_3



erto been reported: thus the action of the manganese complexes *(23)* on diazocyclopentadiene gave not the expected mononuclear cyclopentadienylidene complexes but instead their [2+2] cycloadducts *(55)*. A crystal structure analysis showed these products to contain a novel tricyclic $C_{10}H_8$ dicarbene bridge[89].

8.1. Halocyclopentadienyl and Haloindenyl Complexes

On use of carbonyl halides of manganese[90, 91, 93, 95], rhenium[94], iron[92, 96], ruthenium[97], and rhodium[91] as acceptors for cyclopentadienylidene or indenylidene, however, the aromatization tendency of the C_5 system could be exploited to open up a facile, productive synthesis of halogenated η^5-cyclopentadienyl and η^5-indenyl complexes.



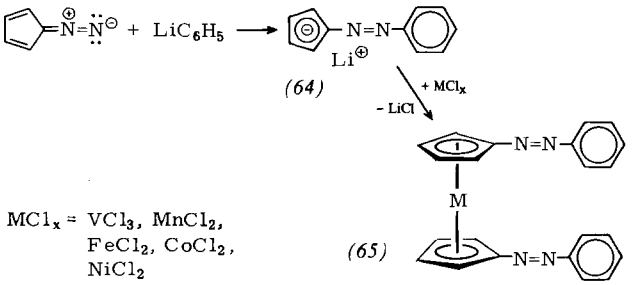
The starting materials are readily available in large quantities[6] and the yields all high or even quantitative. No alternative methods are available for most of the compounds of types *(56)—(62)* synthesized in this way.

The question of when the nitrogen is actually eliminated must remain unanswered. It has been established, however, that insertion of the intact diazo compound or the carbene derived therefrom into the metal—halogen bond takes place either *before* or *immediately after* elimination of N_2: if the reaction is performed without strong heating then not only the *pentahapto*-derivatives but also the *monohapto*-halocyclopentadienyl compounds can be isolated which still contain all five CO groups of the starting compound[90, 95]. It is particu-

R = H, C_6H_5, Cl, Br

larly interesting that on melting the η^1-complexes $(CO)_5Mn(\eta^1\text{-L})$ *(63)* undergo vigorous liberation of CO to give quantitative yields of the η^5-derivatives $(CO)_3Mn(\eta^5\text{-L})$ *(56)*, L = *e.g.* C_5Br_5[95]. This clearly shows that the diene-like η^1 ligand substitutes two CO ligands within the same molecule and aromatizes to the η^5 system. Although the η^1 intermediates have so far proved isolable in just a few cases, it seems reasonable to assume that most syntheses of this kind proceed *via* the η^1 compounds.

X = Cl, Br



The dihalogen complexes $(CO)_4FeX_2$, X = Br, I, correspondingly lead not only to the mono-cyclopentadienylated products of type *(61)*, R = H, but also provide a means of synthesizing 1,1′-dihaloferrocenes *(60)* by consecutive transfer of cyclopentadienylidene. The reactivity of the $Fe(CO)_2X$ fragment determines the product pattern[96].

The diazo procedure for the synthesis of substituted π-cyclopentadienyl complexes differs fundamentally from all other methods in that all substituent positions are already fixed in the starting compounds; the halogen shift from the metal to the cyclopentadienyl unit occurs specifically to the original diazo carbon atom[98]. Thus, this synthetic procedure is characterized by a clear "building-block" principle. Apart from the synthesis of the *pentahapto* complexes, interest also attaches to the synthesis of novel *monohapto* derivatives of the C_5X_5

ligands which is dependent on the reaction conditions and product stability.

8.2. Sandwich-Type Phenylazocyclopentadienyl Complexes

At this point, it is fitting to recall an elegant synthesis of bis(η^5-phenylazocyclopentadienyl)metal complexes developed by *Pauson* and *Knox*[99-101]: the action of LiC_6H_5 on diazocyclopentadiene leads quantitatively to the diazotate *(64)* which affords the sandwich complexes *(65)* in very good yields with the corresponding anhydrous metal chlorides.

Compound *(64)* behaves in the same way as the unsubstituted cyclopentadienide ion. The manganese compound *(65)* undergoes the same reactions as $Mn(C_5H_5)_2$ with $FeCl_2$ and with H_2O [formation of $(C_6H_5—N=N\text{-}\eta^5\text{-}C_5H_4)_2Fe$ and $Mn(OH)_2$, respectively], and should therefore have a similar saltlike structure. The other compounds *(65)* resemble the unsubstituted sandwich complexes $(\eta^5\text{-}C_5H_5)_2M$ in their physical properties; their chemistry has hardly been studied.

8.3. Advantages of the Diazo Method

The development of an effective synthesis of halogenated cyclopentadienyl complexes closes a gap. Even the preparation of η^5-monohalocyclopentadienyl complexes was hitherto frequently possible only *via* tortuous routes involving numerous intermediates[102].

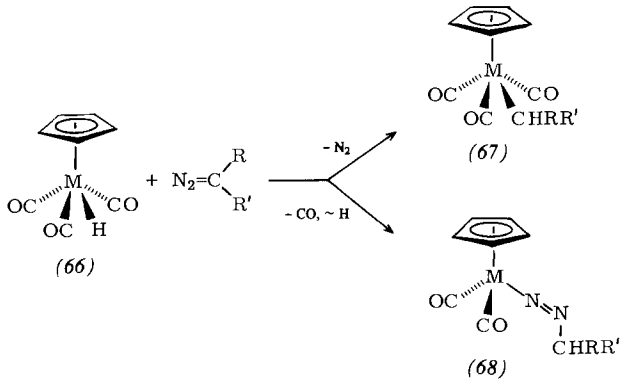
In contrast to the universally applicable reagents such as LiC_5H_5, NaC_5H_5, C_5H_5MgBr, TlC_5H_5, and cyclopentadiene used for preparing unsubstituted C_5H_5 complexes, the halogen derivatives $LiC_5H_{5-n}X_n$, $NaC_5H_{5-n}X_n$, $C_5H_{5-n}X_nMgBr$, $TlC_5H_{5-n}X_n$ are either unknown or thermolabile so that they decompose during the synthesis. Although perchlorocyclopentadiene is commercially available in kilogram quantities it is not suitable for preparing perchlorocyclopentadienyl complexes. The Tl, $P(C_4H_9)_4$, and $(C_2H_5)_3NH$ salts of the C_5Cl_5 anion decompose in solution above $-30°C$ and can only be stored below *ca.* $-15°C$ in the solid state.

The metalation/halogenation procedure is also a known method for the introduction of halogen into π-bonded cyclopentadienyl substituents; the best variants involve organomercury intermediates. This technique has proved of value for the preparation of simple halogen derivatives[103]. With regard to multiple substitutions, the method suffers from the poorly controllable formation of mixtures of isomers, whose components prove inseparable by conventional dissolution or crystallization operations or by sublimations as a result of almost identical solubilities and volatilities. Thin-layer chromatography gives satisfactory results on only rare occasions. Moreover, consecutive metalation/halogenation is only of limited applicability owing to the extremely low yields of perhalogenated cyclopentadienyl complexes. Thus, it is hardly surprising that decachloroferrocene and -ruthenocene[104] (yields $<5\%$) are still the only known perhalogenated C_5 sandwich complexes.

Seen against this background, the facile entry to perhalogenated cyclopentadienyl systems *via* diazo compounds is very welcome, particularly since it is known that strongly electron-withdrawing substituents greatly enhance resistance to oxidative processes[104]. These compounds also permit the first comparative studies on the reactivity of the metal—cyclopentadienyl bond as a function of the electron density in the ring and at the metal center.

9. Diazoalkane Reactions of Carbonyl Transition Metal Hydrides

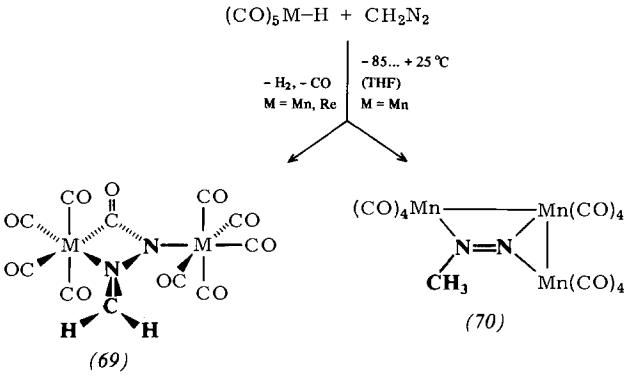
Carbene insertion into metal-hydrogen bonds according to



$$L_xM—H + CH_2N_2 \rightarrow L_xM—CH_3 + N_2$$

provides a simple route for the preparation of alkylmetal compounds[105-107]. In the chemistry of metal carbonyls, this reaction was first reported in 1955 when tricarbonyl(η^5-cyclopentadienyl)methylmolybdenum[108] and -tungsten[109,110] were synthesized from the hydrides with diazomethane as the first stable alkyl(carbonyl)transition metal compounds; tricarbonyl(η^5-cyclopentadienyl)ethyltungsten could be obtained from $(\eta^5\text{-}C_5H_5)W(CO)_3H$ and diazoethane[110]. Under special reaction conditions, $(CO)_5MnH$ can be transformed into $(CO)_5MnCH_3$ in analogous manner[111,112]. In contrast, bis(η^5-cyclopentadienyl)hydridorhenium does not react with diazomethane[113]. While no reports have been published about attempted methylene insertion into tetracarbonyl(hydrido)cobalt, the analogous compound $HCo(PF_3)_4$ reacts at $-50°C$ with diazomethane to give initially the isolable oxonium complex $[(C_2H_5)_2OCH_3]^+[Co(PF_3)_4]^-$ which above $0°C$ undergoes 94% conversion into the methyl derivative $CH_3Co(PF_3)_4$ and 6% conversion into the ethyl derivative $C_2H_5Co(PF_3)_4$[114]; the latter admittedly liberates ethylene under mild conditions to regenerate the hydride[115], and yet its formation *via* the oxonium salt draws attention to an interesting mechanistic aspect of the reaction of strongly acidic transition metal hydrides with simple diazoalkanes[51].

As a whole, the preparative applications of metal hydride alkylation with aliphatic diazo compounds seem to be subject to limitations arising mainly from the extent of organometal-catalyzed decomposition of diazoalkanes, especially since carbonyl hydrides are generally acidic in nature.



A recent comparative study on the model system *(66)* has shown that the interaction between diazoalkanes and carbonylmetal hydrides is far more complex than previously assumed[117-119]. Insertion of alkylidene to form the alkyl complexes *(67)* usually contributes little to the overall reaction. The nitrogenous derivatives *(68)*, containing the *C*-protonated diazoalkanes as monodentate three-electron ligands, then predominate among the products. These reactions, involving carbonyl substitution and 1,4-hydrogen shift, permitted the elegant preparation of the hitherto unknown *alkylazo* complexes. Crystal structure analysis performed on the

complex *(68)*, M=W, R=R'=H, confirmed the proposed geometry and shows the N—N bond (122 pm) to have double bond character[120].

M = Mo, W; R, R' = H, CH_3, $Si(CH_3)_3$, C_6H_5

Formation of nitrogenous products takes precedence over CH_2 insertion with other simple carbonyl hydrides too: even at −80 °C the weak acid $(CO)_5MnH$ reacts with diazomethane in tetrahydrofuran, liberating CO and H_2 but not N_2. The intact diazo molecule and the methylazo group derived therefrom, respectively, are incorporated in the products *(69)*, M=Mn, and *(70)*, which are isolable at room temperature. No fragmentation of the acid-labile diazo substrate has taken place[122,123]. The less reactive homolog $(CO)_5ReH$ behaves in essentially the same way[121].

The reactions leading to the cyclic complexes *(69)* and *(70)* are the first examples of coordination of diazomethane to metal centers *via both* nitrogen atoms. The formation of these complexes underlines the fact that the basicity of the carbon atom does not necessarily determine the reactions of diazomethane with metal compounds. The primary reaction steps may occur exclusively at the diazo function, provided that the organometallic components fulfill the necessary structural conditions. The preparation of μ_3-$CH_3N_2[Mn(CO)_4]_3$ *(70)* once more demonstrates the utility of diazomethane for the synthesis of alkylazo complexes. These compounds are currently being studied, both from a structural viewpoint and with regard to their relevance to problems of nitrogen fixation[124].

10. Closing Remarks

What have we learned in the foregoing discussion? Firstly, diazoalkanes are versatile reagents for the formation of numerous ligand systems on transition metal substrates. The complexes hitherto synthesized from aliphatic diazo compounds belong to the following classes: 1) *Nitrogen-free compounds:* alkyl, olefin, acetylene, carbene, μ-methylene, η^2-ketene, μ-methylidyne complexes, carbene adducts (metallacycles), σ- and π-halocyclopentadienyl- as well as π-(1-haloindenyl) complexes, and halogenated sandwich complexes of the ferrocene type. 2) *Nitrogenous compounds:* dinitrogen complexes, σ- and π-coordinated diazoalkane derivatives, alkylazo, carbene chelate, ketenimine, ketimine, ketazine, and imino amide complexes.

Secondly, it has also been found that the reactions of organometallic compounds with diazoalkanes display a pronounced structural dependence. The syntheses of π-halocyclopentadienyl- and π-haloindenyl complexes of the cymantrene[*] type starting from diazocyclopentadiene and its derivatives and from diazoindene, respectively, can hardly be improved upon as regards simplicity and yield. The σ-halocyclopentadienyl intermediates can be isolated. Repetitive cyclopentadienylation also provides a route to halogenated sandwich compounds. Acyclic diazo compounds preferentially afford carbene or μ-methylene complexes; however, if the metal substrates contain metal—hydride or metal—halogen functions susceptible to carbene insertion, then formation of alkyl- and/or alkylazo complexes will predominate. The production of cyclic carbene addition products is dependent upon the presence of additional basic centers in the diazo component. Thus diazomalonic ester derivatives undergo [2+3]-carbene addition to give five-membered metallacyclic compounds. Complexed carbynes are expected on use of α-mercurated diazoalkanes. In some isolated cases, unfragmented diazo molecules can be attached to transition metal centers. With few exceptions, the 1:1 adducts are rather unstable, in keeping with their main role as primary products.

The wealth of products obtained from the entire area of organometallic complex chemistry can still not disguise our rather crude knowledge of the relevant reaction mechanisms. Many questions await elucidation, which is probably rendered all the more difficult by the frequent superposition of somewhat unpredictable catalytic processes on the stoichiometric reactions. The future of organometallic diazoalkane chemistry therefore lies not only in promising preparative advancements but also in detailed mechanistic studies.

I am indebted to Professor Henri Brunner for his generous support of the work performed in our laboratories and cited in this article, and also to Ms. B. Reiter, Ms. I. Schweizer, Ms. I. Steffl, H. Biersack, M. Huber, and J. Plank for their patient, conscientious, and productive experimental assistance. Thanks are also due to Professor J. L. Atwood (University/Alabama, USA), Professor I. Bernal (Houston/Texas, USA), Professor B. L. Haymore (Bloomington/Indiana, USA), Dr. C. Krüger (Mülheim/Ruhr, Germany), Dr. A. D. Redhouse (Salford/Great Britain), and Professor M. L. Ziegler (Heidelberg/Germany), and their co-workers, for the X-ray structure analyses. I also wish to thank Dr. K. K. Mayer (Regensburg/Germany) for his help with the interpretation of the mass spectra, and Professor P. S. Skell for his hospitality while I was at Pennsylvania State University. Electrostatics, the Chemical Bond and Molecular Stability

By Sidney W. Benson[*]

Electrostatic models of the chemical bond are based on the Virial Theorem and hold promise for providing a reliable and accurate method for predicting heats of formation of molecules and free radicals. The Principle of Alternating Polarity which states that those compounds are most stable in which atoms of opposite polarity are bonded is shown to be quantitatively described by electrostatic models. Current fixed partial-charge models account for ΔH_f^0 of hydrocarbon molecules and radicals. With inclusion of polarization effects, whose energies are small, they also account for the dipole moments in hydrocarbons. A brief account is given of a more general model with significant polarization interaction which is under development and which appears to be able to account for both ΔH_f^0 and dipole moments of polar molecules.

1. Introduction

One of the major goals of theoretical chemistry is to be able to predict equilibrium constants (states) for all possible stoichiometric reactions given composition, volume, solvent, and temperature. To do this requires a knowledge of the heats of formation, entropies and heat capacities of both reactants and products. This is a necessary first step before the broader goal of predicting rates of approach to these equilibrium states can be achieved. An *ab initio* quantum mechanical approach to such a task is not feasible now or in the near future. Empirical quantum approaches have been numerous and more or less encouraging but none of them have demonstrated the required accuracy in ΔH_f^0 (<1 kcal/mol).

An alternative approach which is also empirical, is to try to generalize from known observations on data using physical laws as a guide. This has been very fruitful, culminating in

[*] Prof. Dr. S. W. Benson
Chemistry Department, University of Southern California
Los Angeles, CA 90007 (USA)

a hierarchy of Additivity Laws for molecular properties[1] which are capable of reproducing most data on ΔH_f^0, S^0, and Cp^0 to within the experimental uncertainties. The level at which such accuracy is attained is called the "Law of Additivity of Group Properties". It suffers from at least two deficiencies. The first of these is the requirement of an extensive data base to establish the empirical numbers. A group is defined as a polyvalent atom together with all of its ligands. A typical example would be the methyl group in hydrocarbons, designated by $C—(H)_3(C)$. Since saturated carbon is tetravalent with four ligands there are about 10^4 possible groups centered on carbon if we consider carbon itself and only nine other elements as possible ligands. Trivalent elements such as nitrogen would have 10^3 groups and so on. In practical terms there are not available 10^4 pieces of accurate data on the ΔH_f^0 of chemical compounds from which to provide such a data base.

The second deficiency has to do with the fact that for very polar compounds (*i.e.*, those containing two or more substituents such as F, CN, OH, NO_2, *etc.*) deviations from group additivity can be in excess of 6 kcal/mol. Also, very highly branched compounds with "strained" configurations require extra-group corrections in order to reproduce known values of ΔH_f^0. However, a number of simple and not-so-simple empirical schemes exist for making strain corrections[2,3] to group additivity estimates of ΔH_f^0 so that strain is not as severe a problem as polarity.

These latter problems with group additivity arising from polar and steric interactions are not serious since it is reasonable to anticipate correction schemes to account for such effects. However, the data base requirements do seem prohibitive and so it is tempting to consider alternative approaches. Of the alternatives, the most attractive is the Law of Bond Additivity. The premise of bond additivity which has historic foundations[4,5] is that molecular properties may be considered to be additive in contributions from the bonds comprising the molecule. Since with only about 40 atoms of common chemical interest forming covalent compounds there are at most 800 bonds, the data requirements seem almost modest. For the most commonly occurring 15 atoms only 120 single bonds, 66 double bonds, and 21 triple bonds can exist and it is possible to envision a complete scheme of empirical thermochemistry from existing or readily available data.

An inspection of bond additivity applied to $\Delta H_{f\,298}^0$ data[4] indicates that maximum deviations from an optimized scheme are about 12 kcal/mol for very polar or sterically strained compounds while average deviations are in the range of 4 kcal/mol. Since, as we shall shortly see, these deviations are not random but seem to be systematic with types of substituents in homologous series, it raises the prospect of finding simple empirical schemes for estimating them in the manner suggested by *Zahn*[6] and by *Allen*[7].

2. Theoretical Basis—The Virial Theorem

The Schrödinger Equation for an n-body system obeys the Virial Equation, which states that the total average kinetic energy T of the system is precisely equal to $-\frac{1}{2}$ the total coulombic energy of all the particles, E_c:

$$T = -\tfrac{1}{2} E_c \tag{1}$$

Note that for a stable bound system, E_c is negative and corresponds to the energy required to separate the particles infinitely far from each other with zero final kinetic energy. Hence the binding or total energy of the system E_B which is $T+E_c$ (neglecting small spin interactions) is precisely $\frac{1}{2}E_c$. The total coulombic energy of such a system can then be written as:

$$E_c = \tfrac{1}{2}\sum\sum' \frac{Z_i Z_j}{r_{ij}} + \sum Z_i \int \cdots \int \frac{P_k(\tau_k)\,d\tau_k}{r_{ik}} + \tfrac{1}{2}\int \cdots \int_{n\neq m} \frac{P_n(\tau_n)\,P_m(\tau_m)}{r_{nm}}\,d\tau_m\,d\tau_n \tag{2}$$

where Z refers to nuclear charges and P to electronic charge densities. If we had some prior knowledge of these charge density distributions we would not need to solve the Schrödinger equation to calculate E_c. In the event that the charge density distributions could be written as sums of products of one-electron wave functions the integrations would be straightforward. If on the other hand important correlation effects proscribed such a simplified form for the charge density the integration might be quite complex or indeed impossible.

Microwave and infrared spectroscopy together with modern electron diffraction studies have given us fairly accurate data (± 0.01 Å or better) on the positions of the nuclei in molecules. (Note that the mean amplitudes of nuclear motion of neighboring atoms amount to relative displacements of about ± 0.05 Å.) Thus, if we are willing to accept the empirical details of molecular structures our problem reduces to guessing the electronic density distributions. However, we can extend our empiricism one step further by adopting as a starting point the hypothesis that charge density distributions in localized bonds do not change greatly when one changes neighboring bonds in a molecule. This would be consistent with the Law of Bond Additivity for which deviations, as noted, are usually in the range of ± 4 kcal/mol and seldom reach ± 12 kcal/mol. When we consider that ionization potentials of molecules are in the range 8—15 eV (184—345 kcal/mol) these deviations are indeed very small perturbations of the electron binding energies.

A further empirical support for the hypothesis that bonds are only slightly affected by neighboring substituents is the observation that bond lengths change very little from compound to compound. Thus C—H bonds in alkanes vary very little from a mean value of 1.09 ± 0.01 Å. Even on progessing from C_2H_6 to C_2H_4 to C_2H_2 the decrease in C—H bond length is only about 0.03 Å. The same appears to be true even for very polar bonds such as C—F or C—O, with the result that one can talk of average bond lengths with some confidence. On the other hand, in unsaturated systems where delocalization of electron motions becomes significant we can find larger and more systematic variations in bond lengths. Thus C—C bond lengths can vary from 1.54 ± 0.01 Å in alkanes to 1.46 Å in butadienes, still however only a 5% change[10].

One final observation on the stiffness of bonds is appropriate. Most single bonds have stretching force constants in the range of 5×10^5 dynes/cm. Such a force constant would require an energy of 0.3 kcal/mol to stretch or compress a bond by ± 0.03 Å from its normal length[8]. Since the latter

value circumscribes variations in single bonds in saturated molecules one concludes that the larger variations in binding energies of molecules which are observed must come from interactions other than those arising from changes in bond lengths. Let us consider an actual example. In the endothermic disproportionation reaction[9]

$$CH_4+CF_4 \rightleftharpoons 2CH_2F_2 \quad \Delta H_r^0 = +12\pm3\,\text{kcal/mol}$$

the total number of C—H and C—F bonds are conserved. If bond additivity held, ΔH_r^0 would be zero. The variations in C—F and C—H bond lengths in the above compounds are less than 0.05 Å[10] which would correspond to energy changes far less than the observed heat of reaction. The implication of such observations is that the volume occupied by bonding electrons in a given single bond acts like an incompressible fluid and tends to be conserved in chemical reactions. This further implies that the energy changes in such disproportionation reactions must arise from changes in coulombic interactions involving the electrons of non-bonded atoms.

3. The Electrostatic Model—Hydrocarbons

Atoms in their ground electronic states are electrically neutral and have no dipole moments. A stable diatomic species can be formed between two such atoms only if their interaction distorts their valence shells. The simplest such distortion is to produce a dipole, and single covalent bonds may be looked upon as arising from the interaction of two such dipoles[11]. The valence electrons in the bond must have correlated motions or the dipolar interaction would average to zero. Homonuclear bonds must have identical dipolar distortions. In heteronuclear bonds this is not the case and when the bonded atoms differ enough in their electronegativity we have the case of ionic bonding[12].

The first electrostatic model to successfully correlate bond energies in diatomic molecules was proposed by *Pauling*[12]. He assigned a constant electronegativity to each atom which allowed the estimation of heteronuclear single bond energies from observed homonuclear bond energies. It was not clear how to extend this scheme to polyatomic molecules and a number of efforts have been made[13,14]. *Sanderson*'s[14] is the most comprehensive but it lacks the precision to be of quantitative utility.

The electrostatic model for polyatomic systems designed by the author[15] while less comprehensive than *Sanderson*'s is also simpler. It starts with a description of the valence electrons around each atom in a bond in terms of a deficiency (or excess) similar to the ionicity suggested by *Pauling*. In a homonuclear bond such as C—C or H—H the ionicity is zero. However, in a bond such as C—H or Si—H we may expect some net transfer, ε, of electronic charge from one atom to the other and this gives an electrostatic character to each bond. If we reference heteronuclear bonds to homonuclear standard bonds where such electron transfer does not exist, then we can define an electrostatic energy:

$$E_{el} = -\frac{\varepsilon^2}{r} \tag{3}$$

where r is the bond length across which the electronic charge ε has moved. E_{el}, which is always negative, is a measure of the extra stability of the heteronuclear bond compared to the homonuclear bonds. If, however, we are concerned with the interaction between bonds as in the present case, then this extra self-energy of a bond is not of any real interest to us. Instead the model gives us a method for estimating the interaction between adjacent bonds located on a central atom and, as we shall see, next nearest neighbors as well.

Let us consider a simple example of a divalent species X which may be an atom such as S or O or a grouping of atoms centered as one polyvalent atom such as CH_2 or NH and two different ligands A and B. We can have three different molecules from these species XA_2, XB_2, and the unsymmetrical XAB. From the standpoint of bond additivity we are interested in the heat of the reaction:

$$XA_2 + XB_2 \rightleftharpoons 2XAB \tag{4}$$

The heat of this reaction represents the difference in interaction of the bonds X—A and X—B with each other minus the self-interactions X—A/X—A and X—B/X—B. As we have already remarked, changes in geometry are slight in such reactions and the electrostatic model assigns the bond interactions to the electrostatic interaction which can now occur between the non-bonded atoms. Figure 1 illustrates the case in which A and B bear partial charges $-a$ and $-b$ respectively, and, to preserve molecular neutrality, X must bear the opposite charges as shown.

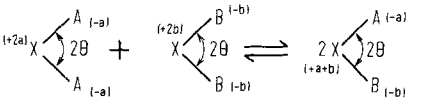

Fig. 1. Electrostatic energy in a simple disproportionation reaction [Eq. (5) and (6)].

$$\Delta E_{el} = 2E_{el}(XAB) - E_{el}(XA) - E_{el}(XB_2)$$

$$= \left(\frac{-2a^2}{r_{XA}} - \frac{2b^2}{r_{XB}} - \frac{2ab}{r_{XA}} - \frac{2ab}{r_{XB}} + \frac{2ab}{r_{AB}}\right) + \left(\frac{4a^2}{r_{XA}} - \frac{a^2}{r_{AA}}\right) + \left(\frac{4b^2}{r_{XB}} - \frac{b^2}{r_{BB}}\right) \tag{5}$$

$$= \frac{2a^2}{r_{XA}} + \frac{2b^2}{r_{XB}} - 2ab\left[\frac{1}{r_{XA}} + \frac{1}{r_{XB}}\right] - \left[\frac{a^2}{r_{AA}} + \frac{b^2}{r_{BB}} - \frac{2ab}{r_{AB}}\right] \tag{6}$$

If bond distances and angles are approximately conserved then it can be shown that the first three terms on the right-hand side of Equation (6) for ΔE_{el} are positive and the last bracketed term in this equation is similarly positive. But it will be noted that the former terms are individually about twice or more as large as the corresponding terms in brackets so that they dominate the value of ΔE_{el}, which is then positive.

When $a=b$ and $r_{XA}=r_{XB}$ then $\Delta E_{el}=0$. When a and b are of opposite sign $\Delta E_{el}>0$. When $r_{XA}\sim r_{XB}$ then ΔE_{el} is given by:

$$\Delta E_{el}(r_{XA} \cong r_{XB}) \approx \frac{2(a-b)^2}{r_{XA}} - \frac{(a-b)^2}{r_{AA}} > 0 \tag{7}$$

since $r_{AA}=2r_{XA}\sin\theta$.

Thus it appears that the disproportionation of symmetrical species to produce unsymmetrical species should in general be endothermic and in fact we find this to be a fairly good rule. Some examples are provided in Table 1, selected for elements of groups 4, 5, 6, and 7. Some exceptions to the general rule are also noted and we shall comment on these later. Note also that the heats of disproportionation tend to be small and usually below 6 kcal/mol in absolute value.

Table 1. Some heats of disproportionation ΔH_r^0 of symmetrical species: $A_2X + B_2X \rightleftharpoons 2ABX$

Reaction	ΔH_r^0 [kcal/mol]	Ref.
$H_2O + Me_2O \rightarrow 2MeOH$	6.0	[15]
$H_2O + F_2O \rightarrow 2HOF$	5 ± 3	[1]
$H_2O + Cl_2O \rightarrow 2HOCl$	1 ± 1	[1, 16]
$H_2S + Me_2S \rightarrow 2MeHS$	2.8	[5]
$H_2S + (HS)_2S \rightarrow 2HSSH$	4.4	[5]
$H_2NH + Me_2NH \rightleftarrows 2MeNH_2$	4.5	[5]
$Me_2NMe + H_2NMe \rightleftarrows 2HNMe_2$	2.4	[5]
$H_2CH_2 + Me_2CH_2 \rightleftarrows 2MeCH_3$	2.5	[5]
$H_2CF_2 + F_2CF_2 \rightleftarrows 2HCF_3$	0 ± 2	[5]
$H_2CH_2 + F_2CH_2 \leftrightarrows 2H_3CF$	12 ± 2	[5]
$H_2CH_2 + Cl_2CH_2 \leftrightarrows 2ClCH_3$	1.5 ± 1.4	[5]
$Cl_2CH_2 + Cl_2CCl_2 \leftrightarrows 2HCCl_3$	-2.7 ± 1	[5]
$H_2CH_2 + I_2CH_2 \leftrightarrows 2ICH_3$	-4.4	[1]

$H_2C{=}CF_2 + F_2C{=}CF_2 \rightarrow 2HFC{=}CF_2$	4.5 ± 4	[5]
$H_2C{=}CCl_2 + Cl_2C{=}CCl_2 \rightarrow 2HClC{=}CCl_2$	-2 ± 4	[5]
$H_2CO + Me_2CO \rightarrow 2HMeCO$	-1.7 ± 1.5	[1]
$Cl_2CO + Me_2CO \rightarrow 2ClMeCO$	-13.5	[1]
$Me_2Hg + Cl_2Hg \rightarrow 2MeHgCl$	-12 ± 3	[1, 15]

We find much larger values for heats of disproportionation when we consider compounds with one or more π bonds. This is illustrated for a few cases in Table 2. Again the values of ΔH_r^0 are all positive and far in excess of anything attributable to changes in bond lengths.

Table 2. Some heats of disproportionation of compounds with one or more π bonds.

Reaction	ΔH_r^0 [kcal/mol]	Ref.
$CO_2 + CS_2 \rightarrow 2COS$	0	[17]
$CO_2 + CH_2{=}C{=}CH_2 \rightarrow 2CH_2{=}C{=}O$	27 ± 2	[1]
$CO_2 + H_2CH_2 \rightarrow 2CH_2CO$	60 ± 2	[1]
$CS_2 + H_2CH_2 \rightarrow 2CH_2CS$	30 ± 4	[17]
$CO_2 + CCl_4 \rightarrow 2COCl_2$	12	[1]
$CO_2 + CF_4 \rightarrow 2COF_2$	14 ± 4	[1]

This simplest model of a fixed electrostatic interaction between non-bonded atoms assigns equal and opposite partial charges δ_{XY} to each atom X and Y connected by a bond. Such a model is useful when δ_{XY} is a transferable constant independently of whatever other atoms may be bonded to X and Y. The test of such a model is that it reproduces the thermal data on heats of reaction using the principle of bond additivity plus the electrostatic energy representing the non-bonded interactions. This behavior has been demonstrated in the case of the simple hydrocarbons, namely the alkanes[18] branched or unbranched, simple olefins, acetylenes and aromatics[19] and finally for the alkyl free radicals[20]. Using a charge ε_i of $+0.278 \times 10^{-10}$ esu on H and -0.278×10^{-10} esu on C in the aliphatic C—H bond it is possible to reproduce ΔH_f^0 (kcal/mol) of all the unbranched and singly branched paraffin hydrocarbon with the simple formula:

$$\Delta H_f^0(C_nH_{2n+2})_{gas} = -2.0(n+1) - 0.5 + E_{el} \quad (8)$$

where E_{el} is the sum of all of the electrostatic interactions in the paraffin:

$$E_{el} = \tfrac{1}{2} \sum_i \sum_j{}' \frac{E_i E_j}{r_{ij}} \quad (9)$$

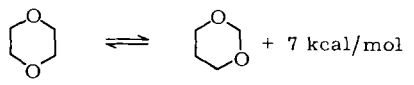
In such a summation it is of sufficient accuracy (≤ 0.1 kcal) to represent all C—C bonds and C—H bonds each by standard lengths 1.54 Å and 1.09 Å respectively and take all angles as tetrahedral. Since the C—C bond is by symmetry, unpolarized, each group CH_3, CH_2, or CH in a hydrocarbon has an excess counter charge on the carbon atom equal to $-0.278k \times 10^{-10}$ esu, where k = the number of H atoms on that C-atom. Each such group then behaves as an electric dipole and its electrostatic interaction with neighboring CH_k groups is small (≤ 0.6 kcal) and falls off rapidly with distance[18].

A similar model works well for olefins, acetylenes, aromatics and free radicals with appropriate assignments of bond energies and charges to each bond. Table 3 summarizes the values used to reproduce the heats of formation for these compounds. With appropriate small corrections for non-bonded steric repulsions arising from *cis* and *gauche* interactions of CH_3 groups the electrostatic model is able to reproduce the $\Delta H_{f\,298}^0$ of the saturated and unsaturated hydrocarbons and alkyl free radicals to within the uncertainties in the data[21].

Table 3. Bond energies and partial charges used for reproducing the heats of formation $\Delta H_{f\,298}$ of hydrocarbons and alkyl radicals at 298 K.—For olefins and aromatics, a 1.0 kcal/mol repulsion is assigned to *cis*- or *ortho*-alkyl groups and 0.3 kcal/mol repulsion to geminal alkyl groups in olefins. For large, highly-branched alkanes 0.7 kcal/mol is assigned to *gauche* interactions and 1.5 kcal/mol to 1,5 methyl interaction (Ref. [1], page 30).

Bond	Energy [b] [kcal/mol]	Partial charge [c] [10^{-10} esu]
C—C	0.25	0
H—H	0	0
C—H	−1.13	0.278(H)
C_d—H	−3.3	0.32(H)
C_B—H	−2.2	0.32(H)
C_t—H	−5.2	0.36(H)
C•—H	11.9	0.12(H)
C_d—C	−5.5	0.12(C)
C_t—C	−8.0	0.16(C)
C_B—C	−2.0	0.12(C)
C•—C	14.0	0.04(C•)
C=C	0.25	0
C_B—C_B	6.5	0
C_d=C_d	34.0	0
C_t≡C_t	67.7	0

[a] The subscripts B, d, t signify benzene, doubly bonded, and triply bonded C-atoms.
[b] These are contributions to $\Delta H_{f\,298}^0$ for each bond.
[c] The strongest positive atom is given.



It is possible to make a similar analysis of organosilicon compounds with similar results[22]. Unfortunately the ΔH_f^0 data are of poorer quality for the silicon compounds and what there is shows such small deviations from bond additivity

that they are not very sensitive to the partial charge assignments.

That the hydrocarbons fit so well a simple model of non-bonded interactions is very likely fortuitous. First the charges involved are on the whole small. Aside from CH_4 itself the maximum partial charge on any atom is that in the CH_3 group where C carries a negative charge of 0.84×10^{-10} esu or about $^1/_6$ of an electronic charge. One consequence of this is that charge-induced charge-dipole interactions turn out to be quite small with energies of the order of less than 0.2 kcal/mol. As we shall see when we consider more polar molecules, net charges become appreciably larger and induction effects are no longer small enough to ignore.

4. The Principle of Alternating Polarity—Polar Molecules

The literature of organic chemistry has, for almost a century, been threaded by qualitative observations to the effect that those compounds are most stable in which elements of alternate polarity are joined to each other. In the case of polar substituents on aromatic nuclei it is known that *ortho* substitution is less stable than *meta* or *para* substitution. Thus *ortho*-dichlorobenzene is less stable than the *meta*- or *para*-isomers by some 2.5 kcal/mol, while *ortho*-difluorobenzene is similarly less stable by about 5 kcal/mol[5]. Larger effects are seen on comparing 1,3- and 1,4-dioxane. The 1,3-isomer is more stable by 7.0 kcal/mol, reflecting presumably the attractive configuration of two O-atoms attached to the same C-atom.

The electrostatic model of non-bonded interactions gives a simple and direct explanation for such observations and permits us to explore them in more quantitative fashion. In the simple example illustrated in Figure 1, the disproportionation of XA_2 with XB_2 is always endothermic when A and B are of opposite polarities (*a* and *b* of opposite signs) and no deviations from this example are known. However, when we try to apply this simple model to very polar species such as the halogens we find gross discrepancies.

These seem to have their origins in two sources. With very electronegative elements such as O and F, the partial charges are no longer small, as they were in the case of the hydrocarbons, and charge-induced charge-dipole effects can no longer be neglected. In addition the partial charges that are needed to account for changes in $\Delta H^0_{f\,298}$ of mono-substituted compounds (*e.g.* MeX and *t*-BuX) are much too small to account for the observed dipole moments of these compounds.

What one is required to do to account for the properties of the very polar molecules is to make an assignment of partial charges to each atom in the bond and in addition an assignment of a fixed dipole moment to the lone pairs on the electronegative atom. In polysubstituted compounds one also has to make explicit account of polarization effects and the energies of such interactions. As a consequence the model requires additional parameters and the calculations are more complex. At the moment only an approximate resolution has been made by the author and so the account given here will be restricted to reviewing some of the data and reporting the early results on a necessarily tentative model.

Table 4. Heats of formation of fluorinated methanes of the type CH_nF_{4-n} [18].

Compound	$-\Delta H^0_{f\,298}$ [kcal/mol]	$\Delta(-\Delta H^0_{f\,298})$	$\Delta^2(\Delta H^0_{f\,298})$
CH_4	17.9		
CH_3F	56.8 ± 2	39 ± 2	
CH_2F_2	108 ± 1	51 ± 2.3	12 ± 4.1
CHF_3	166 ± 1	58 ± 1.4	7 ± 3.0
CF_4	223 ± 1	57 ± 1.4	−1 ± 2.5

A relatively simple way to explore the magnitudes of non-bonded interactions is to examine the changes in ΔH^0_f in simple, homologous series where one group or atom replaces another. Table 4 shows the data for the series CH_nF_{4-n}. If bond additivity held, then the differences in heats of formation on replacing a C—H by a C—F bond would be constant. We see that on the contrary there is a large increase in stability of about 12 kcal/mol in going from CH_3F to CH_2F_2, above and beyond simple additivity. We can express this in terms of the disproportionation reaction:

$$2CH_3F \rightleftharpoons CH_4 + CH_2F_2 + 12 \text{ kcal/mol}$$

The first differences in $\Delta H^0_{f\,298}$, expressed as $\Delta(-\Delta H^0_{f\,298})$ increase to a maximum at CHF_3 and then decrease slightly. If non-bonded interactions could be treated as pairwise additive as is suggested in the simple electrostatic model, then the second differences $\Delta^2(\Delta H^0_f)$ would be constant[23]. The fact that they are not tells us that non-linear interactions must exist. The magnitude of such interactions is represented by the third order differences of about 6 kcal/mol for the fluorinated methanes. We find a similar, albeit smaller, effect in the series of chlorinated methanes shown in Table 5. Here, the first order differences are small and not too much larger than the experimental uncertainty. The second order differences are also small but the reversal of sign is unmistakable, again suggesting significant non-linear interactions between bonds.

Table 5. Heats of formation of the chlorinated methanes CH_nCl_{4-n} [1].

Compound	$-\Delta H^0_{f\,298}$ [kcal/mol]	$\Delta(-\Delta H^0_{f\,298})$	$\Delta^2(-\Delta H^0_{f\,298})$
CH_4	17.9		
CH_3Cl	19.6	1.7 ± 1	
CH_2Cl_2	22.8	3.2 ± 1	1.5 ± 1.4
$CHCl_3$	24.2	1.4 ± 1	−1.8 ± 1.4
CCl_4	22.9	−1.3 ± 0.5	−2.7 ± 1.2

In agreement with these trends in the chlorinated and fluorinated methanes is the comparable data on mixed chloro-fluoro-substituted methanes, CF_nCl_{4-n} shown in Table 6. We note that parallel to the CH_nF_{4-n} data (Table 4), the consecutive substitution of F for Cl leads to increasing stability (more negative ΔH^0_f) with values of the $\Delta(\Delta H^0_f)$ almost equal in absolute magnitude in the two sequences.

Table 6. Heats for formation of the compounds CCl_nF_{4-n} (data from Ref. [5]). Note that a change in ΔH^0_{f298} (CCl_3F) to −66.4 kcal/mol and of ΔH^0_{f298}(CCl_2F_2) to −114.0 kcal/mol would bring all the Δ^2 differences to about the same value of 4.4.

Compound	$-\Delta H^0_{f298}$ [kcal/mol]	$\Delta(-\Delta H^0_{f298})$	$\Delta^2(\Delta H^0_{f298})$
CCl_4	22.9		
CCl_3F	64±2	41±2	
CCl_2F_2	114.8±1.3	51±2.4	10±4.2
$CClF_3$	166.2±1.4	51.4±2	0±3.5
CF_4	223±1	57±1.5	5.5±3.5

Questions have always been raised concerning the reliability of the heat of combustion data on the fluorine compounds and it is of interest to note that what data do exist on oxygenated compounds show an almost identical trend[17]. Table 7 compares such data for some hydroxy-substituted methanes.

Table 7. Heats of formation of some hydroxy-substituted methanes $CH_n(OH)_{4-n}$ (data from Ref. [5] and Ref. [1]).

Compound	$-\Delta H^0_{f298}$ [kcal/mol]	$\Delta(-\Delta H^0_{f298})$	$\Delta^2(-\Delta H^0_{f298})$
CH_4	17.9		
CH_3OH	48.0	30.1	
$CH_2(OH)_2$	93±1	45±1	15±1.5

The second order differences are in surprising agreement with the corresponding fluorine compounds of Table 4. This, together with other such parallels, suggest that we could be quite confident in assigning a value of 7±2.6 kcal/mol to the ΔH^0_r of:

$$CH(OH)_3 + CH_3OH \rightleftharpoons CH_2(OH)_2 - 7\,\text{kcal/mol}$$

and hence a value of $\Delta H^0_{f298}[CH(OH)_3]_{gas} = -141 \pm 2$ kcal/mol. This allows us to predict that HCOOH is unstable with respect to hydration by 7 kcal/mol.

$$HCOOH(g) + HOH(g) \rightleftharpoons HC(OH)_3(g) - 7\,\text{kcal/mol}$$

It would further suggest that ΔH^0_{f298} of monofluorinated and difluorinated saturated hydrocarbons will be about 8±1 kcal and 16±1.5 kcal/mol more stable respectively than their hydroxy analogues.

An especially striking illustration of the principle of alternating polarity is seen on examining the effect of electronegative substitution on polyvalent electronegative elements. The substitution of F or OH for H in hydrocarbons leads to a more stable compound. The reverse turns out to be the case when the substitution takes place on an electronegative element. This is seen in Tables 8 and 9 where we examine the replacement in H_2O of H by F and OH respectively. In both cases we see that HOF and H_2O_2 are both unstable by about

Table 8. Heats of formation of the compounds OH_nF_{2-n} [1].

Compound	$-\Delta H^0_{f298}$ [kcal/mol]	$\Delta(-\Delta H^0_{f298})$	$\Delta^2(-\Delta H^0_{f298})$
H_2O	57.9		
HOF	23.5±2	−34.4±2	
F_2O	5.9±1	−29.4±2.2	5±3

Table 9. Heats of formation of the compounds $OH_n(OH)_{2-n}$.

Compound	$-\Delta H^0_{f298}$ [kcal/mol]	$\Delta(-\Delta H^0_{f298})$	$\Delta^2(-\Delta H^0_{f298})$
H_2O	57.9		
HO(OH)	32.6	−25.3	
$O(OH)_2$	15.8±1.5	−16.8±1.5	8.5±1.5

5—6 kcal/mol with respect to disproportionation into their symmetrical neighbors[24]. These intermediates correspond precisely to the example illustrated in Figure 1, where the partial charges *a* and *b* are of opposite sign and where the above disproportionations should thus always be exothermic.

Another striking example of alternating polarity is afforded by the remarkable regularity in $\Delta(\Delta H^0_f)$ values observed in the pairs of compounds X—H and X—CH_3. Where the X—H bond is very polar with X negative and H positive, then the replacement of H by the negative C-atom of CH_3 should produce a less negative increment in ΔH^0_f than when X bears a positive partial charge. This is illustrated in Table 10 taken

Table 10. Effect of the polarity of X on differences in ΔH^0_f of the compounds H—X and CH_3—X (data from Ref. [17]).

X	$-\Delta H^0_{f298}$(HX) [kcal/mol]	$-\Delta H^0_{f298}(CH_3X)$ [kcal/mol]	$\Delta(\Delta H^0_{f298})$
OH	57.8	48.0	9.8
F	64.8	56.8±2	8.0±2
CH_3COO	103.8	98	5.8
NH_2	11.0	5.5	5.5
CH_3O	48.0	44.0	4.0
NO_3	32.1	28.6	3.5
Cl	22.0	19.6	2.4
Br	8.7	9.5	− 0.8
HS	4.8	5.4	− 0.6
CH_3	17.9	20.2	− 2.3
I	6.3	3.3	− 3.0
CH_3S	5.4	8.9	− 3.5
nC_3H_7	24.8	30.2	− 5.4
C_2H_3	−12.5	− 4.9	− 7.6
C_2H	−54.2	−44.3	− 9.9
CF_3	167	178	−11
CH_3CO	39.7	51.7	−12.0
HOOC	90.5	103.8	−13.3

from data in Ref. [17]. It is of particular interest to note the effect of substitution on the polarity of a polyvalent element. Thus the replacement of H by CH_3 on either O or N or S makes the elements appear much less electronegative in the sequence shown.

5. Electrostatic Model of Polar Bonds

In a simple disproportionation reaction, the uncertainty in the enthalpy of reaction has as at least double the uncertainty in the ΔH^0_f of the intermediate species. In Tables 4 through 9 these ΔH^0_r are given by the second order differences $\Delta^2(\Delta H^0_f)$ and we see that in general they have uncertainties of the order of ±2 kcal/mol or larger. Since the electrostatic model equates these second order differences to the changes in electrostatic energies we see the major current problem in assigning values to the parameters of a more sophisticated model. It is only for the fluorine and oxygen compounds that the $\Delta^2(\Delta H^0_f)$ are sufficiently large relative to the uncertainties

in ΔH_f^0 that we can hope to uniquely assign more than one parameter.

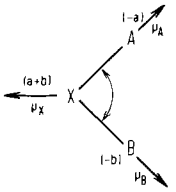


Fig. 2. Electrostatic model of the polar bond with polarization interaction and lone pair dipoles.

The most general model is illustrated in Figure 2 for the case of a divalent atom X with lone pairs attached to atoms A and B each with lone pairs. We must assign partial charges a and b to atoms in each of the bonds as before (Figure 1) and also lone pair moments μ_A, μ_B, and μ_X to each atom. We must also decide on whether or not to use a point dipole or discrete charge distribution to represent the lone pairs and how to orient them.

In the interests of reducing parameters we have chosen for the halogen atoms to represent all the lone pairs by a single point dipole centered at the nucleus and oriented along the bond axis. For oxygen, sulfur and group 6 elements, the dipole is chosen to be oriented along the line bisecting the two bonds and in the plane of these bonds. For nitrogen and group 5 elements, the dipole is stationed along the axis symmetric to the three bonds.

While the introduction of lone pair dipole moments turns out to make a physically more reasonable model[25] it does not introduce the needed nonlinearity[13]. The electrostatic energy associated with fixed partial charges and lone pairs is pair-wise additive in bonds taken two at a time and will always lead to constant second differences in ΔH_f^0 in a homologous series.

In order to obtain second order differences in $\Delta H_f^0[\Delta^2(\Delta H_f^0)]$ in a homologous series which vary we need a non-linear interaction between neighboring bonds. In the electrostatic model this can be introduced by permitting polarization of the various electron distributions. Charge-induced dipole interactions have attractive energies which are proportional to the square of the charge. If for example we consider in Figure 2 the polarization interaction between the charge $(a+b)$ on X and the atom A it can be expressed as:

$$E_{\mathrm{pol(XA)}} = \frac{-(a+b)^2}{2r_{\mathrm{XA}}^4}\alpha_{\mathrm{A}} \tag{10}$$

$$= \frac{-(a^2+b^2)\alpha_{\mathrm{A}}}{2r_{\mathrm{XA}}^4} - \frac{2ab\alpha_{\mathrm{A}}}{2r_{\mathrm{XA}}^4} \tag{11}$$

where α_A is the effective polarizability of the atom A. This polarization energy is no longer a simple superposition of the polarization produced by A and B separately as represented by the first term on the right-hand side of equation 11 but contains cross product terms (ab) which can reduce or increase the total effect depending on the relative signs of a and b. Such polarizations are also required if one is to account for the observed dipole moments of polar molecules. Fixed dipoles and fixed charges could never account for the large decreases observed in dipole moments in such sequences as CH_3Cl ($\mu = 1.87$ D) and $CHCl_3$ ($\mu = 1.01$ D)[26].

The detailed investigation of a polarization model has not been completed and so it must be emphasized that our discussion is highly speculative. Nevertheless, it is of interest to look even at the qualitative results obtained thus far. These indicate that the bonds of carbon to halogen atoms are much less "ionic" than hitherto supposed. For example in the CH_nF_{4-n} series it appears that a lone pair moment assigned to F of about 0.7 D together with a partial charge across the C—F bond of $\pm 0.7 \times 10^{-10}$ esu. will come close to reproducing the thermochemical and dipole data. Interestingly, C—O bonds have about the same properties as C—F. C—Cl bonds are characterized by a partial charge of about $\pm 0.36 \times 10^{-10}$ esu and a Cl lone pair dipole about 0.9 D. The C—Br bond has a partial charge of about $\pm 0.30 + 10^{-10}$ esu and a lone pair moment of about 0.9 D while the C—I bond has a partial charge of about $\pm 0.26 \times 10^{-10}$ esu and a lone pair moment of about 1.0 D.

For ketones and CO_2 the moments for the lone pairs on oxygen turn out to be about 0.6 D while the partial charges across the C=O bond are about double that for the C—O single bond, namely about 1.2×10^{-10} esu. It thus appears that the ionicity of double bonds is about twice that of single bonds and one might guess that the ionicity of the C≡N triple bond will be the largest of all bonds. Again, all of these results must be considered as tentative.

6. Dipole Moments

Propane and isobutane have small but measurable dipole moments of the order of 0.08 D and 0.14 D respectively. The simple fixed charge model of the C—H bond gives zero moment for both molecules even when the accurate geometries are used[18]. It was found in the original study that the small measured dipoles could be satisfactorily accounted for by polarization interactions between the charged atoms. The same situation obtained for the unsaturated olefins, aromatics and acetylene compounds where the dipole moments range from 0.36 to 0.70 D. Static moments accounted for about half or less of the observed moments and polarization the remainder[19].

When we come to polar molecules, the importance of polarization is very evident. Some time ago *Eyring et al.*[27] devised a self-consistent scheme for reproducing the dipole moments of the haloalkanes by a scheme of induced polarizations. This was extended by *Smith et al.*[28] with reasonable success. In both these schemes it is interesting to note that the value chosen for the dipole moment of the C—H bond was 0.32 D, almost precisely the value needed to fit the energies of the alkanes!

An example of the effect of polarization on dipole moment is illustrated in Figure 3 showing simple charge distributions in methyl-X and *tert*-butyl-X compounds.

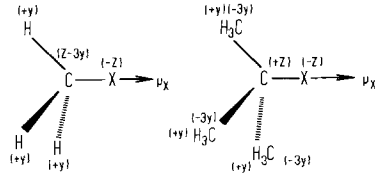

Fig. 3. Application of electrostatic model to polar methyl-X and *tert*-butyl-X compounds.

It was pointed out some time ago[29] that the difference in heats of formation of MeX and *t*-BuX varied systematically with the nature of X and ranged from values near 18 kcal/mol for hydrocarbons to extreme values of about 27 kcal/mol for strongly electronegative X. Along with this correlation we can add the observation that in addition the dipole moments of *tert*-Butyl-X are systematically larger than those of CH_3X. The polarization model is compatible with such an effect as can be seen from the charge distribution shown in Figure 3. In the t-butyl compounds all the atoms attached to the central C-atom are negative and there is relatively little electric field at this atom. In the CH_3—X compound, on the contrary, the charges of the peripheral atoms produce a strong field at the C-atom and in such a direction as to oppose the overall molecular dipole. The charges suggested here for the halogens are in accord with the conclusion that CH_3—X dipoles are smaller than those of *t*-Butyl X because of back polarization in CH_3X.

7. Conclusions

The simple electrostatic model with fixed partial charges works very well for relatively non-polar species such as hydrocarbons and silicon compounds. With these compounds the small but measurable dipole moments can only be reproduced by permitting internal polarization to take place. The polarity of the C—H bond used in this model, $\mu_{CH}=0.32$ Debye, is almost precisely the polarity required by stick dipole models. For more polar molecules internal polarization effects are no longer small and are required in order to fit the data. Research is currently underway on exploring such a model with results that can be described as encouraging. The rewards in discovering a successful model would be enormous in that they would make thermochemistry available as an accurate and practical tool for laboratory and industrial work.

[21] The best modern combustion calorimetry is capable of a precision of about ± 0.03 %. Since the heat of combustion of a typical hydrocarbon is about 160 kcal per CH_2 group, this comes to a precision of ± 0.07 kcal per C-atom in ΔH_f^0 since the heats of combustion of graphite and H_2 are not known with greater precision. The absolute accuracy with which these quantities are known cannot exceed this. There are, unfortunately, very few independent experimental sources of data with which to compare these combustion derived data and it is our feeling that the accuracy of the data is not better than ± 0.1 kcal per C atom in hydrocarbons.
[22] Ian M. Davidson, personal communication.
[23] It can be shown that for pair-wise additivity of bond interaction the second differences $\Delta^2(-\Delta H_f^0)$ are given by $\Delta H(XA/XA) + \Delta H(XB/XB) - 2\Delta H(XA/XB)$ where $\Delta H(XA/XB)$ represents the energy of interaction of the bond X—A with X—B and so on.
[24] It is quite possible that the instability of H_2O_2 observed in alkaline solutions proceeds first through a disproportionation into H_2O and H_2O_3 or their corresponding anions OH^- and HO_2^-.
[25] We are also exploring a physically more reasonable model in which the lone pair point dipole μ_X is displaced from the nucleus by an amount $\Delta x/2$ (in Å) with Δx determined by setting it equal to $\mu_x/4.80$. This is equivalent to setting the displaced lone pair charge equal to that of 1 electron. It turns out that this displacement avoids many problems of treating dipole-induced-dipole interactions which will depend on the 6th power of the distance and can become infinite when the polarizabilities of the atoms are large.

Polyethylene Fibrids: Preparation and Properties[**]

By Wolfgang Gordon, Hans Joachim Leugering, and Harald Cherdron[*]

Dedicated to Professor Karl Winnacker on the occasion of his 75th birthday

Polyethylene fibrids are small fibers having lengths of up to some millimeters, which are highly oriented and which have a morphology similar to that of cellulose fibers. The preparation of polyethylene fibrids is based on shear-induced crystallization, a process in which the polyethylene crystallizes from solution under the influence of an elongated flow in the form of so-called shish-kebabs. Polymerization under shear conditions and the flash spinning of polyethylene solutions are the main processes for the preparation of PE fibrids. They may be hydrophilized by an additional process step.—Because of their cellulose-like morphology, (hydrophilized) polyethylene fibrids have interesting properties, *e.g.* high adsorption capacity and the ability to form hydrogen bonds. In addition, the possibility of undertaking chemical reactions on the surface of the fibrids should be mentioned.

1. Introduction

Attempts to supplement or replace natural polymers in paper by fully synthetic polymers constituted the starting point in dealing with one of the oldest raw materials, which has been of decisive importance in the cultural development of mankind. While the technology of papermaking has always been subject to modification and improvement, nothing was changed for centuries with respect to the raw material since its discovery by *Tsai Lun* in 105 AD. The sources of the raw material were mulberry bast, bamboo fibers and china grass in Asia, and straw and particularly rags (old linen goods) in Europe. It was as late as the middle of the 18th century before groundwood was being employed in papermaking and cellulose fibers became available from wood by different digestion processes. With the development of synthetic polymers, their usefulness for incorporation in cellulose papers was soon realized. The papers of to-day therefore contain synthetic polymers such as polyvinyl alcohol, polyacrylamide, urea formaldehyde resin and polymer lattices in quantities which vary depending on the specific application.

These polymers, however, clearly have the function of an *additive* for the improvement of certain properties and are not used as a substitute for cellulose fibers.

In the past years, efforts have been made in various places, to prepare highly oriented fibers (fibrids) from synthetic polymers, which in their morphology are similar to cellulose fibers and which therefore may also be called synthetic pulp. During the first period of this development, the main aim was to use these fibrids in conventional papermaking processes and—in contrast to the above polymers—to replace portions of groundwood or cellulose pulp. However, it was soon found that some polymer fibrids have a number of additional properties which make them valuable for quite different applications.

The preparation, properties and applications of this new form of polymer will be described using polyethylene fibrids as example.

2. Preparation of Polyethylene Fibrids

2.1. Crystallization of Polyethylene

Polymer fibrids can be obtained from solutions of crystalline polymers, because not only the crystallization kinetics but also the crystalline morphology of the macromolecular starting substance can be completely altered by varying the conditions of crystallization. Thus, for example, the crystallization of polyethylene (PE) from unstirred solutions leads to a completely different morphology than crystallization of the same polymer from solutions exposed to shearing forces.

In 1957 *Fischer, Keller* and *Till* independently observed that single crystals which develop upon cooling of static diluted solutions of polyethylene[1] have a characteristic rhomboid shape. These lamellae have a uniform thickness of about 150 Å, but their lateral dimensions can be of the magnitude of some μm. Since the polyethylene macromolecules are considerably longer than the thickness of the single crystals, it was concluded that the molecules are folded perpendicularly to the basal plane. In fact, it could be shown that on crystallization the PE macromolecules lose their statistical coil form, which they have in solution, and that they fold themselves in a meander-like fashion. The single crystals, therefore, are lamellae in which the PE macromolecules are folded in a planar zigzag conformation (see the disk-shaped parts of Fig. 5). This folded structure is, of course, not completely regular, because structural non-uniformities (molecular end groups, short chain branches) cause disorders in the crystallite constitution.

On crystallization from more concentrated solutions under non-isothermic conditions complicated superstructures (dendrites, spherulites) are formed, which, however, always consist of single crystal lamellae of the type described above. For further details see reviews by *Geil*[2] and *Wunderlich*[3].

The crystallization is completely different, however, if the PE solution is cooled with stirring[4]. Stirring by means of

a rotating cylinder above the critical Reynold's number causes the development of Taylor whirls (see Fig. 2b), at whose edges an elongated flow is generated (see arrows in Fig. 2b). This leads to stretching of the macromolecules and thus to their orientation in the direction of the gradient of flow. The PE molecules can crystallize in this oriented state and, due to the parallel arrangement of the molecules, the change of conformation entropy $\Delta S = \Delta H/T$ is smaller than when there is no preorientation in solution.

This phenomenon is called "shear induced crystallization". Because of the smaller change of entropy, the crystallization temperature is comparatively higher than in crystallization from solutions at rest[2, 3].

It seems to be important for shear-induced crystallization, that the stretched molecular confirmation is stable over a long enough residence time, while in the case of simple shear flow (*e.g.* in the shear field next to a resting wall) the polymer coil rotates and is periodically compressed and stretched. This results in only poor orientation of the macromolecule. These differences can be seen in Figure 1, where the orientation of the macromolecules is presented as a function of the gradient of flow (slope flow rate) for elongated flow (by acceleration) and for shear flow (due to the stationary wall)[7].

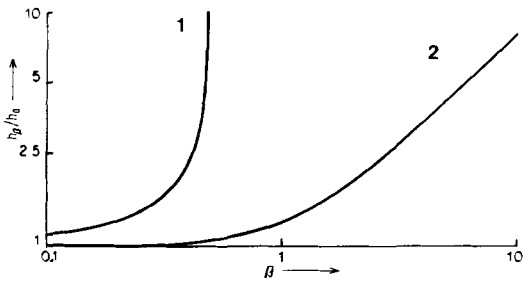

Fig. 1. Avarage elongation of the macromolecular coil h_β/h_0 for the case of elongated flow (1) and shear flow (2) as a function of the dimensionless flow gradient β (see [7]).

These modified conditions of crystallization have a decisive influence on the morphology of the resulting PE crystallites, as described in Section 3.1. The macroscopic form is modified, too. Instead of the usual powder, highly oriented small fibers are obtained upon shear crystallization. For practical use as polyethylene fibrids, they are usually cut and fibrillated (*i.e.* partially split longitudinally) by an additional mechanical treatment.

The most important processes for the preparation of PE fibrids by shear induced crystallization will be described in the following sections. Furthermore, because of their practical importance, methods for the preparation of hydrophilic fibrids will also be presented.

2.2. Shear Induced Crystallization of Polyethylene Solutions

Pennings[4] found that fibrous crystalline material is obtained upon crystallization of polyethylene solutions (about 5%) by turbulent stirring using common laboratory stirring equipment. However, the most important phenomena here can be observed better, if a "reversed" Couette assembly is used for stirring[5, 6]. It consists of one internal and one external cylinder, with the internal cylinder rotating (Fig. 2a).

If a critical Reynold's number is exceeded, the crystalline matter does not separate out uniformly on the rotating cylinder, but in periodic sections (Fig. 2a). These are places of elongated flow due to the Taylor whirls (see arrows in Fig. 2b). In a "true" Couette assembly, in which the exterior cylinder rotates, no shear induced crystallization takes place, because no Taylor whirls develop in this case.

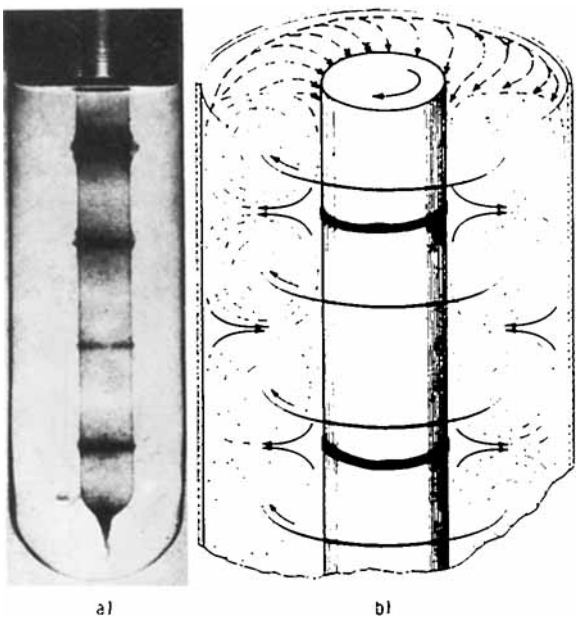

Fig. 2. a) Periodic precipitation of fibrous crystalline polyethylene on the interior rotating cylinder of a "reversed" Couette arrangement [5]. b) Schematic representation of Taylor whirls around a coaxially rotating cylinder (dotted lines). The precipitated PE crystals are marked by dark stripes [5].

A particularly important practical variant is simultaneous polymerization *and* shear induced crystallization. In this case, the suspension polymerization of ethylene with *e.g.* Ziegler catalysts is carried out under such vigorous stirring conditions that the macromolecules formed become stretched before they can crystallize in the usual zigzag conformation[8]. The polymer chains growing at the active catalytic centers require a certain time for crystallization. In the meantime, the growing macromolecules can be oriented to such an extent that fibrous polymer is obtained which has the same morphology as polymers obtained by shear induced crystallization instead of the usual polymer powder. By this process, PE fibrids can be produced with essentially arbitrary high molecular weights, which is difficult to achieve by simple shear induced crystallization of polymer solutions because of the large increase in viscosity of the solutions with increasing molecular weight of the polymer.

2.3. Flash Spinning of Polyethylene Solutions

In this process, which we may call simply the flash process[9], we are dealing with a non-isothermic crystallization of polyethylene. Firstly, polyethylene is dissolved at high temperature under pressure in a solvent with low boiling point. The superheated solution is then allowed to flow through a nozzle, which causes a high degree of orientation of the polymer molecules. Upon discharge of the solution from the nozzle, the solvent rapidly evaporates and the highly oriented polymer

instantly crystallizes in fibrous form; moreover, the sudden evaporation of the solvent causes longitudinal splitting of the fibrous material. Similarly to cellulose fibers, this material can be cut and split in refiners in order to achieve the optimum shape for various applications.

Studies by *Pickup*[10] on the hydrodynamics of the discharge of viscoelastic fluids from nozzles may contribute to an understanding of the phenomena which are of most importance in the flash process. A fluid volume element flowing along the axis is accelerated in the intake zone of the nozzle. In this zone there is elongated flow only. The geometry of the cup-like intake flow depends upon the flowrate and the viscoelastic properties of the fluid. No significant orientation takes place on entry of the volume element into the nozzle. After exit from the nozzle the flowrate of the solution increases further owing to expansion by evaporation of the solvent. The rapid evaporation also causes instant "freezing" of the elongated state of the macromolecules.

2.4. Extrusion of Multiphase Polymer Melts

Polymer fibrids with reproducible fiber length distribution can also be obtained by extrusion of polymer melts consisting of two or more phases, followed by cold elongation, pelletizing and refining[11]. Since the polymers are usually incompatible in the solid state, they split longitudinally at the phase interphase in the elongated state and polymer fibrids are obtained. Their dimensions are determined by both the degree of dispersion of the polymer melt and the degree of elongation of the extruded polymer mixture.

Addition of a hydrophilic polymer, *e.g.* polyvinyl alcohol (PVA) to the polymer melt enables concomitant hydrophilization of *e.g.* polyethylene/polypropylene fibrids. Microscopic and stereoscan photographs show that these fibrids are composed of two kinds of fibers, namely polyethylene/polypropylene fibers, with both polymers highly dispersed, and polyvinyl alcohol fibers.

2.5. Preparation of Hydrophilic Polyethylene Fibrids

Since most non-textile fibers are processed in aqueous systems, it is of great technical interest to render PE fibrids hydrophilic. Some methods used for the hydrophilization are described in the following Sections.

2.5.1. Post Adsorption

PE fibrids are capable of adsorbing a variety of water soluble organic compounds from aqueous solution. This method is technically simple, but only a part of the hydrophilization agent is taken up. Cationic, anionic and non-ionic surfactants of common structure render the hydrophilic fibers wettable, but they are only partially adsorbed and can be readily desorbed. Water soluble polymers like polyvinyl alcohol, polyethyleneimine or polyvinylpyrrolidone[12,13] effect an improved dispersibility of PE fibrids in water. In the case of PVA, the amount adsorbed can be increased by addition of salts (*e.g.* K_2SO_4)[14] or by prior reaction of the PVA with aliphatic aldehydes[15]. The same can be achieved by treatment of PE fibrids in swollen form with aqueous PVA solution[16]. The adsorption of special melamine-formaldehyde resins[17], polyoxalkylated urethane compounds[18] and acetals or ketals[19] as well as special nitrogen compounds[20–22] prevent the aqueous fiber suspension from foaming.

2.5.2. *In Situ* Hydrophilization

In the flash process, the hydrophilization agent is often added to the PE solution beforehand. While low molecular weight surfactants[23] are probably bound only after fibrid formation, in the case of high molecular compounds like polyvinyl alcohol, polyacrylamide, carboxymethylcellulose, sodium polyacrylate or polyvinylpyrrolidone one can expect a more solid anchoring by "freezing" of partially entangled macromolecules[24,25]. Thus, a higher portion of the hydrophilization agent can be bound this way.

2.5.3. Modification of Polyethylene

Special hydrophilization agents can be dispensed with if part of the polymer base is chemically modified. In this connection, copolymers of ethylene with maleic anhydride, sodium maleate, acrylic acid, sodium acrylate or allyl alcohol[26], or special block copolymers of ethylene and vinyl acetate, or also polyethylene, onto which acrylic acid is grafted, have been used[27]. The grafting step can also follow a partial oxidation step, *e.g.* with ozone[28].

3. Properties of Polyethylene Fibrids

3.1. Morphology

After comminution, PE fibrids—in contrast to cut staple fibers—have a highly branched structure of varying length and irregular diameter (Fig. 3).

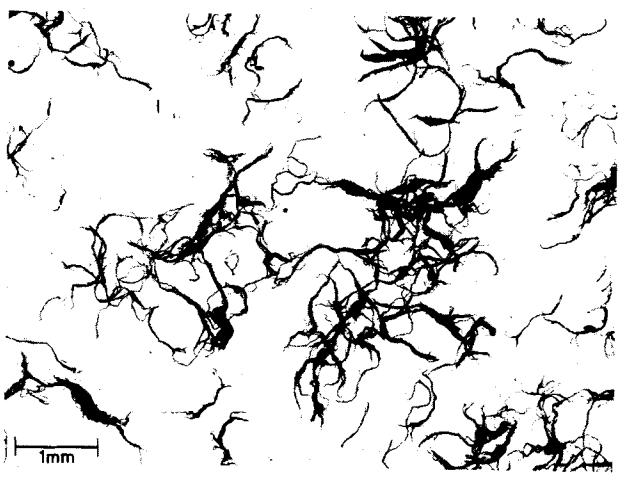

Fig. 3. PE fibrids dispersed in water.

The mean fiber length (CFL = classified fiber length)[29] of commercial PE fibrids ranges from 0.5 to 2.5 mm. Because of the low packing density, the branched fibrids take up a relatively large volume in the suspended form, thus leading to thixotropic flow peroperties of fibrid suspensions and to a high degree of hooking of the fibrids on filtration. The thixotropic flow properties are exploited by the building industry, *viz.* when Hostapulp® is added to trowelling compounds and surfacing textures. Because of this cellulose-like hooking,

papers having thermoplastic character can be manufactured on common paper machines. Since very long fibers in fiber slurries tend to cause flocculation and spinning, efforts are being directed at achieving narrow fiber-length distributions with presence of only small amounts of long fibers.

The crystal morphology of these fibrids is particularly interesting: Under the electron microscope the fibrids look like spindles, onto which disk-like structures are connected laterally, a composite structure reminiscent of a "Schaschlik" skewer (Fig. 4). For this structure, *Lindenmeyer* proposed the name "Shish-Kebab", which has been widely accepted. Figure 5 shows, how the molecular chains are arranged in this "Shish-Kebab" structure[30].

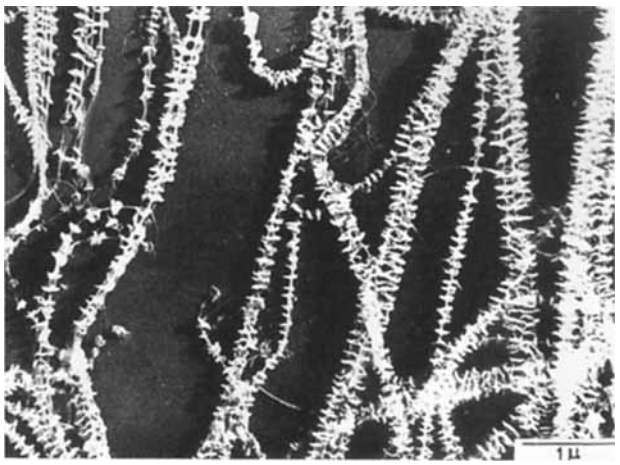

Fig. 4. Electronmicrophotographs of PE crystals obtained by shear induced crystallization [31].

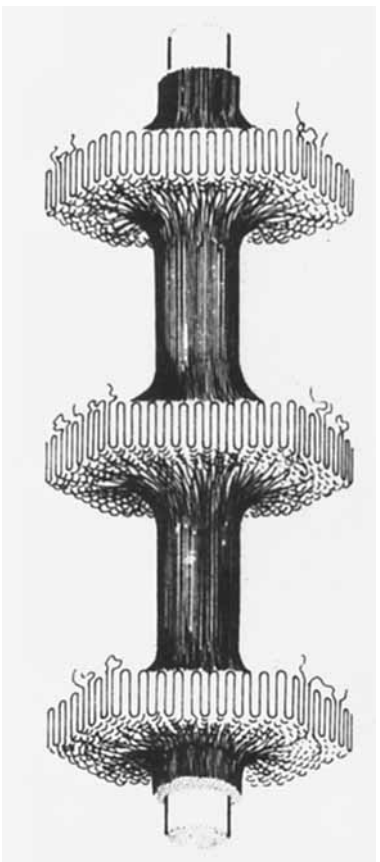

Fig. 5. Schematic arrangement of PE molecules in a Shish-Kebab structure [31].

Modern conceptions of the structure of fibrids have recently been reviewed by *Peterlin*[7]. The macromolecules of the fibril center are staggered and in the stretched state are arranged essentially parallel, while the lateral structures are formed by epitactical growth of folded molecular chains. Thus, the structures of the fibril center and of the lateral disks differ significantly. The latter can be dissolved from the fibril center by treatment with solvents or fuming nitric acid.

3.2. Mechanical Properties

Depending on the process and on the molecular weight, PE fibrids having quite different degrees of orientation and (consequently) quite different mechanical properties can be obtained.

The mechanical properties of shear induced crystals formed under isothermal conditions (see Section 2.2) are shown in Figure 6. These results were obtained by measurement of the stress/strain diagram of a fiber matte, formed around the interior cylinder of a reverse Couette arrangement, and from which the test specimen was taken perpendicularly to the cylinder axis[31].

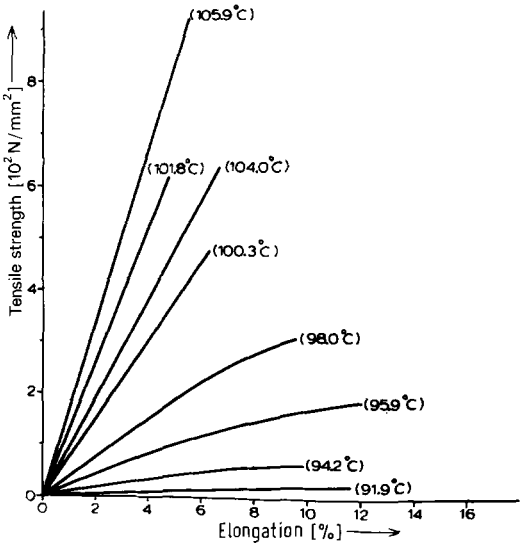

Fig. 6. Mechanical properties of PE crystal mattes obtained by shear induced crystallization [32]. Rate of stretch 3 cm/min. For details see text.

While the material obtained at 92 °C has a tensile strength comparable to that found for unoriented samples, fibers crystallized at higher temperatures have tensile strengths of up to 1000 N/mm^2. The Young's modulus of elasticity is found to increase symbatically with the increase in tensile strength. Determination of the mechanical properties of fibrids prepared by flash spinning of PE solutions, however, pose more problems, since these fibrids may contain internal cavities and the effective cross-section is not known. Even elaborate investigations provide only approximate values of the lower limit of the tensile strength (40—60 N/mm^2).

For most applications, fibrids with low single fiber strength may be used in combination with cellulose fibers, for, owing to their flexibility, they yield a paper having good strength properties. Since the mutual bonding of PE fibrids and cellulose fibers in paper is weaker than the inter-fiber bonding of cellulose fibers, the single fiber strength of the PE fibrids cannot

be exploited anyway. A content of PE fibrids is advantageous, *e.g.* for the dimensional stability (= reduced water absorption, swellability).

3.3. Thermal Properties

Since PE fibrids have two different crystalline morphologies, the DSC (differential scanning calorimeter) diagram of highly oriented fibrids shows two peaks. The peak at lower temperatures is assigned to the lamella form and the peak at higher temperatures to the stretched crystalline form of polyethylene. If the portion which crystallizes in the form of folded lamella is removed by extraction, the peak for the portion melting at lower temperatures is found to decrease[6, 31].

On melting, the stretched crystallized molecules tend to adopt the usual coil conformation, *i.e.* the molecules shrink longitudinally on melting[6]. Due to the necessary transfer of heat the process of shrinkage in a radial direction is delayed and therefore not complete. If the macromolecules melt in the exterior zone only, the are prevented from shrinking by the fibril center, which is still solid. Despite this impairment the degree of shrinkage is measurable and can be correlated with the orientation. According to *Pennings*, the shrinkage is larger, the higher the temperature of the shear induced crystallization[6].

In practice, thermal formability under pressure plays a very important role. For example, addition of PE fibrids renderes papers heat-sealable and embossible, and cardboards and corrugated papers are made considerably stiffer.

3.4. Surface Properties

The specific surface area of commercially available PE fibrids (5—10 m^2/g), measured according to the BET method, is larger than that of synthetic fibers (0.2—0.5 m^2/g) obtained by melt spinning. In some cases, surface areas of up to 100 m^2/g have been reported[32]. It is important that either a more lyophilic or a more hydrophilic character can be imposed on the PE fibrids depending on the chemical modification of the surface. PE fibrids with a large surface area have a high specific adsorption.

3.4.1. Lyophilic Properties

Because of their chemical structure and their shape, PE fibrids are good adsorbents for hydrocarbons. They adsorb hydrocarbons from water and from gases as well as from concentrated phases.

Figure 7 demonstrates the decrease in small quantities of white spirit dispersed in water on addition of PE fibrids[33]. Most of the droplets of hydrocarbons are mopped up due to the special shape and large hydrophobic surface area of the fibers.

Oil, for instance, can be thickened until a solid consistency is reached. Under specified conditions[34], PE fibrids are able to bind up to ten times their own weight of oil. The amount of oil that can be bound increases with increasing degree of fibrillation (degree of branching, see Fig. 3) and with decreasing hydrophilicity. The fibrids can, for example, be spread over oil-spills in inland waters by spraying an aqueous suspension with a fire hose. The resulting fibrid/oil mixture is, in

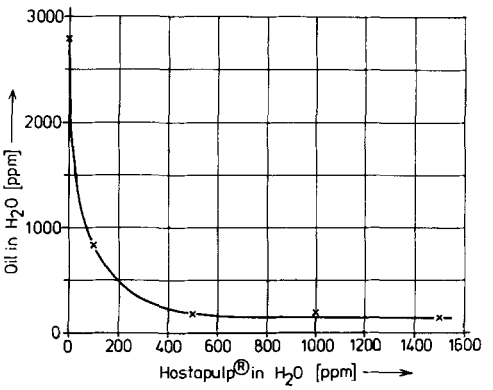

Fig. 7. The concentration of white spirit (b. p. 140—170°C) dispersed in water as a function of the concentration of added PE fibrids (Hostapulp®).

contrast to many other materials, *completely* floatable and can be removed mechanically from the water surface. Thus, PE fibrids are an invaluable material for the protection of the environment.

The removal of finely dispersed tar or nicotine droplets from cigarette smoke constitutes an important example of their use for the sorption of undesirable products from the gas phase. The specific binding capacity of PE fibrids has been found to be significantly higher than that of normal cellulose acetate filters.

3.4.2. Hydrophilic Properties

Hydrophilization not only makes the fibrids wettable, but also dispersible and thus mixable with other hydrophilic agents. The dispersibility is usually characterized by measurement of the flotation (tendency of the PE fibrids to float on account of their lower specific gravity) in 0.5% fiber suspensions (flotation factor[35]) and by measurement of their resistance to filtration (drainage factor) as defined and specified by the TAPPI Standard[36]. The dispersibility depends not only upon the nature and the quantity of the hydrophilization agent, but also largely upon the degree of slenderness and fibrillation of the fibrids. Commercial PE fibrids (*e.g.* Hostapulp®) having a high dispersibility usually contain up to 4% polyvinyl alcohol. The PVA content can be determined IR spectroscopically (peak at 3.0 μm) on molded films (of 0.1 mm thickness)[37].

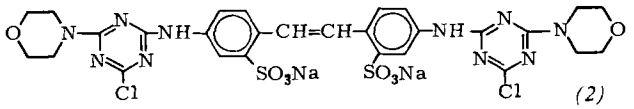
In papermaking, the hydrophilization of PE fibrids is a very important factor regarding the quality of the paper. Even a small number of fiber flocs, formed from insufficiently hydrophylized fibrids, interfere in this case. Other applications, in which hydrophilization is essential, include, for instance, the production of porous pipes by wet molding and the mixing of fibrids in building materials.

3.5. Chemical Properties

PE fibrids modified with polyvinyl alcohol enable further modifications by chemical reactions on the surface. A few examples are described in the following chapters.

3.5.1. Formation of Hydrogen Bonds

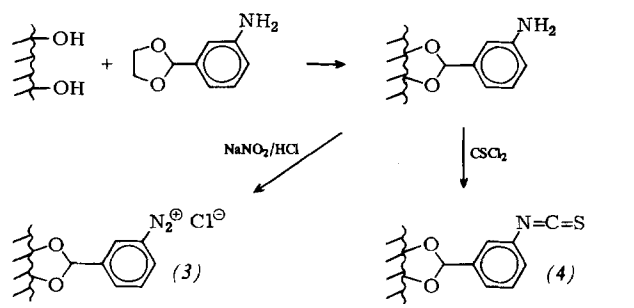
It is assumed that hydrogen bonds, which are important for dispersibility in water, are formed not only between PE



fibrids and water molecules, but also between the fibrids themselves and between fibrids and cellulose. This can be concluded from the mechanical properties of papers containing PE fibrids. Hydrogen bonding, however, is less important than in the case of cellulose fibers, since the latter, after comminution and swelling in water and shrinkage during drying, have a larger contact area than the non-swellable PE fibrids.

3.5.2. Reactions on the Surface

Polyvinyl alcohol can be fixed almost irreversibly to PE fibrids (*e.g.* Hostapulp®). This provides the opportunity for topochemical reactions, in which the reaction product is also fixed to the PE fibrid surface. This can be readily illustrated by the reactions with the fluorogenic dyes *(1)* and *(2)*; in the case of *(1)* the intermediate vinyl sulfone is the reacting agent, and in the case of *(2)* the Cl atom is substituted[38].



(1)

(2)

After acetalization with 2-(3-aminophenyl)dioxolane the diazonium chloride *(3)* or the isothiocyanate *(4)* can be prepared and then enzymes like trypsin or papain can be coupled to the PVA modified PE fibrids[39].

(3) *(4)*

Besides their use as carriers for enzymes, PVA modified fibrids may also be suitable as polymer catalysts and as carriers for affinity chromatography.

Further interesting examples of their practical utility include their reaction with melamine-formaldehyde (for the manufacture of decorative furnishings) and their reaction with isocyanates (incorporation into polyurethane foams). In the latter case, the PVA modified PE fibrids have the advantage of being readily dispersible in polyols. In contrast to common synthetic fibers they contribute by way of surface reaction of the OH groups to the formation of the polyurethane network. In the manufacture of polyurethane foam, PVA modified PE fibrids function not only as crosslinking agents, but also as polymeric fillers. This leads to characteristic changes in the compression curves and to improved comfort in the manufacture of seats *etc.*; this cannot be achieved when fibers are incorporated which do not have reactive groups on their surface[40].

4. Outlook

Since the oil crisis, the development of polyethylene fibrids has been governed by the raw material situation. While initial studies on these new materials were mainly directed at the replacement of cellulose fibers, the fields of application have now broadened in scope. Papermaking is still one area of usage, but only if the *special properties* of polyethylene fibrids like flexibility, dimensional stability or meltability need to be exploited. New possible applications derive from the high adsorption power or from the chemical reactivity of hydrophylized fibrids (*e.g.* analytical and preparative chromatography and biological/clinical analysis). Studies on fibrids containing fillers are still incomplete. The incorporation of (mineral) fillers opens up possibilities for the modification of mechanical and optical properties and for the enlargement of internal surface area by subsequent dissolution of the filler particles.

The objective of future studies will be the extension of these findings to fibrids of other polymers and the exploitation of the novel *combination of properties* of this new class of polymers.

Lise Meitner: Her Life and Times— On the Centenary of the Great Scientist's Birth

By Fritz Krafft[*]

Cooperation between the three scientists *Lise Meitner*, *Otto Hahn*, and *Fritz Strassmann* in the study of the "transuranics" (1934—1938) prepared the way for the chemical identification of a first fission product of uranium by *Otto Hahn* and *Fritz Strassmann* at the end of 1938. Together with her nephew *Otto Robert Frisch*, she also gave the first theoretical interpretation of that experimental finding (barium instead of the expected radium) and suggested the inert gas krypton to be the second fission product, which *Hahn* and *Strassmann* subsequently identified (besides xenon) among the products. But she was kept from direct participation in the experiments conducted at the Kaiser Wilhelm Institute for Chemistry at Berlin—and therefore from the unrestricted claim to being co-discoverer of uranium fission—because she was an Austrian "Jewess". Thus after the "annexation" of Austria by the German Reich, the Nazi racial laws also applied to her and precluded her continuing to work in Germany. She therefore emigrated illegally *via* Holland to Sweden in the middle of 1938. There she continued to work on problems of nuclear physics under less favorable conditions until 1960. Work on radioactivity already started at Vienna had also brought her together with *Hahn* at Berlin in 1907, and she continued the work at the Kaiser Wilhelm Institute studying α-, β-, and γ-radiation and related nuclear processes. Not only because of her descent, but also because of her status of a woman in science, her fate was molded by the circumstances prevailing in Germany prior to World War II. On November 7, 1978 *Lise Meitner* would have celebrated her hundredth birthday, reason enough for recalling her lot as a woman scientist in Germany against the background of her times, which should stand as a warning to us. To that end contemporary documents could be quoted which till now were largely unknown.

"Vintage 1879"

Max Planck once jokingly said of those born in 1879 that they had been especially predestined for physics and chemistry; *Albert Einstein*, *Max von Laue*, and *Otto Hahn* were born in that year, and *Lise Meitner* should also be ranked among them, but as an impetuous female she had already been born in November 1878; she could not wait for the next year[1]. The same fact is documented in a Festschrift "Lise Meitner, Otto Hahn, Max von Laue zum 80. Geburtstag" (Beiträge zur Physik und Chemie des 20. Jahrhunderts)[2]; the contributions are arranged according to their ages: *Meitner* (born November 7, 1878), *Hahn* (born March 8, 1879), *von Laue* (born October 9, 1879). Therefore the name of *Lise Meitner* will also be found alongside those of *Einstein*, *Hahn*, and *von Laue* at the celebrations planned for next year to commemorate the centenary of those German Nobel Laureates in physics and chemistry.

Lise Meitner is to be regarded as one of the most important women in science, whose name ranks on a level with those of *Marie Curie* and her daughter *Irène Joliot-Curie*. *Albert Einstein* therefore once named her "the German Madame Curie". It was not only her quiet female charm, her elegance, her kindness, and cordiality, but also her quality as a physicist of equal standing that gained her admittance to the circle of contemporary physicists. In addition, her femininity also endowed the Berlin circle of scientists of the twenties and early thirties[3] with an exceptional quality that will also become the jubilee triumvirate in 1979. Being "older" than the others, however, she will have her own, earlier celebration, although she always tried to avoid such celebrations of her person and her achievements. Let us therefore consider not her famous historical achievements in the fields of nuclear physics (and chemistry)—that has already happened more often than she would have liked, for example in this journal[4], both during her lifetime[5] and in obituary notices[6] about her long, full, but also hard life—but instead her lot as molded by the times in which she lived[7].

Of the four scientists she certainly led the hardest life—being a woman on the one hand and of Jewish descent on the other. However, that did not make her in the least bitter, but reinforced her natural sense of fairness and formed and kept awake her political thinking. She never worked on the principle that other people should think and act like herself, and even continued to feel friendship for other people after they had disappointed her in precisely that point, as she clearly told them. That characteristic also distinguished her as a teacher and a member of a team; *Fritz Strassmann* referred to the years spent together at Berlin at the Kaiser Wilhelm Institute for Chemistry when he wrote[8]:

> "... it turned out that she deserved just as much respect in her taking care of, and in the training and guidance of the rising scientific generation as in her character as a human and scientist. Herself being inspired by an indefatigable interest in work, she ... knew that in the long run it better serves the ends of research and researchers not to force one's own working speed upon the co-worker; and what

[*] Prof. Dr. Fritz Krafft
Arbeitsgruppe für Geschichte der Naturwissenschaft
Fachbereich Mathematik der Universität
Saarstrasse 21, D-6500 Mainz (Germany)

is more remarkable, she had the self-control to act on that judgment."

From Vienna to Berlin

Lise Meitner was born at Vienna on November 7, 1878 as the third of eight children of a lawyer. Both her parents had Jewish ancestors and her father was a Freethinker, but all the children were baptized and *Lise* was brought up as a Protestant. Even as a child she showed a great interest in mathematics and the working of nature and its causes[9], but in the late 19th century it was still too unusual for a young girl to become a student, especially a science student. So she followed her parents' will and after she left school—not yet with the "Matura" (school leaving certificate) which permits study at a university—she first qualified as a teacher of French, before she was coached privately along with two other girls for the "externe Matura" (external school leaving examination) at the Academic Gymnasium at Vienna, a boy's school. *Arthur Szarvasy* taught her and two other young ladies mathematics and physics. At that time he was a lecturer at Vienna University and later became professor of experimental physics at the Technische Hochschule in Brno. Right until the end of her life she remembered him as a extremely gifted teacher who could not only present the subject matter of mathematics and physics in a most stimulating way but could also—owing to his position at the University—show his girl students new physical apparatus, which would have been impossible at a school. Together with three other girls out of fourteen, *Lise Meitner* passed her Matura examination in 1901 and she began to study physics, mathematics and philosophy—the latter still being a compulsory subject. At the same time she also completed her probationary year at a girls' school in order to keep open the possibility of supporting herself as a teacher if the need should arise. At University she was especially impressed by *Ludwig Boltzmann*'s lectures (1902—1906), which she remembers to have been delivered with enthusiastic passion, but which did not mention the new developments which had been contributed to theoretical physics by *Max Planck* and *Albert Einstein*. *Anton Lampa* too, who directed the practical laboratory courses (which had been equipped with extremely primitive apparatus)[10], was rather sceptical towards modern physics. He had been influenced by *Ernst Mach* and was more interested in epistemological and philosophical questions than in real physics—in the opinion of *Lise Meitner*. Her doctoral thesis "Heat Conduction in Inhomogeneous Materials" was written under the supervision of *Franz Seraphin Exner* and his assistant *Hans Benndorf*. Female candidates for a doctor's degree were still something out of the ordinary at that time at Vienna, too. The first woman postgraduate had been *Gabriele Baronin Possander* (medicine, 1897); *Adele Gräfin Wartensleben* (classics)—who later founded the first commercial school for girls at Vienna—had been a pioneer at the faculty of philosophy; and *Olga Steindler* was the first woman to gain a doctorate in physics in 1903. *Lise Meitner* and *Selma Freud* followed in 1906.

In her thesis *Lise Meitner* had proved experimentally that Maxwell's formula for conduction of electricity in inhomogeneous materials also holds for thermal conduction in mercury ointments. Her second paper dealt with "Conclusions that are to be drawn from Fresnel's reflection formulae"; it was published in 1906 in the proceedings of the Preussische Akademie der Wissenschaften. For her later work it was decisive that after *Ludwig Boltzmann*'s death his institute was taken over temporarily by *Stefan Meyer* and that she could go on with her experimental work. *Meyer* had devoted his attention to the new field of radioactivity. Together with *Egon von Schweidler* he had discovered the magnetic deflection of "radium rays" (later called β-rays) in 1910, and he worked intensively on methods of measurement of radioactive matter. Using ThB and AcB preparations, *Lise Meitner* carried out measurements on the absorption of α- and β-radiation with Pt, Au, Ag, Cu, Sn, and Al[11]. This was her introduction to modern physics. At that time she heard *Max Planck*'s name for the first time, because after *Boltzmann*'s death he had been invited to take his post at Vienna and came to Vienna to look around the institute. That raised her desire to spend several semesters at Berlin in order to gain "a real understanding of physics". Her parents complied with her desire and granted her a small allowance[12]:

> "When I registered with *Planck* at the University in Berlin, so as to attend his lectures, he received me very kindly and soon afterwards invited me to his home. The first time I visited him there, he said to me: "But you are a Doctor already! What more do you want?" When I replied that I would like to gain some real understanding of physics, he just said a few friendly words and I did not pursue the matter any further. Naturally I concluded that he could have no very high opinion of women students, and possibly that was true enough at the time."

Admittedly at that time *Max Planck* was no longer absolutely hostile towards women students, but he did not advocate them without reservation either. That would have contradicted his rather conservative attitude. But *Lise Meitner* could not have known that.

In 1896 girls had been granted permission to take the school leaving examination (Abitur) in Germany, and the general admission to the universities was just a question of time—it was granted by law in 1900, in Prussia in 1908. The contemporary discussion on the *pro* and *contra* is documented by a collection of comments of 104 university professors and lecturers, when they answered the following questions of *Arthur Kirchhoff*: "What are the reasons to be stated in general, and from the special point of view of your discipline, for or against women students at universities? What are the preliminary studies the young girls should receive, and is it permissable for both sexes to study together at university?"[13]. *Max Planck* was one of the "experts" and among other things he wrote[14]:

> "In theoretical physics, the subject which I represent, that question has not as yet become so acute that it would require a special statement as far as I am concerned ... If a woman has a special gift for the tasks of theoretical physics—which does not happen often, but it does happen sometimes—and moreover in herself she feels moved to develop her gift, I do not think it right—both personally and impersonally—to refuse her the chance and means of studying for reasons of principle; *if it is at all compatible*

with academic order, I shall readily consent to their admission—*on approval and always revocably*—to my lectures and my practical courses, and in that respect up to this point I have had nothing but favorable experience.

On the other hand I must keep to the fact that such a case must always be regarded just as an *exception* ... Generally it cannot be emphasized enough that nature herself prescribed to the woman her function as mother and housewife, and that laws of nature cannot be ignored under any circumstances without grave damage, which in the case under discussion would especially manifest itself in the following generation."

Of course, *Lise Meitner* was not aware of that conservative point of view, which was even sanctioned *de jure* in 1907 at Berlin (unlike Vienna). Nor did she ever experience its effects, because *Planck* seems to have realized very soon that the young lady from Vienna was one of his approved gifted exceptions with the "inner urge" for physics. Not only was she one of the older students and assistants whom he invited to his home, but a warm friendship also developed between the *Plancks*, their daughters, and *Lise Meitner*[15]. In 1912 she became his assistant and she held that post until mid-1915, when she volunteered as a X-ray nurse in a hospital on the Austrian front, after she had attended special courses at Berlin-Lichterfelde hospital.

Besides attending theoretical lectures, *Lise Meitner* wanted to continue experimental work, as she had already done at Vienna. So she applied to the head of the institute of experimental physics at Berlin—*Heinrich Rubens*—and asked for a place in his laboratories. The only place *Rubens* was able to offer her was one in his own private laboratory, where she could work "under his direction, that is, to a certain extent with him"[16]: "Now it was quite clear to me [*i.e. Lise Meitner*] then, as a beginner, how important it would be for me to be able to ask about anything I did not understand, and it was no less clear to me that I should not have the courage to ask Professor *Rubens*." When—owing to those considerations—she hesitated to answer, *Rubens* added that *Otto Hahn* had indicated that he would be interested in collaborating with her. *Hahn* wanted the help of a physicist for his new field of radiochemistry which he had introduced at Berlin and in which he had qualified for inauguration as an academic lecturer (Habilitation) in 1907. *Lise Meitner* had already worked on radioactivity as a physicist. Having spent almost a year in America, *Hahn* was accustomed to collaboration with young women who were of the same age. He even had a marked soft spot for the "weaker" sex which he preserved to the last. "... and *Hahn* himself came a few minutes later. *Hahn* was of the same age as myself and very informal in manner, and I had the feeling that I would have no hesitation in asking him all I needed to know. Moreover, he had a very good reputation in radioactivity, so I was convinced that he could teach me a great deal."

But there was a difficulty. *Otto Hahn* did not work at *Rubens*' institute, but instead at the institute of the chemist *Emil Fischer*. And everybody knew that *Emil Fischer* cherished a strong aversion to women in the laboratories. Later on he told *Lise Meitner* that this dislike "stemmed from his constant worry with a Russian student lest her rather exotic hairstyle result in its catching fire on the Bunsen burner". So he refused *Lise Meitner*'s request to work together with the male students in the laboratory of the chemical institute directed by *Otto Hahn*. But there was a chance: In the summer of 1906 *Otto Hahn* had come to *Emil Fischer* with good recommendations from *Ernest Rutherford* and *Sir William Ramsay* and for his radiochemical work *Fischer* had placed at his disposal a room in the basement of the institute that had once been used as a carpenter's workshop (Holzwerkstatt), and that room had a detached entrance[17]. There she was allowed to work, provided she did not enter those rooms of the institute which were used by male students. *Lise Meitner* reported that later, when the attendance of women at university had been officially sanctioned even in the Prussian city of Berlin (1908/09), he immediately lifted that restriction.

What initially appeared to be the usual kind of discrimination—although *Lise Meitner* did not feel that way, since she was only interested in experimental work—soon turned out to be a great opportunity. Even so, it still happened that when the assistants of the chemical institute met her and *Hahn* they somewhat obviously greeted them with: "Guten Tag, Herr Hahn!"[18]. However she was soon admitted to the circle of the Berlin scientists through *Max Planck*, *Emil Fischer*, *Heinrich Rubens*, and *Otto Hahn*. She met *Max von Laue* at *Planck*'s lectures and at his house and other young physicists like *Rubens*' assistants *Otto von Baeyer*, *James Franck*, *Gustav Hertz*, *Robert Pohl*, *Peter Pringsheim*, and *Emil Regener* particularly at the Physical Colloquy. Not only in the twenties, but as early as 1907 that colloquy had been an intellectual center of excellence, where the leading authorities from all over the world gave lectures on the most recent results in physics, chemistry, and astrophysics. "It was quite extraordinary what one could acquire there in the way of knowledge and learning"[19]. At first, *Emil Fischer* had been very sceptical towards the "new-fangled" discipline of radiochemistry and he had accepted *Otto Hahn* merely because of his teachers' recommendations, but as soon as the first successful results were announced from the "Holzwerkstatt" he changed his mind and stood by the young people, who had formerly been left to their own resources, encouraging them where possible—and later on he obtained excellent possibilities of advancement.

The basis for these developments was the close and complementary collaboration of *Otto Hahn* and *Lise Meitner*. What originally had been meant to be a short stay at Berlin in order to benefit from further education turned into more than thirty years of a very cordial friendship and a successful scientific collaboration, which was only terminated in mid-1938 by the Nazi race laws.

As long as she stayed in German, she never had a German passport—even after March 13, 1938, the day of the "annexation" of Austria by the German Reich—but she had worked as a physicist in Germany and there she had gained her reputation: Since 1908 the *Hahn-Meitner* partnership had become a byword among experts, like the *Hahn-Meitner-Strassmann* team in the mid-thirties. When her old friend from Berlin, *Elisabeth Schiemann*, a specialist in plant genetics, asked her in 1947, when they met in London, whether she would not consider going back to Austria, she answered—as she wrote in a letter from June 8, 1947, to *Otto Hahn*[20]—: "I couldn't go *back* to Austria, since I never held a post there, but in Germany." It must have been grievous

for her to draw the possible conclusion from the answer that Austria could set up a post for her that "they do not want me in Germany?" Her real sphere of activity had been Germany and her pathway had been directed by the situation prevailing at various times in Germany. In Sweden she always felt an exile—mainly because she never gained a perfect command of the language—although facilities for work (albeit modest facilities) had been placed at her disposal there. Once having revisited Germany with rather mixed feelings on the occasion of the commemoration held in honor of Max Planck in April 1948 she always enjoyed subsequent visits to Germany. After the war she used all her influence abroad to further the international reinstatement of German scientists. She also helped a great number of colleagues—whether they were friends or not—to get over the first hard post-war years by sending them food parcels. But she could not make up her mind to "come back" to Germany—although *Fritz Strassmann* and *Otto Hahn* had offered her the post of her successor, *Josef Mattauch*, in 1947, *i.e.* then the post of the head of the old Kaiser Wilhelm Institute for Chemistry (now called the Max Planck Institute) which had been transferred to Mainz. Some years later she might have accepted that offer to return to her old sphere of activity, but on December 21, 1947, she wrote to *Strassmann*[21]:

> "The question you asked me in your last letter is rather fateful, and I have tried to think it over with all its consequences. Accordingly, it seems to me that I should be better informed before I can reach a decision with a clear conscience; above all I ought to know who are the present members of the staff of the chemical and physical departments. Quite frankly, if the inquiry hadn't been from you, my answer couldn't have been other than "No", although the longing for my old sphere of activity has never ceased. But what is left of that circle and what does it look like in the minds of the younger generation? Add to this the fact that I'm neither gifted nor inclined to ignore things that are depressing. I closely followed all the horrible events Hitler's system had brought along with it, and tried to understand them on the basis of their reasons and consequences; and that means that my view of various problems will probably differ from those of the majority of my German friends and colleagues. Would we be able to understand each other? And certainly mutual human understanding is the essential basis of a real collaboration. I have no doubts about you, but that is not enough, you know".

And on June 6, 1948, she wrote to *Hahn*[22]:

> "... In any case I believe that I cannot accept the post at Mainz. I am not afraid of unfavorable living conditions, but I do have considerable scruples about the intellectual mentality. If my view about anything which doesn't belong to physics were to differ from that of my colleagues, it would certainly be met by the words: Of course she doesn't understand the German situation, because she is an Austrian, or, because she is of Jewish descent. I also stressed those scruples when I wrote to *Strassmann*, and he didn't reply except by repeating his assertion of how important I'd be to the institute. So he didn't dare refute my scruples. That means that I couldn't count upon the confidence of the younger colleagues which I formerly had and which, in my opinion, is always—and particularly nowadays—the most important basis of good collaboration... It would become a fight similar to that which I had fought from '33 to '38 with very little success—and today it is very clear to me that it was a grave moral fault not to leave Germany in '33, since in effect by staying there I supported Hitlerism. While those moral scruples don't exist today, in view of the general mentality, my personal situation wouldn't differ much from my situation at that time, and I wouldn't really have the confidence of my colleagues, and therefore I couldn't really be of any use ..."

So only the memory of the years shared at Berlin were left to her—in the meantime *Otto Hahn* himself had become president of what was now called the Max-Planck-Gesellschaft and lived at Göttingen.

At the Kaiser Wilhelm Institute for Chemistry at Berlin-Dahlem

After a few years *Emil Fischer* assigned *Otto Hahn* and *Lise Meitner* a further room in addition to the former "Holzwerkstatt", where they could carry out their radiation measurements. From the very first *Alfred Stock*, head of the inorganic department, had placed a room in his private laboratory at *Hahn*'s disposal, where he could carry out his chemical studies and which he had been able to keep when *Alfred Stock* was succeeded by *Franz Fischer*. So the small "radioactive" team had three rooms at their disposal[23], after *Lise Meitner* had been given access to the other rooms. Now she could also participate in purely chemical work, like the fractional crystallization of radioactive preparations. Their first joint studies concerned the absorption of β-radiation of the radioelements. Although the experimental "verification" of a theory due to *Heinrich Willy Schmidt*—that the absorption of homogeneous β-radiation should follow an exponential law—which they provided by exposing aluminum to various kinds of β-radiation[24], later on turned out to be wrong, the studies and their results afforded the ways and means for the discovery of new β-emitters and for the first analysis of radioactive preparations by way of magnetic β-radiation spectra (together with *Otto von Baeyer*). Moreover, those investigations were also the starting point for *Lise Meitner*'s later work on β- and γ-radiation, in which her staff then became engaged. The application of radioaktive recoil to the discovery and separation of new disintegration products from active precipitates (1909) discovered by *Otto Hahn* was also instigated by *Lise Meitner*[25].

Shortly afterwards completely new working facilities became available[26]: In 1887 the Physikalisch-Technische Reichsanstalt had been founded at the instigation of those industries which had a physical and technical slant, and the demand soon arose for a corresponding chemical institute. The plan took shape in 1905 and in 1908 the "Verein Chemische Reichsanstalt" was founded with leading chemists from German universities and from the chemical industry as members (*Emil Fischer, Walther Nernst, Carl Duisberg, et al.*). *Ernst Beckmann*, at that time director of the laboratory for applied chemistry at Leipzig, was persuaded to become the president. In spite of considerable funds raised by the member corporations, the plan could not be realized, because the Reich was unwilling to meet the high costs of maintenance.

However, facilities were made available by the "Kaiser Wilhelm Society for the Advancement of the Sciences" which was proclaimed on October 11, 1910, by Kaiser Wilhelm II at the centenary of Berlin University. The "Verein" decided to join the Kaiser Wilhelm Society in order to found a chemical institute. On December 23, 1911, the contract was signed: The "Verein Chemische Reichsanstalt"—*Emil Fischer* was then chairman of the executive committee—declared their willingness to bear the greater part of the building costs and half the running costs (staff and equipment) of that institute, which was now to further pure research in contrast to the initial intentions. The institute was built in record time and together with the Kaiser Wilhelm Institute for Physical Chemistry and Electro-Chemistry—likewise sponsored by the Leopold-Koppel-Stiftung—the Kaiser Wilhelm Institute for Chemistry at Berlin-Dahlem was the first of the Kaiser Wilhelm Institutes to be established. The inaugural ceremony took place on October 23, 1912. *Ernst Beckmann* was appointed director and head of the department for inorganic and physical chemistry; *Richard Willstätter*—head of the department for organic chemistry—and *Otto Hahn*—head of a small department for radiochemistry—also became academic members (Wissenschaftliche Mitglieder).

In 1916, *Alfred Stock* succeeded *Willstätter* as director. *Beckmann* retired at the end of 1921. The rooms of his department were then occupied by *Kurt Hess*, whose department was completely supported by the IG Farbenindustrie A.G. from 1931 when it assumed the status of "guest department". In 1924 *Otto Hahn* had been appointed "Deputy Director" in order to prevent him from accepting the offer of a chair at the Technische Hochschule of Hannover, and he became executive director when *Stock* retired at the end of 1926. Since *Stock*'s department could not be continued, *Hahn* was made head of the whole institute in 1929, which position he held until he became president of the Kaiser Wilhelm (Max Planck) Society after World War II.

Lise Meitner initially joined *Hahn*'s department at the Kaiser Wilhelm Institute as a guest, but had already been appointed "Wissenschaftliches Mitglied" by 1913.—The University of Prague had offered her a lecturer's post with prospects of a professorship.—From 1912 to 1915 she was still *Max Planck*'s assistant, then she worked in an Austrian hospital at the front until the autumn of 1917. In 1917 she became the head of a department of her own, set up through *Emil Fischer*'s good offices with I.G. Farbenindustrie A.G.[27]. She was also given the title of professor. The department for radioactivity was divided into a "chemical-radioactive" *(Hahn)* and a "physical-radioactive" *(Meitner)* department. However, it continued to be budgeted for as a single unit, the "*Hahn/Meitner* department", until *Otto Hahn* became director and the other departments were dissolved.

At the end of 1921 the "Verein Chemische Reichsanstalt" was dissolved and succeeded by the "Emil Fischer Society for the Advancement of Chemical Research", which till then had born almost the entire costs, while the Kaiser Wilhelm Society had provided only a very small extra allowance. However, it was not only the different financial basis which had created new possibilities for research since 1912. Probably even more important with regard to the subsequent chemical and physical investigation of natural and later also of artificial radioactive substances was the move to a newly erected building. The "Holzwerkstatt" had become radioactively contaminated, and it would soon have been impossible to study weakly radioactive substances. Nevertheless, *Otto Hahn* and *Lise Meitner* learnt from experience. In the new building they worked with extreme care and discipline from the very first, and so did their staff (*e.g.* smoking was prohibited in all the laboratories). As a result there was practically no radioactive contamination to be found in the laboratories until they were moved to Tailfingen in 1944, and they could still work with extremely weak emitters that could barely be detected by the counters available at that time.

Their team work—which in spite of the breaks during the First World War had already led to the discovery of the parent of actinium, *i.e.* "protactinium", in 1917[28] came to an end in 1920. *Lise Meitner*'s department for radiophysical work had then been set up and she had been given assistants of her own, thus enabling her to start independent work. It was not before the autumn of 1934 that *Lise Meitner* and *Otto Hahn* again started working as a team—while simultaneously conducting separate investigations in their respective departments with their own staff. In the meantime, *Lise Meitner* had been occupied particularly with physical research into α-, β-, and γ-radiation and related nuclear processes. Her studies on secondary β-radiation are an outstanding example: In 1925 she decided the controversial question concerning the sequence of fast nuclear processes by proving that the secondary β-radiation derives from the electron shell of the atom formed by the transformation. So γ-radiation had to succeed β-transformation[29]. She did not develop new apparatus, but she introduced *e.g.* Wilson's cloud chamber, which had hardly been used since its invention (in 1911), to Berlin and together with her staff she introduced refinements so that it could be used for the study of slow electrons. She also succeeded in taking the first pictures of traces of positrons excited by γ-radiation[30], and she was one of the first to demonstrate pair production (electron/positron) from high-energy γ-radiation.

In 1934 a new chapter began in nuclear physics. The neutron had been discovered by *James Chadwick* in 1932 and artificial radioactivity by *Irène Joliot-Curie* and *Frédéric Joliot* in 1934. *Enrico Fermi* then realized that the neutron—being devoid of electric charge—is especially equipped to penetrate heavy atomic nuclei where they would trigger nuclear reactions. This field of research led *Lise Meitner* and *Otto Hahn* to embark on a further team project—at that time when she, according to her later judgment[31], should long have left Germany like so many other intellectuals.

The Years between the Wars in Germany

"Sex" and "Race"

At the end of the nineteenth century universities had begun to open their doors to women in the German Reich[32]. During the World War I, girls and women had unselfishly given of their best in various fields. And that undoubtedly accelerated the general admission of women to teaching positions at universities[33], after the introduction of universal suffrage in 1918. In the very same year, the first woman passed her "Habilitation" examination; she was the physicist *Hedwig Kohn*

(born in 1887 at Breslau) at the University of Breslau. In the year 1919, there followed the anatomist *Adele Hartmann* (1881 Neu Ulm—1937 Munich) at Munich, the mathematician *Emmy Noether* (1882 Erlangen—1935 Bryan, Penn./USA) at Göttingen, the archaeologist *Margarete Bieber* (born 1879 Schönau, West-Prussia) at Giessen, and the Germanist *Agathe Lasch* (1879 Berlin—1934) at Hamburg. At the Prussian universities women did not have the chance and right to qualify for a professorship (Habilitation) before a corresponding decree was issued by the Prussian Minister of Science, Arts, and Education on February 21, 1920[34] in reply to a petition of the philosopher and disciple of *Edmund Husserl*, *Edith Stein* (1891 Breslau—1942 Auschwitz), lodged on December 12, 1919. In 1922 *Lise Meitner* became the second woman to receive the *venia legendi* in physics at a German university, and the first one within Prussia. Next came *Herta Sponer* (born in 1895 at Neisse) at Göttingen in 1925[35].—Keeping in mind the novelty of female university lecturers, it is interesting to note that the subject of *Lise Meitner*'s inaugural lecture ("Problems of Cosmic Physics") was reported in the press, due to a "Freudian slip", as "Problems of Cosmetic Physics"[36]. Of course, she was exempted from other obligations which normally go with Habilitation.—Before World War II there were only two women in Germany who received the *venia legendi* in chemistry: *Maria Lipp*, née *Bredt-Savelsberg* (1892 Stollberg—1966 Cologne), 1923 at Aix-la-Chapelle, and *Gertrud Kornfeld* (1891 Prague) 1928 at Berlin.

Apart from *Maria Lipp* all the women mentioned above, like most of the other women who had been university lecturers or instructors, fell victim to Paragraph 3 (the so-called "Arierparagraph": retirement of dismissal of civil servants of non-Aryan descent) or Paragraph 4 (dismissal for political reasons) of the "Gesetz zur Wiederherstellung des Berufsbeamtentums" ("Law for the Re-establishment of the Professional Civil Service")[37] and were discharged or dismissed in 1933/34—*Lise Meitner* lost her authority to teach at Berlin University ("Lehrbefugnis") on September 6, 1939—or they fell victim to the Nazi regime's fundamental aversion to female university lecturers. Of those mentioned, *Margarete Bieber*, *Hedwig Kohn*, *Gertrud Kornfeld*, *Emmy Noether*, and *Herta Sponer* had to emigrate in 1933, and in 1938 *Lise Meitner* and *Edith Stein* escaped to Holland, where the latter was arrested in 1942 and deported to Auschwitz. Thus the well-known losses to German science from 1933 to 1939 resulting from racial and political prosecution by the Nazi regime or by voluntary emigration[38] affected women to a much greater extent, and meant a great setback to the academic feminist movement in Germany. It could be overcome only little by little after World War II[39]. *Lise Meitner* actively supported these efforts, especially after the war, in Sweden, America, Germany, and Austria, and she lectured on her own area of research and on general physical topics at various meetings of women[40].

In 1933 she had not yet been affected personally. The withdrawal of her "Lehrbefugnis" because of her Jewish descent (in 1922 she had become "Privatdozent" and in 1926 appointed extraordinary professor at Berlin University) did not involve any decisive changes, for she had never given any lectures at the university and for the time being she was still allowed to attend the Physical Colloquy at Berlin. Unlike the universities and other Kaiser Wilhelm institutes the K.W.I. for Chemistry was not completely subject to legislation concerning the Civil Service, owing to the fact that it was sponsored by the Emil Fischer Society. Therefore there was no need for any particular intercession for colleagues who were affected—unlike the universities, academies, and public hospitals, where some courageous people stood up for their Jewish colleagues, although in vain[41]. Besides, *Lise Meitner* was not subject to direct public prosecution or discrimination because she was an Austrian (*i.e.* an alien).—All that necessarily changed after the "annexation" of Austria by the German Reich on March 13, 1938.

From that day on, what had begun before the eyes of the German people on April 1, 1933, the "Day of the Boycott of Jews", was intensified. It culminated preliminarily in the organized pogrom of the "Reichskristallnacht" of November 9, 1938, and the consequences that followed the "Atonement of the Jews", ordained on November 12 and completely eliminated Jews from business and cultural life[42]: The Jewish congregations, till then corporations of public law, were declared private associations (March 28); the orders against "camouflage of Jewish trade and business" (April 22), on the declaration of Jewish properties of more than 5000 RM (April 26), and on the registration and special marking of Jewish businesses (June 14) were enacted; the so-called "action against antisocial elements" went into effect (June 14); identity cards for Jews became compulsory after January 1939 (June 23); the licences of Jewish doctors were cancelled on September 30, 1938 (July 25); Jews were to bear the names Sarah or Israel after January 1, 1939, if the name was not already clearly recognizable as Jewish (August 17); the licences of Jewish lawyers were cancelled on November 30 (September 27); the passports of Jews were marked with a "J" (October 5). By November 15 all Jewish children were excluded from general attendance at school; on November 28 housing restrictions came into force; and on January 17, 1939, the protection of tenants was cancelled; while the law on the "Aryanization" of Jewish business had already been enacted on December, 13. On October 28, 1938, about 17000 Jews "having no nationality" had been expelled from Germany over the Polish border, and after the "Reichskristallnacht" more than 26000 Jewish men had been arrested on November 12—and on January 30, 1939, Hitler, in front of the Reichstag, announced "the annihilation of the Jewish race in Europe" in the case of war (to which all visible signs were already pointing). The inferno began, but it had long been coming; and anyone was considered at "Jew" who could not prove "Aryan (*i.e.* non-Jewish) blood" for several generations.

Misinterpretation of the Situation and Lack of Resistance

In the capital Berlin above all, and especially among the scientists working there, everybody should have been conscious of what had been happening since the founding of the Third Reich in 1933. The considerable anti-Semitic sentiment of the twenties was legalized. During the twenties within the scientific community *Albert Einstein* had been particularly affected, but the solidarity of the Berlin scientists under the leadership of *Max Planck* had been able to compensate for the bias of the general public; now (1933) the academy of Berlin and its "president" *Max Planck* dropped him[43]. However, that was only the prelude, opened by the demand of

the Reichskommissar in the Prussian Ministry of Education to start disciplinary action against *Albert Einstein*, who was on a lecture tour of the United States and had reported there on the first signs of arbitrary actions against Jews and persecution in Germany. *Planck*, who had invited *Einstein* to the Berlin Academy 20 years previously, did not approve of *Einstein*'s attitude, saw no possibility of arbitration—and left for several weeks' holiday in Sicily. In February, *Otto Hahn* had left to lecture for several months in America, and in a long interview published in "The Toronto Star Weekly" on April 8 he still denied American newspaper reports on the persecution of Jews; but in a letter of May 4[44] he reported to Max Planck on the American reactions on dismissals of Jews and urgently asked him to intervene. Meanwhile (on April 7, 1933) the "Gesetz zur Wiederherstellung des Berufsbeamtentums" had of course been proclaimed and many scientists and other scholars had lost their posts at the universities or had been suspended (for the time being on full pay, however). Thereupon many of them had emigrated, while others, like *Erwin Schrödinger*, although unaffected, followed them voluntarily in order to express their disapproval of such arbitrary acts, or, like *Werner Heisenberg*, had to be prepared for their dismissal because they had declared themselves to be against the removal of important Jewish colleagues[45]. *Otto Hahn*, who was then safe as director of the Kaiser Wilhelm Institute and entitled to lecture at Berlin University as a member of the Berlin academy, withdrew from the faculty of the University as soon as he returned from America in July 1933. He reports[46] that he had been informed in America by personal letters from home, how Jewish professors and colleagues were being treated. On the basis of the close contacts between *Max Planck*, *Max von Laue*, *Otto Hahn*, and *Lise Meitner* and the nature of their mutual correspondence after 1938 it may certainly be concluded that it was *Max von Laue* and especially *Lise Meitner*, who had informed him about the events in Germany and Berlin. It was also *Lise Meitner*, who in April had informed *Max Planck* (while he was in Sicily) about occurrences in the adjacent Kaiser Wilhelm Institute for Physical Chemistry and had told him that *Fritz Haber* intended to resign from the directorate, having been dismissed from his other posts. At the insistence of *Lise Meitner*, *Max Planck* returned to Berlin at the end of April in order to attend to his duties as the president of the Kaiser Wilhelm Society. (In July 1946 he reported that to *Max Born*, one of the emigrants from 1933, when they met at the Newton celebration in London[47].) No one but *Lise Meitner*—on the basis of long years of cordial friendship with her old teacher[48] and because of her courage and feeling for fairness—seems to have been capable of that "presumption" demanded by the times. She did not have a position that allowed her to take any action, and as a "Jewess" she was hardly able to satisfy her feeling of equity by action. But haste was needed, and her friends *Max Planck* and *Otto Hahn* (who held such positions) had returned too late to reverse what had happened:

Planck made up his mind and tried to intervene, although in vain, on behalf of the Jewish chemist *Fritz Haber* (who had "deserved well of Germany")—but not in favor of the Jewish scientists within the Kaiser Wilhelm Society—when he paid his first visit to *Adolf Hitler*, which has often been mentioned[49]. *Hahn* reported these events[50]:

> "In the first instance *Haber* himself [sc. at the K.W.I. for Physical Chemistry and Electrochemistry] was not affected, but some excellent Jewish members of his staff had lost their posts. Some people who were members of the party or its organizations monopolized the situation and therefore *Fritz Haber* decided to resign from his post as head of his institute. In a letter to the new Minister of Education he declared that he did not want to be treated differently from his Jewish colleagues."

The reports from Berlin-Dahlem (probably from *Lise Meitner*) had made him break off his trip round America. In July he returned to Berlin, where *Planck* and *Haber* asked him to take temporary charge of *Haber*'s institute. *Haber* himself accepted an invitation to America, emigrated to England, and died on January 29, 1934, during a recreational trip to Switzerland. The courageous behavior of *Max Planck* and *Otto Hahn* in connection with the demonstrative commemoration they arranged for *Fritz Haber* on January 29, 1935, is well known[51]. Although the ceremony was not forbidden, the staff of universities, Kaiser Wilhelm Institutes and other associations were prohibited from attending the ceremony by decrees and official circulars. *Hahn* reported[52]:

> "In that grotesque situation *Planck* called for me ... at my institute. We did not know whether we should be hindered by force from entering the Harnack building. But nothing happened. Every seat in the beautiful hall was taken. The participants were a few relatives of *Haber*, but above all Geheimrat *Bosch* and leading men from the I.G. Farbenindustrie, whom *Bosch* had invited by telegram, many wives of the professors who were not allowed to attend at the ceremony, His Excellency *Schmitt-Ott*, Geheimrat *Willstätter*, who had come from Munich, and other close friends of *Haber*. In the back seats there were some members of my institute: *Lise Meitner*, *Fritz Strassmann*, *Max Delbrück*. The ceremony took a dignified and impressive course. Unfortunately Professor *Bonhoeffer* could not deliver his lecture himself. He would have lost his professorship at the university of Leipzig. At his request I read his lecture for him. I myself did not run any risk in the matter, because I had left the faculty in 1934 [correct: 1933] ... That commemoration of *Haber* shows that resistance (although only little) could still be offered during the first years of the Hitler regime, which later became impossible."

However, *Fritz Haber* had earned a great reputation by discovering the synthesis of ammonia and developing poison gas during World War I, and had been of inestimable service to German industry. *Max Planck* had also made that point to *Hitler*, and found the issue most perplexing for his attitude of mind was a rather traditional one of absolute loyalty to public authority[53]. As the "Permanent Secretary" of the Physical-Mathematical Class of the Prussian Academy of Sciences (1912—1938) and as the president of the Kaiser Wilhelm Society (1930—1937) he held positions that would have enabled him to engage in activities going beyond those demonstrations. What had been advantageous before 1933, when he succeeded *Adolf von Harnack* as president of the Kaiser Wilhelm Society in 1930—in addition to his tradition-bound

loyalty to the state which met the interests of business circles—now turned out to be a weakness[54]:

"It was good that the theologian was followed by the scientist *Max Planck* as head of a society with a primarily scientific alignment. It was desirable for the consolidation of the reputation of the Society in the international world that that post be taken by the greatest among the German physicists who was appreciated all over the world; it was necessary that the president not be one of the directors of the institutes, so that he could be both independent and authoritative towards them. But above all it was important that the president should have such a reputation that he spread an almost mythical magnificence around him, like *Harnack* had been known to do. This *Planck* did, although in a different way from that of his predecessor. While *Harnack*'s secret had been his superior gift of oratory, *Planck* was effective by virtue of his quietness and modesty, which raised him above the bustle of political circles, but often above that of the scientific ones too. Moreover, in particular he knew not only how to arouse respect but also love."

At this juncture, a younger and energetic man certainly could have better served the reputation of German science. When *Max Born* expressed his astonishment to *Max Planck* in July 1946 that he "didn't do anything for his Jewish colleagues", *Planck* could only quote his talk with *Hitler* concerning *Fritz Haber*[55]:

"I wonder whether *Max von Laue* would have signed in cases like that [*i.e.* exclusion of *Albert Einstein*, *Max Born*, and others from the Berlin academy], because his manner was more that of a hero and, unlike *Planck*, he was not so conservative that he would have obeyed the orders of the government even when they were bad."

Max Born was of the opinion that *Planck* had not been fainthearted, but that he had known "that any opposition would be in vain and dangerous for German science"—we can doubt that today, but we can neither prove nor disprove it. Too many people saw an unexpected chance for furthering their own personal careers by filling the gaps left by dismissal of Jewis staff, feared for their own fortunes, or were enthusiastic about the new national ideology with all its consequences and brutalities. And far more people thought that way than were ready to admit it later on, *i.e.* after 1938/39, and especially after 1945. *Otto Hahn*—the provisional head of *Haber*'s institute—at least tried to lobby for financial compensation for the Jewish colleagues who had been dismissed. On October 16, 1933, he wrote to his president[56]:

"Dear Geheimrat,
You ... charged me with the leadership of this institute. Now that my responsibility for the institute has come to an end, please permit me to refer once more to some points, the successful settlement of which seems important to me for political and human reasons ... They mainly concern a number of employees who were dismissed on the grounds of the law concerning Civil Servants [which pursuant to § 14 was accordingly applied also to employees], whose change to other livelihoods would be facilitated by severance pay ..."

So far, I have been unable to establish whether anything was undertaken by the presidency, but it is unlikely. Most probably *Hahn*'s efforts were largely due to *Lise Meitner*'s urgent requests. While *Hahn* had been well off as a student, had soon entered paid research work, and only came to know financial hardship for a brief time after the war—when everybody was suffering—*Lise Meitner*, of course, knew from experience what financial straits and need meant. Moreover, she had had to live on the initial salary of an assistant from 1938 to 1946/47, and life was expensive in Sweden. At any rate, *Lise Meitner* was the one who could induce *Otto Hahn* to grant the destitute *Fritz Strassmann* a support of RM 50 per month from mid-1934, taken from a private fund he had at his disposal for special contingencies. As *Strassmann* never talked much about his personal affairs—nor does he today—, his "boss" probably had not even realized his need. Indeed, the members of the staff of the institute never went to *Hahn* with their personal problems, but to *Lise Meitner*; and if he ever heard about such matters it was for the most part *Lise Meitner* who had told him. She was the true life and soul of the institute and her motherly care for the welfare of the members of her former staff—including those who had precipitated her departure at least by their behavior in 1938—is expressed in many of her letters to *Otto Hahn* from 1938 to 1947.

From the "Transuranics" to Uranium Fission (1934 to 1938): The "*Hahn-Meitner-Strassmann* Team"

Having gained his doctor's degree in physical chemistry under the supervision of *Hermann Braune*, *Fritz Strassmann* had been assistant at the Technische Hochschule of Hannover for a short time. With a rather modest scholarship granted by the "Notgemeinschaft der Deutschen Wissenschaft", he then came to the Kaiser Wilhelm Institute in the middle of 1929 in order to receive further training in radiochemical methods. Up to September 1932 the scholarship was prolonged twice. Thereafter he had to support himself by preparing students for their examinations, but he was allowed to continue his work in *Hahn*'s private Laboratory. His studies on (the refutation and modification of) "Hahn's emanation method" (1929—1934) had also earned him a reputation outside the institute. His knowledge and his skill at chemical analysis—*Otto Hahn* was the radiochemist and *Lise Meitner* was the physicist—predestined him as the necessary third man to join the *Hahn-Meitner* team when *Lise Meitner*, in the autumn of 1934 after more than ten years' break, succeeded in "persuading" *Otto Hahn* to embark on another joint study[57], *i.e.* the study of the alleged "transuranics", which *Enrico Fermi* and his collaborators had found by bombarding uranium and thorium with slow (so-called "thermal") neutrons. *Strassmann*, who had refused the offer of a lucrative post at Solvay A. G., thereafter repeatedly offered *via Hahn*, because his entering the firm would have meant his having to join a Nazi organization (a step he resisted until the collapse of the German Reich in 1945), was called on to join the team and was employed as assistant as of January 1, 1935[58].

It was only after *Lise Meitner*'s emigration that that teamwork led to the discovery of the fission of uranium nuclei by *Otto Hahn* and *Fritz Strassmann*.

All three always gladly remembered their collaboration between 1935 and 1938. Contrary to *Otto Hahn*'s statements—which make no mention of that detail among others—*Lise Meitner* was the intellectual leader of the team—at least in the eyes of *Fritz Strassmann*[59], who was the youngest member and the experimentalist of the group. As a witness to her authority, for instance, their signatures under announcements and directions on the bulletin board "*Otto Hahn, Lise Meitner*" were regularly "falsified" by a transposition mark into: "*Otto Hahn*, lies *Meitner*" (*i.e.* "read *Meitner*"). Her frequent saying: "Hähnchen, leave that to me, you have not the faintest notion about physics!" became almost proverbial among the staff. However, tacit acceptance of her authority also had negative consequences: *Strassmann* reports[60] that he had already found barium (instead of radium) on analyzing uranium irradiated with thermal neutrons one night in 1936 but *Lise Meitner*'s sceptical remark of the next morning, that that must be nonsense, had been sufficient for him to throw his records into the wastepaper basket without any regrets. *Hahn* heard nothing at all about that finding. In December 1938 it was precisely that result, which he had completely forgotten in the meantime, which confirmed his conviction that he had actually detected barium, whereas *Otto Hahn*, who wrote the text of the paper[61] without showing it to *Strassmann*, at that time still expressed himself very reservedly. Trying to analyze the parts played by *Lise Meitner* and *Otto Hahn* in their early joint work, *Werner Heisenberg* was certainly right, when he stated in his commemorative address (1968)[62]:

> "It seems to me that *Hahn* owed his success primarily to his qualities of character. His untiring energy, his unbandable industry in acquiring new knowledge, and his incorruptible honesty allowed him to work even more accurately and more conscientiously, to reflect on his own experiments with even more self-criticism, and to carry out even more controls than most of the other scientists who entered the new territory of radioactivity. *Lise Meitner*'s relation to science was somewhat different. She not only asked 'What', but also 'Why'. She wanted to understand ..., she wanted to trace the laws of nature that were at work in that new field. Consequently, her strength lay in the asking of questions and the interpretation of experiment. We may suppose that also in later joint work, *Lise Meitner* exercised a strong influence on the asking of the questions and the interpretation of the experiments and that *Hahn* mainly felt responsible for the thoroughness and accuracy of the experiments. However, that partition did not become obvious in their joint publications."

Yet there is no mention of *Fritz Strassmann*, who had supplied that component of analytical certainty which *Otto Hahn* did not have. Moreover, as a physical chemist he was the connecting link between the fields of the two older team members. *Heisenberg* also reported that when *Hahn* was later asked about *Lise Meitner*'s part in the discovery of uranium fission he was heard to say while enjoying a glass of wine[63]: "I don't know; I'm afraid Lischen would not have allowed me the fission of uranium." If he meant that *Lise Meitner* would not have published the results before they had been given a theoretical interpretation, he may have been right. Nevertheless, together with her nephew *Otto Robert Frisch*, while staying with relatives at Kungälv, she formulated the first correct interpretation of the chemists' experimental results as fission of the uranium nucleus immediately upon receiving a copy of the manuscript (December 30, 1938)[64].—The concept of *Bohr*'s "droplet model" of the atom provided the starting point[65].

Werner Heisenberg thus concluded: "So far one would be inclined to regard the fission of uranium as the ultimate triumph of many years of collaboration between the two scientists" (the name of *Fritz Strassmann* is again missing). But he revoked that conclusion, referring to the quoted remark of *Otto Hahn*[66]: "But perhaps that is not yet the whole truth." As long as he lived, *Otto Hahn* was reluctant to mention *Lise Meitner* in connection with the discovery of uranium fission, whereas *Fritz Strassmann*, the co-discoverer, is convinced that *Lise Meitner*'s part even up to the finding of the barium had already been so great that she must be ranked among the discoverers, not only because of the first correct theoretical interpretation. Other physicists would undoubtedly have reached that interpretation soon after the paper was published on January 6, 1939. *Strassmann*'s unconditional subordination to her authority in 1936 had subsequently given way to mutual respect between the physicist and the analytical experimentalist whose results she took seriously, even though they could not (yet) be interpreted theoretically. In her letters of 1938/39 she often stated her unconditional confidence in the results of the analyses which were inconceivable at the time because they contradicted the theory of physics. *Strassmann* remembers that it was precisely *Lise Meitner*'s objections to the first results and the suggestions she made in her correspondence with *Hahn*, which stimulated and inspired him in particular to reexamine again and again the products found first by *Irene Joliot-Curie* and *Paul Savitch* upon the bombardement of uranium by thermal neutrons. It was *Lise Meitner* who instigated those joint studies on the "transuranics"[67], and up to her departure in July 1938 she had experienced all the ups and downs, the knowledge of which was prerequisite for the discovery. Therefore she could also understand what was being done by *Otto Hahn* and *Fritz Strassmann* in the months after she had left, although *Hahn* hardly informed her about these matters in his numerous letters. She often expressed her regret at that. Presumably *Hahn* could not have given her more detailed information because the experiments were largely carried out autonomously by *Strassmann* alone (even up to the decisive indicator test)—that follows from the "Chemie II" notebook which is preserved at the Deutsches Museum (Munich). She only lacked the direct contact with the investigations; *Fritz Strassmann* still sensed her presence in the background. *Otto Hahn* described the close collaboration of the three scientists unconsciously differentiating between their contributions—realizing that two at a time would not have arrived at their results without their third companion—when he wrote at the end of their paper on the detection of barium, delivered on December 22, 1938[68]:

> "Because of the experiments briefly outlined, as chemists we ought to change the designations of the above scheme

and to insert the symbols Ba, La, Ce instead of Ra, Ac, Th [that was *Fritz Strassmann*'s point of view at that time]. As "nuclear chemists" closely connected with physics in a certain way we [*i.e. Otto Hahn*] cannot yet make up our mind to undertake that leap, which contradicts all previous experience of nuclear physics [*Lise Meitner*'s influence]. A number of strange coincidences might have feigned our results [*Otto Hahn*'s habitual cautiousness]."

Direct participation in the unequivocal identification of a first product of transformation of uranium nuclei bombarded with thermal neutrons, and thus the indisputable claim to being a co-discoverer together with *Otto Hahn* and *Fritz Strassmann*, was denied her owing to her departure, which was dictated by the circumstances prevailing at the time.

Escape from Germany

The situation described above had come to such a crisis in the spring of 1938 that *Otto Hahn* feared for the future of his colleague and tried to obtain an exit permit for her. Even within the institute, safety was no longer guaranteed[69]. The head of the guest department in the upper story of the institute at Dahlem, *Kurt Hess*, was a National Socialist hardly willing to make any concessions, whose "hope of inheriting the institute ... had become even greater after the events of 1933" *(Otto Hahn)*. There were other factors too. *Lise Meitner*—a "Jewess"—, *Otto Hahn*, *Max Delbrück*, and *Fritz Strassmann*—"politically stubborn" (*Strassmann* was later debarred from "Habilitation" for that reason)—brought the institute into disrepute, and that bad reputation also led to increasing discrimination within the Kaiser Wilhelm Society. The institute itself was divided[70]: "The representatives of the party, *[Kurt] Philipp* and *[Otto] Erbacher*, cut a great figure politically at that time and the rest had to hold back." *Gottfried von Droste* had joined the S.A. in 1933 and usually appeared in uniform; in 1938 he joined the N.S.D.A.P. too[71]. Apart from *Kurt Hess*, however, there seem to have been no human lapses towards *Lise Meitner*. Consequently, some members of her staff applied to her later in order to obtain a "Persilschein" during the denazification; she fulfilled such requests, though rather reservedly[72]. In 1963, when the post-war situation had returned to normal, she addressed the "Urania" at Vienna and talked about "Fifty years of physics", and finally on the years at Berlin-Dahlem[73]:

"... I must say that the years up to 1933 were very stimulating. We needed and we developed complicated apparatus in both departments, and we were surrounded by a crowd of young people, students and staff, who not only learned from us, but from whom we too could learn a great deal, as regards human relations and sometimes as regards our work. There was really a very strong feeling of solidarity between us, built on mutual trust, which made it possible for the work to continue quite undisturbed even after 1933, although the staff was not entirely united in its political views. They were, however, all united in the desire not to let our personal and professional solidarity be disrupted. This was a special feature of our circle and I continued to experience it as such right up to the time I left Germany."

Outside their own institute, however, the situation had changed. *Otto Hahn* recollected[74]:

"*Lise Meitner* had retained her position in the institute and there she was not disturbed at all, but she could no longer play any role in the scientific community outside and she could no longer go to the Physical Colloquy of *Laue*. Yet a change for the worse started after the annexation of Austria in early March 1938. The situation then became more difficult. At that time, according to *Graue*[75], *Hess* is said to have remarked: "The Jewess *[i.e. Lise Meitner]* endangers the institute." A report was also made to *Mentzel* (Ministry of Education) on her position, *etc.* Then I [*i.e. Otto Hahn*] too rather lost my nerve and in a conversation with *Hörlein* (our treasurer[76]) I spoke of *Lise Meitner* and the new awkward situation since the annexation of Austria. *Hörlein* suggested that *Lise* might resign from her position, because nothing more could be done; perhaps she could continue working inofficially. I do not exactly remember the concrete proposals. Unfortunately I told *Lise* about that conversation on March 22, 1938... *Lise* was very unhappy and angry with me, because now I had also let her down... I do not remember in detail what happened later. The president *Bosch*[77], who spoke to Dr. *Telschow*[78] with regard to *Lise*, objected resolutely to *Hörlein*'s proposal: it would be alright for her to stay... The situation became more and more unbearable. *Lise* was very angry with me and could not get over my having spoken about her to *Hörlein*. On the other hand I was continually being told that *Lise* ought to have given up her post long ago, because she ought to see that she endangered the institute *etc.* ..."

Carl Bosch then had a rather long talk with *Lise Meitner* and they agreed that in the existing situation—the Ministry had been informed, events had been set in motion, although unintentionally, by *Otto Hahn*'s genuine concern—an official application for an exit permit would be the most reasonable course of action. On May 20, 1938, he submitted to the Reichsminister the written request "to permit the famous scientist Professor *Lise Meitner* to leave for a neutral foreign country, Sweden, Denmark, or Swizerland"[79]. In order to prevent any danger to the person of *Lise Meitner* by measures that might possibly be triggered by that request, she had taken up residence at the "Adlon Hotel". *Max von Laue* had reported that he had heard of an order issued by *Heinrich Himmler*, that no university scholars—whether Jews or not—would be allowed to leave Germany in the future[80]. The answer of the Ministry of June 16, 1938, to *Carl Bosch* turned out accordingly. He advised *Lise Meitner* of it by telephone, and she took it down in shorthand[81]:

"Dear Geheimrat *[Bosch]*!
By order of the Reichsminister Dr. *Fr[ick]* may I most respectfully inform you in answer to your letter of the 20th of last month that there are political objections to the issuing of an Auslandspass [*i.e.* a passport for traveling abroad] to Prof. *M[eitner]*. It is considered undesirable

that renowned Jews [underlined!] should leave Germany for abroad to act there against the interests of Germany according to their inner persuasion as representatives of the German sciences or even with their reputation and experience. The K. W. G. will certainly find a way for Prof. *M[eitner]* to stay in Germany after her retirement and under certain circumstances [...] The Reichsführer-SS and Chief of the German Police in the Reich Ministry of the Interior *[i.e. Heinrich Himmler]* in particular has advocated that opinion.

Yours respectfully"

A retreat now seemed to be impossible without endangering *Lise Meitner*. The forfeiture of her post seemed inevitable, although *Carl Bosch* still intended to intervene directly with *Himmler*[82]. However, events overtook that intention. Immediately after the official reply quoted above, *Otto Hahn* and his friend *Paul Rosbaud*, whose political attitude (at the same time he sent his family to England) and capacity as scientific adviser to the Springer Verlag and actual editor of "Die Naturwissenschaften" had earned him many friends abroad, took pains to arrange *Lise Meitner*'s illegal emigration and a way in which she could continue her work in an institute abroad. Whether she knew all about those endeavors or not, does not follow from the records and letters available until now. Later, however, she felt as if she had been sent away by her friends; only on the evening before her departure had they hastily packed a few things in a suitcase. Through the intervention of *Peter Debye*, at that time director of the Kaiser Wilhelm Institute for Physics at Berlin, their efforts were soon rewarded. Coming from Holland himself, he got in touch with his colleague *Dirk Coster* from Groningen, who was able to arrange that *Lise Meitner* would be allowed to enter Holland at a small frontier crossing without a valid passport and without an entry visa. *Dirk Coster* sent a telegram saying that he would come to Berlin in person. He arrived at Berlin-Dahlem on the evening of probably 13th or 14th July[83]:

"*Coster* stayed in Berlin for a night. Without telling anybody, a suitcase was packed in the evening (only *Rosbaud* and I *[i.e. Otto Hahn]* were present). As far as I remember, she spent the night before her departure with us at the Altensteinstrasse; *Coster* himself only met her in the train. Then they left; with fear and trembling we wondered whether she would get through or not" ... "We had agreed upon a code word by which we were to be informed by telegram on the success or failure of the journey. *Lise Meitner* was especially exposed to the danger of repeated controls by the SS in the trains going abroad. Time and again, people who tried to go abroad had been arrested on the trains and brought back. But *Lise Meitner* was lucky; she got across the border and was safe."

On July 15, *Otto Hahn* could confirm receipt of the news of her safe arrival at Groningen by an encoded postcard[84]:

"Dear Coster family,
First of all I want to congratulate you on the happy arrival of the youngest member of your family. Of course, I was very pleased about the news, since we had been rather worried recently. What will be the name of your darling daughter?—There is not much news here. In the laboratories everything takes its usual course, and vacation starts tomorrow, thank goodness..."

The staff and outsiders thought that *Lise Meitner* was on vacation. That was not suspicious, because the general vacation of the institute started on July 16. Of course, she remained "Wissenschaftliches Mitglied" of the Kaiser Wilhelm Society and head of the physical-radioactive department of the institute. Her contract had been renewed by the Kaiser Wilhelm Society in 1929, being back-dated to April 1, 1928, in order to supplement it by the extension of her status to that of a life employee entitled to the pension of a ordinary professor. Therefore the wording of a letter of the Reich Ministry of Education of August 11, 1938, to the General Administration of the Kaiser Wilhelm Society is all the more peculiar. The formulation was based on a consultation between *Rudolf Mentzel*, the Referee for Sciences and Technology in the ministry, who had also been president of the "Deutsche Forschungsgemeinschaft" since 1936 (succeeding *Johannes Starck*) and consequently permanent member and real "leader" of the Reichsforschungsrat founded in March 1937[85], and the director of the General Administration of the Kaiser Wilhelm Society, *Ernst Telschow*. The letter reads as follows[86]:

"Re: Frau Professor *Lise Meitner*.
Professor *Lise Meitner*, previously an Austrian national, is working as a guest [?] at the Kaiser Wilhelm Institute for Chemistry. Since she has become a German national through union with Austria, it has to be established what percentage of Jewish blood she has. According to previous assessments Mrs. *Meitner* is supposed to have 25 % of Jewish blood.
Referring to the talk which my referee Professor Dr. *Mentzel* had with Dr. *Telschow*, I ask for prompt comment on that matter.

By order,
signed *Dames*"

Thereupon *Ernst Telschow* wrote to the director of the Kaiser Wilhelm Institute for Chemistry, *Otto Hahn*, on August 18, 1938[87]:

"Dear Professor *Hahn!*
I enclose a transcript of a decree of the Reich Ministry for Education [the letter above] for your information. You may discuss the matter with Prof. *Meitner* and inform me about what is necessary for the reply to the Ministry. I suppose that—now that the Ministry has taken up the affair—it would be expedient if Mrs. *Meitner* were herself to apply for leave until the question of her retirement or staying at the Kaiser Wilhelm Society will be cleared up. Such an application would certainly be of use for the future discussion with the Ministry.

Heil Hitler!
Yours faithfully, *Telschow*."

"Taking everything into account", *Otto Hahn* did not inform *Lise Meitner* about that letter; he "thought, you *[i.e. Lise Meitner]* would have preferred to reach your decision without

being influenced"[88]. And, indeed, without knowing about the letter she wrote to him on August 24, 1938[89]:

"Dear *Otto*,
What I have to tell you today will bring about an extremely decisive turning-point in both our lives. Yesterday I asked Geheimrat *Bosch* to agree to my retirement.
We need not speak about feelings, both of us certainly know about such things. I am sure no day will pass, when I shall not think with gratitude and longing of our friendship, our joint work, and the institute. But I don't belong there any longer, and when I reflect on the last months, it seems to me that my retirement will also comply with the wishes of the staff. It's no use talking about it too much; facts are facts, you cannot pass them over.
My Swedish friends offered to let me stay with them, and I have come to the decision that this is the only course left open to me. Actually I would like to express my thanks personally to all the colleagues and employees of the institute for the years of excellent cooperation. But perhaps you think it would be better you alone were to tell them. They all know me, well enough to know that I don't like talking about things that are irrevocable. Think it over calmly and let me know which form you consider suitable. However, please let's not talk about the fact of my leaving.
Of course, my decision involves a number of practical necessities. I also wrote a very short letter to Dr. *Telschow* and asked him to discuss the regulation of my affairs, such as retiring allowance *etc.* with Dr. *Leist*. I'll ask *Annchen* to carry out the dissolution of my flat, with the help of a removal company, of course. I know very little about the legal formalities but I hope for the help of Dr. *Leist*. I have not yet made any detailed plans, I just thought that I would put my things in storage here. And then I must await what the future brings. I also need inner calm to think over everything rationally.
In my inner self I myself have not yet quite realized that what I have just written is real, but it *is* real.—Let me hear from you soon. With very kind regards,
Yours forever,
Lise."

In Swedish Exile

Lise Meitner had meanwhile left for Sweden, with the help of *Peter Debye* and of *Niels Bohr*, who had been her friend since 1920. *Niels Bohr*, who after World War I had already made unparalleled efforts to ensure German scientists should regain recognition abroad, had also started in 1932/33 a worldwide campaign to provide Jewish scientists persecuted by the Nazi regime with posts in foreign institutes. After *Hitler*'s seizure of power he had traveled around Germany officially in order to "visit German universities", but actually in order to gain first-hand knowledge about the effects of the race laws[90]. He procured positions for many people at English, American, Dutch, Danish, Swedish, *etc.* institutes; *e.g.* he had invited *Otto Robert Frisch*, a young physicist from Hamburg and nephew of *Lise Meitner*, who had spent some time with *Patrick Blackett* in London, to his own institute at Copenhagen. For *Lise Meitner*, who would have had entirely different prospects in 1933 at the onset of *Bohr*'s campaign, they had obtained a place to work at *Manne Siegbahn*'s Nobel Institute for Physics, recently founded at Stockholm. Therefore at the end of July 1938 she went to live with her friend *Eva von Bahr-Bergius* at Kungälv near Gothenburg (whence she sent her farewell letter, quoted above), and in mid-September she moved into a small hotel room in Stockholm, where in May 1939 together with some relatives she occupied a flat—for the time being without her belongings, however, the transport of which from Berlin was proving difficult[91].

The working conditions at Stockholm, however, did not come up to all the hopes and expectations raised by *Debye*'s information. Some passages from postcards and letters to *Otto Hahn* illustrate her first disappointment and her situation[92]:

"25/VII '38 ... My journey to her *[Eva von Bahr-Bergius]* could not be arranged yet. *Manne [Siegbahn]* did not quite understand what I am particularly interested in; I have written to him once again [...] 26/VII: Now it seems, that I'll be leaving after all during the next few days. So please write to *Eva*'s address."—"25/IX '38 ... Perhaps you cannot fully appreciate how unhappy it makes me to realize that you always think that I am unfair and embittered, and that you also say so to other people. If you think it over, it cannot be difficult to understand what it means to me that I have none of my scientific equipment. For me that is much harder than everything else. But I am really not embittered—it is just that I see no real purpose in my life at the moment and I am very lonely..."—"6/XI '38 ... On Monday (12th) *Bohr* will deliver a lecture here. I hope I can speak to him a little on his own. *Siegbahn*'s institute is incredibly empty. An excellent building where preparations are being made for a cyclotron and many other large X-ray and spectroscopic apparatus; but experimental work can hardly be *thought* of. There is no pump, no rheostat, no capacitance, no ammeter—*i.e.* nothing for doing experiments, and in the entire building just 4 younger (or young) physicists and very bureaucratic working rules ..."—"15/X '38 ... There is little to tell [from here]. Experimental work is out of the question; it will take a very long time until even the simplest apparatus will be there, and then perhaps also a collaborator. Of course, *Bohr*'s visit was very pleasant and probably useful, too, because he also spoke to *Manne S[iegbahn]*. But *S[iegbahn]* is not at all interested in nuclear physics and I rather doubt whether he likes to have an independent person beside him. *B[ohr]* suggested that I should have patience, what else should he do. And I can't do anything but live my life just as it is..."—"26/XI '38 ... Your suggestions for the apparatus are hardly practicable. It would be so much better, if one could come to *Siegbahn* so to speak with a gift instead of a demand, and if it were only a drawing of a piece of apparatus. However, that doesn't seem possible ..."—"5/XII '38 ... There is little or nothing to tell about myself ... I often feel like a wound-up puppet that does certain things, gives a friendly smile, and has no real life in itself. By that you can judge how valuable my activity is. Nevertheless, I am very grateful for it after all, because it compels me to collect my thoughts, which is not always easy ..."—"21/XII '38 ... As for my so-called work—when I think it over—I can only think and say,

o God! I have set up a single-filament electrometer, some counters, an amplifier, a very poor counter, no help whatever. Mostly my head is really so full of other matters that the rest is all the same to me. Nevertheless, life must be lived in some way or other ..."—"14/I '39 ... It is certainly nice that *Siegbahn* is getting the counter. Once more, he didn't tell me a word about it, I finally asked him. It's all very depressing, but I don't see any possibility of changing things. ..."—"25/I '39 ... If you could but see my day's work! I have *no* help at all, I cement counters, evacuate them, test whether they are leakproof, in short I do the work of Mr. *Dörf[f]el* [technician at the Kaiser Wilhelm Institute at Berlin], only much worse than he does ..."—"5/II '39 ... I don't feel at all happy. Here I just have a workplace no position that would entitle me to anything. Try to imagine what it would be like if, instead of your nice private institute, you had a room in an institute which is not your own, without any help, without any rights and with the attitude of *Siegbahn* who only loves big machines and who is very confident and self-assured—and there am I with my inner shyness and embarrassment! And that I have to do all the petty work which I haven't done for 20 years. Of course, it's my fault; I should have prepared my departure much better and much earlier, I should at least have had drawings of the most important apparatus *etc. Siegbahn* also once told me that *Debye* hadn't written anything about collaborators or assistants (several times I had asked *D[ebye]* for that) and that he had only little room. Yet, that's not true, I think. But the essential thing is that I have come here so empty-handed. Now *Siegbahn* will soon believe—especially after your excellent results—that I didn't do anything and that you both did all the physics too at Berlin Dahlem, Gradually, I am losing all my courage ..."—"12/II '39 ... As for *Debye*, it was he who wrote (July 1938) to *Manne* and obviously he didn't mention anything about co-workers or an assistant ... I have really done everything wrong that could be done wrong. And, in addition, I started from completely wrong premisses. Meanwhile, I have gradually come to know through *Eva von B[ahr-Bergius]* what happened. *Siegbahn* didn't really want me. He said that he had no money; he could give me a place to work but no more. *Eva* then wrote to *Oseen*, and he said that the Nobel foundation could grant money. But no one considered that I can't work without an assistant, especially in an institute where there is nothing available for my field. And when I realized that, I was rather desperate, and that, of course, isn't the right state in which to assert oneself. At Dahlem I used to talk the matter over with *Gille*, when I needed something from the workshop, and he did the mechanical work and also produced the drawings. Here I'm always told: "Make a drawing, please." That means, I do the work which *Dörf[f]el* had done and, strictly speaking, I don't know to do it. And *Siegbahn*, who is a wonderful draftsman and technically highly gifted, will now soon think that I know nothing at all. Perhaps he is right ... I shouldn't have left in such a way; on the contrary I should have had drawings of the most important apparatus ..."—"31/III '39 ... Probably you can't really imagine what it means for a person of my age to have been living in a small hotel room for 9 *months*, without any comfort, without any scientific aids, and with the fear that nobody has the time required to advance my affairs [at Berlin] ... And here in the institute, too, I'm without any help, and I don't think that *Siegbahn* is much inclined to assist me in it ... I found the counter when I came back [from a 4-week stay at *Bohr*'s institute at Copenhagen, which made her perceive even more strongly her situation[93]], and I tried it today, it's all right ..."[94]—"27/X '39 ... My work is equivalent to zero ..."—"12/XI '39 ... The young physicist from Utrecht who wanted to come here wasn't given a Swedish entry visa, we don't know why, and *Manne*, who at first wanted to lend a helping hand, told me some 2 weeks ago that there would be no sense in trying[95]. In principle he may be rather glad that it turned like that. He much prefers to spend the funds of the institute on mechanics and big machines than on scientists and scientific problems. In the whole institute there are only 5 scientists, and even they work almost exclusively on apparatus. Scientifically I'm completely isolated, I don't talk with anybody about physics for months, I'm sitting alone in my room trying to occupy myself; it can't be called "work" ..."—"20/VIII '40 ... That you didn't inform me about the result before the paper was ready for the press, shows to me how much you overrate my facilities and how much you underrate my colleagueship. A pity! ..."—"14/XI '40 ... Unfortunately, within the next few weeks the assistant who is building the cyclotron will go to Upsala, where he'll have a permanent position; Heaven knows what's going to happen about the cyclotron. Particularly sad is *Norling*'s recent sudden death ..., he had worked with *Bothe* for more than a year, he was greatly talented and really interested in nuclear physics and as a person he was such a nice boy ..."—"20/I '41 ... *Manne [Siegbahn]* suggested that I give some lectures in the institute for him and his young people "in order to show them what problems are experimentally solvable". Of course, it's a bit naive to think that you can learn to work independently in a new field by a few lectures, but still the very insight that there is something they can learn from me is progress (reached after several years). And for myself it's good to be compelled to think over the field once again more thoroughly ..."—"15/VI '41 ... My facilities are becoming more and more limited because the problems that can be treated with such a weak neutron source and without any help are very few in number ..."—"3/IX '41 ... Since the beginning of August I'm back and at work, in so far as my rather modest occupation deserves to be called work. This institute is really unique. For three years various apparatus have been built—I have not yet seen a finished one—but problems are not dealt with, except by *Norling*, who unfortunately died a year ago. Once *Manne [Siegbahn]* asked me to help his son prepare a ThB preparation with which a β-spectrograph should to be tested—I heard of its existence then for the first time. Of course, I did so, but when I asked about the results some time later I got an evasive answer, and so far as I know nobody is working with it any longer. The cyclotron is standing around unfinished, lonely and forsaken ..."—"22/X '41 ... Lately I have—*faute de mieux*—worked a little on γ-rays and Compton electrons and I have come across problems of the sensitivity of counters, like those *Droste* dealt with in the year 1938. There would

be a lot to discuss about that, but as I haven't heard anything at all of him, there is no point in asking questions ..."—"26/II '42 ... My life is so empty that there is really no point in saying anything about it. If I had the gift of regret, I would never get over the fact that I returned to Stockholm several years ago [probably after her longer stay at Cambridge]. But there is no use in occupying oneself with that. The cyclotron has been working for several weeks, but irradiation is done only for *Manne [Siegbahn]*, ... and no neutrons are produced in the cyclotron, but deuterons are used directly for activation, *i. e.* the sample to be activated must be placed into the cyclotron; so there is no room for anything else. I don't know how long it will go on like that ..."—"30/XII '42 ... Your wishes for a "successful year" sound almost like irony, which of course you hadn't intended. But if you knew my working conditions! Recently I asked *Manne* whether I could occasionally get something irradiated, whereupon he took out his notebook and said: "Which day? All the work is under my control, you know ..." He doesn't like the young people and myself talking to each other, but nevertheless they do talk to me and consult me. But I suppose you will understand that one can't really work, if one can't try out what one has thought of with any modifications that may be necessary."—"12/IX '43 ... There is not much to tell about my work, as always it's going very slowly. Nevertheless, for 4 weeks I have a young electrical technician working with me, who seems to be qualified and humanly sympathetic. Let's hope for the best ..."—"15/XI '43 ... Dr. *[Sigurd] Eklund*, assistant to *Siegbahn*, urgently needs anhydrous (*i. e.* fused) boron trioxide, but he can't get it here. Could you have 250 g sent to him—on payment, of course? I would be pleased, if it were possible, he is always so ready to alleviate my unfavorable working conditions, so it would be nice, if I could help him in return ..."—"22/IV '44 ... Work is progressing slowly, and it is sometimes also difficult to focus one's thoughts on it. If only the world would but get out of this hubbub! ..."—"21/VI '44 ... One can think of hardly anything but current events. Everything else has become so unimportant, even the scientific work sometimes appears completely pointless to me. Together with my assistant I have been building up a coincidence set-up, which is almost finished. It was so difficult to get the necessary components, especially the amplifier tubes. In Sweden they don't produce any tubes, therefore we are completely dependent upon foreign tubes, and those are hardly available ..." [*Otto Hahn* then sent her two tubes, which, however, never arrived at Stockholm.]

In 1947 *Lise Meitner* retired from the "Forskninginstitutet för Fysik" of the Swedish Academy, after she had spent six months of 1946 as visiting professor at the Catholic University of Washington, D.C., in the United States, where she was nominated "Woman of the Year" by the American press and received honorary doctorates from several universities. The Swedish Atomic Energy Committee had offered to set up a small laboratory for her at the "Försökstation" of the "Ingeniörs-Ventenskapsakademien" at the Royal Institute of Technology at Stockholm, to which she moved at the beginning of 1947. Connected with the laboratory position was the post of a research professorship, the granting of which by the Swedish Parliament nevertheless dragged on for some time. On March 30, 1947, she wrote to *Otto Hahn*[96]:

"I'm to get a research professorship at the Royal Institute, *i. e.* without teaching obligations, but also without an institute or other rights. But the professorship has not yet been passed by parliament. The Ingeniörs Vetenskapsakademie (Professor *Velander*) has set up 3 very small rooms for me in its Försökstation, *i. e.* I have money for the simplest apparatus, voltmeters, ammeters, amplifier tubes, *etc.*, which I am now trying to buy, and I have 2 assistants, a purely technical one and a young engineer, neither of them has any idea of nuclear physics. At the Försökstation a Van de Graaff is being projected, maybe it will be built in 2 years, and a small high voltage installation is being built (smaller than the one *Bosch* had granted to me[97]). Of course, a cyclotron is no longer under discussion, and *Siegbahn* will now be even less willing to have anything irradiated for me ..." And on 24/VI 1947[98]: "... My post at the Royal Institute has come to nothing, despite all the promises the motion wasn't brought before parliament, and *Jacobssen* recently rang me up and tried to prepare me that it would probably come to nothing at all. If *Borelius* hadn't taken care of it at the end of May, there wouldn't have been any salary for me on and after July 1. Now it will be granted for another 6 months [by the Nobel Foundation] ..."

But also that problem was solved at the end of 1947; for on March 4, 1951, when the question of *Lise Meitner*'s retirement salary (a transfer of which hadn't been approved in 1938, but which for some months had been paid to her sisters at Vienna—who had lost their posts, too—up to their flight) was finally settled by the Max Planck Society, the legal successor of the Kaiser Wilhelm Society, she wrote to *Otto Hahn*[99]:

"In regard to the retirement pay awarded to me by the K.W.I. [*i. e.* K.W.G.] I had thought of a short visit to Germany, you know ... But now the Max Planck Soc[iety] tells me that I should specify my salary drawn here at present, which should be set off against the retirement pay. At the moment I have a rather high salary, having had not even the starting salary of a assistant for 9 years ..."

At the end of 1953 she gave up the laboratory at the Försökstation of the Institute of Technology and got "a sort of advisory post at the institute of *Eklund* ..., rather in order to have a room and a library at my disposal, that means a sort of "Altersstübel" [room set aside for an old person]"[100]. *Sigurd Eklund* was then building a research reactor for the Royal Academy of Engineering deep down in a cavern under Stockholm. He and *Lise Meitner* had been friends since the time spent together at *Siegbahn*'s institute, when he had been the only person who cared a little for her.—In 1960 *Lise Meitner* moved to Cambridge, where relatives (among others her nephew *Otto Robert Frisch*) were living, in order to be nearer to them in her old age. There she died on October 27, 1968, shortly before her 90th birthday—and only a few months after her old "companion" *Otto Hahn*.

Late Appreciation of the "Joint" Discovery of Uranium Fission: The Enrico Fermi Award

In her old age it was of little comfort that in 1966, after many other decorations and honors, she was awarded, together with *Otto Hahn* and *Fritz Strassmann*, the Enrico Fermi Award (granted "for especially meritorious contributions to the development, use, or control of atomic energy") of the President of the U.S.A. and the United States Atomic Energy Commission, "for contributions to nuclear chemistry/physics and extensive experimental studies culminating in the discovery of fission"—not because her age prevented her from undertaking the journey to Vienna, where because of her the ceremony had been held instead of Washington, D.C., but rather because *Otto Hahn*, who had already received the Nobel prize for chemistry of 1944 for that discovery[101], was awarded that prize, too, and because the shares of the three "discoverers" up to the discovery and interpretation of the nuclear fission would first be acknowledged so late by the public, because she had had to leave Germany previously and *Otto Hahn* by supplying insufficient information and hasty publication had deprived her of the chance of also contributing her share to that paper on the discovery of the fission products? But that is speculation. However, as far as *Fritz Strassmann* was concerned she was really pleased. Be that as it may, being informed of the award for the prize she wrote in a postcard to *Hahn*[102]:

> "The granting of the Enrico Fermi Award to you, *Strassmann*, and me comes as a great surprise to me, about which I'm really glad for both of you. As for my part, my feelings are rather mixed. However, in some respects I'm sort of pleased about it, too ..."

What would she have said, if she had known—as probably hardly anyone knows even today—that it had been *Otto Hahn* himself whose proposals had led to the granting of the award to the three discoverers of nuclear fission. The General Advisory Committee of the United States Atomic Energy Commission had invited him to nominate a candidate for the award—for the first time at the beginning of 1963, and for the second time on January 9, 1964 (the prize was not awarded in 1965). On both occasions *Hahn* had nominated *Fritz Strassmann* alone[103]—and that would certainly have completely reconciled her.

This paper could not have been written without the help of many people whom I interviewed or asked for sources during my research work in the archives. Among others I am very much obliged to Mrs. Patricia Bradford, archivist of Churchill College at Cambridge, Mrs. Marie-Luise Rehder, the long standing secretary and trustee of the literary estate of Otto Hahn, Mrs. Hildegard Scheld, the librarian of the Max Planck Institute of Chemistry (Otto Hahn Institute) at Mainz, Mrs. Ursula Ringmann from the personnel division of the General Administration of the Max Planck Society at Munich, Dr. Rolf Neuhaus, the director of the Library and Archives for the History of the Max Planck Society in Berlin, my friend Robert S. Westman, Ph.D., at present at Cambridge, and above all Prof. Otto Frisch, Cambridge, and Prof. and Mrs. Fritz Strassmann, Mainz. In translating I was helped by Miss Ingrid Roegner.

[63] *W. Heisenberg* in [6], p. 116.

[64] Cf. the *Hahn-Meitner* correspondence (Nov. 1938—April 1939) edited (incompletely) by *D. Hahn* in *D. Hahn:* Otto Hahn, Erlebnisse und Erkenntnisse. Econ, Düsseldorf 1975, pp. 75—129.—Unfortunately the letters are rendered not very accurately and moreover there are omissions which are not marked. The omissions in letters of *Otto Hahn* include mainly detailed remarks on his official duties and problems regarding his family, which just could have shown that in the second half of 1938 he had hardly any time or patience for scientific work. Much more grave are omissions like the seemingly unimportant small sentence: "(*Strassmann* ist verreist.)", *i.e. Strassmann* is away, in *Otto Hahn*'s letter of December 28, 1938, that follows the sentences: "... and now comes my new phantasy. We have *not* proved that the transuranics are *not* Ma, Ru, Rh, Pd. At least I for my part know so little about those substances that I cannot exclude them chemically."

[65] *L. Meitner, O. R. Frisch*, "Disintegration of Uranium by Neutrons: A New Type of Nuclear Reaction", Nature *143*, 239 (1939) [No. 3615, February 11, 1939; submitted on Jan. 16, 1939). The joint publication was settled by telephone between Copenhagen *(Frisch)* and Stockholm.

[66] *W. Heisenberg* in [6], p. 116.

[67] See ref. [57]. After inquiries on the financial situation of the Emil Fischer Society, *Otto Hahn* filed on November 6, 1934, an application to the treasurer *Arthur von Weinberg* for the granting of 10—12000 RM "for the building of equipment for the splitting of nuclei by protons". Those means were transfered in two yearly instalments to a special account of the department of physics which was at *Lise Meitner*'s disposal (Max Planck Institute for Chemistry, Mainz, file 'Allgem. Angelegenheiten KWI für Chemie').—The apparatus on the so-called "workbench of *Otto Hahn*", exhibited at the Deutsches Museum at Munich—on the table there are also some instruments from the "Messzimmer" (measurements room) of *Lise Meitner*—had been arranged by *Lise Meitner* in 1934/35. It was used by her, *Otto Hahn*, and (in 1938 mainly) *Fritz Strassmann*.

[68] See ref. [61], p. 15.—*Fritz Strassmann* remembers that all the papers published jointly with him were written by *Otto Hahn* alone, and that he himself could not even look over them before they were completed.

[69] Cf. *O. Hahn:* a) Mein Leben. Bruckmann, Munich 1968, especially pp. 145—147; and above all b): Erinnerungen 1901—1945, in: *D. Hahn* [64], pp. 15—73 (especially pp. 50—56).

[70] *O. Hahn* in *D. Hahn* [64], p. 54 sq.

[71] Letter of *Lise Meitner* to *Otto Hahn* dated Feb. 23, 1947; Archives of the Max Planck Society, Berlin (literary estate of Otto Hahn).

[72] See especially her letter of June 24, 1947 to *Otto Hahn* (as in [71]).

[73] *L. Meitner* in [7a], p. 7.

[74] See ref. [70].

[75] *Georg Graue* was then assistant at the "National Socialist Model Institute" (*O. Hahn* in [69a], p. 149), the Kaiser Wilhelm Institute for Physical Chemistry and Electro-Chemistry at Berlin-Dahlem, the former institute of Haber.

[76] *Heinrich Hörlein* was treasurer of the "Emil Fischer Society for Advancement of Chemical Research", which sponsored the KWI for Chemistry.

[77] *Carl Bosch* (I.G. Farbenindustrie A.G.) had been president of the management committee of the KWI for Chemistry and in 1937 he succeeded *Max Planck* as president of the Kaiser Wilhelm Society.

[78] *Ernst Telschow* was managing director of the "Generalverwaltung" of the Kaiser Wilhelm Society and the later Max Planck Society.

[79] Quoted by *O. Hahn* in [69a], p. 149.—The (copy of the) letter has still not been found either in the archives of the Max Planck Society in Berlin or among the documents of the "Generalverwaltung" at Munich (information from *Rolf Neuhaus* and *Ursula Ringmann*, respectively).

[80] *O. R. Frisch* in [6a], p. 410. See also the report by *O. Hahn* in *D. Hahn* [64], p. 55.

[81] Facsimile of page 1 of the shorthand note in *E. Berninger:* Otto Hahn—Eine Bilddokumentation. Persönlichkeit—Wissenschaftliche Leistung—öffentliches Wirken. Moos, Munich 1969, p. 42, and in [41], 67.—The letter has not yet been found; see ref. [79].

[82] *Carl Bosch* was in poor health and had gone in vacation. Cf. *Otto Hahn*'s letter to *Lise Meitner* of October 1, 1938 (Archives of Churchill College, Cambridge, Meitner papers): "Having tried in vain, again and again, to ring up at the Adlon [a hotel at Berlin, where *Carl Bosch* used to live], I contacted the Geheimrat *[i.e. Carl Bosch]* the day before yesterday and yesterday I spent the afternoon with him. At first just the two of us, then with Dr. *Leist* [*Lise Meitner*'s

legal advisor at Berlin]. He confirmed what Dr. *T[elschow]* had already said. The Kaiser Wilhelm Society will try everything it can do for you and *Otto [Heidelberg]*. However, he doesn't know whether the applications [for exit permits] will be passed. As for you, perhaps a certain difficulty could have arisen in so far as in your case a personal consultation with "highest heaven" had been considered [in German: "mit dem obersten Himmel", *i.e.* with *Heinrich Himmler* (?)]. If they should find out now that you are not in Germany they would perhaps be cross ..." Cf. *Otto Hahn*'s letter to *Lise Meitner* of September 12, 1938 (*ibidem*): "... *Telschow* asked me today how the ministry knew about your departure—the ministry had asked him about it. I told him that in my opinion *Erb[acher]* and *Philipp* had told *Graue* about it and he had informed *M[entzel]*. Unfortunately it is still uncertain when *Bosch* will be back ..." Immediately after the institute vacation, on August 29, *Otto Hahn* had reported *Lise Meitner*'s decision to *Erbacher* and *Philipp* and thereafter to the whole staff (see the letter to *Lise Meitner* of that date, *ibidem*).

[83] *O. Hahn* in [17], p. 55, and in [69a], p. 149 sq.—The date of *Dirk Coster*'s arrival and *Lise Meitner*'s departure quoted by *Otto Hahn* (July 16/17, 1938) is certainly wrong, because he had already confirmed that he had heard about her successful flight in a postcard of July 15 (see ref. [84]).

[84] Postcard of *O. Hahn* to the *Coster* family of the July 15, 1938 (Archives of Churchill College, Cambridge, Meitner papers).

[91] See the correspondence in *D. Hahn* [64], which is to be supplemented by several other letters.

[92] Archives of the Max Planck Society, Berlin (literary estate of Otto Hahn).

[93] Because of that short trip it is nearly always erroneously stated that *Lise Meitner* emigrated *via* Holland *and* Denmark to Sweden.

[94] *Otto Hahn* had had the counter made at his institute in Berlin. It had been ordered by *Sieghahn*, as *Hahn* himself had proposed.

[95] On September 1, 1939, World War II began with the invasion of Poland by German troops.

[96] Archives of the Max Planck Society, Berlin (literary estate of Otto Hahn).

[97] See ref. [67].

[98] Archives of the Max Planck Society, Berlin (literary estate of Otto Hahn), and copy in the Archives of Churchill College, Cambridge (Meitner papers).

[99] See ref. [98].

[100] Letter to *Otto Hahn* of October 15, 1953; see ref. [98].

[101] She—and her friends—were very disappointed, when the Nobel prize for Chemistry of 1944 was awarded to *Otto Hahn* alone "for his discovery of the fission of heavy nuclei"—and that he accepted it for himself alone. Intimate colleagues therefore tried in 1946, when the decision of the prize of 1944 (set aside for *Otto Hahn*) was approaching, to suggest *Lise Meitner* as the co-winner. But on Nov. 15, 1946, she informed *Otto Hahn* in a postcard: "... The chance of becoming your Nob[el] Colleague is definitively finished. If you are interested, I can tell you something about that ..." (Archives of the Max Planck Society, Berlin, literary estate of Otto Hahn).

[102] Quoted in a letter of *Marie-Luise Rehder, Otto Hahn*'s secretary and co-worker of long standing, to *Irmgard Strassmann* of the August 10, 1966 (private archives of F. Strassmann).

[103] Cf. the letter of *Otto Hahn* to the Chairman of the General Advisory Committee *Manson Benedict* of Jan. 9, 1964 (copy in archives of F. Strassmann) replying to his repeated invitation of Jan. 6, 1964 to nominate a candidate for the prize: "... For a selection I should like to nominate my colleague Dr. *Fritz Strassmann*, sharing with me the result of the discovery of the fission of Uranium. As you may perhaps know, we have worked together for many years. Dr. *Strassmann* having been acquainted with the subject just as well as myself. As I have received the Nobel Price for the year of 1944 for the discovery of Uranium fission, I should think it justified if Dr. Strassmann would also receive a recognition of his very good and successful researches ..."

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Unusual Selectivity in the Thermal Rearrangement-Elimination Reaction of a Carbene Complex in Solution and in the Solid State [1]

By *Helmut Fischer, Andreas Motsch,* and *Willi Kleine*[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Halocarbene complexes represent potential intermediates in the synthesis of carbyne complexes. The study of their reactivity should increase our understanding of the course of this reaction.

We have now found that pentacarbonyl[chloro(diethylamino)carbene]chromium[2] *(1a)* is transformed almost quan-

[*] Dr. H. Fischer [+], Dipl.-Chem. A. Motsch, Dr. W. Kleine
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

[+] To whom correspondence should be addressed.

titatively with loss of CO into *trans*-chlorotetracarbonyl(diethylaminocarbyne)chromium *(2a)* on warming to above 30 °C *in solution* in higher-boiling aliphatic and olefinic halocarbons, aromatic compounds, or ethers.

$$(CO)_5Cr{=}C\begin{matrix}X\\ \diagdown\\ \diagup\\ N(C_2H_5)_2\end{matrix} \xrightarrow{\Delta} X(CO)_4Cr{\equiv}CN(C_2H_5)_2 + CO \quad (A)$$

(1) *(2)*

(a): X = Cl
(b): X = Br

In contrast, warming of *solid (1a)* to above 30 °C leads to evolution of gas and to a brown coloration of the substance which affords chromium chlorides and undefined polymers, as well as pentacarbonyl(ethyl isocyanide)chromium *(3)* (26–29% yield, according to spectroscopy) as solid products; no *(2)* is formed. The seemingly likely conclusion that *(1a)* reacts *via* elimination of ethyl chloride is not correct; the only gaseous product apart from CO is hexacarbonylchromium and not ethyl chloride (b.p. 12.3 °C):

$$(1a) \xrightarrow[\text{solid}]{>30\,^\circ C} (CO)_5Cr(CNC_2H_5) + (CO)_6Cr + CO + \cdots \quad (B)$$

(3)

Pentacarbonyl[bromo(diethylamino)carbene]chromium[3] *(1b)* reacts *both in solution* (CH_2Cl_2) *and in the solid state* at temperatures above −20 °C according to eq. (A) *via* CO elimination to give the *trans*-bromocarbyne complex *(2b)*.

On the other hand, pentacarbonyl[(diethylamino)fluorocarbene]chromium[4] is thermally very stable and only decomposes above 100 °C. Neither formation of a *trans*-fluorocarbyne complex analogous to *(2)* nor that of another carbonylmetal derivative could be detected.

In order to gain information about the mechanism of the carbene—carbyne rearrangement (A) and possibly also about the course of reaction (B), we have performed a kinetic study on reaction (A). The reaction rates were determined by means of IR data [ν_{CO} of *(1a)*, 2063 m, 1939 vs cm^{-1}; ν_{CO} of *(2a)*, 2100 w, 2020 s, 1995 vs cm^{-1}; in 1,1,2-trichloroethane] in the case of *(1a)* and photometric data [increase in absorption shoulder at 490 nm] in the case of *(1b)*. The rate constants of the rearrangement-elimination reaction of *(1a)* and *(1b)*[5] are listed in Table 1; they show that reaction (A) follows 1st order kinetics:

$$-d[(1)]/dt = k[(1)]$$

Table 1. Rate constants k of reaction of *(1)* according to eq. (A). $[(1a)] = 0.01$ mol/l.

Complex	Solvent	T [°C]	$k \times 10^3$ [s^{-1}]
(1a)	1,1,2-Trichloroethane	31.5	0.59
		39.9	1.92
		47.5	4.61
		55.5	11.0
	1,1,2-Trichloroethane + CO [a]	47.5	4.53
	1,2-Dichloroethane	39.9	1.47
	1,1,2,2-Tetrachloroethane	39.9	5.74
	Trichloroethene	39.9	0.32
	Di-*n*-butyl ether	39.9	0.27
	Diglyme/HMPT (9:1) [b]	49.5	1.42
	Diglyme/HMPT (9:1) [b] + KCl (sat.)	49.4	1.41
(1b)	Dichloromethane	−30.6	0.59
		−23.8	1.30
		−19.2	2.70
		−16.1	4.41

[a] Solvent saturated with CO; CO as protective gas.
[b] HMPT = hexamethylphosphoric triamide.

The values of k depend upon the nature of the solvent; however, there does not appear to be any clear correlation between $\log k$ and $1/D$ or $[(D-1)/(2D+1)]$ (D = dielectric constant). As seen in Table 1, the rate of (A) is not influenced by free CO or by Cl^- in the solution. Even under 50 atm of CO, no significant drop in the reaction rate is observed. Determination of the activation parameters afforded:

(1a): $\Delta H^{\neq} = 23.7 \pm 0.5$ kcal/mol;
$\Delta S^{\neq} = 4 \pm 1$ cal/mol·K (in Cl_2CHCH_2Cl)

(1b): $\Delta H^{\neq} = 18 \pm 1$ kcal/mol;
$\Delta S^{\neq} = -1 \pm 2$ cal/mol·K (in CH_2Cl_2)

The following alternatives merit discussion as possible mechanisms:

a) Liberation of a CO ligand in the first and slowest reaction step (pentacoordinate transition state) and migration of the halogen from the carbene carbon atom to the *trans* position of the metal.

b) Homolytic or heterolytic cleavage of the halogen-carbon bond (hexacoordinate transition state) followed by CO elimination and readdition of the halogen in the *trans* position.

c) Migration of the halogen from the carbene carbon to the metal (heptacoordinate transition state) and loss of CO to form *(2)*.

Alternative (a) can be ruled out on the basis of the activation parameters and the negligible effect of free CO on the reaction rate. The very pronounced decrease in activation energy on going from *(1a)* to *(1b)* suggests rupture or at least pronounced weakening of the C—X bond in the first reaction step.—Evidence opposing formation of the cation $[(CO)_5CrCN(C_2H_5)_2]^+$ in the transition state comes from the lack of any dependence of the reaction rate upon the concentration of Cl^- and the observation that *(1a)* is formed instantaneously from $[(CO)_5CrCN(C_2H_5)_2]^+BF_4^-$ and Cl^- under the reaction conditions; only then does *(1a)* react further to give *(2a)*.—A decision between the two remaining possibilities of the intramolecular (route (c)) and free-radical mechanism (homolysis of the C—X bond) still remains open.

$C_6H_5Sb[Mn(CO)_2C_5H_5]_2$—The First Compound Containing Trigonal-Planar Coordinated Antimony(I)[**]

By *Joachim von Seyerl* and *Gottfried Huttner*[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Phosphinidene and arsinidene complexes containing phenylphosphanediyl[1] and phenylarsanediyl[2] as bridge ligands with trigonal-planar P^I and As^I, respectively, have already

[*] Prof. Dr. G. Huttner, Dipl.-Chem. J. von Seyerl

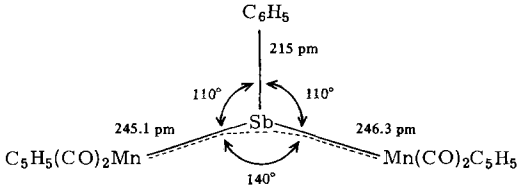
Fachbereich Chemie
Postfach 7733, D-7750 Konstanz (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

been reported. We have now also succeeded in stabilizing phenylstibanediyl, C_6H_5Sb, in a similar way.

The deep-red diiodo(phenyl)stibane complex *(1)* reacts with potassium in tetrahydrofuran (THF) if the reaction is catalyzed by [18]crown-6. In the presence of $C_5H_5(CO)_2Mn\cdot THF$, a product mixture is obtained from which the stibinidene complex *(2)* can be isolated in pure form by chromatography.

$$\underset{(1)}{C_5H_5(CO)_2MnSb(C_6H_5)I_2} + C_5H_5(CO)_2Mn\cdot THF \xrightarrow{K,\ [18]Crown\text{-}6,\ THF} \underset{(2)}{C_6H_5Sb[Mn(CO)_2C_5H_5]_2} + 2KI + \cdots$$

Compound *(2)* forms shiny golden metallic triclinic crystals, which after some initial decomposition at the crystal surface are stable in air. Their extremely air-sensitive solutions in toluene, dichloromethane or *n*-pentane are intense blue in color. In a closed tube, *(2)* melts at 127—128 °C. The mass spectrum corresponds to that of the P and As homologues: The molecular ion (m/e = 550 ref. to ^{121}Sb) is transformed by stepwise cleavage of two pairs of CO groups into the basic ion $C_6H_5Sb[MnC_5H_5]_2^+$ (m/e = 438); a further characteristic fragment is $C_6H_5SbMnC_5H_5^+$ (m/e = 318).—The IR spectrum of *(2)* shows a complex pattern of absorption bands [1966 (m), 1939 (s), 1907 (s), 1900 (m), 1829 (w) cm^{-1}], indicating the presence of rotamers.

The trigonal-planar coordination of the antimony was confirmed by an X-ray structure analysis[3]. The bond angles and bond lengths clearly indicate that the bridging group is stabilized by transition metal-antimony π-bonds.

The method used for the synthesis of *(2)* is also suitable for the preparation of arsinidene complexes.

Experimental

All operations must be carried out under N_2 in anhydrous solvents [Irradiation: Hanau TQ 150, Duran apparatus; structure: Syntex P3]. A solution of $C_5H_5(CO)_3Mn$ (1 g, 4.9 mmol) in THF (400 ml) is irradiated for 150 min. To the resulting red solution of $C_5H_5(CO)_2Mn\cdot THF$ is added bulkwise 2 g (3.2 mmol) *(1)*. A suspension of 480 mg (12 mmol) potassium and 200 mg (0.8 mmol) [18]crown-6 in 20 ml THF is stirred at −90 °C until development of an intense blue color. The two solutions are combined at −90 °C and allowed to warm within 1 h to room temperature. After removal of the solvent, the red residue is taken up in 30 ml toluene and filtered over silica gel at 20 °C, whereupon the color of the solution turns blue-green. The residue obtained after further removal of solvent is absorbed on 3 g silica gel from toluene and chromatographed at −30 °C (Silicagel Merck, particle size 0.063—0.2 mm, column 2.5 × 30 cm). The yellow front is removed from the column with *n*-pentane/CH_2Cl_2 (3:1); on further elution with *n*-pentane/CH_2Cl_2 (1:1) there follows a broad blue zone of *(2)*, which after chromatography and recrystallization from *n*-pentane/CH_2Cl_2 (1:1) affords 250 mg (15 %) of analytically pure *(2)*.

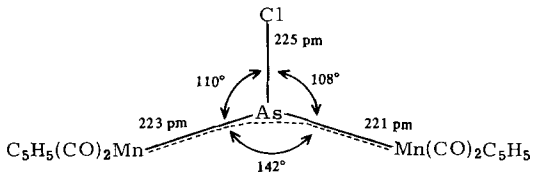
Facile New Synthesis of Chloroarsinidene Complexes[**]

By *Joachim von Seyerl, Ute Moering, Adalbert Wagner, Albin Frank*, and *Gottfried Huttner*[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

The methods (a)[1], (b)[2], (c)[3], (d)[4], and (e)[5] depicted in the following Scheme have previously been developed for the synthesis of phosphinidene, arsinidene and stibinidene complexes.

All these synthetic routes involve several steps and are laborious owing to the complicated working-up procedures; moreover, they enable preparation only of complexes in which R is an organic moiety.



We have now found that arsinidene complexes with R = Cl are accessible in a surprisingly simple way: Reaction of $C_5H_5(CO)_2Mn\cdot THF$ with $AsCl_3$ in tetrahydrofuran (THF) leads to an intense violet solution, from which the chloroarsinidine complex $ClAs[Mn(CO)_2C_5H_5]_2$ *(1)* can be isolated chromatographically in the form of shiny black crystals, m. p. 123—124 °C.

The IR spectrum of *(1)* (*n*-pentane) shows the characteristic pattern of absorption bands for $RX[Mn(CO)_2C_5H_5]_2$ (X = P[5], As[1], Sb[3]), which, with four bands at 2002 (m), 1963 (s), 1950 (m), 1920 (m) cm^{-1}, indicates the presence of a rotameric equilibrium.—The ^1H-NMR signal (C_6D_6) of the cyclopentadienyl protons appears at δ = 4.25 rel. to TMS ext. The mass spectrum shows, besides the molecular ion (m/e = 462 ref. to ^{35}Cl), two series of fragments introduced by initial cleavage of the Cl atom or the CO groups; the base peak corresponds to $As(MnC_5H_5)_2^+$ (m/e = 315).

The expected trigonal-planar coordination of the arsenic in *(1)* is confirmed by the X-ray structure analysis[6].

Also observed is the shortening of the Mn—As distances consistent with the assumed bonding scheme[7], which in the case of *(1)* are shorter again than in the analogous phenylarsinidene complex (227 pm[4]) owing to the electronegative chlorine substituent. The functional groups on the arsenic atom make *(1)* an interesting starting compound for many other reactions. That the present unsatisfactory yields can be considerably improved is indicated, for example, by the analogous synthesis of $ClAs[Cr(CO)_5]_2$ (present yield 20 %).

Experimental

All operations must be carried out under N_2 in anhydrous solvents [irradiation: Hanau TQ 150, Duran apparatus; structure: Syntex P3]. A solution of $C_5H_5(CO)_3Mn$ (5 g, 24 mmol) in THF (400 ml) is irradiated for 2 h. The resulting solution of $C_5H_5(CO)_2Mn \cdot THF$ is stirred together with 2 ml (4.32 g, 24 mmol) $AsCl_3$ for 10 h at 20 °C. After removal of solvent at 20 °C the residue is taken up in 20 ml of toluene and filtered through a 3-cm layer of silica gel. The violet reaction product recovered from this solution on 3 g silica gel is chromatographed at −30 °C (silica gel Merck, particle size 0.063—0.200 mm, column 2.5 × 30 cm). $C_5H_5(CO)_3Mn$ is washed from the column with *n*-pentane; subsequent elution with *n*-pentane/CH_2Cl_2 (1 : 1) affords a broad red-violet zone of *(1)*, from which black crystals of analytically pure *(1)* can be obtained in 6.6 % yield (500 mg) by recrystallization from *n*-pentane/CH_2Cl_2 (1 : 1).

A Substitution with Retention at the Cyclopropane Ring[**]

By *Jürgen Schäffler* and *János Rétey*[*]

Cobalt-substituted cyclopropanes could be of importance in coenzyme B_{12}-catalyzed rearrangements[1]. We have been unable to find any reference to this class of compounds in the literature, apart from in one short communication[2]. In order to attempt a direct substitution at a cyclopropane ring by cobalt(I), we prepared the "*endo*" and "*exo*" isomers *(1)* and *(2)* of doubly benzoannelated 7-bromonorcarane, which itself was obtained by reduction of the 7,7-dibromo derivative *(3)*[3] with tri-*n*-butyltin hydride and subsequent chromatographic purification. The NMR signals of the protons geminal to bromine (see Table 1) permitted unequivocal assignment of the *endo* and *exo* configurations to *(1)* and *(2)*, respectively.

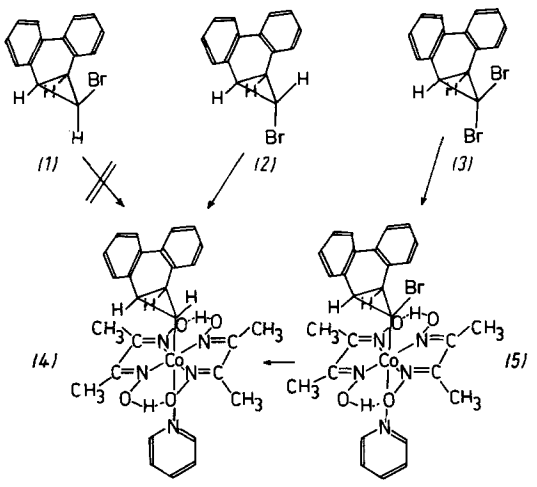

Table 1. Physical data of compounds *(1)*—*(5)*. *(1)*—*(4)* gave correct analytical data.

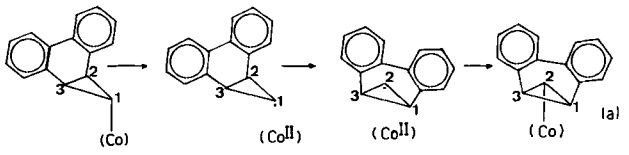
(1): M.p. = 104—105 °C; ^{1}H-NMR ($CDCl_3$): $\delta=2.95$ (d, $J=8$ Hz, 2H), 3.71 (q, $J=8$ Hz, 1H), 7.3—7.5 (m, 6H), 7.9—8.2 (m, 2H); MS (*m/e*) *inter alia* 191 (100 %), 192 (26.5), M^+ 270/272 (1/1)
(2): M.p. = 111—112 °C; ^{1}H-NMR ($CDCl_3$): $\delta=2.32$ (t, $J=3$ Hz, 1H), 2.90 (d, $J=3$ Hz, 2H), 7.3—7.6 (m, 6H), 7.95—8.05 (m, 2H); MS (*m/e*) *inter alia* 191 (100 %), 192 (17), M^+ 270/272 (4/4)
(3): M.p. = 125—126 °C; ^{1}H-NMR (CCl_4): $\delta=3.42$ (s, 2H), 7.2—7.6 (m, 6H), 7.85—8.05 (m, 2H); MS (*m/e*) *inter alia* 269 (100 %), 270 (19.5), 271 (98), 272 (17.5), M^+ 348/350/352 (2.5/5/2.5)
(4): UV/VIS, $\lambda_{max}=457$ nm; ^{1}H-NMR ($CDCl_3$): $\delta=0.7$ (t, $J=4.5$ Hz, 1H), 1.67 (d, $J=4.5$ Hz, 2H), 2.2 (s, 12H), 7.0—7.4 (m), 7.65—7.9 (m), 8.6 (m)
(5): UV/VIS, $\lambda_{max}=458$ nm; ^{1}H-NMR ($CDCl_3$): $\delta=2.25$ (s, 12H), 2.38 (s, 2H), 7.0—7.4 (m), 7.65—7.9 (m), 8.6 (m)

Reaction of *(2)* with cobal(I)oxime[4] gave the cobaloxime derivative *(4)* (see *Experimental*). Both the spectroscopic data of the product (Table 1) and model considerations are reconcilable only with the *exo* structure *(4)*; the *endo* cobaloxime would be sterically unrealizable owing to the dihydrophenanthrene "protective shield".

In contrast to *(2)* the *endo* isomer *(1)* cannot be substituted by cobal(I)oxime, even on prolonged reaction. Cobaloxime *(4)* is also obtained, along with the bromine-containing cobaloxime *(5)*, from the dibromo derivative *(3)*.



The orange-yellow crystalline product *(4)* showed a temperature-dependent ^{1}H-NMR spectrum in perdeuterated hexamethylphosphoric triamide. The signals of the cyclopropane protons at $\delta=0.60$ and 1.70 are broadened at 120 °C, but between 160 and 190 °C they are once again observable as a sharp triplet ($\delta=0.35$) and doublet ($\delta=1.55$). This behavior can be explained in terms of a rapid exchange of the pyridine ligand with solvent molecules. The assumed degenerate rearrangement according to Eq. (a) could not be observed up to 190 °C.

Several mechanisms for the substitution by cobalt(I) have been discussed[2, 5, 6]. A classical S_N2 substitution of the cyclo-

[*] Prof. Dr. J. Rétey, Dipl.-Chem. J. Schäffler

der Universität
Richard-Willstätter-Allee, D-7500 Karlsruhe (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

propane derivatives *(1)* and *(2)* is considered unlikely[7]. The smooth substitution of the *exo*-isomer *(2)* supports the conclusion of *Breslow* and *Khanna*[6] that cobalt(I) complexes can also react with alkyl halides with one-electron transfer:

after elimination of the halide ion the Co—C bond can be formed by combination of the cobalt(II) complex and the alkyl radical. A similar type of substitution cannot take place in the *endo* bromide *(1)* owing to steric hindrance. The retention of configuration observed during the transformation of *(2)* into *(4)* is most likely due to shielding by the dihydrophenanthrene moiety. A retentive alkylation of cobalt(I) oxime has recently also been observed with other sterically hindered alkyl halides[8].

Experimental

A solution of $CoCl_2 \cdot 6H_2O$ (238.6 mg, 1 mmol) and 2,3-butanedione dioxime (232.5 mg, 2 mmol) in analytically pure methanol (60 ml) is prepared under argon. On addition of 2 ml 1 M KOH and 1 ml 1 M pyridine (both in methanol), a color-change from pink to brownish orange is observed. The solution is cooled to -10 °C and treated with a suspension of 80—400 mg (2—10 mmol) $NaBH_4$ (recrystallized from diglyme[9]) in 1 ml 1 M methanolic KOH. After stirring for one hour, the solution turns black; it is now treated dropwise with a solution of 1 mmol *(1)*, *(2)*, or *(3)* (experiments a, b, c) in 30 ml methanol or THF. After 12 h (up to 3 d in the case of a) at room temperature the methanol is removed *in vacuo* and the residue chromatographed on 20 g silica gel (Merck, 0.05—0.2 mm) with ethyl acetate. Yields: a) 90% unchanged *(1)*; b) 7% *(4)* and 27% dibenzoannelated norcarane[10]; c) 60% unchanged *(3)*, 27.5% *(1)*, 4.5% *(2)*, 4—10% *(4)*, and 1—4% (depending on reaction time and amount of $NaBH_4$ used) *(5)*.

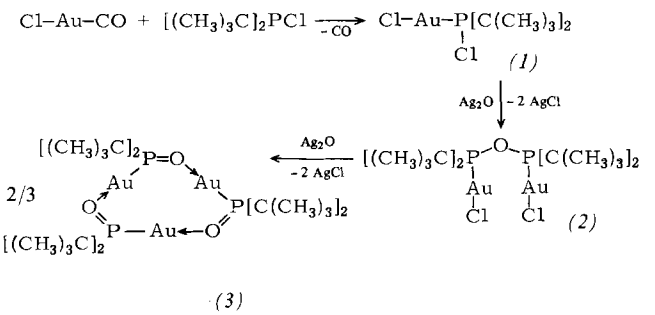
Stabilization of a Phosphinic Anhydride R_2POPR_2 on Gold(I) and Formation of the Trinuclear Complex $(R_2POAu)_3$—Production of an Octahedral Structural Unit $Ag_4Br_2^{2+}$ by Clamping with $R_2PN(R')PR_2$

By *Hubert Schmidbaur, Aref A. M. Aly*, and *Ulrich Schubert*[*]



Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Phosphinic anhydrides (diphosphoxanes) $R_2P—O—PR_2$ are generally unstable and isomerize to $R_2P—P(O)R_2$[1a]. Thus the hydrolysis of halodiorganophosphanes leads not to the acids R_2POH, but to their isomers $R_2P(O)H$ with a P—H bond[1b]. Compounds of type R_2POPR_2 are of considerable potential interest as ligands, since complexes of the analogous imino- and methylene-bisphosphanes exhibit unusual coordination properties[2, 3].

We have prepared the gold complex *(1)*, m.p. 135 °C (dec.), in quantitative yield from carbonylchlorogold(I) and di-*tert*-butylchlorophosphane *via* elimination of CO. The product is characterized by ν(AuCl) and ν(PCl) bands at 344 and 335 (^{35}Cl, ^{37}Cl) and 370 and 566 cm^{-1}, respectively. Its NMR spectra confirm the strong coordination of the chlorophosphane to the gold atom [$^{31}P\{^1H\}$: $\delta P = 144.1$, s; $^{13}C\{^1H\}$: $\delta PC = 40.51$, d, $^1J(PC) = 14.65$ Hz, $\delta PCC = 27.30$, d, $^2J(PC) = 7.32$ Hz; ^1H: $\delta CH_3 = 0.38$, d, $^3J(PH) = 18$ Hz; all spectra in C_6D_6].

Reaction of *(1)* with a substoichiometric amount of silver oxide in benzene over a period of 2 weeks at 20 °C affords AgCl and the benzene-soluble product *(2)*, which crystallizes on addition of pentane (yield 60%). Cryoscopic molecular mass determination in acetone confirms the formula given for the colorless compound, m.p. 287 °C (dec.). In the IR spectrum a strong broad signal appears at 895 cm^{-1} which is assigned to ν(POP)[4], while ν(PCl) is absent; ν(AuCl) remains almost constant at 345 and 335 cm^{-1}. The four *tert*-butyl groups are chemically equivalent (^1H-NMR: $\delta CH_3 = 1.70$, d, $^3J(PH) = 16.0$ Hz). The structure proposed on the basis of these data fits into the series of gold complexes of bisphosphanes, whose structures have also been elucidated by X-ray methods in some cases[3c, d].

Surprisingly, further reaction of *(2)* with Ag_2O or of *(1)* with an excess of Ag_2O does not lead to a diphosphoxane complex of gold(I) oxide Au_2O, but instead to a 75% yield of a colorless and benzene-soluble product of m.p. 301 °C

(dec.): this product was identified as a novel trinuclear gold(I) di-*tert*-butylphosphinite *(3)*. Apart from complete elemental analysis, the mass spectrum is particularly informative; it shows the molecular ion of the trimer ($m/e = 1074$, $3 \times {}^{197}Au$) and fragments formed by loss of butyl groups and entire phosphinite units ($m/e = 1016$, 961, 903, 857, 799, 463, 405, 358, 303). In the IR spectrum of *(3)* there are no bands due to ν(AuCl) or ν(POP), and a new band appears at 995 cm^{-1} ν(P=O...Au). The six *tert*-butyl groups give just one doublet in the ^{1}H-NMR spectrum [$\delta CH_3 = 0.60$, $^3J(PH) = 15.0$ Hz], thus revealing the symmetry of the trimeric structure. Such a structure is still unknown for metal phosphinites[1b]; the formally analogous compound $(C_6H_5)_2POAg$ has been described as an insoluble coordination polymer[5]. In a classical study on the hydrolysis of halophosphane-platinum complexes, the present structural phenomena were anticipated for the neighboring element[6].

We obtained a silver complex of 1,1,3,3-tetraphenyl-2-methyldiphosphazane on reaction of the ligand with AgBr in CH_2Cl_2. The sparingly soluble crystalline product, m. p. 273 °C (dec.), was found analytically to be a 1:2 complex. X-Ray structure analysis[7] revealed the presence of dimeric molecules $\{CH_3N[P(C_6H_5)_2AgBr]_2\}_2$ containing a Ag_4Br_2 octahedron as central unit (Fig. 1). The basal plane made up of four silver atoms is bridged along two sides by two bromine atoms, and the apices of the polyhedron are occupied by two tetragonal-pyramidally coordinated bromine atoms. The other two edges of the base are spanned by PNP units in such a way that slightly twisted chair- and boat-like six-membered rings $BrAg_2P_2N$ can arise.

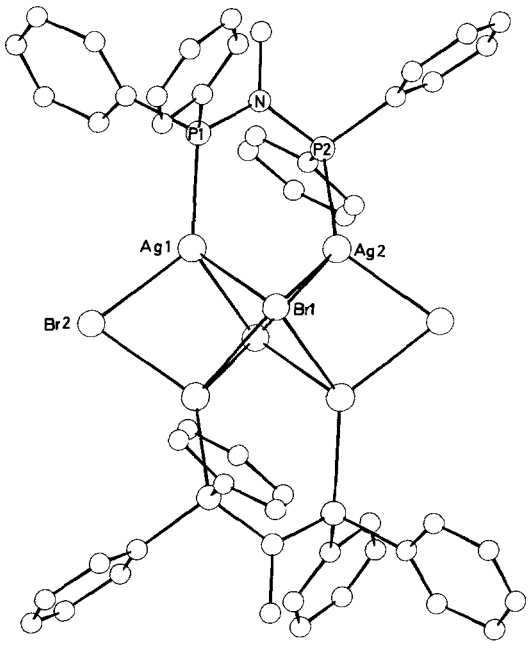

Fig. 1. Structure of the compound $\{CH_3N[P(C_6H_5)_2AgBr]_2\}_2$. The molecule is centrosymmtric.

Unlike *methylene*bisphosphane complexes, which contain Ag_3Br_2 polyhedra[2a], the *imino*bisphosphoranes prefer Ag_4Br_2 polyhedra with greater edge lengths in the same system. We suspect the reason to lie in the difference between the PCP and PNP bond angles[2, 3].

Procedure

A solution of $[(CH_3)_3C]_2PCl$ (0.37 g, 2.0 mmol) in benzene is slowly added to a benzene solution of ClAuCO (0.40 g, 1.5 mmol), whereupon evolution of CO immediately ensues. After 2 h at 20 °C, the solvent can be removed under vacuum; the residue is washed and recrystallized from benzene/pentane. Yield 0.62 g (100 %); colorless substance, soluble in acetone, benzene, CH_2Cl_2.—*(1)* (1.00 g, 2.4 mmol) is stirred at 20 °C for 14 d with Ag_2O (0.42 g, 1.8 mmol) in benzene; AgCl precipitates. Filtration, removal of solvent, and addition of pentane afford colorless, light-sensitive *(2)* (0.55 g, 60 %).

Reaction of *(2)* with Ag_2O (1.9 mmol) in benzene or of *(1)* with an excess of Ag_2O gives further AgCl, and colorless, light-sensitive *(3)* can be isolated analogously from the filtrate; it is soluble in ether, acetone, and CH_2Cl_2.

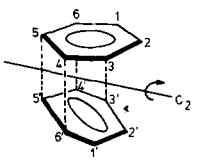
Pentacyclo[6.4.0.0^{2,5}.0^{3,10}.0^{4,9}]dodeca-6,11-diene, an *o,o′*:*o,p′*-Dimer of Benzene[**]

By *Hans-Dieter Martin* and *Peter Pföhler*[*]



Dimers of benzene are of interest because aromatic resonance already becomes partly effective in the transition state of their thermal decomposition to benzene. Moreover, these $(CH)_{12}$ hydrocarbons are suitable for the study of intramolecular π,π- and π,σ-interactions owing to their compara-

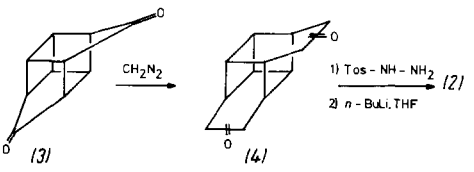
[**] Small Rings, Part 29. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *R. Gleiter* for recording the PE spectrum of *(2)*.—Part 28: *H.-D. Martin, B. Heiser, M. Kunze,* Angew. Chem. *90*, 735 (1978); Angew. Chem. Int. Ed. Engl. *17*, 696 (1978).

tively rigid skeletons. We now report the synthesis, thermolysis kinetics, and intramolecular interactions of the fourfold bridged benzene dimer *(2)*[1], which could be expected *a priori* to have a greater thermal stability than *o,o'*- and *o,p'*-dibenzenes[2].

The relationship between *(2)* and benzene is expressed schematically by *(1)*, which also underlines the C_2 symmetry present.



(1)

(2)

Treatment of bishomocubanedione *(3)* with diazomethane yields a mixture of the homologous diketones *(4)*[3]. Reaction with tosylhydrazine in tetrahydrofuran leads to the isomeric hydrazones. The action of *n*-butyllithium in THF on the mixture at room temperature affords a 22% yield of the diene *(2)*, which is purified by distillation and subsequent gas chromatography. Compound *(2)* is a colorless, slightly air-sensitive liquid having an uncharacteristic odor[4].

(3) *(4)*

The predominant fragmentation to benzene induced by electron impact is also observed on heating. After 2h at 190°C in hexachlorobutadiene, *(2)* has decomposed quantitatively to benzene. The kinetics of the unimolecular reaction was measured in mesitylene (Table 1).

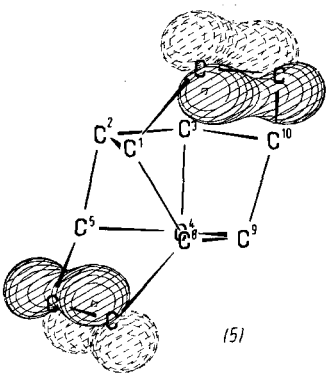


Table 1. Decomposition of *(2)* in mesitylene.

T[°C]	$10^5 \cdot k$ [s^{-1}]	E_a	log$A$
160.1	2.8	36.9 ± 0.3 kcal/mol 154.2 ± 1.3 kJ/mol	14.1 ± 0.2
166.7	5.4		
169.5	6.9		
172.2	8.9		
179.7	18.4		
185.3	29.2		

The activation energy of 36.9 kcal/mol is of the same order of magnitude as the values for basketene (29.7 kcal/mol)[5a] and homobasketene (35.3 kcal/mol)[5b]. The thermal reaction might involve a [4+2] cycloreversion to *o,o'*-dibenzene and its [2+2] fragmentation to benzene.

The formally nonconjugated double bonds in *(2)* could at first sight create the impression that there is no interaction between them. This is not the case. Although the topology of the molecule rules out direct π overlap (homoconjugation), considerable hyperconjugational effects can be expected. Possible transmitters are the 1,8-σ bond and the bicyclo[2.2.0]hexane moiety (C atoms 2,5,4,9,10,3), the latter case being without precedent. CNDO/S calculations[6] predict the energy sequence π_S (HOMO, $\varepsilon = -9.09$ eV) > π_A (third highest occupied MO, $\varepsilon = -9.76$ eV). The splitting of 0.7 eV is due to σ,π-interaction of π_S with σ(1,8) and with the bicyclo[2.2.0]hexane unit.

The perspectively correct structural formula *(5)*[7], which also contains the π-electron densities of the π_S HOMOs, reveals that both the 1,8-σ bond and the four-membered ring bonds

(5)

5,4 and 10,3 could engage in σ,π interaction. These model considerations are confirmed by experiment. The photoelectron spectrum of *(2)* gives $IP_{1,v} = 8.30$ eV and $IP_{2,v} = 9.35$ eV; the second band is more than three times as intense as the first one. Since basketene[8] shows $IP_{1,v} = 8.97$ eV and the inductive effect of an additional vinylene group on $IP_{1,v}$ can be neglected[9] [*(2)* can be regarded as vinylogous to basketene], a through-bond interaction of the kind mentioned above is held responsible for the lowering of $IP_{1,v}$ by $\Delta IP \approx 0.7$ eV.

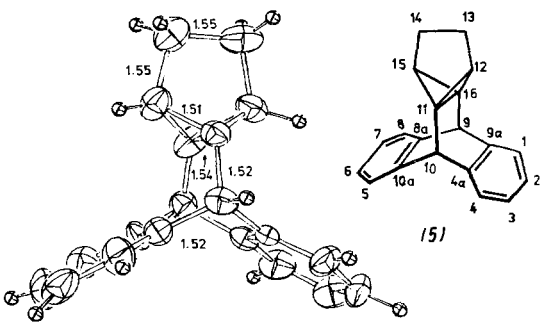
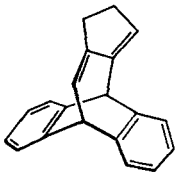
diate[1]. We now report experimental results from which we deduce that the homologous title compound *(1)* can also exist as a reactive species. This new C_6H_6 isomer has the carbon skeleton of benzvalene, from which it differs in the position and energy of its CC double bond.

(2)	a	b	c	d	e
R	H	Li	Cl	n-C_4H_9	C_6H_5

Tricyclo[3.1.0.0^{2,6}]hexane *(2a)*[2] could be metalated with *n*-butyllithium in diethyl ether to give *(2b)*, which afforded a 48% yield of 1-chlorotricyclo[3.1.0.0^{2,6}]hexane *(2c)* on treatment with *p*-toluenesulfonyl chloride[3]. Compound *(2c)* reacts with organolithium compounds by nucleophilic substitution: *n*-butyllithium (molar ratio 1:3) gave an essentially quantitative yield of 1-*n*-butyltricyclo[3.1.0.0^{2,6}]hexane *(2d)* after aqueous workup, and phenyllithium the 1-phenyl derivative *(2e)* in 65% yield. The preparation of 1-(1-tricyclo[3.1.0.0^{2,6}]hexyl)tricyclo[4.1.0.0^{2,7}]heptane *(3)* was accomplished in 25% yield by combination of *(2c)* and 1-tricyclo[4.1.0.0^{2,7}]heptyllithium.

We interpret the course of these reactions as follows: the 1-chloro derivative *(2c)* is lithiated at C-6 by the lithium base to give *(4)*, which undergoes LiCl elimination to form the intermediate *(1)*. The bicyclo[1.1.0]but-1(3)-ene derivative *(1)* adds the lithium base to its highly strained double bond; aqueous workup then leads to the products [*(2d)*, *(2e)*, and *(3)*].





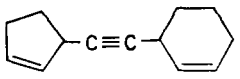


Fig. 1. Molecular structure of *(5)* with the principal bond lengths [Å]. The dihedral angle in the bicyclo[1.1.0]butane system is 113°. Bond angles: (C-12)—(C-11) (C-15), 91°; (C-10)—(C-11)—(C-16), 110°; (C-11)—(C-12)—(C-13), 109°; (C-12)—(C-13)—(C-14), 101°; (C-12)—(C-11)—(C-16), 59°.

Our interpretation of the reaction proceeding *via (1)* as intermediate is based on the formation of the Diels-Alder adduct *(5)*, which was isolated in 36% yield from a mixture of *(2c)*, lithium 2,2,6,6-tetramethylpiperidide, and anthracene in tetrahydrofuran at −20°C (m.p. 155–157°C, from *n*-pentane).

Structural proof for *(5)* is based on spectroscopic data (Table 1) and on an X-ray analysis depicted in detail in Figure 1[4]. The bridgehead atoms C-11 and C-16 of the bicyclo[1.1.0]-butane system of this [4.1.1]propellane[1c] exhibit the "inverted tetrahedron" phenomenon[5], *i.e.* C-11 and C-16 are each located outside the tetrahedron formed by their four respective substituents. Thus the distance between C-11 and the tetrahedral face C-10, C-12, C-15, which intersects the (C-11)—(C-16) bond, is 0.31 Å[6]. The (C-11)—(C-16) bond is significantly longer at 1.54 Å than the corresponding bonds in the other bicyclo[1.1.0]butanes examined so far[7].

At 150°C in C_6D_6, *(5)* undergoes complete rearrangement within 30 min to the diene *(6)* (cf. [1c]).—Compound *(3)* also isomerizes quantitatively at 160°C to the acetylene *(7)*.

(6)

(7)

Table 1 lists NMR data of the new compounds.

Table 1. NMR data (δ values) of *(2c)*, *(2d)*, *(2e)*, *(3)*, *(5)*, *(6)*, and *(7)*.

A Stable σ/π-Organometallic Radical of Vanadium: $(\eta^5\text{-}C_5Me_4Et)_2V\text{—}C{\equiv}C\text{—}C_6H_2Me_3$[**]

By *Frank H. Köhler, Wolfram Prössdorf, Ulrich Schubert*, and *Dietmar Neugebauer*[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Vanadocenes bearing an additional σ-bonded organic group on the metal could provide valuable information about the still unknown V—C bond length[1, 11], about the stability of this bond, about *Hoffmann*'s MO concept of bent metallocenes[2], and about paramagnetic NMR behavior, if only it were possible to adequately stabilize these molecules, which are generally known to be unstable and poorly characterizable[3].

We have successfully stabilized such a molecule by peralkylation of the cyclopentadienyl ligands. Starting from 3-ethyl-1,2,4,5-tetramethylcyclopentadiene *(1)*[4], slight modifications to our previous synthesis[5] yield peralkylated vanadocene *(2)* and vanadocene bromide *(3)*. Reaction of *(3)* with the sodium salt of mesitylacetylene *(4)* gives olive-green, air-sensitive bis(ethyltetramethyl-η^5-cyclopentadienyl)mesitylethynylvanadium *(5)*. While the nonalkylated compound rapidly decomposes at 25 °C[6], compound *(5)* melts at 83—84 °C, can be sublimed (leaving a residue), and survives several hours' heating in boiling toluene without decomposition.

Elemental analysis and mass spectrum (principal metal-containing ions at 70 eV and 75 °C: M^+ (32), $[M+1]^+$ (12), $[M-(4)]^+$ (72), $[M+2-(1)]^+$ (100), $[M-(1)]^+$ (44), $[V\text{—}C{\equiv}C\text{—}C_6H_2Me_3]^+$ (20)) prove the composition of *(5)*; X-ray analysis[7] provides proof of its structure (cf. Fig. 1). The vanadium atom lies in the plane E1 (C20, M1, M2) and can be regarded as surrounded by three hydrocarbon groups in an almost trigonal-planar fashion. Peralkylation of the five-membered rings does not lead to any significant increase in the metal-ring distances compared with other $(\eta^5\text{-}C_5H_5)$-vanadium derivatives[8] studied so far; instead, the M1—V—M2 angle (149.7°) is considerably greater than that in $(\eta^5\text{-}C_5H_5)_2VCl$ (139.5°)[8b]. In spite of this decrease in strain, the methyl groups are bent out of the planes of the five-membered rings away from the vanadium by up to 32 pm. The bond angles and the bond lengths of the acetylene moiety are typical[9], whereas no reference data are available for the $V^{III}\text{—}C_{sp}$ distance of 203.2 pm.

Of particular interest was the question how the plane of the benzene ring E2 would be oriented relative to the coordination plane of the vanadium E1. With regard to the metal orbitals, and especially b_2, according to *Hoffmann et al.*[2] conjugation might conceivably extend from the vanadium to the benzene ring, which should lead to a parallel arrangement of E1 and E2. In contrast, we find these planes to enclose an angle of 86.8°. Thus π-interaction occurs only between V/C20/C201 on the one hand and between C20/C201/mesityl on the other.

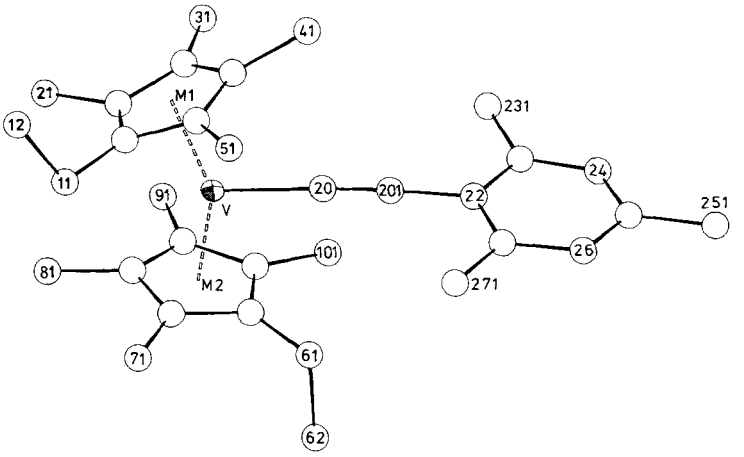

Fig. 1. Molecular structure of the organometallic radical *(5)*.

Distances	[pm]	Angles	[°]
V—M1	197.6	M1—V—M2	149.7 (1)
V—M2	197.0	M1—V—C20	105.4 (4)
V—C20	203.2 (13)	M2—V—C20	104.8 (4)
C20—C201	123.4 (17)	V—C20—C201	176.6 (10)
C201—C22	144.7 (14)	C20—C201—C22	175.5 (12)

A well-resolved paramagnetic ^{1}H-NMR spectrum can be recorded for *(5)*. It exhibits broad signals (300—400 and 120 Hz wide) having large chemical shifts such as are typical for protons located α or β to a cyclopentadienyl ring[5b]: $\delta^{para}(^1H\text{-}31/41/81/91)$[10] $= -22.3$, $\delta^{para}(^1H\text{-}21/51/71/101) = -18.2$, $\delta^{para}(^1H\text{-}11/61) = -10.3$, and $\delta^{para}(^1H\text{-}12/62) = +0.6$. In addition, signals of 20—80 Hz width are observed for the bonded acetylene: $\delta^{para}(^1H\text{-}24/26) = -20.5$, $\delta^{para}(^1H\text{-}231/271) = -10.1$, and $\delta^{para}(^1H\text{-}251) = -8.7$. On comparison with vanadocene halides[5b], these data show *(5)* to be an organometallic radical possessing two unpaired electrons and confirm that the vanadium is surrounded only by two π- and one σ-bonded hydrocarbon groups. Correlation of δ^{para} with the distance from vanadium shows that the delocalization of unpaired electrons is much more pronounced onto the acetylene than onto the π ligands. Thus, elucidation of structure and studies on electron distribution in radicals of the $(\eta^5\text{-}C_5H_5)_2V\text{—}R$ type are seen to be possible by NMR.

Procedure

Sodium mesitylacetylide (0.58 g, 3.5 mmol) is added to a solution of *(3)* (1.45 g, 3.4 mmol) in diethyl ether (50 ml). After removal of ether, the residue is extracted with pentane (30 ml), the olive-green extract treated with ethanol (30 ml), and the pentane removed under reduced pressure. Compound *(5)* crystallizes from the ethanol solution at −78 °C. Recrystallization from ethanol (2×) and from pentane (3×) gives lustrous black crystals of analytically pure *(5)* (0.35 g, 21 %).

Optically Active Tricyclo[6.4.0.0^{4,9}]dodecane[**]

By *Hartmuth Buding* and *Hans Musso*[*]

Dedicated to Professor Hans Brockmann on the occasion of his 75th birthday

Chiral molecules not exhibiting measurable rotation are very rare (for examples see Ref.[1, 2]). According to the Brewster rules[3] the pure enantiomers of the title compound *(5)*—*(5a)* and *(5b)*—ought to be practically optically inactive. It was therefore of interest to prepare the enantiomers and to demonstrate their chirality.

The dihydroxydiketone *(1)*, recently shown to be readily accessible from furanophane[4], has the desired skeleton. The reaction of *(1)* with (−)-(*R*)-2,3-butanedithiol[5] affords a mixture of the diastereomeric dithioacetals *(2)*, which could be separated on silica gel using carbon tetrachloride/acetone (6:1). The first eluted *(2a)* (m.p. 99—101 °C) is clearly distinguishable from the more polar *(2b)* (m.p. 146—147 °C) by ^{1}H-NMR. In the presence of Eu(DPM)$_3$ a mutual contamination of >0.5 % can be ruled out from the signals of the methyl groups. Boiling of *(2a)* and *(2b)* with Raney nickel in methanol affords the alcohols *(3)* (m.p. 219—220 °C) in 60 % yield, which are converted by *Olah*'s method[6] into the bromides *(4)* (m.p. 149—150 °C) in 64 % yield. Dehalogenation is accomplished either with $LiAlH_4$ in dioxane or with tributyltin hydride (neat) to give the enantiomeric hydrocarbons *(5a)* and *(5b)* in 64 % yield (m.p. 47.5—49.0 °C) and having easily measurable optical rotations. A partial racemization was to be feared only in the transition *(3)*→*(4)*; the dibromides *(4)* obtained at 0 °C and +25 °C gave practically the same [α]-values. Neither the ^{1}H-NMR nor the mass spectrum revealed any olefinic contamination of *(5)*, which proved to be >99.6 % pure on VPC. The ^{13}C-NMR spectrum ($CDCl_3$)

(1) *(2)* *(3)*, R = OH; *(4)*, R = Br; *(5)*, R = H

	$[\alpha]_D^{20}$ *(a)*	*(b)*
(1)	—	−103.0° ± 5.0 (*c* = 0.12, dioxane)
(2)	−69.9°	+ 84.4° ± 0.4 (*c* = 0.52, $CHCl_3$)
(3)	−49.6°	+ 49.0° ± 0.4 (*c* = 2.02, CH_3OH)
(4)	−38.8°	+ 38.0° ± 0.4 (*c* = 2.04, $CHCl_3$)
(5)	−30.0°	+ 27.0° ± 2.0 (*c* = 0.23, cyclohexane)

is consistent with the structure *(5)* [δ = 21.1 (t), 27.8 (t), 32.3 (t), 34.2 (d; C-1, C-4), 36.3 (t), 36.7 (d; C-8, C-9)][7].

The dithioacetal *(2b)* afforded some optically active diketone *(1b)* (decomp. pt. 237 °C). The interaction of the carbonyl chromophores raises doubts concerning the validity of the octant rule in this special case. An X-ray structure analysis on *(1)*[4] has shown that all three cyclohexane rings exist in slightly twisted chair conformations. This has also been demonstrated by EFF calculations[8] for the minimum energy conformation of the hydrocarbon *(5)*, and this might be the reason for the unexpectedly high optical rotation.—The determination of the absolute configuration is being attempted.

Lichtenbergstrasse 4, D-8046 Garching (Germany)

room temperature with insertion of the alkyne into the metal-carbene bond to give alkenyl(amino)carbene complexes[2]. *On warming* a typical representative of this class of compounds, pentacarbonyl[diethylamino(α-diethylamino-β-methoxystyryl)carbene]chromium *(1)*, in decane, a CO ligand *cis* to the carbene ligand is substituted intramolecularly by the amino function of the styryl substituent, leading to formation of the tetracarbonyl complex *(2)*. Stronger heating of the solution results in the loss of further CO and attack of the carbene-carbon at the *ortho* position of the phenyl ring. Thus cyclization occurs to give the 2,3-bis(diethylamino)-1-methoxyindene, which remains coordinated as the tricarbonyl complex *(3)* [^{1}H-NMR ([D$_6$]-acetone): δ = 5.53 (m, 4H, H-4,5,6,7), 5.05 (s, 1H, H-1), 3.64 (s, 3H, OCH_3), 4.07 and 3.09 (each m, 4H, NCH_2), 1.14 and 1.09 (each t, 6H, NCH_2CH_3); MS: M^+ at $m/e = 424$].

The ν(CO) IR spectrum (hexane: 1966, 1963; 1903, 1893, 1888 cm^{-1}) shows a double set of the expected absorption bands, indicating that the indene complex preferentially exists as two rotamers in solution (referred to the aromatic-metal axis). An X-ray structure analysis[3] of *(3)* confirmed the insertion of the ynediamine in positions 2 and 3 of the indene ring (Fig. 1). The bond lengths in the five-membered ring are 152(2) pm for C1—C2 and 137(2) pm for C2—C3. The oxygen atom O4 and the hydrogen atom H1 deviate significantly, 110 pm and 88 pm (difference Fourier calculation), respectively, from the C2, C3, N1, N2 plane, which is at an angle of 9° to the six-membered ring bound to the metal. The carbon atom C1 lies 5 pm above each of these two planes. The carbonyl groups are staggered relative to the carbon atoms coordinated to the metal, which are coplanar.

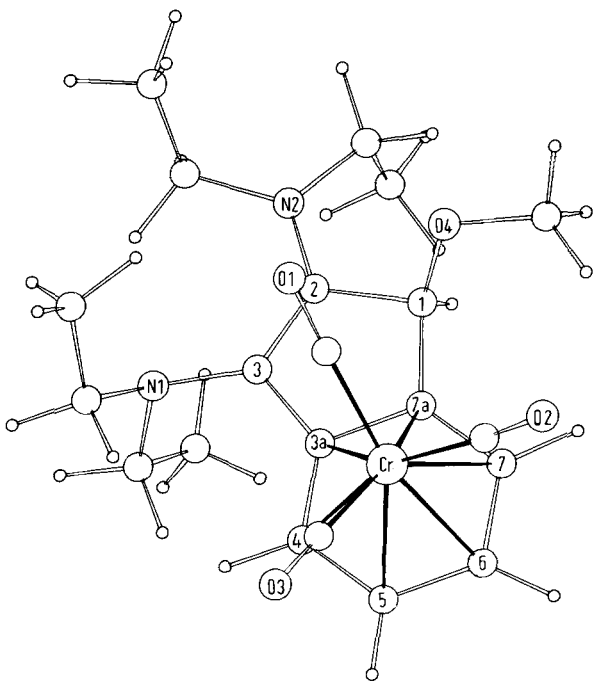

Fig. 1. Crystal structure of the complex *(3)*.

Under the same conditions the corresponding methoxy(phenyl)carbene complex of the higher homolog tungsten reacts with the ynediamine only up to the tetracarbonyl stage. The cyclization to the indene skeletal structure and the accompanying 1,3 hydrogen shift from the *ortho* position of the phenyl ring to the original carbene-carbon must therefore be ascribed to the influence of the chromium, which may be regarded as the active center of a template reaction.

Procedure

All work must be carried out under N_2 with dry (Na) solvents saturated with N_2.—A solution of *(2)*[2a] (0.40 g, 0.885 mmol) in decane (10 ml) is heated at 125 °C for 2 h. The color of the solution becomes paler, finally being yellow. After removal of solvent the residue is chromatographed on silica gel (Merck Act. 2—3) with benzene/pentane (2:1). The main zone affords yellow crystals of *(3)*, m.p. 64 °C, in 75% yield (0.28 g).

PdTeI and Pd_2SeI_3 – The First Chalcogenide Halides of a Platinum Metal[**]

By *Gerhard Thiele, Maria Köhler-Degner, Kurt Wittmann*, and *Gerd Zoubek*[*]

The chalcogenide halides of the coinage metals copper, silver, and gold have been the subject of intensive recent work owing to their interesting physical properties[1]. It seemed an obvious step to extend these studies to corresponding compounds of the platinum metals. However, all attempted preparations yielded only polycrystalline material contaminated with varying amounts of the binary halides and chalcogenides. The structures and precise composition of the new compounds therefore remained unknown. We now report the synthesis and structure analysis of the palladium compounds PdTeI and Pd_2SeI_3.

The ternary compounds can be prepared directly from the elements by low-pressure hydrothermal synthesis[2] in HI solu-

[*] Prof. Dr. G. Thiele, Dr. M. Köhler-Degner, Dipl.-Chem. K. Wittmann, Dipl.-Chem. G. Zoubek

Egerlandstrasse 1, D-8520 Erlangen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

tion. However, single crystals of Pd_2SeI_3 were obtained on reaction of PdI_2 with Se in liquid iodine.

In the brass-yellow crystals of PdTeI, the Te and I atoms are cubic close packed with Pd atoms occupying half of the octahedral vacancies. There is a close relationship to the NaCl type, which can also be substantiated by group theoretical considerations. The $PdTe_{2/2}I_{4/4}$ octahedra are stretched along the c axis (Pd—I 260 and 284, Pd—Te 284 pm, each $2\times$). They are linked alternately *via* edges of two I and two Te atoms to form chains. Since each I atom also represents the apex of two octahedra from adjacent layers, a loose three-dimensional network is formed (cf. Fig. 1). There are no covalent bonds between the Te and I atoms (closest contacts: I—I 339, Te—Te 380, Te—I 391 pm), and the compound should therefore be formulated as palladium(III) telluride iodide $Pd^{3+}Te^{2-}I^-$. The stretching of the coordination octahedron around Pd^{3+} can be explained as Jahn-Teller distortion of a d^7 low spin system. The diamagnetism, the good electrical conductivity (specific resistance at 25°C: $\rho = 4\times10^{-4}\,\Omega$ cm), and the striking color of the compound suggest, however, that the bonding can only be fully explained by the band model.

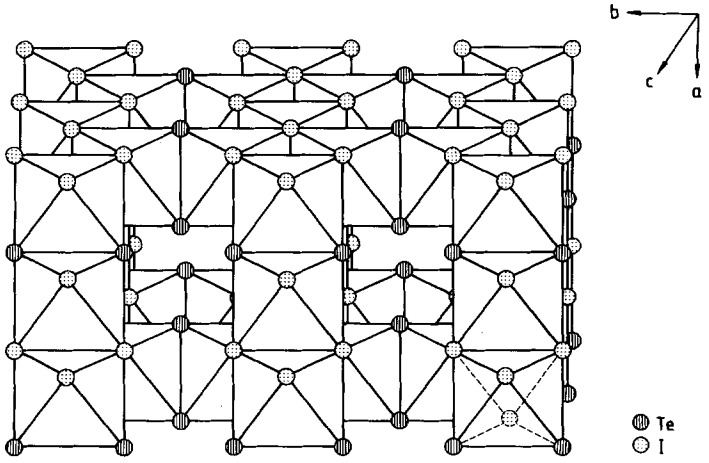

Fig. 1. Linkage of $PdTe_{2/2}I_{4/4}$ octahedra in the tetragonal unit cell of PdTeI [$a = 780.8(2)$, $c = 566.0(1)$ pm; space group $P4_2/mmc$; $Z = 4$].

In the metallic black rhomboid crystals of Pd_2SeI_3, however, Pd is in the formal oxidation state of +2, since in the orthorhombic unit cell the Pd atoms are in a square-planar environment of three I atoms and the Se atom of a Se_2 group. The Se_2^{2-} group links four such squares to form $Pd_4Se_2I_4I_{4/2}$ units (cf. Fig. 2), which in turn are linked *via* the four corners to form puckered layers.

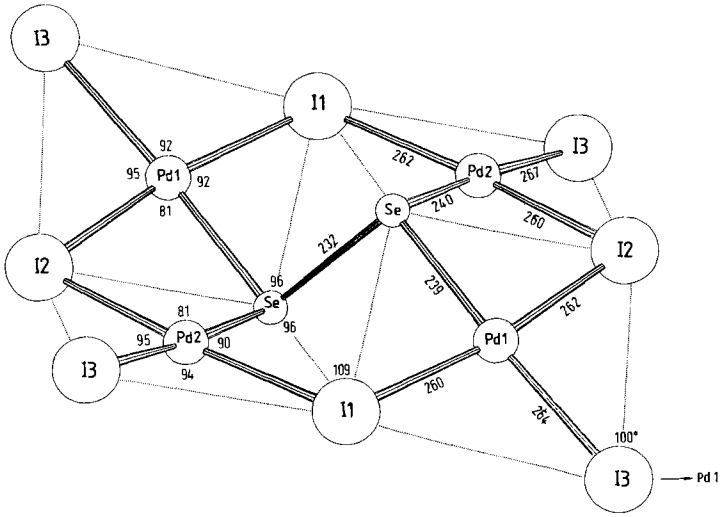

Fig. 2. $Pd_4Se_2I_4I_{4/2}$ structural units in Pd_2SeI_3 with principal distances and angles. The orthorhombic unit cell [$a = 791.1(1)$, $b = 1288.5(3)$, $c = 1432.1(3)$ pm; space group Pbca] contains 8 formula units.

Procedure

Single crystals of PdTeI: Pd sponge (50 mg), Te powder (60 mg), I_2 (120 mg), and KI (30 mg) are heated to 300°C with 55% HI solution (1 ml) for 6 d in a glass ampoule of *ca.* 4 ml capacity. The resulting brass-yellow crystalline needles were filtered off and washed several times with hot water (yield *ca.* 120 mg).

Single crystals of Pd_2SeI_3: PdI_2 (30 mg), Se (120 mg), and I_2 (7.5 g) are heated together to 250°C for 2 d in a glass ampoule, and the melt is slowly cooled (0.5°C/h) to just above the melting point of iodine. Liquid iodine is decanted from the precipitate within the ampoule; residual I_2 can be removed by repeated washing with acetone, and excess Se by heating with conc. H_2SO_4. Powder samples can be prepared more easily by reaction of Pd (70 mg), Se (52 mg), and I_2 (84 mg) in 1 ml of 55% HI solution.

X-ray structural data were recorded with $Mo_{K\alpha}$ radiation between 3° and 25° in a single crystal diffractometer. 229 (PdTeI) and 324 (Pd_2SeI_3) independent data were employed in the solution (program system SHELX[3]); refinement led to $R = 5.42$ and 8.33%, respectively.

Bridged Aza[10]annulenes—10π-Analogues of Pyridine[**]

By *Maria Schäfer-Ridder, Arwed Wagner, Michael Schwamborn, Helmut Schreiner, Eveline Devrout, and Emanuel Vogel*[*]

The potentially aromatic monoaza[4n+2]annulenes—the homologues of pyridine—are still virtually unknown[1–3]. In view of the remote chance of being able to isolate simple aza[10]- and aza[14]annulenes we concentrated our efforts from the very beginning on the synthesis of the two bridged aza[10]annulenes, 2,7-methanoaza[10]annulene *(1)* and 3,8-methanoaza[10]annulene *(2)*, derived from 1,6-methano[10]annulene. Though earlier attempts to prepare these

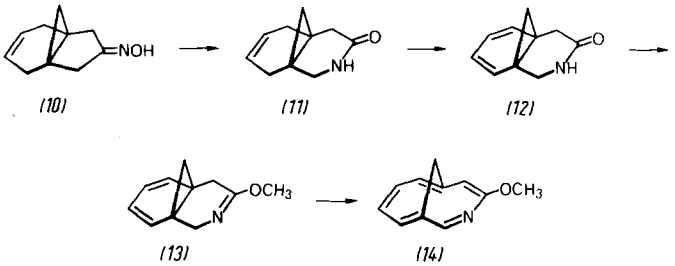
[**] This work was supported by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen (Germany).

novel heterocycles met without success[4], we have now found routes to *(1)* and to a derivative of *(2)*.

As starting compound for the synthesis of *(1)* we used cycloheptatriene-1,6-dicarbaldehyde *(3)*[5]. Reaction of *(3)* with methylene(triphenyl)phosphorane [prepared from $MePh_3PBr$ and $NaN(SiMe_3)_2$] in the molar ratio 1:1.25 in tetrahydrofuran (room temperature, 4 h) and subsequent chromatographic separation on silica gel (dichloromethane/hexane 1:1) afforded 6-vinyl-1,3,5-cycloheptatriene-1-carbaldehyde (40%), which on account of its sensitivity towards oxygen was immediately oxidized with aqueous alkaline silver oxide to the corresponding acid *(4)* [m.p. 116°C (from hexane); yield 82%; ^{1}H-NMR ($CDCl_3$): $\delta = 2.87$ (s, 2H, H-7), 5.27 (d, 1H), 5.87 (d, 1H), 6.48 (m, 1H) (ABX system of the vinyl protons), 6.2–7.0 (m, 3H, H-3, 4, 5), 7.43 (d, 1H, H-2), 11.0 (br. s, 1H, COOH); UV (cyclohexane): $\lambda_{max} = 238$ nm ($\varepsilon = 33000$), 292 (2650), 343 (5000)]. The acid azide *(5)* formed on reaction of the acid chloride of *(4)* with sodium azide in aqueous acetone undergoes Curtius rearrangement on heating in toluene (110°C, 30 min) to give 6-vinyl-1,3,5-cycloheptatrienyl 1-isocyanate *(6)*, a compound isolable under these conditions but prone to polymerize (b.p. 30°C/0.1 torr).

(3) *(4)* *(5)* *(6)* *(7)* *(8)* *(9)* *(1)*



The supposition that the isocyanate *(6)* could isomerize thermally by a 10π-electrocyclic process[6]—or by successive cycloheptatriene-norcaradiene and Cope rearrangements[7]—to the azaenone *(7)*, and that *(7)* could readily be converted prototropically into the thermodynamically more stable lactam *(8)* (2-azabicyclo[4.4.1]undeca-4,6,8,10-tetraen-3-one) has been confirmed experimentally: on heating *(6)*, or better the acid azide *(5)*, for 12 h in toluene the expected lactam *(8)* is formed as main product [yellow needles, m.p. 143–144°C (from ethyl acetate); yield 35% based on *(4)*; ^{1}H-NMR ($CDCl_3$): $\delta = 0.17$ and 1.85 (AX system, $J = 9.6$ Hz, 2H, H-11), 6.17 (d, $J = 11.4$ Hz, 1H, H-4), 6.5–7.4 (m, 4H, H-7, 8, 9, 10), 7.54 (d, $J = 11.4$ Hz, 1H, H-5), 11.7 (br. s, 1H, NH); UV (acetonitrile): $\lambda_{max} = 223$ nm ($\varepsilon = 12700$), 270 (28800), 302 (4700), 373 (3500); IR ($CHCl_3$): 3380, 1620 cm^{-1}].

Analogous to α-pyridone, *(8)* on reaction with trimethyloxonium tetrafluoroborate in dichloromethane (room temperature, 4 h) or on reaction of its silver salt with methyl iodide, experiences almost exclusive *O*-alkylation to 10-methoxy-2,7-methanoaza[10]annulene [bright yellow liquid, b.p. 60–61°C/0.1 torr; yield 54% and 55%, resp.; ^{1}H-NMR ($CDCl_3$): $\delta = 0.22$ and 0.4 (AB system, $J = 9.0$ Hz, 2H, H-11), 4.0 (s, 3H, OCH_3), 6.06 (d, $J = 10.2$ Hz, 1H, H-9), 6.7–7.3 (m, 4H, H-3, 4, 5, 6), 7.47 (d, $J = 10.2$ Hz, 1H, H-8); UV (cyclohexane): $\lambda_{max} = 236$ nm ($\varepsilon = 21500$), 264 (26000), 294 (sh, 5300), 372 (4700)], while with diazomethane a mixture of comparable amounts of *O*- and *N*-methylation products is obtained.

Attempts were made to accomplish the transformation of *(8)* into *(1)* *via* the *O*-tosyl derivative *(9)* [prepared from the potassium salt of *(8)* and *p*-toluenesulfonyl chloride in tetrahydrofuran (room temperature, 1 h), bright yellow needles, m.p. 82–83°C (from methanol); yield 78%]. Reduction of *(9)* with two equivalents of lithium aluminum hydride in boiling tetrahydrofuran (30 min) afforded an unstable product in which, according to ^{1}H-NMR analysis, a mixture of dihydro compounds of *(1)* was present. Consistent with this finding, treatment of the original reaction mixture with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) (room temperature, 10 min) led to dehydrogenation of the reduction product and formation of a nitrogen base, which could be isolated in pure form (yield 36–40%) by chromatographic filtration on aluminum oxide followed by distillation. As confirmed spectroscopically, this compound, a stable yellow liquid of b.p. 63°C/1 torr and having a quinoline-like odor, is the desired 2,7-methanoaza[10]annulene *(1)*.

The most convincing evidence for the structure of *(1)* and for its aromatic character is provided by the ^{1}H-NMR spectrum [90 MHz (CCl_4): $\delta = -0.4$ and 0.65 (AX system, $J = 8.4$ Hz, 2H, H-11b, and H-11a[8]), 6.5 (dd, $J = 9.0$ and 6.3 Hz, 1H, H-9), 6.6–7.2 (m, 3H, H-4, 5, 6), 7.38 (two superposing doublets, 2H, H-3, 8), 8.23 (d, $J = 6.3$ Hz, 1H, H-10)], for it combines the characteristics of the spectra of α-substituted 1,6-methano[10]annulenes and of pyridine and quinoline. Striking similarities to the spectra of the 1,6-methano[10]annulenes are seen not only in the position of the resonances of annulene- and bridge-protons at low field and high field, respectively, but also in the coupling constants of the bridge protons [$J_{H\text{-}11a,H\text{-}11b} = 8.4$ Hz, $J_{^{13}C\text{-}11,H\text{-}11} = 145$ Hz (142 Hz in the case of 1,6-methano[10]annulene)]. Very good agreement is also found in the absorption patterns of the annulene protons of *(1)* and the quinoline protons; however, in parallel with the findings in the pair 1,6-methano[10]annulene/naphthalene, the resonances of the annulene protons appear at higher field.—That *(1)* is to be regarded as a heteroaromatic system is equally evident from the similarity of its UV spectrum [(cyclohexane): $\lambda_{max} = 240$ nm ($\varepsilon = 28300$), 258 (11800), 297 (sh, 2650), 364 (2200)] with that of 1,6-methano[10]annulene; qualitative differences between the two spectra, such as the increased extinction of the long-wave L_b band in the azaannulene spectrum, correspond to those observed between the naphthalene and the quinoline spectrum.

The aza[10]annulene *(1)* has a pK_a value of 3.20 (20°C) and is thus more weakly basic than pyridine or quinoline ($pK_a = 5.23$ and 4.94, respectively)[9]; nevertheless, it forms a stable hydrochloride with dry hydrogen chloride in ether.

(10) *(11)* *(12)* *(13)* *(14)*

Parallel to the synthesis of *(1)* we tried to prepare the isomeric 3,8-methanoaza[10]annulene *(2)* starting from tricyclo[4.3.1.0]deca-3-en-8-one oxime *(10)*[4]. Beckmann rearrangement of *(10)* with phosphorus pentachloride in ether

(0 °C, 5 h) led to the lactam *(11)* [m.p. 93–94 °C; yield 48%], which, on addition of bromine in dichloromethane and subsequent dehydrohalogenation of the resulting dibromide (not isolated) with 1,5-diazabicyclo[4.3.0]non-5-ene in tetrahydrofuran (room temperature, 15 h), could be transformed into the lactam *(12)* present as the norcaradiene valence tautomer [m. p. 128–129 °C; yield 30%; ^{1}H-NMR ($CDCl_3$): $\delta = -0.18$ and 1.71 (AX system, $J = 4.2$ Hz, 2H, H-11), 2.71 (q, $J = 17$ Hz, 2H, H-5), 3.44 (d, $J = 13$ Hz, 1H, one H-2), 3.69 (dd, $J = 13$, and 5 Hz, 1H, one H-2), 5.8 (m, 4H, H-7, 8, 9, 10), 6.9 (br. s, 1H, NH)].

(12) reacts with trimethyloxonium tetrafluoroborate in dichloromethane (room temperature, 4 h) with formation of the iminoether *(13)*, also present as the norcaradiene valence tautomer [b.p. 64–66 °C/0.1 torr; yield 50%; ^{1}H-NMR ($CDCl_3$): $\delta = -0.25$ and 1.44 (AX system, $J = 4.2$ Hz, 2H, H-11), 2.52 (q, $J = 17$ Hz, 2H, H-5), 3.53 (s, 3H, OCH_3), 3.83 (q, $J = 16$ Hz, 2H, H-2), 5.92 (m, 4H, H-7, 8, 9, 10)]. Dehydrogenation of *(13)* with DDQ in dioxane (room temperature, 1 min) led to a complex reaction mixture, from which 10-methoxy-3,8-methanoaza[10]annulene *(14)* could be isolated by chromatography on silica gel (ether/pentane 1:3) as a stable yellow liquid of b.p. 62–63 °C/0.1 torr (yield 4–8%) [^{1}H-NMR (CCl_4): $\delta = -0.14$ and 0.37 (AX system, $J = 9.5$ Hz, 2H, H-11), 3.86 (s, 3H, OCH_3), 5.90 (s, 1H, H-9), 6.66 and 7.28 (multiplet, 4H, H-4, 5, 6, 7), 7.46 (s, 1H, H-2)].

The NMR spectrum of this 3,8-methanoaza[10]annulene derivative, which corresponds to that of the isomeric 10-methoxy-2,7-methanoaza[10]annulene, affords clear evidence of this system also being aromatic[10].

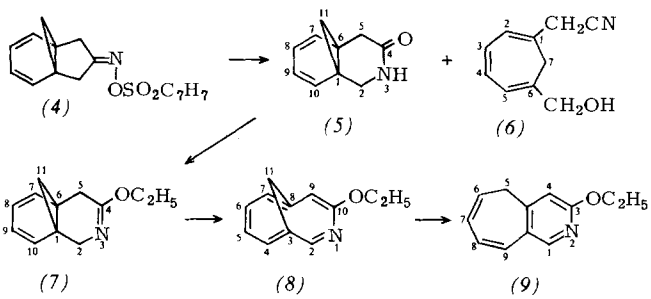
Helmkamp*'s group (University of California, Riverside) [*W. J. Lipa*, Diss. Abstr. Int. B *38* (9), 4243 (1978)].

10-Ethoxy-3,8-methanoaza[10]annulene, a 10π-Electron Analogue of Pyridine[**]



By *Hans-Jürgen Gölz*, *Joseph M. Muchowski*, and *Michael L. Maddox*[*]

The synthesis of 1,6-methano[10]annulene, a hydrocarbon which contains a delocalized 10π-electron system, was reported almost 15 years ago by *Vogel* and *Roth*[1]. In principle, it should be possible to prepare analogues of this compound where one or more heteroatoms participate in the establishment of a 10π-system stabilized by resonance, and indeed, three such compounds *(1)*—*(3)* with potential 10π-systems have been synthesized. Whereas the recently disclosed methanoaza[10]annulene derivative *(1)*[2] possesses spectral properties consistent with those expected for an aromatic system, *(2)* and *(3)* do not. Thus, *(2)* is best regarded as a fluxional molecule[3a], while *(3)* definitely exists in the norcaradiene form[3b]. This publication describes the synthesis of the title compound *(8)*, a methanoaza[10]annulene derivative[4], whose skeleton is isomeric with that present in *(1)*.

(1) *(2)* *(3)*

The *O*-(*p*-toluenesulfonyl) oxime *(4)* (m.p. 115–117 °C)[5], obtained from the corresponding known oxime[6] and *p*-toluenesulfonyl chloride, when heated (40 °C, 3 d) in aqueous dioxane in the presence of 2,6-dimethylpyridine, gave the products of Beckmann rearrangement *(5)* and fragmentation *(6)* in 20—30% and 17% yields, respectively (Table 1). The lactam *(5)* was converted with triethyloxonium tetrafluoroborate (CH_2Cl_2, room temperature, 5 d) into the cyclic imino ether *(7)* which on dehydrogenation with dichlorodicyanoquinone (dioxane, room temperature, 0.5—2 h) gave 10-ethoxy-3,8-methanoaza[10]annulene *(8)* in 8.5—13.5% yield. Compound *(8)*, a stable yellow oil, was isolated by preparative thin-layer chromatography (hexane/ethyl acetate, 10:1, silica gel). The UV spectrum of *(8)* (Table 1) is indicative of a system with extended conjugation, while the low field ^{1}H-NMR signals of the OCH_2- and perimeter-protons, in conjunction with the upfield shift of the hydrogens in the methano bridge, are compatible with the existence of a ring current in the 10-atom periphery. The proton-decoupled ^{13}C-NMR

[**] Contribution No. 515 from the Syntex Institute of Organic Chemistry.

spectrum (Table 1) is also consistent with the presence of a delocalized π-system in *(8)*.

On prolonging the duration of the dehydrogenation of *(7)* from 2 to 22 h, the annulene *(8)* (6—7 %) was accompanied by variable amounts (11—16 %) of 3-ethoxy-5*H*-cyclohepta[*c*]pyridine *(9)*[7], which was separated by thin-layer chromatography (hexane/ethylacetate, 10:1) (Table 1). The isomerization *(8)* → *(9)* could proceed analogously to the rearrangement of 1-benzoxepin[8]. Finally, it is also of interest that the mass spectra of *(8)* and *(9)* are identical [*m/e* 187 (M^+, 66 %)], implying the electron impact induced transformation of the former into the latter.

Wrapping of Noncyclic Donor Molecules around the Sodium Cation

By *Jean Grandjean, Pierre Laszlo, Fritz Vögtle*, and *Heinz Sieger*[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Heptadentate ligands such as the noncyclic crown ether *(1)* are good complexing agents for alkali metal and alkaline earth cations[1]. A crystalline 1:1 complex is obtained between *(1)*[2a] and KSCN[2b]. However, the formation of well-defined complexes does not necessarily reflect the size of the formation constant (K_f) for the complex[2b, 3]. Whereas reactions of charged ligands with metal ions of type A are *entropy*-driven, interactions of uncharged ligands with the soft metal ions of type B are preferably *enthalpy*-driven[3]. Still requiring clarification, however, was the mode of reaction of uncharged open chain ligands such as *(1)* with unpolarized A-type metals. We report here on the determination of the thermodynamic parameters for complexation of *(1)* with the sodium cation by ^{23}Na-NMR spectroscopy[4].

(1)

The ligand *(1)* containing two carboxamide groups competes with the likewise powerful complexing agent pyridine chosen as solvent. For the ^{23}Na-NMR measurements, *(1)* and anhydrous $NaClO_4$ were co-dissolved in anhydrous pyridine[5]. The correlation times are sufficiently small: the NMR absorption curves are true lorentzians and their linewidths at half-height are inversely proportional to the temperature[6]. K_f was determined by the following procedure[4, 6, 7]:

Line broadening
↓
Relaxation rate R
↓
R normalized to unit viscosity R_v
↓
Measurement of R_v as a function of composition (5 or 6 data points)
↓
Computer fitting of parameters to 1:1 complex model

Two separate methods are used for the last step (see Figure 1 and Table 1).

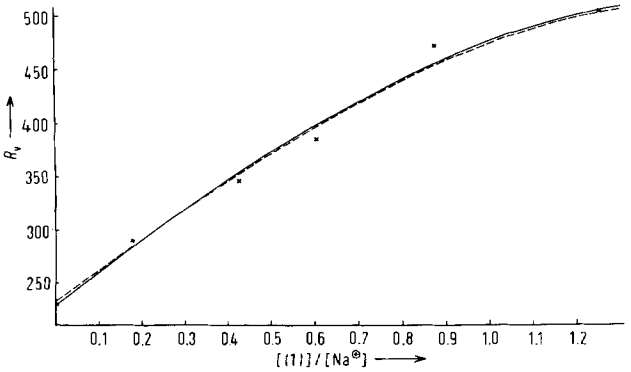

Fig. 1. Plot of R_v *versus* $[(1)]/[Na^+]$ (32 °C = 305 K); the solid line (method A) is the curve for minimization of R_v for each of 5 experimental points (×), corresponding to iteration of the values for K_f and the limiting relaxation rate in the complex from *(1)* and $Na^{\oplus}$ (equation (2) of reference [6a]). The dashed line (method B) corresponds to Simplex optimization [8a] using the equation of *Live* and *Chan* [8b] with simultaneous iteration on K_f, R_v^B, and the relaxation rate for free $Na^{\oplus}$ R_v^F.

Table 1. Complexation constant K_f and limiting relaxation rates for free (R_v^F) and bound (R_v^B) $Na^{\oplus}$ obtained by method A and method B.

T[K]	R_v^F		R_v^B		K_f [l mol^{-1}]	
	A	B	A	B	A	B
279.2	229	223	848	861	750	749
290.6	229	226	691	691	240	241
305.2	229	232.5	575	565.5	75	77.5
321.5		195		600		12.2

A strong complex is indeed formed between *(1)* and $NaClO_4$, in pyridine solution, with a formation constant K_f of 10^3 to 101 mol^{-1} in the temperature range from 5 to 50 °C. From the temperature dependence of K_f it follows that:

$\Delta H_f^0 = -17$ kcal mol^{-1} (-71 kJ mol^{-1}[9])
$\Delta S_f^0 = -48$ cal mol^{-1} K^{-1} (-201 J mol^{-1} K^{-1}[9]).

Usually, only mildly negative entropy terms (*ca.* -10 to -50 J mol^{-1} K^{-1}[10]) are found for inclusion of $Na^{\oplus}$ into the preformed central cavities of cyclic natural or synthetic ionophores in solvents such as H_2O or CH_3OH. It is unlikely that only the change from such protic solvents to pyridine could account for this large difference in complexation entropies. Rather, the strongly negative entropy term found here is highly reminiscent of a *cyclization entropy*, as if $Na^{\oplus}$ complexation locks the ligand molecule *(1)* into a single highly organized conformation: one in which most (if not all)[11] the ether oxygens form van der Waals bonds with the enclosed sodium cation, accounting for the magnitude of the enthalpy change. The complex formation in solution is *enthalpy*-driven. The $Na^{\oplus} - ClO_4^{\ominus}$ distance is likely to increase upon complex formation[6b]. Hence, we feel that the interaction of *(1)* and $Na^{\oplus}$ is best described as a *wrapping* of the heptadentate ligand *(1)*, most probably in a stepwise manner[10c], around the sodium cation. Pyridine, a weakly polar aprotic solvent capable of cation solvation, is a solvent of type B in the recent classification by *Jackman* and *Lange*[12]. From the relatively large equilibrium constants K_f found in pyridine, we feel confident that molecules of the same type as *(1)*[2b] will produce *anionic activation* in a number of organic solvents of type B[12], particularly at low temperatures.

[5] Use of [D_4]methanol leads to very small enhancement of the ^{23}Na relaxation rate, perhaps because of a small K_f in this solvent and/or (more likely) a small quadrupolar coupling constant when mostly oxygen atoms are coordinated to $Na^{\oplus}$. As in an earlier study of sodium-complexation by sugars [6], use of pyridine as the solvent allows for sizable effects.

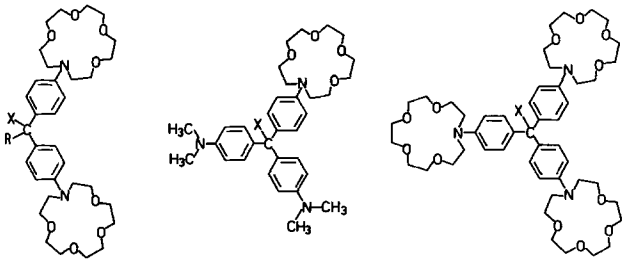
Ion-Selective Crown Ether Dyes

By *J. Peter Dix* and *Fritz Vögtle*[*]

A molecular combination of dyes with crown ethers is desirable for a variety of reasons: one point of interest is the influence of selective complex formation with alkali or alkaline earth metal ions[1], made possible by crown ether structural units, on the absorption of the chromophore. Moreover, crown ether dyes should be suitable for detection of phase transfer of salts and for the study of ion transport through lipophilic media[2].

We have therefore incorporated crown ethers into dye molecules in such a manner that the chromophore is influenced *directly* on complexation with cations: the dimethylamino group in the azo dyes methyl orange, methyl red, *etc.* was



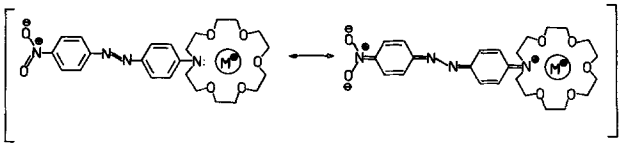
formally replaced by a "crown ether amine" group. In order to synthesize compounds *(1)* to *(8)*, we first prepared the *N*-phenyl crown ether amines *(9)* to *(11)* of various ring widths and transformed them by azo coupling into *(1)* to *(8)*.

[*] Prof. Dr. F. Vögtle [+], Dipl.-Chem. J. P. Dix
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn (Germany)
[+] To whom correspondence should be addressed.

Compound *(9)* was converted into the *p*-nitrosodimethylaniline-analogous crown ether *(12)*; reduction of *(12)* gave *(13)* and *(15)*; Vilsmeyer reaction of *(9)* afforded the aldehyde *(14)* (see Table 1 for data).

In order to compare various dye systems, the dimethylamino groups of the diphenylmethane dye Michler's hydrol blue and the triphenylmethane dyes malachite green and crystal violet were successively replaced by "crown ether amine

(16)-(18) *(19)* *(20)*



groups". Synthesis of compounds *(16)*—*(20)* was achieved by Friedel-Crafts reaction of *(9)* with carbonyl compounds (data for the isolated leuco compounds X=H, see Table 1).

Table 1. Data of the synthesized crown ether dyes. Correct elemental analyses or high resolution mass spectra and uniform thin layer chromatograms were obtained for all the compounds listed.

Cpd.	X	R	*n*	M.p. [°C]	λ_{max} [nm] [a]	Complex with (m.p. [°C])

(20b)	$C_6HCl_4O_2$		1		489.5 470	
(21)						

[a] In acetonitrile. [b] Although detected unequivocally (NMR, MS) this compound could not be obtained absolutely pure. [c] In methanol. [d] R = *p*-$(CH_3)_2N$—C_6H_4-.

The selective inclusion of alkali metal, alkaline earth metal, ammonium, and heavy metal ions, as well as H_3O^+ in such crown ether dyes should exert a selective influence on the chromophore including the nitrogen of the crown ether amine because the lone pair contributing to resonance will be affected to a greater or lesser extent by the positive charge of the guest ion, depending upon the nature of the ion concerned[3]:

(4a)·$M^{\oplus}$ *(4b)*·$M^{\oplus}$

As shown by the UV spectra of the *p*-nitrophenyl azo dyes *(3)*—*(5)*, considerable characteristic differences are observed for the various cations as compared with the only slightly ionically active "parent dye" *(21)* with a dimethylamino group (Table 2).

(21)

Table 2. Difference ($\Delta\lambda$) between the strongest absorption band of the crown ether dyes *(3)*—*(5)* and the reference substance *(21)* before and after addition of salt (in acetonitrile); concentrations of ligand, salt $\leq 1:10$. −: hypsochromic shift, +: bathochromic shift.

Added salt	Difference ($\Delta\lambda$) [nm] *(3)*	*(4)*	*(5)*	*(21)*
$LiClO_4$	−10	− 4	− 7	+1
LiI	− 9.5	− 3.5	− 7.5	
$NaClO_4$	− 8.5	− 10	− 5.5	
NaSCN			− 4.5	
NaI	− 8.5	− 7	− 5	0
KI	0	− 20	− 5.5	+1
KSCN	− 1.5		− 5	
RbI	0	− 6.5	− 7	
CsI	0	− 4.5	−11	
MgI_2	− 1.5	− 13	− 3	[4]
$Ca(SCN)_2$	− 7.5	− 26	−13	+1
NaI_2	[a]	−120		
$Ba(SCN)_2$	[a]	−117.5	− 7	+1
$CuCl_2$	−19		− 2	
$(CH_3)_3CNH_3SCN$		− 2		
NH_4SCN		− 8		
$ZnCl_2$	+ 0.5			

[a] −2 to −10; very dependent upon salt concentration.

On variation of the ring width, the expected selective complexation occurs with added alkali and alkaline earth metal ions, which led to widely varying shifts or changes in intensity of the absorption bands. The alkali metal ion fitting into the crown ether cavity leads to the greatest hypsochromic shift: Li^+/Na^+ for *(3)*, K^+ for *(4)*, Cs^+ for *(5)*. As is also shown by Table 2, the change in the absorption bands is the greatest for the [18]crown dye *(4)* and Ba^{2+} ions ($\Delta\lambda \approx 120$ nm). Much smaller changes in absorption are observed for the smaller and larger crown ether amines *(3)* and *(5)*; neither significant wavelength shifts on addition of ions (*e.g.* $\Delta\lambda = +1$ nm for Ba^{2+}[4]) nor ion selectivity of light absorption are observed for the parent dye *(21)*.

Table 2 shows that the anions have very little effect on the absorption.

The appearance of the band at 357 nm on addition of Ba^{2+} salts to *(4)* could be due to the fact that this cation has such a drastic effect on the "lone" electron pair of the amino nitrogen, because its volume fits the crown ether cavity and because of its high charge density [cf. *(4a)*·$M^+ \leftrightarrow$ *(4b)*·M^+], that almost exclusively the nitro-substituted azobenzene acts as chromophore (λ_{max} 332 nm[3]).

The ability of the crown ether dyes to form stable complexes was also evidenced by the isolation of a number of crystalline alkali metal salt complexes (Table 1).

Since crown ether (or cryptand[5]) structural units can be incorporated into many other dye systems, novel quantitative data can be obtained on the selective modification of host molecules containing chromophores by guest particles in various media.

[4] MgI_2 is an exception, inducing a hypsochromic shift.
[5] In addition to a shift of equilibrium in favor of the complex, cryptand systems should give rise to greatest cation selectivity.

Carbonylation of Transition-Metal Carbyne Complexes, a New Method for the Synthesis of Metal-Substituted Ketenes[**]

By *Fritz R. Kreissl, Wolfgang Uedelhoven*, and *Karl Eberl*[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Only a few examples of reactions of carbon monoxide with carbene- and carbyne-complexes have so far been reported in the literature. One example is the reaction of a mixture of methoxy(phenyl)carbenepentacarbonylchromium and 1-vinyl-2-pyrrolidone with CO at 150 atm and 80 °C to give a highly substituted vinyl ketone; methoxy(phenyl)ketene was postulated as intermediate[1].

If, however, *p*-tolylcarbynecarbonyl(cyclopentadienyl)trimethylphosphane complexes of molybdenum and tungsten[2] are allowed to react with CO, carbonylation at the carbyne carbon already takes place at normal pressure and −30 °C:

$$C_5H_5(CO)[P(CH_3)_3]M{\equiv}C{-}C_6H_4CH_3 + 2\,CO \longrightarrow$$

(1)

$$C_5H_5(CO)_2[P(CH_3)_3]M{-}C(=C{=}O){-}C_6H_4CH_3$$

(2)

(a): M = Mo, *(b)*: M = W

The products *(2a)* and *(2b)*[3] crystallize as bright-yellow needles and are readily soluble in acetone or dichloromethane, but insoluble in ether and pentane. On the basis of secondary reactions[4] at the ketene function the two longwave νCO bands of the new compounds (in CH_2Cl_2: *(2a)* 1943 s, 1855 vs; *(2b)* 1930 s, 1836 vs cm^{-1}) can be assigned to the carbonyl ligand, and the very strong bands at 2029 and 2022 cm^{-1} to the η^1-ketenyl ligand.

The ^{1}H-NMR spectrum (CD_2Cl_2) shows for *(2b)* four signals of relative intensity 4:5:3:9, which correspond to the aryl- (δ = 7.14), cyclopentadienyl- (δ = 5.35), methyl- (δ = 2.33) and *P*-methyl protons (δ = 1.78). The signals at δ = 5.35 and 1.78 appear as doublets owing to ^{31}P-^{1}H coupling (J = 2.2 and 9.2 Hz).—In the $^{31}P\{^1H\}$-NMR spectrum[5] (CD_2Cl_2, rel. to H_3PO_4 ext.) a singlet accompanied by two satellites is observed at δ = −14.99 with $^1J(^{183}W$-$^{31}P)$ = 174.0 Hz.—Valuable information on the structure is provided by the $^{13}C\{^1H\}$-NMR spectrum[5] (CD_2Cl_2, −40 °C, δ-value rel. to CD_2Cl_2 = 54.2 ppm; ^{31}P-^{13}C coupling constants in Hz): W—CO (224.13; 17.1), CO-ketene (156.43), C_6H_4 (137.34, 131.19, 129.14), C_5H_5 (90.95), CH_3 (20.93), PCH_3 (19.63; 34.2), C-ketene (−15.27; 7.3). The appearance of only one signal for both metalcarbonyl C-atoms affords proof of the *trans* orientation of the two CO-ligands, and thus also of the phosphane- and the ketenyl-ligand. The last signal, for the terminal ketene carbon with δ = −15.27, indicates an extraordinarily large shielding for sp^2-hybridized atoms[6].

Experimental

All operations should be carried out in dry (Na, P_4O_{10}) and N_2-saturated solvents.—*(2a)*: A solution of 0.37 g (3 mmol) *(1a)*[2] in 30 ml ether is treated at −30 °C with CO at a pressure of 1 at. The originally dark-red solution slowly decolorizes and a bright-yellow precipitate separates out. After *ca.* 5 h the crude product is decanted off and washed twice with 20 ml each of ether and pentane. Reprecipitation from CH_2Cl_2/ether/pentane affords fine yellow crystals; yield 0.29 g (69 %).—*(2b)*: A solution of 0.46 g (1 mmol) *(1b)*[2] in 30 ml ether is treated with CO and worked-up analogously to *(2a)*. Yellow crystals; yield 0.44 g (86 %).

Deoxygenation—A Novel Reaction Path of Transition Metal-Substituted Ketenes[**]

By *Fritz R. Kreissl, Karl Eberl,* and *Wolfgang Uedelhoven*[*]

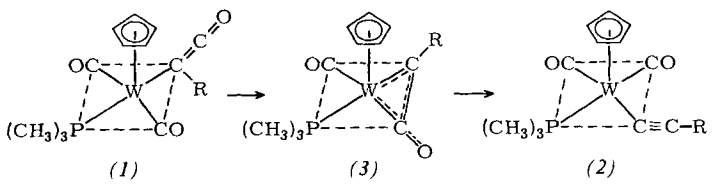
Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Reduction, photolysis, and thermolysis of ketenes proceed almost exclusively with addition at the C=C- or C=O bond or with cleavage of the C=C double bond. The reduction of diphenylketene with triethyl phosphite leads to a 2:1 adduct, which on pyrolysis undergoes cleavage at the C=O double bond with formation of diphenylacetylene[1].

Transition metal-substituted ketenes[2] such as *(1)*, however, react with carbon monoxide cleanly to give the corresponding acetylene, also with cleavage of the C=O double bond.

$C_5H_5(CO)_2[P(CH_3)_3]W-C(=C=O)-C_6H_4CH_3$ + CO ⟶

(1)



$C_5H_5(CO)_2[P(CH_3)_3]W-C\equiv C-C_6H_4CH_3 + CO_2$

(2)

The product *(2)* can be isolated as yellow diamagnetic crystals[3] which are readily soluble in dichloromethane and acetone. The composition and structure of the new complex were confirmed by elemental analysis and by its mass spectrum and IR and NMR spectra.

The IR spectrum (KBr; cm^{-1}) shows one band in the carbonyl region for the C≡C stretching vibration (2048 m) and two for the CO ligands (1935 vs, 1840 vs), the intensity pattern being consistent with a *cis* arrangement of the two CO groups[4].—The ^{1}H-NMR spectrum (CD_3COCD_3) contains four signals of relative intensity 4:5:3:9 which are assigned to the aryl- (δ = 7.21), cyclopentadienyl- (δ = 5.74), methyl- (δ = 2.37) and *P*-methyl-protons (δ = 1.89). The signals at δ = 5.74 and 1.89 occur as doublets (J = 0.6 and 9.8 Hz) as a result of ^{31}P-^{1}H coupling.—The ^{13}C{^{1}H}-NMR spectrum (CD_3COCD_3, δ-values rel. to CD_3COCD_3 = 206.5 ppm; ^{183}W-^{13}C- and ^{31}P-^{13}C-coupling constants in Hz) contains eleven signals: W—CO 247.70 (139.7; 23.5), 232.56 (142.7; 5.9); C_6H_4 135.47, 131.31 (—; 2.9), 129.88, 126.89 (—; 2.9); W—C≡*C* 127.41 (—; 2.9); W—*C*≡C 96.34 (97.1; 41.2); C_5H_5 91.92; CH_3 21.73; PCH_3 19.49 (—; 36.8). We assign the carbonyl resonance at δ = 247.70 to the CO group *trans* to the acetylene residue[2,5].—In the ^{31}P{^{1}H}-NMR spectrum (CD_2Cl_2, rel. to H_3PO_4 ext.) a singlet accompanied by satellites appears at δ = −7.83 with $^1J(^{183}W-^{31}P)$ = 225.8 Hz.

The reorientation of the original η^1-ketenyl ligands and the change in configuration of the two carbonyl ligands from *trans* to *cis* during the conversion of *(1)* into *(2)* would suggest that the reaction probably proceeds *via* the η^2-ketenyl intermediate *(3)*[6], but, does not rule out a 1,2-shift of the *p*-tolyl substituents. In contrast to *(1)*, diphenylketene does not react to give an analogous acetylene derivative under similar conditions.

(1) *(3)* *(2)*

R = *p*-$C_6H_4CH_3$

Anionic and neutral complexes analogous to *(2)* have already been prepared by reaction of alkali-metal acetylides with hexacarbonyltungsten and tricarbonyl(chloro)cyclopentadienylmolybdenum respectively[7].

Experimental

All operations should be carried out in dry (Na/K, P_4O_{10}) and N_2-saturated solvents. A solution of 2.5 g (5 mmol) *(1)*[2] in 40 ml dichloromethane is transferred to a hand autoclave at room temperature. After introduction of CO at 60 atm, the autoclave is allowed to stand for 24 h at 60 °C. On release of pressure the yellow-brown solution is filtered and chromatographed on silica gel at −30 °C with ether/dichloromethane (1:1). Recrystallization from acetone and drying *in vacuo* affords pure *(2)*; yield 2.1 g (80 %).

Oxygen Evolution from Water *via* Redox Catalysis[**]

By *John Kiwi* and *Michael Grätzel*[*]

The production of chemical fuel from light *via* the photoredox reaction

$$A + D \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} A^- + D^+ \qquad (1)$$

encounters two major obstacles, one of which is related to the reversibility of reaction (1), leading to thermal degradation of photon energy. This problem may be overcome by using suitable molecular devices such as micellar or membrane assemblies as a reaction medium[1,2] to suppress or considably retard the back reaction. Once A^- and D^+ have been stabilized the task remains to convert their chemical potential into useful products. For example, A and D may be selected such that

in aqueous solution oxygen and hydrogen evolution becomes thermodynamically feasible.

$$2A^- + H_2O \rightarrow 2A + 2OH^- + H_2 \quad (2)$$
$$4D^+ + H_2O \rightarrow 4D + 4H^+ + O_2 \quad (3)$$

Reactions (2) and (3), which do not usually occur spontaneously, can be accelerated by suitable redox catalysts. These catalysts also prevent other destructive pathways of A^- and D^+ deactivation. Recently[3–5], this principle was successfully applied to hydrogen evolution by process (2).

The present paper reports the first evidence that the production of oxygen *via* reaction (3) may also be mediated by a redox catalyst. The investigations were conducted with the Ce^{4+}/Ce^{3+} couple as D^+/D system. Ce^{4+} is relatively stable in aqueous H_2SO_4 although from its redox potential ($E^0 = 1.44$ V) it should spontaneously liberate oxygen from water. The Ce^{3+} produced can regenerate Ce^{4+} photochemically, with simultaneous production of H_2[6]. Thus the cycle of light-induced water decomposition is closed.

Cerium(IV) sulfate (Merck pro analysis), PtO_2 (Adams catalyst, Fluka puriss.), and IrO_2 (Sigma) were used as supplied. Deionized water was distilled from a MnO_4^- solution, and subsequently twice from a quartz still. UV spectra were recorded on a Cary-219 spectrophotometer. An oxygen electrode (O_2 meter Portomatic model 376, Instrumentation Laboratory) was employed to monitor the evolution of oxygen.

Experiments were carried out with a three-neck flat-bottom flask. Two necks accepted the oxygen electrode and the glass tube for deoxygenation, while the third was plugged with a gas-impermeable septum permitting samples of the solution to be taken for optical analysis. Thus during the procedure of stirring with the catalyst the Ce^{4+} concentration could be checked continuously by absorbance measurements; an extinction coefficient[7] of 5.92×10^3 l mol^{-1} cm^{-1} was used in the calculations.

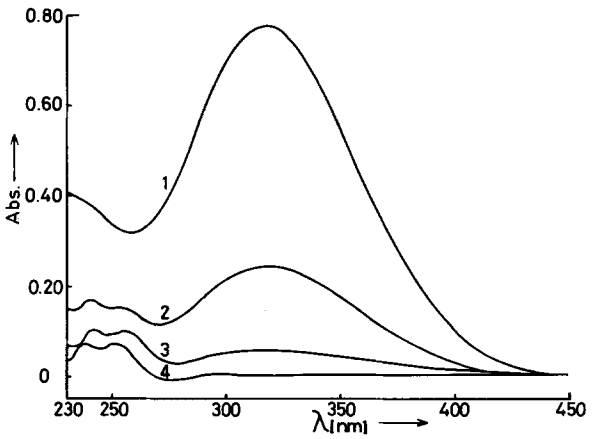

Fig. 1. Temporal behavior of the absorption spectra of solutions of $Ce(SO_4)_2$ (2.7×10^{-3} mol/l) in 1 N H_2SO_4 in the presence of PtO_2 (32 mg/100 ml H_2O). 1, after zero time; 2, after 2 h; 3, after 8 h; 4, after 16 h.

Figure 1 shows the spectral changes observed when a solution of $Ce(SO_4)_2$ is stirred with Adams catalyst. The Ce^{4+} absorption spectrum present at zero time diminishes within a few hours, and a new absorption band appears around 250 nm which is characteristic[8] of Ce^{3+} ions. Figure 2 shows that the conversion of Ce^{4+} into Ce^{3+} is associated with the formation of oxygen from water. In fact, by taking into account the amount of oxygen which escapes from the solution into the gas phase, it was found that for every molecule of oxygen produced four Ce^{4+} ions are reduced to Ce^{3+}.

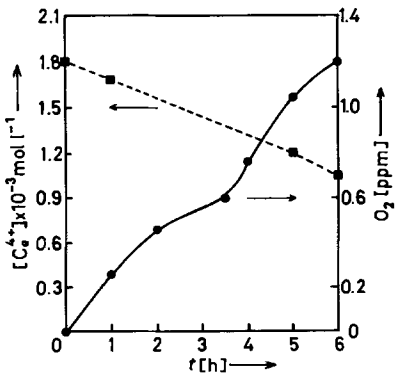

Fig. 2. Evolution of oxygen and decrease of Ce^{4+} concentration in 1 N H_2SO_4 in the presence of PtO_2 (32 mg/100 ml H_2O).

For example, in a typical experiment (Fig. 2) the rate of oxygen evolution was found to be 3×10^{-5} mol l^{-1} h^{-1} while that of Ce^{4+} reduction was 1.2×10^{-4} mol l^{-1} h^{-1}. Hence, water oxidation

$$4Ce^{4+} + 2H_2O \rightarrow 4Ce^{3+} + 4H^+ + O_2 \quad (3a)$$

must occur quantitatively in the presence of the redox catalyst. Blank experiments carried out with solutions containing no redox catalyst showed only a 10 % decrease in Ce^{4+} concentration over 24 h. No oxygen evolution could be detected under these conditions.

The initial rate of Ce^{4+} reduction or O_2 evolution was found to increase linearly with Ce^{4+} concentration. It is also a function of the amount of catalyst present and the rate of stirring, *i.e.* the efficiency of contact between the catalyst and the solution.

Further studies showed that the reduction of tris(2,2'-bipyridine)ruthenium(III) by water according to

$$4Ru(bpy)_3^{3+} + 2H_2O \rightarrow 4Ru(bpy)_3^{2+} + 4H^+ + O_2 \quad (3b)$$

can also be promoted by redox catalysts such as PtO_2 or IrO_2. Thus, reaction (3b) occurs within 3 h in aqueous sulfuric acid solution of pH = 1 in the presence of PtO_2. Under these conditions, $Ru(bpy)_3^{3+}$ is practically stable over the same period[9] in catalyst free solution.

The latter result is particularly important since $Ru(bpy)_3^{2+}$ can be reconverted in a photoinduced redox reaction into $Ru(bpy)_3^{3+}$ with evolution of hydrogen[4, 5]. Hence, the cyclic production of H_2 and O_2 from water by illumination appears to be feasible in such a system.

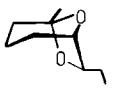
Methyl-1,6-dioxaspiro[4.5]decanes as Odors of *Paravespula vulgaris* (L.)[**]

By *Wittko Francke*, *Gerd Hindorf*, and *Wolfgang Reith*[*]

In contrast to other social insects, no volatile components have yet been identified from the common wasp *P. vulgaris*[1].



After the identification of 2-ethyl-1,6-dioxaspiro[4.5]nonane (chalcogran) *(1)*[2] as the principal aggregation pheromone of *Pityogenes chalcographus* L., we have now studied the mass-spectrometric fragmentation of volatile spiroketals[3] and found (GLC-MS coupling[4]) spiroketals to be present in the pentane extracts of the abdomina of *P. vulgaris* workers.

(1)

(2)

(3)

(4)

(5)

The main component and a trace substance proved to be, respectively, (*Z*)- and (*E*)-7-methyl-1,6-dioxaspiro[4.5]decane *(2)*[5], while two minor components were identified as equal amounts of (*Z*)- and (*E*)-2-methyl-1,6-dioxaspiro[4.5]decane *(3)*[6], along with traces of 2-nonanone.

The racemic compounds *(2)* and *(3)* were prepared from γ-butyrolactone and δ-caprolactone, and γ-valerolactone and δ-valerolactone, respectively, according to the procedure of *Erdmann* and *Ström*[7]. The synthetic substances purified by preparative GLC showed the same mass spectra and had similar retention times on GLC as the natural products, the chirality of which have not yet been clarified.

Remarkably, the new spiroketals *(2)* and *(3)* show an unbranched dihydroxynonanone skeleton, as do chalcogran *(1)*, 7-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1]octane (brevicomin) *(4)*[8], and 1,3-dimethyl-2,9-dioxabicyclo[3.3.1]nonane *(5)*[9]. *(4)* is an attractant, and *(5)* is a compound occurring specifically in attacked spruce. Genetic relations cannot be excluded.

Preliminary bioassays showed that the new compounds might serve as repellents or aggression inhibitors, which could protect the individuals from attack by its fellow wasps. Dead extracted wasps hanging 12 cm in front of the entrance hole of an earth nest frequented by 40 individuals per minute were attacked within two minutes and then at intervals of 30—60 s. In contrast, extracted wasps previously treated with 0.1 mg of the spiroketals mixed in the naturally occurring proportions or freshly killed ones were only attacked after 8—10 min, the intervals between further attacks being much longer than before. Application of 0.1 mg of the spiroketal mixture to heavily frequented dummies inhibited any attack for 8—12 min. Each series of assays was repeated twelve times.

Catalytic Carbon-Carbon Bond Formation with Carbene Intermediates

By *Gisela Henrici-Olivé* and *Salvador Olivé*[*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

We wish to report the transformation of methylamine (C_1) into acetonitrile (C_2), and on the mechanism of this process. Methylamine is a low cost, coal based, industrial chemical, obtained by alkylation of ammonia with methanol:

$$C \xrightarrow{\text{Oxygen}} CO \xrightarrow{\text{Hydrogen}} CH_3OH \xrightarrow{\text{Ammonia}} CH_3NH_2$$

When methylamine is passed over a silica/molybdenum catalyst at 400–500 °C, at a flowrate of 0.8×10^{-3} mol/min, it decomposes almost quantitatively. Traces of acetonitrile are formed, together with large amounts of HCN and NH_3. However, the yield of CH_3CN is greatly increased, if hydrogen accompanies the amine. At a molar ratio of $H_2:CH_3NH_2$ of 12:1, 20—30% of the methylamine is converted into acetonitrile[1]. Some propionitrile (<1%) is also formed; non-nitrogen containing by-products are mainly methane, with minor amounts of higher hydrocarbons (C_2—C_4).

The catalyst is prepared by impregnating silica (particle size 0.2—0.5 mm, Merck) with a water-soluble molybdenum compound (*e.g.* $[NH_4]_6Mo_7O_{24}\cdot 4H_2O$); after drying, the catalyst is oxidized with oxygen (8 h, 500 °C), and subsequently reduced with ammonia (17 h, 500 °C). It has about 5×10^{-4} g/atom of Mo per gram of catalyst. Molybdenum can be replaced by other transition metals, although with decreasing activity, in the series Mo > W > Cr > Ru > Fe ≫ Co ≈ Ni. On silica alone, the methylamine is recovered essentially unchanged. If silica is replaced by alumina in the catalyst, a carbonaceous deposit covers the alumina; no acetonitrile is observed.

The formation of acetonitrile according to the overall equation (1) is thermodynamically favorable; the equilibrium constant at 500 °C is $K_p = 1.6 \times 10^6$ atm[2][2].

$$2\ CH_3NH_2 \overset{K_p}{\rightleftharpoons} CH_3CN + NH_3 + 2\ H_2 \qquad (1)$$

To elucidate the detailed mechanism of the reaction depicted in Eq. (1), we carried out the process using deuterium instead

[*] Dr. G. Henrici-Olivé, Prof. Dr. S. Olivé
Monsanto Triangle Park Development Center Inc.
Research Triangle Park, N. C. 27709 (USA)

of hydrogen, all other conditions remaining the same. Mass spectroscopic analysis[3] of the major hydrocarbon by-product, methane, yielded a very useful piece of information. Two samples of the noncondensable part of the product stream were taken, 30 and 90 min after the onset of the catalytic process. The isotopic distribution in the methane is given in Table 1.

Table 1. Isotopic distribution in methane formed as by-product during the synthesis of acetonitrile from methylamine and D_2 (SiO_2/Mo catalyst; $D_2:CH_3NH_2 = 12:1$).

Component	Distribution [mol %]	
	$t = 30$ min	$t = 90$ min
CH_4	15.7	16.0
CH_3D	18.2	20.1
CH_2D_2	32.9	32.5
CHD_3	25.0	23.6
CD_4	8.2	7.8

Evidently the deuterium has taken part in the formation of the methane. The distribution does not depend on the reaction time, and there is a distinct maximum for CH_2D_2. The latter fact excludes the formation of the deuterated methanes by a metal-catalyzed H/D exchange of CH_4 with D_2. A mechanism involving a carbene intermediate is suggested for the methane formation, in order to account for the maximum in CH_2D_2.

Methylamine is assumed to add oxidatively to the metal [Eq. (2)]. Reductive elimination of ammonia then generates a carbene ligand (carbene formation by α-elimination of H from a methyl ligand is known for several transition metals[4]). Oxidative addition of deuterium leads to species A [Eq. (3)], from which the metal catalyst can be regenerated *via* reductive elimination of the main methane component, CH_2D_2. Alternatively, species A can, in a series of equilibria, lead to CHD_3 and CD_4, in decreasing concentration. (Hydrogenation of carbene ligands to the corresponding saturated hydrocarbons has been demonstrated recently by *Casey et al.*[5].)

$$CH_3NH_2 + M \longrightarrow CH_3\text{–}M\text{–}NH_2 \longrightarrow CH_2{=}M + NH_3 \qquad (2)$$

$$CH_2{=}M + D_2 \rightleftharpoons CH_2(D)\text{–}M\text{–}D \longrightarrow CH_2D_2 \qquad (3)$$

(A) $\rightleftharpoons$ $CHD{=}M\text{–}H$

$CHD{=}M$ (D) $\longrightarrow CHD_3$

$CD_2{=}M$ (D) $\longrightarrow CD_4$

(- HD, + D_2)

The formation of CH_4 and CH_3D takes place in corresponding equilibria, but with H_2 instead of D_2; the required hydrogen is continuously formed in the process, according to Eq. (1), and by the simultaneous thermal decomposition of methylamine to HCN:

$$CH_3NH_2 \longrightarrow HCN + 2\ H_2 \qquad (4)$$

We suggest the carbene complex formed by reaction (2) to be the key intermediate in the catalytic formation of acetonitrile from methylamine. This proposal is essentially inspired by the work of *E. O. Fischer et al.*[6], who reported the insertion of the carbene ligand of a chromium-carbene complex into the H—C bond of HCN, giving rise to a nitrile. Assuming an intermediate oxidative addition of HCN, we formulate for the present case:

$$H_2C{=}M + HCN \longrightarrow H_2C(H)\text{–}M(CN) \longrightarrow CH_3CN + M \qquad (5)$$

The evidence presented for a carbene ligand on a heterogeneous catalyst corroborates the reaction mechanism suggested previously by us for the Fischer-Tropsch synthesis[7].

Heteronuclear Cobalt Clusters by Metal Exchange[**]

By *Harald Beurich* and *Heinrich Vahrenkamp*[*]

The synthesis of heterometallic clusters is even less predictable than that of clusters of a single metallic element. This aim has been achieved in various cases with concomitant cluster enlargement in a semi-systematic manner by "attachment" of additional metal atoms to existing clusters *via* addition or substitution reactions[1]. To our knowledge, specific incorporation of metal atoms by metal exchange has not previously been reported[2]; it has now been accomplished by an addition-elimination sequence.

We have repeatedly observed cobalt-containing, arsenic-bridged polynuclear complexes to undergo decomposition, with formation of an oligomeric, sparingly soluble product of approximate composition $[(CO)_3Co\text{—}AsMe_2]_x$ *(1)*[3], leading to the complexes containing one less metal atom [cf. reaction (A)[4a] and (B)[4b]]. Application of this reaction to the substituted methylidyne-tricobalt cluster *(2)* effects introduction of the heterometal atom in place of a cobalt atom. The addition step of this directed cluster synthesis consists in the attachment of the As—M unit to the $RCCo_3(CO)_9$ unit by tried and tested methods[4a,c]. The elimination step consists in the decomposition reaction (C). So far, we have prepared eleven new hetero-clusters *(3)* by this method (cf. Table 1).

(3k)	p-$C_6H_4CH_3$	W	169	7.02 (m), 2.39	5.33

[a] Decomposition. [b] In CCl_4, rel. to int. TMS; m = multiplet.

The green complexes *(3)*, which are air-stable as solids, can be readily identified on the basis of their simple NMR spectra. The well-populated IR spectra are similar in the CO region [*e.g. (3f)*: 2075 vw, 2066 m, 2035 sh, 2029 vs, 2010 s, 2000 vs, 1991 m, 1944 cm^{-1} m]. Confirmation was sought by determining the crystal and molecular structure of *(3h)*[5] (Fig. 1). The molecular parameters of *(3h)* correspond to those expected from reference substances[1b, 6].

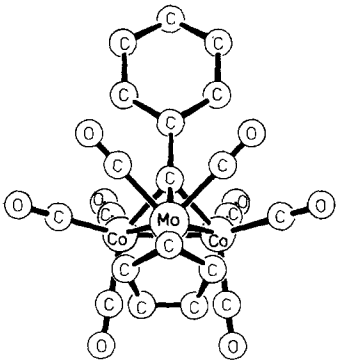

Fig. 1. Molecular structure of the hetero-cluster *(3h)*. Principal bond lengths: Co—Co = 248.3(1), Co—Mo = 267.7(1), Co—C = 193.3(5), Mo—C = 210.4(7) pm; bond angles: CoMoCo = 55.28(3), CoCoMo = 62.36(2), CoCMo = 83.0(2), CoCCo = 79.9(3)°.

Complexes *(3)* demonstrate that the chemistry of methylidyne-trimetal clusters, although so far examined thoroughly only for tricobalt compounds, can also be studied with other metals. Moreover, the incorporation of heterometal atoms in place of cobalt would appear to be a versatile synthetic procedure in view of the large number of known cobalt clusters. Preliminary results[7] support these expectations.

Experimental

$CH_3CCo_3(CO)_8$—$AsMe_2$—$Mo(CO)_3Cp$ *(2e)* (2.34 g, 3.1 mmol) is stirred in cyclohexane (50 ml) for 8 d at 40 °C. After filtration and concentration to a volume of 20 ml, the reaction solution is chromatographed on a silica gel column ($d = 3$, $l = 30$ cm) with hexane/benzene (4 : 1): a short first fraction of $CH_3CCo_3(CO)_9$ is followed by a green solution of *(3e)* which is evaporated to dryness *in vacuo*. Recrystallization from hexane (5 ml) affords *(3e)* (1.24 g, 75 %) as black crystals.

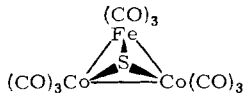
An Entry to Chiral Clusters[**]

By *Felix Richter* and *Heinrich Vahrenkamp*[*]



No optically active metal complex[1] is known whose chirality arises from differences between the metal atoms. On the basis of an analogy proposed between clusters and metal surfaces[2], such a polynuclear complex could serve as a model compound for asymmetric catalysis. We now report the first μ_3-bridged trinuclear complexes whose tetrahedral skeleton is made up of four different entities and should therefore impart chirality to the molecule.

The readily accessible[3] $FeCo_2$ cluster *(1)* and its conventionally prepared[4] substitution products *(2)* are transformed into the new clusters *(3)* containing three different metal atoms by our newly discovered[5] method of eliminating $[(CO)_3Co—AsMe_2]_x$. The complexes *(3)* are dark red to black in the solid state and red in solution, and exhibit a large number of absorption bands in the CO region of their

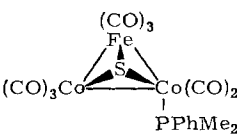
IR spectra [*e.g. (3b)*: 2080 s, 2038 vs, 2035 sh, 2020 s, 1998 s, 1985 m, 1895 cm^{-1} vw]. Their compositions were confirmed by the EI mass spectrum of *(3a)*. They differ from the sole known clusters with three different metal atoms[6] in their facile synthesis and the absence of any symmetry element in the molecule.

(1)

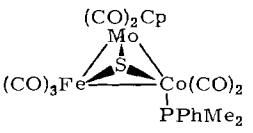
(2), M = Cr, Mo, W



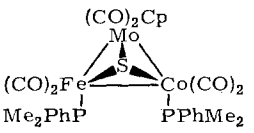
(3)

	M	M.p. [°C]	$\delta(C_5H_5)$ [a]
(3a)	Cr	102	4.20
(3b)	Mo	93	4.35
(3c)	W	112	4.33

[a] In benzene, rel. to int. TMS.



The chirality of the clusters *(3)* can be demonstrated by ^{1}H-NMR spectroscopy of suitable phosphane derivatives with diastereotopic *P*-substituents. The same applies to the starting complex *(1)* which likewise becomes chiral on CO/PR_2R' exchange. With this purpose in mind, the dimethyl(phenyl)-phosphane complexes *(4a)*, *(4b)*, *(5a)*, and *(5b)* were prepared and their structures assigned on the basis of the finding that ligand exchange in *(1)* first takes place at the two cobalt atoms[7] and that the ease of substitution decreases with decreasing number of CO groups attached to a metal atom. In all four substituted clusters the phosphane ligands are attached to asymmetric metal atoms; a *meso* form is present in the case of *(4b)*[8].



(4a)

(4b)

(5a)

(5b)

Table 1 and Figure 1 list the relevant NMR information; in all four cases the spectra have the expected appearance. It is informative to compare the disubstituted clusters: two identical centers of asymmetry are seen for *(4b)*, and two different ones for *(5b)*.

Table 1. ^{1}H-NMR data for the *P*-methyl groups of the clusters *(4)* and *(5)* (in benzene, rel. to int. TMS).

	$\delta(PCH_3)$	$^2J_{PH}$ [Hz]

(4b)	1.25, 1.28	8.8, 8.8
(5a)	1.35, 1.37	9.0, 9.2
(5b)	1.44, 1.46, 1.48, 1.53	9.0, 9.1, 8.5, 8.8

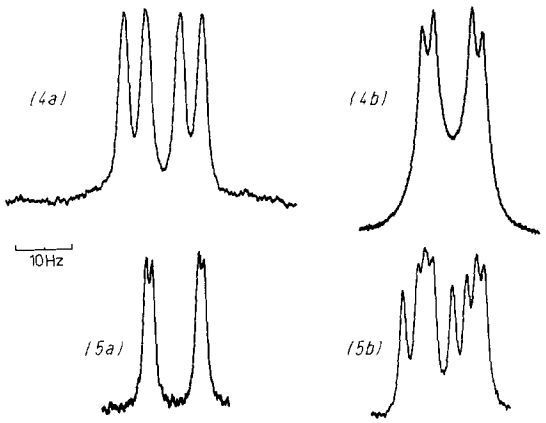

Fig. 1. ^{1}H-NMR spectra of the complexes *(4)* and *(5)* in the *P*-methyl region at 60 MHz.

Our results show that the synthesis of chiral clusters is now feasible. Attempts to introduce other metals into *(1)* and to resolve the enantiomers of the pure clusters are currently in progress.

Experimental

Compound *(2b)* (M = Mo) (0.50 g, 0.64 mmol) is heated in cyclohexane (50 ml) with stirring for 2 d at 70 °C. The reaction mixture is then chromatographed on a silica gel column ($d = 3$, $l = 70$ cm) with benzene/hexane (1 : 2), the second, red, fraction being collected. After evaporation to dryness, recrystallization from hexane (20 ml) affords *(3b)* (0.24 g, 70 %) as black-red crystals.

Compounds *(3a)* and *(3c)* were obtained similarly. The preparation of the phosphane-substituted clusters was accomplished in a manner resembling known procedures[7].

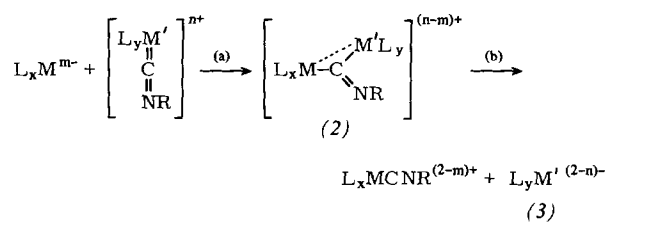
Systematic Formation of Metal Complexes Containing Isocyanide Bridging Ligands: $[\eta^5\text{-}C_5H_5Fe(CNC_6H_5)(\mu\text{-}CNC_6H_5)]_2$ [**]

By *Wolf Peter Fehlhammer, Andreas Mayr,* and *Götz Christian* [*]

Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

Metal complexes containing bridging isocyanide ligands are currently under investigation with regard to their catalytic activity[1], such as has recently been demonstrated for the nickel cluster $Ni_4(CNtBu)_7$[1a]. Most of these complexes have been obtained by reactions of carbonyl bridged metal complexes, which usually proceed in low yield affording mixtures of products.

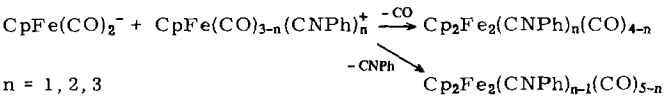


An essentially more effective preparation of μ-isocyanide complexes could be developed on the basis of our *isocyanide syntheses within a complex* from supernucleophilic metal bases and heteroallenes[2]. We had formulated the primary products of these reactions as adducts of type *(1)* which undergo elimination of X^{2-} either spontaneously or in the presence of Lewis acids (*e.g.* phosgene):

(1)

L_xM^{m-} = *e.g.* $Cr(CO)_5^{2-}$; X = NR, O, S

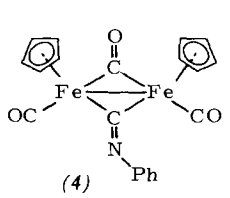
Formal replacement of the 6-electron heteroatoms X by 16-electron metal complex fragments L_yM' leads to an analogous scheme with the dinuclear isocyanide-bridged species *(2)* playing the role of adduct *(1)*:



(2)

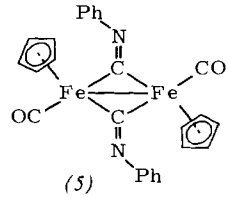
$$L_xMCNR^{(2-m)+} + L_yM'^{(2-n)-}$$

(3)



We have now accomplished the postulated reaction sequence consisting of "isocyanide bridge formation" (a) and "isocyanide transfer" [(a)+(b)].

Stable isocyanide bridges such as in *(2)*, which only occur in combination with a metal-metal bond[3], are known to exist, *e.g.* in the cyclopentadienyliron system. By proper choice of reactants—$CpFe(CO)_2^-$ as nucleophilic metal component and $CpFe(CO)_{3-n}(CNR)_n^+$ as electrophilic "heteroallene"— a systematic preparation of such dinuclear complexes should be possible:

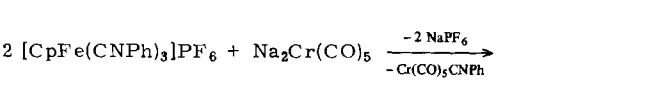


n = 1, 2, 3

As expected, the reactions (at −78 °C) come to a halt after bridge formation; elimination of carbonyl or isocyanide is followed by the formation of singly or doubly isocyanide-bridged complexes *(4)* and *(5)*. They can be separated from each other and from accompanying bis[dicarbonyl(η^5-cyclopentadienyl)iron] by chromatography on silica gel with dichloromethane.

(4)

(5)



The product distribution [%] of the reactions of $CpFe(CO)_2^-$ with $CpFe(CO)_{3-n}(CNPh)_n^+$ is as follows:

n	$[CpFe(CO)_2]_2$	*(4)*	*(5)*
1	<5	73	—
2	5	27	28
3	<5	5	56

Compounds *(4)* and *(5)* were formerly obtained in very poor yields [*(5)*: 0.7%] from $[CpFe(CO)_2]_2$ and phenyl isocyanide[4a]. X-Ray structure analyses now available show *(4)* to have a *cis*(Cp)- and *(5)* a *trans*(Cp)-*anti*(Ph) configuration[4]. A trisubstituted isocyanide derivative of $[CpFe(CO)_2]_2$ could only be prepared with methyl isocyanide[5]; the fourth CO ligand completely resisted replacement by CNR.

It therefore was an attractive challenge to attempt the synthesis of $[CpFe(CNPh)(\mu\text{-}CNPh)]_2$ by our method. However, the $CpFe(CNPh)_2^-$ ion required as metallic base is unknown. In the general reaction scheme, the two-step process of "isocyanide transfer" (a)+(b) formally proceeds *via* transfer of an isocyanide dication from the Lewis acid metal (M') to the Lewis base metal (M) with concomitant liberation of an anionic species *(3)*. This suggests use of the cation $CpFe(CNPh)_3^+$ as Lewis acid metal component and of an anion such as $Cr(CO)_5^{2-}$ as isocyanide acceptor, which *cannot* form a stable dinuclear complex *(2)* with $CpFe(CNPh)_3^+$ but reacts according to (b). The $CpFe(CNPh)_2^-$ generated "*in situ*" should react immediately with excess $CpFe(CNPh)_3^+$ to give the desired neutral compound.

Reaction of *two* equivalents of $CpFe(CNPh)_3^+$ with *one* equivalent of $Cr(CO)_5^{2-}$ is in accord with this concept:

(6)

The stable tetrakis(phenyl isocyanide) complex *(6)* was characterized by elemental analysis, IR [(CH_2Cl_2) 2078, 1646 (s) cm^{-1}], ^{1}H-NMR [20 °C ($CDCl_3$, int. TMS; δ=4.71 (s, C_5H_5, 10H), 6.83—7.60 (m, C_6H_5, 20H)], and mass spectrum [*e.g.* M^+, $[Cp_2Fe_2(CNPh)_n]^+$ (*n*=0—3), $[CpFe(CNPh)_n]^+$ (*n*=0—3)]. X-Ray structure analysis is in progress.

Procedure

Solutions of $[CpFe(CNPh)_3]Cl$[6] (1.3 g, 2.8 mmol) and $Na_2Cr(CO)_5$[7] (0.33 g, 1.4 mmol) in tetrahydrofuran (100 ml each) are combined at −78 °C. The mixture is allowed to slowly warm to room temperature, and the dark violet solution

1,2,3-Tri-*tert*-butylphosphirane Oxide and Its Thermal Decomposition into (*Z*)-2,2,5,5-Tetramethyl-3-hexene and *tert*-Butylphosphinidene Oxide[**]

By *Helmut Quast* and *Manfred Heuschmann*[*]

Phosphirane oxides have been invoked as intermediates in the base-induced rearrangement of α-halo phosphinic esters[1] and α-halo phosphane oxides[2]. Their ring strain makes them attractive precursors for generation of the hitherto rarely investigated phosphinidene oxides[3]. We report here on the synthesis, reactions, and thermolysis of the first phosphirane oxide *(3)*.

Reaction of 1 mol *tert*-butyldichlorophosphane with 3 mol 2,2-dimethylpropylmagnesium chloride in boiling ether/benzene (1 : 1) for 10 days and subsequent oxidation with hydrogen peroxide afforded phosphane oxide *(1)*[4], m. p. 125—126 °C, in 46 % yield. *(1)* was lithiated with 1.05 mol *sec*-butyllithium in tetrahydrofuran/2-methylbutane at −78 °C and then chlorinated with 1.2 mol tetrachloromethane at −100 °C to the diastereomeric α-chlorophosphane oxides *(2)* (30 : 70). Reaction of *(2)* with lithium diethylamide in ether at −80 °C to 0 °C led to ring closure and formation of phosphirane oxide *(3)* (*ca.* 80 %), accompanied by slight reduction to *(1)* and formation of the consecutive product *(4)*. Preparative layer chromatography (SiO_2/ether) and crystallization from pentane at −20 °C afforded 52 % *(3)* as colorless needles, decomp. pt. 119–120 °C; MS: $m/e = 244$ (3 %, M^+), 229 (3 %, $M-CH_3$), 188 (7 %, $M-C_4H_8$), 125 (16 %, C_9H_{17}), 97 (11 %, C_7H_{13}), 83 (20 %, C_6H_{11}), 70 (37 %, C_5H_{10}), 57 (100 %). The P=O frequency in the IR spectrum of *(3)* (1180 cm^{-1}) is 26 cm^{-1} higher than that of *(1)*. The symmetry of *(3)* and hence the *cis*-configuration of the *tert*-butyl groups attached to C-2 and C-3 are indicated by the NMR spectra (Table 1). Ring-closure drastically reduces the ^{31}P-coupling to the ring C-atoms[5] and strongly shifts the ^{31}P-signal towards high field (53.4 ppm) as observed in the case of 1,2,3-tri-*tert*-butyl-diazaphosphiridine oxide[6].

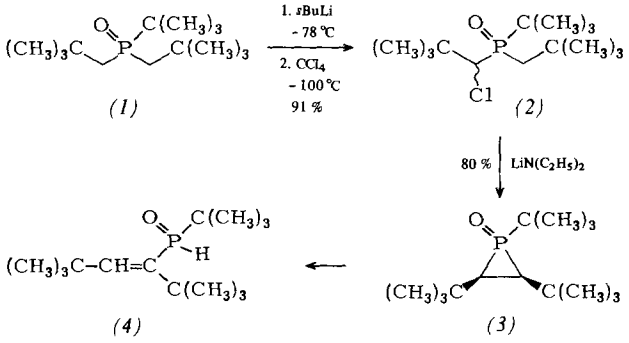

Table 1. NMR data of the phosphane oxides *(1)* and *(2)* and the phosphirane oxide *(3)* in [D]-chloroform. ^{31}P-coupling constants [Hz] in square brackets and multiplicity in the off-resonance decoupled ^{13}C-NMR spectra in round brackets.

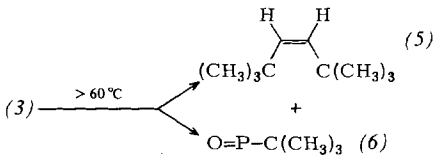
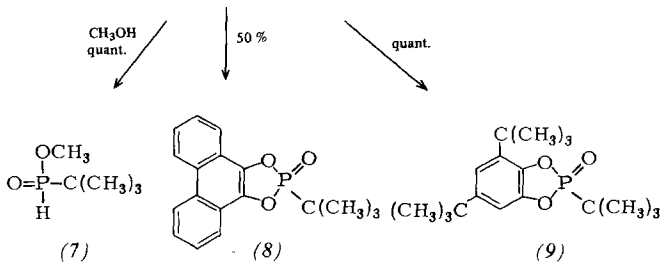
[a] 85 % phosphoric acid as ext. standard (δ = 0). Negative values correspond to higher field. [b] Thermodynamically stable diastereomer. [c] ^{1}H-NMR spectrum in [D_6]-benzene.



Compound *(3)* is remarkably stable towards concentrated hydrochloric acid. On reaction with strong bases, such as lithium piperidide or lithium diethylamide, *(3)* is slowly isomerized to *(4)*. In [D_6]-benzene[7] at 60 °C and above, *(3)* slowly decomposes quantitatively to (*Z*)-2,2,5,5-tetramethyl-3-hexene *(5)* as the sole identifiable product. *tert*-Butylphosphinidene oxide *(6)*, the second product expected to be formed along with *(5)*, could not be trapped with bis(trimethylsilyl)ethylene, 2,2-dimethylpropylidene-*tert*-butylamine, 2,3-dimethylbutadiene, 2,3-butanedione, or benzil. On the other hand, decomposition of *(3)* in methanol (20 h, 70 °C)[8] leads quantitatively to methyl phosphinate *(7)*[9]. Reaction of 2 mol 9,10-phenanthraquinone with 1 mol *(3)* in [D_8]-dioxane at 70 °C gave *(8)* in 50 % yield, which could also be prepared independently from 9,10-dihydroxyphenanthrene and *tert*-butylphosphonyl dichloride in boiling xylene in the presence of 2 mol triethylamine (70 %, m. p. 188—190 °C).



The presumed second thermolysis product *(6)* could be trapped quantitatively in [D_6]-benzene with 3,5-di-*tert*-butyl-

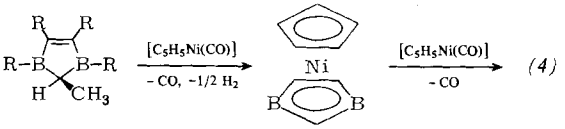
Paramagnetic Triple-Decker Sandwich Complexes[1]

By *Walter Siebert, Joseph Edwin*, and *Manfred Bochmann*[*]



Dedicated to Professor E. O. Fischer on the occasion of his 60th birthday

The previously reported dinuclear complexes containing three parallel five-membered ring ligands[1] are diamagnetic and have 30[2a] or 34 valence electrons. EH calculations[3a] are available for the first triple-decker sandwich[2b], the $3(\pi^6)/2(d^8)$ ion $[(C_5H_5)_3Ni_2]^+$, from which a 30-electron/34 electron rule was derived[3]. We report here on the first paramagnetic triple-decker sandwich complexes *(2)*—*(4)* containing 31, 32, and 33 valence electrons.

Reaction of 1,3,4,5-tetraethyl-2-methyl-1,3-diborolene *(5)* with dimeric η^5-cyclopentadienyl(carbonyl)nickel as supplier

of the three-electron donor fragment $[(C_5H_5)Ni]$ leads to formation of the diamagnetic nickelocene analogue[4] *(6)* and small amounts (10—20 %) of deep-green (shiny-blue in thick layers) complex (4), which is obtained in almost quantitative yield on "stacking" *(6)* with $[(C_5H_5)Ni(CO)]_2$.

(5), R = C_2H_5 *(6)*

The new complex *(4)* is air-stable, readily soluble in nonpolar solvents, and crystallizes from ether/acetonitrile in thin platelets. Having 33 valence electrons the compound is expectedly paramagnetic ($\mu_{eff} = 1.52\,\mu_B$[5a]). In the ^{1}H-NMR spectrum it shows broad signals[5b] which shift in dependence of the potassium content in [D$_8$]-tetrahydrofuran/K solvent.

On reduction, the deep-red diamagnetic $(4)^-$ having 34 valence electrons is formed [^{1}H-NMR: $\delta = 4.83$ (s), 1.74 (q), 1.35 (s), 1.15 (t), 1.2—1.0 (m for B—C_2H_5); ^{11}B-NMR: $\delta = +5.6$ (in [D$_8$]-THF) rel. to $Et_2O \cdot BF_3$ and TMS int., resp.]. The appearance of only one C_5H_5 signal and a quartet for the C—C_2H_5 groups confirm the triple-decker sandwich structure of the anion $(4)^-$, which is rapidly oxidized with oxygen to *(4)*. The complex *(4)* reacts with $Ag^+BF_4^-$ to give the blue, paramagnetic 32 valence-electron triple-decker salt $(4)^+BF_4^-$ (two unpaired electrons). Electrochemical investigations on *(4)* confirm the reversible uptake and release of electrons[6].

The cobalt derivative *(3)* isoelectronic with $(4)^+BF_4^-$ is blue-green in solution, and, analogous to *(4)*, can likewise be prepared by "stacking" the sandwich *(6)* with $[(C_5H_5)Co(CO)_2]$, while *(2)*, which is yellow-green in solution, is obtained only in low yield on reaction of *(5)* with $[(C_5H_5)Co(CO)_2]$. Like *(1)*[7] and *(4)*, complexes *(2)* and *(3)* are air-stable and readily soluble in nonpolar solvents. Complexes *(1)* through *(4)* sublime in melting-point tubes above 130 °C and deliquesce between 220 and 270 °C. In the mass spectrum (70 eV), the molecular peak ($I_{rel} = 100\,\%$) appears in each case together with the expected isotopic pattern; only slight fragmentation is observed.

The bonding in complexes *(1)*—*(4)* and in $(4)^-$ can be considered in terms of the aromaticity and cluster formalisms. In each case there are three π^6-systems held together by two metal ions, which have 12 to 16 d electrons. In the MO diagram[3a] for the triple-decker the e_1' level in $(4)^-$ is completely occupied, as in $[(C_5H_5)_3Ni_2]^+$, while in *(2)* it is only singly occupied. According to the cluster description *(1)*—$(4)^-$ each contain a heptatomic *closo*-system C_3B_2MM', requiring 16 skeletal electrons according to the $(2n+2)$ rule[8]. In the case of *(1)* these are supplied by C(3 × 3), B(2 × 2), Fe(1), and Co(2). $(4)^-$ has four electrons more than *(1)*, so instead

[*] Prof. Dr. W. Siebert, J. Edwin M. Sc., Dipl.-Chem. M. Bochmann
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg 1 (Germany)

of the $(2n+2)$ rule the $(2n+6)$ rule for *arachno*-structures should apply. However, opening of the cage, as in the polyhedral boranes and carbaboranes, is not expected here[2a], but rather a widening of the metal-ring distance as predicted by the EH calculations as a consequence of the successive occupation of the weakly antibonding e_1' level.

The smooth formation of *(4)* from *(6)* and the fragment $[(C_5H_5)Ni]$ is a parallel to the "stacking" of nickelocene[2b, 3b] with $[(C_5H_5)Ni]^+$ to give the $[(C_5H_5)_3Ni_2]^+$ ion, from which $[(C_5H_5Ni)_2C_3B_2]^+$ is derived by replacement of two C by B atoms in the μ-ring.

$(4)^-$ is the second example of a 34-electron triple-decker sandwich with three five-membered rings as ligands. The first triple-decker sandwich ions with a C_8H_8 ring in the bridge position have recently been reported: the diamagnetic complexes $[(C_8H_8)_3Ti_2]^{2-}$[9a] and $[\{(C_5H_5)Co\}_2C_8H_8]^{2+}$[9b] likewise have 34 valence electrons.

μ-(1,3,4,5-Tetraethyl-2-methyl-1,3-diborolenyl)bis[η-cyclopentadienylnickel] (4)

A solution of *(6)*[4] (0.30 g, 0.96 mmol) and $[CpNi(CO)]_2$ (0.16 g, 0.53 mmol) in mesitylene (5 ml) is heated at 140—150 °C for 3 h. After removal of the solvent *(4)* is sublimed at 120—130 °C/0.01 torr. Yield 0.40 g (96 %).—High-resolution MS: $C_{22}H_{33}{}^{11}B_2{}^{58}Ni^{60}Ni$ 437.1431 (calc. 437.14294).

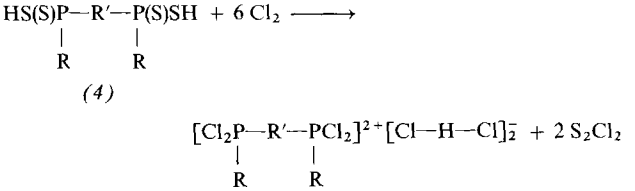
Diorganodichlorophosphonium Hydrogen Dichlorides, a Novel Class of Compounds Containing $[ClHCl]^-$ Ions

By *Wilhelm Kuchen, Dietrich Mootz, Heinrich Somberg, Hartmut Wunderlich*, and *Hans-Georg Wussow*[*]

Dithiophosphinic acids of type *(1)* react with chlorine to give the corresponding diorganotrichlorophosphoranes *(2)*[1]. On carrying out this reaction with the *p*-methoxyphenyl-substituted acids *(1a)*—*(1c)*[2], however, we obtained the novel compounds *(3a)*—*(3c)* as products. They contain chlorine

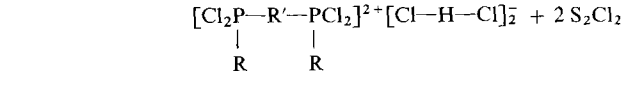
$$RR'P(S)SH + 3Cl_2 \longrightarrow RR'PHCl_4 + S_2Cl_2$$
(1) *(3)*

$$(3) \xrightarrow[CHCl_3,\ 20°C]{N_2\text{-stream},\ 60°C} RR'PCl_3 + HCl$$
(2)



$R = 4\text{-}CH_3OC_6H_4$
$R' = CH_3$ *(a)*, C_6H_5 *(b)*, $4\text{-}CH_3OC_6H_4$ *(c)*

only in the oxidation state-1, and on hydrolysis give quantitatively the phosphinic acids RR'P(O)OH and hydrogen chloride.



Passage of dry nitrogen through a boiling solution of *(3a)*—*(3c)* in trichloromethane leads to liberation of HCl and formation of the trichlorophosphoranes *(2a)*—*(2c)*, which react again with HCl gas at room temperature with regeneration of *(3)*. A compound of composition *(3)*, for which the structure $[(C_6H_5CH{=}CH)_2PCl_3H]^+Cl^-$ has been proposed, had already been obtained by reaction of PCl_5 with styrene[3].

The $^{31}P\{^1H\}$-NMR spectra of *(3a)*—*(3c)* each show only one singlet—in a region typical for phosphonium ions[4] [*(3a)*: δ = 104, *(3b)*: δ = 90.2, *(3c)*: δ = 88.8; saturated solution in $CDCl_3$ rel. to 85 % H_3PO_4]. The presence of penta- or hexacoordinated phosphorus can thus be ruled out. The ^1H-NMR spectra (saturated solution in $CDCl_3$) each show, *inter alia*, an acidic proton (δ = 12—13) and, for the methoxy group, a sharp singlet whose chemical shift and halfwidth is unchanged from that observed in the spectra of the corresponding HCl-free compound *(2)*. Since, in all cases, the FD-mass spectra also show signals for phosphonium ions $[RR'PCl_2]^+$ as peaks of highest intensity, we formulate *(3a)*—*(3c)* as diorganodichlorophosphonium hydrogen dichlorides $[RR'PCl_2]^+[ClHCl]^-$. In the IR spectrum (Nujol) of *(3a)* a band is observed at 1150 cm^{-1}, which from its position, halfwidth and intensity is assigned to the $2\nu_2$ deformation vibration of the $[ClHCl]^-$ ion. This band was accordingly absent in the case of *(2a)*, and was not observed in the IR spectra of *(3b)* and *(3c)* either. This finding, however, does not rule out a phosphonium hydrogen dichloride structure for the latter two compounds[5], which has been confirmed by X-ray structure analysis in the case of *(3a)*.

Analogous chlorination of the difunctional dithiophosphinic acids *(4a)* and *(4b)*[6] leads as follows

(4)

(5)

$R = 4\text{-}CH_3OC_6H_4$
$R' = 1,4\text{-}C_6H_4$ *(a)*, $-(CH_2)_4-$ *(b)*

to products, which according to their composition and properties are likewise hydrogen dichlorides (dichlorohydrogenates), namely *(5a)* and *(5b)*.

Experimental

A slow stream of chlorine gas is passed over a stirred solution or suspension of the acids *(1a)*—*(1c)* or *(4a)* or *(4b)* in CCl_4 at 0 °C in the absence of moisture until absorption ceases. The deep-red solution is decanted from the finely crys-

[*] Prof. Dr. W. Kuchen, Prof. Dr. D. Mootz, Dipl.-Chem. H. Somberg, Dr. H. Wunderlich, Dipl.-Chem. H.-G. Wussow
Institut für Anorganische Chemie und Strukturchemie der Universität Universitätsstr. 1, D-4000 Düsseldorf (Germany)

talline precipitate, which is then repeatedly washed with ligroin (b. p. 30—50 °C). For further purification the hydrogen dichlorides *(3)* and *(5)*, respectively, are dissolved in a small amount of $CHCl_3$ and re-precipitated by slow addition of CCl_4 or ligroin (or in the case of *(3c)* by trimethylchlorosilane) (yield 60—90 %). Colorless needles, extremely sensitive to hydrolysis, soluble in $CHCl_3$, CH_2Cl_2, CH_3CN.

Crystal structure of (3a)

The substance forms monoclinic crystals, space group $P2_1/c$ with $a = 12.834(2)$, $b = 9.363(4)$, $c = 11.900(1)$ Å, $\beta = 113.46(1)°$; $Z = 4$. The structural determination with 1549 significant diffraction data led to an R value of 0.059. Figure 1[7] shows the tetrahedral phosphonium cation and the hydrogen dichloride anion together with the most important bond lengths [Å] and bond angles [°].

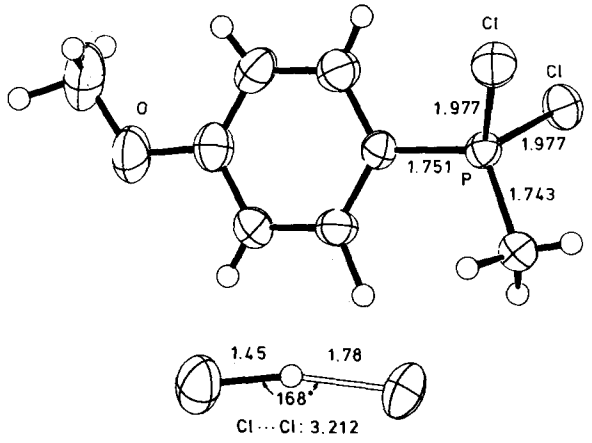


Fig. 1. Structure of dichloro(*p*-methoxyphenyl)methylphosphonium dichlorohydrogenate *(3a)*.

The anion appears asymmetric with respect to the position of the proton and not quite linear. This conclusion is uncertain owing to the high standard deviations (Cl—H 0.09 Å, Cl—H—Cl 6°). However, similar asymmetry has been observed by the more accurate method of neutron diffraction in $[(CH_3)_4N]^+[ClHCl]^-$, the only other reported example of a localized proton in this anion[8].

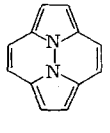
ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.



Cyclazines and related N-bridged annulenes are reported on by *W. Fritsch* and *U. Krämer*. Cyclazines are conjugated unsaturated cyclic molecules held planar by three covalent bonds to an internal N-atom. Stable cycl[3.2.2]azine *(1)* and its derivatives, which, *e.g.* can be prepared from indolizines or 3*H*-pyrrolizines, have aromatic character. On reaction with bromine, *(1)* is converted into the dibromide *(2)*. The unstable cycl[3.3.3]azine *(3)*, which is storable only under N_2, has been synthesized from quinolizinium salt *via* the ester *(4)*. Reaction of *(3)* with bromine vapor gives the dibromide of the cyclazine dication.—Cyclazines with additional heteroatoms in the skeletal structure, and annulenes containing hydrazine bridges, *e.g. (5)*, are also described. [Cyclazines and Related N-Bridged Annulenes. Adv. Heterocycl. Chem. *22*, 321—365 (1978); 123 references]

Photosynthetic membranes as models for solar cells forms the theme of an article by *K. Sauer*. An examination of photosynthesis in plants suggests a set of design criteria which could be fulfilled, at least in part, in solar energy converters for commercial facilities: 1) Absorption of nearly all wavelengths of photochemically active radiation reaching the surface of the earth; 2) rapid and efficient conversion of electronic excitation for charge separation; 3) stabilization against wasteful charge recombination, the chemical species being separated *e.g.* by an impermeable membrane; 4) high conversion of the chemical potential into stable "chemical" products from readily available reactants (*e.g.* H_2O and CO_2). [Photosynthetic Membranes. Acc. Chem. Res. *11*, 257—264 (1978); 49 references]

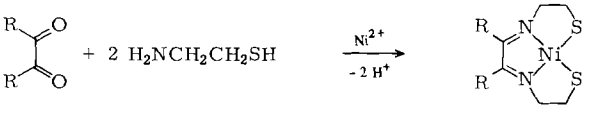
[Rd 39 IE]

Coumarins in the Rutaceae are the theme of a review article by *A. I. Gray* and *P. G. Waterman*. The biogenesis, structural variants, and occurrence of simple coumarins as well as furano- and pyranocoumarins are described. In addition the compounds are discussed regarding their possible biological significance and their usefulness in taxonomic considerations. [Coumarins in the Rutaceae. Phytochemistry *17*, 845—864 (1978); 301 references]

[Rd 43 IE]

The fine control of the conversion of pyruvate (phosphoenolpyruvate) into oxaloacetate in various species is described in an article by *M. C. Scrutton*. Depending upon the species, the catalysts for this reaction are the enzymes pyruvate carboxylase, phosphoenolpyruvate carboxylase and phosphoenolpyruvate carboxytransphosphorylase. Owing to these enzymatic reactions, which enhance the supply of intermediates, the citric acid cycle can serve for both degradation as well as synthesis. Effectors for the above mentioned enzymes are acetyl coenzyme A and other acyl coenzymes A as well as glutamate, aspartate, and α-ketoglutarate. It is hoped that an investigation of the regulation will provide a detailed explanation of the biological function of the enzymes. [Fine Control of the Conversion of Pyruvate (Phosphoenolpyruvate) to Oxaloacetate in Various Species. FEBS Lett. *89*, 1—9 (1978); 60 references]

[Rd 44 IE]



The connection between photosynthetic carbon reduction and photorespiration is discussed in an article by *T. J. Andrews* and *G. H. Lorimer*. The primary reaction of photorespiration consists of the oxidative cleavage of ribulose 1,5-bisphosphate *(1)* to give 3-phosphoglycerate and phosphoglycolate. Photorespiration thus counteracts, in part, the result of photosynthesis. The question arises whether this apparently meaningless debilitating effect on the plants might not be avoidable. The authors show with the aid of experimental findings that all carboxylases for *(1)* are at the same time also oxygenases for *(1)*. The ratio of carboxylation to oxygenation depends upon the relative concentrations of the substrates CO_2 and O_2. It would appear that photorespiration, though of no particular advantage to plants could not be dispensed with in the course of evolution because it is an unevadable consequence of the chemical structure of the active center of ribulose 1,5-bisphosphate carboxylase. [Photorespiration. Still Unavoidable? FEBS Lett. *90*, 1—9 (1978); 103 references]

[Rd 45 IE]

Steric aspects of dopaminergic drugs are dealt with in a report by *D. D. Miller*. At the physiological pH value, dopamine occurs in a variety of molecular species, the phenolic ammonium salt being predominant. Nevertheless, it is still unknown which of these forms is optimal for a dopaminergic action. Hence, a series of analogs which are fixed in their conformation and some more complex molecules with dopaminergic segments have been investigated. The experiments showed that the stretched form is optimal for binding to dopamine receptors, but also that rotamers have to be taken into consideration. The dopaminergic action is largely dependent upon the stereochemistry. [Steric Effects of Dopaminergic Drugs. Fed. Proc. *37*, 2392–2395 (1978); 33 references]

[Rd 46 IE]

Template reactions are the theme of a review by *M. de Sousa Healy* and *A. J. Rest*. Macrocycles were hitherto mainly accessible only *via* laborious routes and in small yields. One of the first examples of the ability of metals and metal ions to promote the formation of macrocycles was the self-condensation of *o*-phthalonitrile to give metal phthalocyanine complexes from which the free ligand was easily displaced. From

(1)

the formation of macrocycles such as *(1)* using Ni^{2+} ions it was recognized that the coordination sphere of the metal ion would hold the reacting groups in the correct positions for cyclization reactions, *i.e.*, the metal ion acts as a "template". K^+ has proven suitable for the synthesis of crown ethers, Ni^{2+} or Cu^{2+} are preferably used for the synthesis of planar macrocycles containing four nitrogen atoms. [Template Reactions. Adv. Inorg. Chem. Radiochem. *21*, 1—40 (1978); 143 references]

[Rd 48 IE]

The use of liquid crystals in chromatography is dealt with in an article by *H. Kelker*. Liquid crystals can be used as stationary phase in gas-liquid chromatography for the separation of isomers whose separation is not easy to achieve with normal isotropic liquids. An example is the resolution of a mixture of *m*- and *p*-xylene using liquid-crystalline 4,4-azooxyanisole. Otherwise, *m*- and *p*-xylene necessitate the use of highly efficient columns, *e.g.* modified bentonites, for their separation. The article contains, *inter alia*, a list of all the previous applications of liquid crystals as stationary phases in chromatography. [Liquid Crystals in Chromatography. Adv. Liq. Cryst. *3*, 237—273 (1978); references]

BOOK REVIEWS

Biotransformation von Arzneimitteln (Bio-Transformation of Drugs). By *S. Pfeifer*, Verlag Chemie GmbH, Weinheim—New York. Vol. 1: 1977 reprint of the 1st edition of 1975, 484 pp., bound, DM 90.00. Vol. 2: 1st edition, 424 pp., bound, DM 70.00.

Volume 1 contains 329 monographs on the metabolism of various antibacterial sulfonamides, antidiabetic preparations, antiepileptic agents, psychopharmaceuticals, sedatives and hypnotics, and synthetic steroid hormones and estrogens with a different structure. The literature is covered up to 1972/73, and a literature supplement gives publications up to the middle of 1975.

Volume 2 contains 211 monographs on the metabolism of analgesics, antineuralgic drugs, antirheumatic preparations,

non-steroidal anti-inflammatory drugs, analgesic antagonists, drugs for arrhythmias, β-receptor blocking agents, antihypertensive agents, chemotherapeutic preparations (nitrogen-containing heterocyclic systems), coronary dilators, and tuberculostatics. The literature is covered up to 1973/74, and a literature supplement gives publications up to the middle of 1976. Besides, the references for volume 1 are also extended.

The third volume is expected to appear this year.

More and more work is being done on the biotransformation of drugs and the field is in a stage of rapid growth. It is therefore extremely difficult to give an account here that is both up to date and comprehensive.

The two volumes reviewed describe over 500 substances. This series of monographs differs from previous reviews by having a high information content and by being based on very recent literature; it is expected that the literature will be updated by special supplements in the following volumes.

Unfortunately, the naming of the substances is not uniform: the international short names are often used, but mainly in the Latin form (*e.g.* calcii benzamidosalicylas and acidum flufenamicum). This causes unnecessary confusion. Furthermore, it is difficult to see how the substances were selected: some of those which have been included are not yet used as drugs, or are no longer used in this way, while others that are very common (*e.g.* reserpine) are missing.

All the monographs are drawn up in the same form. In a condensed and clear manner, they give schemes of biotransformation, routes of elimination, and detection of metabolites in various species, together with the analytical methods used for this purpose. In a final section, called Remarks, we find *e.g.* incomplete or contradictory literature data. The author also gives supplementary data on individual metabolites (*e.g.* activity and distribution in the body) and—without any claims to completeness—further information *e.g.* on pharmacokinetics and drug interactions. In the presentation of this material, clearly no attempt was made to follow a systematic approach.

The collection can be recommended as a reference work for all those involved with the biotransformation of drugs.

K.-O. Vollmer [NB 433 IE]

Molecular Structure and Dimensions. Guide to the Literature 1935—1976. Organic and Organometallic Crystal Structures. Edited by *O. Kennard, F. H. Allen,* and *D. G. Watson* for the Cambridge Crystallographic Data Centre and the International Union of Crystallography. Bohn, Scheltema & Holtema, Utrecht 1977. 683 pp., bound, fl. 150.00.

While this volume, like the "60-year Structure Index" of "Structure Reports" consists of indexes (indexes of substance names, formulas, authors, and literature references), this time all the indexes have been developed with computer programs from the data bank of organic and organometallic crystal structures of the Cambridge Crystallographic Data Centre and printed from magnetic tape with photosetting. This is a prerequisite for greater up-to-dateness, variety, and reliability.

A substance name may contain many structural elements of a chemical compound. The index built up according to the KWIC (Keyword in context) concept records each compound under the word segment relevant to that compound and thus provides not only access to defined substances whose exact nomenclature is difficult but above all to related substances and groups of substances. In Part A are collected 10156 organic compounds and metal-containing organic compounds that include an interesting organic portion. One finds, for example, 49 adenine derivatives, 77 porphine derivatives and complexes, as well as 50 deuterated compounds. In Part B 5777 organometallic compounds and complexes are listed in two-fold arrangement: all the compounds of each metal are sorted again according to their relevant word segments, *e.g.* 139 phosphane complexes of platinum or 8 carbene complexes of chromium.

In Part A the molecular formula index lists all compounds in the usual way (C, H, all other elements in alphabetical order) but in Part B the formulas are permuted once more so that, *e.g.* all the fluorine or all the silicon compounds occur together. In both cases it is not always the true molecular formula that is used, but—when useful—partial molecular formulas of the "residues", *i.e.* of the discrete units of the compound. All the indexes lead, *inter alia*, directly to the original reference.

The printed book cannot offer the variety of entry that is provided in a data bank, because the extent and the cost force compromises. Victims of the compromises are keywords such as "hydrates" and "inclusion compounds", but also the possibility of finding in one place all the complexes of ligands such as salicylaldehyde or thiocyanate.

The reliability of the index is guaranteed by the programmed setting and automatic printing, provided that the basic material is faultless. To this end the material taken into the data bank is subjected on entry to numerous test programs. The logic of our language and spelling are, however, so complicated that variation in nomenclature and mode of writing must sometimes be recognized and corrected mentally, because heterogeneity in naming in conjunction with the strict logic of the sorting program leads sometimes to primitive errors on introduction into the index. The user accustomed to the working of a computer does not stumble over, for example, the separated positions of "vitamin B12" and "vitamin B(12)"; more serious is that compounds of the same type may be named according to different principles, *e.g.* "dichlorophthalocyanato-tin(IV)" or "stannic phthalocyanine".

Such failings are of little account when measured against the value of the total undertaking, and they are shared with traditionally prepared indexes. However, the data bank makes it possible to prepare cumulative indexes relatively easily, and when doing so to eradicate mistakes gradually during further developments of the programs.

Statistical data readily accessible by modern programming show by the numerous replications of the same structure, by the corrections to the data that become necessary, by the distribution of references in the original literature (which enables the completeness of the entries to be tested), and by the content of 28000 structures estimated for 1980 the importance now attaching to joint international efforts in connection with the collection and retrieval of scientific data. It is to be hoped that the development started with this project will not remain restricted to crystal structures.

Günter Bergerhoff [NB 440b IE]

Microbiological Aspects of Pollution Control. By *R. K. Dart* and *R. J. Stretton.* Elsevier Scientific Publishing Company, Amsterdam—Oxford—New York, 1977, 1st edit., vi, 215 pp., bound, Dfl. 85.00.

We read in a publication of the Fonds der Chemischen Industrie, dated October 27, 1977 that "This additional expense, necessitated by environmental protection, can become the 'eye of the needle' for productivity and research". This means that nowadays every chemist should know something about the microbial aspects of environmental protection. The book is aimed at engineers and therefore gives a detailed description of methods, *e.g.* for microbial water control, that have long been known to microbiologists and hygienists. The eleven chapters deal with the microbial formation of polluting compounds, atmospheric pollution and microorganisms,

health hazards of pathogenic microorganisms in water, testing water, effluent treatment, disinfection and the water cycle, eutrophication, thermal pollution, the sulfur cycle and waste recycling, oil pollution and biological degradation, the formation of organic mercury and arsenic compounds, reasons for the occurrence of nitrates, nitrites, and hydroxylamine in water, and the formation of carcinogenic nitrosamines and of aflatoxins.

While effluent treatment is described in detail, biodegradation receives too little space—a mere twenty pages for the degradation of aromatics, heterocyclics, alicyclics, synthetic detergents, and pesticides. The literature is basically confined to English and American sources. The book can be recommended as an introduction.

Comprehensive Biochemistry, Vol. 32: A History of Biochemistry. Part IV. Edited by *M. Florkin* and *E. H. Stotz*. Elsevier/North Holland Biomedical Press, Amsterdam, 1977. 1st edit., xx, 362 pp., 57 figs., bound, Dfl. 98.00.

This is the fourth part of the History of Biochemistry, a separate section of the Comprehensive Biochemistry series, and certainly the one least subject to change. With his historical sense that also characterizes his research in the field of biochemical evolution, dealing with the problems of cause and effect, *M. Florkin* knows very well how to present the parallel development of the concepts of chemistry and biochemistry—the mutual interdependence of nature and person, reality and perception. We saw in Part III[*] that ideas of nutrition had always been bound up with the concept of composition and decomposition, how the parts of the cell components are linked by basic chemical processes, the necessary energy being ensured by redox or group potentials *via* a common donor. This sets the scene, based on assimilation, dissimilation, and energetics, on which the processes of biosynthesis take place. Since the middle of the 18th century these have been developed in step with the advances of experimental and theoretical chemistry. The present volume deals with the early stages of present-day knowledge of the biogenesis of cell components and is illustrated by interesting portraits of many of the protagonists. The story begins with the application of mass and energy balances to living organisms and with the discovery of the assimilation of carbon dioxide by green plants. It ends with the introduction of isotope methods around the middle of the century, which made it possible to put the mechanisms of biosynthesis on a stronger foundation. It is exciting to find the intellectual sources and to learn about the philosophy and changing attitudes of biochemists, which enables us to understand and assess the various contributions in their proper historical context. The network of fruitful contacts during the period of elitist preoccupation with research problems (which seemed irrelevant to the wider public) and the personal contacts surviving the political tensions in the 18th and early 19th centuries—but also the emotional and national movements which influenced scientific thinking and which came in the next hundred years—give an instructive picture and shift the role and the inclination of many an outstanding research worker into a fitting and just perspective. At this time the possibility of reversing catabolic and anabolic processes was postulated as a result of mass action, and scientists discovered the fundamental biogenesis of urea and uric acid, "detoxication" processes as cellular activities, the β-oxidation of fatty acids, and the inability of the body to form certain amino acids. These observations, to which a great number of life scientists in many countries have made important contributions, fill the book with exciting material. The account is written in an elegant style and with warmth, and gives a stirring panorama, which makes us await the last volume with great interest. With its facts, interpretations, references, and portraits, this book is—and will no doubt long remain—a rich source for all who are interested in the history and philosophy of natural sciences.

Immunologie (Immunology). By *G. Bundschuh* and *B. Schneeweiss*. Gustav Fischer Verlag, Stuttgart—New York 1976. 1st edit., xxxiv, 451 pp., linen, DM 42.00.

More than 2000 keywords from the field of immunology are arranged alphabetically in this book and explained briefly, in some cases with references to the original literature. It is certainly not possible to say that the fundamental principles of the immune system could be reconstructed from this collection. For this purpose the book is too concerned with human and clinical immunology, the quality of the individual sections is too varied, and the reported state of knowledge is a couple of years out of date (in this connection it may be mentioned that under the keyword "network theory" one finds a description of the mechanism of the serological precipitin reaction but not that of a general regulation principle based on receptor interactions). Many fundamental aspects of the immune system do not come over clearly, for example the recognition that regulation of the immune apparatus is based to a large extent on cell interactions: one looks in vain for keywords such as "cell interaction", "cooperation", and the like. On the other hand, the book contains a wealth of information that for a non-specialist is often difficult to find (even within the area of immunology). Working myself in "fundamental" immunology, I was particularly struck by the fact there were often very informative sections on matters important in clinical immunology. Summarizing, this is a book in which much can be looked up but in which much is presented incompletely or omitted. A useful supplementary book.

Multistage Organic Redox Systems—A General Structural Principle

By Klaus Deuchert and Siegfried Hünig[*]

A general structural principle for organic compounds that have the capacity for two-stage electron transfer is based on the following reaction sequence:

$$\underset{\text{RED}}{\ddot{X}\text{-}(\text{CH=CH})_n\ddot{X}} \underset{+e}{\overset{-e}{\rightleftharpoons}} \underset{\text{SEM}}{\ddot{X}\text{-}(\text{CH=CH})_n\overset{\oplus}{\ddot{X}} \leftrightarrow \overset{\oplus}{\ddot{X}}\text{-}(\text{CH=CH})_n\ddot{X}} \underset{+e}{\overset{-e}{\rightleftharpoons}} \underset{\text{OX}}{\overset{\oplus}{X}\text{=}(\text{CH-CH})_n\overset{\oplus}{X}}$$

In this scheme one or both of the entities X may be replaced by $Y^{\ominus}$. The radical partners in these systems often have very high thermodynamic stability. The choice of the end groups X and Y, (partial) inclusion of π-systems in rings, alteration of the number of vinylene groups, and aza-substitution make many variations possible. By means of this general structural principle numerous known compounds are brought together and new redox systems are simultaneously set up. The aim of the present review is to demonstrate the broad applicability of this principle, to indicate its significance for science and industry, and to describe some reactions.

1. Reduction and Oxidation—Two Changeable Concepts

Although oxidation and reduction are age-old chemical phenomena, it required centuries before the two concepts could be described from a uniform point of view, on the basis of the "phlogiston" theory[1], according to which phlogiston is *evolved* during combustion of a metal and *taken up again* during its regeneration. After the discovery of oxygen by *Scheele* and *Priestley*, it was *Lavoisier* who, in 1774, showed these ideas to be incorrect and since that time the uptake and removal of oxygen were considered as the characteristic features of oxidations and reductions. This narrow viewpoint persisted even after the development of the ionic theory at the end of the nineteenth century, and only slowly were the concepts of oxidation and reduction expanded and finally defined as the *loss* and the *uptake* of electrons[2], or better as electron *transfer*. Incidentally, in this definition phlogiston has reappeared unnoticed in a new guise.

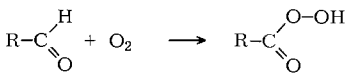
In the field of *molecular* chemistry, and in particular hydrocarbon-based organic chemistry, the concepts of *oxidation* and *reduction* have remained largely associated with the *uptake* or *loss* of oxygen or with the *loss* or *uptake* of hydrogen.

The special role of hydrogen in reactions shown in equations (a) and (b) is in line with the ideas of hydrogenation and dehydrogenation, which are shown by equation (c) to be also valid if the overall reaction consists formally of the loss or uptake of oxygen[3].

$$H_3C\text{-}CH_3 \underset{+2H}{\overset{-2H}{\rightleftharpoons}} H_2C\text{=}CH_2 \qquad \text{(a)}$$

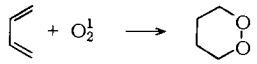
$$R\text{-}CH_2OH \underset{+2H}{\overset{-2H}{\rightleftharpoons}} R\text{-}C(=O)H \qquad \text{(b)}$$

$$R\text{-}C(=O)H \underset{-H_2O}{\overset{+H_2O}{\rightleftharpoons}} R\text{-}C(OH)_2H \underset{+2H}{\overset{-2H}{\rightleftharpoons}} R\text{-}C(=O)OH \qquad \text{(c)}$$



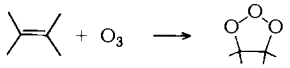
$$Cl^{\bullet} + C_6H_5CH_3 \longrightarrow C_6H_5CH_2^{\bullet} + HCl \qquad \text{(d)}$$

$$(C_6H_5)_3C^{\oplus} + C(H)(OR)_2H \longrightarrow (C_6H_5)_3C\text{-}H + HC(=O^{\oplus}\text{-}R)(O\text{-}R) \qquad \text{(e)}$$



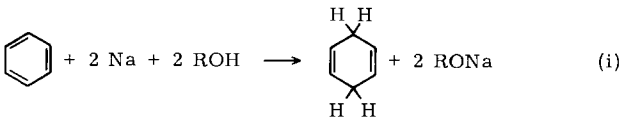
[*] Dr. K. Deuchert, Prof. Dr. S. Hünig
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

Not only reactions of molecular hydrogen, but also transfer of H atoms [eq. (d)] or hydride ions [eq. (e), see also $NAD^{\oplus} + H^{\ominus} \rightleftarrows NADH$[4]] are covered by these concepts.



In contrast to the above hydrogen transfers, there are only a few reactions with triplet or singlet oxygen [eqs. (f)—(g)][5] and with ozone [eq. (h)] that could be regarded as "true oxidations".

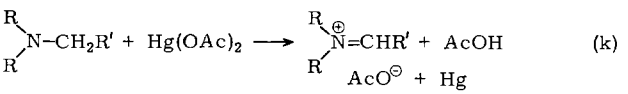
(f)



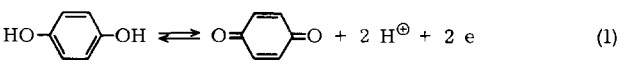
(g)

(h)

In none of these cases does it appear reasonable to consider the electron transfer separately from the element transfer.



Nevertheless, each case must be considered separately, for in reactions according to equations (i)[6], (j)[7], and (k)[8]—which correspond formally to the reactions discussed above—electron transfer is known to occur first, followed by rapid making and breaking of bonds. For the hydroquinone ⇄ quinone transformation [eq. (l)] the rates of the *proton* and *electron transfer* are accurately known[9].

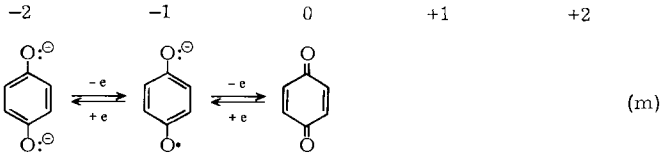


(i)

(j)

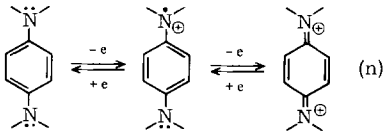
(k)

(l)



Among *organic compounds*, redox processes come into consideration as mere electron transfers only when no formation or rupture of electron-pair single bonds is required. In this case, stepwise transfer of single electrons must in principle be taken into account. It is the aim of this review to show that such multistage electron transfers are more common among organic compounds than is often assumed.

The following account will first describe the structural principle for compounds in which multistage electron transfer is to be expected. This general structural principle will then be explained with a large number of apparently unrelated examples.



2. Two-Stage Redox Systems with Similar Fundamental Structure

2.1. Derivation of a General Structural Principle

Two-stage redox systems with stable radical ions were used unrecognized by chemists for almost 50 years, for the dye salt[10] discovered by *Wurster* in 1879 was recognized only in 1925 by *Weitz* (by a molecular weight determination[11]) as consisting of radical cations in the system shown in eq. (n). Owing to the complication of quinhydrone formation,

(m)

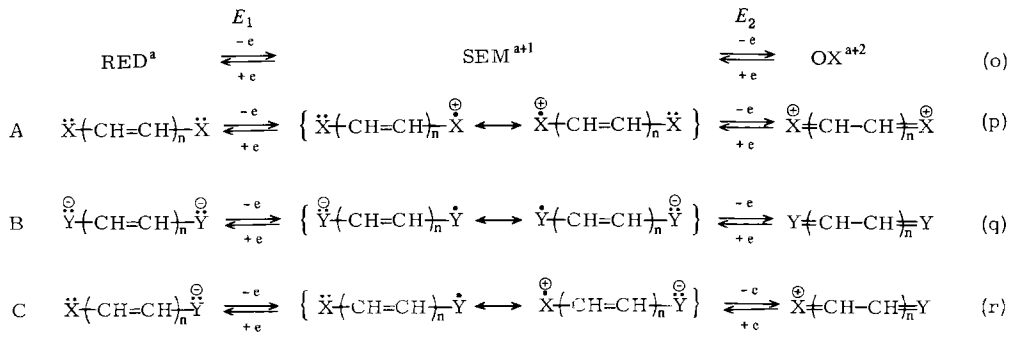
(n)

the radical anion ("semiquinone") formed initially on reduction of quinone was in fact found only in 1938 by *Michaelis*[12] in the redox system of eq. (m).

For the sake of clarity in the following discussion, the radical ion will be written with a fixed single electron, although its strong delocalization is mainly reponsible for the stability of such radical ions, as emphasized by *Weitz*[11,13]. *Weitz* also developed a general structure in which the existence of stable radical ions is to be expected[11,13]. The following structural principle can easily be developed on the basis of these facts:

Reversible redox reactions with transfer of two electrons in two separate steps (stages) are to be expected with compounds in which the end groups X and Y of the reduced form (RED) 1) have free electron pairs or π-systems[14,15] *available and 2) are connected by vinylene groups (n=0,1,2...).*

These structures, shown in equations (p) to (r), have largely "localized" π-systems in the RED and OX stages. In the SEM stage, however, the single electron is strongly delocalized; thus, from eq. (o) (a = charge on the compound), the following can be expected for the SEM form:



1) Measurable thermodynamic stabilization of the radical (ion) in comparison with similar radical systems in which the unpaired electron is not delocalized; and 2) particularly long-wave UV/VIS absorption as a consequence of the delocalization of the radical electron.

The systems A and B differ only by two charges; otherwise they are iso-π-electronic. The SEM radical appears as a cation in A and as an anion in B.

System C can be formally obtained by "crossing" systems A and B, whereby the same halves of A and B are joined together. By this device the RED and OX stages become respectively monoanions and monocations, while SEM becomes a neutral radical. *Katritzky*[16] regards such radicals as "merostabilized", relating the radicals in systems A, B, and C to cyanine, oxonol, and merocyanine dyes. Because of their dissymmetry (dipolar limiting forms), the radicals of system C should have a lower stability than the comparable radical ions of systems A and B. All three redox systems are capable of many variations:

1) Variation of X and Y (N, O, S, P, π systems),

2) Variation of the number of vinylene groups ($n=0,1,2,...$),

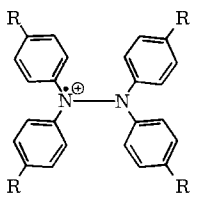
3) Variation of the vinylene groups by introduction into ring systems:
   a) both end groups are substituents of the ring systems,
   b) both end groups are part of the ring systems,
   c) one end group is part of the ring systems, and
4) Aza substitution of methine groups.

All these variations are treated in the following sections by means of examples from widely varying classes of compounds. In this way it should become clear that the general structural principle has a broad range of applicability and that apparently unrelated results can be rationalized by a general ordering principle.

The systems under discussion are presented in the following sections in the SEM radical stage. If the RED and OX stages are also known, these are noted under the formulae. Where these oxidation stages have not been isolated, their existence has been demonstrated by spectroscopic (NMR, UV/VIS, ESR) and electrochemical methods (polarography, cyclic voltammetry). As far as it is known, the semiquinone formation constant K [eq. (t)] is given, determined from the redox potentials according to eq. (s).

$$E_1 - E_2 = 0.059 \log K \quad (K, 25\,^\circ C) \qquad (s)$$

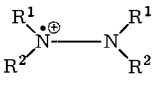
$$K = [SEM]^2/([RED][OX]) \qquad (t)$$



K describes quantitatively the thermodynamic stability of the SEM radical within the redox system; the very different kinetic stability (persistence) cannot be obtained from K.

2.2. Open-Chain Vinylogous Redox Systems

All redox systems of types A—C [eqs. (p)—(r)] in which neither the end groups nor the vinylene groups belong to a cyclic π-system are designated as "open-chain".



Systems with $n=0$, in which the end groups are therefore bonded directly to one another, also belong to this class. In this case hydrazine derivatives result if the end groups are nitrogen. It is certainly no accident that as early as 1927 *Weitz* isolated the first hydrazinylium salts *(1)* (type A, $n=0$)[17]. The aryl groups undoubtedly contribute to the stabilization[17b], for the short-lived tetraalkylhydrazinylium ions *(2)* can be detected only by ESR spectra and by their RED/SEM potentials. The reversible further oxidation to the dication $OX^{2\oplus}$ has not yet been achieved[18–20]; the energy requirements are clearly too high, because of the proximity of the charges.

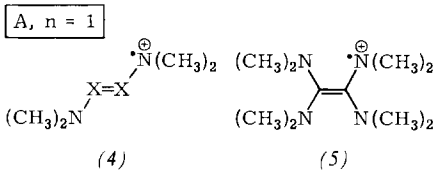
A, n = 0

(1)

RED, SEM

(2)

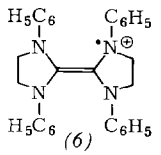
RED, SEM



(3)

RED, SEM, OX

Formally, 1,5-dithiacyclooctane can be included here, for it is oxidized by nitrosyl tetrafluoroborate with S—S bond formation to give the long-lived radical cation *(3)*[21]; an excess of the oxidizing agent even gives the related dication[21].



Members of type A, $n=1$ that have been intensively investigated are, besides derivatives of vinylenediamine *(4a)*[22a] and tetramethyltetrazene *(4b)*[22b], especially derivatives of vinylenetetraamine *(5)*[23] and *(6)*[24]; here the phenyl groups also prolong the lifetime of the SEM radical stage.

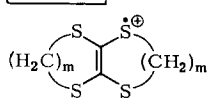
A, n = 1

(4)

(5)

(6)

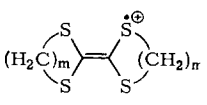
(4a), X = CH RED, SEM



RED, SEM, OX

RED, SEM, OX

(4b), X = N RED, SEM

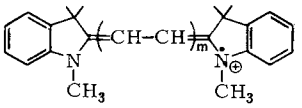


Sulfur is also a suitable end group[25], since, during the two-step oxidation by rapid cyclic voltammetry, the isomeric radical cations *(7)* and *(8)* can be clearly detected. On longer electrolysis, however, only the radical cations *(8)* are obtained, since *(7)* rearranges to *(8)*, presumably *via* the OX stage[26].

A, n = 1

(7), m = 2, 3

RED, SEM, OX



(8), m = 2, 3

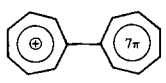
RED, SEM, OX

Example *(9)*, $m=1$[27], should be regarded as an open-chain redox system of type A, $n=2$, since the five-membered rings in which the end groups are included cannot influence the conjugation of the vinylene groups. The bipyrazolinyl

derivative *(10)*[28] can be regarded as a diaza compound of type A, $n=2$. To date *(10)* is the sole example of bis-aza

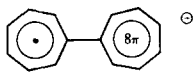
A, n = 2

(9), $K = 10^{6}$-10^{-2}(m = 1-5)
RED,SEM, OX



(10), $K = 10^{8.64}$
RED, SEM, OX

substitution next to the end groups. In both *(9)* and *(10)* the aromatic groups undoubtedly contribute to the thermodynamic stability of the SEM stage; thus, in *(9)*, $m=1$, about 20% of the spin density is found in the annelated benzene ring[27b]. The influence of additional vinylene groups in *(9)*, $m=1$—5, has been studied in detail[27a].



π-Systems are particularly suitable as end groups if cyclic systems with higher stabilization energy are produced at the RED or OX stage. Thus, oxidation of heptafulvalene affords initially the radical cation *(11)*[29], which can be included in type A, $n=0$. Admittedly, heptafulvalene is also reducible—by potassium, even in three stages[29b, 30]; whether the symmetrical radical anion may still be recorded as *(12)*[29b] is left an open question.

A special position is occupied by polyenes with cross-conjugated double bonds as the end groups. These polyenes can not only be oxidized polarographically in two stages but can also be reduced polarographically in two stages, no additional stabilization by cyclic conjugation being possible[33]. Thus, they appear as radical ions *(15)*, *(16)*, *(17)*, and *(18)* belonging to type A and also as *(19)*, *(20)*, *(21)*, and *(22)* belonging to type B[34]. Probably an important role is played in the stabilization of the radical ions by the pentadienyl cation, radical, and anion[35]. Disturbed coplanarity in these systems for $R=CH_3$ is signalized by strongly reduced stability of the radical ions.

A, n = 1-4

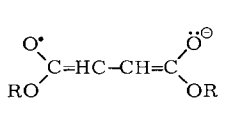
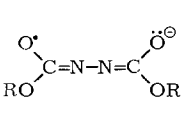
Furthermore, the very ready formation of the semidiones *(24)* by oxidation of α-hydroxy ketones or reduction of 1,2-diketones becomes understandable if one regards them as examples of type B, $n=1$, with oxygen as the end groups. For this class of substances extensive material is available[37], for which ESR-spectroscopic elucidation of the *E*/*Z* isomerism and conformational analysis of alicyclic systems were used. The same is true for the bisalkoxy semidiones *(25)* derived from oxalic esters[38].



If the cyano group is regarded as an end-group unit then, for example, tetracyanoethylene should be included as the OX form of a two-stage redox system of type B, $n=1$, whose very stable radical anion *(26)* has long been known[39]. It should be regarded as a counterpart to the radical cation

B, n = 1



(26)

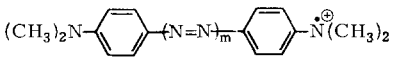
(5). As *E/Z* isomers, the radical anions *(27)*[40] derived from fumaric and maleic esters have different ESR spectra. The diaza derivative of *(27)*, namely the green radical anion *(28)* of the azodicarboxylic ester (OX), is also formed as stable intermediate on reduction to the RED stage[41].

The redox behavior of open-chain compounds of type C does not yet appear to have been studied. The extensive class of aminyl oxides *(29)*, however, could be included as the SEM radical stage in system C, $n=0$, although σ-radicals exist in this case[42].

C, n = 0

(29)



2.3. Redox Systems with Cyclic π-Systems between the End Groups

2.3.1. Two-Stage Wurster-Type Redox Systems

Two-stage redox systems are said to be of the Wurster type if their end groups are located outside a cyclic π-system that has an aromatic character in the reduced form.

Characteristic examples of the Wurster type have already been given in equations (m) and (n). The systems derived from *o*- and *p*-phenylenediamine are so well known from *Michaelis*' extensive investigations that reference to equation (n) is sufficient. *(30)*[43], *(31)*[44], and *(32)*[45] serve as special examples of radical cations of type A with nitrogen end groups. (The formal number of vinylene groups is derived from the shortest possible connecting line between the end groups.)

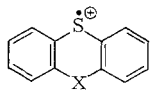
(34)

RED, SEM, OX



A special position[48] is occupied by the radical cations *(35)*[49] and *(36)* derived from phenazine, phenothiazine, phenoxathiin, and thianthrene, because they could also be included among the Weitz type (see Section 2.3.3)[49]. *(36a)*[50] is orange, *(36b)*[51] is blue-violet, and *(36c)*[52] is blue.

A, n = 1

(35)

RED, SEM

The many anionic redox systems of the Wurster type with oxygen as the end group, *e.g.* most of the vat dyes, are sufficiently characterized by eq. (m). Heterocycles such as indigo [SEM: *(37)*] also form two-stage redox systems of type B[53]. Even silicon *(38)*[54a] and phosphorus *(39)*[54b] may serve as end groups.

B, n = 2

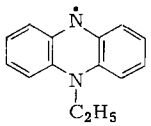
(43)
RED, SEM, OX

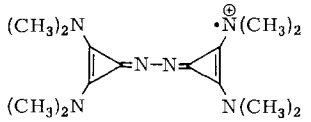


4-Aminophenoxide and its derivatives can be ascribed to type C (RED); extensive ESR investigations have been carried out on the relevant neutral radicals such as *(44)*[60]. The long-known phenazyl radical *(45)* also belongs to this system[61].

C, n = 2

(44)

C, n = 1



(45)

2.3.2. Two-Stage Redox Systems of the Inverse Wurster Type

The designation "inverse Wurster-type" is used for two-stage redox systems whose end-groups are located outside a cyclic π-system that exhibits aromatic character in the oxidized form.

Cyclopropenylium ions as aromatic groups formally fulfil the aforementioned conditions. In particular, substitution in the three-membered rings with $-N(CH_3)_2-$ groups permitted preparation of the very stable radical cation *(46)*[62,63]. The conditions are less favorable for the radical cation *(47)*, in which the three-membered rings function as end groups, but under carefully controlled conditions *(47)* can be obtained by a reversible reduction of the corresponding dication[64].

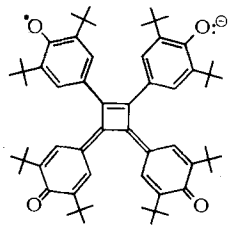
(50)

OX, SEM



If cyclobutadiene dications substituted by donor groups constitute the cyclic π-systems, then *e.g.* the squaric acid dianion can be regarded as a Wurster-type two-stage redox system; the corresponding radical anion *(51)* can be detected polarographically[68]. As a phenylog of *(51)*, *(52)* represents a very stable radical anion in a two-stage redox system[69]. Replacement of the oxygen in *(51)* by nitrogen as in *(53)* leads to a radical anion of unusually high stability ($K = 2 \times 10^{15}$!)[70].

2.3.3. Two-Stage Redox Systems of the Weitz type

The designation "Weitz type" refers to two-stage redox systems in which the end groups form parts of a cyclic π-system that exhibits aromatic character in the oxidized form.

Weitz was the first to recognize the long-disputed reduction of bisquaternary 4,4'-bipyridinium salts $(58)_{OX}$ ("viologens") to violet solutions which become decolorized again on further reduction[72,11b] as two-stage one-electron transfer. These relationships are shown in equation (u).

A, n = 3

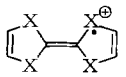
$(58)_{RED}$ $(58)_{SEM}$ $(58)_{OX}$

(u)

The recent systematic investigations of the Weitz type call for a separate progress report[73] and only a few examples will be presented here. The radical cations *(59)*—*(62)*[74-77] and the radical anion *(63)*[78] have been singled out as the simplest systems of this type.

A, n = 1

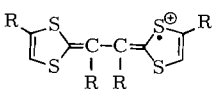
B, n = 1



(59), X = NH; *(60)*, X = NC_2H_5; *(61)*, X = O; *(62)*, X = S

(63)

The stable radical cations *(64)* and *(65)* derived from tetrathio-[79,80] and tetraselenofulvalene[81] (cf. Section 4) are of wide interest. The vinylog *(66)* has also been recently synthesized[82].

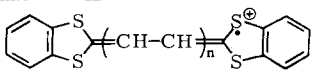


A, n = 1

(64), X = S; *(65)*, X = Se

RED, SEM

A, n = 2



(66)

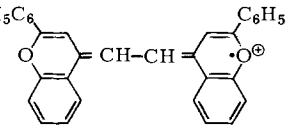
The benzo derivatives *(67)*[80] and *(68)*[83] also form stable radical cations.

A, n = 1,2

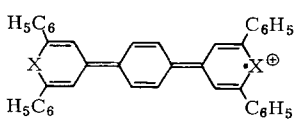


(67), n = 0; *(68)*, n = 1

RED, SEM

Vinylogous bisflavylium salts also exist as two-stage redox systems; for example, *(69)* as a deep blue radical cation[84].

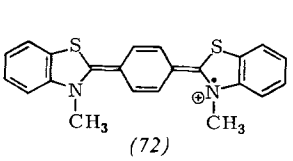
A, n = 4



(69)

RED, SEM, OX

A special position is occupied by the Weitz systems containing inserted *p*-phenylene groups, since these achieve aromaticity either in the OX stage [*(70)*[85], *(71)*[85], *(72)*[86]] or in the RED stage [*(73)*, *(74)*, *(75)*[86]] depending on the length of the system.

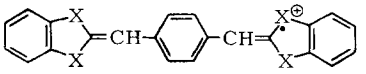


A, n = 5

(70), X = N–CH_3
(71), X = O

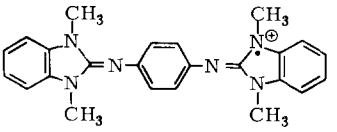
RED, SEM, OX

A, n = 3



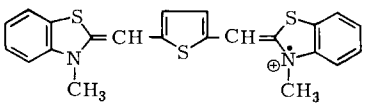
(72)

RED, SEM, OX



Accordingly, *(70)*—*(72)* can be rather easily oxidized, whereas *(73)*—*(75)* can be easily reduced. The thia derivative *(76)* has to be included in this series[86].

A, n = 4



(73), X = N–CH_3
(74), X = S

RED, SEM, OX

(75)

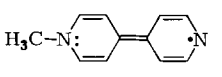
(76)

RED, SEM, OX

Finally, heteroarenes with bridgehead N atoms, such as *(77)*, also belong to the Weitz type[87].

A



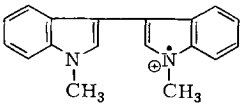
(77)

RED, SEM, OX

In some cases the general redox-type C with a neutral radical as the central member has also been realized as a Weitz type; *(78)* is an example[88]; as a result of the lower symmetry, both the thermodynamic and the kinetic stability of these radicals are greatly reduced in comparison with *(58)*.

C, n = 3

(78)

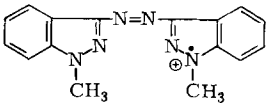


RED, SEM, OX

2.3.4. Two-Stage Redox Systems of the Inverse Weitz Type

The term "inverse Weitz type" denotes redox systems whose end groups are (a) part of a cyclic π-system that (b) exhibits aromatic character in the reduced form.

This type was earlier called a "hybrid type" because the structural characteristic of the Weitz type (a) was bound up with that of the Wurster type (b). Derivatives of indole and indazole should be specially mentioned as examples. Thus, 1,1'-dimethyl-3,3'-biindole forms the stable radical cation *(79)*[89], and four vinylogs of this cation are now also known[89]. Corresponding remarks apply to the aza-vinylogous indazole derivative *(80)*.

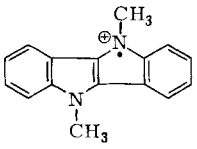


A, n = 2

(79)

RED, SEM, OX

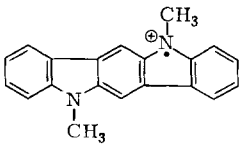
A, n = 3



(80)

RED, SEM, OX

The annelated indole rings in *N,N'*-dimethylindoloindole have the same structural features, so that it proved possible to obtain the very stable radical cation *(81)*[90]. The related radical cation *(82)* could be assigned to the Wurster type[90].

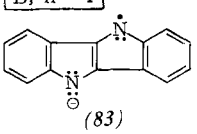


A, n = 1

(81)

RED, SEM, OX

A, n = 2



(82)

RED, SEM, OX

The general type B has been verified in this field, as shown by the stable radical anions *(83)*[90] and *(84)*[91].

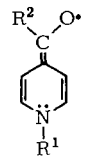
(83)

RED, SEM, OX

B, n = 3

(84)

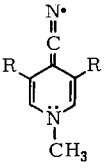


RED, SEM, OX

2.3.5. Two-Stage Redox Systems of Semi-Weitz Type

The semi-Weitz type denotes two-stage redox systems in which one end group is part of a cyclic π-system that exhibits aromatic character in the oxidized form.

This structural type appears to have been verified only as the general redox type C. The neutral radicals are derived mainly from 4-substituted pyridines [*(85)*—*(87)*][16,92a]. *(87)* is green.



C

(85), $R^1 = R^2 = CH_3$

(86), $R^1 = CH_3$, $R^2 = OCH_3$

(87), $R^1 = Si(CH_3)_3$, $R^2 = OCH_3$

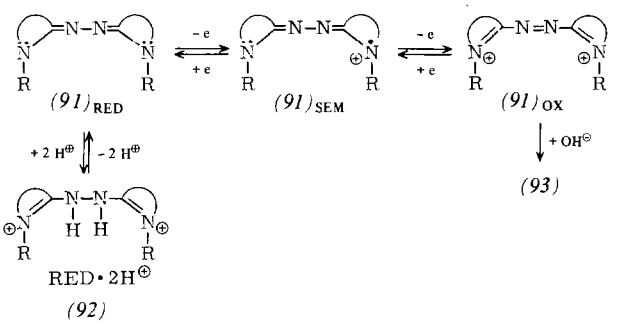
(88), R = H

(89), R = CH_3

Whereas *(86)* is a blue, distillable solid, only tetrahydrofuran solutions of *(88)* are stable for a few days. In acetonitrile *(88)* dimerizes readily with loss of the cyano groups, yielding the Weitz system *(58)*. *(89)* is stabilized by the methyl groups in the *o*-positions[92b].

3. Reactions of Two-Stage Redox Systems

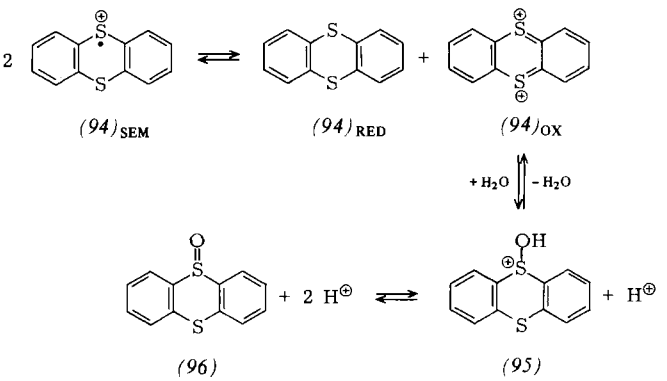
Because of the extremely rapid electron transfer[9,73,93], all three forms of the redox system *(90)* [cf. eq. (o)] are available for reactions, even if one or two of the oxidation stages are present in the equilibrium mixture only in minimal amounts.



RED[a]		SEM		OX^{a-2}
(90)		*(90)*		*(90)*
Reacts with electrophiles (protons)		Assumes an intermediate position		Reacts with nucleophiles (bases)

Since the RED form contains non-bonded electron pairs, it is in principle sensitive to electrophiles (protons!), this property being more pronounced the more negative charges are carried by the RED form and the more negative is the RED/SEM potential.

Correspondingly the OX form, which has two electrons fewer at its disposal, should in principle be able to react with nucleophiles (bases!) and this the more readily the more positive charges are carried by the OX form and the more positive is the SEM/OX potential.

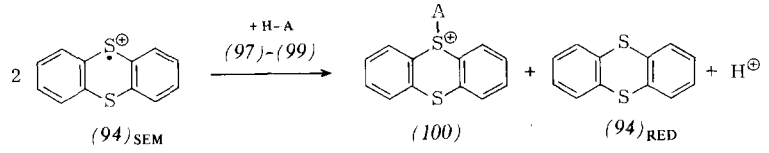


The redox system *(91)* may serve as an example. In accord with the semiquinone formation constant $K = 10^6$—10^{10} [see eq. (t)], the solutions of the violet to blue radical cations $(91)_{SEM}$ contain only traces of $(91)_{RED}$ and $(91)_{OX}$. Yet the color due to the radical disappears immediately on the addition of acid: 50% of RED·$2H^{\oplus}$ *(92)* and 50% of $(91)_{OX}$ are formed. The color change is completely reversible on neutralization, and cannot be visually distinguished from that of an acid-base indicator[94]. Equally, by attack on $(91)_{OX}$, hydroxide ions remove the radical cation $(91)_{SEM}$ from the equilibrium mixture, giving rise to 50% of $(91)_{RED}$ and undefined decomposition products *(93)* of $(91)_{OX}$[95].

$(91)_{RED}$ $(91)_{SEM}$ $(91)_{OX}$ *(93)*

RED·$2H^{\oplus}$ *(92)*

Numerous experiments with the thianthrene radical cation (added as solid) have been particularly informative[48]. The strongly positive potentials $E_1 = 1.23$ V and $E_2 = 1.74$ V ($K = 4.4 \times 10^8$)[96] already show that $(94)_{SEM}$, and particularly $(94)_{OX}$, must be very sensitive to nucleophiles. $(94)_{SEM}$ is stable only in highly purified, non-basic solvents[97]; the dicat-



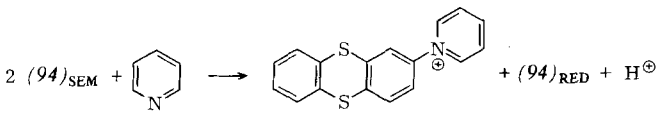
$(94)_{SEM}$ $(94)_{RED}$ $(94)_{OX}$

(96) *(95)*

ion $(94)_{OX}$ is stable only in 100% sulfuric acid[98]. On contact with water it passes, *via* *(95)*, into thianthrene 5-oxide *(96)*, from which $(94)_{OX}$ is formed by the reverse reaction. As a result, $(94)_{SEM}$ can be obtained smoothly from equimolar amounts of $(94)_{RED}$ and *(96)* by means of strong acids[99]. $(94)_{SEM}$ also reacts with water, yielding 50% of $(94)_{RED}$ and 50% of *(96)*, the kinetics showing that the nucleophile attacks $(94)_{OX}$[100].

Furthermore, the *C*- and *N*-nucleophiles *(97)*[101,102], *(98)*[103], and *(99)*[104,105] combine with the thianthrene-sulfur, thus affording *(100)*. Since no radical product is formed,

the stoichiometry shown in the reaction scheme applies throughout.



(94)$_{SEM}$ *(100)* *(94)*$_{RED}$

(97), H–A = H–CH(R′)–C(=O)–R; *(98)*, H–A = H–C$_6$H$_4$–R (R = OCH_3, OH, NH_2);

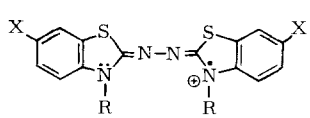
(99), H–A = H–NHC$(CH_3)_3$

One plausible exception is provided by pyridine, which reacts by the same stoichiometry to yield *(101)*[106].

(101)

The mechanism must be carefully investigated in each individual case: whereas *(101)* is very probably formed by way of *(94)*$_{OX}$[106], the nucleophile *(98)* attacks *(94)*$_{SEM}$ directly[107].

4. Applications of Two-Stage Redox Systems



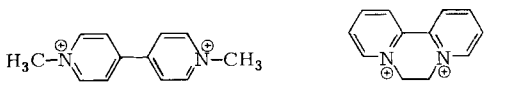
The examples given in this review show clearly how varied are the developments based on the general structural principle presented in equations (p) to (r). Systems are thus accessible that differ very strongly in respect of the position of the redox potentials E_1 and E_2, the thermodynamic and kinetic stabilities of the RED, SEM, and OX partners, the UV/VIS absorption of the RED, SEM, and OX partners, the sensitivity to acids and bases[108], and the solubility in different solvents.

Further, taking into account that the SEM form always shows absorption at by far the longest wavelength and that electron transfer is diffusion-controlled[9,108], then these redox systems can be considered for redox indicators, as electron donors and acceptors, as catalysts for electron transfers, as light-sensitive systems, and as electronic conductors.

Of these possible applications some have already acquired industrial importance and others seem highly promising.

4.1. Redox Indicators

In cerimetric oxidations of metal ions and complex ions the pale yellow form *(103)*$_{RED}$ is a good reversible redox indicator[109]. The usual indication of the equivalence point in bromometric methods, involving an oxidative destruction of an azo dye, could advantageously be replaced by the reversible formation of the radical ions *(102)* or *(103)*, *e.g.* in the titration of ascorbic acid[110].



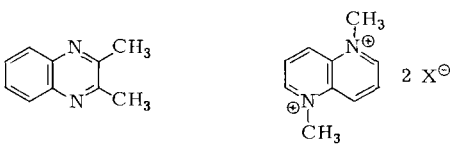
(102), X = H
(103), X = $SO_3^{\ominus}$

R = CH_3, C_2H_5

The application of such redox systems in (automated) biochemical analyses could be profitable.

4.2. Herbicides

The herbicides Paraquat® *(104)* and Diquat® *(105)*[111], which act on the green parts of all plants during illumination, have already gained extensive use. They remove the primary energy for photosynthesis from the plants, in that they trap



(104) 2 $X^{\ominus}$ *(105)* 2 $X^{\ominus}$

electrons and thus prevent photophosphorylation[112]. Their action, *inter alia*, is restricted to a narrow potential region ($E_2 = -0.3$ to 0.5 V/saturated calomel electrode)[113]. Compounds of this type are also used in studies of photosynthesis[114].

4.3. Redox Catalysts for Photographic Purposes

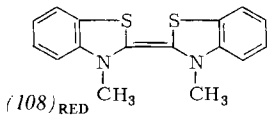
Redox catalysts are used in photography mainly for activation of developers. Thus, the silver halide reduction in the usual photographic process can be accelerated by Weitz systems such as *(104)* and *(105)*[115]. Furthermore, not only the long-known quinozalines[116] such as *(106)* (type B) but also Weitz systems such as *(107)*[117] (type A) are suitable redox catalysts for the oxidation of elemental silver in silver color-bleaching processes.

(106) *(107)*

Moreover, compounds that effect sensitization[118] or desensitization[119] of photographic material are activated by Weitz-type redox catalysts, *e.g.* *(104)* and *(105)*.

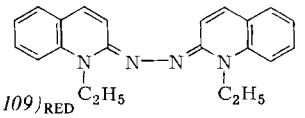
4.4. Image Production by Two-Stage Redox Systems

4.4.1. Photographic Systems



In the manner known for some time for primary and secondary alcohols[120], a bipyridyl salt *(58)*$_{OX}$ of the Weitz type, dissolved in a cross-linked polyvinyl alcohol layer, is reduced by the alcohol on irradiation ($\lambda < 360$ nm), thus affording the radical cation *(58)*$_{SEM}$ [eq. (v)]. On subsequent treatment with a silver salt solution, *(58)*$_{SEM}$ reduces the silver ions to metallic silver [eq. (w)], which serves as a nucleus for

subsequent physical development of the photographic negative[121].



$$2\ (58)^{2\oplus}_{OX} + \text{>C(H)OH} \xrightarrow{h\nu} 2\ H^{\oplus} + \text{>C=O} + 2\ (58)^{\oplus}_{SEM} \qquad (v)$$

$$(58)^{\oplus}_{SEM} + Ag^{\oplus} \longrightarrow (58)^{2\oplus}_{OX} + Ag \qquad (w)$$

A photothermographic material that gives a positive image directly can be made from silver salts of long-chain carboxylic

$(108)_{RED}$

$(109)_{RED}$

$$(108)/(109)_{RED} + Ag^{\oplus} \longrightarrow Ag + (108)/(109)^{\oplus}_{SEM} \qquad (x)$$

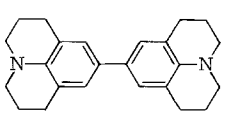
$$(108)/(109)_{RED} + (RCBr_3) \xrightarrow{h\nu} R\dot{C}Br_2 + (108)/(109)^{\oplus}_{SEM}\ Br^{\ominus} \qquad (y)$$

(110)

acids and Weitz systems with relatively high potential in the RED form, *e.g.* *(108)* or *(109)*, for nucleation. Upon heating these compounds produce silver nuclei according to eq. (x), which catalyze the reduction of the silver salts in their neighborhood. When exposed to light, the radical sources of type *(110)* that are present convert the nucleating agents $(108)/(109)_{RED}$ into the SEM form in accord with eq. (y), and in that form these are no longer effective as reducing agents: thus a positive picture is formed[122].

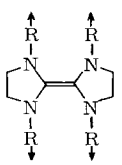
4.4.2. Electro-optical Systems

Transformation of electrical information into an optical image and later erasure thereof is made possible by the use of electrode-plates, of which one is transparent. Between them there is a solution of *e.g.* a bipyridinium salt $(58)_{OX}$. On



$$(58)^{2\oplus}_{OX}\ 2\ X^{\ominus} \underset{-e}{\overset{+e}{\rightleftharpoons}} (58)^{\oplus}_{SEM}\ X^{\ominus} + X^{\ominus} \qquad (z)$$

colorless blue



application of a direct current a blue precipitate of the considerably less soluble radical salt $(58)^{\oplus}_{SEM}X^{\ominus}$ is formed on the cathode within ≤ 10 ms, provided that the *N*-alkyl groups in *(58)* are sufficiently long. The image is instantly erased by reversing the polarity [eq. (z)][123].

4.5. Organic Semiconductors, Organic Metals[124]

Applications in this field, which is in the process of very rapid development, may gain immense importance in the future. Two directions of research stand out: a) Weitz systems are used as salts of the OX form, *e.g.* $(69)_{OX}$ and $(71)_{OX}$[125], or Wurster systems in the RED form, *e.g.* $(111)_{RED}$[125]. These are embedded in a polymer layer. A similar redox system of type A can also be used as a polymer[125], *e.g.* the polymer $(112)_{RED}$ made *via* bifunctional arenes[126]. In this way semiconductor films with an electrical conductivity of $\approx 10^{-2}$ to $10^{14}\ \Omega^{-1}\ cm^{-1}$ can be produced, which could be used for thermistors, photosemiconductors, and solar batteries[127]. In particular, a minimal doping of the OX or RED form with the SEM radical ion produces a strong increase of the conductivity[128]. Such films are therefore suitable for xerographic purposes[125, 126, 4].

(111)

(112), R = Aryl

b) In the second case, deeply colored salts are produced from radical cations and radical anions. Of these, the combination of $SEM^{\oplus}$ from tetrathio- or tetraselenofulvalene *(64)* or *(65)* with the $SEM^{\ominus}$ from tetracyanoquinodimethane *(40)* holds a predominant position. With single crystals at room-temperature a conductivity of $10^{3}\ \Omega^{-1}\ cm^{-1}$ has been achieved; hence the name "organic metals" has been coined for such compounds[129]. Below 60 K superconductivity even seems to appear. The reactants must fulfil definite requirements in respect of the redox potential, polarizability, size, *etc.*, and above all the two oppositely charged radical ions must be anchored columnwise next to one another in a completely defect-free lattice. The extremely high demands made thereby on the purity of all the substances used are at present the main obstacle to the development of this new class of electronic conductors.

5. Outlook

An almost inconceivable variety of multistage redox systems arises on the basis of the general structural principle described. By their use the electrochemical, electrical, and spectral properties and the behavior toward solvents and substrates can be studied in dependence of the molecular and the crystal structure (cf. [130]). The generalizations and rules thus uncovered should pave the way to tailor-made molecules whose redox character depends solely on electron transfer.

For the results of my own research group that are included above I thank my associates whose names are cited in the references. For the support of these investigations we are indebted to the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, Dechema, Frankfurt, and BASF Aktiengesellschaft, Ludwigshafen.

Physical and Chemical Properties of Dissolved Electrons (Excess Electrons)

By Ulrich Schindewolf[*]

Electrons produced in a gaseous, liquid, or solid solvent are called dissolved electrons or excess electrons. These excess electrons can exist as quasi-free particles of high mobility in a delocalized state, comparable with electrons in a metal; or as bound particles of low mobility they can be localized within narrow limits—in a solvent cavity formed by repulsive forces. Localized electrons can also be solvated like normal ions. Characteristically, such solvated electrons exhibit broad and extensive absorption spectra in the visible to near infrared spectral range. The localized and delocalized states of the excess electrons can be in equilibrium with each other, such that a continuous transition of the properties between the limiting extremes can be observed. The reactions of the excess electrons with suitable acceptors (substrates) are initiated by an attachment-detachment equilibrium $A+e^- \rightleftharpoons A^-$ which is followed by further chemical rearrangements. The rate constants of these reactions vary by more than 15 powers of ten depending on the substrates and the solvents. Most of the properties of excess electrons in solution can be interpreted by means of a model which is easily understandable but quantitatively evaluated only with considerable effort.

1. Introduction

The Irish physicist *O. J. Stone* coined the expression "electron" for the unit of electrical charge, after *H. v. Helmholtz*—on the basis of *Faraday*'s investigations on electrolysis—had postulated that electricity is subdivided into very small particles which behave like atoms of electricity. The electron was identified around the turn of the century by proving that the negative particles produced on ionization of air with α- or X-rays, or emitted by β-decay, by photoemission (photoelectric effect), or by the thermoelectric effect, all have identical charge and identical mass. The electrons formed by any of these processes in a vacuum or in highly rarified gases have free mobility (discounting scattering effects). They are, however, scavenged by recombination or reaction with individual molecules (*e.g.* O_2), *i.e.* they have a short lifetime.

On the other hand, electrons produced in a dense phase (gaseous, liquid, or solid solvent) can be stabilized by interaction with the solvent before they are caught in an unoccupied orbital of a single atom or molecule, *i.e.* before they undergo chemical reaction. Depending on the nature of the interaction—which is defined by the system, its density, and temperature—the electron can occupy several states partly in equilibrium with each other. At one end of the scale we have quasi-free electrons of high mobility, comparable with metallic electrons. They are unbound or delocalized, *i.e.* their wave functions, the square of which describes their density, have a wide spatial distribution. At the other end of the scale we have localized electrons of low mobility bound to several solvent molecules (but not occupying any well-defined orbital), such that their wave functions extend only over a few solvent molecules. An extreme of the localized or bound electron state is the solvated state, which occurs in polar solvents, where the electron is trapped in a solvent sphere in a similar way to conventional ions.

[*] Prof. Dr. U. Schindewolf
Institut für Physikalische Chemie und Elektrochemie der Universität Kaiserstrasse 12, D-7500 Karlsruhe (Germany)

Electrons stabilized in any medium by suitable interactions and not bound to single atoms or molecules are called excess electrons (review literature, symposium proceedings[1-13]). Since these electrons are always in a solvent system, we shall also refer to them as dissolved electrons. In accordance with our definition, the mobile electrons of a metallic or semiconducting system can also be classified as excess electrons.

In nonmetallic systems, the excess electrons are unstable from the thermodynamic point of view: they are continuously undergoing recombination or reaction with the solvent or dissolved impurities. They therefore have a limited lifetime which can vary between 10^{-15} s and several months, depending on the system and its state.

Excess electrons can be generated in most systems by any radiation or photochemical reaction which leads to ionization of the solvent[14], *e.g.*

$$H_2O \xrightarrow{\alpha, \beta, \gamma} H_2O^+ + e^- \quad (1)$$

or of dissolved species[15], *e.g.*

$$I^- \xrightarrow{h\nu} I^\bullet + e^- \quad (2)$$

It follows that the reactions of excess electrons might play an important role in all radiation and photochemical processes; in particular, excess electrons might participate in biological radiation damage and in photosynthesis.

Electrical discharges also produce excess electrons, the mobility and lifetime of which determine the quality of an insulator. Sparking and arcing, *e.g.* in high-voltage switches, can be prevented in an atmosphere which contains components (*e.g.* sulfur hexafluoride) that react rapidly with excess electrons.

Forced ionization as described by eq. (1) or (2) leads to excess electron concentrations up to 10^{-5} mol l^{-1}. However, on dissolution in some polar solvents (*e.g.* ammonia) alkali and alkaline earth metals spontaneously dissociate into excess electrons and positive ions:

$$Na \rightleftarrows Na^+ + e^- \quad (3)$$

giving excess electron concentrations of up to 5 mol l^{-1}. In this system, which has been known for more than 100 years[16], the transition from the nonmetallic to the metallic state *via* a semiconducting state can be accomplished[17] by variation of the excess electron concentration:

$$e_l^- \rightleftarrows e_f^- \quad (4)$$

(localized, subscript l, delocalized or quasi-free, f). This is of great importance for the development of semiconductors[18].

The metal-ammonia solutions are metastable, *i.e.* they decay slowly according to

$$e^- + NH_3 \rightleftarrows {}^1/_2 H_2 + NH_2^- \quad (5)$$

until equilibrium is reached[19], at which point the solvated electrons can be detected very conveniently. An industrial-scale process for the production of heavy water by isotope exchange between hydrogen and liquid ammonia, with dissolved potassium amide as catalyst[20], is performed under conditions in which excess electrons are produced in the reverse reaction (5). Their highly corrosive action upon pump seals *etc.* must be taken into consideration during the planning and construction of heavy water plants.

Metal-ammonia solutions often are used for reduction of organic compounds (Birch reaction[21])

$$e^- + A \rightleftarrows A^- \quad (6)$$
$$A^- + HX \rightarrow AH + X^- \quad (7)$$

The intermediate radical anion formed by electron attachment is protonated in a second step (hydrogenation). The radical anions of almost all aromatic molecules are formed conveniently [according to reaction (6)] in metal-ammonia solutions[22] and in metal-ether solutions[23] (*e.g.* tetrahydrofuran, dimethoxyethane). In ethers and in amines (*e.g.* diethylamine) quantitative formation of metal anions is observed[24] ($2e^- + M^+ \rightleftarrows M^-$). Crystalline salts of metal anions can be obtained from these solutions with the aid of cation complexing agents such as crown ethers[24].

Finally, excess electrons are injected from the cathode into the melt during electrolysis of molten metal salts[25]; they reduce the cations to the pure metals.

The above examples show that excess electrons may be formed in many areas of physics, chemistry, biology, and technology, either as desired species or as unwanted interfering particles, and also show that a knowledge of their properties is necessary for the understanding and the control of such processes.

Excess electrons and their reactions are studied by conductivity or light absorption experiments; a time resolution down to a few ps (10^{-12} s)[26, 27] and a limit of detection down to 10^{-11} mol l^{-1}[28] are now feasible. Consequently, the present article examines the electron mobility and light absorption of excess electrons which together provide the basis for a model of excess electrons. This model also permits interpretation of the extreme differences in reactivity of the electrons in different solvents and toward different substrates. In addition to these topics, we shall also mention the nonmetal-metal transition, which is dependent on mutual interactions of excess electrons at high concentrations.

2. Excess Electron Model and Localization Criterion

2.1. Quasi-Free and Localized Electrons

The first two figures demonstrate the statement given before, that the excess electrons can exist in two different states. In Figure 1 the mean electron mobility in gaseous helium at 4.2 K as determined from the drift velocity in an electrical field is plotted as a function of the density of helium[29]. A density

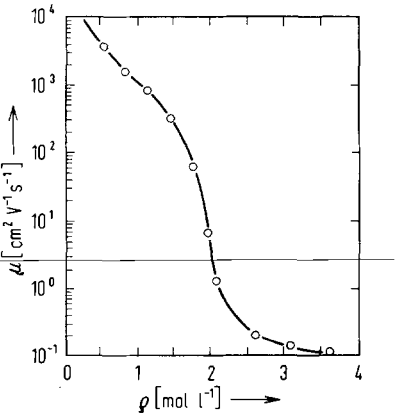

Fig. 1. Mean electron mobility μ in gaseous helium as a function of its density ρ at 4.2 K [29].

decrease in the narrow range between 3 and 1 mol helium per liter (1 to 0.3 bar) results in an increase of mobility by four powers of ten. This increase demonstrates the transition from the localized or bound (but not solvated) state of low mobility to the delocalized or quasi-free state of high mobility (compare Section 3.2).

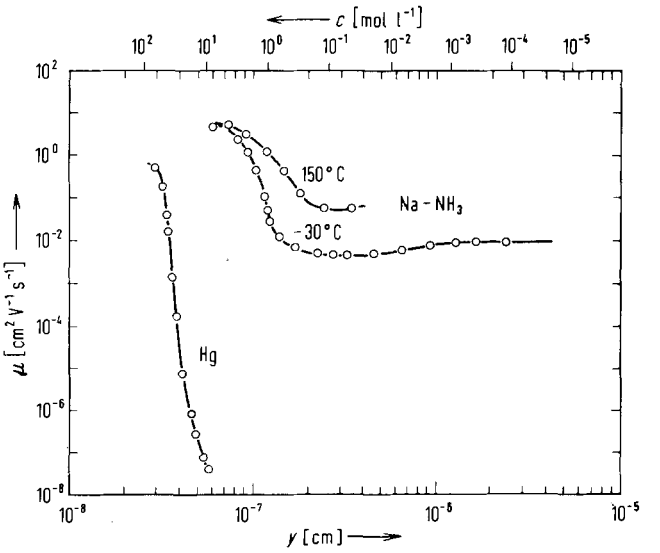

Fig. 2. Mean electron mobility μ in sodium-ammonia solutions at −30 and 150 °C [17, 30] and in supercritical mercury at 1550 °C [31] as a function of the mean distance y between the metal atoms (upper scale metal concentration c).

In Figure 2 the mean electron mobilities in sodium-ammonia solutions[17, 30] and in supercritical mercury[31] measured by

conventional conductometry are shown as functions of the average metal atom distance. At large separations (small concentrations) the mobility of the excess electrons in ammonia is low and independent of concentration, just like that of normal ions in electrolyte solutions: here the electrons are in a solvated, localized state. However, below an average distance of 10 Å (concentration above 1 mol l^{-1}) a mobility increase by three orders of magnitude is again observed, reflecting the transition from the nonmetal to the metal, or in other words, from the localized to the quasi-free electron state (compare Section 4). In supercritical mercury the transition is accompanied by an even larger increase of mean mobility, because in the nonmetallic range the electrons are bound to the nonmobile mercury atoms; they are not excess electrons in the sense of our definition. In the metallic state of both systems the excess electrons have mobilities comparable with those in compact pure metals under normal conditions. However, the mobilities here are still considerably lower than in gaseous helium at low pressure or in some liquid hydrocarbons and some liquified rare gases. Nevertheless, no metallic conductivity can be observed in the latter systems because only very low electron concentrations can be obtained (compare Section 3.2).

2.2. Models

In simplified terms the excess electrons in any medium can occupy two extreme states, the quasi-free, unbound or delocalized state of high mobility and the bound or localized state of low mobility. The distribution between the two states depends on their energy which can be estimated by the formalism of wave mechanics[32-34].

The total energy E of the ground state of the electrons in a solvent is given by the sum of the energy E_e of the electron (kinetic plus potential energy), which follows from the Schrödinger equation with the appropriate boundary conditions, and of the term E_m describing the change in energy of the solvent due to structural changes in the field of the dissolved electrons (rearrangement energy):

$$E = E_e + E_m \tag{8}$$

The quasi-free electron is delocalized over a large volume and hence its charge density is low; consequently the solvent structure will be unaffected and therefore $E_m = 0$.—Polarization of the solvent molecules or atoms (charge shifts within the molecule or atoms) results in an attractive potential, independent of position. Superimposed thereon is the repulsive periodic potential of the solvent molecules, approximated by hard spheres (square well potential) in a periodic arrangement (Fig. 3a). Solution of the Schrödinger equation with this potential leads to the wave function of the excess electrons, the periodic nature of which confirms that the electrons are delocalized over the whole system. It also leads to the energy of the electron E_e, which is identical to the energy V_0 of the lower edge of the conduction band. In highly polarizable liquids the negative potential energy can exceed the positive kinetic energy and therefore the total energy can be negative compared to that of electrons *in vacuo*; *i.e.* energy is released on transferring an electron from vacuum to the solvent.

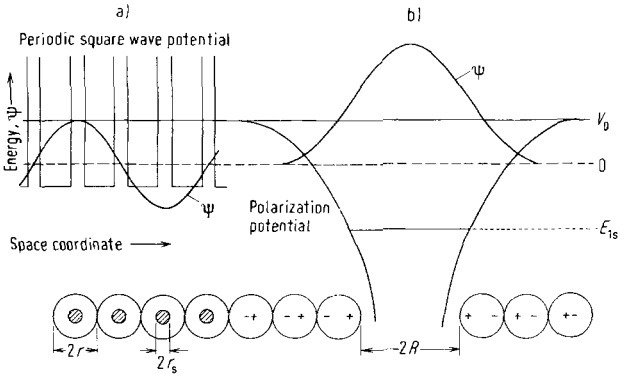

Fig. 3. Simplified representation of energy states and wave functions ψ of a dissolved electron [33]: a) Quasi-free electrons in the periodic square well potential of regularly arranged spherical solvent molecules (the scattering cross section is hatched); the electron is described by a periodic wave function extending over the whole system; the energy of the electron V_0 is identical with the lower edge of the conduction band. b) Localized electron in a solvent cavity, bound by the field of the polarized solvent molecules (indicated by + −). Outside the cavity the wave function asymptotically approaches zero, in the center it assumes a maximum value; the electron has the energy E_{1s} of the 1 s ground state (r radius of solvent molecules, r_s their scattering radius, R cavity radius).

In the localized state the electron is fixed in a small volume with high charge density. Repulsive forces lead to the formation of a solvent cavity ("bubble", "cage") in which the electron is trapped. A decisive role is now played by the attractive polarization potential of the polarized medium which depends upon the spatial coordinates and which is highly negative in polar liquids due to orientational polarization of the solvent molecules. The overall potential interacting with the electron drops steeply inside the cavity; outside the cavity it slowly approaches the V_0 value of the delocalized state (Fig. 3b).

The wave-mechanical treatment results in a wave function which vanishes asymptotically outside the cavity and has a maximum at the center of the cavity, in agreement with the assumption that the electron is fixed therein. In a crude simplification, the localized electron could be described by the model of a particle in a box with a square well potential. But even with the more realistic continuous potential of Figure 3b the positive kinetic energy of the electron increases inversely with the square of the cavity radius R. Again in liquids of high polarization, mainly in those with high orientational polarization, the negative potential energy due to the polarization field might overcompensate the kinetic energy such that the energy of an electron E_e is negative

$$E_e \approx a/R^2 + E_{pot}(R) \tag{9}$$

(in case of the square well potential the constant a is given by Planck's constant h and the electron mass m: $a = 3h^2/8m$).

Formation of the cavity with the accompanying structural changes of the solvent is an energy-consuming process. The rearrangement energy E_m has to be taken into account. It is mainly given by the energy for creating new surface (surface energy $\gamma \times$ cavity surface) and by the pressure volume energy (pressure $p \times$ cavity volume) when forming the cavity:

$$E_m = \gamma 4\pi R^2 + p 4\pi R^3/3 \tag{10}$$

In contrast to E_e of eq. (9), E_m increases with the size of the cavity. The mutually opposing action of the two terms

E_c and E_m in eq. (8) leads to a minimum of the total energy E at a well defined cavity radius, which describes the most stable cavity size of the localized electron.

2.3. Light Absorption

As in a hydrogen atom, the localized electron can also occupy higher energy states while still being localized. The electron can be transferred to these higher states by light absorption in an allowed transition (high transition probability). Consequently the localized electrons absorb light, and their solutions normally display an intense color. The position of the absorption maximum can be estimated, since the energies of the higher localized states (2p, 3p...) can be calculated employing the same formalism as sketched in Section 2.2 for the 1s ground state.

2.4. Results and Localization Criterion

Calculations have been performed using known solvent properties (density, polarizability, static dielectric constant, surface energy, electron scattering cross section). Results are given in Figure 4, in which the total energy of delocalized (V_0) and of localized electrons (ground state 1s, first excited state 2p) in liquid helium, xenon, water, and ammonia are given relative to the energy of the electron at rest *in vacuo*. The energies are partly positive, partly negative; the energy of the localized state can lie above or below that of the delocalized state.

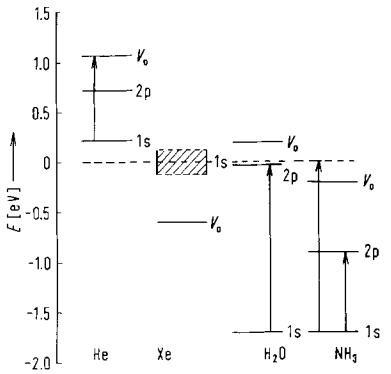

Fig. 4. Energy levels of excess electrons in liquid helium, xenon, water, and ammonia relative to the energy of the resting electron *in vacuo*. V_0 is the energy of the delocalized state, 1s and 2p indicate the energies of the electron in the localized ground state and first excited state. The energy of the 1s state is identical with the solvation energy of the localized electron. Arrows describe observed optical transitions (energy data from [33]).

The localized state is occupied whenever it lies below the delocalized state; the localization criterion is given by

$$E_{(1s)} < V_0 \qquad (11)$$

In all polar liquids with strong orientational polarization (water, alcohols, ethers, ammonia, amines) the localized state has a rather negative energy, the localization criterion is always fulfilled; in these liquids the electron is localized, it is in the solvated state. In nonpolar liquids, which lack orientational polarization, the localized state has a higher energy. It is above that of the delocalized state in liquids of high electron polarizability which have lower V_0 values. (Water and ammonia[33] fit quite well in the series of liquid rare gases in which V_0 decreases with increasing polarizability[36].) Therefore, the localization criterion is no longer obeyed; the excess electrons will stay in the delocalized quasi-free state (liquid heavy rare gases of high polarizability, liquid hydrocarbons, and related compounds with spherical geometry such as methane, tetramethylsilane, neopentane). In weakly polarizable liquified helium or neon, on the other hand, the energy of the delocalized state is still so high that the electrons are localized, although in these solvents the localized state has a positive energy compared to the electron in a vacuum (*i.e.* injection of a vacuum-level electron into liquid helium requires energy, in contrast to the case of ammonia or water, where the solvation energy is released).

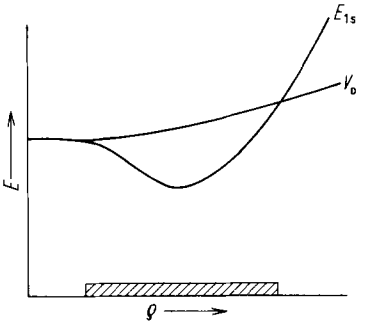

Fig. 5. Dependence of the energy of the quasi-free (V_0) and the localized (E_{1s}) electron state on the density ρ of the solvent (schematic): the electron is localized ($E_{1s} < V_0$) only in the intermediate (hatched) density range.

It follows vividly but not quite correctly from the model presented that a localized electron should be delocalized on increasing *or* decreasing the solvent density (Fig. 5). An increase in density, *e.g.* by applying pressure, leads to a compression of the cavity; this results in an increase of the energy of the localized electron according to eq. (9) such that the localization criterion (11) is no longer fulfilled. With decreasing density on the other hand all interactions will cease more or less abruptly. The electron will assume the properties of a free electron in vacuum.

The calculated energy data of Figure 4 are partly confirmed by experiment: for liquid rare gases and hydrocarbons V_0 values are obtained from the differences of energy thresholds of electron photoemission from a metal into the liquid phase and into vacuum respectively[35, 36]. The energies of the solvated state in water[37, 38] and in ammonia[39, 40] are given by the solvation energies, accessible *via* Born-Haber cycles. The energy differences between the ground and first excited states (1s and 2p) of the solvated electrons follow from the light absorption maxima (see Section 5). The energy difference between the localized and delocalized state in liquid helium is given by the threshold of the inner photoelectric effect[41] (light-induced transfer of an electron from the localized to the delocalized state).

Also theoretical sizes of cavities or "bubbles" in which the electrons are trapped could be confirmed experimentally (effective radius $R \approx 16$ Å in liquid helium from electron mobility applying Stokes' law[42]; ≈ 3.3 Å in liquid ammonia from densities of dilute metal ammonia solutions[43]; < 1.0 Å in water from pressure dependence of electron reaction rates in water[44, 45]).

All data given are of course only average values of a wide distribution function, since thermal density fluctuations of

the solvent lead to fluctuating potentials, cavity sizes, and cavity shapes; they are reflected *e.g.* in the extraordinarily wide absorption spectra of the localized electrons (see Section 5).

3. Electron Mobilities and Diffusion Coefficients

The mobility of electrons μ [$cm^2\ V^{-1}\ s^{-1}$] generated by forced ionization [eq. (1) or (2)] is measured by their drift velocity v in an electric field $\mathfrak{E}$ ($v=\mu\mathfrak{E}$); in a system with time-independent electron concentration (metals, metal solution) the mobility is calculated from the specific conductivity σ ($\sigma=\mu cF$; c metal concentration, F Faraday's constant). The diffusion coefficient D [cm^2/s] follows from the Einstein relation

$$D=\mu kT/e \qquad (12)$$

(k Boltzmann's constant, T temperature, e electronic charge; at 300 K we have $kT/e=2.585\times10^{-2}$ V).

The mobilities vary between the wide limits of 10^4 and $10^{-4}\,cm^2\,V^{-1}\,s^{-1}$ (Fig. 6 and 8; compare Fig. 1, 2) and have led to the distinction between delocalized or quasi-free and localized electrons. We will consider separately solvated electrons in polar solvents and electrons in nonpolar solvents, in which the localized (but not the solvated) or the delocalized states may be occupied with a steady transition between the two.

3.1. Polar Solvents (Dielectric Constant >4)

In all polar solvents so far investigated (alcohols[46], ethers[47], amines[47], water[48], ammonia[17]) the mobility of the solvated electrons is two to fivefold higher than that of normal positive or negative ions[49]. To a first approximation it increases with decreasing viscosity η of the solvent (Fig. 6); however, on going from one solvent to another

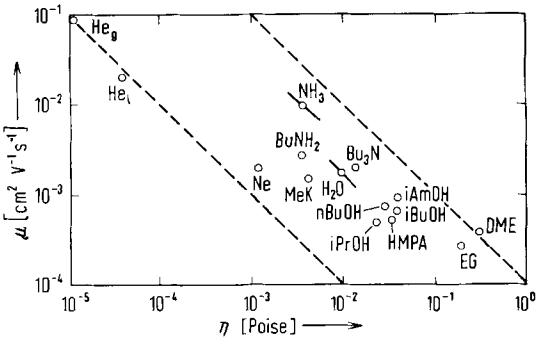

Fig. 6. Relation between mobility μ of localized electrons and viscosity η of the solvent (data from [29, 42, 46—48, 52]); the dotted line on the left follows from Stokes' law with $R=16\times10^{-8}$ cm (He_g, He_l gaseous and liquid helium, respectively; Ne neon, NH_3 ammonia, H_2O water, $BuNH_2$ butylamine, MEK methyl ethyl ketone, Bu_3N tributylamine, iPrOH isopropyl alcohol, iAmOH isoamyl alcohol, iBuOH isobutyl alcohol, nBuOH *n*-butyl alcohol, HMPA hexamethylphosphoramide, EG ethylene glycol, DME dimethoxyethane, all liquid).

Walden's rule ($\mu\sim1/\eta$) is not followed strictly. It cannot be expected to apply exactly because of different solvation structure due to different structure of the solvents or the solvent molecules. In water[50] and ammonia[17], however, the mobility of electrons and that of normal large ions have the same temperature coefficient as the fluidity ($\sim1/\eta$) of the solvent (1.5 to $2.2\times10^{-2}\,K^{-1}$); this proves that the viscosity has a decisive influence on the electron mobility.

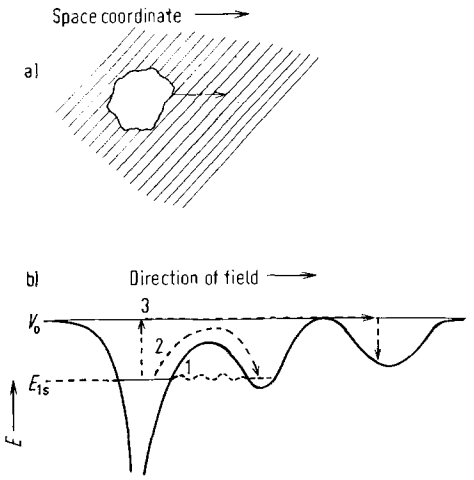

Fig. 7. Illustration of the mobility of a localized electron: a) The electron is pulled with its cavity through the viscous solvent; b) tunnel process (1) or (short range) jump (2) of the electron from its potential well into a neighboring shallow potential trap, formed by random orientation of solvent molecules, or (long range) jump (3) over the conduction band into a distant potential trap.

The higher mobility of electrons as compared to normal ions excludes a normal migration together with their solvation shell (migration of the cavity according to Fig. 7a). The electron, however, can tunnel or jump from its cavity into a neighboring solvent site where the solvent molecules form a shallow potential well by random orientation. Here the electron can be trapped again by forming a stable solvation structure[51] (Fig. 7b).

The approximate inverse proportionality between mobility and viscosity would also be expected for the processes described, for the probability of tunneling or jumping depends upon the probability of forming appropriate potential wells which in turn depends on the mutual mobility of the solvent molecules just as the viscosity does.

3.2. Nonpolar Solvents

Data were collected over a wide temperature interval depending on the range of the liquid states of the respective solvents. Comparison of data should therefore be viewed with some reservation. However, a general trend, is obvious (Fig. 8): the mobilities increase with decreasing energy V_0 of the conduction band.

Group 1: In liquid helium[42] and neon[52] the electrons are localized, because the small polarizability of the liquids leads to high V_0 values ($V_0>E_{1s}$). Consequently the electron mobilities are small ($<10^{-2}\,cm^2\,V^{-1}\,s^{-1}$). They fit roughly in the correlation given by Walden's rule (Fig. 6).

Group 2: In liquid methane[53], argon, krypton, and xenon[54] electrons have high mobilities ($>4\times10^2\,cm^2\,V^{-1}\,s^{-1}$) comparable with those in solid semiconductors. They indicate the quasi-free or delocalized state of the electrons as expected in solvents with low lying conduction band ($V_0<E_{1s}$).

Group 3: In higher hydrocarbons, mobility values between the extremes of localized and delocalized electrons are found.

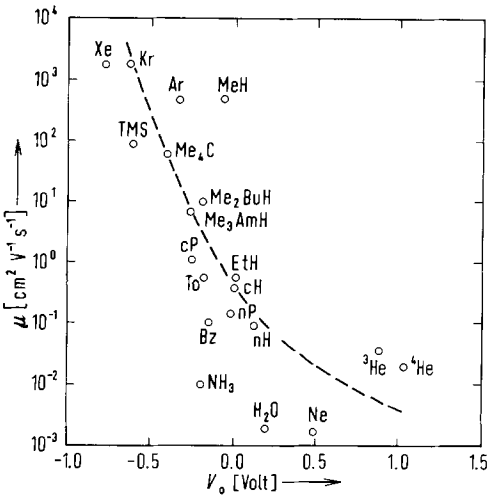

Fig. 8. Electron mobility μ in liquids of varying V_0 values, just below the normal boiling points or at room temperature (μ data from [42, 52—55], V_0 data from [35, 36]; liquified rare gases He, Ne, Ar, Kr, Xe; MeH methane, TMS tetramethylsilane, Me_4C neopentane, Me_2BuH 2,3-dimethylbutane, Me_3AmH 2,2,4-trimethylpentane, cP cyclopentane, cH cyclohexane, EtH ethane, nP *n*-pentane, nH *n*-hexane, To toluene, Bz benzene, NH_3 ammonia, H_2O water).

Some rules can be given[55]: In *n*-alkanes the electron mobility decreases with chain length (methane to dodecane from 4×10^2 to $3 \times 10^{-2}\,cm^2\,V^{-1}\,s^{-1}$). In isomeric hydrocarbons the mobility increases with branching (*e.g.* from 0.09 to $12\,cm^2\,V^{-1}\,s^{-1}$ in the C_6 hydrocarbons). The highest mobilities are found in solvents of spherical molecules such as methane, neopentane, and tetramethylsilane (80 to $400\,cm^2\,V^{-1}\,s^{-1}$).

A normal hydrodynamic movement of the bubble through the viscous medium is assumed for the localized electrons of group 1, which are trapped in a solvent bubble (Fig. 7a). Stokes' law (applied to the mobility) resulted in the large bubble radius in helium[42] and led to the formulation of the cavity model; its theoretical evaluation confirmed this large bubble as the most stable arrangement[33]. Jumping or tunneling is not assumed in this case.

The theory of the quasi-free electrons of metals can be applied to the nonlocalized electrons of group 2[56]. The electrons described as a planar wave are scattered by the molecules or atoms of the liquid phase. The mean free path of the electrons, decisive for their mobility, decreases with temperature due to thermal motion of the scattering centers; this leads to a negative temperature coefficient of the mobility (negative energy of activation, as found *e.g.* in methane[53]).

In the last solvent group with mobilities between the two extremes the quasi-free state of the electrons should lie closely above that of the localized state (V_0 slightly greater than E_{1s}). As in semiconductors, this allows thermal activation of the localized electrons into the quasi-free state of high mobility, from which the electron might jump into a distant potential trap (Fig. 7b). The observed mean mobility is approximated by the product of mobility and relative equilibrium concentration of electrons in the delocalized state[57]. Here again a positive temperature dependence according to Arrhenius is to be expected, because the equilibrium between localized and delocalized state [eq. (4)] is shifted to the right with increasing temperature.

Recent experiments in gaseous helium[58] demonstrate this equilibrium, the density dependence of which can explain the extreme density dependence of the electron mobility of Figure 1.

4. Nonmetal-Metal Transition

The transition from the nonmetal to the metal by transfer of electrons from the localized state of low mobility to the quasi-free state of high mobility is recognized by the steep increase in the electrical conductivity with increasing metal concentration. Examples are metal-ammonia solutions[12, 17, 30] or supercritical mercury[31, 59]. The increase in electron mobility over several powers of ten in a rather narrow concentration range as shown in Figure 2 is characteristic of the transition. However, a metallic state with a specific conductivity above $100\,\Omega^{-1}\,cm^{-1}$ is attained only in solutions with high concentration of the quasi-free electrons ($> 10^{21}\,cm^{-3} \triangleq 1\,mol\,l^{-1}$). Such a concentration is easily obtained in metallic systems by spontaneous ionization. In the nonmetallic systems (Section 3.2) excess electrons can be produced by forced ionization only, *e.g.* by X-rays. This leads to maximal electron concentrations of $10^{16}\,cm^{-3}$. Thus even in xenon, which exhibits the highest electron mobility, a maximal conductivity of only $2\,\Omega^{-1}\,cm^{-1}$ can be achieved, for a very short time only.

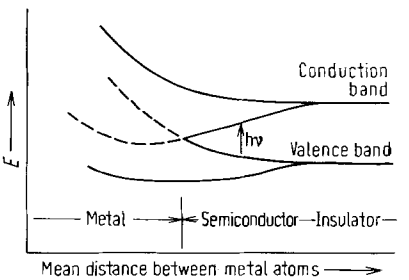

Fig. 9. Illustration of the nonmetal-metal transition by the band model (compare text).

It is easy to give a qualitative interpretation of the concentration dependence of conductivity, *e.g.* of metal-ammonia solutions and of supercritical mercury[60]. Figure 9 represents the energy states of the electrons as a function of the mean distance in terms of a simplified band model. At large distances the electrons are localized in the ammonia solvent cavity or on the mercury atoms. They occupy a discrete level of the valence band (localized state) separated by a wide energy gap from the conduction band (quasi-free state). At smaller distances the electrons undergo mutual interaction which can be described by an overlap of the wave functions; it leads to a broadening of the energy levels which finally form overlapping bands. At large particle distances, *i.e.* large energy differences between the conduction and valence band, the system behaves like an insulator (mercury) or an electrolyte (metal-ammonia solutions). Electrons cannot be promoted from the valence band into the conduction band. At smaller distances, however, the energy gap shrinks and electrons can jump into the conduction band on thermal activation. We then obtain the characteristic of a semiconductor with a positive temperature coefficient of conductivity. Eventually when the bands overlap at smaller distances the electrons can pass into the conduction band without having to overcome an activation barrier and metallic

conduction is observed. In fluid systems the nonmetal-metal transition is smeared out owing to thermal density fluctuations.

Models with a greater degree of sophistication[18,61] give a more detailed but still not exact description of the transition. An almost quantitative description of a series of properties of the metal-ammonia solution was provided by the percolation model[62]. It assumes that the solutions in the transition range are microscopically inhomogeneous, consisting of highly concentrated domains with metallic conduction and dilute domains with electrolytic conduction, each of constant and characteristic concentration. Increase of the overall metal concentration would consequently lead to an increased volume fraction of the metallic domains which finally join to form metallic paths across the solution (Fig. 10).

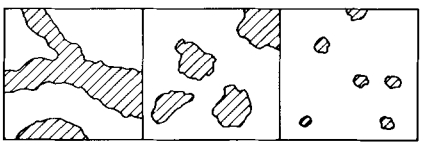

Fig. 10. Illustration of the nonmetal-metal transition according to the percolation theory. Solvent ranges of high metal concentrations are hatched (compare text).

This concept is supported by an opening of the miscibility gap of the solutions at low temperatures[63]; a dilute, nonmetallic and a concentrated, metallic phase are then indeed observed in macroscopic equilibrium. However, it appears doubtful whether the percolation concept is generally applicable to metal-ammonia systems or other systems exhibiting the nonmetal-metal transition.

A common feature of the two models of the transition (compare Fig. 9 and 10) is that the electrons can exist in two equilibrium states—as shown previously for helium[58]. In case of the metal-ammonia solutions a chemical equilibrium

$$e_s^-(iNH_3) \rightleftarrows e_f^- + iNH_3 \qquad (13)$$

could be postulated between solvated electrons (e_s^-) with i ammonia molecules in the solvation shell and quasi-free electrons (e_f^-) with the corresponding number of free ammonia molecules[64]. Addition of electrolytes, *e.g.* sodium iodide, which decreases the concentration of free ammonia by solvation, shifts the equilibrium to the right, *i.e.* favors the metallic state. This follows from the influence of dissolved salts on the miscibility gap.

The thermodynamics of the nonmetal-metal transition of the metal-ammonia solutions are accessible by ammonia vapor pressure measurements[65] or EMF measurements[66] with appropriate electrochemical cells. Figure 11 shows the chemical potential of dissolved sodium relative to solid pure sodium ($\mu_{Na,solid}=0$) plotted as a function of the mole fraction of sodium with temperature as parameter.

The plot demonstrates the nonideal behavior of the solutions, indicating the plateau of the chemical potential in the range of the miscibility gap ($T < -41$ °C), and even at temperatures above it where inhomogeneities according to the percolation concept set in. Further evaluation of the data reveals that the transition to the metallic state is accompanied by a decrease in enthalpy and in entropy and that the miscibility

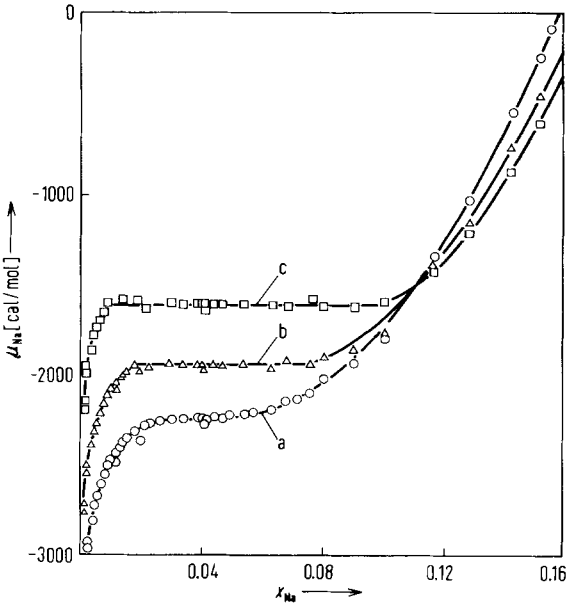

Fig. 11. Concentration dependence of the chemical potential μ of sodium dissolved in ammonia relative to solid sodium ($\mu_{Na,s}=0$; from ammonia vapor pressure [65] and EMF [66] measurements; a -35 °C, b -55 °C, c -75 °C; at -35 °C sodium mole fraction of saturated solution $x_{Na}=0.158$).

gap is a consequence of changes in these thermodynamic functions[18].

5. Absorption of Light

A normal absorption process, in which the energy of the light quantum is transferred to the absorbing species, is not possible with free or quasi-free electrons. Consequently, the quasi-free electrons, such as occur in liquified heavy rare gases or in many hydrocarbons, do not exhibit absorption spectra. A bound or localized electron, however, can interact with a photon, the interaction leading to a higher energy state of the electron. Therefore all solutions containing localized electrons have a strong absorption band (the light absorption is described as a 1s→2p transition (compare Fig. 4) of the electrons for which theory predicts a high transition probability[33]).

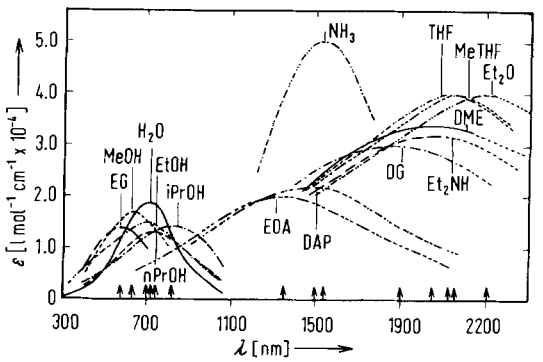

Fig. 12. Absorption spectra of solvated electrons in polar solvents at room temperature [67] (H_2O water, MeOH methyl alcohol, EtOH ethyl alcohol, iPrOH isopropyl alcohol, nPrOH *n*-propylalcohol, EG ethylene glycol, NH_3 ammonia (-33 °C), EDA ethylenediamine, DAP 1,3-diaminopropane, Et_2NH diethylamine, DG diglyme, DME dimethoxyethane, Et_2O diethyl ether, THF tetrahydrofuran, MeTHF methyltetrahydrofuran).

Extensive experimental results have been obtained on the light absorption of localized, and especially solvated electrons

in suitable solvents. The spectra in polar solvents are surveyed[67] in Figure 12, from which the wavelength (λ_{max}) of maximum absorption, the spectral halfwidth (ΔE), and the decadic absorption coefficient (ε) can be read. All spectra are rather broad and lack structure. A relationship clearly exists between λ_{max} and the nature of the solvating group: in solvents containing OH groups (water[68], alcohols from methanol to undecanol[69]) the absorption maximum is located around 700 nm (in branched alcohols λ_{max} is slightly larger than in the corresponding *n*-alcohols[69]), in solvents having NH_2 groups (ammonia[70, 71], amines[72]) between 1200 and 1600 nm, and finally in ethers[72] between 1900 and 2300 nm.

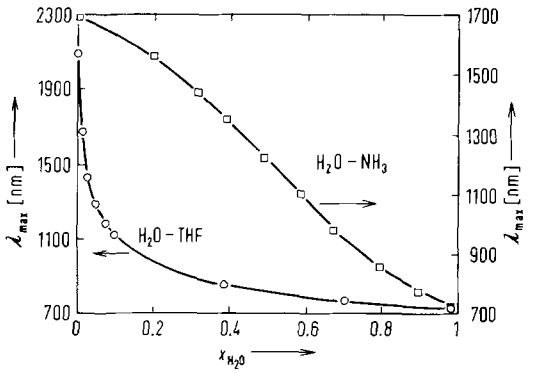

Fig. 13. Wavelength of maximum light absorption λ_{max} of solvated electrons in water-ammonia mixtures [73] and water-tetrahydrofuran mixtures [72] as a function of the mole fraction of x_{H_2O}.

In solvent mixtures the absorption maxima are found between those of the pure components (Fig. 13). In water-ammonia mixtures λ_{max} varies almost linearly with the solvent composition[73], indicating statistical distribution of both water and ammonia between the solvation shell of the electron and the bulk solution. However, in mixtures of solvents with strongly different polarity the more polar solvent molecules are preferentially incorporated in the solvation shell. This follows from the observation that a mere 3% of water in tetrahydrofuran (THF) suffices to shift the absorption maximum to a position halfway between those of the two solvents[72]. Similar effects are observed in alcohol-hydrocarbon mixtures[74].

All attempts to find a simple relation between λ_{max} and typical macroscopic properties of the solvent (dielectric constant, refractive index, surface tension, polarizability, *etc.*) have failed. However, since the size of the solvent cavity in which the electrons are trapped plays a decisive role in determining the energy of the dissolved electrons[33] [compare eq. (9)], the dependence of λ_{max} on the solvent might indicate a variation in cavity size. An evaluation[67] on the basis of the simplified theory leads to cavity radii R of around 0.9 to 1.5 Å in water and alcohols, of 2.5 to 3 Å in ammonia and amines and 3.1 to 4 Å in ethers.

In solid and molten alkali halides a quadratic relation has been confirmed between λ_{max} and a geometric factor d of the solvent (cavity radius $R \sim$ lattice constant d)[75, 25], as is postulated by the simple model of an electron in a box. A red shift of spectra with increasing temperature[68, 71] and blue shift with increasing pressure[44, 71, 76] are interpreted in terms of the cavity model by thermal expansion and compression, respectively, of the cavity.

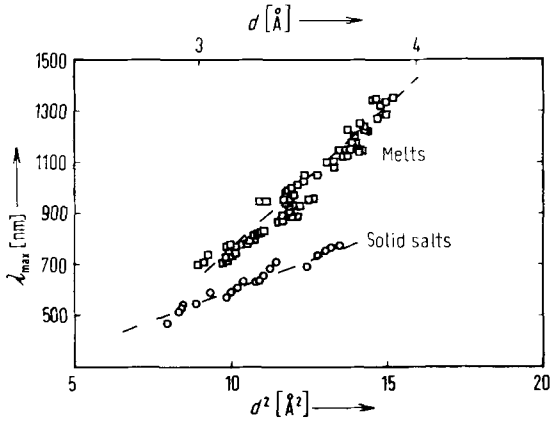

Fig. 14. Quadratic relationship between lattice parameter d and wave length of maximum light absorption λ_{max} of excess electrons in solid (20—400°C [75]) and molten (500—1000°C [25]) pure alkali metal halides and their mixtures (d represents the size of the anionic lattice defects in which the excess electrons are trapped).

The large halfwidth of the spectra can likewise be interpreted with this model. In the disordered liquid phase the thermal motion of the molecules precludes the formation of cavities of uniform size. Instead, the cavity sizes are expected to follow a distribution function with a maximum at the most probable or most stable cavity size. If an electron absorbs only light of a definite wavelength determined by the size of the cavity, the broad absorption spectra indirectly reflect the cavity size distribution function[77]. This view is supported by experiments with alkali metal halides: in the melts the electron spectra are three to four times broader[25] than in the crystal[75] where the electrons are localized in anion vacancies of well defined geometry (F-centers).

Laser experiments with metal-ammonia solutions on a picosecond time scale[27, 78] reveal that the cavity size distribution function is established very quickly. A high intensity laser flash of sharp wavelength in the range of the electron absorption leads to diminished absorption (bleaching) over the *whole* spectrum due to depopulation of the light absorbing state. Selective bleaching of the solution at the wavelength of the laser light is not observed. Immediately after completion of the flash, the spectrum regains its original intensity. This not only proves that the cavity size distribution function is established within a few ps (*i.e.* as fast as molecular reorientations), but also shows that the electrons in the excited state return to the ground state within the same time[79, 80].

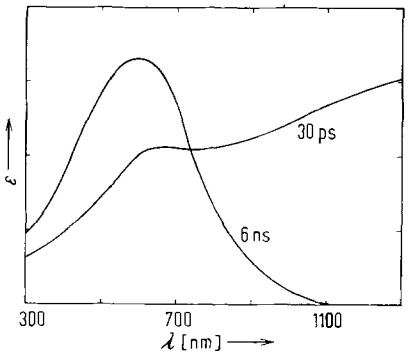

Fig. 15. Absorption spectra of excess electrons in propanol at −12°C, 30 ps and 6 ns after their generation by pulse radiolysis [82] (absorption coefficients in arbitrary units).

In frozen glassy solvents, *e.g.* THF, in which the rate of reorientation of the molecules is decreased by many orders of magnitude, a persistent selective bleaching is observed[81]. This proves the concept that the electrons are trapped in states of various energies or in cavities of various sizes, from which they can be selectively excited, and that here a perturbation of the distribution function is not smoothed out again.

Further picosecond experiments give information on the time scale of the solvation process of electrons[26, 82]. Figure 15 displays the absorption spectrum of electrons in propanol at −12°C, about 30 ps and 6 ns after their generation by a ps-radiolytic pulse. The spectrum is time-dependent. The electron is formed first in a state with an absorption maximum above 1300 nm, which with some delay relaxes to the normal state with an absorption maximum around 600 nm, as shown in Figure 12.

It is assumed that the electron is first trapped in a region of the solvent in which the solvent molecules form a shallow potential well by random orientation. Reorientation of the molecules by the field of the trapped electrons then leads to the stable solvent cavity configuration. The relaxation time of this process increases from 11 to 50 ps in the series of alcohols from methanol to decanol[83], in good agreement with relaxation times for molecular rearrangements in these solvents as determined by dielectric measurements.

Electron solvation is not limited to a condensed solvent phase, but also can occur in the vapor phase. As mentioned in the introduction, however, the solvation process requires a certain minimum density of the solvent. Optical investigations in supercritical ammonia and water vapor, in which the density can be varied at will, reveal the limits: in ammonia[84] just below 0.1 g cm^{-3}, in water[85] around 0.01 g cm^{-3}. The spectra observed in these vapors hardly differ from those in the liquid. At lower densities the solvating interactions are too weak; the electrons remain in a quasi-free delocalized state just as they do in low density helium gas (Fig. 1).

Only little information is available about the absorption spectra of localized electrons in other solvents. In hydrocarbons[86], such as hexane, cyclohexane, methylcyclohexane, and isopentane, the absorption maximum is located at slightly higher wavelengths than in ethers. According to theory, localized electrons in helium should absorb light in the same range[87] (compare Fig. 4).

6. Reaction Rates

The reactions of dissolved electrons in aqueous systems have been investigated most thoroughly: the rate constants of reactions with nearly 700 different substrate molecules have been compiled in tabular form[88]. However, activation energies are given only for 16 of these reactions and hence evaluation of the rate constants—varying between 10^7 and 10^{11} l mol^{-1} s^{-1}—is virtually impossible. Slower reactions ($k < 10^7$ l mol^{-1} s^{-1}) cannot be observed in water because the lifetime of the electrons is limited to 10^{-3} s by reaction with water molecules:

$$e^- + H_2O \rightarrow \tfrac{1}{2}H_2 + OH^- \quad (14)$$

Superimposed upon this is a pseudo-bimolecular reaction

$$2e^- + 2H_2O \rightarrow H_2 + 2OH^- \quad (15)$$

(pseudo-bimolecular rate constant $k = 5 \times 10^9$ l mol^{-1} s^{-1}) which becomes very fast at higher electron concentration. In ammonia the corresponding reaction

$$e^- + NH_3 \rightarrow \tfrac{1}{2}H_2 + NH_2^- \quad (16)$$

is slower by many orders of magnitude [in pure metal-ammonia solutions the lifetime of electrons exceeds several weeks; the pseudo-bimolecular reaction corresponding to eq. (15) has not been observed]. Therefore even extremely slow reactions can be followed in ammonia. In nonpolar solvents, reactions many times faster than those occurring in water have been found. Thus the rate constants of electron reactions in different solvents cover the range from $k < 1$ to about 10^{15} l mol^{-1} s^{-1}. However, the experimental rate constants of a reaction such as

$$e^- + A \rightarrow \text{Products} \quad (17)$$

(A electron acceptor molecule) describe only the overall rate with which the electrons disappear from the solution without revealing any details of a reaction mechanism.

The experimental information available so far shows the electron reaction rates to be strongly dependent on the solvent:

1) *via* its viscosity or other properties which influence the mobility or the rate of diffusion of the electrons
2) *via* its influence on the properties or the reactivity of the electrons and their reaction partners
3) *via* its dielectric constant which is decisive for the Coulomb interaction in reactions with ions
4) *via* its participation in consecutive reactions.

These four points will be illustrated separately with the aid of examples; the sparse experimental data obtained in nonaqueous solvents and solvent mixtures will also be considered.

6.1. Diffusion-Controlled Reactions

We speak of diffusion-controlled reactions whenever the actual reaction step, *i.e.* the chemical transformation of the reactants, is faster than the diffusion processes in which the reactants are brought together or are separated again[89]. For these reactions the bimolecular rate constant k_D is given by the sum of the diffusion coefficients D of the two partners and by the maximum collision distance σ from which the electron can jump or tunnel to the reaction partner

$$k_d = 4\pi N_L D\sigma/1000 \ [\text{l mol}^{-1}\ \text{s}^{-1}] \quad (18)$$

(N_L Loschmidt number). The diffusion coefficient of the substrate can be neglected because it is small compared to that of the fast moving electron. The diffusion coefficients of the electrons follow from their mobilities *via* eq. (12).

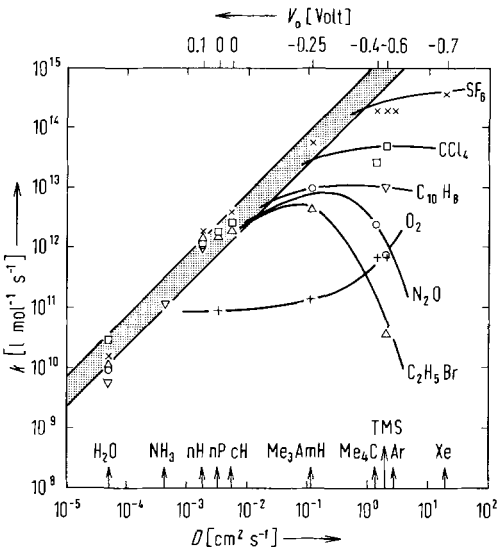

Fig. 16. Relation between rate constant k of some reactions of excess electrons and their diffusion coefficients in several solvents. The reaction partners are given on the right-hand side, the solvents on the abscissa, their V_0-values are indicated at the top of the figure. The hatched area is calculated for diffusion-controlled reactions according to eq. (18) with the collision distance $\sigma = 3 \times 10^{-8}$ to 1×10^{-7} cm (data from [88, 90, 91]; H_2O water, NH_3 ammonia, nH *n*-hexane, nP *n*-pentane, cH cyclohexane, Me_3AmH trimethylpentane, Me_4C neopentane, TMS tetramethylsilane, Ar argon, Xe xenon; $C_{10}H_8$ naphthalene).

In Figure 16 the relation between the rate constant of diffusion-controlled reactions of the electrons and their diffusion coefficient calculated according to eq. (18) with collision distances between 3×10^{-8} and 10^{-7} cm is shown hatched. The experimental rate constants of some selected reactions in a series of solvents are included for sake of comparison[88, 90, 91]. All the reactions with rate constants in the hatched area are diffusion controlled beyond any doubt. Here the individual properties of the solvent, of the reaction partner, and of the electron (localized or quasi-free) are without influence on the reaction rate. The sole decisive factor for the rate is the electron diffusion coefficient.

6.2. Influence of Solvent

In liquids of extremely high electron mobility the proportionality between k_d and D shown in eq. (18) is no longer valid. The rate constants lie below the diffusion-controlled limit (Fig. 16). We have reached the domain in which the actual chemical transformations become rate determining.

This can be stated more precisely. According to the laws of diffusion the electron will pass through the distance σ, from which the electron can be transferred to the reaction partner, in a time

$$\tau_D = \sigma^2/2D \tag{19}$$

In a diffusion-controlled reaction the actual reaction time τ_R in which the electron can be transferred must be smaller than τ_D. Thus, for $\sigma = 5 \times 10^{-8}$ cm and $D = 1$ cm^2 s^{-1}, τ_R should be smaller than 10^{-15} s.

It is obvious that rearrangements of the solvent structure or of the reaction partner to obtain a reactive configuration cannot occur on such a short time scale. Only tunneling would allow such fast processes and there are adequate arguments[7] in support of the assumption that the reactions of excess electrons occur *via* tunneling. But then why are not all electron reactions as fast as diffusion would allow, and why are some reactions up to 10^{15} times slower?

To explain the differences in reactivity of electrons with the same substrate in different solvents or with different substrates in the same solvent we modify the simplified theory of charge transfer reactions (redox reactions, *e.g.* electrode-electrolyte) which is based on the concept of tunneling[92]. Applied to the reactions of dissolved electrons this means that the electron has to tunnel from its state in the solvent to an unoccupied orbital of the acceptor molecule[93, 94]. Since tunneling is very fast the molecular configurations of the system cannot change during electron transfer. This is comparable to electronic excitation of a molecule where the geometric configuration initially also remains unchanged (vertical transition according to the Frank-Condon principle). The resulting negative molecule ion is formed not in its most stable state but in the equilibrium configuration of the neutral molecule, from which it goes to the stable state with dissipation of excess energy. The solvent area in which the electron was trapped will likewise rearrange to its normal state after some time has elapsed, dissipating the rearrangement energy E_m of eq. (10). Thus the reaction enthalpy ΔH will clearly be set free with some delay after the electron transfer.

Since tunneling is possible only between states of identical energy (interpretable on a simplified level as resonance), electron transfer will occur only when the acceptor molecule has a free orbital in the energy range of the free electron. The theory of tunneling rather vividly describes the tunneling probability at a given energy E as the product of three parameters: the tunneling frequency $\nu(E)$ depending on the width and height of the potential barrier, and the two densities of states $D_0^e(E)$ and $D_0^A(E)$ describing the density of occupied (o) energy levels of the dissolved electron (e) and that of the unoccupied (u) levels of the acceptor molecule (A), all three at the energy E. To obtain the overall transition probability we have to integrate over all energies from $-\infty$ to $+\infty$. Apart from constant factors we obtain

$$k \sim \int_{-\infty}^{\infty} \nu(E)\, D_0^e(E)\, D_0^A(E)\, \mathrm{d}E \tag{20}$$

Figure 17 schematically shows the density of states of delocalized electrons described by the sharp V_0 values in *n*-hexane (a), 2,2,4-trimethylpentane (b), and tetramethylsilane (c), as well as the densities of the unoccupied energy states of several acceptor molecules 1 to 3. These follow from electron affinities and the solvation energies of the molecules; they are independent of solvent, at least in hydrocarbons of low dielectric constant.

The $D_0^A(E)$ functions of sulfur hexafluoride and carbon tetrachloride (example 2 of Fig. 17) have broad maxima in the range of V_0 values of all hydrocarbon solvents. The consequences are high reactivities so that the limits of diffusion-controlled reactions are reached in almost all solvents. The $D_0^A(E)$ functions of ethyl bromide and nitrous oxide (example 1 of Fig. 17) are narrower and shifted to higher energies. The rate constant then decreases with decreasing V_0 value (upper scale in Fig. 16). In the case of oxygen (example 3 of Fig.

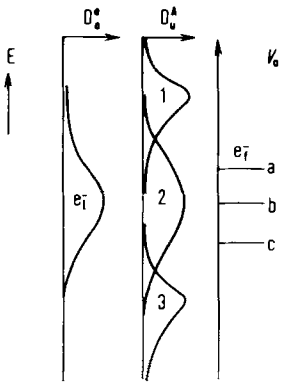

Fig. 17. Schematic representation [93, 94] of the density of state functions of the occupied states $D_o^e(E)$ of a localized electron e_i^- (left) and of a quasi-free electron e_f^- with the sharp energy V_0 in three different solvents (a cyclohexane, b 2,2,4-trimethylpentane, c tetramethylsilane) and of unoccupied states $D_u^A(E)$ of three sorts of acceptor molecules (1 ethyl bromide or nitrous oxide, 2 carbon tetrachloride or sulfur hexafluoride, 3 oxygen).

17) whose distribution function has a maximum at lower energies, the rate constant increases with decreasing V_0.

Decreasing temperature shifts the distribution function of these molecules to lower[93], and the V_0 values to higher energies[35]. Thus decreasing temperature results in better overlap, leading to faster reactions; *i.e.*, a negative activation energy is observed as with nitrous oxide or ethyl bromide in tetramethylsilane. However, other effects might contribute to negative activation energies: equilibrium (4) between localized and delocalized electron states may be shifted in favor of the localized states by a decrease in temperature. The localized state with a lower and wider distribution function can, in certain cases, lead to a better overlap and therefore to higher reaction rates.

These differences are not so sharp in reactions of solvated electrons, because their density functions are wider (Fig. 17, left). Therefore overlap may still occur with molecules whose density of state function is shifted to lower or higher energies. Moreover, since the diffusion-controlled reactions of solvated electrons are considerably slower, differences in tunneling probability or reactivity of different substrate molecules like oxygen, ethyl bromide or sulfur hexafluoride could not be detected at all. In cases of substrates which do not react at all, or if so only slowly, with solvated electrons (methane, nitrogen, or benzene, respectively), we may always assume that the unoccupied orbitals are too high (molecule 1 in Fig. 17).

Without going into details, one other experimental result concerning kinetics in polar solvents will be mentioned. Electrons generated by any energy consuming process, *e.g.* radiolysis, are initially formed in a quasi-free or in a weakly localized state of high energy before they are transformed, on a ps-time scale, into the stable solvated state (compare Fig. 15). In accord with their higher energy, quasi-free electrons will react faster with substrates of higher-lying distribution function (*e.g.* acetone, case 1 of Fig. 17) and slower with those of lower-lying distribution function (H^+ ions, case 3 of Fig. 17) than do solvated electrons. This explains the starteling observation[95] that acetone—reacting slowly with solvated electrons—decreases the radiation chemical yield of solvated, and hence optically detectable electrons, whereas the fast reacting H^+ ions do not[93].

Thus the wide variation of rate constants of the excess electrons in condensed fluid phases is due partly to the electron mobilities covering a range of five orders of magnitude, and partly to the tunnel probabilities which vary from solvent to solvent and from reaction partner to reaction partner and which depend on the overlap of the energy states.

Of course, the kinetics of the electron reactions also can be interpreted in terms of transition state theory, according to which the rate constant of a bimolecular reaction is given by the enthalpy of activation ΔH^* ($\approx E_a$ activation energy) and the entropy of activation ΔS^*

$$k = \frac{RT}{N_L \cdot h} \exp(\Delta S^*/R) \cdot \exp(-\Delta H^*/RT) \tag{21}$$

(R gas constant, h Planck's constant).

Apart from very few exceptions, the activation energy of all electron reactions investigated so far lies in the range of 2 to 5 kcal mol^{-1}[88]; therefore the entropy of activation, *i.e.* the entropy difference between the activated complex and the reactants ($\Delta S^* = S^* - S_{e^-} - S_A$) must be responsible for the variation of the rate constant over so many powers of ten[71, 73]. For high reaction rates, ΔS^* is more positive than for low reaction rates; the general relation between entropy and probability therefore leads back to the concept of tunneling probability which depends on the density of energy states.

According to thermodynamic estimates the entropy of the solvated electrons is more positive by 13 cal mol^{-1} K^{-1} in ammonia than in water[38, 40]. If all other parameters of eq. (21) remain constant, the activation entropy of a reaction in ammonia should be more negative by 13 cal mol^{-1} K^{-1} than in water; in other words the reaction in ammonia should be slower by a factor of 600 than that in water. Differences in the rate constants of this order have been found for some non-diffusion-controlled reactions of electrons with neutral molecules in ammonia and water[96].

The transition state theory describes the pressure dependence of a chemical reaction

$$\frac{d \ln k}{dp} = -\frac{\Delta V^+}{RT} \tag{22}$$

in terms of the activation volume[89] given by the volume difference of the activated complex and the reactants: $\Delta V^+ = V^+ - V_e - V_A$.

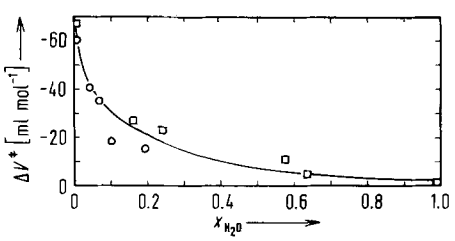

Fig. 18. Activation volume ΔV^+ of the reaction of solvated electrons with water (□ [73]) and with acetonitrile (○ [96]) in water-ammonia mixtures.

In water and alcohols only small effects of pressure on reaction rates are found, *i.e.* the activation volume of the electron reactions is close to zero[44, 45, 97]; in ammonia on the other hand some of the electron reaction rates are increased

up to fifteenfold by application of 1000 bar[73, 96], the activation volume can be up to $-65\,cm^3\ mol^{-1}$; in water-ammonia mixtures values between 0 and -65 are obtained (Fig. 18). The activation volume with inverse sign reflects the cavity volume of the solvated electrons, which is fairly large in ammonia ($R \approx 3\,Å \triangleq V_e \approx 68\ cm^3\ mol^{-1}$), relatively small in water ($R < 1\,Å \triangleq V_e < 3\ cm^3\ mol^{-1}$), and between these values in mixtures of the two, as follows from the absorption spectra (Fig. 13) in connection with theory. Thus the kinetic data support the concept of the cavity model of the solvated electrons (compare Section 2.2).

6.3. Influence of the Dielectric Constant on Ion Reactions

For reactions of electrons with ions, transition state theory leads to a term depending on the dielectric constant ε[89]

$$\ln k = \ln k_\infty + \frac{N_L Z_A e^2}{\varepsilon R T r^*} \tag{23}$$

It describes the electrostatic interaction between charged particles (k, k_∞ rate constant of a reaction in a solvent of dielectric constant ε and in one with $\varepsilon = \infty$, Z_A charge of the ionic reaction partner, r^* radius of the activated complex). Therefore reactions with positive ions ($Z_A > 0$) become slower with increasing dielectric constant because of diminished Coulomb attraction of the oppositely charged particles, whereas those with negative ions ($Z_A < 0$) become faster due to diminished repulsive interaction. The linear plot of $\log k$ *versus* $1/\varepsilon$ in

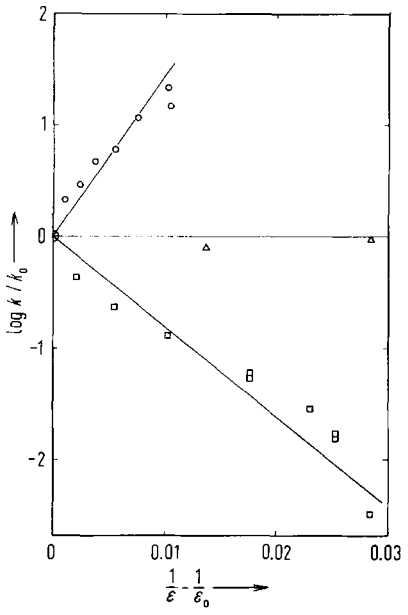

Fig. 19. Inverse dependence of log rate constant k of the reaction of solvated electrons with acetone, nitrate ions, and zinc ions on the dielectric constant ε in water-ethanol mixtures [98] (△ acetone ($Z_A = 0$); □ NO_3^- ($Z_A = -1$); ○ Zn^{2+} ($Z_A = 2$); ε_0 dielectric constant of water, k_0 rate constant of the reactions considered in water).

Figure 19 for several reactions in water-alcohol mixtures[98] ($\varepsilon = 17$ to 80) proves relation (23). The same trend has also been found for reactions in water-ammonia mixtures[96].

6.4. Participation of Solvent in Consecutive Reactions

In some cases the reaction rates have been found to depend on the composition of solvent mixtures, an observation which cannot be interpreted by any of the concepts discussed so far: *e.g.* the reactions of electrons with acetonitrile[96], benzene[99], or fluorobenzene[100] are extremely slow in pure ammonia, but addition of a few mol % of water or methanol leads to a considerable increase in reaction rate: further addition, *e.g.* of water, has a less pronounced effect and finally no effect at all (Fig. 20).

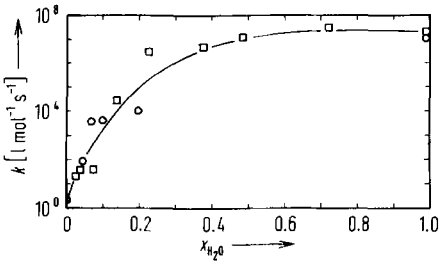

Fig. 20. Rate constant k of the reactions of solvated electrons with benzene (□ [99]) and with acetonitrile (○ [96]) in water-ammonia mixtures.

This solvent dependence of the reaction rate suggests a more complex kinetic situation which might be described by the following reaction mechanism:

$$e^- + A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} A^- \tag{24}$$

$$A^- + H_2O \xrightarrow{k_3} \text{Products} \tag{25}$$

The electron attachment is formulated as an equilibrium reaction, the resulting radical anion is protonated in a consecutive reaction step by water or alcohol[101] (ammonia with its 10^{14} fold smaller dissociation constant as compared to water can react only slowly, if at all, with the A^- ion). The reaction mechanism [eq. (24) and (25)] leads, with the aid of the concept of the quasi-stationary state, to the experimental rate constant[89]

$$k = \frac{k_1 \cdot k_3\,[H_2O]}{k_2 + k_3\,[H_2O]} \tag{26}$$

which, with appropriate rate constants k_1 to k_3, fits the data of Figure 20. Since electron attachment is an exothermic step, equilibrium (24) is shifted to the right with decreasing temperatures; this would explain the negative activation energy found for some reactions in ammonia rich mixtures with methanol[100].

7. Chemical Equilibria

Chemical equilibria can be observed only in those solvents, which react neither with the excess electrons nor with their reaction products. These are mainly ammonia and its derivatives, and some aliphatic ethers, all of which dissolve alkali metals with formation of excess electrons (viewed thermodynamically, all these systems are unstable; the long lifetime of the excess electrons is due to kinetic hindrance). The electrons

and most of their reaction products have a very short lifetime in reactive solvents; in a few cases the equilibrium constant K ($K=k_1/k_2$) of a reaction like (24) could be obtained by investigation of the rate constants of the reactions in the forward and reverse direction. Owing to the high reducing power of the excess electrons (standard potential *versus* the hydrogen electrode: -1.95 V in ammonia[19, 102, 66b], -2.75 in water[37]), most of the equilibria (24) lie so far to the right hand side that they can hardly be determined.

The equilibrium constant of the reactions of solvated electrons with solvent

$$e^- + NH_3 \rightleftarrows {}^1/_2 H_2 + NH_2^- \quad (27)$$
$$e^- + H_2O \rightleftarrows {}^1/_2 H_2 + OH^- \quad (28)$$

as calculated from the standard potentials at 25°C are of the order of 10^4 and 10^{32} bar$^{1/2}$ l mol^{-1}, respectively; they prove the instability of the dissolved electrons (the equilibrium concentration of electrons in both systems with 1 M base anions and 100 bar hydrogen are about 10^{-5} and 10^{-33} mol^{-1}, respectively). The ammonia equilibrium is shifted to the right by application of pressure[103], whereas the water equilibrium is hardly affected[45]. From the observed data and with

$$\frac{d \ln K}{dp} = -\frac{\Delta V}{RT} \quad (29)$$

it again follows that the electrons create a large cavity in ammonia, but only a small one in water. Both reactions are exothermic ($\Delta H \approx -15$[19] and -50 kcal mol^{-1}[38], respectively), *i.e.* the equilibrium concentrations of electrons increase with increasing temperature.

Quantitative data on equilibria according to (24) are available only for a few aromatic molecules (styrene, naphthalene, phenanthrene, triphenylene) in some hydrocarbons (*n*-hexane, 2,2,4-trimethylpentane, tetramethylsilane). They were obtained by kinetic measurements[91]. The following regularities are observed: electron attachment reactions are connected with negative changes of the free enthalpy, enthalpy, and entropy; *i.e.* the equilibrium constants are larger than 1 ($\Delta G^0 = -RT \ln K$) but decrease with increasing temperature ($d \ln K/dT = \Delta H^0/RT^2$). The standard free reaction enthalpy ΔG^0 ($= G^0_{A^-} - G^0_A - G^0_{e^-}$) is the more negative the higher the electron affinity of the aromatic molecules and the higher the energy of the electrons in the solvents (described by V_0). The entropy decrease indicates that the electrons are less localized in the solvent than in the aromatic molecule (delocalization corresponds to a state of low order or of high entropy) and is therefore also dependent on the size of the molecules.

Not enough data are presently available to yield more information on the thermodynamics of excess electrons and their reactions.

8. Unsolved Problems

The known properties of dissolved electrons can be described qualitatively by theory. Quantitative agreement between experiment and theory, as has been reported now and again, should not be overestimated because the theory is often adapted to fit the experimental results. However, preliminary *ab initio* calculations[104, 105] match some of the experimental results and led to additional information on the structure of the solvent shell of the solvated electrons.

Many problems still remain unsolved. There is no convincing theoretical explanation for the diamagnetic dimer[106], a pair of electrons formed from two paramagnetic solvated electrons by spin compensation. This entity prevails in metal-ammonia solutions of moderate to low concentrations; it has an absorption spectrum differing only slightly from that of the solvated electrons. It might be that the relative stability of this dimer prevents the pseudo-bimolecular reaction of electrons in ammonia; in water this reaction [eq. (15)] decisively restricts the lifetime of the solvated electrons.

Another question concerns the absorption spectra of the electrons which were attributed to the 1s→2p transition: are there further hidden additional transitions to higher levels (3p, 4p...)[106], such as are observed in the hydrogen atom, or is the broad spectrum explained solely by the wide cavity size distribution function as described in Section 5? Moreover, transitions to higher s levels should also be observable, albeit only by two photon absorption[106].

The localized excess electrons detected in helium by mobility studies should also be observable by light absorption[87]. Photoconductivity of the localized electrons which again were observed in helium or some glasses definitely has not been found in liquid ammonia[107], although UV light causes an outer photoelectric effect[108] (transfer of an electron from the solution to the gas phase). Do the nonlocalized electrons in ammonia or water vapor of densities too low for solvation have a higher mobility and modified reactivity compared to their solvated state, as was found for hydrated electrons before full solvation was established[95]?

Since solvated electrons in ammonia can be produced very conveniently by electrochemical means[109] owing to the high hydrogen overvoltage, the electrode kinetics of this reaction and further reduction reactions should be investigated. A quantitative relation might be obtained between reaction rates or equilibria and the energetics of electron reactions. Such investigations cannot be carried out in aqueous systems because hydrogen formation sets in long before formation of dissolved electrons is possible.

The list of unsolved problems relating to excess electrons is long, probably longer than that of solved problems. The efforts to solve outstanding problems is definitely worthwhile, not only in order to answer these academic problems but also because we might touch upon other chemical, biological, or technical aspects, as mentioned in the introduction. Even new industrial processes might result from our endeavors. Two new chemical processes have indeed already been developed on the basis of research relating to dissolved electrons[110]: a process for the safe disposal of poisonous cyanide wastes[111] resulting from tempering baths for steel hardening on a thousand ton per year scale; and a process for the production of heavy water, used as neutron moderator in nuclear power plants with natural uranium fuel[20]. A novel process for the enrichment of the lithium isotope of mass 6 is being developed, which might serve, together with deuterium, for energy production by nuclear fusion (overall reaction $D + {}^6Li \rightarrow 2\,{}^4He + 21$ MeV).

I am grateful to Prof. Dr. R. Ahlrichs and Dr. P. Krebs for extensive discussions concerning dissolved electrons; financial support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for our investigations mentioned here is gratefully acknowledged.

Pore Sizes of Solids

By István Halász and Kornél Martin[*]

Dedicated to Professor Hermann Hartmann

A new, fast, and simple method based on size exclusion chromatography permits determination of the volumes of open and closed pores of rigid solids such as silica or porous glasses, together with the specific surface and the pore-size distribution for pore diameters ranging from 10 to 4000 Å. The results are in good agreement with those obtained by classical methods (capillary condensation, mercury porosimetry).

1. Introduction

The determination of the pore-size distribution of catalysts, absorbents, and other solids of technological significance is an important task which, however, is frequently very time-consuming. The fundamentals of the classical methods such as capillary condensation and mercury porosimetry will first be briefly outlined.

Given a knowledge of the sorption isotherm of nitrogen on solids at the temperature of its atmospheric boiling point[1], it is then possible to assign a pore diameter ϕ[***] to the adsorbed mass (volume) which corresponds to the relative pressure p/p_0, assuming that capillary condensation takes place. Neglecting the layer adsorbed prior to the commencement of the capillary condensation, it is possible to calculate ϕ according to

$$\phi\,[\text{Å}] = \frac{8.28}{\log p_0/p} \tag{1}$$

where p_0 is the vapor pressure and p the equilibrium pressure of nitrogen[2]. If the adsorbed layer is also taken into consideration, the ϕ-value calculated from eq. (1) increases as a function of the pressure, *e.g.* by an increment of 9 Å at $p/p_0 = 0.2$ and by an increment of 40 Å at $p/p_0 = 0.9$[2]. However, the accuracy of the measurements decreases with increasing relative pressure, so that in practice it is only possible to use this method for a pore diameter range of 20 to 200 Å (and at the most up to 400 Å).

[*] Prof. Dr. I. Halász, Dr. K. Martin [**]
Angewandte Physikalische Chemie der Universität
D-6600 Saarbrücken (Germany)
[**] Permanent address: Tungsram Research Institute, Budapest (Hungary)
[***] Here and in the following it is arbitrarily assumed that the pores are cylindrical.

Comparison of the adsorption isotherms for a nonporous solid and a microporous material ($\phi < 20$ Å)—the "t-method"—allows an approximate determination of the pore-size distribution in the microporous substances[3].

In mercury porosimetry the penetration of mercury into the solid under pressure is measured[4, 5]. By using the empirical approximation:

$$\phi\,[\text{Å}] = \frac{150000}{p\,[\text{atm}]} \tag{2}$$

it is possible to calculate the pore diameter ϕ as a function of the applied pressure p. Because of instrumental difficulties, so far it has only been possible to determine pore diameters greater than 75 Å. Since the measurements require pressures of up to 2000 atm, the results are falsified if the material collapses during the determination.

In order to establish the complete pore-size distribution, the results of capillary condensation and mercury porosimetry should partly overlap for each specimen. The apparatus required is expensive, as is its maintenance, and in addition the measurements on just a single sample may take as long as 30 h. With these classical methods a precise determination of the pore-size distribution of fine-grain solids (mean particle size $d_p < 20\,\mu$m) is often difficult.

The specific surface and the mean pore diameter (but not the pore-size distribution) of porous materials may also be determined by small-angle X-ray scattering[6, 7].

Below we shall describe a new method for the determination of the pore-size distribution in solids by size exclusion chromatography (SEC)[8, 9], which requires simpler equipment and is less time-consuming than the classical methods. Further advantages of the SEC method are that the measurements are not carried out at very low temperatures (−183 °C) or

very high pressures (2000 atm or more) and that the mass transport phenomena are similar to those that occur in adsorption and catalytic processes.

Finally, it should be noted that it is also possible to use the SEC method for the examination of solids that have been swelled in solvents, *i.e.* for materials that could be examined by classical methods only in the dry state. Examples of such materials are the copolymers of styrene and divinylbenzene.

At this stage it is appropriate to draw attention to the different boundary conditions that must be assumed to exist both in the classical methods and in the new method.

2. Size Exclusion Chromatography

Size exclusion chromatography (SEC)[10], frequently also referred to as gel-permeation chromatography[11], gel-filtration chromatography[12], or molecular sieve chromatography[13], makes it possible to separate mixtures dissolved in the mobile phase according to molecular size. To this end the eluent must be such that the molecules of the substance under test are not sorbed by the solid stationary phase. The method is generally used for the separation of polymer mixtures, though this is not an invariable rule.

Swellable polymers (gels) were originally used as the stationary phases. Later on solids with a rigid matrix (*e.g.* porous glasses or silica gels) were also employed, whose pore structure could be determined by means of classical methods[14]. The quality of these stationary phases was often characterized by SEC itself. For this purpose the logarithm of the weight-average molecular weight $\bar{M}_w$ of the polymer substances was usually plotted as a function of the elution volume V_e[15–25]. The polymers were then assigned "rotation coil diameters" as a function of $\bar{M}_w$[15–17, 19, 21, 25]. Such calculated and variously defined "radii" of "monodisperse" polymeric test materials were likewise called upon for the characterization of column packings as a function of the elution volume V_e[16, 17, 19, 21, 24]. In the case of stationary phases with a rigid matrix the results were comparable with the pore-size distributions determined by the classical methods[15, 18, 19, 25].

In classical exclusion chromatography the pore structure of the stationary (solid) phase is thus known; what is to be determined is the molecular-weight distribution of the polymer mixture dissolved in the eluent.

Surprisingly, the inverse procedure—*i.e.* the determination of the pore-size distribution of a rigid solid by means of exclusion chromatography—has not yet been reported. In this method the molecular weights of the "monodisperse" polymers are known.

3. Boundary Conditions of the Method

In what follows we assume that for a given column geometry and pore structure of the packing the elution volume V_e of a test material is a function only of the molecular size of this test material. However, this can only be a justifiable assumption if the following essential boundary conditions are fulfilled:

1) The test material is not adsorbed on the solid surface.
2) There is a reversible "quasi"-distribution equilibrium[26] of the test material between the flowing eluent and the eluent held within the pores of the solid packing. This equilibrium is established instantaneously, provided that the linear flow velocity of the eluent is sufficiently small and that the column is not overloaded with the test material.
3) The probability that the test material is present in the flowing eluent or in the stagnant eluent inside the pores is proportional to the volume of the flowing eluent (interstitial volume) and to the pore volume accessible to the test material. This is equivalent to saying that the Bunsen distribution coefficient between the two phases is unity.
4) The elution peak approximates closely to a Gaussian curve.
5) The matrix of the solid is rigid. It neither swells nor shrinks, and the solid's pore-size distribution is not affected by changes in the eluent or in the eluent pressure.

In addition, there is a necessary boundary condition that the working temperature and the flow velocity of the eluent are kept constant, and that sample injection is instantaneous.

The condition that no adsorption of the test material occurs from a number of eluents could be demonstrated experimentally for polystyrene standard and silica gels from various sources. Within the limits of experimental error, the elution volumes of benzene or polystyrene samples were independent:

a) of the flow velocity of the eluent (1—5 mm/s, for particle sizes of the solid smaller than 100 μm);
b) of the sample concentration at the column inlet (*i.e.* independent of the sample volume), provided that the column was not overloaded and that the sample concentration in the eluent was less than about 300 ppm;
c) of the eluent polarity (dichloromethane, chloroform, tetrahydrofuran, dimethylformamide), even though the dielectric constants of these eluents differ widely;
d) and of whether the samples were started and run individually or as a mixture. This made it possible to largely exclude the mutual interactions of the polymer molecules.

Other authors[27] had already pointed out that no measurable molecular-weight-dependent adsorption of polystyrene samples (standard) occurred on polystyrene gels with chloroform (at 35°C) or *o*-dichlorobenzene (at 87°C) as the eluent.

4. Experimental Conditions

The basic principles, apparatus, and measurement method of exclusion chromatography[13, 28] are almost identical with those in high-pressure liquid chromatography[29, 30]. In the work described here, for example, the following components were set up in series: a high-pressure pump with a constant flow rate (M 6000, Waters Associates, Inc., Milford, Ma., USA), a sample injector (U6K, Waters Associates, Inc.) for sample volumes between 0.5 μl and 2 ml, a stainless steel tube (separation column)[31] with a drilled-out internal diameter of 4.2 mm, and a UV detector of our own design (254 nm, cell volume 10 μl)[31] (see also [32]). All the measurements were carried out at room temperature.

The flow rate through the pump was constant to $\pm 1\,\%$ during the longest elution times. By measuring the breakthrough (elution) times t_e of the individual samples it was possible to determine the elution volumes V_e with an accuracy of $\pm 1\,\%$ or better.

The column is packed with the solid whose pore-size distribution is to be determined. In order to achieve a sufficiently homogeneous packing density along the column, experience has shown that the column should be packed wet[31,33–35] for a mean particle size $d_p < 20\,\mu m$ and dry[36,37] for particles with $d_p > 20\,\mu m$[36,37]. The sieve fractions of the solid may be relatively broad: the lower limit may be 40 % below and the upper limit 40 % above the arithmetic mean of the sieve fraction. Thus, a sieve fraction of 30 to 70 µm is acceptable. The column length required (30 to 100 cm) decreases with decreasing particle size. The column must be designed in such a way that it corresponds to at least 200 (and preferably 500) theoretical plates n[13]. Experience has shown that it is best to pack the columns with sieve fractions whose arithmetic mean lies between 25 and 80 µm. If the particles are smaller they should be packed wet, if they are larger then the column should be made longer than 1 m (because the increased particle size reduces the number of theoretical plates) and the linear velocity of the eluent be reduced (because of the longer diffusion distances). The elution times are thus extended.

The standard test materials were benzene and polystyrenes with various degrees of polymerization in dichloromethane (1—10 mg/ml). The polydispersity ($\bar{M}_w/\bar{M}_n$)[38] of the polystyrenes (Waters Associates, Inc.), where $\bar{M}_w$ and $\bar{M}_n$ are the weight-average and number-average molecular weights, had an average value of around 1.1[27].

The standards were applied to the separation column packed with the solid either singly or in combination (*ca.* 1 µl of solution per component) and the elution volumes were determined. The elution volume is defined by the peak maximum. This requires that the peak be symmetrical; an asymmetry factor As[2][31] smaller than 2 is required. Peak asymmetry may be caused by

- a poor column packing,
- an insufficient number of theoretical plates,
- excessive sample volume (overloading of the column),
- adsorption of polystyrene on the solid packing, and
- an impermissibly high polydispersity of the polystyrene.

The calibration series was made up using polystyrenes of known molecular weight, since these polymers are commercially available from several sources within a wide range of $\bar{M}_w$ (600—3 700 000) and with low polydispersity.

Dichloromethane or chloroform (in exceptional cases tetrahydrofuran or dimethylformamide) were used as the mobile phase (eluent). The relative humidity of the eluents must be below 60 %, as erroneous values may otherwise be obtained because a proportion of the pores is filled with water[39]. When dimethylformamide is used as the eluent a differential refractometer (Waters Associates, Inc., cell volume 10 µl) should be used in place of the UV detector. In series measurements the linear velocity of the benzene sample is between 0.1 and 0.5 cm/s (0.7—3.5 cm^3/min). The pressure drop required to attain this velocity is less than 100 atm. As the flow velocity increases, the number of theoretical plates becomes smaller and the bands may become asymmetric. For a given sieve fraction and column length, the eluent flow velocity used is the highest at which the bands of all the test substances still remain sufficiently symmetrical.

5. Principles of the Method[*]

A portion of the eluent in the separation column fills the voids between the particles of the packing (the interstitial volume V_z) and passes through the column in the axial direction.

The volume fraction V_p is the pore volume, *i.e.* the volume of eluent that has penetrated the pores of the solid. A ϕ-value was assigned to all the polystyrenes of the calibration series (standard) and benzene. This magnitude ϕ [Å] defines the smallest pore diameter into which a standard sample of molecular weight M_i can diffuse "unhindered". The distribution equilibrium between the flowing eluent and the eluent present in the pores is then set up instantaneously.

Naturally, none of the molecules of the standard material of molecular weight M_i can penetrate pores with diameters smaller than ϕ_i. This means that the ϕ-values should be regarded as "exclusion values".

If the molecules of the standard are too large to enter the pores, they pass axially through the column with the linear velocity of the moving eluent. The elution volume of such a standard will be the smallest of all possible elution volumes ($V_{e,min}$). Since in the method described here we work with a homologous series of standard materials, an increase in the molecular weight $\bar{M}$ results in an increased ϕ-value

[*] The most commonly used symbols are listed below:

d_p	mean particle diameter of a disperse solid
ε_c	volume fraction of closed pores in a separation column
ε_p	pore-porosity; fraction of the pore volume in a separation column
ε_s	fraction of the solid skeleton volume in a separation column
ε_T	total porosity; volume fraction of the separation column occupied by the eluent
ε_z	interstitial porosity; fraction of the interstitial volume in a separation column
F	flow rate of the eluent
m	mass of the solid packing in a separation column
$\bar{M}_n$	number-averaged molecular weight
$\bar{M}_w$	weight-averaged molecular weight
n	number of theoretical plates in a separation column
O_{sp}	specific surface
ϕ	pore diameter (assuming the pores to be cylindrical); also the exclusion value of a polymer standard
$\bar{\phi}$	geometric mean of the exclusion values of two consecutive standards in the calibration series
ϕ_m	mean pore diameter (calculated assuming a log-normal distribution)
ϕ_r	calculated coil diameter of a polymer standard
ψ	void fraction; volume ratio of open pores to the nominal solid volume (solid + pores)
R	sum of residues; fraction of the total pore volume accessible to a molecule with an exclusion value of ϕ.
ρ_s	true density of the solid
t_e	elution time, breakthrough time of a polymer standard
u	cross-section-averaged linear velocity of the eluent
V_c	volume of pores inaccessible to the eluent
V_e	chromatographic elution volume of a polymer standard
$V_{e,max}$	maximum elution volume in a calibration series (elution volume of the standard with the lowest molecular weight)
$V_{e,min}$	minimum elution volume in a calibration series (elution volume of the standard with the highest molecular weight)
V_k	volume of the empty separation column
V_p	pore volume; volume of eluent that has penetrated the pores
$V_{p,s}$	specific pore volume; = pore volume per gram of the solid
V_s	skeletal volume of the solid (without the pore volume)
V_z	interstitial volume; volume of eluent flowing in the axial direction

of the polymer. In accordance with this nomenclature we obtain $V_{e,min}$ with $\bar{M}_{max}$ and ϕ_{max}. The largest elution volume $V_{e,max}$ corresponds to the standard sample with the lowest molecular weight ($\bar{M}_{min}$) and the smallest exclusion value (ϕ_{min}).

The volume of the empty separation column V_k is the sum of the volume of the solid skeleton V_s, the volume V_c which represents the pores inaccessible (closed) to the eluent, the interstitial volume V_z, and the pore volume V_p (see above):

$$V_k = V_z + V_p + V_s + V_c \tag{3}$$

The volume V_k is readily determined from the column geometry. It follows from the above definitions that V_z must be determined by:

$$V_z = V_{e,min} \tag{4}$$

According to eq. (4), the volume of pores with a diameter greater than ϕ_{max} is contained in the interstitial volume V_z. The V_z values determined by size exclusion chromatography may therefore be larger than those obtained by mercury porosimetry.

The rule for the determination of the total pore volume V_p likewise follows from the definitions given above:

$$V_p = V_{e,max} - V_{e,min} \tag{5}$$

By using standards of arbitrary $\bar{M}$ and ϕ-values between the two limits it becomes possible to determine the pore-size distribution of rigid solids. For example, determination of the evolution volumes of two standard samples with molecular weights $\bar{M}_1$ and $\bar{M}_2$ (where $\bar{M}_1 < \bar{M}_2$) gives the relationship $\Delta V = V_{e,1} - V_{e,2}$. ΔV is the volume of the pores within the column that have a diameter greater than ϕ_1 and smaller than ϕ_2.

The total pore volume of the solid, V_p, is determined by at least three parallel measurements in which standards with $\bar{M}_{min}$ ($V_{e,max}$) and $\bar{M}_{max}$ ($V_{e,min}$) are initially injected into the column together. The elution time t_e and the flow velocity F are measured at the same time. The reproducibility of the elution volume for benzene ($V_{e,max} = F \cdot t_{e,max}$) must be better than $\pm 1\,\%$. The subsequent measurements with the remaining standards are referred to $V_{e,max}$, which enables one to do without the rather cumbersome measurement of the flow velocity in subsequent determinations. Benzene is injected simultaneously with each polystyrene standard mixture and its elution time $t_{e,max}$ is used for normalization. How many standards may be injected simultaneously depends on the sharpness of the separation (number of theoretical plates n). The elution volumes of the standards are generally determined by taking the mean value from several chromatograms. The accuracy of the elution volumes—especially that of their differences—measured in this way is better than $\pm 0.5\,\%$.

The skeletal volume V_s is calculated from the mass m of the solid material in the column and from its true density ρ_s. The true density of a solid may be determined, for example, volumetrically with helium or by X-ray diffraction[40].

Finally, V_c (the volume of the closed pores) may be calculated from eq. (3). The value of V_c is subject to relatively large error due to small differences between large numbers. Experience has shown that the calculation of V_c is meaningful only when V_c/V_k is greater than 0.05.

The results become rather more general if use is made of the ratio of volumes (the porosity ε) in place of the volumes themselves:

$$\varepsilon_i = V_i/V_k \tag{6}$$

For example, the interstitial porosity $\varepsilon_z = V_z/V_k$ is the fraction of the free column cross-section area available to the eluent flowing in the axial direction. The pore porosity $\varepsilon_p - V_p/V_k$ is the pore volume relative to the volume of the empty column. The total porosity

$$\varepsilon_T = \varepsilon_z + \varepsilon_p \tag{7}$$

is the fraction of the free column cross-sectional area occupied by the flowing eluent and the eluent present within the pores.

In order to make the values independent of the column packing dimensions, we introduce the void fraction ψ[21]:

$$\psi = \frac{\varepsilon_p}{1-\varepsilon_z} \tag{8}$$

The void fraction expresses the proportion of the total solid volume contributed by the pores. The mass m of the solid in the column may be calculated from:

$$m = (1-\varepsilon_T-\varepsilon_c)\rho_s V_k \tag{9}$$

Neglecting the volume of the closed pores ($\varepsilon_c = 0$),

$$m \approx (1-\varepsilon_T)\rho_s V_k \tag{9a}$$

However, eqs. (9) and (9a) should be used with considerable caution, because $(1-\varepsilon_T-\varepsilon_c)$ and $(1-\varepsilon_T)$ are small differences between large numbers. The mass of solid m may be determined with much greater accuracy if the column packing is carefully removed at the end of the measurements, dried, and weighed. From the value of m, we can obtain ε_c by means of eq. (9). The greatest source of error lies in the fact that the true density ρ_s of the solid is very seldom accurately known. The true density of silica gel is around $2.3\,g/cm^3$. If an error of $\pm 10\,\%$ in ρ_s is accepted, the error in the determination of the closed-pore volume (V_c) is smaller than $\pm 2\,\%$, since the skeletal volume V_s as determined using ρ_s ($V_s = m/\rho_s$) is generally less than 20 % of the column volume V_k. In some silica gels V_c was up to 9 % of the column volume V_k and up to 30 % of the total pore volume V_p.

6. The Calibration Curve

The elution volumes V_e of the polystyrene standards of the calibration series were determined on several silica gels

whose relatively narrow pore-size distributions had been determined in other laboratories by the classical methods[*].

Exclusion values (pore diameters ϕ) were now assigned by trial and error to the standards of the calibration series, in such a way that the maxima of the pore-size distribution curves as measured by exclusion chromatography agreed with the values obtained by "classical" measurements.

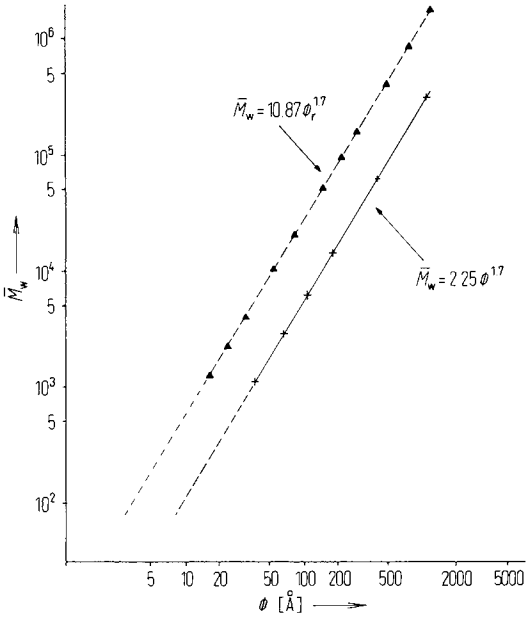

Fig. 1. Calibration curve (——) for the assignment of molecular weights $\bar{M}_w$ of the standards to exclusion values (=pore diameters) ϕ of silica gels. The calibration curve was obtained by comparing the maxima of the pore-size distribution measured by SEC (standards: polystyrenes and benzene; eluent: CH_2Cl_2; solid: various silicas and porous glasses) and the maxima determined by "classical" methods. (– – – –) Correlation of the $\bar{M}_w$ of polystyrene and the coil diameter ϕ_r in THF (after measurements by *Kreveld* and *van den Hoed* [21]).

If $\log\bar{M}_w$ is plotted against the $\log\phi$ values thus obtained (Figure 1; continuous line), then the points are found to lie on a straight line closely described by the equation

$$\bar{M}_w = 2.25\,\phi^{1.7} \tag{10}$$

where ϕ is expressed in Å. Eq. (10) gives ϕ to good approximation as:

$$\phi\,[\text{Å}] \simeq 0.62(\bar{M}_w)^{0.59} \tag{11}$$

According to eq. (11), benzene was arbitrarily assigned an exclusion value of $\phi = 8.1$ Å. Strictly speaking, the numerical values given in eqs. (10) and (11) are valid only for dichloromethane, but they should also be good approximations for other "good" solvents. The first two columns of Table 1 give the molecular weights $\bar{M}_w$ for polystyrene of the calibration series and the ϕ-values assigned by means of the calibration line.

Table 1. Pore diameters (=exclusion values) ϕ assigned to the benzene and polystyrene standards, elution volumes V_e, and the sum of residues R. Solid: Merckogel SI 100; sieve fraction 7–11 µm; $V_k = 4.717\,cm^3$; $\varepsilon_p = 0.382$; $\varepsilon_c = 0.047$; $\psi = 66.4\,\%$; $\varepsilon_z = 0.423$; $\varepsilon_T = 0.805$; $\varepsilon_s = 0.147$; $m = 1.59$ g.

Polystyrenes are linear polymers which in solution may be regarded as random coils. On the basis of polymer-statistical considerations[41] and the results of light-scattering measurements[42], *Kreveld* and *van den Hoed*[21] tabulated the calculated coil diameters ϕ_r for polystyrenes in tetrahydrofuran (THF). Fig. 1 shows a log-log plot of $\bar{M}_w$ *vs* ϕ_r. The broken straight line may be described by the equation:

$$\bar{M}_w = 10.87(\phi_r)^{1.7} \tag{12}$$

Since THF is considered a "good" solvent, just like dichloromethane, one would expect similar ϕ-values for the latter.

It may be seen from Eqs. (10) and (12) that the pore diameter ϕ of a solid assigned by us to a standard polystyrene of molecular weight $\bar{M}_w$ is 2.5 times as large as the coil diameter ϕ_r of molecules of the same polystyrene[21]. To put it in another way, the rotational coil diameters ϕ_r must be some 2.5 times smaller than the diameter of the pores in the solid to allow the polymer unhindered access to the pores (*i.e.* to enable "instantaneous equilibrium" to be achieved). The actual numerical value of this factor is open to discussion. *Cantow* and *Johnson*[15] had pointed out earlier that the factor should be 2 or more. The work of *Verhoff* and *Sylvester*[43] suggests a factor of 2.5[44]. Measurements on a porous glass have yielded a factor of 2 to 2.5[45,46]. On the other hand, *Yau et al.* state in the same publication[46] that "the shape of the GPC calibration curve for flexible polymer molecules is different from the pore size distribution curve of the packing".

[*] "Merckogels" (E. Merck AG, Darmstadt) with most frequent pore diameters (pore volume maxima) of around 60, 100, 200, 500, and 1000 Å and sieve fractions of around 10 µm; CPG-10 (Controlled Pore Glass, Serva, Heidelberg) with most frequent pore diameters of around 75, 170, 500, 1000, and 2000 Å and sieve fractions of 37—74 µm; silica gels prepared by Prof. *K. Unger* (Eduard-Zintl-Institut, Technische Hochschule Darmstadt) and in our own laboratory, with sieve fractions of around 10 µm. In the CPG-10 series only the most frequently occurring pore diameters were known, while the complete pore-size distribution curves had been available for the other products.

7. Determination of the Specific Surface of Silica Gels

Assuming that the pores are cylindrical and continuous (*i.e.* open at both ends), the specific surface O_{sp} is given by:

$$O_{sp}[cm^2/g] = \frac{4\,V_{p,s}[cm^3/g]}{\phi_m[cm]} \tag{13}$$

where $V_{p,s}$ is the specific pore volume and ϕ_m the mean pore diameter calculated from the Gaussian distribution. If the pores are not all open, the error in the specific surface is less than 5 %, provided that the cylindrical pores are 5 times as long as their diameters.

For the sake of convenience eq. (13) is written in the form:

$$O_{sp}[m^2/g] = \frac{40\,V_{p,s}[\mu l/g]}{\phi_m[\text{Å}]} \tag{13a}$$

If the results of measurements by SEC are compared with the BET surfaces[1], it is our experience that the discrepancy is less than 5 %, at least for silica gels with $O_{sp} > 300\,m^3/g$. For silica gels with smaller specific surfaces the available measurements are still insufficient.

8. Experimental Results

Figure 2 illustrates the determination of elution volumes on a particularly favorable example. The pore volume of the silica gel used here was unusually high ($2.07\,cm^3/g$) and the particle diameter was small (10–15 μm). About 3000 theoretical plates were obtained for benzene in a separation column 30 cm in length. It was thus possible, in this case, to determine the elution volumes of seven components in a single measurement. In routine determinations benzene and one or two of the 12 polystyrene standards are injected simultaneously. The determination of the 13 elution volumes in duplicate takes about an hour under routine conditions.

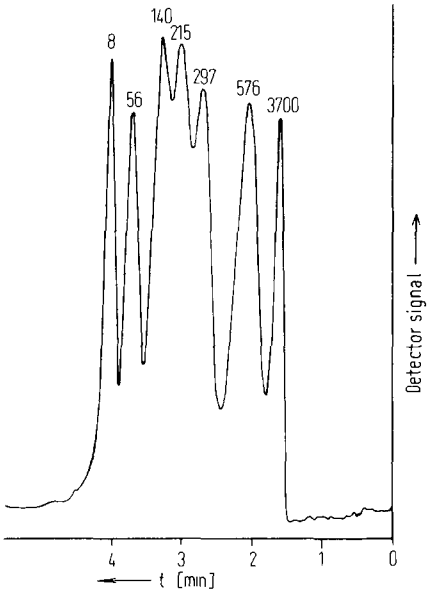

Fig. 2. Elution volumes V_e of some polystyrene standards on silica gel. The peaks are characterized by the assigned values of pore diameter ϕ [Å]. Solid: silica gel (Prof. *Unger*, Darmstadt, 733 Hk 4b): specific surface O_{sp}: $285\,m^2/g$; pore volume: V_{sp}: $2.07\,cm^3/g$; $\varepsilon_z = 0.37$; $\varepsilon_p = 0.55$; sieve fraction: 10–15 μm; packing density: $0.266\,g/cm^3$. Column: internal diameter 4.34 mm, length 30 cm, volume of empty column $V_k = 4.43\,cm^2$.—Eluent: dichloromethane. $\Delta p = 22$ atm; $u = 1.25$ mm/s.—Amount of sample per component: 0.5–1 μg (0.5–1 μl of solution in CH_2Cl_2); UV detector (254 nm): full scale deflection $= 4 \times 10^{-2}$ extinction units; number of theoretical plates for benzene: 3000.

The record of a typical run is reproduced in the first three columns of Table 1. Based upon the standards available, only the pores with an entrance diameter of more than 8 Å and less than 4530 Å are included in the total pore volume. Table 1 enables us to calculate a pore volume $V_p = (3802 - 1997) = 1805\,\mu l = 1.805\,cm^3$, and a porosity $\varepsilon_p = 1805/4717 = 0.38$. Similarly, the ε_z of the sample with the highest molecular weight ($\phi = 4530$ Å) was found to be $1997/4717 = 0.42$ from the elution volume. ε_c was calculated with the aid of eq. (9). It follows from eqs. (3) and (6) that:

$$\varepsilon_z + \varepsilon_p + \varepsilon_c + \varepsilon_s = 1 \tag{14}$$

ε_s was calculated by means of this equation and the void fraction ψ was obtained from eq. (8). The specific pore volume follows from $V_{p,s} = V_k \varepsilon_p / m$. In order to facilitate checking, Table 1 gives the calculated values with an accuracy greater than the limits of error of the SEC method permit.

9. Possible Methods of Presentation of the Pore-Size Distribution

Experience has shown that the pore-size distribution of many solids may best be illustrated by a log-normal distribution curve. Figure 3 shows a plot of the sum of residues R (column 4 in Table 1) as a function of $\log\phi$ (calculated according to column 2).

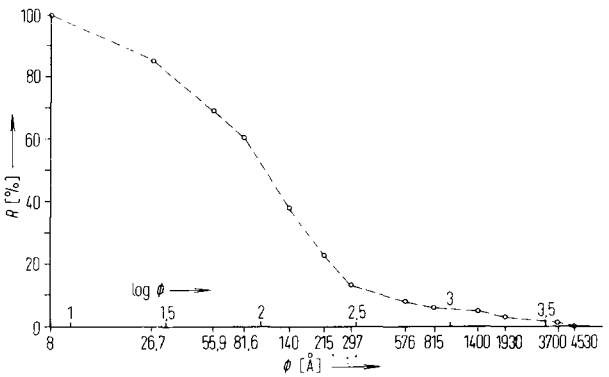

Fig. 3. Sum of residues distribution of the pore diameters of Merckogel SI 100 silica gel (integral distribution curve). For the parameters see Table 1 (see text).

The sum of residues R of a given pore diameter ϕ_i is defined as the fraction of total pore volume V_p formed by all the pores with a diameter greater than ϕ_i. A sum of residues of 38.1 % at a pore diameter of 140 Å, for example, means that the volume of pores whose diameter exceeds 140 Å constitutes 38.1 % of the total pore volume. Figure 3 may also be regarded as an integral distribution curve.

From the values of ΔR (column 6 of Table 1) we may, for example, read off that 15.6 % of the total pore volume should be assigned to pores whose diameter ϕ is between 140 and 215 Å. Because of the log-normal distribution this

pore volume is by definition assigned to the geometric mean value of 140 and 215 Å ($\phi = 173$ Å). The ϕ-values corresponding to ΔV_e are found in the last column of Table 1. The absolute frequency may be represented by a plot of ΔV_e against $\log\bar{\phi}$.

In the present calibration series with polystyrene standards the distances between $\log\bar{\phi}$ and the ratio of the ϕ-values are comparatively large and not equal. For this reason we present the relative frequency by plotting

$$100 \times \frac{\Delta V_e}{V_p} / \Delta \log\phi$$

against $\log\phi$; such a "difference distribution curve" has greater information value[47]. Figure 4 (broken line) shows the relative frequency of the pore diameters for a silica gel.

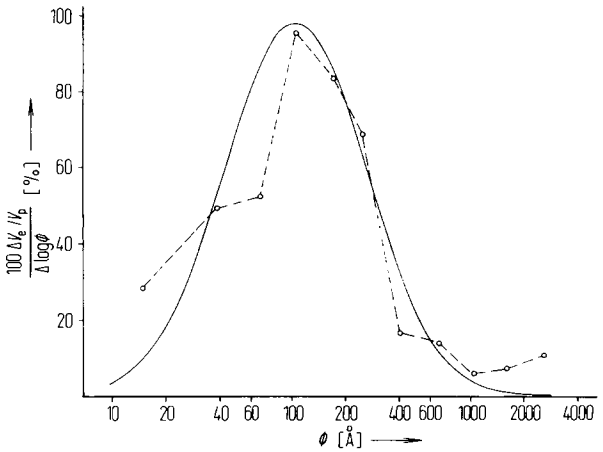

Fig. 4. Relative frequency (---) of the pore diameters of Merckogel SI 100 silica gel (difference distribution curve). (——) Gaussian curve obtained by evaluation of Fig. 5. For the parameters see Table 1.

By introducing the sum of residues R as a function of $\log\phi$ (plot on probability graph paper) one obtains a straight line by means of which it is possible to calculate the mean pore diameter ($\log\phi_m$) and its standard deviation ($\log\sigma$). Such presentation (Figure 5) enables us to determine $\log\phi_m = 2.02$

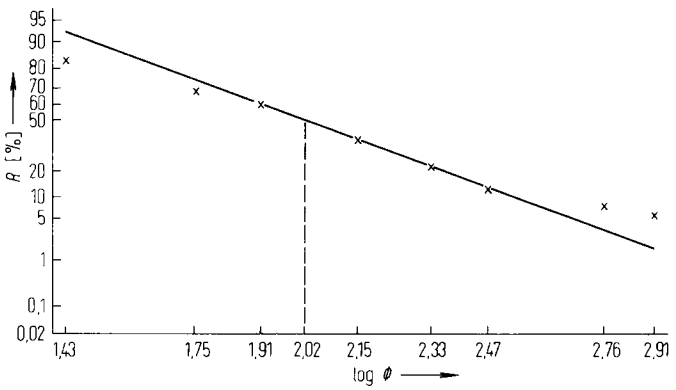

Fig. 5. R and $\log\phi$ (measured values taken from Table 1) for Merckogel SI 100 silica gel, plotted on probability paper.

and $\log\sigma = 0.40$ for Merckogel silica gel (SI 100). The mean pore diameter ϕ_m is thus 105 Å. The Gaussian curve calculated on the basis of these values is likewise shown in Figure 4 (continuous line). The small scatter of the values around the straight line in the probability plot (Figure 5) indicates that the assumption of a log-normal distribution is an acceptable approximation. The calculation of the mean pore diameter from the differential distribution curve gave a value of 107 Å. Such good agreement of the ϕ_m-values must be regarded as fortuitous.

Experience has shown that the deviations may amount to 30%. This will be illustrated by means of an example. Figure 6 shows the relative frequency and the Gaussian curve

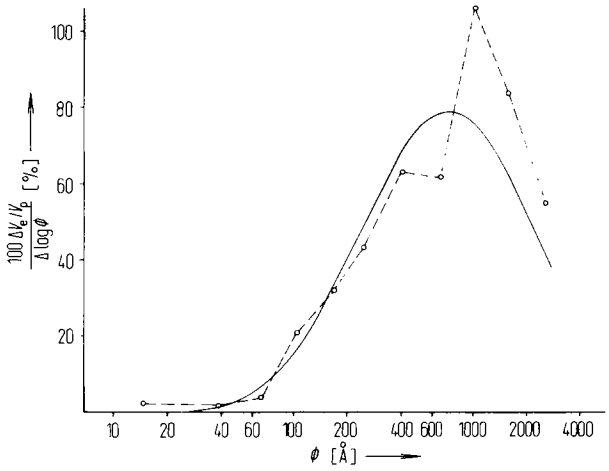

Fig. 6. Relative frequency (---) of the pore diameters of Merckogel SI 100 silica gel. Pore volume V_{sp}: 0.80 cm³/g, $\varepsilon_z = 0.443$; $\varepsilon_p = 0.365$; sieve fraction: 10 µm; packing density: 0.46 g/cm³. Experimental conditions as in Fig. 2. (——) Gaussian curve.

for the pore diameters of a silica gel with large pore diameters. Values of 1070 and 741 Å were obtained here for the mean pore diameter ϕ_m, indicating that in this case the log-normal distribution is only a very rough approximation. It is not impossible that the pore structure had been formed here by two different processes. When comparing the two areas between the limits of 14.7 and 2670 Å, we should note that the difference curve (broken line) within these limits has been normalized to 100, while the Gaussian curve is normalized to 100 between $-\infty$ and $+\infty$.

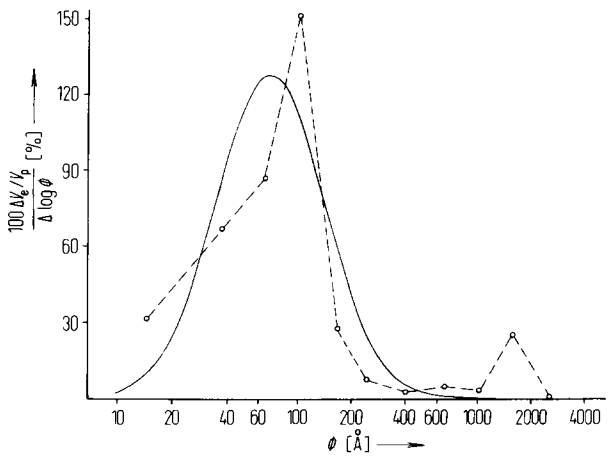

Fig. 7. Relative frequency (---) of the pore diameters of Controlled Pore Glass CPG-10-75 Å; pore volume V_{sp}: 0.50 cm³/g; $\varepsilon_z = 0.444$; $\varepsilon_p = 0.313$; sieve fraction: 37—74 µm; packing density: 0.62 g/cm³. Column length 30 cm. Number of theoretical plates for benzene: 220 at $u = 3.2$ cm/s. (——) Gaussian curve.

In order to illustrate the wide applicability of the method, Figure 7 shows the pore-size distribution of a porous glass. The specific pore volume is here small (0.50 cm^3/g) and the material was available only in the form of a relatively coarse fraction (37—74 μ). The mean pore diameter taken from the Gaussian curve ($\phi_m = 72$ Å) is in good agreement with the value of 84 Å given by the manufacturer. This example also points to some limitations of the method. At a linear eluent velocity of 32 mm/s the 30 cm long separation column has no more than 220 theoretical plates for benzene. Despite the relatively broad elution bands, it was possible to determine the elution volumes V_e in an entirely acceptable manner.

10. Concluding Remarks

The exclusion chromatography method described here allows a quick and simple determination of many morphological properties of solids. The measurements may be carried out under the usual conditions of application of the solids, *e.g.* in catalysis or chromatography. Extremely high pressures and low temperatures are unnecessary. In contrast to the classical methods, the SEC method enables us to determine the pore-size distribution within the entire range of (so far) 10 to 4000 Å.

There is excellent experimental agreement with the results for the specific pore volumes and the mean pore diameter ϕ_m obtained by classical methods, while the agreement with respect to the specific surface is adequate.

Experience has also shown that, for a given solid, capillary condensation, the mercury porosimetry, and the SEC method yield increasingly broad pore-size distributions. This seems to be due to the different boundary conditions of these methods and will not be discussed here.

The SEC method is applicable only if the solid to be investigated can be packed into a separation column and if sorption of the polymer standards can be excluded.

The SEC method has so far been applied to silica gels, porous glasses, aluminum oxides, and tungsten oxides[8]. Preliminary experiments suggest that the method may also be used for the determination of the pore-size distribution in swollen solids such as polystyrene gels. In such cases the pore structure may be a function of the swelling liquid. No such measurements are possible by the classical methods.

The authors are indebted to the Deutsche Forschungsgemeinschaft for supporting this work.

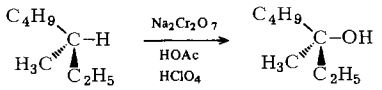
Superacid-Catalyzed Oxygenation of Alkanes[1]

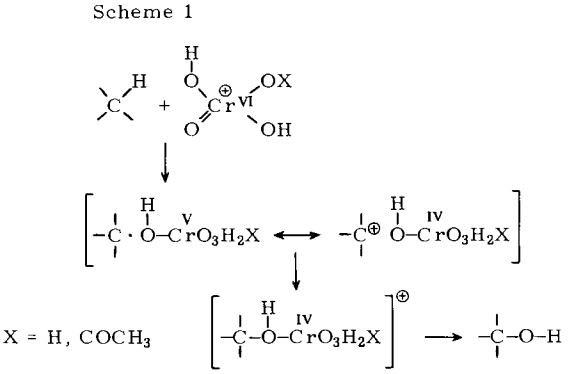
By Georg A. Olah, David G. Parker, and Norihiko Yoneda[*]



New synthetic methods (26)

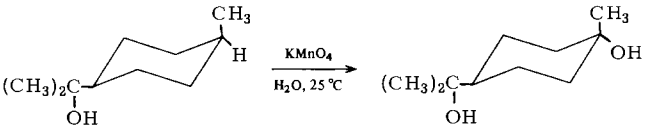
Owing to the ready availability of the starting materials, the functionalization of saturated hydrocarbons for preparing chemical intermediates and products represents an attractive goal. The possibility of converting alkane in a controlled way into alcohols, ketones *etc.*, *i.e.* to oxyfunctionalize them, is particularly challenging. After a short account of previous methods used for the oxidation of alkanes, particular emphasis will be given to recently developed reactions of alkanes with oxygenating agents in superacidic media.

1. Older Methods of Oxidation



1.1. Chromic Acid Oxidations

Chromic acid has found wide applicability as an oxidizing agent in organic chemistry[2]. Its reactions with alkanes has been extensively studied, and its selectivity in attacking tertiary C—H bonds forms the basis of the Kuhn-Roth determination of the number of *C*-methyl groups in a molecule[3]. Essentially this procedure consists of oxidizing the substrate molecule with hot chromic acid, and from the resultant mixture acetic acid and higher homologues are recovered. The yields of these acids give a measure of the number of *C*-methyl groups present. The original method has undergone a number of modifications[4], for example addition of vanadium pentoxide or manganese(II) sulfate in the oxidation[5]. Although it has largely been superceded by instrumental methods such as NMR spectroscopy, it still finds application where spectroscopic analysis is difficult[6]. Under less severe conditions tertiary C—H bonds yield tertiary alcohols, and a high degree of stereospecificity has been observed, as exemplified by the oxidation of 3-methylheptane[7], which occurs with 70—85% retention of configuration.



The rate of oxidation of paraffins is largely independent of structure. Steric hindrance only affects rates in highly shielded branched hydrocarbons such as 2,2,4-trimethylpentane[8], while from a study of various alkyl-substituted cyclohexanes steric acceleration was shown to play no role[9]. The relative rates of oxidation of primary : secondary : tertiary hydrogen atoms in $CH_3:CH_2:CH$ were determined as 1:114:7000–18000, and it was proposed[8] that the rate determining step involved hydride anion transfer from the hydrocarbon to the chromium(VI) complex. An alternative explanation involved the intermediacy of a radical and chromium(V) species. However, the reaction is perhaps best regarded as proceeding *via* the intermediacy of a resonance hybrid of these two complexes[9] (Scheme 1).

Scheme 1

1.2. Permanganate Oxidations

Permanganate solutions have also been extensively used as oxidizing agents[2], but they do not react like chromic acid with alkanes. For the oxidation of (4-methylcyclohexyl)-2-propanol in alkaline permanganate solution it appears that the tertiary hydroxyl group of the starting material is essential for reaction[10].

1.3. Lead(IV) Oxidations

Lead(IV) compounds have also been used for oxidizing alkanes. Thus heptane on treatment with lead(IV) trifluoroacetate is converted in 45±10% yield into trifluoroacetic acid esters[11], whilst lead(IV) acetate in trifluoroacetic acid/dichloromethane readily oxidizes bridgehead hydrocarbons[12]. With the latter reagent 94% 1-adamantanol was obtained from adamantane, after hydrolysis of the initially formed ester.

1.4. Cobalt(III) Oxidations

Cobalt(III) compounds have also been shown capable of functionalizing alkanes. Although cobalt(III) acetate in acetic acid is only slowly reduced in the presence of heptane, addition of a stronger organic or inorganic acid to the system causes rapid reduction of the cobalt(III) ion with concomitant oxidation of the alkane substrate. The products obtained from this reaction are different according to whether oxygen is

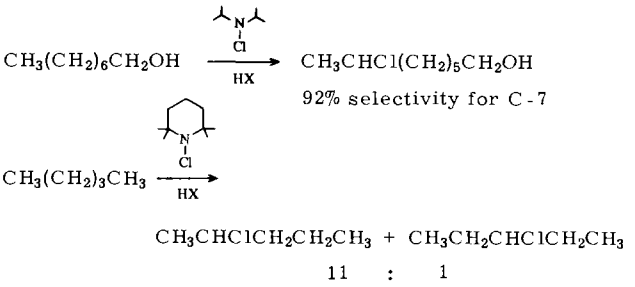
present or not. Under nitrogen, acetic esters of heptanols are formed, whereas ketones are the principal products if oxygen is present[13].

Table 1. Oxidation of heptane with $Co(OAc)_3/HOAc/H_2SO_4$; attack at C-1, C-2, C-3, or C-4.



Atmosphere	Yield	Isomer Distribution			
		C-1	C-2	C-3	C-4
N_2	69% acetates	0	64	27	9
O_2	69% ketones	0	60	27	13

The mechanism is believed to involve initial attack by cobalt(III) on the alkane to give reversibly cobalt(II) and an alkyl radical. Cobalt(III) was quantitatively reduced to cobalt(II) within 23 hours at 30°C. However, only 1/3 equivalent of oxidized product was found[14].

$$c\text{-}C_6H_{12} + 2Co(O_2CCF_3)_3 \rightarrow c\text{-}C_6H_{11}O_2CCF_3 + 2Co(O_2CCF_3)_2 + CF_3CO_2H$$
35%

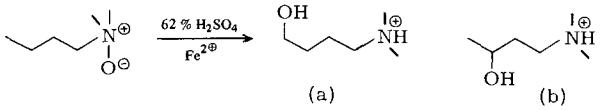
1.5. Chloramine Reactions

Highly selective free-radical chlorinations have been achieved with *N*-chloroammonium ions. The degree of selectivity can be modified by both polar and steric effects; exemples are, respectively, the reaction of 1-octanol[15] and the reaction of pentane[16].

1.6. Amine Oxide Reactions

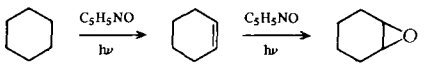
In an analogous reaction *Deno* has successfully oxygenated alkanes using amine oxides[17]. Cyclohexane was oxidized by equimolar amounts of Et_2NOH or Et_3NO in trifluoroacetic acid in the presence of iron(II) ions. Cyclohexyltrifluoroacetate was isolated as the sole reaction product (25% yield). Both polar and stereoselectivity effects are observed. Thus, oxidation of octyltrifluoroacetate with Et_2NOH gave 10% of bis-esters, with oxidation at C-7 accounting for 72% of the product distribution illustrating the polar effect. Selectivity for C-7 was greater with Et_3NO, thus demonstrating the steric effect. A reaction mechanism was proposed in which an alkyl radical is converted into the ester product *via* an encumbered carbonium ion formed by Fe(III) oxidation (Scheme 2).

Scheme 2



$$R_3NOH^{\oplus} + Fe^{2\oplus} \rightarrow Fe^{3\oplus} + R_3N^{\bullet\oplus} + OH^{\ominus}$$

$$R_3N^{\bullet\oplus} + R'H \rightarrow R_3NH^{\oplus} + R'^{\bullet}$$



$$R'^{\bullet} + Fe^{3\oplus} \rightarrow Fe^{2\oplus} + R'^{\oplus}$$

$$R'^{\oplus} + CF_3CO_2H \rightarrow CF_3CO_2R' + H^{\oplus}$$

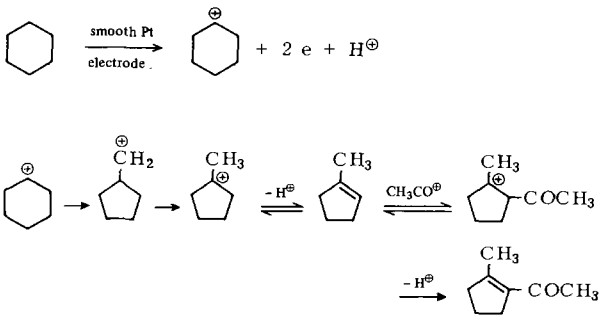
Presumably the intermediate carbonium ions are encumbered, either by solvent relaxation during formation or by a Fe—R^+ interaction. It was argued that such an encumbered carbonium ion would account for *Norman*'s observation of a primary alcohol (a) in the reaction[18]; a free carbonium ion would lead to total rearrangement to the secondary alcohol (b).

Another example of an amine oxide oxidation is the photolysis of pyridine-*N*-oxide in the presence of cyclohexane[19]. Interestingly, the initial step involves a dehydrogenation of cyclohexane to cyclohexene and is followed by epoxidation.

Parallels between these radical/carbocation oxidations and enzymic oxidations have been drawn and an excellent review discussing this topic has been published[20].

1.7. Electrochemical Oxidations

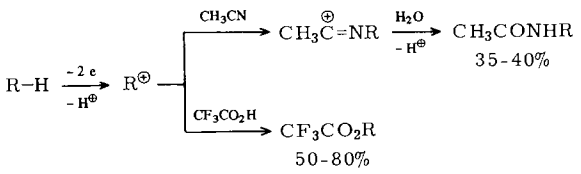
In recent years a new area of study for alkane oxidation—the electrochemical oxidation—has evolved, and has rapidly developed into a potentially very useful synthetic technique. *Fleischmann* and *Pletcher* found by using tetrafluoroborates or hexafluorophosphates as inert electrolytes, instead of more common salts, that it was possible to extend the electrochemical potential range in acetonitrile; at the anodic limit this enabled the study of aliphatic hydrocarbons containing weak (*e.g.* tertiary) C—H bonds[21]. They proposed the following reaction path:



$$RH \rightarrow R^{\oplus} + H^{\oplus} + 2\,e$$

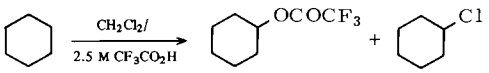
$$R^{\oplus} + CH_3CN \rightarrow CH_3\overset{\oplus}{C}{=}N{-}R \xrightarrow{H_2O} CH_3CONHR + H^{\oplus}$$

Use of fluorosulfuric acid as a solvent medium extended the range of C—H bonds that could be oxidized[22]. With a smooth platinum anode in fluorosulfuric acid which was 1 M in acetic acid, alkanes with more than four carbon atoms could be oxidized. From this reaction α,β-unsaturated ketones containing an additional two carbon atoms (derived from the acetic acid) were obtained. From cyclohexane, the α,β-unsaturated methyl(2-methyl-1-cyclopentenyl)ketone was recovered in *ca.* 30% yield (Scheme 3).



Scheme 3

$$CH_3CO_2H + FSO_3H \rightarrow CH_3CO^{\oplus} + FSO_3^{\ominus} + H_2O$$



It was subsequently shown that by adding less base (acetic acid is readily protonated and hence a strong base in FSO_3H) the anodic oxidation of butane, propane and ethane became possible[23]. In stronger acid solutions, however, alkanes were found to undergo spontaneous chemical reactions yielding identical products as the electrode reactions, providing acetyl cations were present in solution. It was suggested that carbenium ions were initially formed *via* protolysis. An alternative, of course, would be electrophilic insertion of the acetyl cation into a C—H σ bond.

Electrochemical oxidation of the *n*-alkanes pentane to octane has been achieved at a smooth platinum anode in acetonitrile or trifluoroacetic acid containing a tetraalkylammonium tetrafluoroborate as electrolyte[24]. The following reaction sequences were realized.

Interestingly, in trifluoroacetic acid, cyclohexane gave cyclohexyl trifluoroacetate, in contrast to the ring contracted product obtained in FSO_3H (Scheme 3). *Fritz* and *Würminghausen*[25] likewise obtained a cyclohexyl ester.

Furthermore, these workers found that the isomer distribution observed from the electrochemical oxidation of *n*-decane in CH_2Cl_2/CF_3CO_2H solution paralleled the calculated differences in reactivity of the various methylene groups, thus indicating the participation of free carbocations.

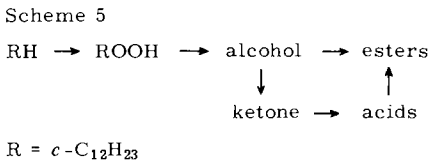
From studies so far carried out in this area it would appear that the electrochemical oxidation of alkanes as a preparative route has an interesting and potentially useful future.

1.8. Autoxidations

The reaction of alkanes with molecular oxygen has been widely studied[26]. A representative reaction of this type is the autoxidation of isobutane in the presence of hydrogen bromide at 158 °C giving di-*tert*-butyl peroxide as the major product together with *tert*-butyl alcohol and isobutyraldehyde. High yields of *tert*-butyl hydroperoxide (75 %) could also be obtained[27]. The mechanism shown in Scheme 4 was proposed.

Scheme 4

$$HBr + O_2 \longrightarrow Br\bullet + HOO\bullet$$

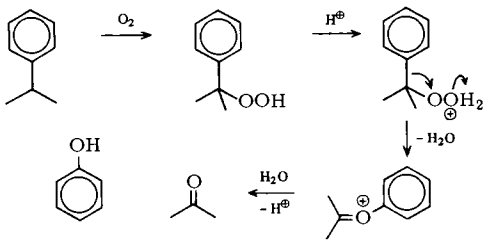


$$CH(CH_3)_3 + Br\bullet \longrightarrow \bullet C(CH_3)_3 + HBr$$

$$\bullet C(CH_3)_3 + O_2 \longrightarrow (CH_3)_3COO\bullet$$

$$(CH_3)_3COO\bullet + HBr \longrightarrow (CH_3)_3COOH + Br\bullet$$

For cyclododecane it has been shown by kinetic studies that the cycle illustrated in Scheme 5 is operative[28].



Scheme 5

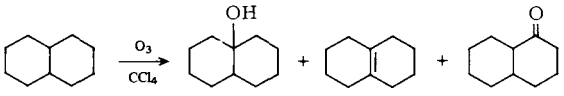
R = c-$C_{12}H_{23}$

The most important example of this type of reaction is the oxidation of cumene to cumene hydroperoxide. Originally discovered by *Hock* and *Lang*[29] it forms the basis of the industrial production of phenol and acetone *via* the acid-catalyzed decomposition of the hydroperoxide (Scheme 6). As might be expected the industrial importance of this reaction has stimulated much research towards increasing the efficiency of the overall process. Much of this work is described in the patent literature and some of these developments have been discussed in a review by *Hock*[30].

Scheme 6

The intermediary dimethylphenylcarboxonium ion has recently been characterized by NMR spectroscopy[31]. It was prepared by treating cumyl peroxyacetate with magic acid in SO_2ClF solution at −78 °C.

Other important examples of industrial autoxidation processes are the oxidation of *p*-xylene to terephthalic acid, an intermediate in the synthesis of terylene[32], and the oxidation of cyclohexane[33] to a mixture of cyclohexanol and cyclohexanone. This mixture is then further oxidized by nitric acid to adipic acid, which is an intermediate in the production of nylon.



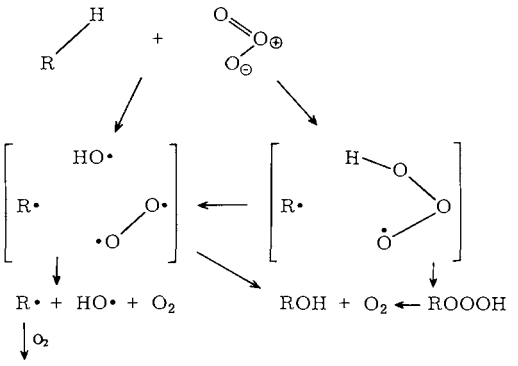
A major problem in the autoxidation (and indeed in all other oxidations) of alkanes is that the initial products of oxidation—alcohols, ketones, *etc.*—are often more easily oxidized further than is the starting alkane itself. This problem has been alleviated by the use of boric acid additives which tend to give products with enhanced alcohol content. *Illingworth* and *Lester*[34] found that by using boric acid, at a conversion of 15 %, *n*-dodecane gave a product having an alcohol/ketone ratio of 9:1, whereas without boric acid a ratio of 1:1 was obtained. The authors proposed that the boric acid captured the initially formed hydroperoxide and the intermediates were then converted into *sec*-alkyl borates.

As with many important industrial discoveries, an understanding of the mechanistic aspects of autoxidation lagged behind the commercialization of the processes. Efforts towards identification of the initial state of attack by oxygen on long-chain hydrocarbons illustrate this point. Early work suggested oxidation occurred at the terminus of the chains[35], whilst from a study of the oxidation of *n*-heptane it was thought that attack took place preferentially at the 2-position[36]. From experiments on the oxidation of *n*-decane *Leibnitz et al.*[37] concluded that attack was either at the 1- or 3-position. This

rather uncertain state of affairs was given a sounder footing during the 1950's[38]. It was shown that in fact oxidation of *n*-decane yielded the isomeric 2-, 3-, 4- and 5-decanols in approximately equimolar amounts, whilst only trace amounts of the 1-decanol was detected, indicating that initial attack occurs at all positions in the chain, with only minor reaction occurring at the terminus.

1.9. Ozone Oxidations

The action of ozone towards unsaturated hydrocarbons has long been employed as a means of functionalization, and the subject has been extensively reviewed. In contrast, the reaction of ozone towards saturated hydrocarbons has received scant attention. Early work showed that ozone reacted with alkanes, though the results were not encouraging in terms of synthetic usefulness. For example, it was found that *cis*-decalin reacted more rapidly than *trans*-decalin and that, under controlled conditions, the *cis* isomer gave as principle isolated products 4a-decalol, 1,2,3,4,5,6,7,8-octahydronaphthalene and some 1-decalone, whereas the *trans*-isomer yielded only 4a-decalol and 1-decalone. The reaction also produced large amounts of uncharacterized material thought to be carboxylic acids[39].

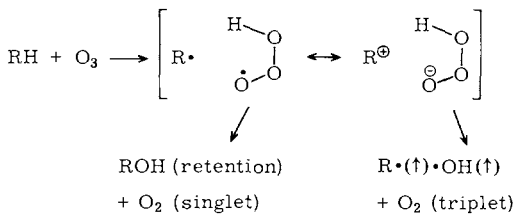


Reports since the work of *Durland* and *Adkins*[39] have mostly dealt with mechanistic aspects of the ozonolysis of C—H bonds. *Schubert* and *Pease*[40] studied the gas-phase ozonization of methane, propane, butane, and isobutane and determined the second order rate constants, which they found to depend on the strength of the C—H bond. Isobutane with a tertiary C—H bond showed a 14-fold rate increase and a fall in activation energy from 14.9→10.3 kcal/mol over methane, which has only primary C—H bonds. However, in subsequent work the same group[41,42] observed that there was no difference in activation energies from the ozonization of methane, ethane, and propane, and that ethane with only primary C—H's exhibited a greater reactivity than propane, which has two secondary C—H bonds.

Williamson and *Cvetanović*[43] examined the ozonolysis of alkanes in carbon tetrachloride solution, and found the reactivity to be similar to that of benzene, with comparable rate constants to those for ozonolysis in the gas phase.

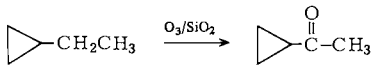
Hamilton et al.[44] deduced from the liquid-phase ozonolysis of isopentane, that the relative reactivities of primary : secondary : tertiary hydrogens are approximately 1 : 13 : 110. Comparing these ratios with those obtained for chromate oxidations of alkanes (1 : 110 : 7000, see Section 1.1) it is apparent that the transition state for alkane ozonization cannot have a great deal of carbenium ion character. However, ozonization of tertiary C—H's to tertiary alcohols gave 60—70% retention of configuration, which is inconsistent with the usual observations for free radical mechanisms. A mechanism was proposed in which the initial step is an insertion reaction, the transition state of which has considerable radical character. It was suggested that the observed retention of configuration could be explained by a solvent caged radical intermediate(s) (Scheme 7).

Scheme 7



ROH (racemized; + ketone + peroxides + fragmentation products)

From consideration of bond strengths *Benson*[45] estimated that the reaction



$$RH + O_3 \rightarrow R\cdot + \cdot OOOH$$

is endothermic by at least 20 kcal/mol and concluded that an ion pair mechanism for alkane ozonolysis could not be ruled out. *Hamilton*[46] has revised his mechanism to allow for some degree of ionic character in the transition state (Scheme 8).

Scheme 8

More recently, synthetically useful ozonizations have been reported. These have been achieved by *Mazur et al.*[47] using a dry ozonization method, which involves presorbing the alkane on silica gel followed by passing a stream of ozone over the bed at −78 °C until it becomes saturated with ozone[47]. On warming to room temperature and elution of the organic material from the bed, almost quantitative conversions were obtained. From *cis*-decalin and the isomeric *cis*- and *trans*-1,4-dimethylcyclohexane, tertiary alcohols were formed with almost complete retention of configuration[48]. The dry ozonization technique has been successfully used for the oxidation of alkylcyclopropanes in the α-position to the cyclopropyl group[49].

95%

The selectivities found for reactions utilizing the dry ozonization method makes it a promising tool for future synthetic work.

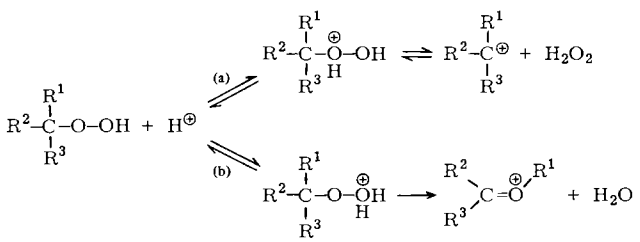
2. Superacid Catalyzed Oxygenations

The discovery and development of highly acidic and weakly nucleophilic solvents such as FSO_3H-SbF_5-SO_2[*], FSO_3H-SbF_5-SO_2ClF[*] and HF-SbF_5-SO_2ClF has enabled the prep-

[*] FSO_3H-SbF_5 is known as "magic acid".

aration and study of a wide variety of carbocations[50]. Furthermore, by using the above solvent systems as reaction media the chemistry of alkanes has been greatly extended[50, 51].

In connection with these studies it was also found that the electrophilic oxygenation of alkanes with ozone and hydrogen peroxide takes place readily in the presence of superacid media under typical electrophilic conditions. The reactions, giving oxyfunctionalized products, can be explained as proceeding *via* initial electrophilic attack by protonated ozone, *i.e.* HO_3^+, and the hydroperoxonium ion, $H_3O_2^+$, respectively, on the σ-bonds of alkanes through pentacoordinated carbonium ions. (It is suggested, to differentiate conventional "oxidations" from acid catalyzed electrophilic "oxygenations".)

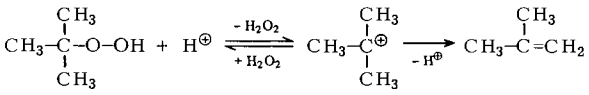


The study of the superacid catalyzed oxygenation reactions, was initiated by investigations of the acid induced decomposition of a series of peroxy compounds. Characterization of the reaction paths and intermediates of these reactions in superacidic media by NMR spectroscopy enabled the elucidation of the mechanism of the superacid induced electrophilic oxygenation of saturated hydrocarbons and allowed subsequent development of direct oxygenation methods for alkanes.

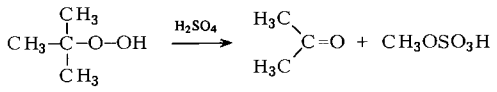
2.1. Protolytic Cleavage of Peroxy Compounds

2.1.1. Hydroperoxides

Consideration that superacid media would allow the direct observation of the intermediates involved in the acid-induced decomposition of hydroperoxides called for investigation of the reaction of a series of *tert*-alkyl hydroperoxides with magic acid-SO_2ClF solution. As shown in Scheme 9, initial protonation can occur at either oxygen of the hydroperoxide[52].



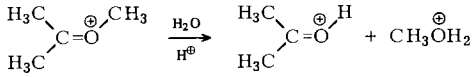
Scheme 9



Reaction *via* route (a) would lead to an overall equilibrium between the precursor hydroperoxide and its corresponding carbenium ion. Indeed, such an equilibrium has been found to interfere with kinetic studies of the acid induced rearrangement reaction of a number of aryl- and alkaryl hydroperoxides[53], *i.e.* the rearrangement shown as route (b), resulting in irreversible formation of the corresponding carboxonium ion. The relative migratory aptitude of the migrating group R, shows the following trend[54]:

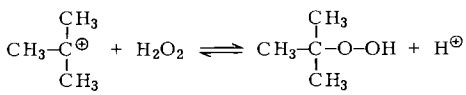
phenyl > vinyl > cyclopentyl > propyl > ethyl ≫ methyl
hydrogen ≈ propyl

The investigation of hydroperoxides centered on that of *tert*-butyl hydroperoxide since this compound is readily available commercially. Previous workers had found it to be remarkably resistant towards rearrangement in the presence of acid. When treated with sulfuric or perchloric acid in acetic acid it failed to undergo rearrangement. Instead, C—O cleavage occurred [route (a), Scheme 9] resulting in formation of isobutene and hydrogen peroxide[55].



On the other hand, reaction *via* O—O cleavage [route (b), Scheme 9] occurred exclusively when *tert*-butyl hydroperoxide was treated with 90—98 % sulfuric acid at −25 °C[56].

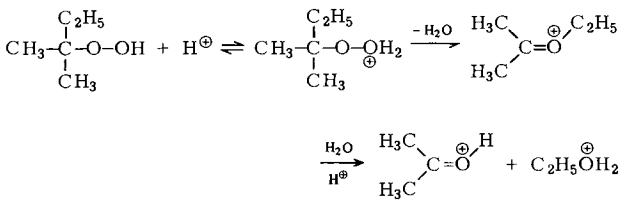
These findings indicate that the acid concentration determines the course of reaction taken[52]. Indeed, spectroscopic analysis of the solution obtained when *tert*-butyl hydroperoxide was allowed to react with a twofold excess of magic acid-SO_2ClF at −78 °C showed the products to be consistent with exclusive reaction *via* O—O cleavage, the major species identified by ^{13}C- and ^1H-NMR being the dimethylmethylcarboxonium ion. However, water liberated from the hydroperoxide caused some hydrolysis of the carboxonium ion, indicated by the presence of acetone and methanol as minor species.



Scheme 10

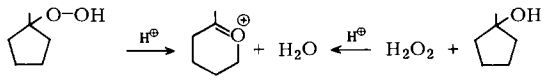
Similar treatment of *tert*-butyl hydroperoxide with a fivefold excess of magic acid again gave the carboxonium ion as the dominant species (85 %) *via* O—O bond cleavage. However, a significant amount (15 %) of the trimethylcarbenium ion was also formed, thus indicating some reaction *via* C—O cleavage (cf. Scheme 9, route (a)).

It was concluded from the observation of both mechanistic pathways in a strong acid medium that the nucleophilicity of the liberated hydrogen peroxide is reduced by protonation, thus preventing the reverse reaction formulated in Scheme 11.



Scheme 11

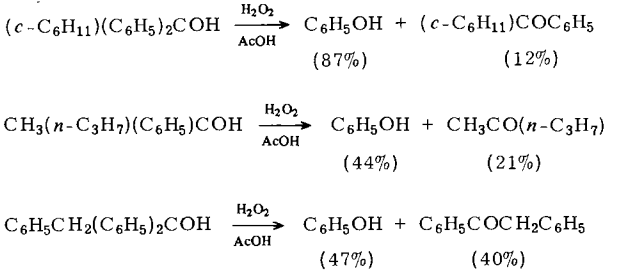
The large excess of acid is necessary for effective protonation of the hydrogen peroxide[57].



On treatment of *tert*-alkyl hydroperoxides other than *tert*-butyl hydroperoxide with a fivefold excess of magic acid, no species due to C—O cleavage could be detected. All observable products being accounted for by the O—O cleavage route, as exemplified for the case of *tert*-pentyl hydroperoxide (Scheme 12).

Scheme 12

The same results were also obtained with alkyl hydroperoxides generated *in situ*. Thus, treatment of 1-methyl-1-cyclopentanol and hydrogen peroxide with magic acid yielded the same cyclic carboxonium ion as 1-methylcyclopentylhydroperoxide (Scheme 13).



Scheme 13

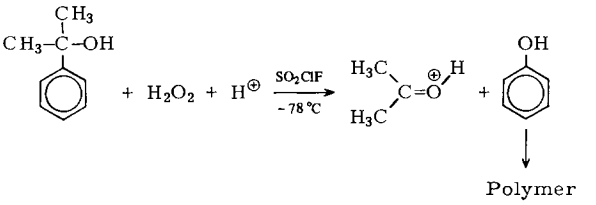
NMR spectroscopy was found to be a most convenient method for the analysis of the carboxonium ions thus obtained. ^{13}C-NMR parameters of typical carboxonium ions are shown in Table 2.

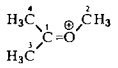
if one of the products was stable towards the reaction medium. Thus, for example, in the reaction of cumyl alcohol with

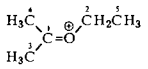
Scheme 14

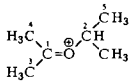
hydrogen peroxide/magic acid (or FSO_3H) acetone was detected as a product (Scheme 15).

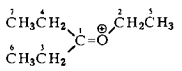
Scheme 15

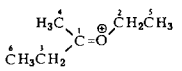












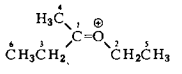


Table 2. ^{13}C-NMR parameters of some intermediary carboxonium ions (in SO_2ClF, TMS ext., −40°C).

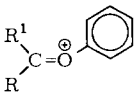

Structure	δ(^{13}C) 1	2	3	4	5	6	7
	245.21	68.81	32.2	27.01			
	243.13	82.47	32.37	27.27	13.03

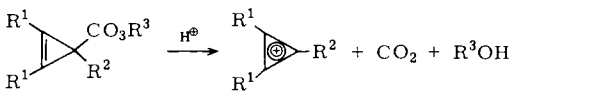
	247.92	80.74	34.3	28.72	13.04	11.03	8.05
	241.8	84.63	37.73	30.17	20.46	14.72	
	248.61	87.35	40.24	32.83	28.38	25.23	21.49
	243.64	81.57	39.86	25.27	12.05	5.25	
	246.57	80.52	33.80	28.70	12.05	7.49	

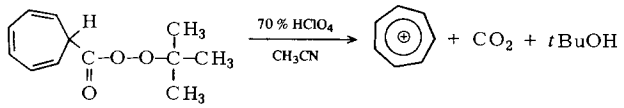
2.1.2. Arylalkyl Hydroperoxides

The reactivity of some α-arylalkyl alcohols with hydrogen peroxide/magic acid has also been studied[58]. *Kharasch* had previously found that hydrogen peroxide/acetic acid was able to induce aryl group migration in arylalkyl alcohols *via* their hydroperoxides[59] (Scheme 14).

No intermediates were characterized from this study. Hydrogen peroxide/magic acid was found to be too powerful a reagent for arylalkyl alcohols, the reactions yielding polymeric materials. However, the course of reaction could be ascertained

Polymerization of phenol is induced by the excess hydrogen peroxide. Hydrogen peroxide in the presence of strong acid is an extremely powerful electrophilic hydroxylating agent (cf. Sections 2.2 and 2.3 and also [60]). No polymerization was observed on reacting the corresponding hydroperoxides with magic acid. Cumyl hydroperoxide, for example, gave protonated phenol and acetone (see Scheme 6). The intermediary carboxonium ions, however, could not be observed on starting from the hydroperoxides, as ions of this type appear extremely susceptible towards hydrolysis.

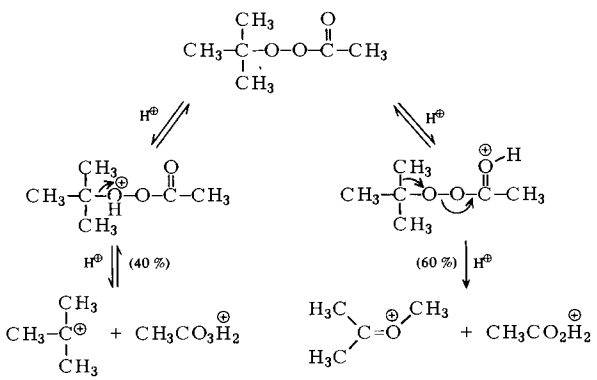




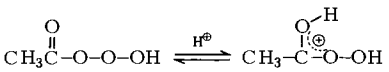
However, these intermediates may be obtained from aryl-alkyl peroxy esters.

2.1.3. Peroxy Esters

The acid induced decomposition of a series of *tert*-alkyl peroxyacetates in superacid media was studied in order to gain a better understanding of the mechanism of the reaction discussed in Section 2.1.2 by observation of the intermediary carboxonium ions.

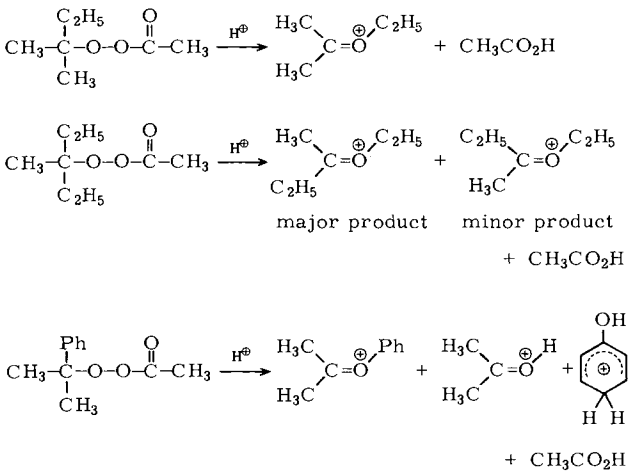


Protolytic cleavage of peroxy esters has previously been used for the preparation of stable carbocations. For example, cyclopropeneperoxycarboxylates yielded the corresponding cyclopropenylium ion, whilst the tropylium ion was obtained from the corresponding cycloheptatrienyl peroxy ester[61].



Recent studies[31] revealed that treatment of simple peroxy esters, such as *tert*-butyl or *tert*-pentyl peroxyacetates in superacids gave results similar to those of the corresponding hydroperoxides. Thus *tert*-butyl peroxyacetate reacts with a fivefold excess of magic acid as outlined in Scheme 16.

Scheme 16



As in the case of *tert*-butyl hydroperoxide both O—O and C—O cleavage was observed. As expected in the reaction with a twofold excess of magic acid only O—O cleavage was observable. The formation of the trimethylcarbenium ion in the former case is due to the deactivation of the liberated peroxyacetic acid as a nucleophile by its protonation.

This reaction was shown to be reversible; warming of the reaction mixture from −78 to −10°C resulted in complete disappearance of the *tert*-butyl cation, leaving the O—O cleavage products as the only observable species in solution.

When *tert*-alkyl peroxyacetates other than *tert*-butyl peroxyacetate were treated with a fivefold excess of magic acid the only observable products were those due to O—O cleavage (Scheme 17).

Scheme 17

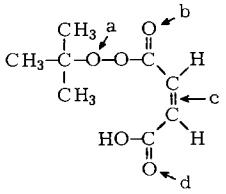
The stability of the carbenium ion formed as a result of C—O cleavage is not an important factor in determining the course of reaction. This is demonstrated by the fact that only O—O cleavage products were observed in the decomposition of cumyl peroxyacetate. Had the carbenium ion stability had a significant effect, then the dimethylphenylcarbenium ion, which is more stable than the trimethylcarbenium ion[62], should have been observed.

It was concluded that the carbenium ion formed as one of the decomposition products of peroxy esters is generally dependent on the rate of protolytic deactivation of peroxyacetic acid, formed *via* C—O cleavage, being greater than the rate of alkyl group migration following O—O cleavage. Only in the case of *tert*-butyl peroxyacetate (*i.e.* methyl migration) is this not the observed pattern.

The reaction of cumyl peroxyacetate with magic acid allowed direct observation of the dimethylphenylcarboxonium ion. This ion has long been proposed as the key intermediate in the industrially important conversion of cumene hydroperoxide into acetone and phenol[63].

Table 3. Products of the reaction of *tert*-butyl peroxy esters with magic acid [a]

$(CH_3)_3C-O-O-CO-R \rightarrow$



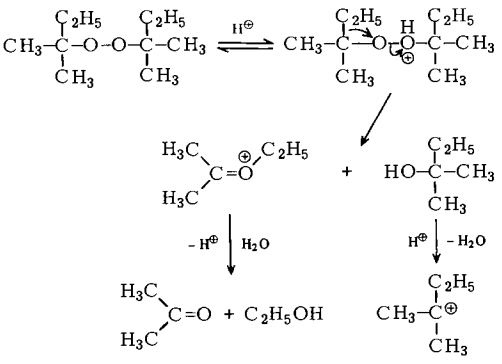
$(CH_3)_2C{=}O{-}CH_3$ (*1*) + $(+(CH_3)_3C^{\ominus})$ (*2*) + ···

Peroxy ester R	% O—O Cleavage	% C—O Cleavage	Products
CH_3	60	40	(*1*), (*2*), acetic acid, peracetic acid
C_6H_5	85	15	(*1*), (*2*), benzoic acid, perbenzoic acid
H	>95	<5	(*1*), (*2*), formic acid
cis-CH=CH—COOH	>95	<5	(*1*), (*2*), maleic acid, fumaric acid
α-Pyridyl	100	0	(*1*), α-picolinic acid

[a] All reactions with fivefold excess of magic acid in SO_2ClF at −78°C.

Attempts to observe dimethylphenylcarboxonium ions by reacting cumene hydroperoxide in superacids failed[58]. Only protonated acetone and phenol were detected, reflecting the ease with which the ion is susceptible to hydrolysis.

In the study of a series of *tert*-butyl peroxy esters it was shown that the extent of C—O cleavage was dependent on the pK_a of the acylperoxy leaving group (see Table 3) and the number of additional sites available for initial protonation, *i.e.* sites other than the peroxy ester oxygen atoms, as for



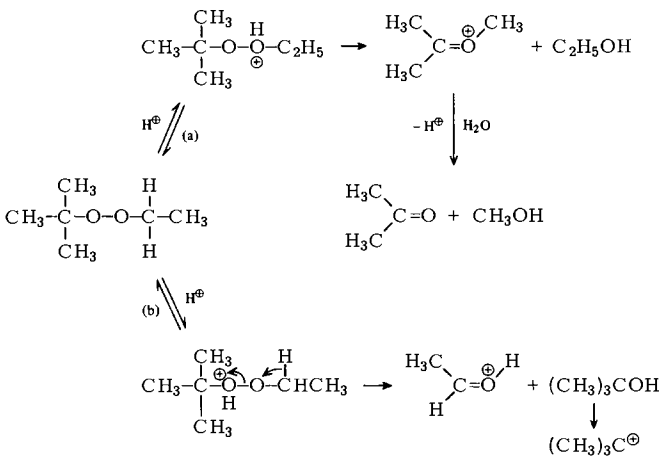
example in the case of *tert*-butyl peroxymaleate. Protonation at (a) leads to C—O cleavage, at (b), (c) and (d) to O—O cleavage.

2.1.4. Dialkyl Peroxides

Another class of peroxy compounds studied under superacidic conditions was the dialkyl peroxides. Although these compounds have been the subject of extensive research in homolytic decompositions[64] there has previously been little or no data available on their behavior in acidic media.

The solutions obtained upon treating dialkyl peroxides with magic acid[65], unlike in the case of their hydroperoxide counterparts, always showed the presence of alkylcarbenium ions as reaction products. However, this did not arise from a C—O cleavage, but rather from ionization of the alcohols produced as a result of O—O cleavage. This is illustrated in Scheme 18 showing the reaction of di-*tert*-pentyl peroxide with magic acid.

Scheme 18



Analogous results were obtained with di-*tert*-butyl peroxide and dicumyl peroxide.

An interesting feature of dialkyl peroxides is that they also can be obtained with dissimilar alkyl groups. The two oxygen atoms are now in differing environments. Thus, initial protonation is influenced by the relative difference in steric crowding and/or the basicity of each oxygen.

The result of the reaction of *tert*-butylethyl peroxide as shown in Scheme 19 seems somewhat surprising, since one might expect the reaction path (b) to be preferred, hydrogen being a much better migrating group than methyl. However,

Scheme 19

examination of molecular models shows that the oxygen adjacent to the ethyl group is sterically less shielded, consequently it is this oxygen atom that is preferentially protonated (path (a)).

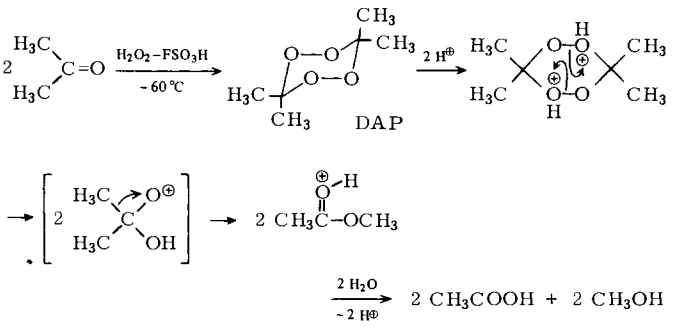
2.2. Baeyer-Villiger Oxidation in Strong Acids

The Baeyer-Villiger oxidation of ketones is generally not applicable to methyl alkyl ketones.

Hudlecky reported the first example of a Baeyer-Villiger oxidation of methyl alkyl ketones with hydrogen peroxide in hydrofluoric acid[66]. More recently, *Deno et al.* observed that solutions of $K_2S_2O_8$ in 50% sulfuric acid gave quantitative yields of the Baeyer-Villiger products for simple aliphatic ketones[56]. In these examples, the reaction was generally carried out at a temperature of 10—40 °C, and products arose exclusively from migration of the ethyl, propyl or higher alkyl groups rather than methyl.

Subsequently, FSO_3H-H_2O_2 was found to be an extremely effective reagent for the oxidation of simple methyl ketones even at −40 °C or below[67]. The results obtained for a number of ketones are summarized in Table 4.

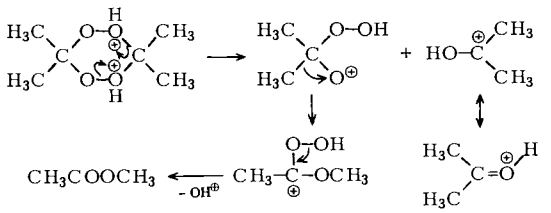
Table 4. Baeyer-Villiger oxidation of aliphatic ketones [a].



Ketone	Products [b]
2-Butanone	$CH_3CO—OC_2H_5$ [c]
2-Pentanone	$CH_3CO—OC_3H_7$ [c]
3-Pentanone	$C_2H_5CO—OC_3H_7$ [c]
2-Hexanone	$CH_3CO—OC_4H_9$ [d]
2-Heptanone	$CH_3CO—OC_5H_{11}$ [d]
4-Heptanone	$C_3H_7CO—OC_3H_7$ [c]

[a] Ketone/FSO_3H/H_2O_2/SO_2ClF, −40 °C. [b] Determined by ^{1}H-NMR spectroscopy. [c] For ketone:H_2O_2 = 1:2; 60% conversion. [d] For ketone:H_2O_2 = 1:5; quantitative conversion.

Because of the great difficulty of methyl migration, there has been no previous report on the Baeyer-Villiger oxidation of acetone. However, it was found that even acetone reacts with hydrogen peroxide in FSO_3H giving Baeyer-Villiger oxidation products[68].

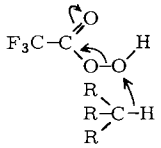


With acetone in excess FSO_3H-hydrogen peroxide solution no reaction was observed at −78 °C, but on raising the temperature to −60 °C, ^{1}H-NMR spectroscopy showed the appearance of the axial and equatorial methyl groups of dimeric acetone peroxide (3,3,6,6-tetramethyl-1,2,4,5-tetraoxane,

Scheme 20

"DAP"). At −20°C, conversion of acetone to this compound was almost complete.

Scheme 21



Formation of dimeric acetone peroxide was confirmed by comparison of the spectra of an authentic sample (synthesized by the method of *Criegee*[69] and of *Sanderson*[70]) and the spectra of the reaction products in strong acid.

On allowing the solution to stand at room temperature, the formation of methyl acetate, methyl alcohol, acetic acid, as well acetone was observed. The first three of these are Baeyer-Villiger oxidation products (as shown in Scheme 20). The formation of acetone can be depicted as shown in Scheme 21.

2.3. Electrophilic Oxygenation of Alkanes with Hydrogen Peroxide in Superacids

Previously reported hydroxylation reactions of hydrocarbons with hydrogen peroxide in acid solution were mainly those of π-donor systems, such as aromatic hydrocarbons[71] and alkenes[72].

The reaction of alkanes with 85% hydrogen peroxide in hydrogen fluoride/boron trifluoride was first observed by *Alder* and *Whiting* to be exceptionally destructive and unselective[71d]. On the other hand, *Frommer* and *Ullrich* reported that the hydroxylation of alkanes with 85% hydrogen peroxide in the presence of trifluoroacetic acid at 20°C gives the corresponding alcohols[73]. They suggested a nonionic transition state to be involved in the course of the reaction. *Deno et al.* have recently studied in detail the hydroxylation of alkanes with 30% hydrogen peroxide in trifluoroacetic acid. Good yields of alcohols were obtained without further oxidation to ketones.

Hamilton et al. also observed that oxidation of cyclohexane and 1,2-dimethylcyclohexane with peracetic acid gives the corresponding alcohols[74].

As mentioned above, and also suggested by *Alder* and *Whiting*[71d], hydrogen peroxide is expected to be protonated in strong acids, giving the hydroperoxonium ion, *i.e.* $H_3O_2^+$. In superacids the protonation equilibrium is expected to be substantially on the side of the hydroperoxonium ion. This ion may be considered to be effective enough for the electrophilic hydroxylation of single (σ-) bonds in alkanes, and thus be able to effect reactions similar to such electrophilic reactions as hydrogen/deuterium exchange, protolysis[75], chlorination (chlorolysis)[76] and nitration (nitrolysis)[77].

2.3.1. Branched Chain Alkanes

The reaction of branched chain alkanes with hydrogen peroxide in magic acid-SO_2ClF solution was carried out with various ratios of alkane and hydrogen peroxide, and at different temperatures[68]. Some of the results are summarized in Table 5.

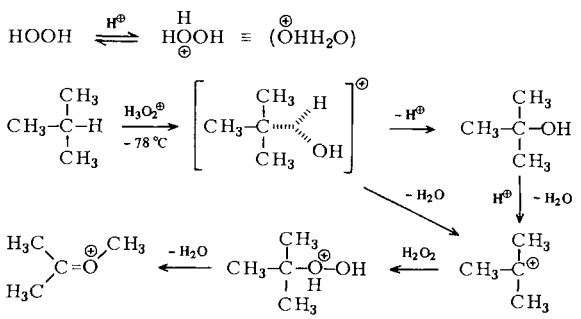


Table 5. Products of the reaction of branched chain alkanes with H_2O_2 in magic acid-SO_2ClF solution [a].

Alkane	Alkane [mmol]	H_2O_2 [mmol]	Temp. [b] [°C]	Major Products
	2	2	−78 → −20	$(CH_3)_2C{=}\dot{O}CH_3$
	2	4	−78 → −20	$(CH_3)_2C{=}\dot{O}CH_3$
	2	6	−78 → −20	$(CH_3)_2C{=}\dot{O}CH_3$
	2	6	+20 [c]	$(CH_3)_2C{=}\dot{O}CH_3$ (trace), DAP [d] (25%), CH_3OH (50%), $CH_3CO{-}O{-}CH_3$ (25%)
	2	3	−78 → −20	$(CH_3)_2C{=}\dot{O}C_2H_5$, $C_2H_5(CH_3)_2C^{\oplus}$
	2	6	−78 → −20	$(CH_3)_2C{=}\dot{O}C_2H_5$
	2	4	−78	$(CH_3)_2C{=}\dot{O}CH_3$ (50%), $(CH_3)_2C{=}OH$ (50%)
	2	6	−40	$(CH_3)_2C{=}\dot{O}CH_3$ (50%), DAP [d] (50%)

[a] All experiments were carried out using a solution of 1 ml magic acid in 1 ml SO_2ClF. The resultant solutions were transferred to precooled NMR tubes for analysis. [b] NMR probe temperature. [c] The ratio of these products can be determined by using the characteristic ^{1}H-NMR signals of the methyl groups (separate singlets). [d] "Dimeric acetone peroxide" (see Scheme 20).

As neither hydrogen peroxide nor magic acid-SO_2ClF alone led to any reaction under the conditions employed, the reaction must be considered to proceed *via* electrophilic hydroxylation. Protonated hydrogen peroxide inserts into the C—H bond of an alkane. A typical reaction path is as depicted in Scheme 22. The reaction proceeds *via* a pentacoordinate hydrooxycarbonium ion transition state, which decomposes to either *tert*-butyl alcohol or the *tert*-butyl cation. Since 1 mol of isobutane requires 2 mol of hydrogen peroxide to complete reaction one can conclude that intermediate alcohol or carbocation reacts with excess hydrogen peroxide, giving *tert*-butyl hydroperoxide. The superacid induced rearrangement and

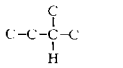
Scheme 22

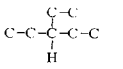
cleavage of the hydroperoxide results in very rapid formation of the dimethylmethylcarboxonium ion (cf. Scheme 9a).

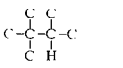
When the reaction was carried out at room temperature, by means of passing isobutane into a solution of magic acid and excess hydrogen peroxide, the formation of methyl alcohol, methyl acetate and some dimethylmethylcarboxonium ion together with dimeric acetone peroxide was observed. These results clearly show that the products observed can be rationalized as arising from hydrolysis of the carboxonium ion and from Baeyer-Villiger oxidation of acetone.

The reactions of alkanes with hydrogen peroxide in the presence of acids weaker than magic acid, such as FSO_3H, HF, and H_2SO_4 (96 %), have also been studied. The results are summarized in Tables 6, 7 and 8, respectively.

The products formed in the reaction using FSO_3H were almost identical with those formed in magic acid. Some of the differences observed in FSO_3H, compared to those observed under the same reaction conditions in the magic acid system, were lower conversion rate of alkanes and increased formation of products due to hydrolysis of the carboxonium ions or esters. This is due to the lower acidity of FSO_3H, which enhances the nucleophilic activity of water (the hydronium ion in equilibrium with unprotonated water increases).







As expected, this tendency increases when the reactions are carried out in the presence of hydrogen fluoride or sulfuric acid. In order to induce the reaction of alkanes with hydrogen peroxide a temperature of at least −40 °C (or higher) is needed in the case of hydrogen fluoride and −10 °C (or higher) in the case of sulfuric acid. A constant relationship in the ratio of reaction products was observed. For example, in H_2SO_4, isobutane gave methyl alcohol and acetic acid in the molar

Table 6. Products of the reaction of branched chain alkanes with H_2O_2 in FSO_3H solution [a].

Alkane	Alkane [mmol]	H_2O_2 [mmol]	Temp. [b] [°C]	Reaction Time [min] [c]	Conversion of Alkane [%]	Products

	2	6	40	60	≈20	CH_3OH (60 %), CH_3COOH [d] (40 %)

[a] Reaction procedures and analysis cf. Table 5. [b] 0.1 mol of isobutane was passed through the acid solution at a flow rate of 15 ml/min. [c] Based on H_2O_2. [d] Trace of *tert*-butyl sulfate was also observed. [e] Together with ethyl sulfate. [f] Unidentified products were also observed. [g] Tr = traces.

ratio 2:1 at −10 °C (or at room temperature), while isopentane gave methyl alcohol, ethyl alcohol, and acetic acid in the molar ratio 1:1:1 at 40 °C. Under the same reaction conditions, 2,2,3-trimethylbutane gave methyl alcohol and acetic acid in the molar ratio 3:2. The reactions in hydrogen fluoride gave the same products, thus indicating the same reaction pattern as reactions with the other strong acids, despite the fact that hydrogen fluoride cannot form a peracid. This suggests that the oxidation reactions using hydrogen peroxide in strong acids can indeed be due to protonated hydrogen peroxide ($H_3O_2^+$). In HF-SbF_5 or HF-BF_3, similar products are formed as in HF. Further, it should be pointed out that at low temperatures, both magic acid and fluorosulfuric acid, only protonate water (to the hydronium ion) with no evidence of any hydrolysis. Hydrogen peroxide being a thousand times weaker nucleophile than water would, therefore, be even less expected to form peroxyacids (*i.e.* Caro's acid). The effective hydroxylating agent consequently is considered to be the hydroperoxonium ion, $H_3O_2^+$. Direct observation of the latter as a static species (similar to the H_3O^+ ion) in superacidic systems was not possible owing to rapid intramolecular hydrogen exchange or exchange with the solvent system, probably involving diprotonated hydrogen peroxide $H_4O_2^{2+}$.

The product pattern in the reaction of tertiary isoalkanes with hydrogen peroxide in superacid solutions can be summarized as follows:

2.3.2. Straight-Chain Alkanes

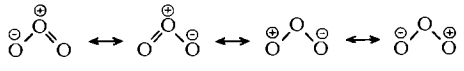
Under the same reaction conditions as employed in the case of branched-chain alkanes, straight-chain alkanes such as ethane, propane, butane, and even methane give related oxygenation products[68] (Table 9).

Methane, when reacted with hydrogen peroxide-magic acid above 0 °C, gave mainly methyl alcohol. A similar result is obtained with hydrogen peroxide-FSO_3H at 60 °C. Ethane with hydrogen peroxide-magic acid at −40 °C gave ethyl alcohol.

The reaction of propane with hydrogen peroxide took place more easily than that of methane or ethane and yielded isopropyl alcohol as the initial oxidation product. On raising the temperature, isopropyl alcohol gave acetone, which underwent further oxidation with hydrogen peroxide, giving dimeric acetone peroxide, methyl acetate, methyl alcohol, and acetic acid, as mentioned previously. The related reaction of butane with

Table 9. Products of the reaction of straight chain alkanes with H_2O_2 (molar ratio 1:6) in strong acids.

Acid	Alkane	Reaction Temp. [°C]	Major Products [a]
Magic acid	CH_4	0, 20	CH_3OH
FSO_3H	CH_4	60	CH_3OH
Magic acid-SO_2ClF	C_2H_6	−40	C_2H_5OH
	C_3H_8	−78	$(CH_3)_2CHOH$ (40 %), $(CH_3)_2C{=}O$ (60 %)
	C_3H_8	−40	$(CH_3)_2CHOH$ (10 %), $(CH_3)_2C{=}O$ (40 %), DAP [b] (50 %)
FSO_3H	C_3H_8	−78	$(CH_3)_2CHOH$
	C_3H_8	−60	DAP [b]
	C_3H_8	−40	CH_3OH (20 %), CH_3COOH (20 %), CH_3COOCH_3 (60 %)
H_2SO_4 [c]	C_3H_8	0	$(CH_3)_2CHOH$ (50 %), CH_3COOH (30 %), CH_3OH (20 %)



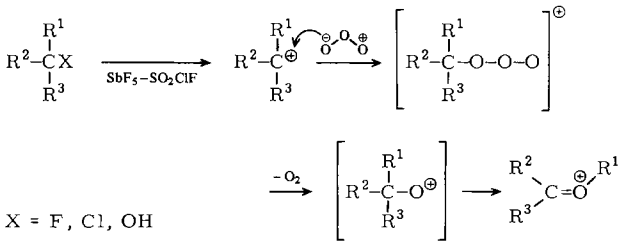
[a] In the case of magic acid systems, conversion is almost 100 % except for methane and ethane reactions. In another systems, no attempt was made to calculate the conversion. [b] Dimeric acetone peroxide. [c] 1 mol of propane was passed through the H_2O_2-acid solution at a flow rate of 15 ml/min.

hydrogen peroxide in magic acid at −78 °C gave *sec*-butyl alcohol. On raising the temperature, *sec*-butyl alcohol was converted into trimethylcarbenium ion. When excess hydrogen peroxide was used in the reaction, the dimethylmethylcarboxonium ion was obtained, formed by the reaction of H_2O_2 with the *tert*-butyl cation and subsequent cleavage-rearrangement of the intermediate *tert*-butyl hydroperoxide *(vide supra)*.

From the products obtained in the reactions, the relative order of reactivity of single bonds in alkanes towards $H_3O_2^+$ was found to be $R_3C{-}H > R_2HC{-}H > RH_2C{-}H > C{-}C$. This order is similar to that observed for electrophilic insertion of protonated ozone, HO_3^+, into the single bonds of alkanes (see Section 2.4).

2.4. Ozonolysis of Alkylcarbenium Ions[78]

In the course of studies on the oxyfunctionalization of hydrocarbons in superacid media, the reaction of ozone towards carbenium ions has also been investigated.



(a) (b) (c) (d)

Since the ozone molecule is shown to be a resonance hybrid of canonical structures (a)—(d)[79], one might expect ozone to react as a 1,3 dipole, an electrophile or a nucleophile. The electrophilic nature of ozone has been recognized in its reactions towards alkenes, alkynes, arenes, amines, sulfides, phosphanes *etc.*[80–84]. Reactions of ozone as a nucleophile, however, are less well documented[85].

As shown in Scheme 23, in the reaction of ozone with carbenium ions[86] the initial attack would be expected to be nucleophilic in nature giving rise to an intermediate trioxide[87], which would then be anticipated to undergo carbon to oxygen alkyl group migration with simultaneous cleavage of a molecule of oxygen, similarly as in the acid catalyzed rearrangement of hydroperoxides to carboxonium ions.

Scheme 23

The products of the reaction of the *tert*-butyl and isopropyl cations with ozone (in oxygen) in magic acid-SO_2ClF solution at −78 °C are listed in Table 10.

Table 10. Products of ozonolysis of alkylcarbenium ions at −78 °C.

Carbenium ion	Conversion [a] of $R^{\oplus}$ [%]	Product Distribution [a]
$(CH_3)_3C^{\oplus}$ [b]	55	$(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (99 %), $CH_3\overset{\oplus}{C}{=}O$ (trace)
$(CH_3)_2CH^{\oplus}$ [c]	85	$(CH_3)_2C{=}\overset{\oplus}{O}H$ (95 %), $CH_3\overset{\oplus}{C}{=}O$ (5 %), CO_2 [d]

[a] In all experiments, equal amounts of O_3 and $R^{\oplus}$ were used. Conversion of starting material and product distribution were calculated from the ^{1}H-NMR spectrum. [b] $(CH_3)_3CCl$-FSO_3H-SbF_5-SO_2ClF solution. [c] $(CH_3)_2CHCl$-SbF_5-SO_2ClF solution. [d] The ^{13}C-NMR spectrum of this solution indicated the presence of CO_2 ($\delta = 125$).

It should be noted that the isopropyl cation is more reactive towards ozone than the *tert*-butyl cation. This was also confirmed in competitive reactions, in which equimolar amounts of the two cations were ozonolyzed. This also indicates that the reaction can be attributed to the nucleophilic nature of ozone, since the isopropyl cation is more electrophilic than the *tert*-butyl cation.

In the reaction, further oxidation products such as CH_3CO^+ and CO_2 are also formed. These products could not be accounted for by the reaction of ozone with either carbenium ions or the subsequently formed carboxonium ions or their hydrolysis products (ketones, aldehydes and alcohols) in the superacidic media. It must be assumed that oxygen liberated in the rearrangement step is in its highly reactive singlet state and is as such responsible for the further oxidation products.

2.5. Electrophilic Oxygenation of Alkanes with Ozone in Superacids

2.5.1. Branched Alkanes[87]

When a stream of oxygen containing 15 % ozone was passed through a solution of isobutane in FSO_3H-SbF_5-SO_2ClF solution held at −78 °C, the colorless solution immediately turned brown in color. ^{1}H-NMR and ^{13}C-NMR spectra of the resultant solution were consistent with formation of the dimethylmethylcarboxonium ion in 45 % yield together with trace amounts of acetylium ion (CH_3CO^+)[88].

Similar treatment of isopentane, 2,3-dimethylbutane, and 2,2,3-trimethylbutane resulted in formation of related carboxonium ions as the major product (Table 11).

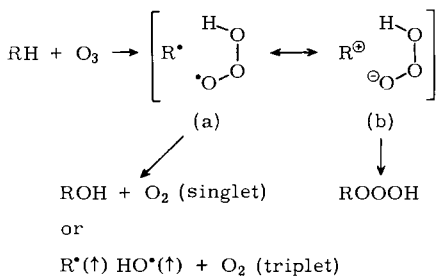


Table 11. Products of the reaction of branched alkanes with ozone in magic acid-SO_2ClF at $-78°C$ [a].

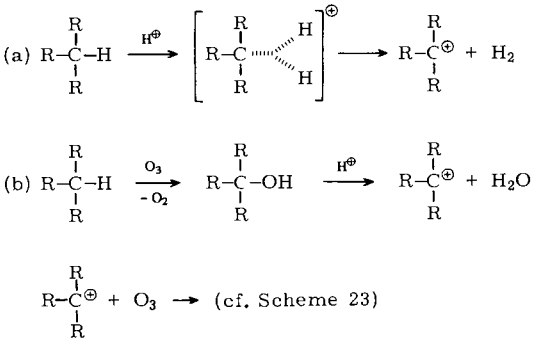
Alkane	Major Products
	$(CH_3)_2C{=}\overset{\oplus}{O}CH_3$
	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$
	$(CH_3)_2C{=}\overset{\oplus}{O}CH(CH_3)_2$ (60 %), $(CH_3)_2C{=}\overset{\oplus}{O}H$ (40 %)
	$(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (50 %), $(CH_3)_2C{=}\overset{\oplus}{O}H$ (50 %)

[a] In all experiments, a three-to-four mol excess of ozone to alkanes was used. Conversion of alkanes was almost 100 % in all cases. (For equimolar amounts of ozone and alkane, 45 % of isobutane, and 40 % of isopentane were observed.) [b] Product distributions were calculated from the ^{1}H-NMR spectrum. Spectroscopy indicated the presence of CO_2 in most reaction solutions. Major products as shown in the Table represent up to 90—95 % of all products.

It has been reported that the first step in the ozonization of alkanes has some characteristics of a radical reaction and some of an insertion reaction[89]. However, there is still considerable doubt as to the nature of the initial intermediate depicted in Scheme 24[90].

Scheme 24

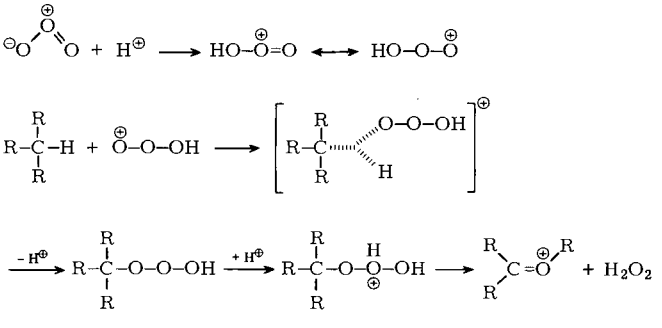


Varkony, *Pass* and *Mazur*[47] proposed formation of an ozone-hydrocarbon complex, followed by electrophilic insertion of oxygen into a C—H bond, whereas *Hellmann* and *Hamilton*[90] favor the species (a) as the major contributing form since this would readily undergo O—O bond cleavage leading to formation of the observed products. Contributions from (b), which would give the trioxide, were considered to be insignificant, since experiments by *Whiting*[91] showed no evidence for a trioxide intermediate in the ozonization of alkane under conditions where the trioxide formed in isopropyl alcohol oxidation is readily detected.

In reactions under superacidic conditions a possible pathway is the formation of an alkylcarbenium ion *via* protolysis of the alkane[75] prior to the ozone quenching of that ion, as shown in Scheme 25 (route (a)). Alkylcarbenium ions may also be generated *via* initial oxidation of the alkane to an alcohol followed by protonation and dehydration (route (b)); there have already been a number of reports of ozone reacting with alkanes to give alcohols and ketones[90-92]. In both cases, intermediary alkylcarbenium ions would then undergo nucleophilic reaction with ozone (see Scheme 23).

The products obtained from isobutane and isoalkanes are in accord with either of the reaction pathways shown in Scheme 25.

Scheme 25



However, it should be noted that the rate of formation of the dimethylmethylcarboxonium ion from isobutane is considerably faster than that of the trimethylcarbenium ion from isobutane in the absence of ozone under the same conditions. Indeed, a solution of isobutane in excess magic acid-SO_2ClF solution showed only trace amounts of the trimethylcarbenium ion after standing for five hours at $-78°C$. Passage of a stream of oxygen gas through the solution—for ten times longer a period than in the ozonization experiments—showed no effect. It was only when ozone was introduced into the system, that rapid reaction took place.

On the other hand, *tert*-butyl alcohol itself in magic acid-SO_2ClF solution gave readily and quantitatively the trimethylcarbenium ion, even at $-78°C$; in the presence of ozone under the same conditions it gave the dimethylmethylcarboxonium ion.

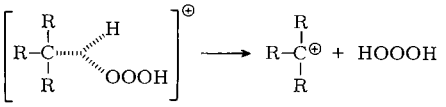
Although isobutane did not give any oxidation products in the absence of magic acid under the same low temperature ozonization conditions, it was not possible to determine whether formation of intermediate oxidation products, such as alcohols, plays any role in the ozonization of alkanes in magic acid. There is no experimental evidence that for reactions proceeding *via* the intermediacy of carbenium ions initial oxidation of the alkanes to alcohols is important. This oxidation, indeed was found to be extremely slow in the acidic media studied.

One may on the other hand also postulate another path for these reactions, namely electrophilic attack by protonated ozone on the alkanes, resulting in oxygen insertion into the involved σ bonds (Scheme 26).

Scheme 26

Since ozone has a strong 1,3-dipole[79,93], or at least strong polarizability, even if a singlet biradical structure is also fea-

sible, it thus is expected to be readily protonated in superacids, in an analogous manner to its alkylation by alkylcarbenium ions. Protonated ozone, O_3H^+, once formed should have a much higher affinity (*i.e.* be a more powerful electrophile) for σ-donor single bonds in alkanes than neutral ozone. It thus would be expected to initiate ozonolysis of alkanes, in a similar manner to nitrolysis by the nitronium ion NO_2^+[77], chlorolysis by the incipient chloronium ion Cl^+[76], or the more generally studied protolysis by superacids[75].

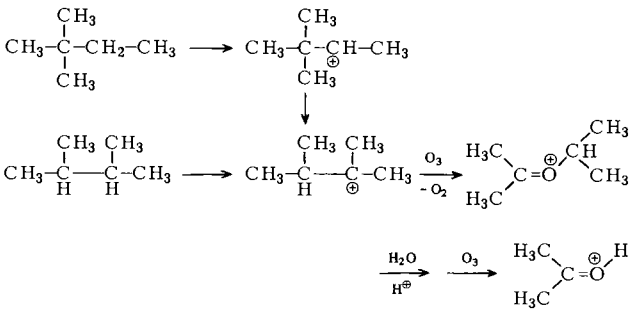


Attempts to directly observe protonated ozone by ^{1}H-NMR spectroscopy, were inconclusive because of hydrogen exchange and the difficulty in differentiating between the chemical shifts of HO_3^+ and H_3O^+.

Alkyl hydrotrioxides have been proposed as intermediates in the decomposition of *tert*-alkyl hydroperoxides with lead tetraacetate[94] and in the ozonization of ethers[95], aldehydes[96], and alcohols[97].

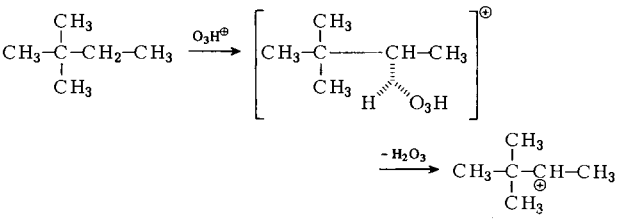
More recently, *Bartlett* and *Lahar*[98] isolated crystalline trioxides, stable below −30°C, by ozonolysis of *tert*-butyl hydroperoxide, of the sodium salt of *tert*-butyl hydroperoxide, and of the sodium salt of cumyl hydroperoxide.

$$RO^\bullet + ROOH \rightarrow ROH + ROO^\bullet$$
$$RO^\bullet + ROO^\bullet \rightleftharpoons ROOOR$$



Another possible mode of cleavage of the activated complex of Scheme 26 would give an alkylcarbenium ion and hydrogen trioxide.

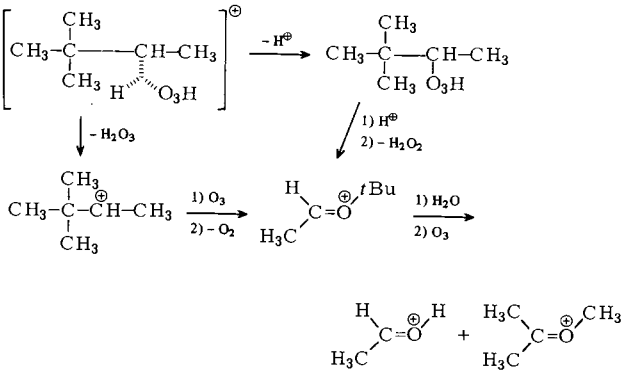
Although extremely unstable, hydrogen trioxide was detected; it decomposes into water and oxygen[99].



2,2-Dimethylbutane and 2,3-dimethylbutane in magic acid solution gave almost the same distribution of major products upon treatment with ozone at −78°C, namely dimethylisopropylcarboxonium ions and protonated acetone in the ratio 3:2. This clearly demonstrates the intermediacy of alkylcarbenium ions in these reactions (Scheme 27).

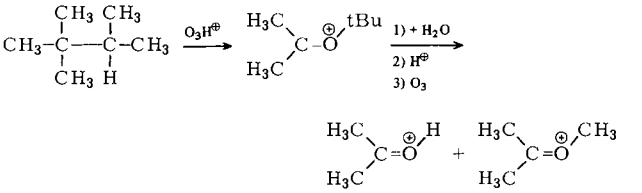
Scheme 27

The methyl-*tert*-butylcarbenium ion can be derived from the pentacoordinated carbonium ion by cleavage of hydrogen trioxide.



Isopropyl alcohol, the expected hydrolysis product of the dimethylisopropylcarboxonium ion could not be observed in either reaction. Isopropyl alcohol can, however, readily

undergo ionization giving first the isopropyl cation which can then react with ozone and form acetone. Indeed, after completion of the ozonization reaction at −78°C, concomitant formation of acetone and disappearance of the carboxonium ion was observed on increasing the temperature to −20°C. However, the observed amount of isopropyl alcohol was almost negligible. It is thus reasonable to assume that the isopropyl alcohol formed from the carboxonium ion reacts with hydrogen peroxide or trioxide, which in turn are respectively formed as shown in Scheme 26 from protonated ozone and an alkane.

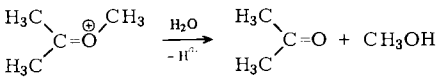


In the reaction of 2,2-dimethylbutane, some acetaldehyde and dimethylmethylcarboxonium ion was also obtained. These can be formed as shown in Scheme 28.

Scheme 28

2,2,3-Trimethylbutane gave protonated acetone and dimethylmethylcarboxonium ions in the ratio 1:1 (Scheme 29).

Scheme 29



The carboxonium ion intermediate could not be detected under the conditions employed; it is very unstable and decomposes into acetone and dimethylmethoxycarbenium ion.

The observed reactions of alkanes with ozone in superacid media indicate initial electrophilic attack of HO_3^+ at the single σ-bond of alkanes.

In order to provide further evidence in support of the ozonization reaction *via* protonated ozone, the reactions were also studied in the presence of weaker acids such as HF-BF_3, FSO_3H, and H_2SO_4 under conditions in which the acids themselves do not react with any of the alkanes studied to give alkylcarbenium ions. Ozonolysis of alkanes in these acids

yielded products identical to those formed in magic acid (cf. Table 11). Consequently, these results afford further proof that the reactions involve electrophilic oxygenation of the alkanes by HO_3^+. The yield of dimethylmethylcarboxonium ion obtained in the reaction of isobutane with ozone in SO_2ClF solutions of these weaker acids at $-78\,^\circ C$ systems was, however, low (5—10 %). Ozone in the presence of these acids thus seems to be less effectively protonated than in the presence of magic acid. Another aspect of this reaction must also be taken into consideration: the formation of methanol and acetone, which are formed by hydrolysis of the intermediary carboxonium ions.

Since there is little water present in the system at the outset of the reaction, it must be formed as the reaction proceeds. A probable source of water is hydrogen trioxide[99], formed from cleavage of the pentacoordinated carbonium ion in the hydrogen abstraction step.

$$H_2O_3 + H^\oplus \rightarrow H_3O^\oplus + O_2$$

The hydrolysis of carboxonium ions in magic acid solution at $-78\,^\circ C$ is not significant, as water formed is protonated to give H_3O^+, thus deactivating it as a nucleophile. With increasing temperature, however, there is increased hydrolysis, since the carbonium ion deprotonation equilibrium is favored.

2.5.2. Straight Chain Alkanes

Under the same ozonization conditions (magic acid in SO_2ClF at $-78\,^\circ C$), ethane gave protonated acetaldehyde as the major reaction product together with some acetylium ion (Scheme 30, Table 12).

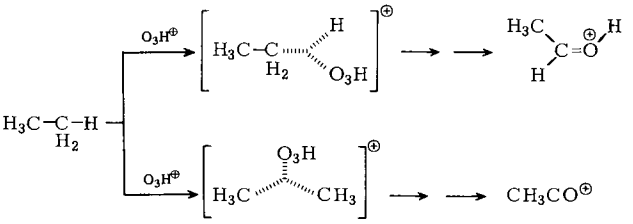


Table 12. Products of the reaction of straight chain alkanes with ozone in magic acid-SO_2ClF [a].

Alkane	Reaction Temp. [°C]	Major Products	
CH_4	−50 [b]	$(CH_3)_2C{=}\overset{\oplus}{O}H$	$(CH_3)_2C{=}\overset{\oplus}{O}CH_3$
C_2H_6	−78	$CH_3(H)C{=}\overset{\oplus}{O}H$	
C_3H_8	−78	$(CH_3)_2C{=}\overset{\oplus}{O}H$	
C_4H_{10}	−78	$CH_3(H)C{=}\overset{\oplus}{O}C_2H_5$	$C_2H_5(CH_3)C{=}\overset{\oplus}{O}H$
	20 [b]	$(CH_3)_2C{=}\overset{\oplus}{O}CH_3$	
C_5H_{12}	−78	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$	$(C_2H_5)_2C{=}\overset{\oplus}{O}H$
		$C_3H_7(H)C{=}\overset{\oplus}{O}CH_3$	$C_2H_5(C_3H_7)C{=}\overset{\oplus}{O}H$

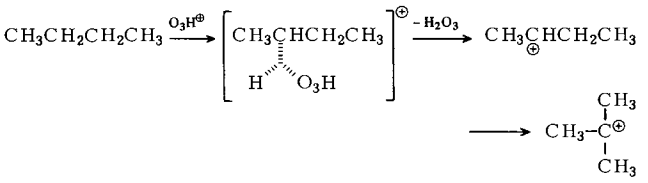
[a] Cf. footnotes [a] and [b] in Table 11. (For equimolar amounts of ozone and alkane (propane, butane and pentane), around 30 % conversion of alkane was observed.) [b] A mixture of 4 mol excess ozone and alkane was passed through magic acid-SO_2ClF. For room temperature reactions neat magic acid was used.

Propane gave mainly protonated acetone (90 %) together with some acetylium ion. These products, excluding the acetylium ion, could also be derived from the corresponding alkyl-

Scheme 30

carbenium ions formed by the protolysis of the alkanes, which are attacked nucleophilically by ozone.

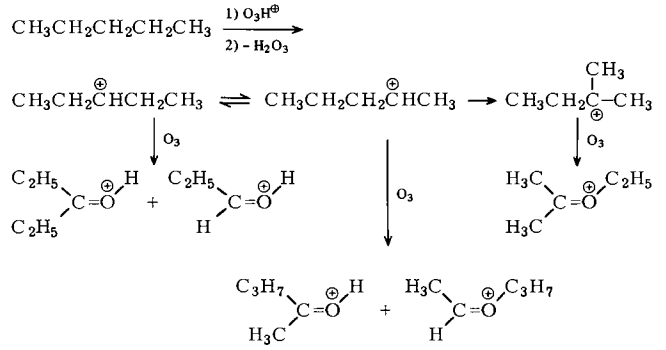
However, the product distributions obtained are not in accord with those predicted on the basis of the order of protolytic reactivity of single bonds in alkanes, *i.e.* $R_3C{-}H > C{-}C > R_2HC{-}H > RH_2C{-}H$[75]. Thus, if carbenium ions are first formed, the major product should be protonated formaldehyde (*via* the methyl cation) in the case of ethane, and protonated acetaldehyde in the case of propane (*via* the ethyl cation).



As mentioned above, the reactivity of single bonds of alkanes towards electrophiles generally shows the decreasing order tertiary C—H > C—C > secondary and primary C—H. This order agrees with the experimental data, not only of the protolysis[75], but also of the chlorolysis[76] and the nitrolysis[77] of ethane and propane. However, as pointed out previously[75], additional factors such as, for example, steric hindrance, can influence the relative order of reactivity; therefore, the findings must be limited to the specific system studied. Thus, the relative reactivity of the alkane single bonds towards HO_3^+ (ozonolysis) might be expected to differ from that towards H^+ (protolysis) because of the bulkiness of the protonated ozone. Consequently, preferential ozonolysis would occur at the more available C—H bonds of ethane and secondary C—H bonds in propane to give subsequently protonated acetaldehyde and acetone, respectively.

When treated with ozone in magic acid-SO_2ClF solution at $-78\,^\circ C$, butane gave protonated methyl ethyl ketone and methylethylcarboxonium ions (the former in slight excess), together with lesser amounts of the dimethylmethylcarboxonium ions and acetylium ions.

It should again be noted that the alkylcarbenium ions expected to be formed on protolysis of butane, cannot give methyl ethyl ketone and methylethylcarboxonium ion as the main products after nucleophilic ozonization, because of the general preference in magic acid solution of C—C over C—H bond protolysis. One would expect these main products to be formed by reaction of ozone with the *sec*-butyl cation, which can be formed by protolysis of secondary C—H bonds in butane or by dehydration of *sec*-butyl alcohol, the initial oxidation product of butane. However, attempts to obtain the *sec*-butyl cation from butane or 2-butanol in the absence of ozone under the reaction conditions ($-50\,^\circ C$) resulted only in the formation of the trimethylcarbenium ion; in the latter case protonated *sec*-butyl alcohol was also found. Consequently, even if the initial product of oxidation of butane were 2-butanol, it would subsequently give exclusively the dimethylmethylcarboxonium ion. Indeed, under similar reaction conditions at $-78\,^\circ C$, 2-butanol did not react with ozone, but as the temperature was raised above $-50\,^\circ C$ reaction did occur, yielding the dimethylmethylcarboxonium ion.



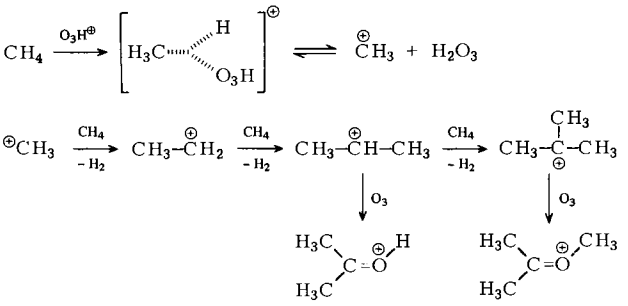
The oxygenation of secondary C—H bonds of butane with HO_3^+, which seems to have precedence over reaction with C—C bonds, can give methyl ethyl ketone and methylethylcarboxonium ion as the major products. However, in sharp contrast to isobutane and other branched alkanes, it should be noted that in order to form the dimethylmethylcarboxonium ion, even though it is a minor product, skeletal rearrangements involving methyl and hydrogen migration must occur in the course of reaction. In fact when the reaction was carried out at room temperature, the major product was the dimethylmethylcarboxonium ion, strongly indicating in this case the formation of an alkylcarbenium ion prior to reaction with ozone.

These data conclusively show that in the oxygenation with HO_3^+, the carbonium ion transition state can cleave losing hydrogen trioxide to give the incipient primary of the secondary butyl cations, followed by rearrangement *via* methyl (hydrogen) migration to the trimethylcarbenium ion.

When treated with ozone in magic acid-SO_2ClF at $-78\,°C$, pentane gave more complex products, with the dimethylethylcarboxonium ion as one of the major products. This indicates that significant skeletal rearrangement of the linear molecule occurs, even at $-78\,°C$ (Scheme 31).

Scheme 31

Brouwer and *Oelderick* have found that the isomerization of the secondary to the tertiary butyl cation proceeds much slower than in the case of higher alkyl cations, in agreement with the results described here.



The other major identified product in the reaction was protonated diethyl ketone, which could arise from direct nucleophilic attack by ozone of the diethylcarbenium ion, or by electrophilic insertion by HO_3^+ into the secondary C—H bond in pentane.

Further evidence for initial electrophilic attack by HO_3^+ comes from the reaction of methane with ozone in magic acid.

When an equimolar mixture of methane and ozone was passed through magic acid-SO_2ClF solution at $-50\,°C$ the major reaction product was protonated acetone (see Table 12), whereas reaction in neat magic acid at room temperature afforded preferably the dimethylmethylcarboxonium ion. No formaldehyde could be detected on NMR spectroscopic analysis of the products.

These findings indicate that the reaction is almost exclusively nucleophilic oxygenation by ozone of the alkylcarbenium ions which arise from the oligocondensation of methane (Scheme 32).

Scheme 32

It was previously reported that methane can undergo oligomerization in magic acid solution giving ethane, propane, isobutane, and higher alkanes *via* the corresponding carbocations[101]. However, this reaction generally takes place only above 60 °C. Indeed, when a stream of methane was passed through 20 % magic acid solution in SO_2ClF at a flow rate of 10 ml/min at $-30\,°C$ for 48 hours, only trace amounts of the trimethylcarbenium ion could be detected in the resultant solution. Since significant amounts of oxyfunctionalized products were obtained in the presence of ozone under the same conditions with a reaction time of 6 hours, formation of alkylcarbenium ions from methane under these conditions seems to be a consequence of the electrophilic attack of HO_3^+ at the C—H bonds of methane. Alternatively it could be visualized that the formation of carbenium ions in the absence of ozone is slow, because of the unfavorable equilibrium

$$RH + H^{\oplus} \rightleftharpoons R^{\oplus} + H_2$$

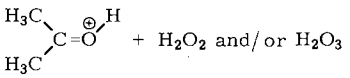
This equilibrium, however, does not seem to be of major significance at low concentrations and atmospheric pressure of H_2.

2.5.3. Behavior of Peroxy Compounds formed from Alkanes and Ozone

Attempts to directly observe protonated ozone by ^{1}H-NMR spectroscopy were inconclusive because of difficulty in differentiating between the chemical shifts of HO_3^+ and H_3O^+. In principle, however, it should be possible to distinguish between the electrophilic insertion by HO_3^+ (Scheme 19) and the nucleophilic reaction with O_3 (Scheme 23 and 25), since in the former case hydrogen peroxide should be formed, while in the latter case oxygen is formed as the cleavage-product of the intermediary trioxide. Analysis of the final reaction solution for hydrogen peroxide proved negative. However, it is known that hydrogen peroxide reacts readily not only with ozone[102], but also with alkylcarbenium ions, and with alkanes in acid solution (as discussed previously). Hydrogen peroxide formed in the reaction of alkanes with ozone in magic acid-SO_2ClF solution therefore would react further by one or more of the above mentioned reactions. In a more detailed study[58]

of the temperature dependence of the reaction of normal alkanes with ozone in FSO_3H-SbF_5-SO_2ClF solution the formation of alcohols was observed. For example, in the oxidation reaction of propane at −78 °C there is almost exclusive formation of (protonated) acetone with 30 % conversion of the alkane. When raising the temperature to −65 °C in the absence of ozone for 2 hours, the formation of isopropyl alcohol was observed. A similar observation was made for ethane at −40 °C and butane at −65 °C, respectively (Table 13).

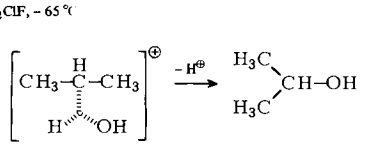
Table 13. Effect of secondary reactions [a] on the product distribution in the reaction of straight chain alkanes with ozone in magic acid-SO_2ClF.



Alkane	Temp. [b] [°C]	Reaction Time [b] [min]	Product Distribution [%] [c]
C_2H_6	−78	0	$CH_3(H)C{=}\overset{\oplus}{O}H$ (≈95 %) [d]
C_2H_6	−78	120	
C_2H_6	−40	60	$CH_3(H)C{=}\overset{\oplus}{O}H$ (90 %), $C_2H_5\overset{\oplus}{O}H_2$ (10 %)
C_3H_8	−78	0	$(CH_3)_2C{=}\overset{\oplus}{O}H$ (≈95 %) [d]
C_3H_8	−78	120	$(CH_3)_2C{=}\overset{\oplus}{O}H$ (≈95 %)
C_3H_8	−65	60	$(CH_3)_2C{=}\overset{\oplus}{O}H$ (85 %), $(CH_3)_2CH{-}\overset{\oplus}{O}H_2$ (15 %)
C_4H_{10}	−78	0	$C_2H_5(CH_3)C{=}\overset{\oplus}{O}H$ (40 %), $CH_3(H)C{=}\overset{\oplus}{O}C_2H_5$ (60 %) [d]
C_4H_{10}	−78	120	$C_2H_5(CH_3)C{=}\overset{\oplus}{O}H$ (40 %), $CH_3(H)C{=}\overset{\oplus}{O}C_2H_5$ (60 %)
C_4H_{10}	−65	60	$C_2H_5(CH_3)C{=}\overset{\oplus}{O}H$ (30 %), $CH_3(H)C{=}\overset{\oplus}{O}C_2H_5$ (50 %), $C_2H_5(CH_3)CH{-}\overset{\oplus}{O}H_2$ (20 %) [e]

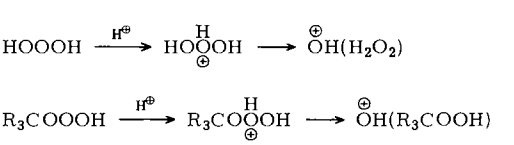
[a] Equal amounts of ozone and alkane were used in the presence of a threefold excess of FSO_3H-SbF_5-SO_2ClF at −78 °C. Conversion of propane and normal butane was around 30—40 %. Then, the reaction solution was allowed to stand at the given temperature [b]. For ethane, the mixture of alkane and ozone (1 : 1 molar ratio) was passed through the acid solution at −78 °C. Then the ethane was passed through into the resultant solution without O_3/O_2 gas at the given temperature [b]. [b] The temperature and time of secondary reactions. [c] Product assignments were made as described in Table 5. [d] $CH_3\overset{\oplus}{C}{=}O$ and CO_2 were found as minor products. [e] $(CH_3)_2C{=}\overset{\oplus}{O}{-}CH_3$ was found as minor product.

The results can be explained as in Scheme 33.



Scheme 33

$$CH_3CH_2CH_3 \xrightarrow[FSO_3H-SbF_5-SO_2ClF,\ -78\,^\circ C]{O_3H^\oplus \text{ and } O_3}$$



$$+\ H_2O_2 \text{ and/or } H_2O_3$$

$$CH_3CH_2CH_3 \xrightarrow[FSO_3H-SbF_5-SO_2ClF,\ -65\,^\circ C]{H_2O_2 \text{ or } H_2O_3}$$

On the other hand, tertiary isoalkanes did not give any alcohols under these conditions. It is considered that a tertiary alcohol, once formed, would readily undergo ionization in the superacid to give the corresponding alkylcarbenium ion, which would then undergo further reaction with ozone or with excess hydrogen peroxide. Indeed, *tert*-butyl alcohol in FSO_3H-SbF_5-SO_2ClF gives readily and quantitatively the trimethylcarbenium ion, even at −78 °C, and dimethylmethylcarboxonium ion when ozone or hydrogen peroxide is present.

Upon electrophilic insertion by protonated ozone into the C—H bonds of alkanes the formation of not only hydrogen peroxide but other peroxy compounds, such as hydrogen trioxide and alkyl hydrotrioxides, is expected. These peroxy compounds also can be considered to have hydroxylating ability for alkanes.

2.5.4. Neoalkanes

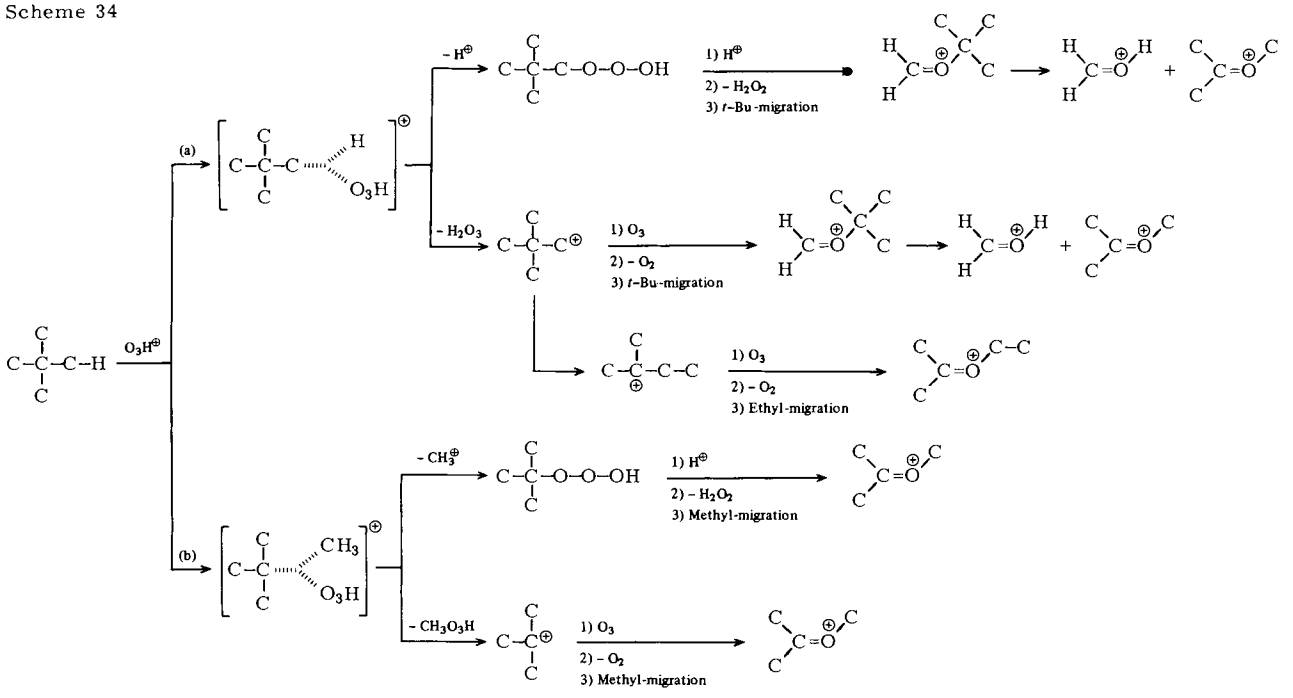
When a stream of oxygen containing ≈5 % ozone was passed through a solution of neopentane in FSO_3H-SbF_5-SO_2ClF at −78 °C the ^{1}H-NMR and ^{13}C-NMR spectra of the resultant solution showed the formation of the dimethylethylcarboxonium ion as the major product, together with dimethylmethylcarboxonium ion and (protonated) neopentyl alcohol. The conversion of the alkane was found to be almost 100 %. The results obtained under various reaction conditions are summarized together with those for 2,2,3,3-tetramethylbutane in Table 14.

The possible reaction pathways for the reaction of neopentane with ozone in FSO_3H-SbF_5-SO_2ClF at −78 °C are shown in Scheme 34.

The reaction course under conditions where dimethylethylcarboxonium ion is formed almost exclusively, can be best explained by the alternative reaction path (a) involving C—H bond ozonolysis, H_2O_3 elimination from the carbonium ion transition state, formation of the neopentyl cation being followed by immediate rearrangement to the *tert*-pentyl cation and its quenching by ozone.

It should be emphasized that the protolysis of neopentane in FSO_3H-SbF_5-SO_2ClF solution at −78 °C is very slow and can be neglected. In fact, after 5 hours at −40 °C, no formation of any kind of alkylcarbenium ion can be detected in the solution. It was only when ozone was introduced into the system that rapid reaction took place under these conditions. However, when the reaction was carried out at temperatures above 0 °C, the formation of dimethylmethylcarboxonium ion was predominant. Under these conditions, as shown in Scheme 35, alkylcarbenium ion formation *via* σ-bond protolysis of neopentane is preferential. Intermediate alkylcarbenium ions would then undergo nucleophilic reaction with ozone to give the corresponding carboxonium ions.

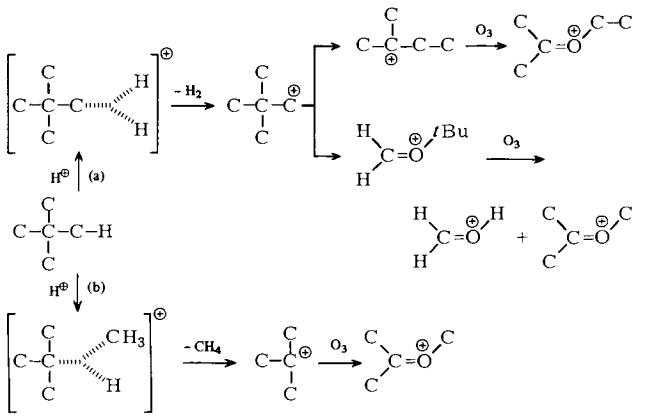
In FSO_3H-SbF_5-SO_2ClF solution at elevated temperatures, neopentane is known to undergo protolytic C—C bond cleavage [path (b)] giving *tert*-butyl cation[75], which subsequently can give the dimethylmethylcarboxonium ion by quenching with ozone and rearrangement[78].



Similar results were also obtained when the reaction was carried out in HF-SbF_5-SO_2ClF or SbF_5-SO_2ClF solution, even at temperatures as low as −78 °C. In these systems,

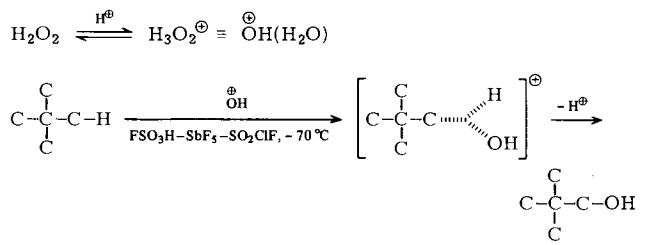
Table 14. Products of the reaction of neoalkanes with ozone in superacids [a].

Alkane	Acid	Reaction Temp. [°C]	Major Products
	FSO_3H-SbF_5-SO_2ClF	−78	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$ (95 %), $(CH_3)_3C{-}CH_2\overset{\oplus}{O}H_2$ (5 %)
	FSO_3H-SbF_5-SO_2ClF	−20	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$ (90 %), $(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (10 %)
	FSO_3H-SbF_5	0	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$ (15 %), $(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (85 %)
	FSO_3H-SbF_5	+20	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$ (5 %), $(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (95 %)
	HF-SbF_5-SO_2ClF	−78	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$ (25 %), $(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (75 %)
	HF-SbF_5-SO_2ClF	−20	$(CH_3)_2C{=}\overset{\oplus}{O}C_2H_5$ (10 %), $(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (90 %)
	FSO_3H-SbF_5-SO_2ClF	−78	$(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (35 %), $(CH_3)_2C{=}\overset{\oplus}{O}H$ (35 %), $(CH_3)_3C{-}(CH_3)_2C{-}CH_2\overset{\oplus}{O}H_2$ (30 %)
	FSO_3H-SbF_5-SO_2ClF	−50	$(CH_3)_2C{=}\overset{\oplus}{O}CH_3$ (70 %), $(CH_3)_2C{=}\overset{\oplus}{O}H$ (30 %)



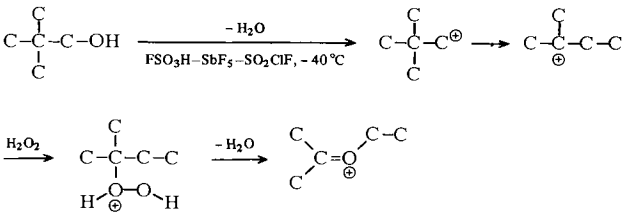
[a] See footnotes [a] and [b] in Table 11.

Scheme 34



neopentane can undergo protolysis *via* path (a) or path (b) (Scheme 35). In HF-SbF_5-SO_2ClF solution, neopentane readily undergoes protolytic C—C bond cleavage to give *tert*-butyl cation (and methane) [path (b)], while in the presence of ozone under the same conditions the dimethylmethylcarboxonium ion is formed as major product. On the other hand, in SbF_5-SO_2ClF solution, which can be considered always to contain sufficient protic acid impurity to act as an extremely strong superacid, protolytic C—H bond cleavage [path (a)] of neopentane is preferential giving *tert*-pentyl cation and thus in the presence of ozone the dimethylethylcarboxonium ion as the major product. The differing behavior of neopentane depending on the kind of superacid media used reflects the differing nature, such as steric requirements due to differing solvation of the proton, of each system in effecting the reactions of C—C or C—H bonds in neopentane.

Scheme 35

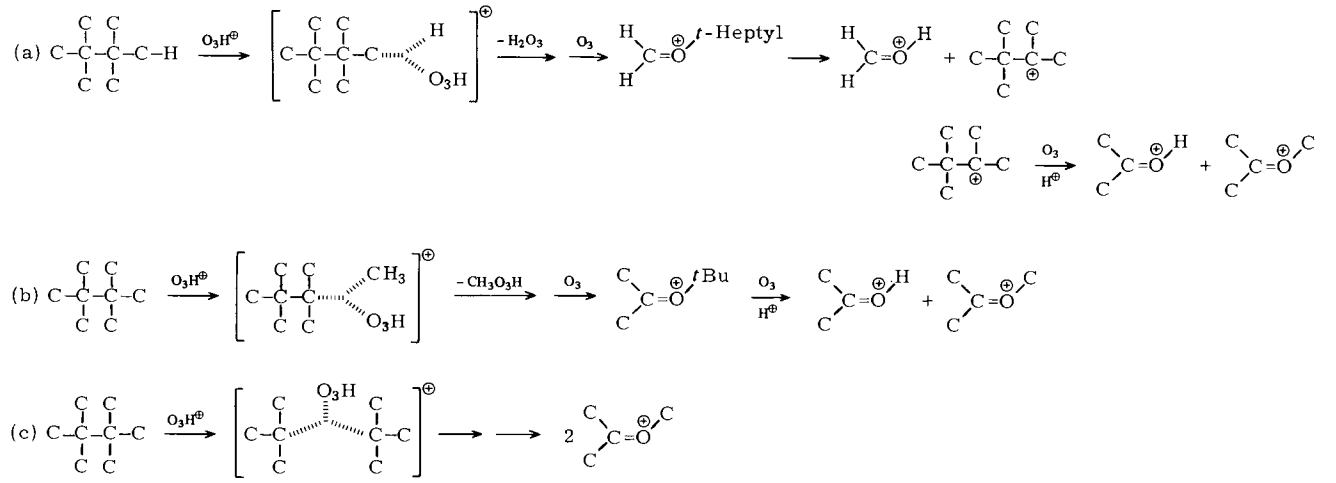


The significant difference between the reaction of neopentane with ozone in FSO_3H-SbF_5-SO_2ClF and in HF-SbF_5-SO_2ClF or SbF_5-SO_2ClF, respectively, is the formation of neopentyl alcohol in the first system. In the case of the reaction of alkylcarbenium ions with ozone (Scheme 28), there is no reason for alcohol formation. On the other hand, under conditions where electrophilic attack of protonated ozone on the σ-bonds of alkanes is preferential, the subsequent formation of hydrogen peroxide or trioxide in the course of the reaction leads to the formation of reactive hydroxylating agents in the superacidic media. Indeed, when neopentane was treated with hydrogen peroxide in FSO_3H-SbF_5-SO_2ClF solution at $-70\,^{\circ}C$, the formation of neopentyl alcohol was observed (Scheme 36).

Scheme 36

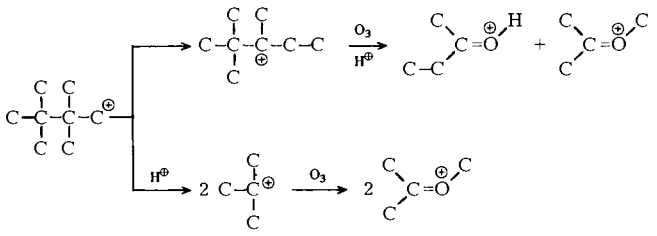
Since no other products apart from neopentyl alcohol were observed under the reaction conditions, the attack of protonated hydrogen peroxide on neopentane is exclusively at the C—H bonds. On raising the temperature to $-60\,^{\circ}C$, the rate of formation of the alcohol is remarkably increased. At $-40\,^{\circ}C$, however, formation of *tert*-pentyl cation was observed and when excess hydrogen peroxide was used in the reaction dimethylethylcarboxonium ion was obtained (Scheme 37).

Scheme 37



2,2,3,3-Tetramethylbutane, when treated with ozone in FSO_3H-SbF_5-SO_2ClF solution at $-78\,^{\circ}C$ gave dimethylmethylcarboxonium ion and (protonated) acetone together with 2,2,3,3-tetramethylbutyl alcohol as major products. The dimethylmethylcarboxonium ion and acetone were formed in the molar ratio 1:1. Formaldehyde, methyl ethyl ketone, acetylium ion and carbon dioxide were also found in small amounts. These findings once again indicate that the reaction takes place by initial electrophilic σ-bond insertion by protonated ozone into the alkane, as shown in Scheme 38.

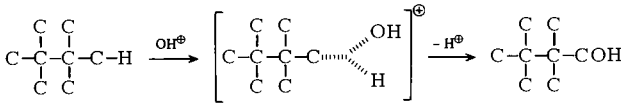
Although in principle, the reaction can take place by attack of protonated ozone at either the C—H, C^1—C^2 or C^2—C^3 bond (paths (a), (b) or (c), respectively, in Scheme 38), the reactivity of the C—H bonds is considered to be much higher than that of the sterically highly hindered C^1—C^2 or C^2—C^3 bonds. Indeed, the product distribution obtained shows that there is little C^2—C^3 bond cleavage [path (c)]. Although cleavage of the C^1—C^2 or C—H bonds would also be in accordance with the experimental results (product ratio dimethylmethylcarboxonium ion : acetone = 1 : 1), the results of the reaction of ethane giving almost exclusively acetaldehyde under the same reaction conditions (see Scheme 30) suggest that attack by protonated ozone preferentially takes place at the C—H bonds.



As shown in Scheme 38 (path (a)), elimination of hydrogen trioxide from the pentacoordinated carbonium ion can give the neooctyl cation, which then rearranges to the more stable

Scheme 38

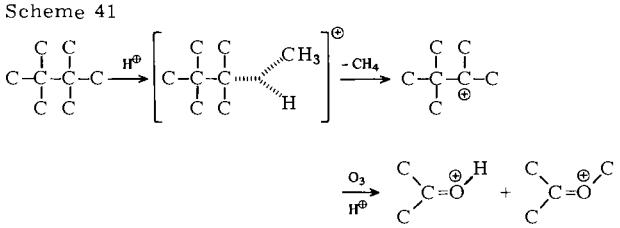
cation tBu(Me)EtC$^+$ or cleave to the *tert*-butyl cation, as shown in Scheme 39. However, no methyl ethyl ketone was formed, and the product distribution shown in Table 14 would suggest that rearrangement or cleavage of the neooctyl cation is only a minor reaction path.



Scheme 39

The *O-tert*-heptylcarboxonium ion has not been observed as long-lived species in solution. It seems to readily decompose, giving formaldehyde and the dimethyl-*tert*-butylcarbenium ion, which then readily reacts with ozone giving the dimethyl-*tert*-butylcarboxonium ion, which in turn immediately cleaves to (protonated) acetone and the dimethylmethylcarboxonium ion. Indeed, the reaction of triptane (2,2,3-trimethylbutane) under the same reaction conditions showed exclusively the formation of dimethylmethylcarboxonium ion and acetone in the ratio 1:1 (see Scheme 29).

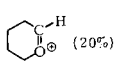
2,2,3,3-Tetramethylbutane gave the corresponding alcohol (2,2,3,3-tetramethylbutyl alcohol) in higher yield (30%) than did neopentane (5%) under the same conditions (Scheme 40).

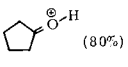


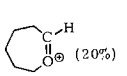
Scheme 40

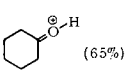
The differing yields of the corresponding alcohols from neoalkanes seems to reflect the differing reactivity of hydroxylating agent towards the σ-bonds involved. Similar observations were made in the reaction of hydrogen peroxide in the presence of FSO_3H-SbF_5-SO_2ClF. The lowest temperature for formation of the corresponding alcohols is, in the case of methane, ethane, neopentane and 2,2,3,3-tetramethylbutane, about −20, −40, −70 and −75 °C, respectively. The differing reactivity of the C—H bonds in these alkanes is interesting, but the reasons are not yet fully understood.

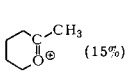
In HF-SbF_5-SO_2ClF solution, the reaction of 2,2,3,3-tetramethylbutane with ozone gave dimethylmethylcarboxonium ion and protonated acetone in a molar ratio of about 1:1, but no alcoholic products. This clearly demonstrates protolysis of the alkane prior to ozonolysis, as shown in Scheme 41.











Scheme 41

2.5.5. Cycloalkanes

When cyclopentane was allowed to react with ozone in the presence of FSO_3H-SbF_5-SO_2ClF at −78 °C, the NMR spectra of the resultant solution were consistent with formation

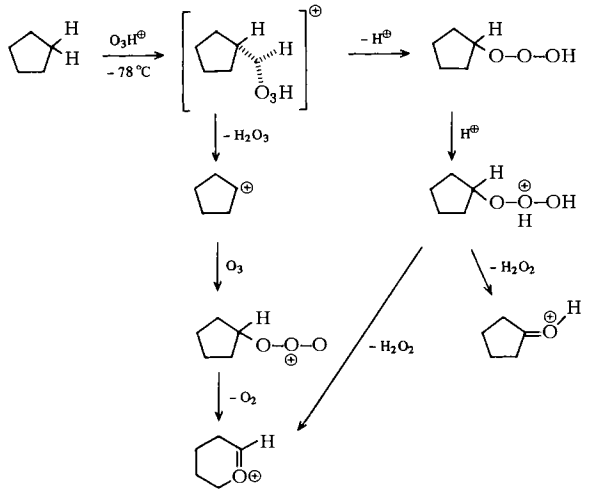


Table 15. Products of the reaction of cycloalkanes in magic acid-SO_2ClF [a].

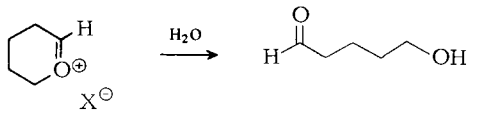
Alkane	Reaction Temp. [°C]	Oxidizing Agent	Major Products
	-78	O_3	 (20%)  (80%)
	-78	O_3	 (20%)  (65%)  (15%)
	-78	O_3	
	-78	O_3	
	-60	H_2O_2	
	-60	H_2O_2	
	-78	O_3 or H_2O_2	



[a] 10 mmol of alkane in threefold excess of magic acid-SO_2ClF solution were treated with 30 mmol of ozone or 5—10 mmol of H_2O_2. See also footnotes [a] and [b] in Table 11.

of protonated cyclopentanone and cyclic carboxonium ions (Scheme 42; cf. Table 15).

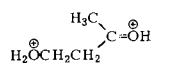
Scheme 42

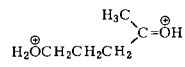
The cyclic carboxonium ion that is formed gives 5-hydroxypentanal on hydrolysis.

The reaction of cycloalkanes with ozone or hydrogen peroxide in the presence of superacids is presently being investigated[67].

2.6. Electrophilic Oxygenation of Functionalized Compounds. Preparation of Bifunctional Derivatives[103]

Despite the high reactivity of protonated ozone with alkanes in superacids, methyl alcohol, acetone or acetaldehyde were not found to be further oxidized by ozone in magic acid-SO_2ClF solution under the reaction conditions employed. In the superacidic system, they are present as completely protonated species, *i.e.* as $CH_3\overset{+}{O}H_2$, $(CH_3)_2C{=}\overset{+}{O}H$ and $CH_3(H)C{=}\overset{+}{O}H$; thus protonated ozone will not readily react with σ-bonds located in the proximity of the carboxonium center in the protonated substrates. On the other hand, σ-bonds which are located sufficiently far away from the charged carboxonium center may be attached and undergo reaction.





In order to clarify the behavior of oxygenated products in ozone-superacid systems, the reaction of aliphatic alcohols, ketones and aldehydes with ozone in magic acid-SO_2ClF or FSO_3H solution has been investigated.

2.6.1. Alcohols

Alcohols with short alkyl chains, such as methyl, ethyl and propyl alcohol do not react with ozone under superacidic conditions. However, butyl and higher homologous primary alcohols react readily, giving hydroxyketones as products. The products obtained are listed in Table 16.

The data of Table 16 show that tertiary or secondary C—H bonds of primary alcohols located γ- or farther away from the oxonium center undergo insertion reactions with protonated ozone, giving oxidation products in good yield. In general, straight chain primary alcohols give hydroxyketones (in their protonated form), whereas branched chain primary alcohols give dimethyl-ω-oxonioalkylcarboxonium ions. The latter, upon hydrolysis, give acetone and the corresponding glycol.

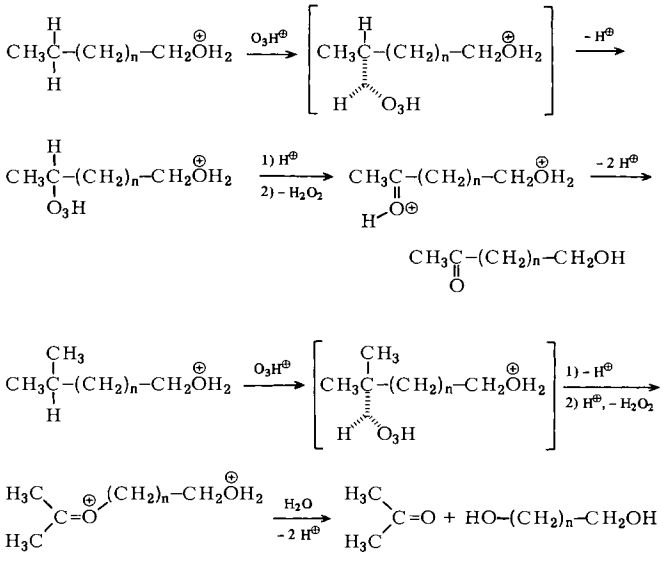


Table 16. Products of the reaction of aliphatic alcohols, ketones and aldehydes with ozone in magic acid [a].

Substrate	Reaction Temp. [°C]	Conversion [b] [%]	Product
$CH_3CH_2CH_2CH_2OH$	-40	30	
$CH_3CH_2\underset{\underset{OH}{|}}{C}HCH_3$	-40	100	
$CH_3\underset{\underset{CH_3}{|}}{C}HCH_2CH_2OH$	-40	60	
$CH_3CH_2CH_2CH_2CH_2OH$	-78	100	
$CH_3CH_2CH_2\underset{\underset{O}{\|}}{C}-CH_3$	-40	[c]	
$CH_3CH_2CH_2CH_2\underset{\underset{O}{\|}}{C}CH_3$	-78	100	
$CH_3CH_2CH_2CH_2\underset{\underset{O}{\|}}{C}H$	-78	80	

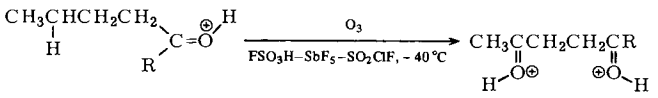
[a] See footnotes [a] and [b] in Table 11. [b] Based on substrate. [c] No reaction.

As discussed previously, the relative order of reactivity of σ-bonds in alkanes with protonated ozone is generally $R_3C{-}H > R_2(H)C{-}H, R(H_2)C{-}H > C{-}C$. A similar order of reactivity was found in the reactions of protonated alcohols and carbonyl compounds. 3-Methyl-1-butyl alcohol (with a tertiary C—H bond at the γ position) undergoes reaction with protonated ozone more readily than butyl alcohol (with a secondary C—H bond at the γ position) giving oxidation-rearrangement products as shown in Scheme 43.

Scheme 43

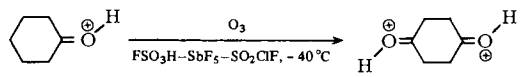
These results are in sharp contrast to those observed in the absence of magic acid. In trichlorofluoromethane solution,

ozonization of alcohols was reported to give exclusively products of α-oxidation, *i.e.* carboxylic acids and ketones[104]. It is thus reasonable to assume that reactions in superacids proceed *via* electrophilic oxygenation of the involved C—H bonds of the alcohols with protonated ozone, analogously to the previously discussed alkanes, as shown in Scheme 43. The superacid fully protonates the hydroxymethyl groups and thus protects them from oxidation.



Similar reactions also take place in FSO_3H at −40 °C in the case of aliphatic alcohols in which *n* is larger than 4. However, the yield of bifunctional oxygenated products is lower than that obtained in magic acid-SO_2ClF solution. In the weaker FSO_3H acid, ozone is less completely protonated and is thus a weaker electrophilic reagent than it is in magic acid solution.

2-Propyl and 2-butyl alcohol do not react with ozone in magic acid-SO_2ClF at −78 °C, but at −40 °C they give protonated acetone and dimethylmethylcarboxonium ions, respectively. This indicates that in these systems protolytic ionization of the alcohols takes place at −40 °C, giving rise to the corresponding alkylcarbenium ions, which then readily react with ozone, yielding the oxygenation products described previously.



2.6.2. Ketones and Aldehydes

The results of the reactions of aliphatic ketones and aldehydes with ozone in superacids are summarized in Table 16.

In contrast to the behavior of the previously discussed aliphatic alcohols, secondary C—H bonds of aliphatic ketones and aldehydes, such as 2-pentanone, butyraldehyde or cyclopentanone, located γ to the carbonyl oxygen do not react with protonated ozone in the presence of magic acid-SO_2ClF solution at −40 °C. The strong electron-withdrawing effect of the protonated carbonyl group is sufficient to inhibit reaction at these C—H bonds. Higher homologous ketones and aldehydes, however, do react, giving oxygenated products arising from oxygen insertion into farther located σ-bonds.

R = H, CH_3, C_2H_5

In the case of cyclohexanone, the yield of 1,4-cyclohexanedione is low, even at a reaction temperature of −40 °C. However, the reaction of cycloheptanone, having two methylene groups γ to the carbonyl carbon, produces 1,4-cycloheptanedione in 60% yield at −78 °C.

In previously studied ozonolysis reactions of aldehydes with neutral ozone, *White* and *Bailey*[105] and *Erickson et al.*[106] suggested that the attack by ozone is a concerted 1,3-dipolar insertion, having electrophilic character. There was, however, no other attack observed than on the carbonyl carbon. Reactions of ketones with neutral ozone also yielded only products due to attack on the carbonyl carbon[55].

In contrast, using superacidic conditions the reaction with oxygen containing 5% ozone gave no products arising from carbonyl-carbon oxidation. Hence, these reactions can be again best described as involving electrophilic oxygenation of C—H σ-bonds by protonated ozone.

In summary the oxygenation of alkanes in highly acidic (superacidic) media shows promise of developing into a field of substantial interest, allowing the preparation of a wide variety of oxyfunctionalized products in selective, frequently highly productive reactions.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Use of a Photoelectron Spectrometer in Gas Phase Analysis: Cyanogen and Hydrogen Cyanide[1]

By *Hans Bock*, *Bahman Solouki*, and *Jörg Wittmann*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 75th birthday

Photoelectron spectra permit observation of all Koopmans radical cation states of a molecule, and, therefore, patterns of ionization bands recorded represent a "molecular fingerprint". If the PE spectra of various molecules do not overlap completely, and provided that separate characteristic bands are recognizable, the course of a gas phase reaction can be traced visually: the PE fingerprints of the reactants give way to those of the products, depending on the reactants[2a, b], temperature[2c–e], and pressure[2a]. Moreover, comparison of the intensities of the reactant and product bands—if proportional to concentration—affords information about conversion rates and about detection limits.

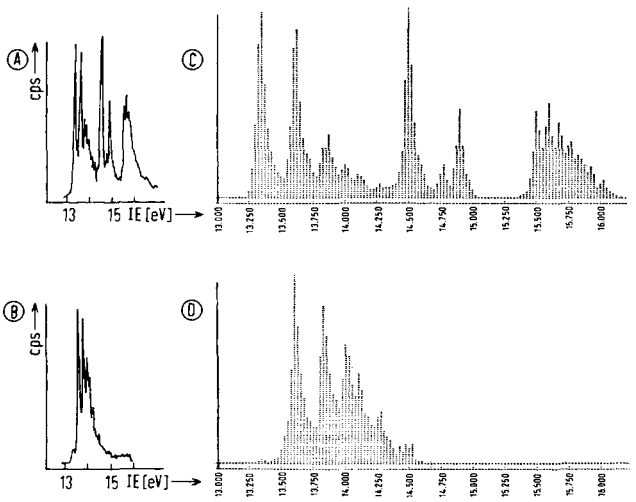

Fig. 1. PE spectra (12—17 eV) of NCCN/HCN mixtures in the partial pressure ratios 75:25 (A) and 2:98 (B), and their computer simulation [3] (C) and (D).

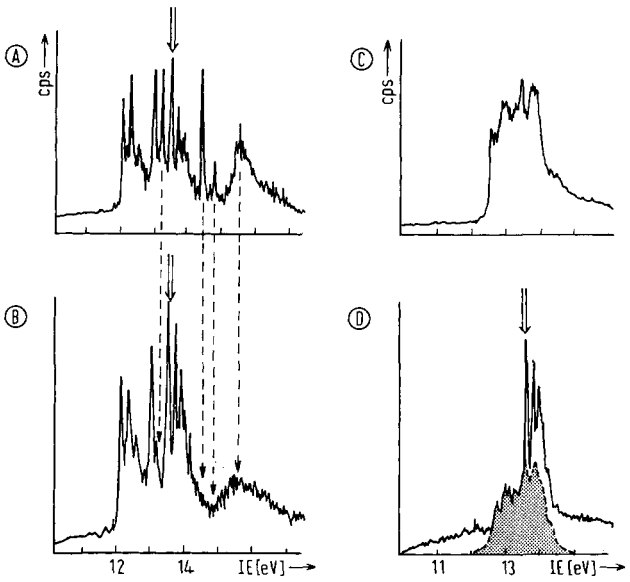
The development and application of a gas phase analytical technique based on PE spectroscopy will be illustrated for the poisonous pseudohalogen derivatives cyanogen and hydrogen cyanide. These gases are mixed in a 1-liter round-bottom flask (fitted with a manometer and attached to the PE spectrometer) in various pressure ratios $P_{NCCN} : P_{HCN}$ and the spectra of the series of mixtures are recorded (Fig. 1: (A) and (B)).

Assuming a linear dependence between PE band intensity and partial pressure, the spectra can be computer-simulated for any mixing ratio (Fig. 1: (C) + (D)). It is advantageous to use the relative intensities of the needle-like peaks at 13.3 eV (NCCN) and 13.6 eV (HCN + NCCN) for the analysis. Obviously, only about 25 parts of HCN in 75 parts of NCCN, but still 2 parts of NCCN in 98 parts of HCN can be detected (Fig. 1).

The PES analysis method, which can be set up within 1—2 days, permits rapid elucidation of gas phase reactions. For instance, on heating of acetonitrile and cyanogen in a quartz flow tube[2b, e], an increase in the peak at 13.6 eV above 1300 K indicates the formation of HCN (Fig. 2 (A): ⇓). If the H_3CCN partial pressure is increased tenfold at the same temperature, then the NCCN signals disappear completely (Fig. 2 (B): ↓). No other PE bands appear; a layer of graphite is deposited outside the furnace zone.



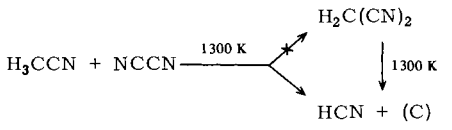


Fig. 2. PE spectra of H_3CCN/NCCN mixtures heated to 1300 K, $P_{H_3CCN} : P_{NCCN} = 1:1$ (A) and 10:1 (B), and of malononitrile at 300 K (C) and 1300 K (D).

Thus the thermal reaction of acetonitrile and cyanogen at 1300 K does not lead to malononitrile but to hydrogen cyanide and carbon:

Pyrolysis of malononitrile at 1300 K confirms that the compound decomposes at this temperature to hydrogen cyanide with deposition of graphite (Fig. 2: (C) + (D)).

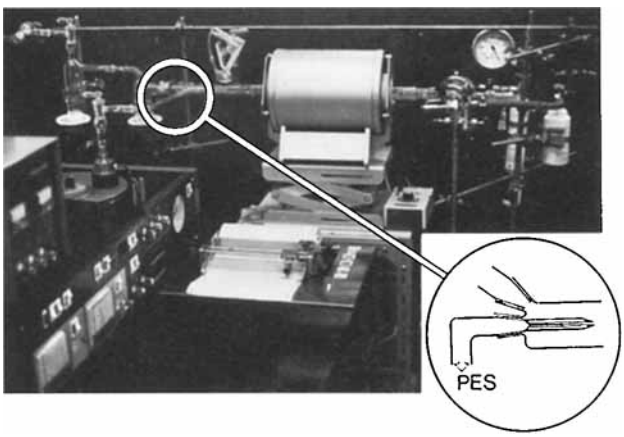
Copper-Catalyzed Cyanation of Benzene in the Gas Phase[1, 2]

By *Hans Bock, Bahman Solouki, Jörg Wittmann*, and *Hans-Jürgen Arpe*[*]

Dedicated to Professor Werner Schultheis on the occasion of his 75th birthday

The early tempestuous years of photoelectron spectroscopy—development of the method, commercial production of high-resolution spectrometers, measurement of the ionization patterns of thousands of molecules—have now been superseded by a time of reflection about practical applications[3]. Based on the experience gathered, it is now feasible, for example, to optimize gas phase reactions in a flow tube, including those which are heterogeneously catalyzed, with the aid of continuously recorded PE spectra (Fig. 1).



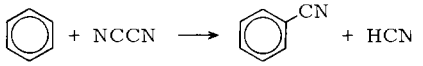


Fig. 1. Apparatus for the study of gas phase reactions on a preparative scale with variation of pressure and temperature [right to left: steel gas containers (warmed if necessary), mixing vessel, furnace with temperature control, bleeding valve to PE spectrometer, cold traps, oil pump].

In the standard apparatus (Fig. 1) the capillary Pitot tube of variable length permits up to 1000-fold reduction of the pressure of the hot gases leaving the reaction tube, at temperatures up to 1500 K, to the PE measuring pressure of about 13 Pa. This apparatus has been used, for instance, to examine the thermal reaction of benzene with cyanogen, employing the PES analysis technique developed for NCCN/HCN mixtures[1]. PES analysis in 50-K steps shows that the reaction[4]

starts at about 1300 K (Fig. 2).

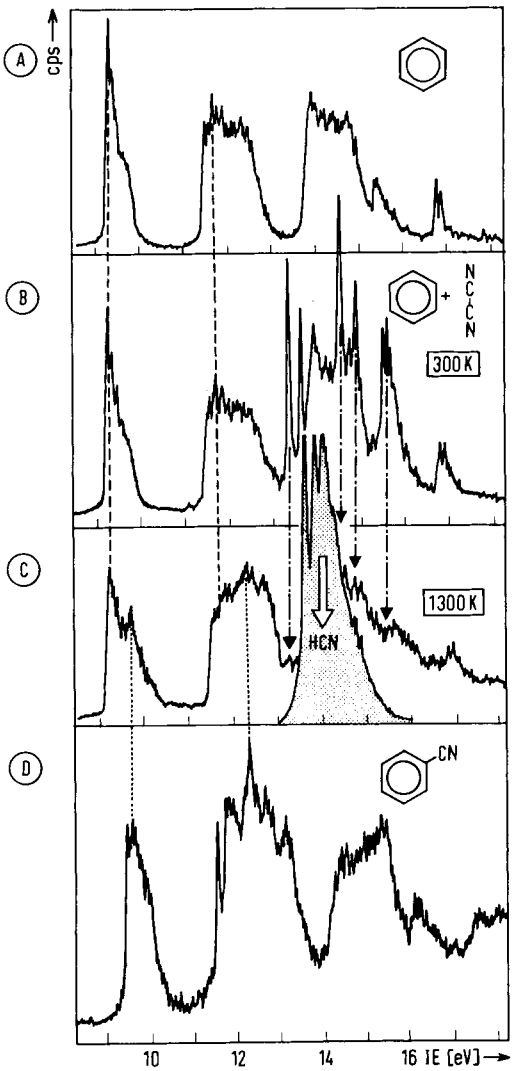

Fig. 2. PE spectrum of benzene (Ⓐ), its mixture with cyanogen at 300 and 1300 K (Ⓑ+Ⓒ), and of benzonitrile (Ⓓ) (assignment: ⇓ HCN, –·–·– NCCN, – – – C_6H_6, ····· C_6H_5CN).

The PE spectra (Fig. 2) clearly show that the bands of NCCN in the benzene/cyanogen mixture at 1300 K are replaced by those of HCN; simultaneously, benzonitrile can be detected.

Various copper catalysts were introduced in screening tests with the aim of reducing the high reaction temperature: a drop of 700 degrees to 600 K has been achieved with Cu/Al_2O_3. Moreover, one observes that the catalyst becomes inactive on raising the temperature to 700 K, only to regain its activity at 800 K—presumably owing to the temporary occupation of the active centers by products and/or undesired side products.

Cyanation of benzene on a preparative scale under conditions optimized by PES (standard apparatus (Fig. 1), Cu/Al_2O_3, 10 torr, 850 K) affords *ca.* 40 wt-% of benzonitrile in a single passage.

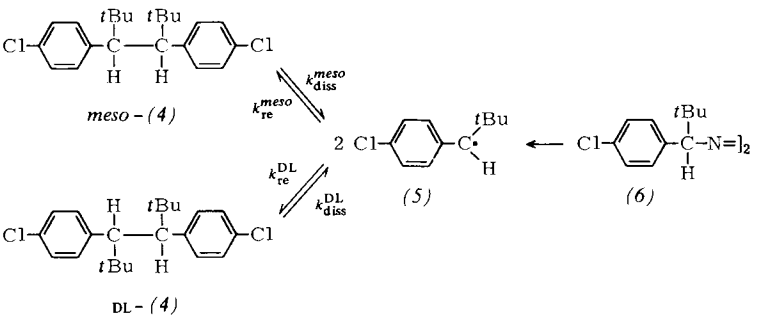
Diastereoselective Radical Recombination and Variation in Thermal Stability of Diastereomeric Hydrocarbons[**]



By *Karl-Heinz Eichin, Kevin J. McCullough, Hans-Dieter Beckhaus*, and *Christoph Rüchardt*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 65th birthday

The rate of dimerization of simple alkyl radicals in solution is determined by their rate of diffusion[1]; 1-phenylethyl and 2-phenyl-3-methylbutyl each give two diastereomeric dimers in the ratio 1:1[1a,2]. Bulky alkyl radicals such as di-*tert*-butylmethyl or triisopropylmethyl, on the other hand, are persistent[3] and do not dimerize. The dimerization of medium-sized radicals therefore ought to proceed *via* an activation threshold. An indication of this was provided by kinetic investigation of the thermolysis of highly-strained alkanes *(1)*[4], from which it could be concluded that 40% of the strain enthalpy of *(1)* is retained in the transition state *(2)* of homolytic decomposition.

$$R^1R^2R^3C{-}CR^1R^2R^3 \xrightarrow{\Delta} [R^1R^2R^3C\cdots CR^1R^2R^3]^{\ddagger} \longrightarrow 2\ R^1R^2R^3C^{\bullet}$$
(1) *(2)* *(3)*

Hence, the dimerization of *(3)* to *(1)* should also have to overcome a corresponding activation barrier; the distribution of the diastereomeric dimers *(1)* is then no longer random. their dimers *meso*- and DL-3,4-di(*p*-chlorophenyl)-2,2,5,5-tetramethylhexane *(4)*, since the radicals *(5)* cannot disproportionate, owing to the fact that there are no β-H atoms[1a] and because blocking of the *p*-position leads to formation of only the α,α-dimer *(4)*, but no α,*p*-dimer[5]. In addition, the different thermal stability of the non-chlorinated dimers corresponding to *(4)* and their different conformations were known[8] from X-ray structural[7a] and NMR analysis[7b]. The configurational and conformational analyses of *(4)* could therefore be carried out analogously as in Ref.[6].

The thermolyses of *meso*- and of DL-*(4)* in 1-methylnaphthalene with 10 vol-% thiophenol was investigated kinetically and preparatively. At 300°C, 1-(p-chlorophenyl)-2,2-dimethylpropane is formed in 80% yield from *meso-(4)* and 75% yield from DL-*(4)*. In addition, the stable DL-*(4)* was also formed from *meso-(4)* by cage recombination[9] (*ca.* 10% in 3 halflives). From DL-*(4)* we also obtained *ca.* 3% of a product which was most likely 1,2-di(*p*-chlorophenyl)-3,3-dimethylbutane. Hence, the thermolysis of *(4)* proceeds almost exclusively by cleavage of the central C—C bond; the cage effect does not seriously interfere in the kinetic investigation. The rate of decomposition was determined by measuring the decrease in concentration of *(4)* by GC at 6 temperatures over a range of 50—60°C. The results are listed in Table 1[10].

Table 1. Kinetics of the thermolysis of *meso-(4)* and DL-*(4)* in 1-methylnaphthalene with 10 vol-% thiophenol.

(4)	$\Delta G^{\ddagger}$(300°C) [kcal/mol]	$\Delta H^{\ddagger} \pm \sigma$ [a] [kcal/mol]	$\Delta S^{\ddagger} \pm \sigma$ [a] [cal/mol·K]	k_{rel}(300°C) [b] [s^{-1}]	$T(\tau_{1/2} = 1\ h)$ [c] [°C]
DL	39.4	50.0±0.6	18.5±0.9	≡1.0	301
meso	37.5	47.8±1.0	18.0±1.9	5.5	279

[a] Standard deviation, $r > 0.999$; [b] $\sigma \pm 2.5\%$; [c] temperature for halflife $\tau_{1/2} = 1$ h.

The ratio of the yields is determined by the different strain enthalpy of the diastereomers of *(1)*. As has been demonstrated experimentally[4], the *meso*- and DL-forms of *(1)* with R^1 = *tert*-butyl, R^2 = cyclohexyl, and R^3 = H, differ in strain enthalpy and thermal stability. 1-Cyclohexyl-2,2-dimethylpropyl, or other similarly bulky radicals, should therefore recombine diastereoselectively.

As model compounds for testing this hypothesis we chose the 1-(*p*-chlorophenyl)-2,2-dimethylpropyl radicals *(5)* and

For determination of the diastereoselectivity of the recombination of *(5)*, 1-(*p*-chlorophenyl)-2,2-dimethyl-1-azopropane *(6)* was thermolyzed at 135.2°C in *n*-decane; *(4)* was obtained in 98% yield and, according to GC analysis, consisted of DL-*(4)* and *meso-(4)* in the ratio 1.66±0.05:1. This constitutes the first demonstration of the diastereoselectivity of a radical recombination[11]. For the recombination of *(5)* it is calculated that $\Delta\Delta G^{\ddagger}(135.2°C) = 0.4$ kcal/mol. Attempts to determine the temperature dependence of the yield of diastereoisomers by photolysis of *(6)* have so far failed because of the photolability[12] of *(4)* towards 253.7-nm light. From the activation parameters of the thermolysis of *meso*- and of DL-*(4)* it follows that $\Delta\Delta G^{\ddagger}(135.2°C) \approx 2.0$ kcal/mol for homolytic decomposition. Accordingly DL-*(4)*, with $\Delta\Delta G^{\ddagger} = 2.4$ kcal/mol, is thermodynamically more stable than *meso-(4)*. Since $\Delta S^{\ddagger}$ of the thermolysis of *meso*- and DL-*(4)* is constant within the error of measurement, a difference in strain enthalpy of $\Delta\Delta H = 2.4$ kcal/mol is obtained for the

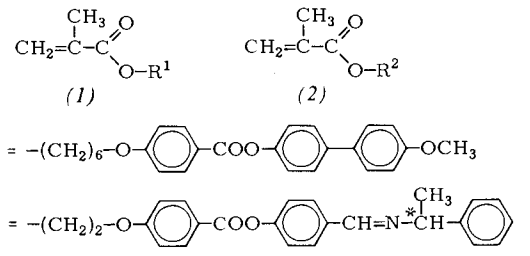
[9] *T. Koenig, H. Fischer* in *J. K. Kochi*: Free Radicals, Vol. 1, p. 157. Wiley-Interscience, New York 1973.
[10] The *p*-chloro substitution leads in *meso-(4)* to 1.1-fold acceleration, but in DL-*(4)* to 1.8-fold acceleration (300°C) relative to the thermolysis of *meso*- and DL-3,4-diphenyl-2,2,5,5-tetramethylhexane [6]. An increase of the dipole moment by substitution is expected only in the case of DL-*(4)* because of its *gauche* conformation [6, 7].
[11] In the dimerization of substituted benzyl radicals the *meso* dimer is often isolated in higher yields as the DL-form. Conclusions on the composition of the crude product, which was not analyzed in any one of the cases, are unreliable. Cf. *P. Gouverneur*, Ind. Chim. Belge *39*, 467 (1974) and [6].
[12] Contrathermodynamically, DL-*(4)* is photochemically more labile than *meso-(4)*.
[13] Using the force field of *Allinger* (1971) and the phenyl parameters of *Mislow* (SET-B), a difference in strain enthalpy of $\Delta\Delta H = 2.9$ kcal/mol [6] was calculated for the non-chlorinated analogues of *meso*- and DL-*(4)*.

Synthesis and Characterization of Liquid-Crystalline Polymers with Cholesteric Phase

By *Heino Finkelmann, Johanna Koldehoff*, and *Helmut Ringsdorf*[*]

We have already demonstrated by means of models that it should be feasible to systematically produce polymers with thermotropic liquid-crystalline phases by analogy with low molecular-weight liquid crystals[1]. The synthetic principle of these polymers lies in a side-chain type linkage to a polymeric backbone of known molecular units leading to a liquid-crystalline phase (mesogenic groups). It is essential that the mesogenic groups be bonded *via* flexible spacer groups (*e.g.* alkyl chains) to the polymer backbone, thus uncoupling the motions of the main and side chains. Nematic and smectic polymers have been synthesized in this way[1].

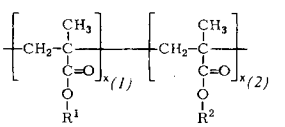
The synthesis of cholesteric polymers[2] requires that the polymerizable molecules be chiral. Apart from a known copolymeric cholesterol derivative[4], all attempts to polymerize cholesteric monomers led only to smectic polymers[3].



Studies on low molecular-weight liquid crystals have shown that a cholesteric helical structure can be induced in a nematic phase by addition of a chiral compound, even if the chiral component itself is not liquid crystalline[5]. Thus copolymerization of a nematogenic monomer, exhibiting a nematic phase as homopolymer, with a chiral monomer should yield induced cholesteric polymers.

The known biphenylyl benzoate derivative *(1)* served as nematogenic monomer[1]. Its homopolymer exhibits a smectic phase at low temperature in addition to a broad nematic phase (see Table 1). The chiral component *(2)*, which is itself not liquid crystalline as homopolymer, was chosen with the following points in mind:

1) Owing to the amount of chiral (−)-1-phenylethylamine present, small pitches *p* are expected for the cholesteric phase[6] at low concentration of *(2)* in the polymer.



2) In order to minimize perturbation of the nematic phase of polymeric *(1)*, compound *(2)* likewise contains a mesogenic group (phenyl benzoate unit).

3) To ensure random incorporation of monomers *(1)* and *(2)* in the polymer and that their contribution to the polymer corresponds to the composition of the monomeric mixture, the polymerizable groups should have approximately equal reactivities. The chiral monomer *(2)* is therefore also a methacrylate.

Both monomers *(1)* and *(2)* undergo radical polymerization. The phase transitions of the polymers are compiled in Table 1. Studies under a polarizing microscope show that above the glass transition temperature T_G a layer of the polymers located between glass slides spontaneously assumes a cholesteric Grandjean texture. For polymers having $x_{(2)} > 0.17$ this texture is to be seen in the reflection of visible circularly polarized light. It is particularly interesting that the reflecting Grandjean texture remains fixed in the glassy state of the polymer on cooling.

Table 1. Composition, phase transitions, and reflection wavelengths λ_R of the polymers

flected light of wavelength λ_R as a function of temperature and composition (Fig. 1a). According to *de Vries*[7], λ_R and the pitch p and mean index of refraction $\bar{n}$ are related by $\lambda_R = \bar{n}p$. The reciprocal reflection wavelength ($1/\lambda_R$) is a direct

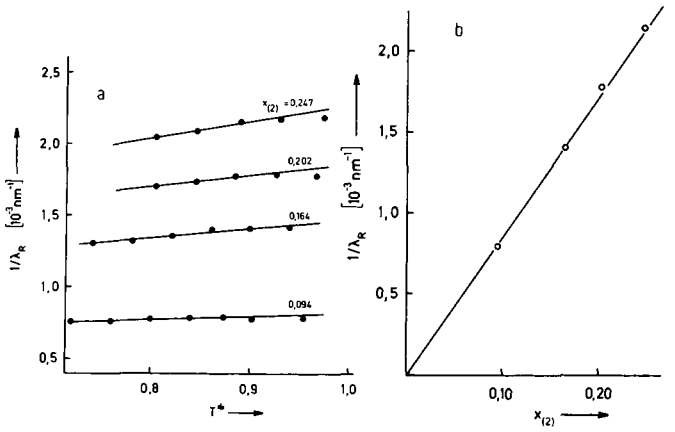

Fig. 1. a) Dependence of the reciprocal of the reflection wavelength $1/\lambda_R$ of cholesteric polymers on the reduced temperature T^* ($T^* = T_{measurement}/T_{clearing\ point}$) and composition (Table 1). b) Dependence of the reciprocal of the reflection wavelength $1/\lambda_R$ on the mole fraction $x_{(2)}$ of the chiral monomer unit *(2)* in the polymer at $T^* = 0.9$. In order to measure the reflection wavelength, the polymeric samples were placed in a layer thickness of *ca.* 20 µm between two plane parallel quartz plates above their glass transition temperature, whereupon the reflecting Grandjean texture immediately appears. The apparent absorption resulting from the reflection was measured in a temperature-controlled measuring cell in a Cary 14 spectral photometer.

measure of helical twisting. $1/\lambda_R = 0$ for nematic phases. As the temperature increases all the polymers show a blue shift of the reflection wavelength, the positive gradient $d(1/\lambda_R)/dT^*$ increasing with increasing amount of chiral component *(2)* in the polymer. Below the glass transition temperature T_G, λ_R is no longer observed to be temperature dependent. The light reflected by the samples investigated is levo-circularly polarized. The polymers accordingly have a cholesteric *l* helix if *(2)* is synthesized from (−)-1-phenylethylamine. The halfwidth of λ_R, determined by measurement of the apparent absorption, lies between 80 and 350 nm for a sample layer thickness of *ca.* 20 µm. The halfwidth increases with increasing temperature and with increasing concentration of the chiral component.

In Figure 1b, $1/\lambda_R$ is plotted as a function of the mole fraction $x_{(2)}$ of the chiral monomer unit. It is seen from this plot (cf. Table 1) that the polymers reflect in the visible region for $0.2 < x_{(2)} < 0.3$. Moreover, it is remarkable that $1/\lambda_R$ is a linear function of $x_{(2)}$ within the limits of experimental accuracy. The optical properties of the polymers thus correspond to those of ideal low-molecular cholesteric mixed systems[6].

The polymers obtained from *(1)* and *(2)* therefore provide the first demonstration that cholesteric polymeric phases can be produced by copolymerization of nematogenic and chiral monomers, by analogy with low molecular-weight cholesteric phases. The optical properties of the polymers resemble those of conventional cholesteric phases. However, it is a novel and characteristic feature of the polymers that the texture reflecting circularly polarized light can be fixed in the glassy state. New applications thus come to mind, such as the production of circular and linear polarization filters and reflectors for light of adjustable wavelength. Uses in display technology and as memory units are also conceivable.

Experimental

Synthesis of the chiral monomer *(1)*: (+)- or (−)-1-phenylethylamine (16 ml) is slowly added dropwise to a hot solution of *p*-hydroxybenzaldehyde (15 g) in toluene (150 ml); the water formed is removed by azeotropic distillation. On completion of reaction, the solution is cooled, and the crude product filtered off. It is recrystallized from ethanol (m. p. 170 °C (dec.)) and transformed into the phenoxide with sodium ethoxide in solution in ethyl alcohol. 4-(4-Chlorocarbonylphenoxy)ethyl methacrylate (50 mmol) in ether (20 ml) is added slowly with stirring at room temperature to sodium 4-(1-phenylethyl)-iminomethylidyne phenoxide (50 mmol). After two hours' stirring the reaction mixture is poured into ether (250 ml), washed with water, and the solvent is removed after drying with Na_2SO_4. Crude *(2)* is recrystallized from ethanol (m. p. 82 °C); *(2)* gives correct analytical values and compatible IR, UV, and ^{1}H-NMR spectra.

Polymerization of *(1)* or *(1)* and *(2)*: The monomer or mixture of monomers is subjected to radical polymerization in 10% tetrahydrofuran solution in the absence of oxygen at 55 °C with 1 mol% of azodiisobutyronitrile as initiator. The polymers are purified by reprecipitating twice from acetone. The ratio of incorporation of the monomers is established by measurement of the optical rotation, and shows the expected agreement with the mixing ratio (see Table 1).

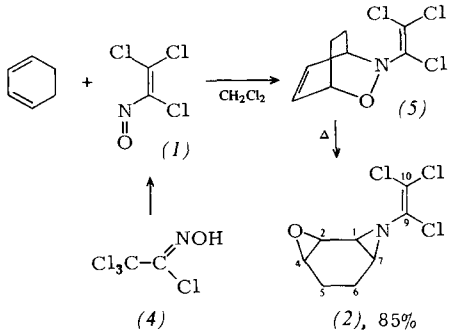
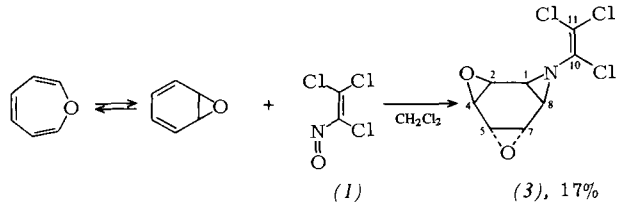
trans-3,6-Dioxa-9-azatris-σ-homobenzene and *cis*-Epoxyepimino-1,3-cyclohexadiene[**]

By *Eric Francotte, Robert Merényi*, and *Heinz Günter Viehe*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 65th birthday



We recently reported the first case of a one step stereospecific epoxyepimination of cyclopentadiene with chloro(nitroso)ethenes[1]. Whereas the addition of nitroso groups to 1,3-dienes is well known, the subsequent rearrangement of the product with stereospecific functionalization of the four sp^2 carbon atoms of the diene constitutes a new reaction, analogous to the rearrangement of endoperoxides to diepoxides[2].



We now report on the stereospecific synthesis of the *N*-trichloroethenyl derivative of *cis*-epoxyepimino-1,3-cyclohexadiene *(2)* and of *trans*-3,6-dioxa-9-azatris-σ-homobenzene *(3)* by reaction of trichloro(nitroso)ethene *(1)* with 1,3-cyclohexadiene and with oxepin[5], respectively. The nitroso compound *(1)* is not stable in pure form at room temperature and

[*] Prof. Dr. H. G. Viehe, Dr. E. Francotte, Dipl.-Ing. R. Merényi

Place Louis Pasteur 1, B-1348 Louvain-la-Neuve (Belgium)
[**] Aza-Analogy to Singlet Oxygen, Part 2. — Part 1: [1a].

is therefore generated *in situ* from trichloroacetohydroximoyl chloride *(4)*[3].

While oxepin reacts directly with *(1)* to give *(3)*, reaction of *(1)* with 1,3-cyclohexadiene gives cycloadduct *(5)* as intermediate. This thermally labile compound rearranges even at room temperature, and more rapidly on heating, to give *(2)* in quantitative yield.

The structures of the products *(2)* and *(3)* follow from their ^{1}H- and ^{13}C-NMR spectra (see Table 1). In the case of *(2)* the NMR data are comparable with those of the adduct of 1,1-dichloro(nitroso)ethene and cyclopentadiene[1] and with those of the diepoxy-1,3-cyclohexadiene[4].

The vicinal coupling constant $^3J_{1,2}$ in the ^{1}H-NMR spectrum of *(2)* is compatible only with a *cis* configuration. The ^{13}C-NMR spectrum of *(3)* shows six non-identical ring carbon atoms; of the possible stereoisomeric dioxaazatris-σ-homobenzenes[6, 7] *(3)* has the lowest symmetry.

Experimental:

Trichloronitrosoethene *(1)*: A solution of the hydroximoyl chloride *(4)*[3] (2.0 g) in 50 ml of dichloromethane is stirred with 5 g of $NaHCO_3$ for 10 min at room temperature.—IR (CH_2Cl_2): ν = 1610, 1460, 1050, 920, 830 cm^{-1}.—UV/VIS (CH_2Cl_2): λ_{max} = 320 and 740 nm.

8-Trichloroethenyl-*cis*-3-oxa-8-azatricyclo[5.1.0.0^{2,4}]octane *(2)*: A mixture of *(4)*[3] (0.01 mol), cyclohexadiene (0.015 mol) and 4 g of Na_2CO_3 in 50 ml of dichloromethane is stirred for 10 h at room temperature. After evaporation of the solvent, the remaining oil is purified by chromatography [silica gel; cyclohexane/ether (1:1)]; the isomers *(2)* and *(5)* are obtained in variable ratio (overall yield: 85%). *(5)*: colorless liquid; IR ($CHCl_3$): ν = 2980, 1590 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ = 2.33—1.17 (4H, m), 3.90 (1H, m), 4.57 (1H, m), 6.45 (2H, d of m). *(2)*: white solid, m.p. 64—65 °C; IR ($CHCl_3$): ν = 2990, 1595 cm^{-1}; MS: *m/e* = 239 (M^+), 204, 136, 95, 77, 67.

9-Trichloroethenyl-*trans*-3,6-dioxa-9-azatetracyclo-[6.1.0.0^{2,4}.0^{5,7}]nonane *(3)*: 50 ml of a solution of *(1)*, prepared as above, is added dropwise with stirring at −20 °C to a solution of 2.0 g of the oxepin[5] in dichloromethane. After 6 h at room temperature, the solvent is evaporated off and the residue is purified by column chromatography (silica gel; $CHCl_3$). Yield of *(3)*, m.p. 135—136 °C, 17%. IR ($CHCl_3$): ν = 2990, 1600, 880 cm^{-1}; MS: *m/e* = 253 (M^+), 160, 129, 94, 81, 53.

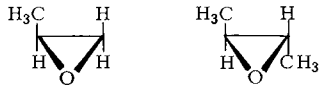
Correlation of the Absolute Configuration of Chiral Epoxides by Complexation Chromatography; Synthesis and Enantiomeric Purity of (+)- and (−)-1,2-Epoxypropane[**]

By *Volker Schurig, Bernhard Koppenhöfer*, and *Waldemar Bürkle*[*]



Optically active oxiranes are of interest for the investigation of reaction mechanisms and as synthons in the preparation of chiral natural products[1a]. For use in such studies it is

[*] Univ.-Doz. Dr. V. Schurig, B. Koppenhöfer, W. Bürkle

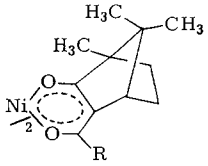
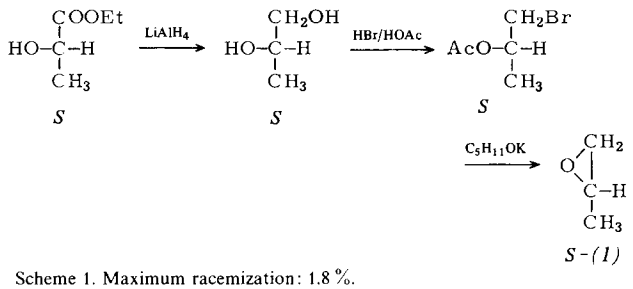
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



essential that the enantiomeric purity and the absolute configuration of the oxiranes are known with certainty.

We recently described the rapid and quantitative resolution of the enantiomers of the racemic oxiranes 1,2-epoxypropane *(1)* and *trans*-2,3-epoxybutane *(2)* by complexation chromatography on optically active nickel(II) bis(3-trifluoroacetyl-1*R*-camphorate) *(3a)* in squalane solution as selective stationary phase[2].

S-*(1)*



2*S*, 3*S*-*(2)*

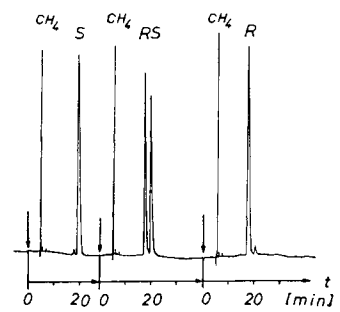
(3a), R = CF_3
(3b), R = $CF_2CF_2CF_3$

We have now found that replacement of the trifluoroacetyl group by a heptafluorobutyryl group *(3b)* increases the capability of enantiomer differentiation of the separating phase and leads to the greatest separation factors so far observed for chiral recognition by enantiospecific "one point" coordination [*(1)*, $\alpha = 1.24$; *(2)*, $\alpha = 1.43$, 50°C]. We describe here the use of this method for the determination of enantiomeric purity, for the extrapolation of the optical rotation of the *pure* enantiomer, and for the correlative determination of configuration using as example *R*- and *S*-epoxypropane.

(−)-*S*-*(1)* was synthesized from ethyl (−)-*S*-lactate according to the method of *Golding et al.*[1b] (Scheme 1).

Scheme 1. Maximum racemization: 1.8%.

The complexation chromatogram (Fig. 1, left) of the reaction product, $[\alpha]_D^{20} = -14.14°$ (neat)[3], shows 1.8% of the *R*-antipode corresponding to an enantiomeric purity of 96.4% for (−)-*S*-*(1)*. This yielded the following corrected optical rotations for pure *S*-*(1)*: $[\alpha]^{20} = -14.65° \pm 0.05°$ (D); −15.15° (578); −16.70° (546); −23.35° (436); −26.28° (365); $[\alpha]_D^{16} = -14.90° \pm 0.05°$. The lower values reported in the literature thus correspond to samples of lower enantiomeric purity[4].



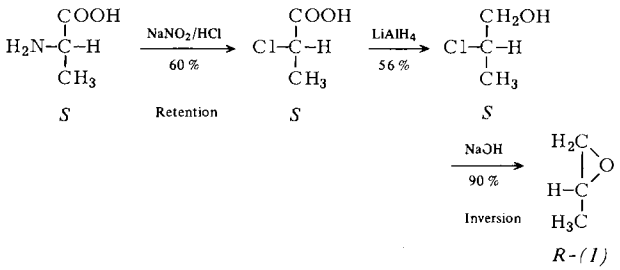


Fig. 1. Resolution of *(1)* by complexation gas chromatography on 1*R*-*(3b)* [0.13 *m* (monomer) in squalane] at 70°C. Column: 100 m × 0.5 mm nickel capillary, carrier gas: 3.8 ml/min N_2, split 1 : 50. Left (−)-*S*-*(1)*; center: racemic *(1)*; right: (+)-*R*-*(1)*.

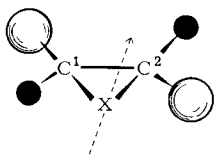
In the case of the (+)-*R*-*(1)* antipode we have worked out a productive method for the synthesis of chiral 1,2-epoxides of high optical purity from naturally occurring L(*S*)-amino acids by a combination of classical reaction steps (Scheme 2).



Scheme 2. Maximum racemization only 2.7% despite twofold direct substitution at the asymmetric carbon atom.

(+)-*R*-*(1)* was synthesized from L-alanine *via* *S*-2-chloropropionic acid[5] and *S*-2-chloro-1-propanol. The complexation chromatogram (Fig. 1, right) showed 2.7% of the *S*-antipode, corresponding to an enantiomeric purity of 94.6% for (+)-*R*-*(1)*. These investigations also make it possible to draw conclusions on the stereochemical course of the reaction of L-alanine with aqua regia (!) to give 2-chloropropionic acid[6]. The reaction must proceed with at least 89.4% retention, since (+)-*(1)*, $[\alpha]_D^{20} = +11.25°$ (neat), prepared *via* this route contains only 10.6% of the *S*-enantiomer, corresponding to 78.8% enantiomeric purity. The corrected optical rotation for (+)-*R*-*(1)* is thus $[\alpha]_D^{20} = +14.6° \pm 0.3°$.

It follows from Figure 1 that one of the enantiomers of 1,2-epoxypropane is formed according to Scheme 1, the other enantiomer according to Scheme 2. Thus, the configuration of L-alanine and L-lactic acid have been assigned *via* an independent route[7].

The *S*-*(1)* enantiomer is eluted later than the *R*-antipode on the nickel complex derived from (+)-1*R*-camphor. *Gil-Av et al.* were the first to correlate the absolute configuration of chiral substrates from the chromatographic retention behavior on an optically active stationary phase of defined chirality[8]. We extend this method, which does not necessitate knowledge of the absolute configuration of the separating phase, to the enantiospecific ligand-metal coordination interaction and we formulate a *quadrant rule* for the retention behavior of chiral three-membered ring heterocycles of structure *(4)* on (+)-*(3b)* as stationary phase, with (−)-*S*-*(1)* as reference compound:

When the molecule is viewed from the donor heteroatom in the direction of the horizontal C—C bond, the absolute configuration of the enantiomer eluting *later* is that in which the bulkier group(s) is(are) situated on the upper left at C-1 and/or lower right at C-2.

X = NH, O, S *(4)*

According to this rule, *e.g.*, the enantiomer of 1,2-epoxybutane ($\alpha = 1.11$, 50°C) eluting later on (+)-*(3b)* would be assigned the *S*-configuration. As expected, in the case of *trans*-2,3-epoxybutane *(2)* the 2*S*,3*S*-enantiomer[9] exhibits stronger interaction than the *R*-antipode with (+)-*(3b)* and is thus more strongly retarded.

As a further consequence of the rule, it can be predicted that chiral unsymmetrically substituted 1,1- or 1,2-*cis* derivatives ought to show only a slight enantiomeric resolution on *(3)*, compared to monosubstituted compounds, whereas 1,2-disubstituted *trans*-isomers ought to exhibit greater enantiomeric resolution. Indeed, it is found that the difference in free association enthalpy of the enantiomers of *(2)* ($\Delta_{S,R}(\Delta G) = -0.23$ kcal/mol, 323 K) on (+)-*(3b)* is almost double that observed in the case of the enantiomers of *(1)* ($\Delta_{S,R}(\Delta G) = -0.14$ kcal/mol, 323 K).

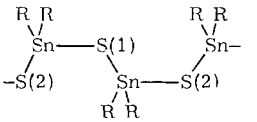
Structure of the First Open-Chain Diorganotin Chalcogenide[**]

By *Heinrich Puff, Anne Bongartz, Rolf Sievers*, and *René Zimmer*[*]

In previous X-ray crystallographic investigations on diorganotin chalcogenides either six-membered puckered[1] or four-membered planar[2] ring structures have been found. Besides these cyclic species we have also been able to isolate some compounds in modifications whose properties such as very low solubility, high and indefinite melting point, and special features in the vibrational spectrum[3] would indicate a polymeric structure. We have now found that colorless single crystals of polymeric diisopropyltin sulfide are formed if the initially low-molecular form of the product[4] obtained according to



$$i\mathrm{Pr_2SnCl_2} + \mathrm{Na_2S} \rightarrow 2\,\mathrm{NaCl} + i\mathrm{Pr_2SnS}$$

is allowed to stand under solvent (DMF). The new modification crystallizes orthorhombically (space group $Pna2_1$-C_{2v}^9; $a = 16.319$, $b = 9.455$, $c = 5.988$ Å) with four formula units $(C_3H_7)_2SnS$ in the unit cell.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The X-ray structure analysis[5] ($R = 0.042$) showed that tin and sulfur atoms are coupled alternatively in a planar chain in the direction of the *c*-axis[6].

Bond length	[Å]	Angle	[°]
Sn—S(1)	2.45	S—Sn—S	100.7
Sn—S(2)	2.40	Sn—S—Sn	105.6
Sn—C	2.17, 2.19	C—Sn—C	119.9

The SSnS angle (100.7°) in the chain lies between the values observed in six-membered[1] (106.1—108.7°) and four-membered rings[2] (94.0—94.3°). A comparison of the $(R_2SnX)_n$ structures so far investigated shows that the ring size in the *cyclo* forms and the relative stability of the *cyclo* and *catena* modifications are determined more by electronic effects of the organic groups R than by spatial requirements.

Ozone Cleavage of Olefins with Formation of Ester Fragments[**]

By *Joachim Neumeister, Helmut Keul, Mahendra Pratap Saxena*, and *Karl Griesbaum*[*]

Despite the manifold analytical and preparative applicability of the ozone cleavage reaction[1], there is as yet no method available which upon ozonolysis of 1,2-disubstituted ethylenes *(1)* affords directly the corresponding ester fragments *(5)*. We have now found that this is possible, however, if the ozonolysis of olefins *(1)* is carried out in an alcohol (R^1OH) in the presence of anhydrous hydrochloric acid.

The olefin *(1)* is ozonized at low temperatures (−50° to −70°C) until the double bonds are totally cleaved. The mixture is then allowed to warm to room temperature without further addition of ozone. During this time, an exothermic reaction occurs and concurrently the mixture becomes free of peroxide. Finally, ozone treatment is continued at −10° to +20°C until formation of ester is completed.

Kaiserstrasse 12, D-7500 Karlsruhe 1 (Germany)

[**] This work was supported by a DAAD (Deutscher Akademischer Austauschdienst) fellowship to *M. P. S.* and by the Fonds der Chemischen Industrie.

GLC analysis of the crude reaction products revealed yields of over 90 % of the corresponding esters. The yields of isolated esters were lower (62—85 %), this being partly due to difficulties in the separation of the esters *(5)* from the excess alcohol employed (Table 1).

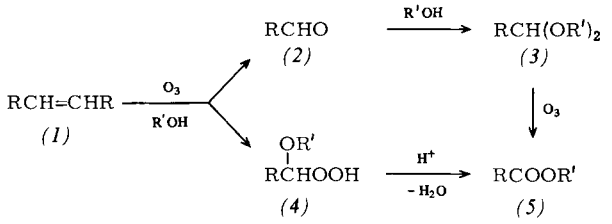

Table 1. Yields of esters on ozonolysis of olefins in the presence of HCl/R'OH [a].

Olefin *(1)*	Ester *(5)*	Yield [%]
4-Octene	$CH_3CH_2CH_2COOCH_3$	65
Stilbene	$C_6H_5COOCH_3$	72
Cyclopentene	$CH_3OOC(CH_2)_3COOCH_3$	78
Cyclohexene	$CH_3OOC(CH_2)_4COOCH_3$	85
Cyclooctene	$CH_3OOC(CH_2)_6COOCH_3$	80
Cyclodecene	$CH_3OOC(CH_2)_8COOCH_3$	62
[b]	$C_2H_5OOC(CH_2)_8COOC_2H_5$	69
[c]	$C_3H_7OOC(CH_2)_8COOC_3H_7$	80
1,5-Cyclooctadiene	$CH_3OOC(CH_2)_2COOCH_3$	64
Norbornene	Dimethyl 1,3-cyclopentane dicarboxylate (*cis*:*trans* = 9:1)	83

[a] Unless otherwise stated R' = CH_3. [b] R' = C_2H_5. [c] R' = *n*-C_3H_7.

Model reactions using selected olefins have shown that the reaction apparently proceeds *via* the following steps: Initially, the Criegee-fragments *(2)* and *(4)* are formed[2]. Acid-catalyzed dehydration of the alkoxy hydroperoxide *(4)* affords in an exothermic reaction the ester *(5)*[3], and at the same time aldehyde *(2)* is converted into the acetal *(3)*. On further treatment with ozone, *(3)* is finally converted into ester *(5)*[4].

Further work is underway concerning the course of the reaction, possible side-reactions, and the scope of this method with respect to variation of olefin and alcohol.

Typical Procedure

A mixture of 8.2 g (0.1 mol) of cyclohexene and 87 ml of a *ca.* 1 M solution of anhydrous hydrochloric acid in methanol was ozonized at −78 °C until ozone left the reaction vessel (KI-trap). The mixture was then flushed with nitrogen and subsequently allowed to warm. At approx. 0 °C an exothermic reaction set in (the mixture was cooled in an ice-bath so that the temperature did not exceed 35 °C). When the mixture was free of peroxide, ozone treatment was continued for 24 h at 0 °C. Then the mixture was flushed with nitrogen, refluxed for 3 h, and cooled to room temperature. Solid sodium bicarbonate was added, the mixture filtered, and the filtrate concentrated by evaporation at 35 °C/15 torr. The liquid residue was dissolved in 50 ml of ether, washed with 3 × 20 ml of water, dried over sodium sulfate, and the ether distilled off. Distillation of the residue (15.9 g) afforded dimethyl adipate, b.p. of 88—90 °C/0.3 torr (purity 98.4 %); yield 14.8 g (85.1 %).

Demonstration of Diastereomeric Electron-Donor-Acceptor Complexes by ^{1}H-NMR Spectroscopy[**]

By *Albrecht Mannschreck*, *Peter Roza*, *Hans Brockmann Jr.*, and *Thorsten Kemmer*[*]

Electron-donor-acceptor (EDA) complexes can frequently be detected in the UV/VIS spectrum by a band at long wavelength. This is rendered more difficult if the band is situated close to the absorption of a component. The change of NMR shifts can also provide proof of EDA complexes[1]; however, further influences upon the δ values, *e. g.* diamagnetic anisotropies, have to be taken into account besides genuine charge-transfer effects. In the case of *chiral* components, chiroptical properties[2] as well as ^{1}H-NMR signal splitting[3] by diastereomeric complexes represent further possibilities of investigation. The latter phenomenon may in principle be caused by all types of molecular association, although *Pirkle et al.*[3a] were the only ones to discuss such signal splittings in terms of an EDA interaction. *Pirkle et al.* suggested an EDA contribution besides hydrogen bonds for the complexation of dinitrophenyl compounds with 1-(1-naphthyl)ethylamine or 1-(9-anthryl)-2,2,2-trifluoroethanol. We have now succeeded in detecting diastereomeric EDA complexes unequivocally by NMR spectroscopy.

For this purpose we chose components for association which are available in optically active and in racemic form and for which, in addition, a high tendency for complexation was to be expected[4].

The fluorene derivative (*R*)-*(2)* which is used for preparative and analytical separation of enantiomers[5] served as a π-acceptor. The carbazole derivatives[6] (*RS*)-*(1)*, (*RS*)-*(3)*, (*RS*)-*(4)*, and (*RS*)-*(5)* were chosen as π-donors. The charge-transfer band of such EDA complexes around 500 nm overlaps with the absorption of *(2)* at longest wavelength (λ_{max} = 355 nm, lgε = 4.2, $CHCl_3$)[2a]. The ^{1}H-NMR signals of H-1, H-6, and H-8 in (*R*)-*(2)* as well as of H-4/H-5 in (*RS*)-*(2)* are shifted to *higher* field by 0.1 to 0.3 ppm when the mixture in [D_6]-acetone is cooled from +25 °C to −68 °C (Fig. 1, Table 1). At the same time, the *H*—C—CH_3 quartet of (*RS*)-*(1)* moves to *lower* field by 0.13 ppm, while all other C—H signals (except the non-analyzed absorptions of further ring protons in (*RS*)-*(1)*) approximately retain their positions. This behavior is compatible with equilibria shifted in favor of the association complexes by lowering the temperature, the shifts[4] being mainly due to the diamagnetic anisotropies of the two aromatic

[**] Application of NMR Spectroscopy of Chiral Associates, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. Some of the measurements were carried out by Dr. *T. Burgemeister* and *H.-H. Henschel*. We are grateful to Dr. *G. Becher* and Dr. *M. Holík* for discussions.—Part 6: *M. Holík*, *A. Mannschreck*, Org. Magn. Reson., in press.

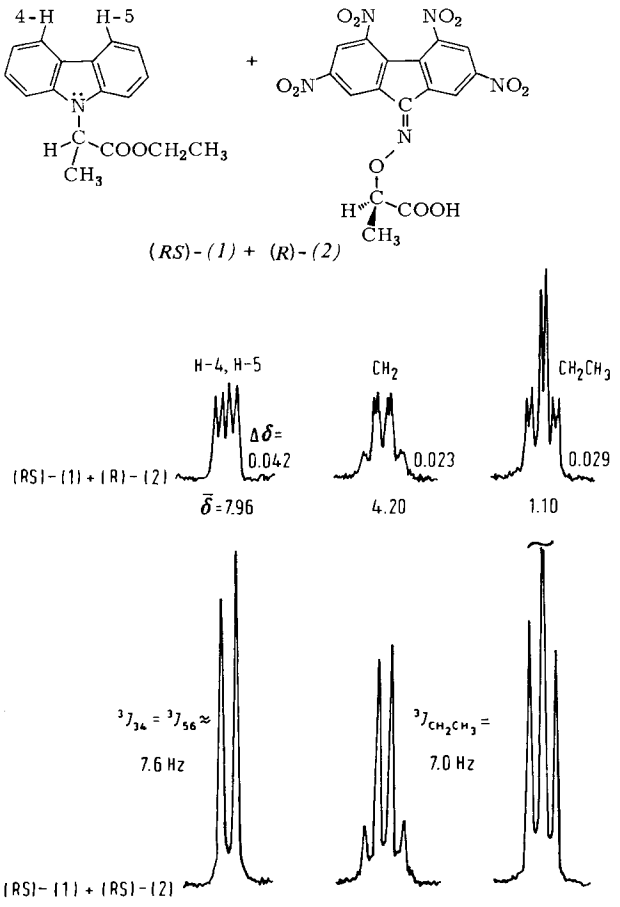

Fig. 1. Some ^{1}H-NMR signals (90 MHz, PFT method) of the π-donor (*RS*)-*(1)* in [D_6]-acetone at −68 °C in the presence of 1.15 equivalents of the π-acceptor (*R*)-*(2)* (top) and (*RS*)-*(2)* (bottom). $\bar{\delta}$: Mean shift of corresponding protons in (*R*)-*(1)* and (*S*)-*(1)*. $\Delta\delta$: Difference of shifts of corresponding protons in (*R*)-*(1)* and (*S*)-*(1)*. See Table 1 for details.

systems. The existence of the diastereomeric complexes[7] (*R*)-*(2)*···(*R*)-*(1)* and (*R*)-*(2)*···(*S*)-*(1)* follows from the additional splittings of several absorptions of (*RS*)-*(1)* at −68 °C, which are diminished by raising the temperature. As expected[3], these shift differences ($\Delta\delta$ in Fig. 1, top, and in Table 1) disappear by averaging, if the *racemic* compound (*RS*)-*(2)* is used instead of the optically active one (Fig. 1, bottom).

tation[8] of the components in the complex, which means a change in the shift differences $\Delta\delta$.—As expected, some signals of the fluorene derivative (*RS*)-*(2)* are split (Fig. 2), if the carbazole (*R*)-*(3)*[6] is used as the optically active component.

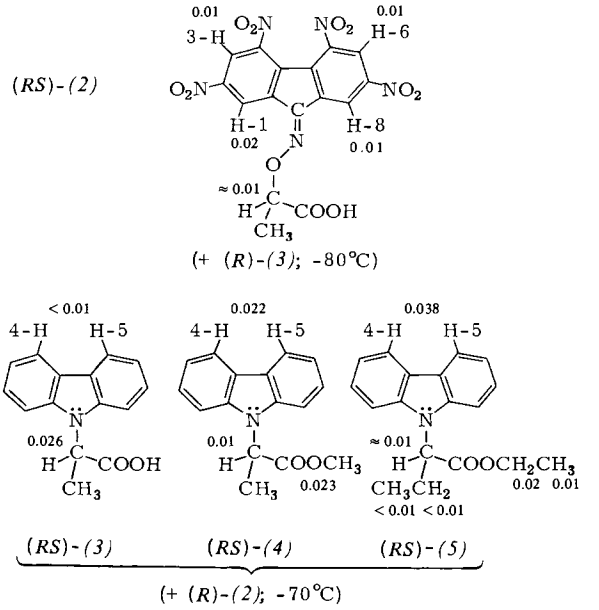

Fig. 2. π-Acceptor (*RS*)-*(2)* and π-donors (*RS*)-*(3)*, (*RS*)-*(4)*, and (*RS*)-*(5)*. The numbers are $\Delta\delta$ values in [D_6]-acetone, *i.e.* differences between the ^{1}H-NMR shifts of the (*R*)- and the (*S*)-enantiomer for the given combinations. The molar ratio of optically active compound to (*RS*)-substrate is 1.1 : 1.

The above association complexes might be caused not only by the EDA interaction, but also by hydrogen bonds of carbonyl groups. This possibility is excluded when two carboxylic *esters* are paired. Thus, the ester (*RS*)-*(1)* behaves largely analogously in the presence of the carboxylic acid (*R*)-*(2)* (Fig. 1 and Table 1) and in the presence of its methyl ester[9]; in addition, the $\Delta\delta$ values for both mixtures are very similar. These findings, combined with literature statements[10], enable us to conclude, that the EDA interaction, and not a possible hydrogen bond, is of decisive importance for the relative orientation of the partners in the above complexes of esters with acids.

The phenomenon described in this paper can serve to demonstrate the presence of EDA complexes and, if optimized,

Table 1. ^{1}H-NMR signals of a mixture of (*RS*)-*(1)* and 1.15 equivalents (*R*)-*(2)* in [D_6]-acetone at −68 °C. δ: Chemical shifts; in the case of (*RS*)-*(1)*, δ represents the *averaged* shift of (*R*)-*(1)* and (*S*)-*(1)*. $\Delta\delta$: Difference of shift of corresponding protons in (*R*)-*(1)* and (*S*)-*(1)*.

	(*RS*)-*(1)*						(*R*)-*(2)*				
δ	7.96	7.5—6.8	5.85	1.78	4.20	1.10	9.36	8.97	8.79, 8.65	5.34	1.85
J [Hz]	$J_{34}=J_{56}\approx 7.6$	?	7.0	7.0	7.0	7.0	$J_{13}=2.1$	$J_{13}=2.1$	$J_{68}=2.1$	7.0	7.0
$\Delta\delta$	0.042	?	0.01	[a]	0.023	0.029	—	—	—	—	—
Assignment	H-4, H-5 [b]	H-1, H-2, H-3 H-6, H-7, H-8	H—C—CH_3	H—C—CH_3	CH_2—CH_3		H-1 [c]	H-3	H-6, H-8	H—C—CH_3	H—C—CH_3

[a] This value cannot be determined precisely because the H—C—CH_3 absorption of (*R*)-*(2)* is close; $\Delta\delta$ is probably <0.01. [b] Assignment analogous to carbazole and 9-methylcarbazole, the protons of which were assigned *via* ^{13}C-NMR shifts and selective $^{13}C\{^1H\}$ decoupling experiments. We are grateful to Dr. *L. Ernst*, Braunschweig-Stöckheim, for these measurements. Cf. *P. J. Black, M. L. Heffernan*, Aust. J. Chem. *18*, 353 (1965). [c] Assignment analogous to *H. Paulsen, K. Todt, H. Ripperger*, Chem. Ber. *101*, 3365 (1968), and references cited therein.

The comparison of the $\Delta\delta$ values of the carbazole derivative (*RS*)-*(1)* (Table 1) with those of (*RS*)-*(3)*, (*RS*)-*(4)*, and (*RS*)-*(5)* (Fig. 2) shows that the spatial positions of H-4 and H-5 in the complexes with (*R*)-*(2)* are changed by modifications of the distant substituent in the 9-position of the carbazole nucleus. The spatial position of the N—C—*H* atom is apparently changed to a lesser extent. The modification of a substituent probably brings about a change in relative orientation to measure the enantiomeric purity. Independently, we aim to understand the δ- and $\Delta\delta$-values in terms of the orientation of the components in solution.

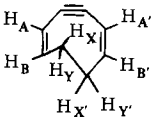
1,5-Cyclooctadien-3-yne—A Novel, Highly Reactive C_8H_8 Hydrocarbon[**]

By *Herbert Meier, Toni Echter*, and *Hermann Petersen*[*]

To the prominent family of C_8H_8 hydrocarbons belong the well-known members styrene, cyclooctatetraene, cubane, barrelene, semibullvalene, and 1,5-cyclooctadiyne. We have now succeeded in isolating a new isomer, namely the highly strained and thus highly reactive eight-membered ring compound 1,5-cyclooctadien-3-yne *(7)*.



In the synthesis of *(7)* the route to *(4)* described by *Cantrell* and *Solomon*[1] has been shortened by one step and the yield of *(4)* vastly improved. 1,2,3-Selenadiazole *(6)* is accessible *via* the semicarbazone *(5)*[2]; thermolysis of *(6)* over copper powder in an atmosphere of N_2 leads to *(7)*. As soon as reaction sets in, the initial pressure is reduced from 70 to 1 torr and the volatile fragmentation product *(7)* is frozen out in a cold trap with liquid nitrogen. *(7)* can be trapped *in situ* in much higher yields; besides tetracyclone *(8)*, which has proven suitable for Diels-Alder cycloaddition, rhodium complexes of type *(10)*[3] are particularly efficient trapping reagents:

The cyclooctadienyne *(7)* can be stored in the solid state in the absence of oxygen. Above the melting point at *ca.* −15°C it begins to decompose. When dissolved in $CDCl_3$ its halflife at 27°C is about 2 h. The lifetime of *(7)* is not only limited by di- and oligomerizations, as expected for strained cycloalkynes, but also by an intramolecular process with a low energy barrier: The transformation into cyclooctatetraene can be explained in terms of two thermally allowed, suprafacial 1,5 H-shifts. A mechanistic alternative is intramolecular $[\pi 2 + \sigma 2 + \sigma 2]$ cycloaddition, a novel type of reaction with σ_{CH} bonds, reminiscent of the diimine reduction of olefins[4].

The extremely high degree of ring strain *(7)* is also manifested in the spectroscopic properties. The ^{13}C-NMR spectrum shows four signals: The saturated C-atoms absorb at $\delta = 32.6$, the olefinic C-atoms at $\delta = 152.0$ and 112.7; for the sp centers an extremely large downfield shift of $\delta = 116.3$ is observed. From these data an energy of geometrical strain[5] of *ca.* 18 kcal/mol is estimated (cyclooctyne has a geometrical strain energy of 12 kcal/mol). From the data it also follows that the molecule must have a symmetry axis or a symmetry plane (C_2 or C_s conformation). From the ^1H-NMR spectrum recorded at −40°C it can be concluded that no rapid ring inversion takes place under these conditions (AA'BB'XX'YY' system). According to a simple force-field calculation, the C_s conformation ought to have a higher energy than the C_2 conformation. Analysis of the ^1H-NMR spectrum is fully consistent with a C_2 conformation.

(7) (C_2)

We thus have the relatively rare case of a chiral hydrocarbon without an asymmetric C-atom. At room temperature the X and Y parts of the spectrum (at $\delta = 1.2$ and 2.9, respectively) broaden and lose their fine structure; the AB part remains practically unchanged [$\delta = 5.8$ (H_A), 6.6 (H_B)]. The coalescence point is reached at 60°C, corresponding to a $\Delta G^{\neq}$ of *ca.* 16 kcal/mol for the transition state. At room temperature, 1,5-cyclooctadiene and 1,3,5-cyclooctatriene exhibit rapid ring inversion; the coalescence temperature lies, *e.g.* for the triene, at −136°C[6]. Replacement of a CC single or double bond by a triple bond leads to a rigid conformation owing to increased ring strain. The coalescence temperatures of cyclooctyne and the cyclooctenynes[7], however, lie below room temperature. Only introduction of the second double bond into the eight-membered ring alkyne effects freezing-in of ring inversion. If the double bond is replaced by annelated benzene units, then the effect is enhanced[6, 8].

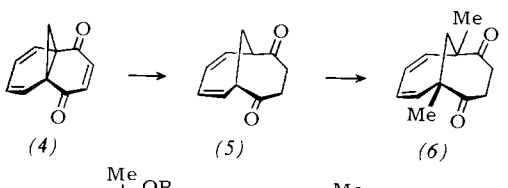
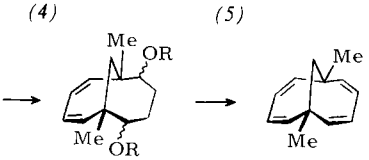
1,6-Dimethylbicyclo[4.4.1]undeca-2,4,7,9-tetraene—A Higher Vinylog of Norbornadiene



By *Jürgen Frank, Wolfram Grimme*, and *Johann Lex*[*]

The homoconjugation between the unsaturated bridges in norbornadiene *(1)* and bicyclo[4.2.1]nonatriene *(2)* is revealed in the PE-spectroscopic[1a] as well as the chemical[1b, 1c] behavior of the two compounds. A corresponding interaction is to be expected in the next higher vinylog of this series, the previously unknown bicyclo[4.4.1]undecatetraene *(3)*.



(1) *(2)* *(3)*

Actually, the fully-conjugated skeleton, *i.e.* 1,6-methano[10]annulene[2] has been known for some 15 years, but of its dihydro derivatives only the 1,2-[3a] and the 2,5-isomer[3b] have so far been reported. The elusiveness of the structure *(3)* with two sp^3 hybridized bridgeheads might be due to the particularly large increase in strain (estimated as 2×6.8 kcal/mol[4]) on going from 1,6-methano[10]annulene to *(3)*. Hence, owing to the easy double bond shift to be expected in *(3)* we have synthesized the methyl-stabilized title compound *(8)*.

(4) *(5)* *(6)*

(7a), R = H *(8)*
(7b), R = O_2SMe

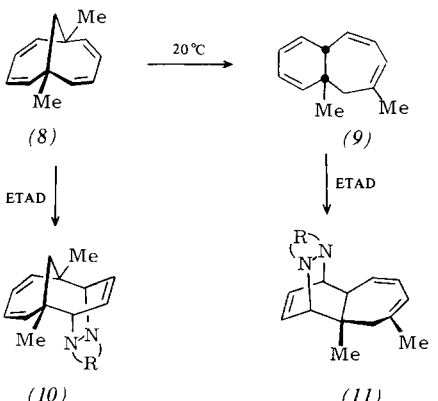
The tricyclic "2,5-quinone" *(4)*[5a] is reduced by zinc dust in 95% acetic acid at room temperature to the bicyclic 2,5-dione *(5)*[5b] (92% yield), which can be methylated at both bridgeheads with methyl iodide to give *(6)* (42%) *via* the bisenolate generated with lithium diisopropylamide in tetrahydrofuran at 0°C (for physical data see Table 1). Reaction of *(6)* with sodium tetrahydroborate in methanol affords the stereoisomeric diols *(7a)* (62%) as a 3:2 mixture of a *cis*-isomer of unknown configuration and the *trans* compound (m.p. 157°C). On esterification of the mixture with methanesulfonyl chloride in pyridine the bismethanesulfonates *(7b)* are obtained (88%), which are then allowed to react with potassium *tert*-butoxide in ice-cold dimethyl sulfoxide. Low-pressure chromatographic separation (silica gel, pentane) of a pentane extract of the reaction mixture at −10°C affords the title compound *(8)* (22%) as a product of twofold elimination. The NMR spectra (Table 1) confirm its C_{2v} symmetry; the UV spectrum shows a bathochromic shift of about 17 nm compared to that of 1,3-cycloheptadiene, which can be explained in terms of a homoconjugation or planar fixation of the diene units.

Table 1. Physical data of compounds *(5)*, *(6)*, *(8)*, *(9)*, *(10)*, and *(11)*. The ^{1}H-NMR spectra were recorded at 90 MHz in $CDCl_3$ [*(8)* and *(9)* in CCl_4].

(5), m.p. 35°C; ^{1}H-NMR: $\delta = 6.10$ (AA'BB', H-7, 8, 9, 10), 3.70 (m, H-1, 6), 2.63 (AA'BB', H-3, 3', 4, 4'), 2.33 (tripletted AB, $\Delta_\nu = 31.6$ Hz, $J = 16.5$ Hz, H-11, 11')

(6), m.p. 52°C; ^{1}H-NMR: $\delta = 6.1$–5.5 (AA'BB', H-7, 8, 9, 10), 3.1–2.4 (AA'BB', H-3, 3', 4, 4'), 2.10 (AB, $\Delta_\nu = 25.8$ Hz, $J = 15$ Hz, H-11, 11'), 1.28 (s, 6H, CH_3)

(8), m.p. 18°C; ^{1}H-NMR: $\delta = 5.43$ (narrow AA'BB', 8 olefin-H), 2.53 (s, 2H, CH_2), 1.25 (s, 6H, CH_3); ^{13}C-NMR ($CDCl_3$, 20 MHz): $\delta = 140.81$ (C-2, 5, 7, 10), 122.31 (C-3, 4, 8, 9), 50.77 (C-11), 44.39 (C-1, 6), 31.60 (2C, CH_3); UV (hexane): $\lambda_{max} = 245$ nm ($\varepsilon = 4200$), 255 (5000), 265 (3600)



(9), ^{1}H-NMR: $\delta = 5.8$–5.2 (m, 7 olefin-H), 2.72 (t, H-1), 2.05 (AB, $\Delta_\nu = 72.7$ Hz, $J = 15$ Hz, H-6, 6'), 1.90 (s, 3H, 5-CH_3), 1.03 (s, 3H, 7-CH_3); UV (cyclohexane): $\lambda_{max} = 236$ nm ($\varepsilon = 10000$), 257 (6600) sh

(10), m.p. 152°C; ^{1}H-NMR [a]: $\delta = 6.13$ (AA'XX'-half-spectrum, H-3, 4), 5.7 (narrow m, H-7, 8, 9, 10), 4.50 (AA'XX' half-spectrum, H-2, 5), 3.62 (q, 2H, CH_2CH_3), 2.02 (AB, $\Delta_\nu = 35.7$ Hz, $J = 13.5$ Hz, 2H, CH_2), 1.27 (t, 3H, CH_2CH_3), 1.25 (s, 6H, CH_3); MS: $m/e = 299$ (M^+)

(11), m.p. 137°C; ^{1}H-NMR [b]: $\delta = 6.42$ (t, H-9, 10), 5.87 (m, H-2, 3, 4), 4.67 (m, H-11), 4.30 (t, H-8), 3.87 (q, 2H, CH_2CH_3), 2.23 (AB, $\Delta_\nu = 104.5$ Hz, $J = 13.5$ Hz, H-6, 6'), 1.95 (s, 3H, 5-CH_3), 1.57 (m, H-1), 1.20 (t, 3H, CH_2CH_3), 1.00 (s, 3H, 7-CH_3); UV (ethanol): $\lambda_{max} = 248$ nm ($\varepsilon = 10300$)

[a] Molecular skeleton numbered analogously to *(8)*.
[b] Molecular skeleton numbered analogously to *(9)*.

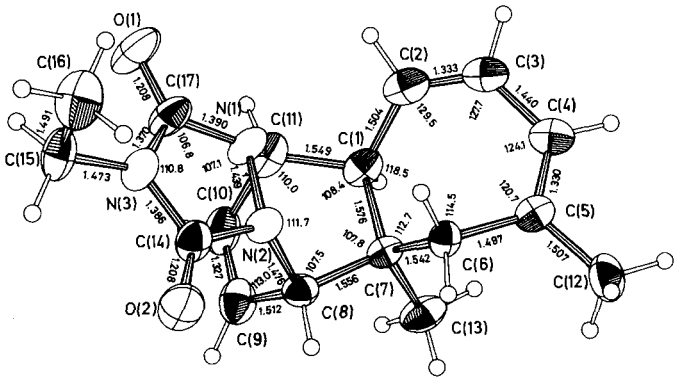
Reaction of *(8)* with 4-ethyl-1,2,4-triazolinedione (ETAD) in acetone at 0°C affords the monoadduct *(10)* (67%); the bicyclic compound thus reacts like its next lower vinylog *(2)*[6] and not analogously to norbornadiene *(1)* across the 2,10 positions.

(8) *(9)*
(10) *(11)*
R = –CO–NEt–CO–

The most surprising property of compound *(8)* is its thermal lability: at room temperature it is already converted into 5,7-dimethyl-*cis*-bicyclo[5.4.0]undeca-2,4,8,10-tetraene *(9)* (100%).

[*] Dipl.-Chem. J. Frank, Dr. W. Grimme, Dr. J. Lex
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

In CCl_4 solution at 26 °C the transformation proceeds as a first order reaction; $k = (1.31 + 0.06) \times 10^{-5}\ s^{-1}$. Unequivocal proof of the presence of *(9)* is provided by the X-ray structure analysis (Fig. 1) of its cycloadduct *(11)* with ETAD, which is formed together (ratio 3:4) with its stereoisomer having an *endo* seven-membered ring (m.p. 112 °C) in acetone at 0 °C. In the low-pressure chromatographic separation on silica gel with hexane/ethyl acetate (4:1), *(11)* is eluted as second component (20 %) and is subsequently recrystallized from ether. The adduct *(11)* is formed by attack of the dienophile on the six-membered ring from the concave side of the bicyclic compound *(9)*. The planes of the double bonds in the seven-membered ring of the adduct form an angle of 38.5°.



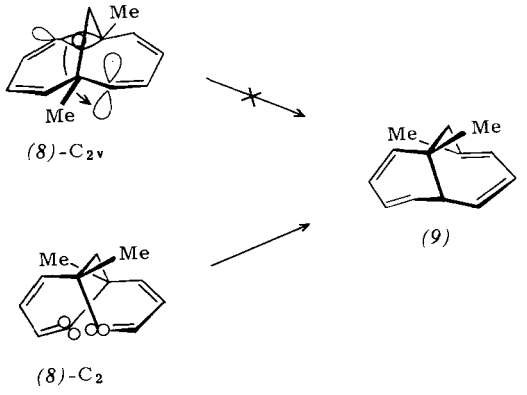


Fig. 1. Molecular structure of the cycloadduct *(11)* of 4-ethyl-1,2,4-triazolinedione (ETAD) and 5,7-dimethyl-*cis*-bicyclo[5.4.0]undeca-2,4,8,10-tetraene *(9)* (bond lengths in Å, bond angles in °). Compound *(11)* forms monoclinic crystals, space group $P2_1/c$ with $a = 13.684(3)$, $b = 7.607(2)$, $c = 16.142(4)$ Å; $\beta = 109.84(2)°$; $Z = 4$; $\rho_{calc} = 1.258$, $\rho_{exp} = 1.263\ g/cm^3$. The intensity measurements were carried out with an automatic single crystal diffractometer (CAD-4, Enraf Nonius) with MoK_α radiation ($3° \leq \theta \leq 30°$). The heavy atoms could be localized by direct methods; a Fourier difference synthesis gave the positions of the hydrogen atoms. Refinement of the atomic parameters (C, N, O anisotropic, H isotropic) with the structural factors of 1441 observed reflections ($I > 2\sigma_I$) converged at $R = 0.045$.

The rearrangement *(8)* → *(9)* can formally be described as a sigmatropic 1,5 shift[7] of a butadieno bridge; however, this type of reaction occurs only at elevated temperatures in the lower vinylogs *(2)* and *(1)* and is restricted to shifts of the methano bridge[1c, 8]. Another reaction course would therefore appear more likely: From a molecular model it is clear that besides the angularly-strained C_{2v} conformation for *(8)*, a twisted conformation with C_2 symmetry is possible in which the angular strain disappears but the butadiene π-orbitals are mutually pressed together with one terminus in a σ-like fashion.

The rearrangement of *(8)*-C_2, which should begin with the formation of the transannular bond, proceeds either with simultaneous loosening of bridgehead bond (cf. the photochemical di-π-methane rearrangement[9]) or *via* a twofold allyl-stabilized diradical. Thus the interaction of the two butadieno-bridges in *(8)* manifests itself rather as transannular σ-overlapping than as cyclic homoconjugation.

1-(1-Adamantyl)-1-methylethoxycarbonyl: A New Protecting Group for Peptide Syntheses

By *Hubert Kalbacher* and *Wolfgang Voelter*[*]

Although the well-known amino protecting groups of the urethane type (*tert*-butyl- and benzyloxycarbonyl) fullfil many requirements of straightforward peptide synthesis[1], it is often desirable to liberate NH_2 groups under very mild acidolytic conditions so that an optimal protection of acid-labile residues can be achieved in syntheses involving repetitive coupling and deblocking steps (solid phase method) and the indole system of tryptophan-containing peptides remains intact.

The protecting groups Ppoc[2a], Bpoc[2b], Ddz[3], or Azoc[4] accommodate these requirements; however, only the first two have found general use. In both cases the storage of the protected amino acids is not unproblematical[5] owing to autocatalytic decomposition and photolability. Also the Bpoc phenyl carbonate frequently used for introduction of the Bpoc group tends to decompose even at low temperatures[6]. Bpoc-Trp-OH can be synthesized in only low yields.

The new protecting group 1-(1-adamantyl)-1-methylethoxycarbonyl (Adpoc) not only has all the advantages of the above mentioned α,α-dimethylbenzyloxycarbonyl-type protecting groups but is also stable towards hydrogenolysis in peptide syntheses. Incorporation of the Adpoc group can be achieved by means of the crystalline 1-(1-adamantyl)-1-methylethyl phenyl carbonate (Adpoc-OPh) *(4)*.

The Adpoc group can be removed in mild acidolytic medium, preferably 3 % trifluoroacetic acid in dichloromethane, within 4—5 min at 0 °C or 2—3 min at room temperature. Under these conditions the Adpoc group is removed 10^3 times faster than the Boc group; consequently it is possible to use Adpoc selectively in conjunction with the Boc group,

[*] Prof. Dr. W. Voelter, Dipl.-Chem. H. Kalbacher
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

and naturally also benzyloxycarbonyl-, benzyl ether-, and benzyl ester-protecting groups. On the other hand, under acidolytic conditions the Adpoc amino acids are about two to three times more stable than the Bpoc amino acids. The properties of some Adpoc amino acids and peptides (commercially available from Senn Chemicals, CH-8157 Dielsdorf, Switzerland) are listed in Table 1.

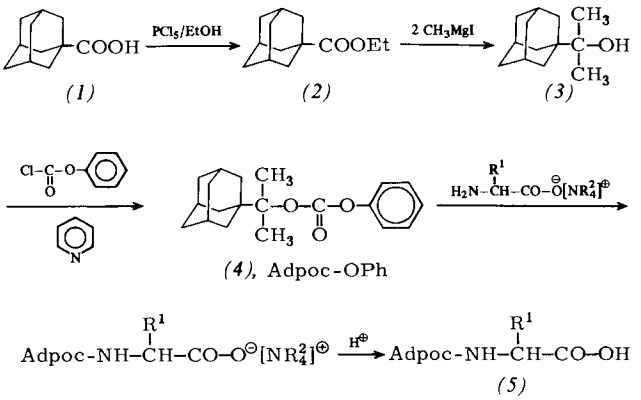

Table 1. Yields and physical data of selected Adpoc amino acids and peptides.

Compound	Yield [%]	M.p. [°C]	$[\alpha]_D^{20}$ [°]
Adpoc-L-Ala·DCHA [a]	75	155	+6.22 (c = 0.65 EtOH)
Adpoc-L-Trp-OH	72	116	−6.8 (c = 1.04 MeOH)
Adpoc-L-Trp-L-Lys(Z)-OH	73	114—116	−8.7 (c = 0.5 MeOH)
Adpoc-L-Thr(Bzl)-L-Phe-OH	67	75—76 (dec.)	−18.67 (c = 0.7, DMF)

[a] DCHA = dicyclohexylamine.

For the synthesis of Adpoc-OPh *(4)*, 1-adamantanecarboxylic acid *(1)* is converted by reaction with phosphorus pentachloride/ethanol into the ethyl ester *(2)*, which on reaction with Grignard reagent (from methyl iodide and magnesium) affords the tertiary alcohol 2-(1-adamantyl)-2-propanol *(3)*[7]. The carbonate *(4)* can be obtained by treatment of *(3)* with phenyl chloroformate.

Experimental

Synthesis of *(4)*: A solution of *(3)* (19.4 g, 0.1 mol) in dichloromethane (100 ml) is treated dropwise at −5 °C with a solution of phenyl chloroformate (15.2 ml) in dichloromethane (50 ml). The precipitate formed during the addition is redissolved on stirring the mixture overnight at 0 °C. The solution is poured onto ice, diluted with 150 ml dichloromethane and the organic phase is washed three times with water before drying over sodium sulfate. Removal of solvent by evaporation *in vacuo* at 30 °C and two recrystallizations from benzene/*n*-hexane affords long colorless crystals, m.p. 72 °C, yield 26.25 g (83.5 %).

Synthesis of *(5)*, $R^1 = CH_3$: 891 mg (10 mmol) of L-Ala-OH is dissolved with gentle warming in 4.6 ml of a *ca.* 40% solution of Triton B (benzyltrimethylammonium hydroxide) in methanol. After removal of solvent the residue is rendered free of water by azeotropic distillation with 2 × 30 ml dimethylformamide. The residue is taken up in 30 ml dimethylformamide at 50 °C and treated with 3.8 g (12 mmol) of *(4)*. After three hours' stirring at 50 °C the reaction mixture is partitioned between water and diethyl ether/petroleum ether (1:1) and the separated aqueous phase acidified at 0 °C with 1 N citric acid solution (pH = 2—3) and exhaustively extracted with diethyl ether. After the usual washing and drying the ether extracts are evaporated down *in vacuo*. The residue is taken up in a small amount of ether and finally crystallized by addition of dicyclohexylamine.

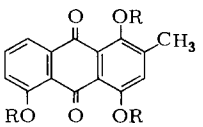
Regioselective Synthesis of the Anthraquinones Digitopurpone and Islandicin[**]

By *Manfred Braun*[*]



The importance attained by the anthracycline antibiotics daunomycin *(1a)* and adriamycin *(1b)* as chemotherapeutic agents against various types of cancer[1a] has recently led to an intensive search for new routes for the synthesis of such anthraquinones[1b–1e]. Astonishingly, however, the methods previously adopted for the synthesis of such simple anthraquinones as those of the isomeric digitopurpone *(2a)* (from *Digitalis purpurea*)[2a] and islandicin *(3a)* (from *Penicillium islandicum*)[2b] are mostly tedious, unproductive, and, in part, non-regioselective *i.e.* a mixture of *(2a)* and *(3a)* is obtained[3].

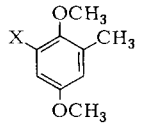
[**] This work was supported by the Deutsche Forschungsgemeinschaft.



We have now tried to add aryllithium compounds such as *(4b)* to the anhydride *(5)* in such a way that only the sterically less hindered carbonyl group *meta* to the methoxy group is attacked[4]. The acid *(7a)* or its tautomer *(7a')* formed in this way could then be converted into the trimethyl ether *(2b)* by intramolecular Friedel-Crafts acylation and subsequently into digitopurpone *(2a)* by demethylation.

(9)

Reaction of the anhydride *(5)* with a solution of *(4b)* (prepared from the bromide *(4a)*[5] and *n*-butyllithium) in hexane/tetrahydrofuran (THF)/tetramethylethylenediamine (TMEDA) did not lead to the desired result. A crude product mixture (m.p. 115—160°C, 58% yield) was formed, which on reaction with diazomethane afforded a 1:1 mixture of the thin-layer chromatographically (neutral $Al_2O_3/CHCl_3$) separable isomeric esters *(A)* ($R_F = 0.55$) and *(B)* ($R_F = 0.44$). The constitution of *(A)* as *(8b)* was proven by mixed melting point (127—128°C) and by the agreement of the IR and ^{1}H-NMR spectra with those of the ester *(8b)* prepared from authentic[3a] acid *(8a)* and diazomethane. The isomer *(B)* thus has the constitution *(7b)*.

On the other hand, reaction of the Grignard compound *(4c)* with *(5)* in THF/TMEDA and esterification of the crude product with diazomethane leads, according to the ^{1}H-NMR spectrum, to a mixture of the esters *(7b)* and *(8b)* in the ratio 97:3. Single recrystallization of the crude adduct formed from *(4c)* and *(5)* affords the isomer-free, analytically pure pseudo acid *(7a')*. This can be converted by 15 hours' stirring in conc. sulfuric acid at room temperature into *(2b)*, whose demethylation in 48% HBr/glacial acetic acid leads to digitopurpone *(2a)* in 51% overall yield. Both *(2a)* and *(2b)* are characterized by their spectroscopic data and by mixed melting points with authentic[3a] samples of *(3a)* and *(3b)*, respectively; the ^{1}H-NMR spectra of *(2a)* and *(2b)* show no traces of the isomers *(3a)* and *(3b)*.

Islandicin *(3a)* can be prepared analogously: Reaction of the Grignard compound *(6b)*, obtained from the bromide *(6a)*[6], with *(5)* in THF/TMEDA and recrystallization of the crude product from methanol/water leads to the isomer-free, analytically pure pseudo acid *(9)*[7] in 38% yield. In conc. sulfuric acid *(9)* is converted into *(3b)*, whose demethylation affords islandicin *(3a)* in 75% yield [based on *(9)*]; the spectroscopic data and the mixed melting point are identical with those of an authentic[3a] sample, and no *(2a)* is obtained.

Application of this new, regioselective anthraquinone synthesis—giving digitopurpone *(2a)* and islandicin *(3a)* in 51 and 29% overall yields, respectively—to the preparation of *(1)* and *(2)* is under investigation.

Experimental[8]

Synthesis of *(7a')*: To 10 ml THF, which is heated to boiling along with 150 mg (6.2 mmol) magnesium turnings and 5 mg iodine under N_2, are added 2 ml of a solution of *(4a)* (1.155 g, 5 mmol) in THF (8 ml), then 20 µl methyl iodide and finally the remaining solution of the bromide *(4a)*. The mixture is boiled for 90 min, cooled to room temperature, treated with 2 ml TMEDA and the resulting solution finally added within 5 min at −78°C to a stirred suspension of *(5)* (890 mg, 5 mmol) in THF (30 ml) under N_2. After one hours' stirring at −78°C the mixture is allowed to warm to room temperature within *ca.* 12 h; 5 ml H_2O is added and the solvent removed in a rotary evaporator. The residue is taken up in 100 ml ether and 200 ml 7% aqueous KOH solution. After separation of the aqueous phase and repeated extraction of the ethereal phase with 100 ml 7% KOH solution the combined KOH phases are cooled with ice, brought to pH = 1 with conc. hydrochloric acid, and extracted with a total of 300 ml $CHCl_3$. Washing of the combined $CHCl_3$ phases with saturated NaCl solution, drying over Na_2SO_4, and removal of the solvent *in vacuo* affords 1.12 g of an oil, which freezes on addition of $CHCl_3$/pentane. Recrystallization from CH_3OH/H_2O yields 1.04 g (63%) *(7a)*, m.p. 183—185°C; IR (KBr): 3350 (OH), 1735 (C=O) cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 4.02$ (s), 3.89 (s), 3.57 (s) (each 3H, OCH_3); 2.21 (s, 3H, aryl-CH_3). *(9)* is synthesized analogously: m.p. 175—176°C (CH_3OH/H_2O); IR (KBr): 3370 (OH), 1745 (C=O) cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 4.03$ (s), 3.98 (s), 3.62 (s) (each 3H, OCH_3); 2.34 (s, 3H, aryl-CH_3).—Ester *(7b)*: b.p. 120°C (bath)/0.002 torr; IR ($CHCl_3$): 1725 (C=O) cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 3.90$ (s), 3.79 (s), 3.75 (s), 3.60 (s) (each 3H, OCH_3); 2.27 (s, 3H, aryl-CH_3).—Ester *(8b)*: m.p. 128—129°C; IR (KBr): 1720 (C=O) cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 3.87$ (s), 3.72 (s), 3.70 (s), 3.39 (s) (each 3H, OCH_3); 2.24 (s, 3H, aryl-CH_3).

Synthesis of *(2b)*: A solution of *(7a')* (78 mg, 0.24 mmol) in conc. sulfuric acid (10 ml) is stirred for 15 h at room temperature, diluted with 200 ml ice-water, and extracted with $CHCl_3$. After drying over Na_2SO_4 and removal of the solvent there remain 74 mg (100%) *(2b)*, m.p. 161°C (163°C after recrystallization from ethanol, Ref. [3b] 163—164°C).

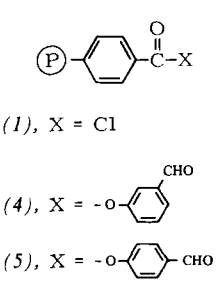
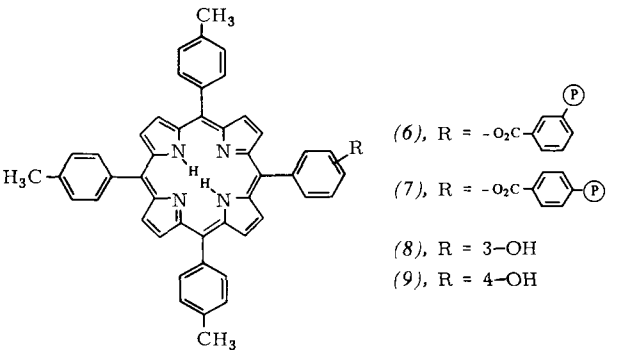
[7] According to the ^{1}H-NMR spectrum, formation of up to a maximum of 5% of the isomer—by addition of *(6b)* to the sterically more hindered carbonyl group of *(5)*—cannot be ruled out.
[8] Correct analytical values were obtained for the new compounds.

The Synthesis of Unsymmetrical Tetraarylporphyrins on Solid Phases[**]



By *Clifford C. Leznoff* and *Polina I. Svirskaya*[*]



There has been tremendous interest recently directed toward the synthesis of model porphyrin systems related to the oxygen-binding proteins[1]. In addition, the synthesis of model dimers and higher aggregates of porphyrins are of particular interest in studies of the photo-oxidation of water to oxygen during photosynthesis[2]. The *symmetrical* tetraarylporphyrins had long been widely used as models in both of these systems due to their ease of preparation[3], but some more recent sophisticated work required the synthesis of *unsymmetrical* tetraarylporphyrins, which were synthesized in yields ranging from 0.5—5%[4]. Furthermore, the desired product could only be isolated from the many other compounds produced by extensive chromatographic separations.

Although preformed hemes and porphyrin models have been attached to insoluble supports[5] and unusual synthetic polymers incorporating the heme function have been described[6], the actual synthesis of a porphyrin on polymer supports from its simple precursors has not been described. Insoluble polymer supports provide a suitable means of "fishing out" a minor component from a complex reaction mixture[7a] and we have utilized these supports in this way to prepare monoblocked derivatives of a wide variety of symmetrical difunctional compounds[7b].

We now report that insoluble polymer supports can be used to prepare unsymmetrical tetraarylporphyrins and aid in their isolation. Thus a 2% crosslinked divinylbenzene-styrene copolymer *(1)* containing 1.7 mmol of benzoyl chloride functional groups per g polymer[8], was treated with 3-hydroxybenzaldehyde *(2)* or 4-hydroxybenzaldehyde *(3)* to give the polymer-bound benzoylbenzaldehydes *(4)* and *(5)*, respectively. Cleavage of *(4)* and *(5)* with 0.5 M sodium hydroxide/dioxane (1:1) at room temperature for 20 h liberated 0.73 mmol of *(2)* and 1.06 mmol of *(3)*/g of *(4)* and *(5)*, respectively. Treatment of *(4)* and *(5)* with *p*-tolualdehyde and pyrrole in hot propionic acid for 1 h yielded upon filtration black polymers which were readily washed free of tetratolylporphyrin by extraction in a Soxhlet extractor with chloroform for 2 h to yield the polymer-bound unsymmetrical tetraarylporphyrins *(6)* and *(7)*, respectively. Cleavage of *(6)* and *(7)* with potassium carbonate in methanol for 24 h yielded black powders *essentially free of tetratolylporphyrin* present in large amounts in a comparable solution synthesis[4a].

The black powders can be readily purified by a quick filtration through a silica column using chloroform as eluant followed by preparative thin-layer chromatography using benzene/ether/chloroform (7:2:1) as eluant to give 5-(3-hydroxyphenyl)-10,15,20-tritolylporphyrin *(8)* in 2% yield and 5-(4-hydroxyphenyl)-10,15,20-tritolylporphyrin *(9)* in 4.5% yield,

both as purple crystals. The NMR spectra of *(8)* and *(9)* were identical with the published spectra[4a] and the mass spectra exhibited peaks of 672 (M^+) and 336 (M^{2+}) typical of tetraarylporphyrins[9].

specifically formed *trans*-stilbene structural unit could be isolated. The analogous reaction with phosphanes *(1b)* and *(1c)*[1b] likewise led stereospecifically to the phosphane oxides *(2b)* and *(2c)*, respectively. The products *(2a)*—*(2c)* formed by formal addition of H_2O could be characterized on the basis of their spectroscopic data[2].

(a), R, R' = H; *(b)*, R = —≡—Ph, R' = H; *(c)*, R, R' = —≡—Ph

Compounds *(1a)*—*(1c)* remained completely stable in hot anhydrous ethanol and could be recrystallized "normally". Hence, the added H_2O must have originated from the commercial ethanol. The reaction was found to take place also in other water-containing solvents, *e.g.* acetone/H_2O. On using aprotic solvents (*e.g.* acetone) and D_2O the deuterated *trans*-olefins were formed.

The course of the reaction is discussed in more detail for bis(phenylethynyl)phosphane *(1b)*, since in this case a further product *(3)* could be isolated which affords additional information on the mechanism of the reaction.

Intramolecular nucleophilic attack of the phosphorus at a sterically favorable acetylene C-atom[3] in *(1b)* leads to the intermediate *(1b')*, which can be stabilized in the presence of H_2O as the hydroxyphosphorane *(1b'')*. *(1b'')* decomposes with cleavage of the apical P—C_{olefin} bond to the intermediate *(1b''')*, which on protonation of the carbanionic olefin C-atom affords the stable end-product *(2b)* (route A). However, the carbanionic olefin C-atom can also attack a benzene ring nucleophilically leading to formation of the compound *(3)* containing a spiro-cyclohexadiene-allene structural unit (route B). In the presence of HCl only *(2b)* is formed: apparently the protonation of the carbanion C-atom proceeds more rapidly than that of the nucleophilic addition to the benzene ring. The unusual structure of *(3)* was confirmed by X-ray structure analysis[4].

The reaction *(1)* → *(2)* appears remarkable on two counts: On simple "recrystallization", the *o*-phenylethynyl-substituted triphenylphosphanes *(1a)*—*(1c)* can be transformed stereospecifically into triphenylphosphane oxides with *trans*-stilbene and tolan structural units. Reduction of these phosphane oxides *(2)* with $SiHCl_3$[5] leads to formation of novel transition metal ligands with phosphane, acetylene, and olefin donor sites within *one* molecule. Furthermore, the reaction route B represents on of the few examples[6] in which a phenyl substituent is attacked nucleophilically by the leaving group after apical ring-opening of a cyclic hydroxyphosphorane.

Exclusive attack of the phenylethynyl-substituted phenyl ring in *(1b'')* might therefore be explained by formation of a cyclohexadiene-allene system capable of conjugation.

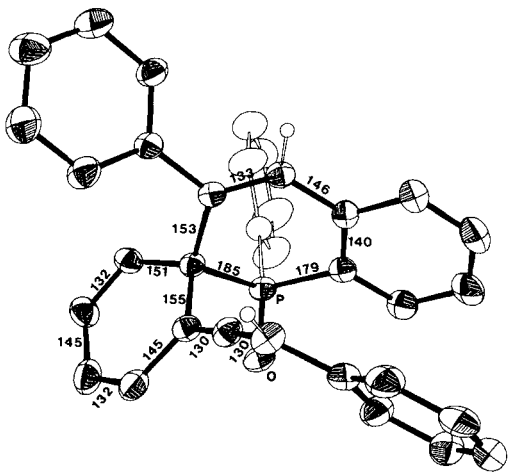

Fig. 1. Molecular structure of *(3)*. For sake of clarity only the "added" H atoms are shown. The standard deviations of the bond lengths (in pm) are on average 0.5 pm [4].

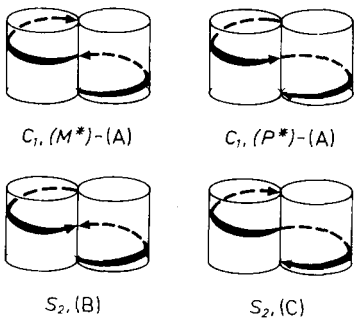
Enantiomerism and Diastereoisomerism of Bishelical Bilatriene Dimers in the Crystal Lattice

By *Harald Lehner, Silvia E. Braslavsky*, and *Kurt Schaffner*[*]

The *all-Z-all-syn* stereoisomers of bilatrienes are helical in the crystal lattice[1, 2]. In addition, appropriately structured



[*] Dr. H. Lehner [+], Prof. Dr. S. E. Braslavsky, Prof. Dr. K. Schaffner [++] Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung Stiftstrasse 34—36, D-4330 Mülheim-Ruhr (Germany)

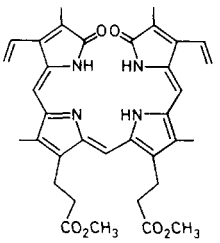
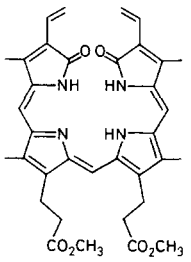
[++] To whom correspondence should be addressed.

molecules form bishelical dimers, by way of intermolecular N—H···O bridges. If a helical bilatriene monomer possesses C_2 symmetry, *i.e.*, if the substitution patterns of rings *A* and *D* and of rings *B* and *C* are identical, dimerization can lead to *one* such bishelical arrangement only; it has a center of inversion and consequently it is achiral.



Structural data[1,3] of the unsymmetrically substituted biliverdin dimethyl ester *(1)* reveal positional disorders of the substituents which have not been satisfactorily explained as yet. The single helices have no symmetry element in this case (C_1). Instead, they are characterized by an orientation as defined, *e.g.*, by the sequence of rings $A \rightarrow D$, which for the dimerization to bishelices now offers *four* possible combinations, *(M*)*-(A), *(P*)*-(A), (B), and (C).



(B) and (C) are achiral, and they are diastereoisomeric with respect to each other and to the enantiomers *(M*)*-(A) and *(P*)*-(A)[5]. If the substituents do not strongly perturb the C_2 symmetry of the bilatriene skeleton, the three bishelical aggregates (A), (B), and (C) will differ only slightly in energy, and they can be expected therefore to coexist with comparable probabilities in the crystal lattice. It is now evident that, whenever more than one of these three bishelical arrangements occur simultaneously, positional disorders of the substituents will be simulated and thus impede the interpretation of X-ray data.

(1)

(2)

(3)

Biliverdin dimethyl ester *(1)*, with the substitution pattern unsymmetrical only with respect to the methyl and vinyl positions at rings *A* and *D*, fulfils the requirements for testing the relevance of our model considerations. A recent X-ray analysis[1] does in fact show a considerable disorder for the ring *A* and *D* substituents. However, the homogeneity of the crystal used had not been ascertained conclusively[6]. A single crystal X-ray analysis[3] of pure *(1)*[4] has now revealed a qualitatively similar disorder[1].

The result could also arise from a crystal composed of a 1:1 complex of *(2)* and *(3)*. This possibility was unequivocally ruled out in an isotope dilution experiment. Equal amounts of $[D_6]$-*(1)*[7] and *(2)* were dissolved in boiling chloroform and then separated again by chromatography[4]. The two products were indistinguishable from the corresponding starting materials by 270 MHz ^{1}H-NMR and mass spectra, thus confirming the isomeric homogeneity of our X-ray sample.

The X-ray analytical disorder of the substituents of *(1)* can thus be rationalized in terms of head-to-head, head-to-tail, and tail-to-tail dimerizations of the single helices occurring with comparable probabilities, *i.e.* by the presence of several diastereoisomeric and/or enantiomeric bishelical bilatriene dimers. A similar situation has possibly been encountered in the case of bilirubin with ridge-tile conformation[8].

Dipotassium Hexaisobutyldialuminate, a Complex Containing an Al—Al Bond

By *Heinz Hoberg* and *Siegfried Krause*[*]

The dehalogenation of diisobutylaluminum halides with alkali metals can lead, under certain conditions, to the formation of tetraisobutyldialuminum[1].

This observation encouraged us to investigate the possibility of isolating intermediates in the previously reported reaction

[*] Priv.-Doz. Dr. H. Hoberg, Dr. S. Krause
Max-Planck-Institut für Kohlenforschung
Postfach 011325, D-4330 Mülheim-Ruhr 1 (Germany)

(a)[2] which, at 100 °C, leads to separation of Al and formation of tetraalkylaluminate complexes.

$$4\,R_3Al + 3\,M \rightarrow 3\,M[R_4Al] + Al \qquad (a)$$
R = alkyl; aryl; M = alkali metal

When triisobutylaluminum is allowed to react with potassium in a non-polar solvent at 20 °C the separation of aluminum is completely suppressed, and we were able to isolate the novel dipotassium hexaisobutyldialuminate *(1)* containing an Al—Al bond in 63 % yield.

$$2(i\text{-}C_4H_9)_3Al + 2\,K \rightarrow K_2[(i\text{-}C_4H_9)_3Al{-}Al(i\text{-}C_4H_9)_3] \qquad (b)$$
(1)

The brown, crystalline compound *(1)*[3] (m. p. 40 °C) is readily soluble in organic solvents (toluene, diethyl ether, tetrahydrofuran) and is diamagnetic both in the crystalline state and in the solvated state. The molecular mass of 483 determined vaporimetrically in benzene (calc. 475) confirms the reported empirical formula. Solvolysis with *n*-$C_4H_9CH(C_2H_5)CH_2OD$ affords *i*-C_4H_9D and D_2 in the molar ratio 5.94 : 1 (calc. 6 : 1). In solution ionic dissociation takes place; this follows from comparison of the specific conductivity ($\varkappa = 2.87 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$; 0.2 M solution, THF, 20 °C) with that of complexes such as $K[(i\text{-}C_4H_9)_4Al]$ ($\varkappa = 4.0 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$).

The ^1H- and ^{13}C-NMR spectra of *(1)* reveal magnetic equivalence of the six *i*-C_4H_9 groups at 20 °C. No signal splitting is observed on lowering the temperature to −70 °C ([D_8]toluene), thus ruling out bridging association[4]. The upfield shift of the α-protons upon complex formation is of the expected order (Table 1).

Table 1. ^1H- and ^{13}C-NMR signals of *i*-C_4H_9—Al compounds in [D_6]benzene at 20 °C (R = *i*-C_4H_9).

	R_3Al	$K[R_4Al]$	$K_2[R_3Al{-}AlR_3]$ *(1)*
$\delta(^1H)(Al{-}CH_2)$	0.28 (d)	−0.25 (d)	−0.30 (d)
$\delta(^{13}C)(Al{-}C)$	25.3 (s)	26.4 (br.)	27.2 (s)

(1) behaves ambifunctionally towards electrophiles. On reaction with trimethylchlorosilane in THF the Al—Al bond remains intact; the product *(2)* can be regarded as a bistetrahydrofuran adduct of tetraisobutyldialuminum. On the other hand *(1)* reacts like alkali metal aromatic complexes[5] with allyl bromide to give 1,5-hexadiene *(3)* and $(i\text{-}C_4H_9)_3Al$.

$$(1) + 2(CH_3)_3SiCl + THF \rightarrow \underset{\displaystyle THF}{\overset{\displaystyle THF}{R_2Al{-}AlR_2}} + 2\,KCl + 2(CH_3)_3SiR$$
(2), 80 %

$$(1) + 2\,CH_2{=}CH{-}CH_2Br \rightarrow$$

$$CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 + 2\,KBr + 2\,R_3Al$$
(6), 55 %

R = *i*-C_4H_9

Hydrocarbons with an affinity for electrons (naphthalene, anthracene, biphenyl, and cyclooctatetraene) accept electrons from *(1)* with formation of radical anions and dianions, and liberation of $(i\text{-}C_4H_9)_3Al$.

It can be concluded from the spectra and the chemical and physical behavior of *(1)* that there is a σ-bonding interaction between the two Al atoms.

Experimental

Triisobutylaluminum (83.7 g, 104.7 ml) is added dropwise at −30 °C to a vigorously stirred mixture of potassium (16.5 g, 422.0 mmol; pellets, ϕ *ca.* 1 mm) in hexane (900 ml) at a rate slow enough to prevent caking of the potassium pellets (*ca.* 8 h). The mixture is then warmed to room temperature, whereupon the potassium gradually dissolves and a viscous brown-colored product is obtained. After *ca.* 3 weeks the supernatant is removed and the residue taken up in *ca.* 300 ml toluene and filtered to remove any unreacted potassium. The filtrate is cooled to −78 °C. The crystalline product is recovered on a cold frit and dried at 10^{-3} torr. Yield 65.6 g (133.0 mmol, 63 %) *(1)*·0.2 toluene.

IR (KBr): no Al—H stretching vibrations at about 1800 cm^{-1}[6]. ^1H-NMR (Bruker WP 80 FT; [D_6]benzene, 80 MHz, TMS): δ = 7.10 (d, 0.5 H, C_6H_5), 2.17 + 2.12 (m, 1.3 H, $C_6H_5{-}CH_3$, CH), 1.3 (d, 6.0 H, CH_3), −0.3 (d, 1.9 H, CH_2); ^{13}C-NMR (Varian-XL-100-15; [D_6]benzene, 25.2 MHz, ext. TMS): δ = 27.2 (C—Al), 28.65 (CH), 29.82 (CH_3).

2,2′-Bipyridine(tetramethylcyclobutadiene)nickel(0)

By *Udo Griebsch* and *Heinz Hoberg*[*]

Nickel(0) is equally suitable both for the complexation and the synthesis of cyclic alkenes[1]. Cyclobutadienes were first stabilized by coordination to Ni(II)[2]; and only recently has the synthesis of bis(tetraphenylcyclobutadiene)nickel(0) been reported[3]. We have now been able to prepare 2,2′-bipyridine(tetramethylcyclobutadiene)nickel(0) *(2)* as an example of the previously unknown monocyclobutadienenickel(0) complexes, which are of interest in nickel-catalyzed cyclooctatetraene synthesis[4].

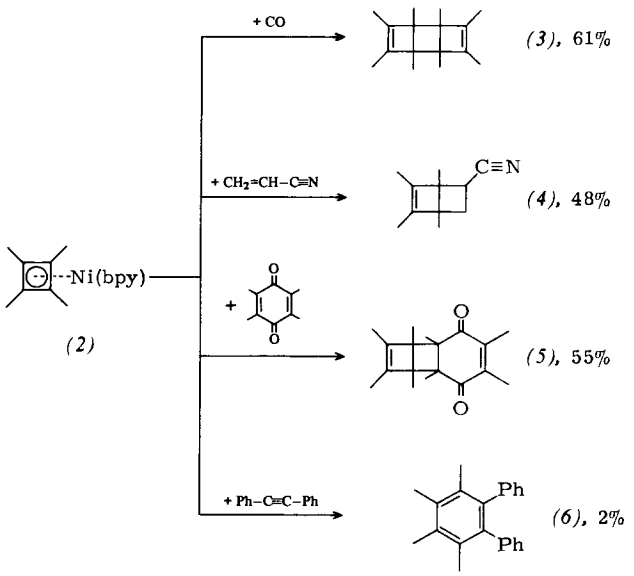
Reaction of tetramethylcyclobutadienenickel dichloride *(1)*[2] with sodium in the presence of bpy affords *(2)* in 63 % yield.

$$[\{(CH_3)_4C_4\}NiCl_2]_2 + 4\,Na \xrightarrow{+\,bpy}$$
(1)

$$2[(CH_3)_4C_4]Ni(bpy) + 4\,NaCl$$
(2)

(2) crystallizes in the form of lustrous copper-colored platelets and dissolves in organic solvents such as ether, tetrahydrofuran, or benzene giving intense blue solutions. The complex

[*] Priv.-Doz. Dr. H. Hoberg, Dr. U. Griebsch
Max-Planck-Institut für Kohlenforschung
Postfach 01 1325, D-4330 Mülheim-Ruhr 1 (Germany)



(2) is diamagnetic, exceptionally thermally stable, melts at 225°C (decomp.), and can be sublimed at 130°C/10^{-3} torr. The mass spectrum shows the molecular ion $m/e=322$ and a characteristic fragment $m/e=214$ (bpy-Ni). The relative molecular mass of 330 (calc. 323) determined cryoscopically in benzene establishes the monomeric structure.

The IR spectrum (KBr) contains the aromatic bands of bpy together with characteristic bands at 1515 (s, C=C) and 1370 and at 1435 (C—CH_3) cm^{-1}. The ^{1}H-NMR spectrum ([D_6]benzene) shows in addition to the signals of the bpy protons only one signal ($\delta=1.53$) for the 12 methyl protons of the $(CH_3)_4C_4$ system. This indicates η^4-coordination of the C_4-ring to the nickel atom. In the ^{13}C-NMR spectrum ([D_6]benzene) only two signals are observed for the C-atoms in the $(CH_3)_4C_4$ moiety. Gated-decoupled, the signal at $\delta=82.23$ could be assigned to the ring C-atoms and that at $\delta=8.48$ to the methyl C-atoms[5].

The cyclobutadiene moiety in *(2)* can be hydrogenated only with difficulty. Even after addition of catalysts such as bis(1,5-cyclooctadiene)nickel, Raney nickel, PtO_2 or Pt/C, no hydrogen is taken up in THF at 65°C (24 h, 1 atm). Only lithium in liquid ammonia effects partial hydrogenation; hydrolysis of the product affords tetramethylcyclobutene.

Tetramethylcyclobutadiene is not displaced from *(2)* by ligands (L) such as 2,2'-bipyridine or triphenylphosphane [*(2)*: L = 1:5] at 20°C in THF (8 days). However, reaction with CO (20°C, 1 atm THF) produces the dimer *(3)* (see Scheme 1).

The tetramethylcyclobutadiene system of *(2)* reacts with dienophiles (acrylonitrile, duroquinone, tolan) even at 20°C in THF (3 h) to give the Diels-Alder adducts [*(4)*, *(5)*] or their valence isomers [*(6)* (see Scheme 1).

Scheme 1. The structures of the products *(3)*—*(6)* were determined spectroscopically (MS, IR, ^{1}H-NMR), the yields by GC. *(3)* is present in the *syn*-form. There are two isomers of *(4)* (94%, 6%); presumably the *exo* isomer is the main product. *(5)* forms only one isomer (GC).

Experimental

To a vigorously stirred suspension of 7.75 g (32.6 mmol) *(1)*[2] and 5.07 g (32.5 mmol) 2,2'-bipyridine in 700 ml diethyl ether at room temperature is added 1.5 g (65 mmol) sodium (pellets, ϕ *ca.* 1 mm). The solution immediately turns blue. After *ca.* 24 h the precipitate is filtered off and washed with diethyl ether. The combined filtrates are evaporated down and dried in a high vacuum. The residue is almost analytically pure *(2)* [yield 6.55 g (20.5 mmol, 63%)]. *(2)* can be recrystallized from toluene/hexane (1:1).

Redox Properties of Zinc Tetrabenzporphyrin[**]

By *Arnd Vogler, Birgit Rethwisch, Horst Kunkely, Jürgen Hüttermann*, and *Jürgen Otto Besenhard*[*]

Electron transfer processes involving metalloporphyrins play an important role in photosynthesis and other biological redox reactions. So far, the redox potentials of porphyrins could essentially only be modified by variation of the central metal and additional axial ligands[1]. A third possibility lies in the modification of the porphyrin ring. Whereas simple substituents have only a slight effect on the redox properties, an extension of the π-electron system of porphyrins could lead to a drastic decrease of the redox potentials[1]. We have found that this is indeed the case with tetrabenzporphyrin (TBP). We now report the redox behavior of zinc tetrabenzporphyrin, ZnTBP *(1)*[2], which contains a redox-inert metal center.

The results of cyclic voltammetry are explained with the aid of the reaction scheme:

$$[Zn(TBP^-)]^{\ominus} \underset{+e}{\overset{-e}{\rightleftharpoons}} [Zn(TBP)] \underset{+e}{\overset{-e}{\rightleftharpoons}}$$
(4) *(1)*

$$[Zn(TBP^+)]^{\oplus} \underset{+e}{\overset{-e}{\rightleftharpoons}} [Zn(TBP^{2+})]^{2\oplus}$$
(2) *(3)*

(1) can be oxidized to *(2)* and *(3)* in two reversible one-electron steps, $E_{1/2}=+0.36$ and $+0.97$ V (*versus* SCE, at Pt in 1 M $LiClO_4$/DMSO). The first reduction of *(1)* to *(4)* is also reversible. The potential difference of 1.84 V found between the first ring oxidation and ring reduction of TBP is much lower than that observed for other porphyrins, which usually exhibit differences of about 2.25 V[1]. The low first oxidation potential of *(1)* ($E_{1/2}=+0.36$ V) is remarkable; zinc octaethylporphyrin and zinc tetraphenylporphyrin are not oxidized below $E_{1/2}=+0.63$[3] and $+0.71$ V[4], respectively.

Since porphyrin π radical ions warrant particular interest[5], we examined the species *(2)* more thoroughly[6]. Oxidation of *(1)* by iodine in methanol/dimethyl sulfoxide (10:1) affords *(2)* which has an absorption spectrum (Fig. 1) typical for porphyrin π radical cations[1, 5]. Species *(2)* can be completely reduced back to *(1)* (*e.g.* by dithionite).

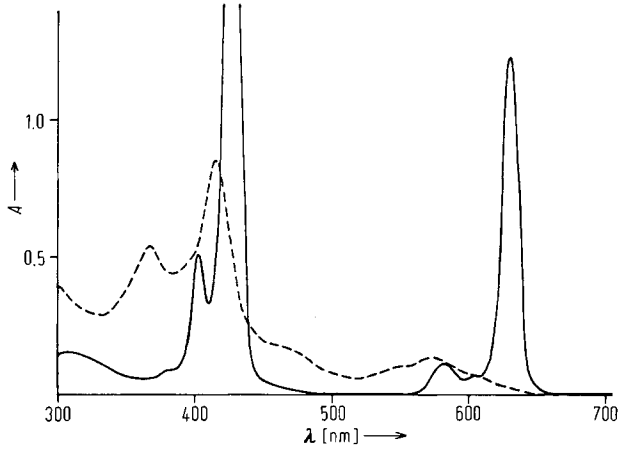

Fig. 1. Absorption spectrum of ZnTBP (——), 8.13×10^{-5} mol/l in methanol/dimethyl sulfoxide (10:1), 1-mm cuvette; after oxidation by iodine (----).

Further characterization of *(2)* was by ESR spectroscopy: in methanol/pyridine (10:1) the room temperature spectrum of *(2)* consists of a single line having a width of 5.5 G and a *g* value of 2.0029. No hyperfine structure could be observed at 77 K.

Carbonyl(pyridine)iron(II) Tetrabenzporphyrin π-Radical Cation[**]

By *Arnd Vogler, Birgit Rethwisch, Horst Kunkely*, and *Jürgen Hüttermann*[*]

Iron porphyrins transfer electrons in biological systems. In cytochromes, electron transfer proceeds *via* the redox pair Fe^{II}/Fe^{III}. There are indications, however, that a π electron of the porphyrin ring participates in the initial step of such redox reactions[1]. While the oxidation of some Ru^{II} porphyrins does indeed lead to the loss of a porphyrin electron forming stable porphyrin π-radical cations[2], one-electron oxidation of Fe^{II} porphyrins has so far only been observed to give the corresponding Fe^{III} complexes[3]. This is because Fe^{II} is oxidized at lower potentials than the porphyrin ring, and Ru^{II} at higher potentials. If the oxidation potential of a porphyrin could be lowered below that of Fe^{II}, then it should be possible to obtain a stable Fe^{II} porphyrin π-radical cation. The existence of such a compound would be of interest not only in connection with the mechanism of biological reactions. A Fe^{II} porphyrin π-radical cation is isomeric ("oxidation state isomerism"[3]) with the corresponding Fe^{III} porphyrin; the two forms differ merely in the localization of an electron. In the case of the low spin Fe^{III} porphyrins known so far, the isomeric Fe^{II} porphyrin π-radical cation is a low energy, electronically excited CT state[4] to be observed in the absorption spectrum[5]. This CT state would become the new ground state in a stable Fe^{II} porphyrin π-radical cation.

We have now found that the oxidation of $[Fe^{II}(TBP)(CO)(py)]$ *(1)* (TBP = tetrabenzporphyrin) does indeed lead to the loss of a π electron from the porphyrin ligand to form $[Fe^{II}(TBP^{+})(CO)(py)]^{\oplus}$ *(2)*. The following criteria determine the choice of *(1)*: TBP has a very low oxidation potential[6] and the CO ligand stabilizes Fe^{II} relative to Fe^{III}[3]; thus the oxidation of Fe^{II} is shifted to higher potentials.

(1) was obtained by dissolution of $[Fe^{II}(TBP)(py)_2]$[7] in $CHCl_3$ saturated with CO. The IR spectrum of *(1)* in $CHCl_3$ shows a CO stretching band at 1975 cm^{-1}. Oxidation with iodine affords *(2)*, whose absorption spectrum (Fig. 1) is typical of porphyrin oxidation. The IR spectrum of *(2)* contains a νCO band at 2020 cm^{-1}. Fe^{III} carbonyl complexes are unknown. The 45 cm^{-1} shift occurring upon oxidation of *(1)* is probably due to the overall positive charge on *(2)*.

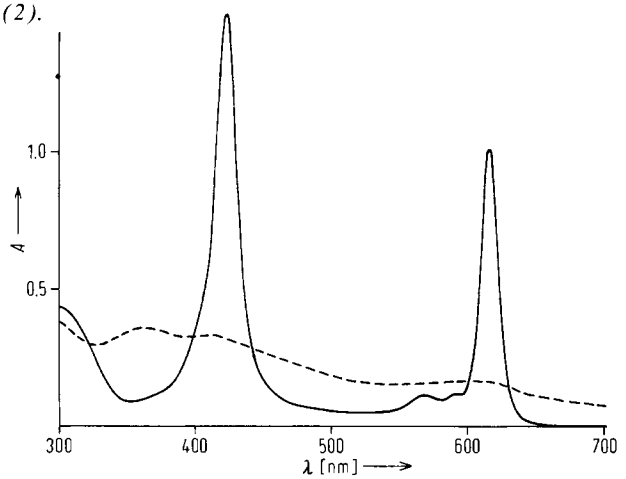

Fig. 1. Absorption spectrum of FeTBP(CO)(py) (——), 1.1×10^{-5} mol/l in $CHCl_3$, 1-cm cuvette; after oxidation by iodine (----).

The ESR spectrum of *(2)* in $CHCl_3$/methanol (1:1) consists of a single line having a width of 5.0 G and a *g* value of 2.0032. This signal, which only appears clearly below 77 K, closely resembles that of $[Zn(TBP^{+})]^{\oplus}$[6] and is completely different from the ESR spectra of the Fe^{III} porphyrins[8]. The reduction of *(2)* in dimethyl sulfoxide (*e.g.* by dithionite) completely regenerates *(1)*.

A New Example of a Dichromium Compound with a Supershort CrCr Quadruple Bond[**]

By *F. Albert Cotton, Brian E. Hanson*, and *Gary W. Rice*[*]

The first compound now recognized to contain a quadruple bond, $Cr_2(O_2CCH_3)_4(H_2O)_2$, was discovered in 1844[1]. In 1970 it was shown[2] that the Cr—Cr distance is 2.3855(5) Å. More recently it has been shown[3] that Cr—Cr distances in 14 compounds of type *(1)* vary from 2.214(1) Å to 2.541(1) Å, this variability being consistent with the results of an SCF-HF-CI study[4]. However, it has also been known for several years that several quadruply bonded Cr_2^{4+} species have bond lengths slightly below 2.00 A, *viz.* $[Cr_2(CH_3)_8]^{4-}$ with 1.980(5) Å[5a], the closely similar $[Cr_2(C_4H_8)_4]^{4-}$ with 1.975(5) Å[5b] and $Cr_2(allyl)_4$ with *ca.* 1.97 Å[5c].

(1) *(2)* *(3)*

To complicate the picture further, it has been found in the last two years that species of type *(2)* (where the X, Y, Z atoms may be C, N, O, or S) have CrCr bond lengths in the range 1.830(4) Å to 1.889(1) Å; the shortest one of these is the shortest of all known metal-metal bonds[6]. Thus far, no explanation for the occurrence of such extremely short CrCr bonds in compounds of type *(2)* has been proposed, but the presence of an aromatic ring as the one common feature tended to suggest that the properties of that moiety might, in some way, be critical.

We wish to report here evidence that the presence of an aromatic ring is not essential to the occurrence of a "supershort" (< 1.90 Å) CrCr bond. The preparation of the compound $Cr_2[(CH_2)_2P(CH_3)_2]_4$ *(3)* was reported in 1974[7], but no structural information whatsoever has heretofore been available. We have now determined by X-ray crystallography[8] the molecular structure (Fig. 1). The familiar paddle wheel pattern of four bidentate bridging ligands forming five-membered rings with a common metal-metal axis is displayed; qualitatively, then, the structure is not surprising, although other possibilities existed[9]. The surprising and significant feature of *(3)* is the CrCr quadruple bond distance of 1.895(3) Å. This very short distance is found without the presence of any aromatic character in the ligand. The dimensions of the molecule are otherwise not unusual, the average values of the principal bond lengths and angles being Cr—C, 2.22(1) Å; P—C, 1.80(3) Å; Cr—Cr—C, 103.3(4)°; C—Cr—C, 87.0(6)°.

The fact that compound *(3)* contains a supershort CrCr bond is fortunate for several reasons. It is a molecular compound that is sufficiently volatile to allow measurements of its photoelectron spectrum either in the gas or solid phase, or both, as well as the ordinary electronic absorption spectrum. It is a simple enough molecule to permit detailed treatment of its electronic structure and bonding by both SCF-HF-CI and SCF-Xα-SW methods. In view of the difficulties encountered in obtaining and reconciling the results obtained by these two methods[4, 10] for the systems of type *(1)*, this will afford a welcome opportunity to enhance our comprehension of the theoretical aspects of metal-to-metal multiple bonds.

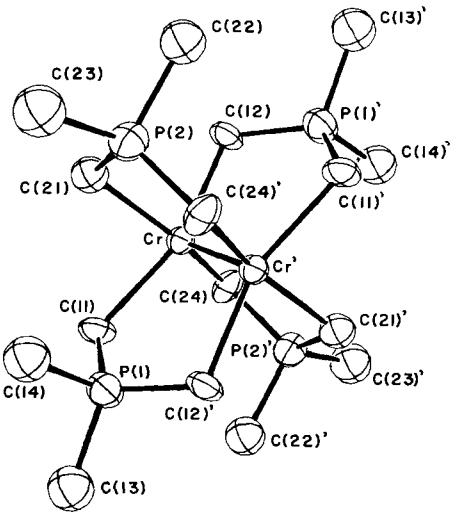

Fig. 1. The structure of the dichromium compound *(3)*; each atom is represented by its ellipsoid or sphere of thermal vibration, scaled to enclose 50% of its electron density [8].

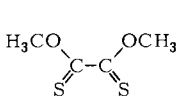
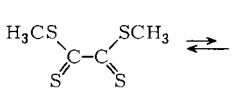
Thiooxalates as Dithiabutadienes

By *Klaus Hartke, Thomas Kissel, Josef Quante*, and *Günter Henssen*[*]

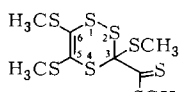


Thiocarbonyl compounds are known to react as 2π components in cycloadditions[1]. Examples of 1,2-dithiocarbonyl

[*] Prof. Dr. K. Hartke, Dr. Th. Kissel, Dipl.-Chem. J. Quante, Dipl.-Chem. G. Henssen
Institut für Pharmazeutische Chemie der Universität
Marbacher Weg 6, D-3550 Marburg/Lahn (Germany)

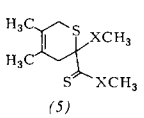


compounds as 4π components in cycloadditions have, to our knowledge, not been described[2]. We have now found that the dithionooxalate *(2)*[3] and the tetrathiooxalate *(3)*[4] undergo numerous cycloadditions owing to their very reactive dithiabutadiene system. These thioesters may function as 2π- or 4π-components, depending upon the reaction partner involved.

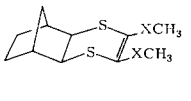


(1)

(2)



(3)



(4)

In the series *(1)*→*(3)*, the tetrathiooxalate *(3)* shows the least resonance stabilization and hence the highest reactivity. Thus, although *(3)* is monomeric in the crystalline form, in nonpolar solvents such as carbon tetrachloride and tetrahydrofuran the [4+2] dimer *(4)* is already present in equilibrium at room temperature up to about 20% [*(4)*, ^{1}H-NMR (CCl_4): δ=2.10 (C-3-SCH_3), 2.42 and 2.49 (C-5-, C-6-SCH_3), 2.68 (C(S)SCH_3); ^{13}C-NMR (CD_2Cl_2): δ=16.0, 17.8, 20.2, 21.6 (SCH_3), 88.4 (C-3), 132.8 and 133.6 (C-5, C-6), 231.2 (C=S)]. Other cycloaddition products with *(3)* are also formed under milder conditions than with *(2)*. As examples of [4+2] cycloadducts of *(2)* and *(3)*, the compounds *(5)*—*(13)* have been chosen; the experimental data are listed in Table 1.

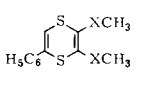


Table 1. Experimental data for the formation of cycloaddition products *(5)*—*(13)*. Owing to partial decomposition on distillation the liquid products (yellow oils) could only be purified by chromatography. All the compounds gave correct analyses and IR, ^{1}H-NMR, and ^{13}C-NMR spectra consistent with the quoted structures.

Norcaradiene and Cycloheptatriene Endoperoxides[**]

By *Waldemar Adam* and *Metin Balcı*[*]

Cycloheptatriene represents a fascinating and challenging substrate for cycloaddition. Thus its norcaradiene valence isomer could give [2+4] adducts of type *(A)*, whereas cycloheptatriene could yield the uncommon [2+6] adducts *(B)*, besides the more normal [2+4]-adducts *(C)*. We now report the successful preparation, isolation, and characterization of

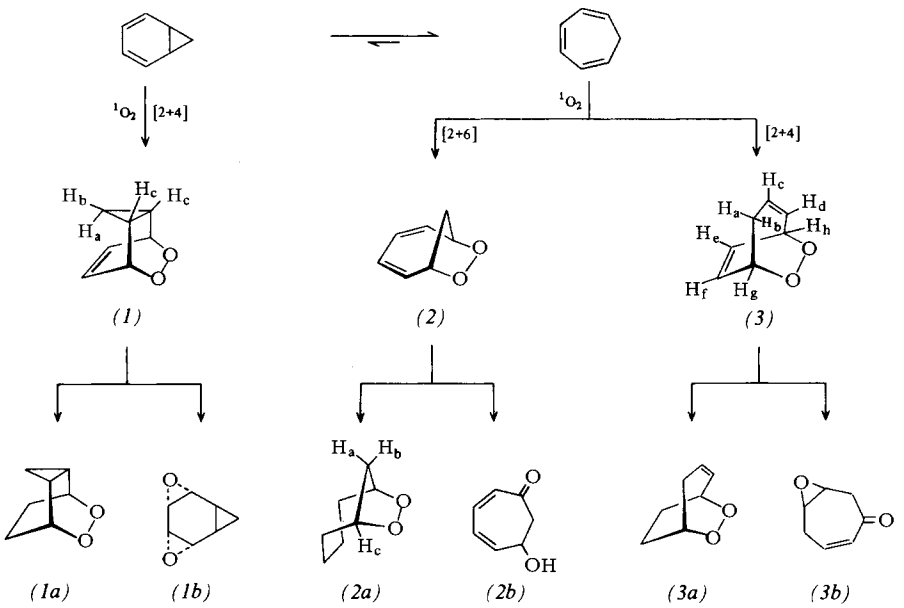
[**] Cyclic Peroxides, Part 77. Acknowledgments are made to the Donors of the Petroleum Research Fund (11022-AC-1) administered by the American Chemical Society, the National Science Foundation (CHE-78-12621), and the National Institutes of Health (GM-21119-03, GM-00141-04, and RR-8102-06).—Part 76: *W. Adam* and *K. Sakanishi*, Photochem. Photobiol., in press.



(A) (B) (C)

the endoperoxides *(1)*, *(2)*, and *(3)*—corresponding to types *(A)*, *(B)*, and *(C)*—produced by oxygenation of cycloheptatriene with singlet oxygen. To the best of our knowledge, this constitutes the first observation of all three possible Diels-Alder adducts in a cycloheptatriene cycloadditon.—Compound *(3)* has been isolated on photooxidation of cycloheptatriene in the presence of α-dicarbonyl compounds[1a]; *(2)* and *(3)* have been postulated as intermediates in the photooxygenation of cycloheptatriene with singlet oxygen[1b].

Photooxygenation of cycloheptatriene in CCl_4 (150-W Na lamp) at 0°C and tetraphenylporphyrin as sensitizer, followed by low temperature silica gel chromatography at −50 to −60°C (elution with CH_2Cl_2/pentane (1:1)) afforded *(1)*, *(2)*, and *(3)* in 3.5, 37, and 40% yield, respectively. The structure assignments of these unstable endoperoxides rests on ^{1}H-NMR and IR spectral data (Table 1). In addition, the following chemical transformations confirm the proposed structures.

The norcaradiene adduct *(1)* led to the saturated, bicyclic peroxide *(1a)* on diazene reduction in methanol at 0°C[2]. Furthermore, on heating in CCl_4 at 100°C in a sealed tube, *(1)* was converted into the hitherto unknown[3] isomer *(1b)* of norcaradiene diepoxide.

Treatment of the unusually strained [2+6] cycloadduct *(2)* with methanol at 30°C afforded the rearrangement product

(2b). For this reason the diazene reduction had to be carried out in the nonprotic solvent CH_2Cl_2 at *ca.* 0°C[4], resulting in the novel bicyclic peroxide *(2a)*.

Finally, diazene reduction at 0°C in methanol[2] of the [2+4] cycloadduct *(3)* led to the expected bicyclic peroxide *(3a)*. On heating in toluene at 180°C in a sealed tube *(3)* was converted into the epoxyenone *(3b)*.

The spectral and chemical data substantiate the novel endoperoxide structures beyond any reasonable doubt. Thus, *(1)* represents the first unsubstituted norcaradiene [2+4] cycloadduct, while *(2)* constitutes the first confirmed [2+6] cycloadduct with singlet oxygen. More significantly, photooxygenation of cycloheptatriene opens up a convenient entry to unusual bicyclic peroxides which are difficult to prepare by alternative routes.

Table 1. Selected physical data of compounds of types *(1)* to *(3)*. The ^{1}H-NMR and IR spectra were recorded in CCl_4 (except for *(2b)*, recorded in $CDCl_3$ and $CHCl_3$, respectively).

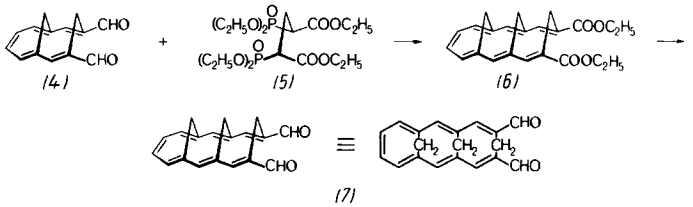
syn,syn-1,6:8,17:10,15-Trismethano[18]annulene

By *Wolfgang Wagemann, Masahiko Iyoda, Hans M. Deger, Johannes Sombroek*, and *Emanuel Vogel*[*]

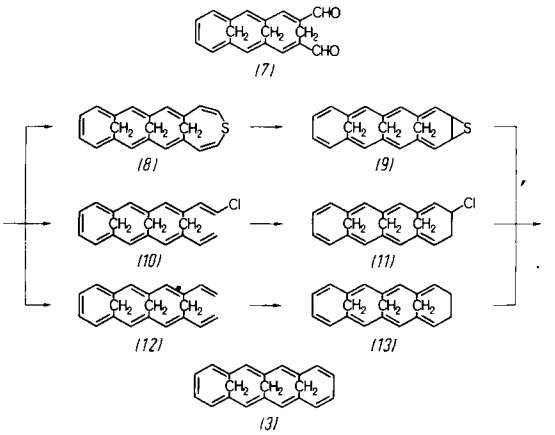


Dedicated to Professor Heinrich Hellmann on the occasion of his 65th birthday

Interestingly, *syn*-1,6:8,13-bismethano[14]annulene *(2)*[1], the next higher homologue (*syn*-series) of 1,6-methano-[10]annulene *(1)*, has been shown to be a Hückel aromatic, although steric interaction of the inner bridge hydrogen atoms in *(2)* causes appreciable bending of the annulene ring[2]. This finding is of interest from both the theoretical as well as the synthetic standpoint and called for extension of the [4*n*+2]annulene series *(1)*, *(2)*, *(3)*, *etc.* beyond *(2)*, in particular to establish more accurately, the position of the bridged [4*n*+2]annulenes with an acene perimeter between the acenes on the one hand and the [4*n*+2]annulenes of *Sondheimer*[3a], *Nakagawa*[3b], and *Boekelheide*[3c] on the other.

(1) *(2)* *(3)*

For synthesis of the 18π homologue of *(1)* and *(2)*, *i.e.* *syn,syn*-1,6:8,17:10,15-trismethano[18]annulene *(3)*, which we report here, the conformational features of the known bicyclo[5.4.1]dodeca-2,5,7,9,11-pentaene-3,5-dicarbaldehyde[1] have served as a guide. Since this α,ω-pentaenedialdehyde exists as the *syn*-conformer *(4)*, the homologous α,ω-heptaenedialdehyde ought also to exist in the *syn*-conformation [*(7)*] and thus represent an ideal synthon for *(3)*.



(4) *(5)* *(6)* *(7)*

To synthesize the carbon skeleton of the heptaenedialdehyde, *(4)* was allowed to react with the Horner-Wittig reagent 1,3-diethoxycarbonyl-1,3-propanylenebis(diethylphosphonate) *(5)*, readily obtainable by Michaelis-Arbuzov reaction of diethyl α,α'-dibromoglutarate with triethyl phosphite[4] (generation of the biphosphonate dicarbanion with sodium hydride in ether; olefination conditions: dichloromethane/benzene, reflux, 3 h). Although ring closures with difunctional olefinating agents usually proceed unsatisfactorily we obtained the heptaene diester *(6)* in 58% yield [orange-red needles (methanol), m. p. 162—163 °C] after chromatography on silica gel. Reduction of the diester with diisobutylaluminum hydride (benzene, room temperature) led to the corresponding diol [yellow needles (acetone), m. p. 211—212 °C (decomp.), yield 71%], which on oxidation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (= DDQ; dioxane, room temperature) gave the dialdehyde *(7)* [red needles (dichloromethane), m. p. 264—267 °C (decomp), yield 75%]. That the dialdehyde was present as the expected *syn*-conformer, both in the crystalline state and in solution, was confirmed by X-ray structure analysis[5] and by the chemical transformations of the compound.

Our concept for the subsequent synthetic route to *(3)* was as follows[4]: olefination of *(7)* to give an appropriately terminally substituted nonaene and "cyclodehydrogenation" of this product by a sequence of disrotatory 18π electrocyclic process[6] and β-elimination.

On the basis of previous successful experiments[1], an attempt was made to react *(7)* with the difunctional Wittig reagent formed from thiodimethylenebis(triphenylphosphonium bromide) and lithium methoxide to give the thia[19]annulene *(8)*, since *(8)* was expected to be readily convertible into *(3)* *via* the [18]annulene episulfide *(9)*. Despite variation of the reaction conditions we have so far been able to obtain *(3)* only in traces (<1%) *via* this route.

(7) *(8)* *(9)* *(10)* *(11)* *(12)* *(13)* *(3)*

As an alternative approach we considered the consecutive olefination of *(7)* by two judiciously selected monofunctional Wittig reagents: the monovinyl compound [carmine-red platelets (ethyl acetate), decomp. 178—180 °C; IR: 1665 cm^{-1} (C=O); yield 55%] initially obtainable as main product of reaction with methylene(triphenyl)phosphorane (molar ratio 1:1.2) in tetrahydrofuran (room temperature, 3 h), can be converted by reaction with chloromethylene(triphenyl)phosphorane[7] in tetrahydrofuran (−70 °C, then room temperature, 3 h) into *(10)* [mixture of *cis/trans* isomers, yellow crystals (ethyl acetate/chloroform); m/e = 306 (^{35}Cl) (M^+, base peak); yield 70%]. In boiling dimethylformamide (90 min), *(10)* smoothly cyclizes to *(11)*, which spontaneously undergoes dehydrohalogenation with formation of *(3)*[8] [yield 83% of NMR spectroscopically pure, crystalline hydrocarbon after chromatographic filtration on aluminum oxide Act. III (hexane/dichloromethane 8:1)]. Regarding the combination of the 18π electrocyclic process with a dehydrogenation step it would appear that the divinyl compound *(12)* [yellow crystals (ethyl acetate/chloroform), decomp. >180 °C; yield 75%] obtainable from *(7)* and methylene(triphenyl)phosphorane (molar ratio 1:3) could serve as a useful nonaene intermediate. Indeed, *(12)* afforded the annulene when it was thermolyzed (yield 40%; after chromatography) with DDQ (molar ratio 1:1.4) in anisole (quartz ampoule; 270 °C, 7 min). Attempts to detect *(13)*, the dihydro[18]annulene precursor of *(3)*, have so far failed. The new [18]annulene *(3)* crystallizes from toluene[9] as golden-brown scales (decomp. >180 °C); in contrast to *(1)* and *(2)* it is air-sensitive and is storable only at low temperature (under protecting gas). The olefinic reactivity of *(3)* is determined more by Baeyer- and Pitzer-strain than by loss of resonance, for according to its spectroscopic properties the hydrocarbon exhibits distinct aromatic character.

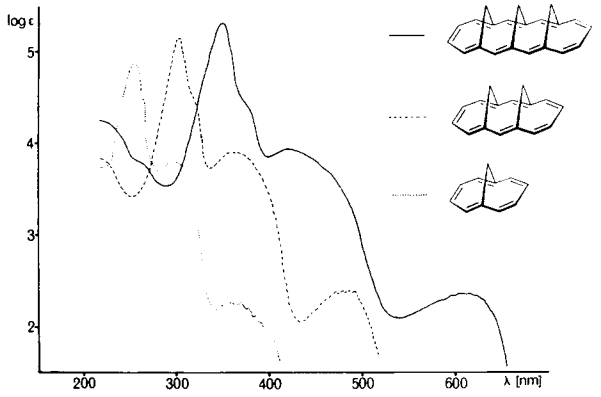

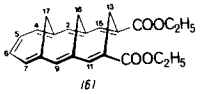

Fig. 1. Electronic spectra of *(1)*, *(2)*, and *(3)* in cyclohexane.

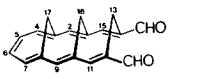
That *(3)* is to be regarded as aromatic is supported quite impressively by the relationship of its electronic spectrum to those of its lower homologues *(1)* and *(2)* (Fig. 1). The spectra of the three annulenes are remarkably similar in shape but on progression from [10]- to [14]- to /18]annulene all of the bands undergo bathochromic shifts, as theoretically predicted. The NMR spectrum of *(3)* (Table 1), showing a downfield position of the resonances of the annulene protons and an upfield position of the resonances of the bridge protons, is indicative of a diamagnetic ring current and, moreover, due to its absorption pattern, affords evidence that the expected *syn-syn*-stereoisomer having C_{2v} symmetry is present, and not the *syn,anti*-isomer, likewise compatible with the configuration of *(7)*. This stereochemical result follows independently from the marked positive nuclear Overhauser effect[10] which the doublet of the inner protons of the two terminal CH_2 bridges experiences when irradiated with the resonance frequency of the protons of the central CH_2 bridge.



It follows from a comparison of the chemical shifts of the corresponding bridge protons in *(3)* and *(2)* that the steric compression of the inner bridge protons and consequently the relevant H—H distances [1.78 Å in the case of *(2)*[2]] are very similar in the two annulenes. Considering the rigidity of the carbon skeleton in annulenes of this type, which hardly permits any notable deviation of the molecule from the C_{2v} symmetry, this finding enables the molecular architecture of *(3)*, especially the curvature (or bending) of its annulene ring to be derived with a great degree of certainty[11].

Table 1. Spectral data of the diester *(6)*, the dialdehyde *(7)*, the divinyl compound *(12)*, and the *syn,syn*-1,6:8,17:10,15-trismethano[18]annulene *(3)*.

[6] *R. B. Woodward, R. Hoffmann*, Angew. Chem. *81*, 797 (1969); Angew. Chem. Int. Ed. Engl. *8*, 781 (1969); *R. Huisgen*, Chim. Ind. (Milan) *51*, 963 (1969).—The cyclizations of *(8)*, *(10)*, and *(12)* to the corresponding dihydro[18]annulenes, interpreted here as disrotatory 18π-electrocyclic processes, can be alternatively explained in terms of a 6π-electrocyclic process (cycloheptatriene-norcaradiene isomerization) followed by a number of Cope rearrangements equal to the number of bridges.
[7] *G. Köbrich, H. Trapp, K. Flory, W. Drischel*, Chem. Ber. *99*, 689 (1966).
[8] It could be shown by thermolysis of the β,β-dideuteriovinylchlorovinyl compound that the cyclization of *(10)* does not proceed *via* an acetylene intermediate. This finding warrants mention, since in the meantime it has been found that the ethynylvinyl compound also gives *(3)* on thermolysis (unpublished experiments in collaboration with *M. Hanelt*); cf. also the benzene synthesis by thermal cyclization of 1,3-hexadien-5-yne described by *H. Hopf* and *H. Musso*, Angew. Chem. *81*, 704 (1969); Angew. Chem. Int. Ed. Engl. *8*, 680 (1969).
[9] Other solvents have proved less suitable; on recrystallization of the NMR-spectroscopically pure annulene *(3)* from toluene (−20 °C) *ca.* 50 % of the substance remains in the mother liquor.
[10] *G. E. Bachers, T. Schaefer*, Chem. Rev. *71*, 617 (1971).
[11] An X-ray structure analysis of compound *(3)* has so far been impossible due to the state of the crystals (thin, flaky platelets).

syn,syn-1,6:8,17:10,15-Trismethano[18]annulene Dication— Dication of a [4*n*+2]Annulene

By *Hans M. Deger, Klaus Müllen*, and *Emanuel Vogel*[*]

The dications of polycyclic arenes, which can be regarded as 4*n*π electron systems, have been known for some time[1,2]. Annulene dications have also been described on a number of occasions[3]; however, in this case, all the species studied—with exception of the hexachlorobenzene dication[4]—have been aromatic (4*n*+2)π-electron systems derived from [4*n*]annulenes. The formal structural relationship between *syn,syn*-1,6:8,17:10,15-trismethano[18]annulene *(1)*[5] and naphthacene *(3)*, which is oxidized to *(4)* in superacid solution[2a], would suggest [4*n*+2]annulene *(1)* as being a possible candidate for the formation of a potentially antiaromatic dication.

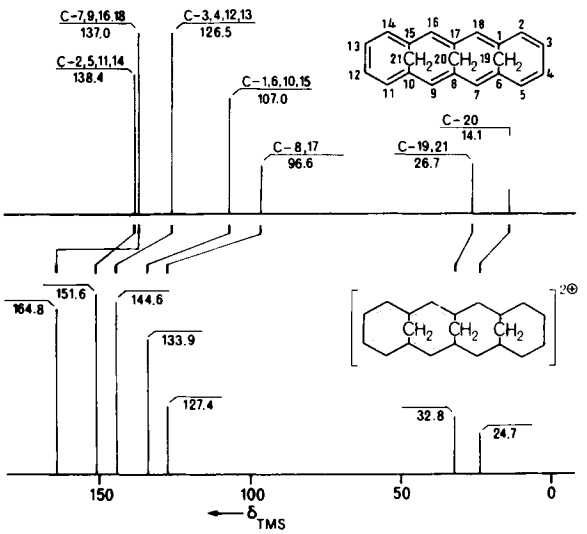
(1) (2)

(3) (4)

Addition of *(1)* in dichloromethane to a solution of fluorosulfonic acid in SO_2ClF cooled to $-80°C$ leads to a violet reaction mixture whose color changes irreversibly to olive-green on warming to 0°C. The NMR spectra of this solution, which can be stored for weeks in a sealed tube at $-20°C$, show that the dication *(2)* is indeed present[6, 7].

The main supporting evidence for the existence of *(2)* is afforded by the seven-line ^{13}C-NMR spectrum (Fig. 1), from which it follows that the C_{2v} symmetry of the starting material is retained in the product. The downfield shift of the center of the ring carbon signals observed during conversion of *(1)* into *(2)* is 17.7 ppm and thus corresponds to the value expected owing to the deshielding effect of the two positive charges in *(2)*. Since the shifts of the signals of the C atoms 7, 9, 16, and 18 are most pronounced, it may be assumed—by analogy with the situation in the naphthacene dication *(4)* and in agreement with MO calculations—that a build up of charge occurs at these positions.



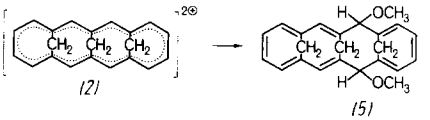


Fig. 1. Schematic representation of the ^{13}C-NMR spectra of *(1)* and *(2)*.

In agreement with the expectation that the dication *(2)* (as a $4n\pi$-electron system) exhibits a paramagnetic ring current, the resonances of the bridge protons in the ^1H-NMR spectrum of *(2)* [$(SO_2ClF/CD_2Cl_2/FSO_3H, -10°C)$: $\delta = 4.35$ and 7.58 (AX system, $J = 14.4$ Hz, 4H, H-19, 21), 6.07 (s, 4H, H-7, 9, 16, 18), 7.01—7.35 (AA'XX'' system, 8H, H-2, 3, 4, 5, 11, 12, 13, 14), 8.25 (s, 2H, H-20)] appear considerably further downfield than those of *(1)*. In contrast there is essentially no difference between the spectra of *(2)* and *(1)* as regards the resonance positions of the annulene protons. This is understandable if one assumes that an upfield shift of the annulene protons due to the ring current in *(2)* is compensated by the influence of the positive charge.

(2) (5)

Chemical evidence for the existence of *(2)* was provided by the isolation of a solvolysis product: on treatment of a solution of *(2)* in dichloromethane at $-80°C$ with methanol and subsequent chromatography of the mixture on silica gel (dichloromethane/ether/hexane, 1:1:2) a dihydrodimethoxy derivative of *(1)* is obtained [bright yellow rhombohedra, m. p. 205—206°C (methanol/ethyl acetate); yield 13%], which according to the spectra has the structure *(5)* with *cis* arrangement of the methoxy groups[8] [^1H-NMR ($CDCl_3$): $\delta = 0.00$ and 3.75 (AX system, $J = 12$ Hz, 2H, H-19), 1.09 and 4.25 (AX system, $J = 15$ Hz, 2H, H-21), 3.75 and 4.22 (AX system, $J = 12$ Hz, 2H, H-20), 3.98 (s, 2H, H-7, 18), 5.70—5.84 and 6.18—6.37 (AA'XX' system, 4H, H-2, 3, 4, 5), 6.05 (s, 2H, H-9, 16), 6.18—6.37 and 6.67—6.82 (AA'XX' system, 4H, H-11, 12, 13, 14), 3.37 (s, 6H, $2OCH_3$)].

It is conceivable that the oxidation of $[4n+2]$annulenes to dications is not restricted to the example described here, but is a general reaction for higher $[4n+2]$annulenes.

[6] The mechanism of the oxidation of *(1)* to *(2)* is still an open question. We are currently carrying out investigations in an attempt to elucidate whether a σ-complex is initially formed or whether the reaction proceeds *via* a radical cation. The reaction of *(1)* with antimony pentafluoride in SO_2ClF, which also leads to *(2)*, might involve a radical cation mechanism.

[7] As already found by *P. Warner* and *S. Winstein*, under the conditions employed for the generation of *(2)* from *(1)*, 1,6-methano[10]annulene affords a stable σ-complex, cf. J. Am. Chem. Soc. *91*, 7785 (1969).

[8] From the spectra it is not certain which configuration the methoxy groups assume with respect to the CH_2 bridges. An X-ray structure analysis is expected to resolve this problem.

SUBJECT INDEX

FP = Full paper (review article) LA = Literature abstract
SC = Short communication
G.E. = Reference to Volume *90* (1978) of the German Edition of Angewandte Chemie.
References are given for Review Articles and Short Communications only.

ABSOLUTE configuration, Correlation of ~ of chiral epoxides by complexation chromatography; synthesis and enantiomeric purity of (+)- and (−)-1,2-epoxypropane (SC) 937 [G.E. 993]
Acetone, Thermal degradation of cellulose and chitin in supercritical ~ (SC) 754 [I.E. 802]
Acetylenes, Intramolecular cycloaddition of a "P O-activated" acetyleneallene derivative (SC) 196 [G.E. 208]
General and facile synthesis of aryl- and heteroaryl-~ (SC) 609 [G.E. 643]
Activation of carboxyl group, New method for selective activation of amino, hydroxy, and mercapto carboxylic acids at the carboxyl group: preparation of thiol and selenol esters (SC) 267 [G.E. 283]
Acylation, Cathodic ~ of aryl olefins (SC) 460 [G.E. 483]
Acylation catalysts, 4-Dialkylaminopyridines as highly active ~ (FP) 569 [G.E. 602]
Acyl chlorides, Mixed carboxylic-dichlorophosphoric anhydrides—reactive intermediates in synthesis of ~ with $POCl_3$ (SC) 695 [G.E. 740]
Acyl transfer, 4-Dimethylamino-3-butyn-2-one as activating agent for peptide synthesis (SC) 597 [G.E. 625]
1-(1-Adamantyl)-1-methylethoxycarbonyl: a new protecting group for peptide syntheses (SC) 944 [G.E. 998]
Addition of water to o-phenylethynyl-substituted triphenylphosphanes (SC) 947 [G.E. 1003]
Adrenergic receptors, Identification and regulation of α- and β-~ (LA) 540
Affinity chromatography on columns containing nucleic acids (LA) 618
Aldehydes, tert-Alkylierung of ketones and ~ (SC) 48 [G.E. 50]
$Co_2(CO)_x/Ph_3P$-catalyzed reaction of ~ with hydrosilane and carbon monoxide (SC) 119 [G.E. 139]
α-Amino acids as nucleophilic acyl equivalents: synthesis of ketones and ~ by means of oxazolin-5-ones (SC) 450 [G.E. 493]
Aldol reactions, Regiospecific and enantioselective ~ (SC) 206 [G.E. 219]
Alkali metal compounds, Skeletal rearrangements of organo-~ (FP) 313 [G.E. 317]
Alkaloids, General methods for synthesis (LA) 71
Alkanes, Superacid-catalyzed oxygenation of ~ [New synthetic methods (26)] (FP) 909 [G.E. 962]
Alkenes, Photochemical rearrangements and fragmentations of ~ and polyenes (FP) 150 [G.E. 161]
Reactivity in free-radical additions (SC) 66 [G.E. 62]
Alkene synthesis via β-functionalized organosilicon compounds (LA) 288
Alkyl groups, $\mathscr{S}_f$ Parameters—a measure of the front strain of ~ (SC) 593 [G.E. 633]
tert-Alkylation of ketones and aldehydes (SC) 48 [G.E. 50]
Alkynes, Cobalt-catalyzed pyridine syntheses from ~ and nitriles (FP) 505 [G.E. 517]
Synthesis of 1,2-diazepin-3-one derivatives by reaction of ~ with the N N group coordinated to $Fe_2(CO)_6$ (SC) 369 [G.E. 388]
Allene derivatives, Intramolecular cycloaddition of a "P O-activated" acetyleneallene derivative (SC) 196 [G.E. 208]
Allenyl cations, [4+3]-Cycloadditions (SC) 130 [G.E. 129]
Alloys, Structure and properties of amorphous ("glassy") metals and ~ (LA) 216
Allyl anions, Reduction of 1,3-diphenyl-~ via dianion radicals to trianions with lithium, sodium, potassium, and cesium as gegenions (SC) 284 [G.E. 291]
Allylation, Catalytic ~ of phenylhydrazones (SC) 353 [G.E. 399]
N-Allylcarboxamides, Facile synthesis of 2-aryl- and 2-heteroarylpyrroles from ~ (SC) 676 [G.E. 719]
Allyl cations, Acceptor-substituted ~ as ambifunctional electrophiles (SC) 760 [G.E. 808]
Allylnickel compounds, Reactions with carbon dioxide (SC) 124 [G.E. 144]
Alumina surfaces, Organic reactions at ~ (FP) 487 [G.E. 527]
Aluminum compounds, Selective reactions with organo-~ (FP) 169 [G.E. 180]
Aluminum tris(dihydrogen phosphate) (SC) 272 [G.E. 286]
Synthesis and properties of tris(trimethylgermyl)aluminum (SC) 604 [G.E. 631]
Dipotassium hexaisobutyldialuminate, a complex containing an Al—Al bond (SC) [G.E. 1013]
Ambifunctional electrophiles, Acceptor-substituted allyl cations as ~ (SC) 760 [G.E. 808]
Amides, Hydrosulfuration-thionation of unsaturated ~ (SC) 689 [G.E. 722]
Amination, Electrophilic ~ of "carbanions" with N,N-dialkyl-O-arylsulfonylhydroxylamines (SC) 687 [G.E. 733]
Amines, Anodic NN linkage by oxidation of anions of primary and secondary ~ (SC) 202 [G.E. 214]
Contamination with N-nitrosamines (SC) 367 [G.E. 379]
Amino acids, Production and utilization (FP) 176 [G.E. 187]
Protein biosynthesis: Codon-specific activation of ~ (FP) 648 [G.E. 682]
Asymmetric synthesis of α-alkyl-α-~ by alkylation of 1-chiral substituted 2-imidazolin-5-ones (SC) 117 [G.E. 136]
Chiral polysiloxanes for resolution of optical antipodes (SC) 363 [G.E. 396]
α-~ as nucleophilic acyl equivalents: synthesis of ketones and aldehydes by means of oxazolin-5-ones (SC) 450 [G.E. 493]
Amino acid sequence, Prediction of spatial structure of a protein from the ~ (LA) 289
Aminoiminophosphane, Structure of the 1:1 adduct of ~ and tert-butyl azide (SC) 136 [G.E. 135]
Aminopyridines, 4-Dialkyl-~ as highly active acylation catalysts (FP) 569 [G.E. 602]
Amino sugars, Effective synthetic principle for ~ of the daunosamine type (SC) 682 [G.E. 728]
(Amino)sulfonium salts, New synthetic entry to mono-, bis-, and tris-~ (SC) 64 [G.E. 61]
Ammonia, Phase equilibria and critical curves of binary ~-hydrocarbon mixtures (FP) 728 [G.E. 775]
Ammonium cyanate, Transformation into urea (LA) 470
Ammonium salts, Quaternary ~ as catalysts of nucleophilic substitution reactions in a solid-liquid two-phase system (SC) 62 [G.E. 58]
Analysis, Use of a photoelectron spectrometer in gas phase ~: cyanogen and hydrogen cyanide (SC) 932 [G.E. 985]
Analytical methods, Photoacoustic spectroscopy of condensed matter [New analytical methods (11)] (FP) 238 [G.E. 250]
A quick method for the microanalytical evaluation of the dissolving power of supercritical gases [New analytical methods (12)] (FP) 731 [G.E. 778]
Chromatography with supercritical fluids [New analytical methods (13)] (FP) 738 [G.E. 785]
High-resolution, higher-order UV/VIS derivative spectrophotometry [New analytical methods (14)] (FP) 785 [G.E. 840]
Anhydrides, Mixed carboxylic-dichlorophosphoric ~—reactive intermediates in acyl chloride synthesis with $POCl_3$ (SC) 695 [G.E. 740]
Annulenes, Alkali metal salts of RC(O)-substituted cyclononatetraenyl anions: aromatic [9]annulene anion of olefinic nonafulvene structure as function of gegenion and solvent (SC) 283 [G.E. 290]
Benzenoid versus annulenoid aromaticity: synthesis and properties of kekulene (SC) 372 [G.E. 383]
Synthesis and stereochemical consequences of protonation of a bishomodihydrotetraaza[14]annulene: a new macrocyclic complex ligand (SC) 765 [G.E. 812]
Direct synthesis of metal-free 1,8-dihydrotetraaza[14]-~ utilizing the metal-template effect (SC) 772 [G.E. 818]
Bridged aza[10]-~—10π-analogues of pyridine (SC) 853 [G.E. 894]
10-Ethoxy-3,8-methanoaza[10]annulene, a 10π-electron analogue of pyridine (SC) 855 [G.E. 896]
syn,syn-1,6:8,17:10,15-Trismethano[18]annulene (SC) 956 [G.E. 988]
syn,syn-1,6:8,17:10,15-Trismethano[18]annulene dication—dication of a [4n+2]annulene (SC) 957 [G.E. 990]
Cyclazines and related N-bridged ~ (LA) 870
Anodic oxidation, Azoalkanes by ~ of anions of N,N'-dialkylsulfamides (SC) 370 [G.E. 390]
Anthraquinone derivatives, Regioselective synthesis of the anthraquinones digitopurpone and islandicin (SC) 945 [G.E. 1000]
Antidiabetic agents, Blutzuckersenkende Sulfonamide - Standort der modernen Substanzen im Vergleich zu älteren Antidiabetika (Book Review) 291
Antimony compounds, Isomerization with methyl migration in trimethyl phosphite-arsenido and -antimonido complexes of transition metals (SC) 211 [G.E. 221]
$C_6H_5Sb[Mn(CO)_2C_5H_5]_2$—the first compound containing trigonal-planar coordinated antimony(I) (SC) 843 [G.E. 911]
Antimony(V) oxide, Crystal structure of Sb_2O_5 (SC) 137 [G.E. 141]
Aromaticity, The realities of extended homo-~ (FP) 106 [G.E. 114]
Benzenoid versus annulenoid ~: synthesis and properties of kekulene (SC) 372 [G.E. 383]
Arsanes, Difluoroarsoranes and homologous compounds $R'R_2EF_2$ (E = As, Sb, Bi) by oxidative direct fluorination of organo-~, organostibanes, and organobismuthanes (SC) 214 [G.E. 226]
Arsenic compounds, Molecular and crystal structure of an organocyclotriarsane (SC) 135 [G.E. 133]
Isomerization with methyl migration in trimethyl phosphite-arsenido and -antimonido complexes of transition metals (SC) 211 [G.E. 221]
cyclo-Triarsenic as μ,η-ligand in transition-metal complexes (SC) 676 [G.E. 720]

Trimethylphosphoranediyl- and arsoranediylmethyl(trimethylsiloxy)carbene complexes by 1,3-silyl shift (SC) 780 [G.E. 827]
Arsinidene, An ~ as a cubane-type structural unit: synthesis and structure of $[(CO)_3FeAsCH_3]_4$ (SC) 273 [G.E. 294]
Facile new synthesis of chloro-~ complexes (SC) 844 [G.E. 912]
Arsoranes, Difluoro-~ and homologous compounds $R'R_2EF_2$ (E = As, Sb, Bi) by oxidative direct fluorination of organoarsanes, organostibanes, and organobismuthanes (SC) 214 [G.E. 226]
L-(+)-Ascorbic acid radical anions, Stable ~ (SC) 365 [G.E. 392]
Asymmetric synthesis, ~ of α-alkyl-α-aminocarboxylic acids by alkylation of 1-chiral substituted 2-imidazolin-5-ones (SC) 117 [G.E. 136]
~ (LA) 697
Atropisomerism, 8,13-Dichloro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene: ~ about a C_{sp^3}–CH_2 bond (SC) 518 [G.E. 549]
Aza[10]annulenes, Bridged ~—10π-analogues of pyridine (SC) 853 [G.E. 894]
10-Ethoxy-3,8-methanoaza[10]annulene, a 10π-electron analogue of pyridine (SC) 855 [G.E. 896]
Azaphosphole, Various adducts of isothiocyanates to the λ^5-phosphazene group of an ~ (SC) 443 [G.E. 469]
Azides, Reactions of methanesulfonyl azide with ketenimines (a revision) (SC) 352 [G.E. 394]
Energetic materials (Book Review) 139
Aziridine, Enantioselective synthesis and thermal reorganization of an optically active methylene-~ (SC) 213 [G.E. 224]
Azoalkanes by anodic oxidation of anions of N,N'-dialkylsulfamides (SC) 370 [G.E. 390]
Azo compounds, Consecutive nucleophilic and electrophilic attack on N_2 ligands: synthesis of ~ from molecular nitrogen (SC) 269 [G.E. 295]
Azodicarboxylate, Reactions of nucleosides with the triphenylphosphane/diethyl ~ system (SC) 679 [G.E. 725]
Azomethines, γ-Sultenes and 1,3-oxazolidinethiones by 1,3-dipolar cycloaddition of thioketene S-oxides to ~ (SC) 455 [G.E. 480]

BARIUM disilicide, New high-pressure phase of ~ (SC) 538 [G.E. 562]
Barrelenone, Bicyclo[2.2.2]octa-5,7-dien-2-one ("~") (SC) 603 [G.E. 630]
Benzene, Unusual ~/~ through-space interaction (SC) 271 [G.E. 297]
Heterocyclohexaaromatic compound with face-to face arrangement of two ~ rings (SC) 755 [G.E. 804]
Pentacyclo[6.4.0.0^{2,5}.0^{3,10}.0^{4,9}]dodeca-6,11-diene, an o,o':o,p'-dimer of ~ (SC) 847 [G.E. 901]
Copper-catalyzed cyanation of ~ in the gas phase (SC) 989 [G.E. 986]
Benzocyclobutadiene, Molecular structure (SC) 127 [G.E. 142]
Benzonitrile, Copper-catalyzed cyanation of benzene in the gas phase (SC) 933 [G.E. 986]
Benzoxetes, Oxepinobenzofurans—the true nature of sterically hindered "~" (SC) 121 [G.E. 128]
Benzyne, Synthesis of polycyclic systems by intramolecular ring closure (LA) 783
Berson-Willcott rearrangement of 11,11-dimethyltricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene and its radical anion (SC) 208 [G.E. 216]
1,1'-Biazetidinyl, Synthesis and conformation (SC) 680 [G.E. 726]
Bicyclohexyls, Substituted ~—a new class of nematic liquid crystals (SC) 133 [G.E. 133]
Bicyclo[2.2.2]octa-5,7-dien-2-one ("barrelenone") (SC) 603 [G.E. 630]
Bicyclo[4.4.1]undeca-2,4,7,9-tetraene, 1,6-Dimethyl-~—a higher vinylog of norbornadiene (SC) 943 [G.E. 1002]
Bilatriene dimers, Enantiomerism and diastereoisomerism of bishelical ~ in the crystal lattice (SC) 948 [G.E. 1012]
Biochemical systems in organic chemistry, Applications (Book Review) 218
Biochemistry, Comprehensive ~ (Book Review) 699, 873
Grundlagen der Biochemie I and II (Book Review) 783
Biophysics, Biophysik – ein Lehrbuch (Book Review) 541
Bio-transformation, Biotransformation von Arzneimitteln (Book Review) 871
2,2'-Bipyridine(tetramethylcyclobutadiene)nickel(0) (SC) 950 [G.E. 1014]
Bismuthanes, Difluoroarsoranes and homologous compounds $R'R_2EF_2$(E = As, Sb, Bi) by oxidative direct fluorination of organoarsanes, organostibanes, and organo-~ (SC) 214 [G.E. 226]
Block copolymers—overview and critical survey (Book Review) 71
Blood-clotting disorders, Methodische Fortschritte im medizinischen Laboratorium. Band 4: Diagnostik hämorrhagischer Diathesen (Book Review) 376
Blood group substances, Synthesis of the tetrasaccharide chains of the determinants of ~ A and B (SC) 771 [G.E. 823]
Blood substitutes, Perfluoro compounds as ~ (FP) 621 [G.E. 654]
Bombykal, a second pheromone component of the silkworm moth Bombyx mori L. (SC) 60 [G.E. 74]
Bond, Electrostatics, the chemical ~ and molecular stability (FP) 812 [G.E. 868]
Bond length, An alkylsulfur imide amide (methanesulfinamidine)- relation between coordination number and ~ (SC) 58 [G.E. 73]
Borates, Tetraphenylphosphonium tetrakis(difluorooxosulfimidato)borate (SC) 212 [G.E. 226]
Boron compounds, The boratobis(dimethylphosphiniomethylide) anion, a novel ligand system for organometallic compounds (SC) 126 [G.E. 126]
Structural changes during the oxidation of B-, C-, Si-, and P-substituted hydrazines (SC) 286 [G.E. 308]
Synthesis and structure of the tetradecker complex bis(tricarbonylmanganese-μ,η-thiadiborolene)iron (SC) 527 [G.E. 558]
2,4-Bis(dimethylcarbamoyl)-1,1-dioxo-3-phenyl-1λ^6,2,4,3-thiadiazaboretidine: a BN_2S ring by "insertion" of sulfonyl diisocyanate (SC) 599 [G.E. 626]
Butadienes, Thiooxalates as dithia-~ (SC) 953 [G.E. 1016]
Polymerization (LA) 71
Butenolides, Facile synthesis of functionally substituted cyclopentenones and ~ from functional vinyl carbanions (SC) 204 [G.E. 220]
tert-Butyl azide, Structure of 1:1 adduct of aminoiminophosphane and ~ (SC) 136 [G.E. 135]
3-Butyn-2-one, 4-Dimethylamino-~ as activating agent for peptide synthesis (SC) 597 [G.E. 625]

"CAPTO-dative" substitution, Stabilization of radicals by ~: C C addition to radico philic olefins (SC) 691 [G.E. 741]
Carbanions, Electrophilic amination of "~" with N,N-dialkyl-O-arylsulfonylhydroxylamines (SC) 687 [G.E. 733]
Carbene addition, Influence of cyclopropyl substituents on the relative rate of dichloro-~ to olefins (SC) 674 [G.E. 716]
Carbene-carbene rearrangements in solution (LA) 216
Carbene complexes, Synthesis of carbocyclic ~ by metal-induced diazocyclopentadiene fragmentation (SC) 777 [G.E. 817]
Trimethylphosphoranediyl- and arsoranediylmethyl(trimethylsiloxy)-~ by 1,3-silyl shift (SC) 780 [G.E. 827]
Dichloro-~ of iron(II)-porphyrins—crystal and molecular structure of Fe(TPP)(CCl_2)(H_2O) (SC) 781 [G.E. 828]
Unusual selectivity in the thermal rearrangement-elimination reaction of a carbene complex in solution and in the solid state (SC) 842 [G.E. 914]
Carbenes, High-pressure carbonylation of metal-coordinated ~ and hydrogenolysis of the ketene complexes (SC) 525 [G.E. 555]
Temperature dependence of carbene selectivities: a new example of the isoselective relationship (SC) 595 [G.E. 636]
1,3-Bis(dimethylamino)vinylcarbene (SC) 762 [G.E. 810]
Catalytic carbon-carbon bond formation with carbene intermediates (SC) 862 [G.E. 918]
Carbenium ions, Mechanistic and preparative aspects of vinyl cation chemistry (FP) 333 [G.E. 346]
Carbohydrates, Effective synthetic principle for amino sugars of the daunosamine type (SC) 682 [G.E. 728]
Synthesis of the tetrasaccharide chains of the determinants of blood group substances A and B (SC) 771 [G.E. 823]
Short-term effects of hormones on carbohydrate and lipid metabolism (LA) 138
Developments in food carbohydrate (Book Review) 700
Carbon bond cleavage, Elimination of CH_3 from the radical cation of methyl isobutyrate: Fast C C cleavage after rate-determining H-migration (SC) 678 [G.E. 724]
Carbon-carbon bond formation, Catalytic ~ with carbene intermediates (SC) 862 [G.E. 918]
Carbon dioxide, Reactions with allylnickel compounds (SC) 124 [G.E. 144]
Carbon monoxide, $Co_2(CO)_8$/Ph_3P-catalyzed reaction of aldehydes with hydrosilane and ~ (SC) 119 [G.E. 139]
Carbon reduction, Connection between photosynthetic ~ and photorespiration (LA) 871
Carbonylation, High-pressure ~ of metal-coordinated carbenes and hydrogenolysis of the ketene complexes (SC) 525 [G.E. 555]
Regioselective hydrogenation and ~ of functionalized dienes on photocleavage from their tricarbonyliron complexes (SC) 690 [G.E. 736]
~ of transition-metal carbyne complexes, a new method for the synthesis of metal-substituted ketenes (SC) 859 [G.E. 908]
Carbonylcobalt clusters, Tetrahedral ~ (FP) 392 [G.E. 417]
Carbonyldiimidazole, N-Terminal cyclization of peptides with N,N-~ or N,N'-thio-~ (SC) 467 [G.E. 495]
Carbonyl-protecting group, 2,4,6-Tri-tert-butylphenoxyl (TBPO) as sterically active ~—a new nucleophilic dimethylaminomethylating reagent (SC) 274 [G.E. 296]
Carbonyl(pyridine)iron(II) tetrabenzoporphyrin π-radical cation (SC) 952 [G.E. 1011]
Carboxylic acids, New method for selective activation of amino, hydroxy, and mercapto carboxylic acids at the carboxyl group: preparation of thiol and selenol esters (SC) 267 [G.E. 283]
Simple method for esterification (SC) 522 [G.E. 556]
Carboxylic anhydrides, Mixed carboxylic-dichlorophosphoric anhydrides—reactive intermediates in acyl chloride synthesis with $POCl_3$ (SC) 695 [G.E. 740]
Carbyne complexes, Carbonylation of transition-metal ~, a new method for the synthesis of metal-substituted ketenes (SC) 859 [G.E. 908]
Carcinogenic hydrocarbons, 1,2,8,9-Tetrahydrodicyclobuta[b,g]phenanthrene and 1,2,7,8-tetrahydrodicyclobuta[b,h]phenanthrene, potentially carcinogenic activated hydrocarbons (SC) 615 [G.E. 648]
Catalysis (Book Review) 618
Catalysts, Polymeric ~ (FP) 657 [G.E. 691]
CC-linkage, Double deprotonation of 3-nitropropene and 4-nitro-1-butene: derivatives of their dianions as novel reagents for ~ (SC) 458 [G.E. 479]

Cellobiosides, Structural elucidation of diastereoisomeric 1,3,6-trioxacyclooctane systems by simultaneous relaxation and double resonance experiments (SC) 447 [G.E. 472]
Cellulose, Thermal degradation of ~ and chitin in supercritical acetone (SC) 754 [G.E. 802]
Cell walls, Linkage between teichoic acid and peptidglycan in bacterial ~ (LA) 698
Cerebroside, Role of ~ sulfate as opiate receptor (LA) 540
Cerium oxide sulfide, $Ce_4O_4S_3$: A mixed-valence cerium oxide sulfide (SC) 451 [G.E. 476]
Charge distribution in complex compounds (FP) 400 [G.E. 442]
Chemical bond, Electrostatics, the ~ and molecular stability (FP) 812 [G.E. 868]
Chemical oscillations (FP) 1 [G.E. 1]
Chiral clusters, An entry to ~ (SC) 864 [G.E. 916]
Chirality, Optically active polyvinyl compounds with ~ in the main chain (SC) 535 [G.E. 567]
Chitin, Thermal degradation of cellulose and ~ in supercritical acetone (SC) 754 [G.E. 802]
Chlorination, N,N-Dichlorourethane—a selective ~ reagent; synthesis of corticoids (SC) 281 [G.E. 289]
Chlorine compounds, Diorganodichlorophosphonium hydrogen dichlorides, a novel class of compounds containing $[ClHCl]^-$ ions (SC) 869 [G.E. 903]
Chlorofluorocarbons, Mineralization in the sunlight of the troposphere (SC) 366 [G.E. 398]
Cholesteric polymers, Production and characterization of liquid-crystalline polymers with cholesteric phase (SC) 935 [G.E. 992]
Chorionic gonadotropin, Human ~, its receptor and mechanism of action (LA) 137
Chromans, Selectivity in reactions between metal phenoxides and isoprene. Facile synthesis of 2,2-dimethyl-~ (SC) 684 [G.E. 731]
Chromatography, ~ with supercritical fluids [New analytical methods (13)] (FP) 738 [G.E. 785]
Complete enantiomer separation by ~ on potato stearch (SC) 612 [G.E. 645]
Affinity ~ on columns containing nucleic acids (LA) 618
Use of liquid crystals in ~ (LA) 871
Modern practice of ~ (Book Review) 291
Chromium compounds, $(CO)_5Cr \cdot SFeCo_2(CO)_9$: An organometallic donor-acceptor complex (SC) 444 [G.E. 474]
(η^{12}-[2.2]paracyclophane)chromium(0) (SC) 531 [G.E. 560]
Template reactions on chromium(0): synthesis of a functionalized indene from pentacarbonyl[methoxy(phenyl)carbene]chromium and bis(diethylamino)acetalene (SC) 851 [G.E. 898]
Chromium-chromium quadruple bond, New example of a dichromium compound with a supershort ~ (SC) 953 [G.E. 1015]
Clathrates, Crystalline ~ (LA) 470
Cyclophosphazene ~ (LA) 540
Cluster compounds, Tetrahedral carbonylcobalt clusters (FP) 392 [G.E. 417]
An entry to chiral clusters (SC) 864 [G.E. 916]
Cobalt catalysts, Cobalt-catalyzed pyridine syntheses from alkynes and nitriles (FP) 505 [G.E. 517]
Cobalt clusters, Tetrahedral carbonyl-~ (FP) 392 [G.E. 417]
Heteronuclear ~ by metal exchange (SC) 863 [G.E. 915]
Cobalt complexes, Reductive elimination reactions of cationic acylcobalt complexes; transformation of a Co^{III}–COR bond into a Co^{I}–CO bond (SC) 464 [G.E. 496]
$(CO)_5Cr \cdot SFeCo_2(CO)_9$: An organometallic donor-acceptor complex (SC) 444 [G.E. 474]
cyclo-Triarsenic as μ,η-ligand in transition-metal complexes (SC) 676 [G.E. 720]
Synthesis and structure of the ylide complex $[(Ph_3P{-}C_5H_4)Co(CO)_2]^+[Co(CO)_4]^-$. Its use in the cyclotrimerization of alkynes (SC) 686 [G.E. 732]
Cobalt compounds, Intramolecular electron transfer from iron(II) to cobalt(III) through 2,4,6-pyridinetricarboxylate as mediating bridging ligand (SC) 205 [G.E. 218]
Intramolecular electron transfer of coordinated pyrazinecarboxylato radicals to cobalt(III): a pulse radiolytic study (SC) 608 [G.E. 632]
Complexation chromatography, Quantitative resolution of enantiomers of trans-2,3-epoxybutane by ~ on an optically active nickel(II) complex (SC) 132 [G.E. 132]
Correlation of the absolute configuration of chiral epoxides by ~; synthesis and enantiomeric purity of (+)- and (−)-1,2-epoxypropane (SC 937 [G.E. 993]
Complexes, ~ of short-chain oligo(ethylene glycol ethers) bearing only one rigid donor end group (SC) 197 [G.E. 211]
Alkaline earth metal ~ of simple oligo(ethylene glycol ethers) (SC) 198 [G.E. 212]
Complexing agents, Wrapping of noncyclic molecules around the sodium cation (SC) 856 [G.E. 902]
Compressed gases, Separation of nonvolatile substances by means of ~ in countercurrent processes (FP) 746 [G.E. 749]
Conductors, Solid ionic ~: principles and applications (FP) 37 [G.E. 38]
Conjugated hydrocarbons, Synthesis of penta- and hexacyclic ~ by cycloaddition reactions (SC) 763 [G.E. 812]
Cooperativity, Directed ~ and site separation of mercapto groups in synthetic polymers (SC) 537 [G.E. 568]
Coordination compounds, Versatility of tertiary phosphane ligands in coordination and organometallic chemistry (FP) 183 [G.E. 195]
Distribution of charge in complex compounds (FP) 400 [G.E. 442]
Hemoglobin—an inspiration for research in coordination chemistry (FP) 407 [G.E. 425]
Coordination number, An alkylsulfur imide amide (methanesulfinamidine)—relation between ~ and bond length (SC) 58 [G.E. 73]
Corticoids, N,N-Dichlorourethane—a selective chlorination reagent; synthesis of ~ (SC) 281 [G.E. 289]
Coumarins in the Rutaceae (LA) 871
Countercurrent processes, Separation of nonvolatile substances by means of compressed gases in ~ (FP) 746 [G.E. 749]
Coupling constants, Effect of shift reagents on NMR ~ (SC) 49 [G.E. 51]
Critical curves, Phase equilibria and ~ of binary ammonia-hydrocarbon mixtures (FP) 728 [G.E. 775]
Crown ether dyes, Ion-selective ~ (SC) 857 [G.E. 893]
Crown ethers, Complexes of short-chain oligo(ethylene glycol ethers) bearing only one rigid donor end group (SC) 197 [G.E. 211]
Alkaline earth metal complexes of simple oligo(ethylene glycol ethers) (SC) 198 [G.E. 212]
Cryptates, Chemistry of macrolytic inclusion complexes (LA) 376
Cubane structure, An arsinidene as a cubane-type structural unit: synthesis and structure of $[(CO)_3Fe\ AsCH_3]_4$ (SC) 273 [G.E. 294]
Cyanogen, Use of a photoelectron spectrometer in gas phase analysis: ~ and hydrogen cyanide (SC) 932 [G.E. 985]
Copper-catalyzed cyanation of benzene in the gas phase (SC) 933 [G.E. 986]
Cyclazines and related N-bridged annulenes (LA) 870
Cyclizations, Intramolecular ene reactions in organic synthesis (FP) 476 [G.E. 506]
Methylene chloride as a reagent for ~ with SO_3 as HCl trapping agent (SC) 367 [G.E. 382]
Cycloadditions, ~ with [n]cyclophanes (SC) 602 [G.E. 629]
Synthesis of penta- and hexacyclic conjugated hydrocarbons by ~ (SC) 763 [G.E. 812]
Cyclobutadiene, Bis(tetraphenyl-~)nickel (SC) 123 [G.E. 138]
Molecular structure of a benzo-~ (SC) 127 [G.E. 142]
Valence isomeric η^2- and η^4-~-Rh^I complexes (SC) 128 [G.E. 142]
2,2'-Bipyridine(tetramethyl-~)nickel(0) (SC) 950 [G.E. 1014]
Cyclobuta[b,g]phenanthrene, 1,2,8,9-Tetrahydrodi-~ and 1,2,7,8-tetrahydrodicyclobuta[b,h]phenanthrene, potentially carcinogenic activated hydrocarbons (SC) 615 [G.E. 648]
β-Cyclodextrin dodecahydrate: crowding of water molecules within a hydrophobic cavity (SC) 694 [G.E. 738]
Cycloheptatriene, Norcaradiene and ~ endoperoxides (SC) 954 [G.E. 1014]
Cyclohexaaromatic compound, Hetero-~ with face-to-face arrangement of two benzene rings (SC) 755 [G.E. 804]
Cyclohexadienimines, Dienylketenimines—an entry to linearly conjugated ~ (SC) 465 [G.E. 497]
Cyclononatetraenyl anions, Alkali metal salts of RC(O)-substituted ~: aromatic [9]annulene anion or olefinic nonafulvene structure as function of gegenion and solvent (SC) 283 [G.E. 290]
1,4,7-Cyclononatrienes, Rearrangement of tris-σ-homobenzenes to ~ (SC) 441 [G.E. 471]
1,5-Cyclooctadiene, Facile preparation of cyclooctatetraene from ~ by metalation and oxidation (SC) 371 [G.E. 380]
Novel mode of formation of *cis, trans*-~ (SC) 696 [G.E. 735]
1,5-Cyclooctadien-3-yne—A novel, highly reactive C_8H_8 hydrocarbon (SC) 942 [G.E. 997]
Cyclooctatetraene, Facile preparation from 1,5-cyclooctadiene by metalation and oxidation (SC) 371 [G.E. 380]
Cyclooctenynes (SC) 461 [G.E. 483]
Cyclopentadienone, Tetra-tert-butyl-~ (SC) 519 [G.E. 551]
Cyclopentenones, Facile synthesis of functionally substituted ~ and butenolides from functional vinyl carbanions (SC) 204 [G.E. 220]
Cyclophanes, ~ having orthogonal benzene rings (SC) 46 [G.E. 49]
Attempts to synthesize zwitterionic donor-acceptor ~: The diastereomeric 12,15-bis(dimethylamino)-[2](2,5)-p-benzoquinono[2]-para-~ (SC) 374 [G.E. 385]
(η^{12}-[2.2]paracyclophane)chromium(0) (SC) 531 [G.E. 560]
Cycloaddition with [n]-~ (SC) 602 [G.E. 629]
[2.2.2.2](1,2,4,5)cyclophane quinhydrone—a donor-acceptor cyclophane with an extremely short transannular distance (SC) 756 [G.E. 805]
Indirect donor-acceptor interactions in quinhydrones of quadruple-layered [2.2]para-~ (SC) 757 [G.E. 807]
Cyclophosphazene clathrates (LA) 540
Cyclopropabenzenes, Synthesis and chemistry (LA) 782
Cyclopropane, Substitution with retention at the ~ ring (SC) 845 [G.E. 906]
Cyclopropenylium ion, S_E reactions on the C_3^+-ring: π-attack (SC) 445 [G.E. 484]
S_E reactions on the C_3^+-ring: σ-attack (SC) 446 [G.E. 486]
Cyclopropenylium salts, σ-Dicarbonylcyclopentadienyliron derivatives of cyclopropenes and ~ (SC) 456 [G.E. 490]
Coordinatively unsaturated transition metal-substituted cyclopropenylium systems (SC) 457 [G.E. 491]
Cyclopropyl substituents, Influence on the relative rate of chlorocarbene addition to olefins (DC) 674 [G.E. 716]

Cyclotetra(azadithiane), A ~ - the first twelve-membered sulfur-nitrogen ring (SC) 778 [G.E. 825]
Cyclotriarsane, Molecular and crystal structure of an organo-~ (SC) 135 [G.E. 133]
Cyclotrimerization, Synthesis and structure of the ylide complex $[(Ph_3P\ C_5H_4)Co(CO)_2]^+[Co(CO)_4]^-$. Its use in the ~ of alkynes (SC) 686 [G.E. 732]
Cytidine, Simple synthesis of 2'-deoxy-2'-fluoro-~ by nucleophilic substitution of 2,2'-anhydro-~ with potassium fluoride/crown ether (SC) 525 [G.E. 557]

DAUNOSAMINE, Effective synthetic principle for amino sugars of the ~ type (SC) 682 [G.E. 728]
cyclo-Decasulfur, X-Ray structure analysis of ~, S_{10} (SC) 57 [G.E. 55]
(Z)-5-Decenyl acetate, a sex attractant for the male turnip moth Agrotis segetum (Lepidoptera) (SC) 768 [G.E. 815]
Dediazoniations, Nitrogen as leaving group: ~ of aromatic diazonium ions (FP) 141 [G.E. 151]
Defense substances, Phytoalexins, chemical ~ of higher plants? (FP) 635 [G.E. 668]
Dehydrogenation, Deprotonation-hydride elimination as a method of ~ (SC) 278 [G.E. 285]
Deoxygenation—a novel reaction path of transition metal-substituted ketenes (SC) 860 [G.E. 908]
Deprotonation, ~-hydride elimination as a method of dehydrogenation (SC) 278 [G.E. 285]
Double ~ of 3-nitropropene and 4-nitro-1-butene: derivatives of their dianions as novel reagents for CC-linkage (SC) 458 [G.E. 479]
Derivative spectrophotometry, High-resolution, higher-order UV/VIS ~ [New analytical methods (14)] (FP) 785 [G.E. 840]
Dialkoxyalkene radical cation, Evidence for a ~ in aqueous solution (SC) 604 [G.E. 639]
Dianion radicals, Reduction of 1,3-diphenylallyl anions via ~ to trianions with lithium, sodium, potassium, and cesium as gegenions (SC) 284 [G.E. 291]
Diastereoisomerism and enantiomerism of bishelical bilatriene dimers in the crystal lattice (SC) 948 [G.E. 1012]
Diastereoselectivity, Diastereoselective radical recombination and variation in thermal stability of diastereomeric hydrocarbons (SC) 934 [G.E. 987]
1,4-Diaza-1,3-dienes, New compounds from ~ and iron carbonyls: hexacarbonyl(1,4-diazadiene)diiron and substituted 2(3H)-imidazolones (SC) 64 [G.E. 56]
Diazene, Trapping of unstable fulvene/singlet oxygen adducts by reduction with ~ (SC) 210 [G.E. 223]
Trapping of unstable α-pyrone/singlet oxygen adducts by reduction with ~ (SC) 211 [G.E. 223]
1,2-Diazepin-3-one, Synthesis of ~ derivatives by reaction of alkynes with the N N group coordinated to $Fe_2(CO)_6$ (SC) 369 [G.E. 388]
Diazidotetracyanoplatinate(IV), Photochemical reductive trans-elimination from trans-~ (SC) 524 [G.E. 554]
Diazoalkanes, Organometallic syntheses with ~ (FP) 800 [G.E. 855]
Diazocyclopentadiene, Synthesis of carbocyclic carbene complexes by metal-induced ~ fragmentation (SC) 777 [G.E. 817]
Diazonium ions, Nitrogen as leaving group: dediazoniations of aromatic ~ (FP) 141 [G.E. 151]
N,N-Dichlorourethane—a selective chlorination reagent: synthesis of corticoids (SC) 281 [G.E. 289]
Dictionary, Basis-Römpp (Book Review) 699
Dienes, Regioselective hydrogenation and carbonylation of functionalized ~ on photocleavage from their tricarbonyliron complexes (SC) 690 [G.E. 736]
Digitopurpone, Regioselective synthesis of the anthraquinones ~ and islandicin (SC) 945 [G.E. 1000]
Diisopropyltin sulfide, Structure of the first open-chain diorganotin chalcogenide (SC) 939 [G.E. 995]
γ-Diketones, New preparation of symmetrical ~ (SC) 131 [G.E. 130]
4-Dimethylamino-3-butyn-2-one as activating agent for peptide synthesis (SC) 597 [G.E. 625]
Dimethylaminomethylating reagent, 2,4,6-Tri-tert-butylphenoxyl (TBPO) as sterically active carbonyl-protecting group—a new nucleophilic ~ (SC) 274 [G.E. 296]
1,6-Dimethylbicyclo[4.4.1]undeca-2,4,7,9-tetraene a higher vinylog of norbornadiene (SC) 943 [G.E. 1002]
trans-3,6-Dioxa-9-azatris-σ-homobenzene and cis-epoxyepimino-1,3-cyclohexadiene (SC) 936 [G.E. 991]
1,6-Dioxaspiro[4.5]decanes, Methyl-~ as odors of Paravespula vulgaris (L.) (SC) 862 [G.E. 915]
2,3-Dioxa-7-thiabicyclo[2.2.1]heptane: a new heterobicyclic system possessing the thiaozonide structure (SC) 765 [G.E. 811]
1,3-Diphenylallyl anions, Reduction via dianion radicals to trianions with lithium, sodium, potassium, and cesium as gegenions (SC) 284 [G.E. 291]
Disparlure, Synthesis by Kolbe electrolysis (SC) 47 [G.E. 48]
Dissolving power, A quick method for the microanalytical evaluation of the ~ of supercritical gases [New analytical methods (12)] (FP) 731 [G.E. 778]
Distannanes, The first reversible thermal dissociation of ~ $R_3Sn\ SnR_3$ (SC) 59 [G.E. 74]
Dithiabutadienes, Thiooxalates as ~ (SC) 953 [G.E. 1016]
Dyestuff analysis, The analytical chemistry of synthetic dyes (Book Review) 139
Diylides, Novel ~ containing tricoordinate phosphorus (SC) 199 [G.E. 209]
Donor-acceptor complexes, Demonstration of diastereomeric electron-~ by ^{1}H-NMR spectroscopy (SC) 940 [G.E. 995]
Donor-acceptor cyclophane, Attempts to synthesize zwitterionic ~-s: the diastereomeric 12,15-bis(dimethylamino)-[2](2,5)-p-benzoquinono[2]paracyclophanes (SC) 374 [G.E. 385]
[2.2.2.2](1,2,4,5)cyclophane quinhydrone—a ~ with an extremely short transannular distance (SC) 756 [G.E. 805]
Donor-acceptor interactions, Indirect ~ in quinhydrones of quadruple-layered [2.2]paracyclophanes (SC) 757 [G.E. 807]
Dopaminergic drugs, Steric aspects (LA) 871
Doping, Ion implantation into semiconductors (FP) 496 [G.E. 537]
Drugs, Biotransformation von Arzneimitteln (Book Review) 871
Drug synthesis, Organic chemistry of ~ (Book Review) 218
Dyes, Ion-selective crown ether ~ (SC) 857 [G.E. 893]

ELECTROCHEMISTRY, Anodic NN linkage by oxidation of anions of primary and secondary amines (SC) 202 [G.E. 214]
Azoalkanes by anodic oxidation of anions of N,N'-dialkylsulfamides (SC) 370 [G.E. 390]
Cathodic acylation of aryl olefins (SC) 460 [G.E. 483]
Elektrolytgleichgewichte und Elektrochemie (Book Review) 540
Elektrokinetische Grenzflächenvorgänge (Book Review) 542
Grundlagen der Technischen Elektrochemie (Book Review) 783
Electrolyte equilibria, Elektrolytgleichgewichte und Elektrochemie (Book Review) 540
Electrolytes, Solid ionic conductors: principles and applications (FP) 37 [G.E. 38]
Solid ~ based on silver iodide (LA) 618
Electron-density plots, Use in applied quantum chemistry (FP) 80 [G.E. 86]
Electron-donor-acceptor complexes, Demonstration of diastereomeric ~ by ^{1}H-NMR spectroscopy (SC) 940 [G.E. 995]
Electronegativities, Extremely high ~ (SC) 355 [G.E. 390]
Electrons, Physical and chemical properties of dissolved ~ (excess ~) (FP) 887 [G.E. 939]
Electron spectroscopy: theory, techniques, and applications (Book Review) 289
Electron transfer, Intramolecular ~ from iron(II) to cobalt(III) through 2,4,6-pyridinetricarboxylate as mediating bridging ligand (SC) 205 [G.E. 218]
Intramolecular ~ of coordinated pyrazinecarboxylato radicals to cobalt(III): a pulse radiolytic study (SC) 608 [G.E. 632]
Mild oxidative removal of the p-methoxybenzyl ether protecting group by homogeneous ~ (SC) 673 [G.E. 717]
Electrophiles, Reactions between ~ and σ-bonded organotransition metal complexes (LA) 470
Electrostatics, the chemical bond and molecular stability (FP) 812 [G.E. 868]
Elimination, Reductive ~ reactions of cationic acylcobalt complexes: transformation of a Co^{III} COR bond into a Co^{I} CO bond (SC) 464 [G.E. 496]
Photochemical reductive trans-~ from trans-diazidotetracyanoplatinate(IV) (SC) 524 [G.E. 554]
Enamides, Photochemistry (LA) 698
Enaminones, N C C C O compounds (LA) 138
Enantiomerism and diastereoisomerism of bishelical bilatriene dimers in the crystal lattice (SC) 948 [G.E. 1012]
Enantiomer resolution, Chiral polysiloxanes for resolution of optical antipodes (SC) 363 [G.E. 396]
Complete enantiomer separation by chromatography on potato starch (SC) 612 [G.E. 645]
Correlation of the absolute configuration of chiral epoxides by complexation chromatography: synthesis and enantiomeric purity of (+)- and (−)-1,2-epoxypropane (SC) 937 [G.E. 993]
Endonucleases, Restriction ~ (FP) 73 [G.E. 79]
Endoperoxides, Norcaradiene and cycloheptatriene ~ (SC) 954 [G.E. 1014]
Enediol phosphates, Phosphorylation by means of cyclic ~ (LA) 698
Ene reactions, Intramolecular ene reactions in organic synthesis (FP) 476 [G.E. 506]
Energetic materials (Book Review) 139
Enzymatic analysis, Grundlagen der enzymatischen Analyse (Book Review) 139
Enzymes, Histidine in enzyme active centers (FP) 583 [G.E. 616]
Epoxidation, Conformationally induced stereospecificity in the multiple ~ of syn-9-chloro-cis-bicyclo[6.1.0]nona-2,4,6-triene (SC) 614 [G.E. 646]
trans-2,3-Epoxybutane, Quantitative resolution of enantiomers of ~ by complexation chromatography on an optically active nickel(II) complex (SC) 132 [G.E. 132]
Epoxypropane, Correlation of the absolute configuration of chiral epoxides by complexation chromatography; synthesis and enantiomeric purity of (+)- and (−)-1,2-~ (SC) 937 [G.E. 993]
Erbium compounds, Tris[(N,N,N',N'-tetramethylethylenediamine)lithium]hexamethylerbate(III) and -lutetate(III) (SC) 276 [G.E. 307]
Esterification, Simple method for ~ of carboxylic acids (SC) 522 [G.E. 556]
Esters, Ozone cleavage of olefins with formation of ester fragments (SC) 939 [G.E. 999]
Estrogen receptors, Affinity-labeling (LA) 540
Ethers, Organic syntheses using sheet silicate intercalates: low-temperature conversion of olefins into secondary ~ (SC) 282 [G.E. 290]

Excess electrons, Physical and chemical properties of dissolved electrons (~) (FP) 887 [G.E. 939]
Extraction, Extraction with supercritical gases—a foreword (FP) 701 [G.E. 747]
Separation with supercritical gases: practical applications (FP) 702 [G.E. 748]
Fluid ~ of hops, spices, and tobacco with supercritical gases (FP) 710 [G.E. 756]
Physicochemical principles of ~ with supercritical gases (FP) 716 [G.E. 763]
Phase equilibria and critical curves of binary ammonia-hydrocarbon (FP) 728 [G.E. 775]
Quick method for the microanalytical evaluation of the dissolving power of supercritical gases (FP) 731 [G.E. 778]
Large-scale industrial plant for ~ with supercritical gases (FP) 751 [G.E. 799]

α-FERROCENYLISOBUTYL cation, Direct formation from ferrocene and isobutyraldehyde (SC) 689 [G.E. 734]
Fibrids, Polyethylene ~: preparation and properties (FP) 820 [G.E. 833]
Flavor, Papers presented at the symposium "Chemistry and ~" (LA) 782
Fluorination, Difluoroarsoranes and homologous compounds $R'R_2EF_2$(E = As, Sb, Bi) by oxidative direct ~ of organoarsanes, organostibanes, and organobismuthanes (SC) 214 [G.E. 226]
Fluorine compounds, Perfluoro compounds as blood substitutes (FP) 621 [G.E. 654]
Extremely high electronegativities (SC) 355 [G.E. 390]
Xenon tetrakis(pentafluoroorthotellurate), $Xe(OTeF_5)_4$ (SC) 356 [G.E. 391]
Methylenesulfur tetrafluoride, $H_2C{=}SF_4$ (SC) 516 [G.E. 547]
Simple synthesis of 2'-deoxy-2'-fluorocytidine by nucleophilic substitution of 2,2'-anhydrocytidine with potassium fluoride/crown ether (SC) 525 [G.E. 557]
Synthesis of N-methyliminosulfur tetrafluoride, $CH_3N{=}SF_4$, from the cation $CH_3NSF_3^+$ (SC) 530 [G.E. 561]
Reactions of CF_3-substituted arenes with nucleophilic reagents (LA) 697
Fluorocarbons, Mineralization of chloro-~ in the sunlight of the troposphere (SC) 366 [G.E. 398]
N-Fluorosulfonylsulfimide, (N-(Fluorosulfonyl)sulfur imide dioxide) (SC) 129 [G.E. 127]
Food carbohydrate, Developments (Book Review) 700
Force constant, Stretching frequency and ~ of the tungsten-carbon triple bond (SC) 50 [G.E. 51]
Fragmentations, Photochemical rearrangements and ~ of alkenes and polyenes (FP) 150 [G.E. 161]
Freezing temperature, Possibilities of reducing the ~ in biological systems (LA) 618
Front strain, S_f^i Parameters—a measure of ~ of alkyl groups (SC) 593 [G.E. 633]
~ of π and σ radicals (SC) 594 [G.E. 635]
Fulvene, Trapping of unstable ~/singlet oxygen adducts by reduction with diazene (SC) 210 [G.E. 223]

GAS chromatography, Chiral polysiloxanes for resolution of optical antipodes (SC) 363 [G.E. 396]
Gaschromatographie (Book Review) 140
Fundamentals of Integrated GC-MS (Book Review) 290
Gas-Solid Reactions (Book Review) 290
Germanium compounds, Synthesis and properties of tris(trimethylgermyl)aluminum (SC) 604 [G.E. 631]
5'-O-Glycosyl-ribo-nucleosides, Synthesis (SC) 772 [G.E. 819]
Gold(I) compounds, $[Au_3(WS_4)_2]^{2-}$, a novel inorganic ring system (SC) 52 [G.E. 57]
Stabilization of a phosphinic anhydride R_2POPR_2 on gold(I) and formation of the trinuclear complex $(R_2POAu)_3^+$ - production of an octahedral structural unit $Ag_4Br_2^{2+}$ by clamping with $R_2PN(R')PR_2$ (SC) 846 [G.E. 905]
Gonadotropin, Human chorionic ~, its receptor and mechanism of action (LA) 137
Glycoproteins, Mouse histocompatibility antigens (FP) 342 [G.E. 337]
Group theory, Molecular symmetry and ~ (Book Review) 218

HELICAL molecules, New helical molecular skeleton (SC) 268 [G.E. 293]
Heme biosynthesis, Influence of metals on ~ and heme metabolism (LA) 376
Hemoglobin—an inspiration for research in coordination chemistry (FP) 407 [G.E. 425]
Hemorrhagic diatheses, Methodische Fortschritte im medizinischen Laboratorium. Band 4: Diagnostik hämorrhagischer Diathesen (Book Review) 376
cyclo-Heptasulfur, Synthesis of ~, S_7, from S_8 (SC) 56 [G.E. 54]
λ^3-Heterobenzenes containing group V elements (LA) 618
Heterocyclohexaaromatic compound with face-to-face arrangement of two benzene rings (SC) 755 [G.E. 804]
Hexaarylethane, Hexakis(2,6-di-tert-butyl-4-biphenylyl)ethane—the first unbridged ~ (SC) 692 [G.E. 737]
Hexafluorophosphate of the bis(naphthalene) radical cation (SC) 275 [G.E. 305]
Hexahydropyridazines, Conformational studies (LA) 289
Hexaisobutyldialuminate, Dipotassium ~, a complex containing an Al—Al bond (SC) 949 [G.E. 1013]
cyclo-Hexasulfur oxide, Preparation of ~ S_6O (SC) 134 [G.E. 134]
Histidine in enzyme active centers (FP) 583 [G.E. 616]
Histocompatibility antigens, Mouse ~ (FP) 342 [G.E. 337]
Homoaromaticity, The realities of extended ~ (FP) 106 [G.E. 114]
Homobenzene, Thermolysis of endo,exo-tetracyclo[6.1.0.0^{2,4}.0^{5,7}]-nonane (trans-tris-σ-~) (SC) 440 [G.E. 470]
Rearrangement of tris-σ-~-s to 1,4,7-cyclononatrienes (SC) 441 [G.E. 471]
trans-3,6-Dioxa-9-azatris-σ-~ and cis-epoxyepimino-1,3-cyclohexadiene (SC) 936 [G.E. 991]
Homoconjugation, Spiroconjugation (FP) 559 [G.E. 591]
Hops, Fluid extraction of ~, spices, and tobacco with supercritical gases (FP) 710 [G.E. 756]
Hormone action, Comprehensive biochemistry (Book Review) 699
Hormones, Short-term effects on the carbohydrate and lipid metabolism (LA) 138
Host-guest complexes, Design (LA) 289
Hydantoin peptides, N-Terminal cyclization of peptides with N,N-carbonyldiimidazole or N,N'-thiocarbonyldiimidazole (SC) 467 [G.E. 495]
Hydrazines, Anodic NN linkage by oxidation of anions of primary and secondary amines (SC) 202 [G.E. 214]
Structural changes during the oxidation of B-, C-, Si-, and P-substituted ~ (SC) 286 [G.E. 308]
Synthesis and conformation of 1,1'-biazetidinyl (SC) 680 [G.E. 726]
Hydrazones, Catalytic allylation of phenyl-~ (SC) 353 [G.E. 399]
Hydride elimination, Deprotonation-~ as a method of dehydrogenation (SC) 278 [G.E. 285]
Hydrocarbon, Phase equilibria and critical curves of binary ammonia-~ mixtures (FP) 728 [G.E. 775]
Synthesis of penta- and hexacyclic conjugated ~-s by cycloaddition reactions (SC) 763 [G.E. 812]
Hydrogenation, Regioselective ~ and carbonylation of functionalized dienes on photocleavage from their tricarbonyliron complexes (SC) 690 [G.E. 736]
Hydrogen bonds, Complex stabilization by bifurcated ~: bis[2-(o-methoxyphenoxy)ethoxyethyl] ether-thiourea (SC) 534 [G.E. 565]
Hydrogen cyanide, Use of a photoelectron spectrometer in gas phase analysis: cyanogen and ~ (SC) 932 [G.E. 985]
Hydrogen-metal bond, Demonstration of "sulfene" insertion into the ~ (SC) 285 [G.E. 292]
Hydrogen migration, Elimination of CH_3 from the radical cation of methyl isobutyrate: Fast C C cleavage after rate-determining ~ (SC) 678 [G.E. 724]
Hydrosilane, The $Co_2(CO)_8/Ph_3P$-catalyzed reaction of aldehydes with ~ and carbon monoxide (SC) 119 [G.E. 139]
Hydrosulfuration-thionation of unsaturated amides (SC) 689 [G.E. 722]
Hydroxylamine, Dipicolinato(hydroxylamido-O,N)(nitrosyl)aqua-vanadate—a nitrosyl complex of vanadium with "side on" coordinated ~ (SC) 351 [G.E. 381]
Electrophilic amination of "carbanions" with N,N-dialkyl-O-arylsulfonyl-~-s (SC) 687 [G.E. 733]
Hyperoxide ion, Organic chemistry (LA) 71

IMIDAZOLE, Histidine in enzyme active centers (FP) 583 [G.E. 616]
2-Imidazolin-5-ones, Asymmetric synthesis of α-alkyl-α-aminocarboxylic acids by alkylation of 1-chiral-substituted ~ (SC) 117 [G.E. 136]
2(3H)-Imidazolones, New compounds from 1,4-diaza-1,3-dienes and iron carbonyls: hexacarbonyl(1,4-diazadiene)diiron and substituted ~ (SC) 64 [G.E. 56]
Imines, Dienylketenimines—an entry to linearly conjugated cyclohexadien-~ (SC) 465 [G.E. 497]
Iminium salts in organic chemistry (Book Review) 219
Immune surveillance, Mouse histocompatibility antigens (FP) 342 [G.E. 337]
Immunology, Immunologie (Book Review) 873
Inclusion complexes, Chemistry of macrolytic ~ (LA) 376
Inclusion compounds, β-Cyclodextrin dodecahydrate: crowding of water molecules within a hydrophobic cavity (SC) 694 [G.E. 738]
Indene, Template reactions on chromium(0): synthesis of a functionalized ~ from pentacarbonyl[methoxy(phenyl)carbene]chromium and bis (diethylamino)acetylene (SC) 851 [G.E. 898]
Industrial photochemistry, Industrial applications of photochemical syntheses (FP) 16 [G.E. 17]
Insertions, Metal-induced rearrangements and ~ into vinylcyclopropanes (LA) 698
Interfacial processes, Elektrokinetische Grenzflächenvorgänge (Book Review) 542
Intermediates, Novel method for the detection of indirectly identifiable photochemical ~ (SC) 52 [G.E. 53]
Iodides, Unusually versatile solid-state structure: poly-~ of type $Tl_6I_6M^{n+}_{2/n}(I_4)^{2-}$(M = Ag, Au, Tl, Pb, Bi, Ln, Zr, Hf, Th) (SC) 599 [G.E. 627]
Ion exchangers, Insoluble acid salts of tetravalent metals (LA) 698
Ionic conductors, Solid ~: principles and applications (FP) 37 [G.E. 38]
Ion implantation into semiconductors (FP) 496 [G.E. 537]
Ionization, Chemical ~—a mass-spectrometric analytical procedure of rapidly increasing importance (FP) 424 [G.E. 449]
Ion-selective crown ether dyes (SC) 857 [G.E. 893]
Iron complexes, New compounds from 1,4-diaza-1,3-dienes and iron carbonyls: hexacarbonyl(1,4-diazadiene)diiron and substituted 2(3H)-imidazolones (SC) 64 [G.E. 56]
Binuclear ~ containing unsymmetrically substituted silanediyl bridges (SC) 120 [G.E. 140]

An arsinidene as a cubane-type structural unit: synthesis and structure of $[(CO)_3Fe AsCH_3]_4$ (SC) 273 [G.E. 294]
Synthesis of 1,2-diazepin-3-one derivatives by reaction of alkynes with the N N group coordinated to $Fe_2(CO)_6$ (SC) 369 [G.E. 388]
$[Fe_2(NO)_6]^{2+}$, a binary nitrosyliron cation (SC) 545 [G.E. 477]
$(CO)_5Cr \cdot SFeCo_2(CO)_9$: An organometallic donor-acceptor complex (SC) 444 [G.E. 474]
σ-Dicarbonylcyclopentadienyliron derivatives of cyclopropenes and cyclopropenylium salts (SC) 456 [G.E. 490]
Synthesis and structure of the tetradecker complex bis(tricarbonylmanganese-μ,η-thiadiborolene)iron (SC) 527 [G.E. 558]
Dimethylsilanediyl-~ (SC) 674 [G.E. 718]
Regioselective hydrogenation and carbonylation of functionalized dienes on photocleavage from their tricarbonyl-~ (SC) 690 [G.E. 736]
Systematic formation of metal containing isocyanide bridging ligands: $[\eta^5$-$C_5H_5Fe(CNC_6H_5)$ $(\mu$-$CNC_6H_5)]_2$ (SC) 866 [G.E. 920]
Iron(II) compounds, Intramolecular electron transfer from iron(II) to cobalt(III) through 2,4,6-pyridinetricarboxylate as mediating bridging ligand (SC) 205 [G.E. 218]
Iron-methyl bond, Selenium dioxide insertion into the iron-methyl bond of η^5-$C_5H_5Fe(CO)_2CH_3$ (SC) 53 [G.E. 60]
Iron(II)-porphyrins, Dichlorocarbene complexes of ~ — crystal and molecular structure of $Fe(TPP)(CCl_2)(H_2O)$ (SC) 781 [G.E. 828]
Islandicin, Regioselective synthesis of the anthraquinones digitopurpone and ~ (SC) 945 [G.E. 1000]
Isobutyraldehyde, Direct formation of the α-ferrocenylisobutyl cation from ferrocene and ~ (SC) 689 [G.E. 734]
Isobutyrate, Elimination of CH_3 from the radical cation of methyl ~: Fast C C cleavage after rate-determing H-migration (SC) 678 [G.E. 724]
Isocyanide bridging ligands, Systematic formation of metal complexes containing: $[\eta^5$-$C_5H_5Fe(CNC_6H_5)$ $(\mu$-$CNC_6H_5)]_2$ (SC) 866 [G.E. 920]
Isocyanides, Synthesis of aryl and heteroaryl ~ from nitroso compounds (SC) 688 [G.E. 731]
Isoindoles, Tricyclic ~ (SC) 68 [G.E. 65]
Isoprene, Selectivity in reactions between metal phenoxides and ~. Facile synthesis of 2,2-dimethylchromans (SC) 684 [G.E. 731]
Isoselective relationship, Temperature dependence of carbene selectivities: a new example of the ~ (SC) 595 [G.E. 636]
Scope of application (SC) 775 [G.E. 816]
Isothiocyanates, Various adducts of ~ to the λ^5-phosphazene group of an azaphosphole (SC) 443 [G.E. 469]

KEKULENE, Benzenoid versus annulenoid aromaticity: synthesis and properties of ~ (SC) 372 [G.E. 383]
Ketene complexes, High-pressure carbonylation of metal-coordinated carbenes and hydrogenolysis of the ~ (SC) 525 [G.E. 555]
Ketenes, Carbonylation of transition-metal carbyne complexes, a new method for the synthesis of metal-substituted ~ (SC) 859 [G.E. 908]
Deoxygenation — a novel reaction path of transition metal-substituted ~ (SC) 860 [G.E. 908]
Ketenimines, Reactions of methanesulfonylazide with ~ (a revision) (SC) 352 [G.E. 394]
Dienyl-~ — an entry to linearly conjugated cyclohexadienimines (SC) 465 [G.E. 497]
Ketones, tert-Alkylierung of ~ and aldehydes (SC) 48 [G.E. 50]
Stable [2+2]-cycloadducts of ~ with phosphazenes having five-membered rings (SC) 55 [G.E. 64]
α-Amino acids as nucleophilic acyl equivalents: synthesis of ~ and aldehydes by means of oxazolin-5-ones (SC) 450 [G.E. 493]
Kolbe electrolysis, Synthesis of disparlure by ~ (SC) 47 [G.E. 48]

LEARNING, Gedächtnis und Lernen in psychologischer Sicht (Book Review) 290
Lectins (LA) 783
Lipase, Hormone-dependent ~ of adipose tissue (LA) 70
Lipid, Short-term effects of hormones on carbohydrate and ~ metabolism (LA) 138
Liquid crystals, Substituted bicyclohexyls — a new class of nematic ~ (SC) 133 [G.E. 133]
Production and characterization of liquid-crystalline polymers with cholesteric phase (SC) 935 [G.E. 992]
Use in chromatography (LA) 871
Lithium compounds, C_4Li_4, tetralithiotetrahedrane? (SC) 276 [G.E. 306]
Tris[(N,N,N',N'-tetramethylethylenediamine)lithium]hexamethylerbate(III) and -lutetate(III) (SC) 276 [G.E. 307]
Facile preparation of cyclooctatetraene from 1,5-cyclooctadiene by metalation and oxidation (SC) 371 [G.E. 380]
Ring contraction in the reaction of cationic $C_5H_5Mo(CO)_2$ chelate complexes with methyllithium (SC) 453 [G.E. 478]
Lithium ortho-lithiobenzyl alkoxides (SC) 521 [G.E. 553]
Lutetium compounds, Tris[(N,N,N',N'-tetramethylethylenediamine)lithium]hexamethylerbate(III) and -lutetate(III) (SC) 276 [G.E. 307]

MAGIC acid, Superacid-catalyzed oxygenation of alkanes [New synthetic methods (26)] (FP) 909 [G.E. 962]
Malononitrile, New applications (LA) 470
Manganese complexes, Molecular structure of $[Mn(CO)_4NSOF_2]_2$ — a dinuclear transition metal complex containing difluorooxosulfimidato bridges (SC) 280 [G.E. 287]
Synthesis and structure of the tetradecker complex bis(tricarbonylmanganese-μ,η-thiadiborolene)iron (SC) 527 [G.E. 558]
Synthesis of carbocyclic carbene complexes by metal-induced diazocyclopentadiene fragmentation (SC) 777 [G.E. 817]
$C_6H_5Sb[Mn(CO)_2C_5H_5]_2$ — the first compound containing trigonal-planar coordinated antimony(I) (SC) 843 [G.E. 911]
Mass spectrometry, Quantitative ~ in biochemistry and medicine (FP) 221 [G.E. 233]
Chemical ionization — a mass-spectrometric analytical procedure of rapidly increasing importance (FP) 424 [G.E. 449]
Fundamentals of Integrated GC-MS (Book Review) 290
Meitner, Lise: Her life and times — on the centenary of the great scientist's birth (FP) 826 [G.E. 876]
Melittin, Biosynthesis (LA) 138
Membranes, Photosynthetic ~ as models for solar cells (LA) 870
Transport durch biologische Membranen (Book Review) 699
Memory, Gedächtnis und Lernen in psychologischer Sicht (Book Review) 290
Mercury compounds, Organo-~ in organic synthesis (FP) 27 [G.E. 28]
Metabolism, Short-term effects of hormones on carbohydrate and lipid ~ (LA) 138
Metalation, Facile preparation of cyclooctatetraene from 1,5-cyclooctadiene by ~ and oxidation (SC) 371 [G.E. 380]
Metal exchange, Heteronuclear cobalt clusters by ~ (SC) 863 [G.E. 915]
Metal ions in biological systems (Book Review) 377
Metal-metal bonds, What do we know about the metal-metal bond? (FP) 379 [G.E. 403]
Metals, Structure and properties of amorphous ("glassy") ~ and alloys (LA) 216
Methanesulfinamidine, An alkylsulfur imide amide (~) — relation between coordination number and bond length (SC) 58 [G.E. 73]
Methanesulfonyl azide, Reactions with ketenimines (a revision) (SC) 352 [G.E. 394]
3,8-Methanoaza[10]annulene, 10-Ethoxy-~, a 10π-electron analogue of pyridine (SC) 855 [G.E. 896]
p-Methoxybenzyl ether, Mild oxidative removal of the ~ protecting group by homogeneous electron transfer (SC) 673 [G.E. 717]
Methylation, Mechanism of biological ~ of metals (LA) 288
Methyl-1,6-dioxaspiro[4,5]decanes as odors of Paravespula vulgaris (L.) (SC) 862 [G.E. 915]
Methyleneaziridine, Enantioselective synthesis and thermal reorganization of an optically active ~ (SC) 213 [G.E. 224]
5-Methylenebicyclo[2.2.0]hex-2-ene, a bicyclic isomer of toluene: synthesis and thermal behavior (SC) 606 [G.E. 641]
Methylene chloride as a reagent for cyclizations with SO_3 as HCl trapping agent (SC) 367 [G.E. 382]
Methylenesulfur tetrafluoride H_2C SF_4 (SC) 516 [G.E. 547]
N-Methyliminosulfur tetrafluoride, Synthesis of ~, CH_3N SF_4, from the cation $CH_3NSF_3^+$ (SC) 530 [G.E. 561]
Methyl migration, Isomerization with ~ in trimethyl phosphite-arsenido and -antimonido complexes of transition metals (SC) 211 [G.E. 221]
Michael acceptor, Divinyl ketone as ~ (SC) 197 [G.E. 213]
Microbiology, Microbiological aspects of pollution control (Book review) 872
Molecular sieves, Molecular sieve properties of polymeric Schiff base-metal complexes (SC) 610 [G.E. 642]
Molecular structure and dimensions (Book Review) 872
Molecular symmetry and group theory (Book Review) 218
Molybdenum complexes, $[(S_2)_2Mo(S_2)_2Mo(S_2)_2]^{2-}$, a novel complex containing only S_2^{2-} ligands and a Mo-Mo bond (SC) 279 [G.E. 286]
Ring contraction in the reaction of cationic $C_5H_5Mo(CO)_2$ chelate complexes with methyllithium (SC) 453 [G.E. 478]
Directed synthesis of $[Mo_3S_{13}]^{2-}$, an isolated cluster containing sulfur atoms in three different states of bonding (SC) 535 [G.E. 564]
Preparation and crystal structure of $Pd_2Mo_2(\eta^5$-$C_5H_5)_2(\mu_3$-$CO)_2(\mu_2$-$CO)_4(PEt_3)_2$. A planar, triangulated, palladium-molybdenum-carbonyl cluster (SC) 596 [G.E. 637]
Montmorillonites, Reactivity of a sulfonium ion in layer silicates of montmorillonite type (SC) 274 [G.E. 305]

NAPHTHALENE, Hexafluorophosphate of the bis(~) radical cation (SC) 275 [G.E. 305]
Nickel complexes, Bis(tetraphenylcyclobutadiene)nickel (SC) 123 [G.E. 138]
Reactions of carbon dioxide with allylnickel compounds (SC) 124 [G.E. 144]
Quantitative resolution of enantiomers of trans-2,3-epoxybutane by complexation chromatography on an optically active nickel(II) complex (SC) 132 [G.E. 132]
Ethylenebis(diphenylphosphane)dihydrogenselenidonickel(II) (SC) 598 [G.E. 630]
2,2'-Bipyridine(tetramethylcyclobutadiene)nickel(0) (SC) 950 [G.E. 1014]
Nickelocene, Unusual reaction with bis(diphenylphosphino)maleic anhydride (SC) 462 [G.E. 488]
Nickel oligomerization catalyst, Novel coordination of (benzoylmethylene)triphenylphosphorane in a ~ (SC) 466 [G.E. 493]
Nitrate, Mechanism for transport and reduction of ~ (LA) 70
Nitriles, Cobalt-catalyzed pyridine syntheses from alkynes and ~ (FP) 505 [G.E. 517]
Nitro compounds, Double deprotonation of 3-nitropropene and 4-nitro-1-butene: deriva-

tives of their dianions as novel reagents for CC-linkage (SC) 458 [G.E. 479]
Nitrogen, Consecutive nucleophilic and electrophilic attack on N_2 ligands: synthesis of azo compounds from molecular ~ (SC) 269 [G.E. 295]
Nitrogen compounds, A cyclotetra(azadithiane) — the first twelve-membered sulfur-nitrogen ring (SC) 778 [G.E. 825]
N-Nitrosamines, Contamination of amines with ~ (SC) 367 [G.E. 379]
Nitroso compounds, Synthesis of aryl and heteroaryl isocyanides from ~ (SC) 688 [G.E. 731]
Nitrosyliron cation, $[Fe_2(NO)_6]^{2+}$, a binary ~ (SC) 454 [G.E. 477]
NMR Spectroscopy, ^{17}O-~ as a structural probe (FP) 246 [G.E. 258]
Sodium-23 ~ (FP) 254 [G.E. 271]
Effect of shift reagents on NMR coupling constants (SC) 49 [G.E. 51]
Structural elucidation of diastereoisomeric 1,3,6-trioxacyclooctane systems by simultaneous relaxation and double resonance experiments (SC) 447 [G.E. 472]
Electron-donor-acceptor complexes. Demonstration of diastereomeric electron-donor-acceptor complexes by ^1H-~(SC) 940 [G.E. 995]
Interpretation of carbon-13 NMR spectra (Book Review) 217
Nonafulvene, Alkali metal salts of RC(O)-substituted cyclononatetraenyl anions: aromatic [9]annulene anion or olefinic ~ structure as function of gegenion and solvent (SC) 283 [G.E. 290]
Norcaradiene and cycloheptatriene endoperoxides (SC) 954 [G.E. 1014]
Norcaradiene endoperoxides and cycloheptatriene endoperoxides (SC) 954 [G.E. 1014]
Nucleases, Restriction endo-~ (FP) 73 [G.E. 79]
Nucleic acids, Transfer RNA (LA) 216
Affinity chromatography on columns containing ~ (LA) 618
Nucleophilic substitution, Quaternary ammonium salts as catalysts of ~ in a solid-liquid two-phase system (SC) 62 [G.E. 58]
Nucleosides, Reactions with the triphenylphosphane/diethyl azodicarboxylate system (SC) 679 [G.E. 725]

ODORS, Methyl-1,6-dioxaspiro[4.5]decanes as ~ of Paravespula vulgaris (L.) (SC) 862 [G.E. 915]
Olefin metathesis with polymer-bound tungsten complexes (SC) 131 [G.E. 131]
Olefins, $Co_2(CO)_8$/Ph_3P-catalyzed reaction of aldehydes with hydrosilane and carbon monoxide (SC) 119 [G.E. 138]
Organic syntheses using sheet silicate intercalates: Low-temperature conversion of ~ to secondary ethers (SC) 282 [G.E. 290]
Cathodic acylation of aryl ~ (SC) 460 [G.E. 483]
Influence of cyclopropyl substituents on the relative rate of dichlorocarbene addition to ~ (SC) 674 [G.E. 716]
Stabilization of radicals by "capto-dative" substitution: C C addition to radicophilic olefins (SC) 691 [G.E. 741]
Ozone cleavage of ~ with formation of ester fragments (SC) 939 [G.E. 999]
Oligo(ethylene glycol ethers), Complexes of short-chain ~ bearing only one rigid donor end group (SC) 197 [G.E. 211]
Alkaline earth metal complexes of simple ~ (SC) 198 [G.E. 212]
Oligomerization catalyst, Novel coordination of (benzoylmethylene)triphenylphosphorane in a nickel ~ (SC) 466 [G.E. 493]
Opiate receptor, Role of cerebroside sulfate as ~ (LA) 540
Optical resolution, Functional derivatives of D- and L-ribose by ~ with recycling (SC) 769 [G.E. 821]
d-Orbital participation, Molecular structure of F_5SOSF_5, $F_5SeOSeF_5$, and $F_5TeOTeF_5$: ~ in bonds between main group elements (SC) 69 [G.E. 66]
Orbitals, Use of electron-density plots in applied quantum chemistry (FP) 80 [G.E. 86]
Organomercury compounds in organic synthesis (FP) 27 [G.E. 28]
Organometallic chemistry, Annual surveys (LA) 376
Organometallic syntheses with diazoalkanes (FP) 800 [G.E. 855]
7-Oxa-5-aza-1-phosphabicyclo[3.2.0]hept-2-enes, Stable [2+2]-cycloadducts of ketones with phosphazenes having five-membered rings (SC) 55 [G.E. 64]
Oscillations, Chemical ~ (FP) 1 [G.E. 1]
Oxaloacetate, Fine control of conversion of pyruvate (phosphoenolpyruvate) into ~ in various species (LA) 871
1,3-Oxazolidinethiones, γ-Sultenes and ~ by 1,3-dipolar cycloaddition of thioketene S-oxides to azomethines (SC) 455 [G.E. 480]
Oxazolin-5-ones, α-Amino acids as nucleophilic acyl equivalents: synthesis of ketones and aldehydes by means of ~ (SC) 450 [G.E. 493]
Oxepinobenzofurans — the true nature of sterically hindered "benzoxetes" (SC) 121 [G.E. 128]
Oxostannate(II), The first ~: $K_2Sn_2O_3$ (SC) 449 [G.E. 475]
Oxygen adducts, Trapping of unstable fulvene/singlet ~ by reduction with diazene (SC) 210 [G.E. 223]
Trapping of unstable α-pyrone/singlet ~ by reduction with diazene (SC) 211 [G.E. 223]
Oxygenation, Superacid-catalyzed ~ of alkanes [New synthetic methods (26)] (FP) 909 [G.E. 962]
Oxygen evolution from water via redox catalysis (SC) 860 [G.E. 900]
Ozone cleavage of olefins with formation of ester fragments (SC) 939 [G.E. 999]

PALLADIUM compounds, Coordinatively unsaturated transition metal-substituted cyclopropenylium systems (SC) 457 [G.E. 491]
Preparation and crystal structure of $Pd_2Mo_2(\eta^5\text{-}C_5H_5)_2(\mu_3\text{-}CO)_2(\mu_2\text{-}CO)_4(PEt_3)_2$. A planar, triangulated, palladium-molybdenum-carbonyl cluster (SC) 596 [G.E. 637]
PdTeI and Pd_2SeI_3 — the first chalcogenide halides of a platinum metal (SC) 852 [G.E. 897]
[2.2]Paracyclophane, $(\eta^{12}$-~)chromium(0) (SC) 531 [G.E. 560]
Pentacyclo[6.4.0.0^{2,5}.0^{3,10}.0^{4,9}]dodeca-6,11-diene, an o,o′:o,p′-dimer of benzene (SC) 847 [G.E. 901]
Peptides, Chiral polysiloxanes for resolution of optical antipodes (SC) 363 [G.E. 396]
N-Terminal cyclization of ~ with N,N-carbonyldiimidazole or N,N′-thiocarbonyldiimidazole (SC) 467 [G.E. 495]
Peptide synthesis, Syntheses with 2-phosphonioethoxycarbonyl protecting groups: ~ in water (SC) 67 [G.E. 63]
1-(1-Adamantyl)-1-methylethoxycarbonyl: a new protecting group (SC) [G.E. 998]
Peptidoglycan, The linkage between teichoic acid and ~ in bacterial cell walls (LA) 698
Peracid oxidation, Ring contraction by ~: preparation of cyclo-heptasulfur dioxide, S_7O_2, from S_8 (SC) 611 [G.E. 644]
Pericyclic reactions (Book Review) 471
Peroxides, Regioselective synthesis of isomeric bicyclic ~ (SC) 209 [G.E. 216]
Pesticides, Chemie der Pflanzenschutz- und Schädlingsbekämpfungsmittel (Book Review) 471
Phallotoxin model, L,L-3,6-[methanothio(2,3-indolo)methano]piperazine-2,5-dione, the smallest ~ (SC) 54 [G.E. 67]
Phase equilibria and critical curves of binary ammonia-hydrocarbon mixtures (FP) 728 [G.E. 775]
Phenanthrene, 1,2,8,9-Tetrahydrodicyclobuta[b,g]-~ and 1,2,7,8-tetrahydrodicyclobuta[b,h]-~, potentially carcinogenic activated hydrocarbons (SC) 615 [G.E. 648]
Phenoxides, Selectivity in reactions between metal ~ and isoprene. Facile synthesis of 2,2-dimethylchromans (SC) 684 [G.E. 731]
Phenylhydrazones, Catalytic allylation of ~ (SC) 353 [G.E. 399]
Pheromones, Synthesis of disparlure by Kolbe electrolysis (SC) 47 [G.E. 48]
Bombykal, a second-~ component of the silkworm moth Bombyx mori L. (SC) 60 [G.E. 74]
Phosphane ligands, Versatility of tertiary ~ in coordination and organometallic chemistry (FP) 183 [G.E. 195]
Phosphanes, Structure of the 1:1 adduct of aminoiminophosphane and tert-butyl azide (SC) 136 [G.E. 135]
Ethylenebis(diphenylphosphane)dihydrogenselenidonickel(II) (SC) 598 [G.E. 630]
Reactions of nucleosides with the triphenylphosphane/diethyl azodicarboxylate system (SC) 679 [G.E. 725]
Phosphates, Aluminum tris(dihydrogen phosphate) (SC) 272 [G.E. 286]
Phosphazenes, Stable [2+2]-cycloadducts of ketones with ~ having five-membered rings (SC) 55 [G.E. 64]
Various adducts of isothiocyanates to the λ^5-phosphazene group of an azaphosphole (SC) 443 [G.E. 469]
Phosphinic anhydride, Stabilization of a ~ R_2POPR_2 on gold(I) and formation of the trinuclear complex $(R_2POAu)_3$, production of an octahedral structural unit $Ag_4Br_2^{2+}$ by clamping with $R_2PN(R')PR_2$ (SC) 846 [G.E. 905]
Phosphinidene oxide, 1,2,3-Tri-tert-butylphosphirane oxide and its thermal decomposition into (Z)-2,2,5,5-tetramethyl-3-hexene and tert-butyl-~ (SC) [G.E. 921]
Phosphirane oxide, 1,2,3-Tri-tert-butyl-~ and its thermal decomposition into (Z)-2,2,5,5-tetramethyl-3-hexene and tert-butylphosphinidene oxide (SC) 867 [G.E. 921]
2-Phosphonioethoxycarbonyl, Syntheses with ~ protecting groups: peptide synthesis in water (SC) 67 [G.E. 63]
Phosphonium hydrogen dichlorides, Diorganodichloro-~, a novel class of compounds containing $[ClHCl]^-$ ions (SC) 869 [G.E. 903]
Phosphonium salts, Tetraphenylphosphonium tetrakis(difluorooxosulfimidato)borate (SC) 212 [G.E. 226]
Phosphoranes, Synthesis of a Δ^4-1,4,2λ^5-selenazaphospholine, the first selenophosphorane (SC) 774 [G.E. 824]
Phosphoric anhydride, Mixed carboxylic-dichloro-~ — reactive intermediates in acyl chloride synthesis with $POCl_3$ (SC) 695 [G.E. 740]
Phosphorus compounds, Synthesis and crystal structure of a methylenebis(diphenylphosphane) complex of silver bromide containing a trigonal bipyramidal Ag_3Br_2 central unit (SC) 125 [G.E. 125]
Boratobis(dimethylphosphiniomethylide) anion, a novel ligand system for organometallic compounds (SC) 126 [G.E. 126]
Intramolecular cycloaddition of a "P O-activated" acetyleneallene derivative (SC) 196 [G.E. 208]
Novel diylides containing tricoordinate phosphorus (SC) 199 [G.E. 209]
Isomerization with methyl migration in trimethyl phosphite-arsenido and -antimonido complexes of transition metals (SC) 211 [G.E. 221]
Structural changes during the oxidation of B-, C-, Si-, and P-substituted hydrazines (SC) 286 [G.E. 308]
Phosphorus compounds, Unusual reaction of nickelocene with bis(diphenylphosphino)maleic anhydride (SC) 462 [G.E. 488]
Novel coordination of (benzoylmethylene)triphenylphosphorane in a nickel oligomerization catalyst (SC) 466 [G.E. 493]
4-Alkoxy-1-phenylphosphacyclohexadiene → 1-alkoxy-1-phenyl-λ^5-phosphorin rearrangement (SC) 528 [G.E. 566]
1λ^3,4λ^3-Diphospha-2,3,5,6,7-pentastanna-

bicyclo[2.2.1]heptane, a bicyclic compound rich in tin (SC) 767 [G.E. 814]
Trimethylphosphoranediyl- and arsoranediylmethyl(trimethylsiloxy)carbene complexes by 1,3-silyl shift (SC) 780 [G.E. 827]
Synthesis and reactions of heterocycles containing P N N linkage (LA) 783
Phosphorylation by means of cyclic enediol phosphates (LA) 698
Photoacoustic spectroscopy of condensed matter (FP) 238 [G.E. 250]
Photochemical intermediates, Novel method for the detection of indirectly identifiable ~ (SC) 52 [G.E. 53]
Photochemistry, Industrial applications of photochemical syntheses (FP) 16 [G.E. 17]
Solid-state ~ — a method of generating unusual valence states (FP) 89 [G.E. 95]
Photochemical rearrangements and fragmentations of alkenes and polyenes (FP) 150 [G.E. 161]
Mineralization of chlorofluorocarbons in the sunlight of the troposphere (SC) 366 [G.E. 398]
Photochemical reductive trans-elimination from trans-diazidotetracyanoplatinate(IV) (SC) 524 [G.E. 554]
Regioselective hydrogenation and carbonylation of functionalized dienes on photocleavage from their tricarbonyliron complexes (SC) 690 [G.E. 736]
Novel mode of formation of cis,trans-1,5-cyclooctadiene (SC) 696 [G.E. 735]
Novel photochemical synthesis of propellanes (SC) 758 [G.E. 803]
~ of enamides (LA) 698
Photoelectron spectroscopy, Copper-catalyzed cyanation of benzene in the gas phase (SC) 933 [G.E. 986]
Use of a photoelectron spectrometer in gas phase analysis: cyanogen and hydrogen cyanide (SC) 932 [G.E. 985]
Photorespiration, Connection between photosynthetic carbon reduction and ~ (LA) 871
Photosynthetic carbon reduction, Connection between ~ and photorespiration (LA) 871
Photosynthetic membranes as models for solar cells (LA) 870
Phytoalexins, chemical defense substances of higher plants? (FP) 635 [G.E. 668]
Plant protection, Chemie der Pflanzenschutz- und Schädlingsbekämpfungsmittel (Book Review) 471
Platinum compounds, Photochemical reductive trans-elimination from trans-diazidotetracyanoplatinate(IV) (SC) 524 [G.E. 554]
Platinum hydrides, New cationic mono-hydride-bridged binuclear plantinum(II) dihydride (SC) 778 [G.E. 826]
Pollution control, Microbiological aspects of ~ (Book Review) 872
Polyaminolactam, Use of the "zip" reaction for the synthesis of a 53-membered ~ (SC) 200 [G.E. 210]
Polyethylene fibrids: preparation and properties (FP) 820 [G.E. 833]
Polyenes, Photochemical rearrangements and fragmentations of alkenes and ~ (FP) 150 [G.E. 161]
Polyiodides, Unusually versatile solid-state structure: ~ of type $Tl_6I_6M^{n+}_{3/n}(I_4)^{2-}$ M = Ag,Au,Tl,Pb,Bi,Ln,Zr,Hf,Th) (SC) 599 [G.E. 627]
Polymeric catalysts (FP) 657 [G.E. 691]
Polymer networks, Interpenetrating ~ (FP) 97 [G.E. 104]
Polymers, Optically active polyvinyl compounds with chirality in the main chain (SC) 535 [G.E. 567]
Directed cooperativity and site separation of mercapto groups in synthetic ~ (SC) 537 [G.E. 568]
Production and characterization of liquid-crystalline ~ with cholesteric phase (SC) 935 [G.E. 992]
Structure-solubility relationships in ~ (Book Review) 291
Polymethylene sulfides, Copolymerization of tetrameric thioformaldehyde with oligomeric thioformaldehydes, substituted analogs, or sulfur (SC) 51 [G.E. 52]
Polysiloxanes, Chiral ~ for resolution of optical antipodes (SC) 363 [G.E. 396]
Polytelluride, K_2Te_3: The first binary alkali-metal ~ with Te_3^{2-} ions (SC) 684 [G.E. 731]
Polyvinyl compounds, Optically active ~ with chirality in the main chain (SC) 535 [G.E. 567]
Pore size of solids (FP) 901 [G.E. 954]
Porphyrins, Simple template synthesis of zinc tetrabenzporphyrin (SC) 760 [G.E. 808]
Dichlorocarbene complexes of iron(II)porphyrins — crystal and molecular structure of $Fe(TPP)(CCl_2)(H_2O)$ (SC) 781 [G.E. 828]
Synthesis of unsymmetrical tetraaryl-~ on solid phases (SC) 947 [G.E. 1001]
Redox properties of zinc tetrabenz-~ (SC) 951 [G.E. 1004]
Carbonyl(pyridine)iron(II) tetrabenzporphyrin π-radical cation (SC) 952 [G.E. 1011]
Potato starch, Complete enantiomer separation by chromatography on ~ (SC) 612 [G.E. 645]
Propellanes, Novel photochemical synthesis (SC) 758 [G.E. 803]
Prostacyclins, Synthesis and biological properties of prostaglandin endoperoxides, thromboxanes, and ~ (FP) 293 [G.E. 360]
Prostaglandin endoperoxides, Synthesis and biological properties of ~, thromboxanes, and prostacyclins (FP) 293 [G.E. 360]
Protecting group, Syntheses with 2-phosphonioethoxycarbonyl~: peptide syntheses in water (SC) 67 [G.E. 63]
2,4,6-Tri-tert-butylphenoxyl (TBPO) as sterically active carbonyl-~ — a new nucleophilic dimethylaminomethylating reagent (SC) 274 [G.E. 296]
The 2,2,2-trichloro-tert-butyloxycarbonyl group (TCBOC) — an acid- and base-resistant ~ removable under mild conditions (SC) 361 [G.E. 388]
Mild oxidative removal of the p-methoxybenzyl ether ~ by homogeneous electron transfer (SC) 673 [G.E. 717]
1-(1-Adamantyl)-1-methylethoxycarbonyl: a new ~ for peptide syntheses (SC) 944 [G.E. 998]
Protein biosynthesis: The codon-specific activation of amino acids (FP) 648 [G.E. 682]
Proteins, Prediction of the spatial structure of a protein from the amino acid sequence (LA) 289
Pulse radiolysis, Applications to chemical research (LA) 782
Pyrazine, Intramolecular electron transfer of coordinated ~-carboxylato radicals to cobalt(III): a pulse radiolytic study (SC) 608 [G.E. 632]
Pyridines, 4-Dialkylamino-~ as highly active acylation catalysts (FP) 569 [G.E. 602]
Simple method for the esterification of carboxylic acids (SC) 522 [G.E. 556]
Bridged aza[10]annulenes — 10π-analogues of pyridine (SC) 853 [G.E. 894]
Pyridine syntheses, Cobalt-catalyzed ~ from alkynes and nitriles (FP) 505 [G.E. 517]
2,4,6-Pyridinetricarboxylate, Intramolecular electron transfer from iron(II) to cobalt(III) through ~ as mediating bridging ligand (SC) 205 [G.E. 218]
α-Pyrone, Trapping of unstable ~/singlet oxygen adducts by reduction with diazene (SC) 211 [G.E. 223]
Pyrophosphate, Reactions in which inorganic ~ replaces ATP as a source of energy (LA) 137
Pyrroles, Facile synthesis of 2-aryl- and 2-heteroaryl-~ from N-allylcarboxamides (SC) 676 [G.E. 719]
Pyruvate, Fine control of the conversion of ~ (phosphenol-~) into oxaloacetate in various species (LA) 871
QUANTUM chemistry, Use of electron-density plots in applied ~ (FP) 80 [G.E. 86]
Quinhydrone, [2.2.2.2](1,2,4,5)cyclophane ~ — a donor-acceptor cyclophane with an extremely short transannular distance (SC) 756 [G.E. 805]
Indirect donor-acceptor interactions in ~-s of quadruple-layered [2.2]paracyclophanes (SC) 757 [G.E. 807]
RADICAL anions, Stable L-(+)-ascorbic acid ~ (SC) 365 [G.E. 392]
Radical cations, Hexafluorophosphate of the bis(naphthalene) radical cation (SC) 275 [G.E. 305]
Evidence for a dialkoxyalkene radical cation in aqueous solution (SC) 604 [G.E. 639]
Carbonyl(pyridine)iron(II) tetrabenzporphyrin π-radical cation (SC) 952 [G.E. 1011]
Radicals, Reactivity of alkenes in free-radical additions (SC) 66 [G.E. 62]
More about π- and σ-succinimidyl ~: ring opening reactions (SC) 515 [G.E. 546]
Front strain of π and σ ~ (SC) 594 [G.E. 635]
Stabilization of ~ by "capto-dative" substitution: C C addition to radicophilic olefins (SC) 691 [G.E. 741]
A stable σ/π-organometallic radical of vanadium: $(\eta^5\text{-}C_5Me_4Et)_2V\text{-}C\text{-}C\text{-}C_6H_2Me_3$ (SC) 850 [G.E. 912]
Diastereoselective radical recombination and variation in thermal stability of diastereomeric hydrocarbons (SC) 934 [G.E. 987]
Radicophilic olefins, Stabilization of radicals by "capto-dative" substitution: C C addition to ~ (SC) 691 [G.E. 741]
Reaction mechanisms in organic chemistry (Book Review) 542
Rearrangements, Photochemical ~ and fragmentations of alkenes and polyenes (FP) 150 [G.E. 161]
Skeletal ~ of organoalkali metal compounds (FP) 313 [G.E. 317]
Metal-induced ~ and insertions into vinylcyclopropanes (LA) 698
Receptor, Role of cerebroside sulfate as opiate ~ (LA) 540
Identification and regulation of α- and β-adrenergic ~-s (LA) 540
Affinity-labeling of estrogen ~-s (LA) 540
Redox catalysis, Oxygen evolution from water via ~ (SC) 860 [G.E. 900]
Redox potentials of cytochromes, Structural basis for variations (LA) 138
Redox properties of zinc tetrabenzporphyrins (SC) 951 [G.E. 1004]
Redox systems, Multistage organic ~ — a general structural principle (FP) 875 [G.E. 927]
Reductive eliminations, ~ of cationic acylcobalt complexes; transformation of a Co^{III} COR bond into a Co^{I} CO bond (SC) 464 [G.E. 496]
Photochemical reductive trans-elimination from trans-diazidotetracyanoplatinate(IV) (SC) 524 [G.E. 554]
Regioselective synthesis of the anthraquinones digitopurpone and islandicin (SC) 945 [G.E. 1000]
Responsibility, The ~ of the scientist (FP) 670 [G.E. 651]
Restriction endonucleases (FP) 73 [G.E. 79]
Rhenium sulfides, Ternary ~ with $[Re_6S_8]$-clusters (SC) 368 [G.E. 382]
Rhodium(I) complexes, Valence isomeric η^2- and η^4-cyclobutadiene-~ (SC) 128 [G.E. 142]
Ribonucleic acids, Protein biosynthesis: The codon-specific activation of amino acids (FP) 648 [G.E. 682]
Ribose, Functional derivatives of D- and L-~ by optical resolution with recycling (SC) 769 [G.E. 821]
Ribosomes, Structure and function of Escherichia coli ~ (LA) 138
Ring closure, Synthesis of polycyclic systems by intramolecular ~ (LA) 783

Ring contraction, ~ in the reaction of cationic $C_5H_5Mo(CO)_2$ chelate complexes with methyllithium (SC) 453 [G.E. 478]
~ by peracid oxidation: preparation of cycloheptasulfur dioxide, S_7O_2, from S_8 (SC) 611 [G.E. 644]
Ring opening reactions, More about π- and σ-succinimidyl radicals: ~ (SC) 515 [G.E. 546]
Ruthenium(0) complex, New type of ~ with a half-sandwich structure: $C_6H_6RuL_2$ (SC) 683 [G.E. 721]

SANDWICH complexes, Paramagnetic triple-decker ~ (SC) 868 [G.E. 917]
Schiff base-metal complexes, Molecular sieve properties of polymeric ~ (SC) 610 [G.E. 642]
Science and the public, The responsibility of the scientist (FP) 670 [G.E. 651]
B-Seco-tetranortriterpenoids, Toonacilin and 6-acetoxytoonacilin, two novel B-seco-tetranortriterpenoids with antifeeding activity (SC) 452 [G.E. 476]
Selectivity, Temperature dependence of carbene ~: a new example of the isoselective relationship (SC) 595 [G.E. 636]
~ in reactions between metal phenoxides and isoprene. Facile synthesis of 2,2-dimethylchromans (SC) 684 [G.E. 731]
Scope of application of the isoselective relationship (SC) 775 [G.E. 816]
Unusual ~ in the thermal rearrangement-elimination reaction of a carbene complex in solution and in the solid state (SC) 842 [G.E. 914]
Δ^4-1,4,2λ^5-Selenazaphospholine, Synthesis of a ~, the first selenophosphorane (SC) 774 [G.E. 824]
Selenides, Reactivity of phenyl vinyl selenide with nucleophiles and bases (SC) 526 [G.E. 550]
Seleninato complex, Selenium dioxide insertion into the iron-methyl bond of η^5-$C_5H_5Fe(CO)_2CH_3$ (SC) 53 [G.E. 60]
Selenium compounds, Molecular structure of F_5SOSF_5, $F_5SeOSeF_5$, and F_5TeF_5: d-orbital participation in bonds between main group elements (SC) 69 [G.E. 66]
Extremely high electronegativities (SC) 355 (G.E. 390]
Xenon tetrakis(pentafluoroorthotellurate), $Xe(OTeF_5)_4$ (SC) 356 [G.E. 391]
Ethylenebis(diphenylphosphane)dihydrogenselenidonickel(II) (SC) 598 [G.E. 630]
PdTeI and Pd_2SeI_3 — the first chalcogenide halides of a platinum metal (SC) 852 [G.E.897]
Selenium dioxide insertion into the iron-methyl bond of η^5-$C_5H_5Fe(CO)_2CH_3$ (SC) 53 [G.E. 60]
Selenocarbonyls, Transition-metal thiocarbonyls and ~ (LA) 216
Selenol esters, New method for selective activation of amino, hydroxy, and mercapto carboxylic acids at the carboxyl group: preparation of thiol esters and ~ (SC) 267 [G.E. 283]
Selenophosphorane, Synthesis of a Δ^4-1,4,2λ^5-selenazaphospholine, the first ~ (SC) 774 [G.E. 824]
Semiconductors, Ion implantation into ~ (FP) 496 [G.E. 537]
Separation, ~ with supercritical gases: practical applications (FP) 702 [G.E. 748]
~ of nonvolatile substances by means of compressed gases in countercurrent processes (FP) 746 [G.E. 749]
Sex attractant, (Z)-5-Decenyl acetate, a ~ for the male turnip moth Agrotis segetum (Lepidoptera) (SC) 768 [G.E. 815]
Shift reagents, Effect on NMR coupling constants (SC) 49 [G.E. 51]
Silanediyl bridges, Binuclear iron complexes containing unsymmetrically substituted ~ (SC) 120 [G.E. 140]
Silanediyliron complexes, Dimethyl-~ (SC) 674 [G.E. 718]
Silanes, One-step synthesis of vinyl-~ and vinylenebis-~ (SC) 279 [G.E. 288]
Preparation and some reactions of dimethyl(trimethylsilylimino)silane, Me_2Si $NSiMe_3$ (SC) 362 [G.E. 393]
Silica, Pore sizes of solids (FP) 901 [G.E. 954]
Silicates, Reactivity of a sulfonium ion in layer silicates of montmorillonite type (SC) 274 [G.E. 305]
Organic syntheses using sheet silicate intercalates: Low-temperature conversion of olefins to secondary ethers (SC) 282 [G.E. 290]
Silicides, New high-pressure phase of barium disilicide (SC) 538 [G.E. 562]
Silicon compounds, Structural changes during the oxidation of B-, C-, Si-, and P-substituted hydrazines (SC) 286 [G.E. 308]
Alkene synthesis via β-functionalized organosilicon compounds (LA) 288
Role of silicon in organic chemistry (LA) 470
Silicon dioxide, IR spectroscopic detection of molecular SiO_2 (SC) 616 [G.E. 638]
Silver bromide, Synthesis and crystal structure of a methylenebis(diphenylphosphane) complex of ~ containing a trigonal bipyramidal Ag_3Br_2 central unit (SC) 125 [G.E. 125]
Silver iodide, Solid electrolytes based on ~ (LA) 618
Singlet oxygen, Trapping of unstable fulvene/~ adducts by reduction with diazene (SC) 210 [G.E. 223]
Trapping of unstable α-pyrone/~ adducts by reduction with diazene (SC) 211 [G.E. 223]
Size exclusion chromatography, Pore sizes of solids (FP) 901 [G.E. 954]
Sodium, Wrapping of noncyclic molecules around the sodium cation (SC) 856 [G.E. 902]
Solar cells, Photosynthetic membranes as models for ~ (LA) 870
Solid ionic conductors: principles and applications (FP) 37 [G.E. 38]
Solid phase synthesis, Synthesis of unsymmetrical tetraarylporphyrins on solid phases (SC) 947 [G.E. 1001]
Solids, Pore sizes of ~ (FP) 901 [G.E. 954]
Solid-state photochemistry — a method of generating unusual valence states (FP) 89 [G.E. 95]
Solvent effects, ^{15}N-NMR investigation of ~ on sulfonamides (SC) 442 [G.E. 489]
Spectrophotometry, High-resolution, higher-order UV/VIS derivative ~ [New analytical methods (14)] (FP) 785 [G.E. 840]
Spectroscopy, IR spectroscopic detection of molecular SiO_2 (SC) 616 [G.E. 638]
Vibrational spectra of organometallic compounds (Book Review) 542
Spices, Fluid extraction of hops, ~, and tobacco with supercritical gases (FP) 710 [G.E. 756]
Spiro compounds, Syntheses of carbocyclic ~ by cycloaddition (LA) 376
Spiroconjugation (FP) 559 [G.E. 591]
Stability, Electrostatics, the chemical bond and molecular ~ (FP) 812 [G.E. 868]
Stannyl radicals, First reversible thermal dissociation of distannanes R_3Sn SnR_3 (SC) 59 [G.E. 74]
Starch, Complete enantiomer separation by chromatography on potato ~ (SC) 612 [G.E. 645]
Steric effects, $\mathcal{S}_f$ Parameters — a measure of the front strain of alkyl groups (SC) 593 [G.E. 633]
Steroid hormones, Relationship between ~ and the growth and development of plants (LA) 289
Steroid receptors, Physical characterization of cytoplasmatic gluco- and mineralo-~ (LA) 289
Stibanes, Difluoroarsoranes and homologous compounds $R'R_2EF_2$ (E = As, Sb, Bi) by oxidative direct fluorination of organoarsanes, organo-~, and organobismuthanes (SC) 214 [G.E. 226]
Strain, $\mathcal{S}_f$ Parameters — a measure of the front ~ of alkyl groups (SC) 593 [G.E. 633]
Front ~ of π and σ radicals (SC) 594 [G.E. 635]
Stretching frequency and force constant of the tungsten-carbon triple bond (SC) 50 [G.E. 51]
Succinimidyl radicals, More about π- and σ-~: ring opening reactions (SC) 515 [G.E. 546]
Sulfamides, Azoalkanes by anodic oxidation of anions of N,N'-dialkyl-~ (SC) 370 [G.E. 390]
"Sulfene" insertion, Demonstration of ~ into the metal-hydrogen bond (SC) 285 [G.E. 292]
Sulfonyl diisocyanate, 2,4-Bis(dimethylcarbamoyl)-1,1-dioxo-3-phenyl-1λ^6,2,4,3-thiadiazaboretidine: a BN_2S ring by "insertion" of ~ (SC) 599 [G.E. 626]
Sulfides, Ternary rhenium ~ with $[Re_6S_8]$-clusters (SC) 368 [G.E. 382]
Sulfilimines (sulfimides) (LA) 70
Sulfimidates, Tetraphenylphosphonium tetrakis(difluorooxosulfimidato)borate (SC) 212 [G.E. 226]
Sulfimides, N-Fluorosulfonylsulfimide (N-(fluorosulfonyl)sulfur imide dioxide) (SC) 129 [G.E. 127]
Sulfilimines (~) (LA) 70
N-Sulfinylamines, Reactive derivatives of aliphatic ~ — alkylation of N-sulfinylalkylamines and bis(tert-butyl)sulfur diimide (SC) 63 [G.E. 61]
Sulfonamides, ^{15}N-NMR investigation of solvent effects on ~ (SC) 442 [G.E. 489]
Sulfone pyrolysis, Triptycenophanes — synthesis via "double nonbenzylic sulfone pyrolysis" (SC) 60 [G.E. 58]
Sulfonium ion, Reactivity of a ~ in layer silicates of montmorillonite type (SC) 274 [G.E. 305]
Sulfonium salts, New synthetic entry to mono-, bis-, and tris-(amino)-~ (SC) 64 [G.E. 61]
Synthesis of donor-substituted ~ (SC) 460 [G.E. 487]
Sulfonylhydroxylamines, Electrophilic amination of "carbanions" with N,N-dialkyl-O-aryl-~ (SC) 687 [G.E. 733]
Sulfonyl isocyanates, Synthesis of 1λ^6,2,4-thiadiazetidin-3-ones from tris(imido)sulfur(VI) derivatives and ~ (SC) 677 [G.E. 722]
Sulfur, Copolymerization of tetrameric thioformaldehyde with oligomeric thioformaldehydes, substituted analogs, or ~ (SC) 51 [G.E. 52]
Synthesis of cyclo-hepta-~, S_7, from S_8 (SC) 56 [G.E. 54]
X-Ray structure analysis of cyclo-deca-~, S_{10} (SC) 57 [G.E. 55]
Sulfur compounds, $[Au_2(WS_4)_2]^{2-}$, a novel inorganic ring system (SC) 52 [G.E. 57]
Molecular structure of F_5SOSF_5, $F_5SeOSeF_5$, and F_5TeF_5: d-orbital participation in bonds between main group elements (SC) 69 [G.E. 66]
$[(S_2)_2Mo(S_2)_2Mo(S_2)_2]^{2-}$, a novel complex containing only S_2^{2-} ligands and a Mo Mo bond (SC) 279 [G.E. 286]
Molecular structure of $[Mn(CO)_4NSOF_2]_2$ — a dinuclear transition metal complex containing difluorooxosulfimidato bridges (SC) 280 [G.E. 287]
Methylenesulfur tetrafluoride H_2C SF_4 (SC) 516 [G.E. 547]
Synthesis of N-methyliminosulfur tetrafluoride, CH_3N SF_4, from the cation $CH_3NSF_3^+$ (SC) 530 [G.E. 561]
Directed synthesis of $[Mo_3S_{13}]^{2-}$, an isolated cluster containing sulfur atoms in three different states of bonding (SC) 535 [G.E. 564]
Directed cooperativity and site separation of mercapto groups in synthetic polymers (SC) 537 [G.E. 568]
Ring contraction by peracid oxidation: preparation of cyclo-heptasulfur dioxide, S_7O_2, from S_8 (SC) 611 [G.E. 644]
Bis(thioacyl) sulfides from acyl thioacyl sulfides (SC) 675 [G.E. 718]
Reactions of organo-~ (LA) 138

Sulfur diimide, Reactive derivatives of aliphatic N-sulfinylamines – alkylation of N-sulfinylalkylamines and bis(tert-butyl)-~ (SC) 63 [G.E. 61]
3d-orbital participation in ~-s (SC) 468 [G.E. 481]
Sulfur imide amide, An alkyl-~ (methanesulfinamidine) – relation between coordination number and bond length (SC) 58 [G.E. 73]
Sulfur-nitrogen compounds, A cyclotetra(azadithiane) – the first twelve-membered sulfur-nitrogen ring (SC) 778 [G.E. 825]
Sulfur oxides, Preparation of cyclo-hexasulfur oxide, S_6O (SC) 134 [G.E. 134]
Sulfur trioxide, Methylene chloride as a reagent for cyclizations with ~ as HCl trapping agent (SC) 367 [G.E. 382]
γ-Sultenes and 1,3-oxazolidinethiones by 1,3-dipolar cycloaddition of thioketene S-oxides to azomethines (SC) 455 [G.E. 480]
Superacids, Superacid-catalyzed oxygenation of alkanes [New synthetic methods (26)] (FP) 909 [G.E. 962]
Supercritical ammonia, Phase equilibria and critical curves of binary ammonia-hydrocarbon mixtures (FP) 728 [G.E. 775]
Supercritical fluids, Chromatography with ~ [New analytical methods (13)] (FP) 738 [G.E. 785]
Supercritical gases, Extraction with ~ – a foreword (FP) 701 [G.E. 747]
Separation with ~: practical applications (FP) 702 [G.E. 748]
Physicochemical principles of extraction with ~ (FP) 716 [G.E. 763]
Quick method for the microanalytical evaluation of the dissolving power of ~ [New analytical methods (12)] (FP) 731 [G.E. 778]
Large-scale industrial plant for extraction with ~ (FP) 751 [G.E. 799]
Surfaces, Chemical physics of ~ (Book Review) 471
Surface science, A coordination chemist's view of ~ (FP) 545 [G.E. 577]
Sweeteners, Properties and syntheses (LA) 288
Synthesis, Reflections on an anniversary of chemical ~ (FP) 473 [G.E. 503]
Synthetic methods, Organomercury compounds in organic synthesis (FP) 27 [G.E. 28]
Selective reactions with organoaluminum compounds (FP) 169 [G.E. 180]
Intramolecular ene reactions in organic synthesis (FP) 476 [G.E. 506]
Organic reactions at alumina surfaces (FP) 487 [G.E. 527]
Cobalt-catalyzed pyridine syntheses from alkynes and nitriles (FP) 505 [G.E. 517]
4-Dialkylaminopyridines as highly active acylation catalysts (FP) 569 [G.E. 602]
Superacid-catalyzed oxygenation of alkanes (FP) 909 [G.E. 962]

TANTALUM compounds, Coordination number 5 and 6 in $RbTaO_3$; $Rb_4^2[Ta_4O_{12}]$ (SC) 354 [G.E. 387]
Teichoic acid, Linkage between ~ and peptidoglycan in bacterial cell walls (LA) 698
Tellurium compounds, Molecular structure of F_5SOSF_5, $F_5SeOSeF_5$, and F_5TeF_5: d-orbital participation in bonds between main group elements (SC) 69 [G.E. 66]
K_2Te_3: The first binary alkali-metal polytelluride with Te_3^{2-} ions (SC) 684 [G.E. 731]
Extremely high electronegativities (SC) 355 [G.E. 390]
Xenon tetrakis(pentafluoroorthotellurate), $Xe(OTeF_5)_4$ (SC) 356 [G.E. 391]
PdTeI and Pd_2SeI_3 – the first chalcogenide halides of a platinum metal (SC) 852 [G.E. 897]
Template reactions on chromium(0): synthesis of a functionalized indene from pentacarbonyl[methoxy(phenyl)carbene]chromium and bis(diethylamino)acetylene (SC) 851 [G.E. 898]
~ (LA) 871
Template synthesis, Simple ~ of zinc tetrabenzporphyrin (SC) 760 [G.E. 808]
Direct synthesis of metal-free 1,8-dihydrotetraaza[14]annulenes utilizing the metal-template effect (SC) 772 [G.E. 818]
Tetraarylporphyrins, Synthesis of unsymmetrical ~ on solid phases (SC) 947 [G.E. 1001]
Tetraaza[14]annulenes, Synthesis and stereochemical consequences of protonation of a bishomodihydro-~: a new macrocyclic complex ligand (SC) 765 [G.E. 812]
Tetrabenzporphyrin, Simple template synthesis of zinc ~ (SC) 760 [G.E. 808]
Tetra-tert-butylcyclopentadienone (SC) 519 [G.E. 551]
Tetra-tert-butyltetrahedrane (SC) 520 [G.E. 552]
Tetradecker complex, Synthesis and structure of the ~ bis(tricarbonylmanganese-μ,η-thiadiborolene)iron (SC) 527 [G.E. 558]
Tetrahedrane, C_4Li_4, Tetralithio-~? (SC) 276 [G.E. 306]
Tetra-tert-butyl-~ (SC) 520 [G.E. 552]
2-Tetrazenes, Triazene transfer with activated ~ (SC) 203 [G.E. 215]
1λ⁶,2,4-Thiadiazetidin-3-ones, Synthesis from tris(imido)sulfur(VI) derivatives and sulfonyl isocyanates (SC) 677 [G.E. 722]
Thiadiborolene, Synthesis and structure of the tetradecker complex bis(tricarbonylmanganese-μ,η-~)iron (SC) 527 [G.E. 558]
Thiaozonide, 2,3-Dioxa-7-thiabicyclo[2.2.1]-heptane: a new heterobicyclic system possessing the ~ structure (SC) 765 [G.E. 811]
Thiiranimine, A stable ~ (SC) 195 [G.E. 207]
Thioamides, Hydrosulfuration-thionation of unsaturated amides (SC) 689 [G.E. 722]
Thioacyl sulfides, Bis(thioacyl) sulfides from acyl ~ (SC) 675 [G.E. 718]
Thiocarbonyls, Transition-metal ~ and selenocarbonyls (LA) 216
Thioformaldehyde, Copolymerization of tetrameric ~ with oligomeric thioformaldehydes, substituted analogs, or sulfur (SC) 51 [G.E. 52]
Thioketene S-oxides, γ-Sultenes and 1,3-oxazolidinethiones by 1,3-dipolar cycloaddition of ~ to azomethines (SC) 455 [G.E. 480]
Thiol esters, A new method for selective activation of amino, hydroxy, and mercapto carboxylic acids at the carboxyl group: preparation of ~ and selenol esters (SC) 267 [G.E. 283]
Thionation, Hydrosulfuration-~ of unsaturated amides (SC) 689 [G.E. 722]
Thiooxalates as dithiabutadienes (SC) 953 [G.E. 1016]
Thiourea, Complex stabilization by bifurcated hydrogen bonds: bis[2-(o-methoxyphenoxy)ethoxyethyl] ether-~ (SC) 534 [G.E. 565]
Thromboxanes, Synthesis and biological properties of prostaglandin endoperoxides, ~, and prostacyclins (FP) 293 [G.E. 360]
Through-space interaction, Unusual benzene/benzene ~ (SC) 271 [G.E. 297]
Tin compounds, The first oxostannate(II): $K_2Sn_2O_3$ (SC) 449 [G.E. 475]
1λ³,4λ³-Diphospha-2,3,5,6,7-pentastannabicyclo[2.2.1]heptane, a bicyclic compound rich in tin (SC) 767 [G.E. 814]
Structure of the first open-chain diorganotin chalcogenide (SC) 939 [G.E. 995]
Titanium compounds, An organometallic complex with coordinatively bound water: $[\{(\eta\text{-}C_5H_5)_2Ti(H_2O)\}_2O][S_2O_6]$ (SC) 531 [G.E. 559]
An organotitanium compound with ylide clamps between two octahedrally coordinated metal atoms (SC) 601 [G.E. 628]
Toluene, 5-Methylenebicyclo[2.2.0]hex-2-ene, a bicyclic isomer of ~: synthesis and thermal behavior (SC) 606 [G.E. 641]
Toonacilin and 6-acetoxytoonacilin, two novel B-seco-tetranotriterpeniods with antifeeding activity (SC) 452 [G.E. 476]
Toxicological-chemical analysis, Die toxikologisch-chemische Analyse (Book Review) 71
Transfer ribonucleic acids, Protein biosynthesis: The codon-specific activation of amino acids (FP) 648 [G.E. 682]
~ (LA) 216
Transition metal complexes, Reactions between electrophiles and σ-bonded organo-~ (LA) 470
Triazene transfer with activated 2-tetrazenes (SC) 203 [G.E. 215]
2,2,2-Trichloro-tert-butyloxycarbonyl group (TCBOC) – an acid- and base-resistant protecting group removable under mild conditions (SC) 361 [G.E. 388]
Tricyclo[6.4.0.0^{4,9}]dodecane, Optically active ~ (SC) 851 [G.E. 899]
Tricyclo[3.1.0.0^{2,6}]hex-1(6)-ene, Existence of a new C_6H_6 isomer: ~ (SC) 848 [G.E. 904]
Tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene, Berson-Willcott rearrangement of 11,11-dimethyl-~ and its radical anion (SC) 208 [G.E. 216]
Trifluoromethanesulfonyl, Uses of the ~ group in organic synthesis (LA) 70
1,3,6-Trioxacyclooctane, Structural elucidation of diastereoisomeric ~ systems by simultaneous relaxation and double resonance experiments (SC) 447 [G.E. 472]
Triphenylphosphanes, Addition of water to o-phenylethynyl-substituted ~ (SC) 947 [G.E. 1003]
Triple bond, Stretching frequency and force constant of the tungsten-carbon ~ (SC) 50 [G.E. 51]
Triple-decker sandwich complexes, Paramagnetic ~ (SC) 868 [G.E. 917]
Triptycene derivatives, 8,13-Dichloro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene: atropisomerism about a C_{sp^3}–CH_2 bond (SC) 518 [G.E. 549]
Triptycenophanes – synthesis via "double nonbenzylic sulfone pyrolysis" (SC) 60 [G.E. 58]
Tris-σ-homobenzene, Thermolysis of endo,exo-tetracyclo[6.1.0.0^{2,4}.0^{5,7}]-nonane (trans-~) (SC) 440 [G.E. 470]
Rearrangement of ~-s to 1,4,7-cyclononatrienes (SC) 441 [G.E. 471]
Tris(imido)sulfur(VI) derivatives, Synthesis of 1λ⁶,2,4-thiadiazetidin-3-ones from ~ and sulfonyl isocyanates (SC) 677 [G.E. 722]
syn,syn-1,6:8,17:10,15-Trismethano[18]annulene (SC) 956 [G.E. 988]
syn,syn-1,6:8,17:10,15-Trismethano[18]annulene dication – dication of a [4nπ+2]annulene (SC) 957 [G.E. 990]
Troposphere, Mineralization of chlorofluorocarbons in the sunlight of the ~ (SC) 366 [G.E. 398]
Tryptathionine, L,L-3,6-[Methanothio(2,3-indolo)methano]piperazine-2,5-dione, the smallest phallotoxin model (SC) 54 [G.E. 67]
S-(2-Tryptophanyl)cysteine, L,L-3,6-[Methanothio(2,3-indolo)methano]piperazine-2,5-dione, the smallest phallotoxin model (SC) 54 [G.E. 67]
Tungsten compounds, Stretching frequency and force constant of the tungsten-carbon triple bond (SC) 50 [G.E. 51]
Olefin metathesis with polymer-bound ~ (SC) 131 [G.E. 131]
$[Au_2(WS_4)_2]^{2-}$, a novel inorganic ring system (SC) 52 [G.E. 57]
Turnip moth, (Z)-5-Decenyl acetate, a sex attractant for the male ~ Agrotis segetum (Lepidoptera) (SC) 768 [G.E. 815]

ULLMANN's Encyclopedia of Industrial Chemistry, Ullmanns Encyklopädie der technischen Chemie (Book Review) 217
Uranium fission, Lise Meitner: Her life and times – on the centenary of the great scientist's birth (FP) 826 [G.E. 876]
Urea, Transformation of ammonium cyanate into ~ (LA) 470
UV Spectroscopy, Higher-order derivative spectrophotometry for the fine resolution of UV/VIS spectra (SC) 532 [G.E. 563]

VALENCE states, Solid-state photochemistry — a method of generating unusual ~ (FP) 89 [G.E. 89]
Vanadium(V) complex, Dipicolinato(hydroxylamido-O,N)(nitrosyl)aqua-vanadate — a nitrosyl complex of vanadium with "side on" coordinated hydroxylamine (SC) 351 [G.E. 381]
Vanadocenes, A stable σ/π-organometallic radical of vanadium: $(\eta^5\text{-}C_5Me_4Et)_2V\text{—}C\equiv C\ C_6H_2Me_3$ (SC) [G.E. 912]
Vibrational spectra of organometallic compounds (Book Review) 542
Vinyl carbanions, Facile synthesis of functionally substituted cyclopentenones and butenolides from functional ~ (SC) 204 [G.E. 220]
Vinyl cation chemistry, Mechanistic and preparative aspects (FP) 333 [G.E. 346]
Vinylcyclopropanes, Metal-induced rearrangements and insertions into ~ (LA) 698
Vinyl ketones, Divinyl ketone as Michael acceptor (SC) 197 [G.E. 213]
Vinylsilanes, One-step synthesis of ~ and vinylenebis-silanes (SC) 279 [G.E. 288]
VIS Spectroscopy, Higher-order derivative spectrophotometry for the fine resolution of UV/VIS spectra (SC) 532 [G.E. 563]
WASP, Methyl-1,6-dioxaspiro[4.5]decanes as odors of Paravespula vulgaris (L.) (SC) 862 [G.E. 915]
Water, An organometallic complex with coordinatively bound ~: $[\{(\eta\text{-}C_5H_5)_2Ti(H_2O)\}_2O]S_2O_6$ (SC) 531 [G.E. 559]
β-Cyclodextrin dodecahydrate: crowding of ~ molecules within a hydrophobic cavity (SC) 694 [G.E. 738]
Addition of ~ to o-phenylethynyl-substituted triphenylphosphanes (SC) 947 [G.E. 1003]
Weitz type, Multistage organic redox systems — a general structural principle (FP) 875 [G.E. 927]
Wurster type, Multistage organic redox systems — a general structural principle (FP) 875 [G.E. 927]
XENON tetrakis(pentafluoroorthotellurate), $Xe(OTeF_5)_4$ (SC) 356 [G.E. 391]
YLIDE complexes, Synthesis and structure of the ylide complex $[(Ph_3P\text{—}C_5H_4)Co(CO)_2]^+[Co(CO)_4]^-$. Its use in the cyclotrimerization of alkynes (SC) 686 [G.E. 732]
Ylides, Novel di-~ containing tricoordinate phosphorus (SC) 199 [G.E. 209]
An organotitanium compound with ylide clamps between two octahedrally coordinated metal atoms (SC) 601 [G.E. 628]
ZINC tetrabenzporphyrin, Simple template synthesis (SC) 760 [G.E. 808]
Redox properties (SC) 951 [G.E. 1004]
"Zip" reaction, Use for the synthesis of a 53-membered polyaminolactam (SC) 200 [G.E. 210]
Zirconium(IV) compounds, The formation of stereoisomeric $(\eta^2\text{-aroyl})$arylbis$(\eta^5\text{-}$cyclopentadienyl)-~ (SC) 605 [G.E. 640]
