Mouse Histocompatibility Antigens

By Roland Henning[*]

In this article experimental findings and new theories concerning the chemical structure and biological function of histocompatibility antigens in the immune surveillance of virus-infected and malignant cells are discussed. Amongst these antigens, the H-2 antigens of the mouse have been studied most extensively. They are membrane bound glycoproteins causing the rejection of transplants from foreign tissue. One future aim of this field of research is to utilize the immune surveillance system in the therapy of diseases which as yet cannot be treated.

1. Introduction

Histocompatibility antigens are membrane bound glycoproteins which are responsible for the rejection of tissue transplants from foreign organisms. Recent results suggest that these membrane proteins participate in immune reactions in order to protect the body against virus infections and tumor formation. These antigens are polymorphic proteins which, in the mouse, are coded for in the histocompatibility complex located on chromosome 17 (see Fig. 1). Many findings made on this system which has been investigated best in the mouse, can also be demonstrated in the largely analogous human HL-A system.

Experimentally sound and properly interpreted observations on tissue rejection date from the turn of the century[1] when inbred mice strains (*i.e.* genetically uniform animal material) were reared. Mice from such an inbred strain are almost like identical twins. In 1938 *Gorer*[2] investigated the blood group system of the mouse and found that the antigen II which he had described correlated with tissue rejection and was genetically determined. This antigen II was later renamed the H-2 antigen[3]. In 1944 *Medawar*[4] described the phases of tissue rejection and applied these observations to human skin transplantations. The introduction of congenic inbred strains by *George D. Snell*[5] was the next critical step. Congenic strains are, for example, two inbred strains of mice which differ at only one locus in the histocompatibility complex. Antibodies specifically directed against a single gene product of the histocompatibility complex (alloantibodies) can be produced by cross immunization of such congenic strains. These alloantisera are the main tools of modern transplantation serology and with their aid histocompatibility antigens can be characterized, isolated and chemically investigated with a high degree of specificity.

Using immunogenetic methods, it was established that histocompatibility antigens and the specificity of humoral immune responses are often closely coupled. From this it was concluded that the responsible genes involved (Ir genes) must be coded for on the same chromosome as the H antigens[6]. In 1971 *Klein* and *Shreffler* put forward the hypothesis[7] that the histocompatibility antigen responsible for tissue rejection is coded for by two loci, the K and the D loci, which are on chromosome 17 of the mouse (two locus model). In addition to the K and D loci, the histocompatibility complex contains the above mentioned I region and also the S region. The latter codes for a certain component of the complement system. Figure 1 gives a schematic summary of the organization of the histocompatibility complexes on chromosome 17 of the mouse and chromosome 6 of man.

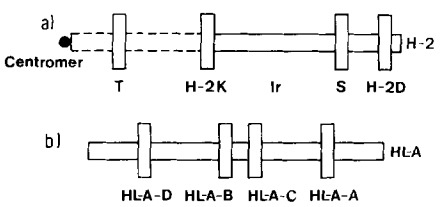

Fig. 1. H-2 and HL-A gene complexes (histocompatibility complexes). a) The H-2 gene complex on chromosome 17 of the mouse is limited by the K and D loci. The I and S regions are located within the gene complex. b) The HL-A gene complex on chromosome 6 of man is similar to the H-2 gene complex of the mouse apart from the fact that the HL-A-D region, which corresponds to the I region of the mouse, lies outside the loci HL-A-A and HL-A-B. The latter two loci are equivalent to the K and D loci of the mouse (according to [8]).

2. Chemical Structure of the H-2 Antigens

The histocompatibility antigens of the mouse (H-2 antigens) are found on almost all cells and in highest concentration on lymphocytes[8]. These substances are characterized by an extremely high, genetically determined polymorphism which is expressed by a variability in the amino acid sequence. H-2 antigens are integral membrane glycoproteins which consist of at least two polypeptide chains—a heavy chain with a molecular weight of approximately 45000[9] and a light chain with a molecular weight of 12000. The heavy chain (a glycopolypeptide) carries the antigenic properties. The light chain (a polypeptide) corresponds to β_2-microglobulin isolated from human urine[10]. In the mouse and man both chains are non-covalently associated[11–13].

2.1. Molecular Structure of H-2 Antigens in Solution

The following properties of the H-2 antigens make their isolation difficult: 1. their genetically determined polymorphism, 2. their low concentrations on the cell surface membrane and 3. their insolubility in aqueous media. Normal mouse lymphocytes or mouse leukemia cells which can be permanently maintained in culture are used as starting material.

H-2 antigens can be extracted from these cells with detergents (*e.g.* Nonidet P 40, sodium deoxycholate[14]) with little or no loss in their antigenic properties. Water soluble, fully immunologically active fragments of H-2 antigens can also be obtained by controlled proteolytic digestion of the cell surface with the plant protease papain[15].

Due to their low concentrations, H-2 antigens are preferably isolated after they have been radioactively labeled. Cells which have been labeled with ^{125}I or with ^{3}H- or ^{14}C-labeled amino acids are best for this purpose. H-2 antigens can be isolated from detergent or papain extracts of these labeled cells by immunoprecipitation and can be examined by SDS polyacrylamide gel electrophoresis. The molecular weights of the polypeptide chains and the nature of the binding between them are determined in this electrophoresis system with or without reducing agents (Table 1)[16].

On polyacrylamide gels of detergent-solubilized H-2 antigen ($H\text{-}2_{det}$) in the presence of reducing agents, a heavy chain (H chain) of molecular weight 46000 and a light chain (L chain) of molecular weight 12000 are observed. In the absence of reducing agents, the molecular weight of the heavy chain in the SDS gel is doubled (approximately 92000). After re-electrophoresis of this material in the presence of reducing agents (*e.g.* mercaptoethanol), only a heavy chain with a molecular weight of 46000 is found. Therefore, the heavy chains of H-2 antigens in detergent solution must be linked by at least one disulfide bridge to form a dimer. The light chains are not covalently bonded either to the heavy chains or to each other. Antigens solubilized with papain ($H\text{-}2_{pap}$) contain only a fragment (F_H) of the heavy chain with a molecular weight of 39000 and an intact light chain. In papain-solubilized material no disulfide bridges are found between the fragments of the heavy chain.

The molecular weights of H-2 antigens can also be determined under non-denaturing conditions (Table 1) by gel chromatography and ultracentrifugation[16]. Under these conditions the antigens can be monitored in their biologically active form by means of a biological test—the cytotoxicity inhibition test. The molecular weight of H-2 antigens in detergent solution was calculated to be 116000. From the determination of the molecular weights of the individual polypeptide chains by SDS gel electrophoresis and of the biologically active molecule in detergent solution a working model (Table 1 and Fig. 2) for the molecular structure of the H-2 antigens can be postulated[16]. In detergent solution there are two heavy chains which are linked by at least one disulfide bridge and two non-covalently associated light chains. The papain-treated molecule contains only one fragment of a heavy chain (F_H) and one light chain. Similar findings hold for the human HL-A antigens.

Table 1. Molecular weight (M_r) determinations of denatured H-2 antigens by SDS gel electrophoresis and of biologically active H-2 antigens in detergent or papain solution by Sephadex gel chromatography ("gel filtration") and ultracentrifugation [16]. Abbreviations: r = Stokes radius; D = diffusion constant; S = sedimentation constant; DOC = Na deoxycholate; SDS = polyacrylamide gel electrophoresis in Na dodecylsulfate; red. = reduced with mercaptoethanol; H chain, L chain, β_2, F_H see Fig. 2.

Antigen	M_r	Gel filtration		Ultracentrifugation
		r [Å]	D [$cm^2\,s^{-1}$]	S
Detergent-solubilized H-2-antigens (DOC) ($H\text{-}2_{det}$)	116000 [a]	47	$4.5\cdot10^{-7}$	5.9 S
H-chain (unreduced, SDS)	92000			
H-chain (reduced, SDS)	46000			
L-chain (β_2) (red. + unred., SDS)	12000			
2H + 2L (SDS)	116000			
Papain-solubilized H-2-antigens ($H\text{-}2_{pap}$)	49000	31	$6.9\cdot10^{-7}$	3.7 S
H-chain (F_H) (red. + unred., SDS)	39000			
L-chain (β_2) (red. + unred., SDS)	12000			
1 F_H + 1 L	51000			

[a] Calculated according to the Svedberg equation.

2.2. Molecular Structure and Orientation of H-2 Antigens at the Cell Surface

The biological functions of H-2 antigens are expressed on the cell surface. It is therefore extremely important to know whether the structural model for the solubilized H-2 antigens

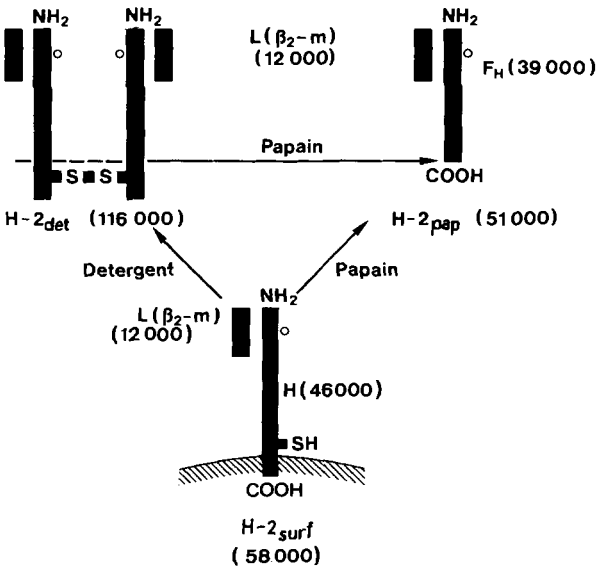

Fig. 2. A model of the molecular structure of H-2 antigens on the cell surface and in solution. The H-2 antigens are solubilized with non-ionic detergents or papain. Abbreviations: L(β_2 – m) = light chain (corresponds to β_2-microglobulin); H = heavy chain; $H\text{-}2_{pap}$ = water soluble fragment after papain treatment; F_H = papain fragment of the H chain; $H\text{-}2_{det}$ = detergent-solubilized H-2 antigen; $H\text{-}2_{surf}$ = H-2 antigen at the cell surface; ○ = carbohydrate. The molecular weights are given in brackets (modified according to [16]).

is equally applicable to the antigens bound to the cell surface. In order to establish whether H-2 antigens at the cell surface are also dimers with disulfide bridges, intact cells were treated with iodoacetamide before detergent extraction; free SH groups are thus already blocked on the surface of the intact cells[16]. If immunoprecipitates of these alkylated cells are examined by SDS gel electrophoresis, it is seen even in the absence of reducing agents that the heavy chains of the H-2 antigens exist mainly as monomers whereas, as has already been mentioned, the heavy chains of H-2 antigens from non-alkylated cells are disulfide linked dimers. This implies that the disulfide bridges are formed during or after detergent extraction of the antigen from the cell membrane (Fig. 2). Non-covalently associated dimers are perhaps already formed in the membrane. Mild oxidizing agents can initiate the formation of disulfide bridges between heavy chains and thus increase the concentration of membrane-bound, disulfide-bonded dimers[16]. Apparently however, dimer hybrids (*e.g.* between the products of the K and D loci or between the K and D antigens of different H-2 types (haplotypes)[17,18]) are not formed.

The orientation of the peptide chains of the H-2 antigens on the cell membrane is also very important for understanding their biological functions. For this purpose the N-terminal amino acid sequence of the heavy chains of the detergent-solubilized H-2 antigens is compared with that of the F_H fragment from the papain-cleaved material. Using this method it can be shown which end of the heavy chain is directed outwards and which end is associated with the cell membrane. Radiochemical sequence analyses of the heavy chains and their papain fragments demonstrate that the positions of tyrosine, histidine and arginine (positions 3, 6 and 7 respectively) are identical[16]. From this it can be concluded that the C-terminal end of the H-2 antigen is associated with the membrane and is cleaved off during papain treatment so that a new C-terminal end is formed on the cleaved fragment. Consequently, the N-terminal end is directed outwards. This arrangement resembles the orientation of the few sequenced membrane proteins (*e.g.* glycophorin or immunoglobulin[19–21]). Figure 2 shows the present concepts of the molecular anatomy of H-2 antigens.

2.3. Comparison of the Protein Chemistry of the H-2K and H-2D Gene Products

According to the results of immunogenetic analyses, it can be assumed that the H-2K and H-2D genes arose by gene duplication[7]. Can a molecule be recognized as being a K or D antigen solely on the basis of its physical or chemical properties? It is conceivable that the differences between the two types of gene products could be established by the following methods: 1. molecular weight determination of the heavy chains, 2. comparative peptide analyses after enzymatic cleavage, 3. amino acid sequence analyses.

Comparison of the behavior of the heavy chains of the K or D antigens on SDS polyacrylamide gel electrophoresis shows slight but exactly reproducible differences. On a molecular weight scale these small differences never amount to more than approximately 5 %[22]. These variations cannot be interpreted with certainty as being due to differences in molecular weight, they could also be explained by differing binding capacities for SDS due to different carbohydrate structures. The behavior of the heavy chains on fragmentation with clostridiopeptidase, papin or chemical methods exhibits characteristic features for each gene product; neither in this case, however, is it possible to derive generally valid rules which could serve as criteria for the recognition of K or D gene products[22].

Comparative peptide analyses of tryptic fragments of different H-2 antigens on ion exchange columns[14] or by two-dimensional thin layer chromatography[22] give the same results. These peptide analyses show a high degree of similarity which is to be expected in the case of gene duplication; the differences are not however characteristic of the K or D gene products. The results of amino acid sequencing will be fully discussed below. In summary it can be said that, as yet, there are no unequivocal physical or chemical criteria for distinguishing between the K and D gene products.

Fundamental questions concerning the molecular principles of polymorphism, the evolutionary relationships between histocompatibility antigens and immunoglobulins, and finally the molecular biology of their function can be answered solely by unravelling the primary structure of the antigenic units of the H-2 antigens.

The complete amino acid sequence of human β_2-microglobulin has been reported[23,24]. This molecule shows very striking similarities with the constant regions of the heavy and light chains of immunoglobulins. This finding has restarted speculation about a common evolutionary origin for histocompatibility antigens and immunoglobulins (cf. Section 1)[25,26]. β_2-Microglobulin is only species specific (*i.e.* no differences have been found between individuals of the same animal species). The variation between species is not very marked. If the amino acid sequences of the microglobulins from the guinea pig, rabbit, dog and mouse are compared with that of man, only a few differences are observed[27]. These amino acid sequences are compiled in Table 2.

The polymorphism, and thus the antigenic properties of the H-2 antigens, are limited to the heavy chains. Their low concentrations together with the hydrophobic nature of the K and D antigens, demanded a new approach for their isolation and sequence analysis. Conventional Edman degradation techniques cannot be directly applied to establish their primary structures; radiochemical sequencing methods must be used[28]. The technique of indirect immunoprecipitation with monospecific H-2 antisera was utilized to isolate the K and D antigens. H-2 antigens from mouse lymphoma cells are individually labeled in tissue culture with either ^{3}H- or ^{14}C-labeled amino acids. The cells are then extracted with the detergent Nonidet P 40. The antigenic properties of the H-2 antigens are not affected by non-ionic detergents, the H-2 antigens can be precipitated out of the mixture of labeled proteins by a monospecific mouse anti-H-2 antiserum and subsequent addition of goat anti-mouse immunoglobulin. Subsequently, the antigens are isolated by preparative SDS polyacrylamide gel electrophoresis. After addition of a carrier protein, this material can be subjected to sequential Edman degradation in an automatic protein sequencer. The resulting phenylthiohydantoin amino acids can be identified by thin layer chromatography or high pressure liquid chromatography (for a discussion of this methodology see[22]). The N-terminal amino acid sequences of the H-2 and HL-A antigens are compiled in Table 2.

Table 2. Comparison of the partial N-terminal amino acid sequences of H-2 antigens (mouse) [16, 22, 29—32, 74], HL-A antigens (human) [33—35] and β_2-microglobulins (human, rabbit, dog, mouse and guinea pig) [23, 24, 70—73]. X: Amino acids which have been identified at this position in other H-2 haplotypes were not found in this location. □: These positions are common to H-2 and/or HL-A antigens and/or β_2-microglobulins.

All five H-2-gene products given in Table 2 have N-terminal amino acid sequences which are largely homologous within the first 30 positions. This observation supports the theory proposed by *Klein* and *Shreffler* in 1971[7] which states that the K and D loci arose by gene duplication. The homology of the N-terminal sequences is so extensive that the expected polymorphism can be recognized only at a small number of positions. In addition to the positive differences, it was also shown that certain amino acids were absent in individual gene products (positions indicated by X in Table 2). The absence of methionine from position 1 in K^b, of proline, valine and valine from positions 2, 9 and 12 respectively in K^d are examples of such negative variations. The amino acids in these positions have still not been identified due to the limitations of the methodology.

H-2 and HL-A antigens apparently are structurally homologous. The N-terminal amino acid sequences of several HL-A gene products were reported almost simultaneously by two laboratories[33–35]. Sequence analyses of the HL-A antigens were performed by conventional Edman degradation methods. If the N-terminal sequences of H-2 and HL-A antigens are aligned, it can be seen that the same amino acids can be found in at least 13 of the first 27 positions. The amino acids in positions 6, 7, 15, 20 and 27 are the same in all cases. In positions 8, 10, 12 and 14 the variation is small. The products of the two gene loci of one system (*e.g.* the H-2 system) resemble one another much more than the products of the corresponding loci from other species. From this, it can be concluded that gene duplication in the two species mouse and man took place independently and after the evolution of the species had occurred. From Table 2 it can also be seen that the H-2 and HL-A antigens have several positions in common with those of β_2-microglobulins from various species. Although it can be presumed that β_2-microglobulins are evolutionarily related to the heavy chains of the histocompatibility antigens, the sequence homologies shown in Table 2 only allow very vague conjectures to be made about the extent of this relationship.

The long suspected structural homologies between immunoglobulins and histocompatibility antigens have recently been shown to be probably correct. Partial amino acid sequences of internal peptides from the heavy chains of HL-A antigens have been examined[35]. *Strominger et al.* found extensive sequence homologies with the immunoglobulins in the vicinity of the third cysteine residue of the heavy chain of HL-A antigens (see Fig. 3) and thus, could provide evidence for the long discussed theories of evolutionary and structural relationships between the two systems[25, 26]. The tentative positions of the intrachain disulfide bridges also suggest that there is a structural and therefore an evolutionary

relationship between histocompatibility antigens and immunoglobulins (Fig. 3).

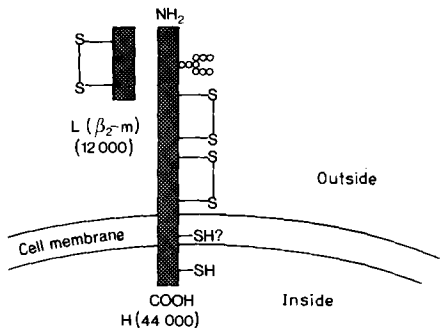

Fig. 3. Model of an HL-A antigen on the cell surface (modified according to [35]). This model indicates the position of the disulfide bridges in the heavy chains which, like the immunoglobulins, are arranged in a "domain structure". The binding site for β_2-microglobulin in the N-terminal region is a theoretical assumption and is not based on experimental findings.

The supposition that there is an evolutionary relationship between H antigens and immunoglobulins is also supported by the additional sequence homologies which have recently been established between immunoglobulins, C-reactive protein and components of the complement system[36, 37] all of which belong to the immune system. Phylogenetic studies of the individual components suggest that the histocompatibility antigens appeared earliest in evolution. Biological evidence for transplantation immunity has recently been obtained from coral reefs[38]. Transplanted sections of coral reefs are rejected and, what is more important, on repeated transplantation this occurs in a considerably shorter time (immunity including memory).

The application of the radiosequencing technique to H-2 antigens obtained by highly specific immunoprecipitation methods soon yielded a series of fundamental results. A completely new methodology was developed for the investigation of the primary structure of membrane proteins which had, until then, remained inaccessible to structural analysis. Thanks to the method of isolation by immunoprecipitation, all cell membrane antigens against which specific antibodies can be raised are now open to detailed structural studies. In the human HL-A system structural homologies between immunoglobulins and histocompatibility antigens could be demonstrated by conventional sequencing procedures as a result of higher concentrations of HL-A antigens on lymphoma cells.

3. Histocompatibility Antigens as Recognition Sites in Immune Defense

The transfer of tissues between individuals fails due to histocompatibility antigens which constitute the biological barrier for tissue transplants. Special cells of the immune system, T lymphocytes which are transformed into killer cells, destroy foreign cells; this is one basic principle of the cellular immune response. Tissue transplantation did not contribute to the evolutionary process and, therefore, one can assume that these very potent defense mechanisms must perform an important function within the individual organism[25]. Transplantation antigens seem to be marker proteins for distinguishing abnormal cells from the individual's own, normal cells. According to the most recent findings, H-2 antigens are involved in the recognition and destruction of abnormal cells by cytotoxic lymphocytes. Examples of abnormal cells which must be recognized and eliminated are virus-infected cells, chemically modified cells and tumor cells.

3.1. Histocompatibility Antigens are Necessary for the Elimination of "Foreign" Cells

The effectiveness of cytotoxic cells produced to act against abnormal cells seems to depend on whether an H-2 antigen originally present on the cells used for immunization also exists on the target cell[39]. The following model experiment should serve to explain this complicated process: an inbred mouse (which has for example type H-2^b histocompatibility antigens) is infected with virus X and cytotoxic lymphocytes directed against the virus-X-infected cells are produced in the animal. The lytic activity of these lymphocytes can be detected by a cytotoxicity test in which the release of ^{51}Cr from ^{51}Cr-labeled target cells is followed. In the present experiment only those ^{51}Cr-labeled target cells are recognized and killed which (*i*) are infected with the same virus X and (*ii*) have the same type H-2^b histocompatibility antigens as the virus-X-infected cells[39]. The model experiment described has been tested on a large number of different type H-2 mouse strains and cell lines with several viruses (ectromelia[40], lymphocytic choriomeningitis[41], Sendai[42], SV-40[43], rabies[39], mouse sarcoma[44], Friend's mouse leukemia[45] and vaccinia[46]). In most cases a clear dependence on the type of H-2 antigen was observed (H-2 restriction). Similar results were found by chemical modification of the cell surface with trinitrobenzenesulfonic acid (TNB)[47]. The universal importance of these observations was further underlined by similar findings made on virus transformed tumor cells[48–50].

These observations can be summarized as follows:

1. If the cytotoxic cell and the target cell are syngeneic (*i.e.* their surfaces carry the same H-2 antigens), an additional antigen (neoantigen) is required for the recognition and destruction of the target cell (*e.g.* a virus antigen, a chemically modified protein or a tumor antigen, one of the weak H antigens[51, 52] or the product of the Y gene[53]).

2. If the histocompatibility antigens of the cytotoxic lymphocyte and the target cell are different (allogeneic situation), an additional antigen is not necessary for recognition and destruction of the target cell. This situation corresponds to that in tissue transplantation.

3. Cytotoxic lymphocytes must have been confronted with at least one H-2 gene product (K or D) of the target cell during the immunization process.

4. Anti-H-2 sera which are directed against the H-2 antigens of the target cell and are added to the target cells before contact with the cytotoxic lymphocytes, block the activity of the cytotoxic lymphocytes; the target cell is not destroyed.

5. Mutations in an H-2 antigen known to the cytotoxic lymphocytes, block all cytotoxic activity; the target cell is not destroyed[57].

A greatly simplified hypothesis explaining these findings would be that all the processes in cell destruction which are directly dependent on cytotoxic lymphocytes proceed only with the aid of the H-2 antigens. The reaction mechanisms in both the syngeneic and allogeneic situations seem to be the same. In the allogeneic case only the foreign H-2 antigen

and not the additional neoantigen is necessary for recognition. From this it could be concluded that an H-2 antigen which has been modified by the neoantigen ("altered self")[39] is employed for recognition of the foreign material in the syngeneic case.

3.2. "Killer" Cells Require One or Two Receptors for the Destruction of Target Cells

In 1959 *Lawrence* had already put forward an hypothesis according to which abnormal cells in an individual can only be destroyed in a cytotoxic reaction if, in addition to a known antigen, an antigen X is recognized[54]. This "self" plus X antigen was supposed to form a molecular complex and corresponds in principle to what, much later, was described as the basis of T-B cell collaboration[55, 56]. According to present experimental findings, virus-coded antigens and tumor transplantation antigens (see Figs. 6 and 7) can act as X antigens and together with H antigens as "antigen hybrids", serve as recognition sites.

Two hypotheses explaining these processes are currently under discussion. How can cytotoxic lymphocytes recognize only one antigen (the alloantigen) in an allogeneic situation and the syngeneic antigen + neoantigen in a syngeneic situation? In the syngeneic situation it has to be assumed that the cytotoxic lymphocyte possesses two separate receptors (two-receptor model)—one receptor for the recognition of the syngeneic H-2 antigen and another for the neoantigen. It could also be possible, however, that the cytotoxic lymphocyte has only one receptor which recognizes a molecular complex formed from the H-2 antigen and the neoantigen (antigen hybrid) or a modified H-2 antigen ("altered self") (one-receptor models). In the allogeneic situation only one receptor is required, and therefore a theory must be postulated in which one receptor in the syngeneic situation is sufficient.

3.3. "Killer" Cells with One Receptor for the Destruction of Target Cells

Some experiments which support the one-receptor model will now be briefly described. Due to spatial considerations (*i.e.* the maximum possible length of a protein receptor), it is necessary that a molecular complex consisting of the H-2 antigen and the neoantigen is formed. The antigenic determinant is either a cell product, namely the H-2 antigen, which has been modified by physical or chemical interaction with the neoantigen or is one determinant formed from both the H-2 antigen and the neoantigen (H-2-antigen-virus-antigen hybrid complex). Since, in this case, the H-2 antigens still react with the relevant monospecific H-2 antisera and the cytotoxic reaction can thus be blocked, it must be presumed that the serological properties of the H-2 antigens have not been altered. The modification therefore cannot be due to drastic chemical changes but to slight alterations which do not affect the antigenic determinants. Chemical modifications are unlikely because even simple mutations in the H-2 antigen completely block the cytotoxic reaction[57]. Recent experiments in which the neoantigen was added externally in the form of an inactivated Sendai virus[58] also largely ruled out a direct chemical modification of the H-2 antigen by the neoantigen.

Molecular associations on the cell surface can be studied with the simple experimental technique of "cocapping" (see Ref.[59] and Figs. 4 and 5). Antibodies coupled to a fluorescent dye are used to specifically label certain cell surface antigens. After a few minutes, patching occurs on the cell surface by passive diffusion. If the cells are incubated for a further 15–30 min at 37 °C, the small, fluorescently labeled aggregates slowly cap at one pole of the cell. If one wants to see whether another molecule is also moved during this process, a second fluorescently labeled antibody directed against this molecule must be added. After capping of the first antigen, the second antigen is either diffusely distributed over the cell surface or is at the same pole of the cell as the first antigen. Simultaneous observations of this type are made possible by the fact that the two antibodies are coupled to different fluorescent dyes which can be distinguished by suitable choice of filters and the wavelength of the ultraviolet light (Fig. 4).

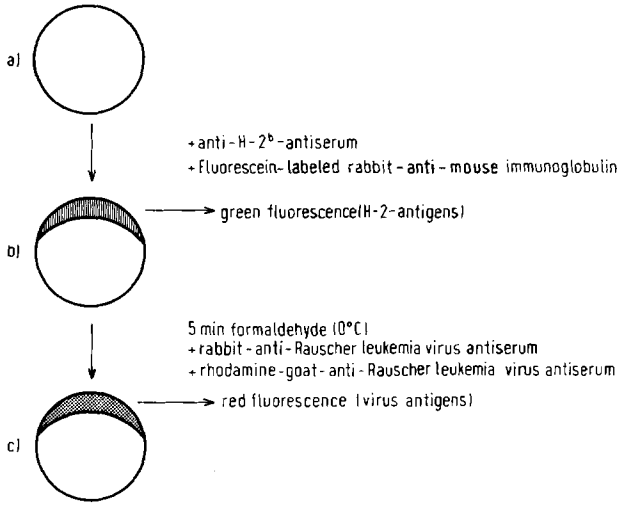

Fig. 4. Experimental scheme for inducing "cocapping" of H-2 antigens and leukemia virus antigens in mouse leukemia cells. a) Mouse lymphoma cells (H-2^b) infected with leukemia virus; b) H-2 antigens at one pole of the cell after capping; c) virus antigens in the same position as the H-2 antigens after cocapping.

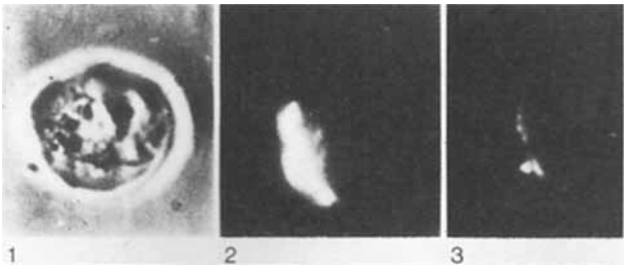

Fig. 5. Cocapping of H-2 antigens and leukemia virus antigens (see also Fig. 4). 1. Phase contrast photograph of a mouse leukemia cell (EL 4). 2. "Capping" of H-2 antigens (visualized by immunofluorescence (fluorescein). 3. "Cocapping" of leukemia virus antigens (visualized with rhodamine coupled antibodies). Results taken from Ref. [48].

The following problem has been investigated with this experimental procedure—do virus antigens (*e.g.* mouse leukemia virus glycoprotein gp 69/71) cocap after capping of H-2 antigens in type H-2^b mouse lymphoma cells (*e.g.* EL-4 cells),

or are they diffusely distributed over the cell surface? In almost every case virus antigens were cocapped with H-2 antigens[48]. An example is shown in Figure 5. Similar findings were obtained[62] with another serological method—the "lysostrip" technique[60,61]. Although both types of results are no direct evidence for the formation of an antigen-virus antigen hybrid complex, they can however be used for a working hypothesis (Fig. 6).

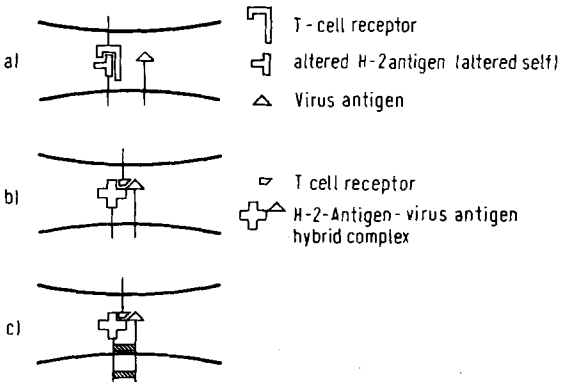

Fig. 6. One-receptor models for the immune surveillance of virus-infected cells or tumor cells by cytotoxic lymphocytes. Presentation of the participation of histocompatibility antigens. a) Cytotoxic lymphocytes (killer cells) possess one receptor which recognizes an H-2 antigen modified by the neoantigen ("altered self"). b) A T cell receptor recognizes a hybrid formed from H-2 and virus antigens by protein interactions. c) As b) but additional contractile proteins lying above or below the cell surface are necessary.

It is not easy to describe the chemical and physical basis of molecular associations of this type. Do stoichiometric ratios have to be presumed (*i.e.* complexes made up of one H-2 antigen and one virus antigen) or can larger, non-stoichiometric molecular associations between the two antigens be expected? If only 1:1 complexes exist, each of the two molecules should possess one specific, monovalent binding site which does not permit any further linkages. If the H-2 antigens have a strong tendency to associate with other proteins, then they will form molecular complexes with many different cell surface proteins (*e.g.* with weak histocompatibility antigens[51,52] and the product of the Y gene[53]). In the case of a multispecific binding site the degree of association between the H-2 and virus antigens as observed in the "cocapping" and "lysostrip" experiments would be extremely high.

The results of the "cocapping" and "lysostrip" experiments can, however, also be accounted for by special binding properties of the virus proteins. For functional reasons virus proteins have a high capacity for adsorbing onto cell surface proteins and could therefore also form molecular complexes with H-2 antigens in the cell membrane. In this case, the extent of H-2 antigen-virus antigen hybrid complex formation as observed in the cocapping experiments would not be necessary for the cytotoxic reaction. However, the interpretation of these findings with regard to the mechanism for the cytotoxic reaction would be correct. It is known that H-2 antigens do not build such strong molecular complexes with other cell surface antigens which have been studied. H-2 antigens do not form complexes amongst themselves, neither are they associated with immunoglobulins or Ia antigens as has been shown in "cocapping" and "lysostrip" experiments[17,48,61–63].

No currently known experiments allow a definite decision to be made in favor of a single receptor model of the recognition and elimination of abnormal cells by cytotoxic lymphocytes.

3.4. "Killer" Cells with Two Receptors for the Destruction of Target Cells

In this model (Fig. 7a), the cytotoxic lymphocyte possesses two receptors: one which specifically recognizes H-2 antigens (H-2 receptor) and another for neoantigen. The H-2 receptor can be genetically determined on a similar basis as the products of the H-2K and H-2D loci. Furthermore, a mouse must always have a stock of cells which have receptors for all H-2 antigen types. Those H-2 receptors which recognize syngeneic H-2 antigens must be selected by special tolerance mechanisms so that they can recognize very slight differences from the individual's cells. The neoantigen receptor needs a high degree of polymorphism in order to recognize a large number of different antigens.

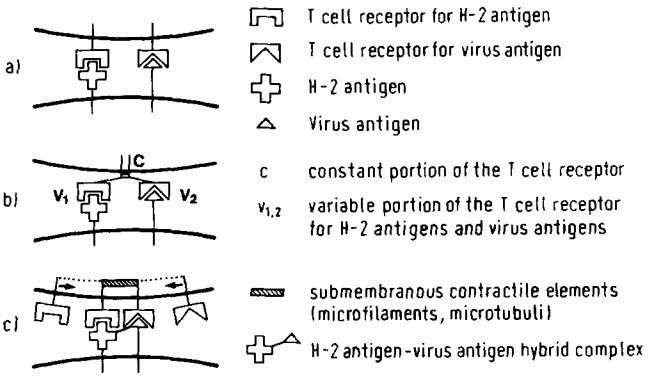

Fig. 7. Two-receptor models for the immune surveillance of virus-infected cells or tumor cells by cytotoxic lymphocytes. Representation of the participation of histocompatibility antigens. a) Cytotoxic lymphocytes ("killer" cells) possess two genetically separately coded receptors for H-2 antigens and neoantigens. b) Cytotoxic lymphocytes have a bivalent disulfide linked immunoglobulin-like receptor with two different variable regions and two possibly identical constant regions. c) Two receptors as in a); the two receptors can be drawn together by a hybrid complex and thus trigger signals for cell division and differentiation of T lymphocytes (see also Ref. [68]).

With the introduction of a second receptor system, a problem arises which initially seems to contradict a two receptor model. According to the known serological and cell immunological findings, the two receptors must both be present on the same cytotoxic cell. This was shown by using simultaneously cytotoxic T cells directed against either the H-2 antigens or the neoantigen. Cytotoxicity against the desired target cell (having a defined H-2 antigen and a defined neoantigen) could not be produced by mixing these two types of T cells. The frequency expected for a clonal distribution of two polymorphic receptors on the same cell should be sufficiently high to initiate a cellular immune response. Since the statistical probability of two heterogeneous receptors on one cell is low, a two-receptor model in this form still involves many problems.

It can easily be imagined from this large number of arguments how confused the situation still is at the present time. Although serological and cell immunological experiments have recently been greatly improved, and several combinations have

been tested, little progress is being made in present discussions (for summaries see Ref. [64]). Significant progress can only be expected either when direct evidence is obtained for the formation of an H-2-antigen-virus-antigen hybrid complex, or when two types of T cell receptors can be demonstrated on the same cell. Very elegant and promising experiments have been reported by two laboratories which seem to characterize at least one T cell receptor in molecular terms[65, 66]. It appears to be an immunoglobulin-like molecule consisting of two disulfide linked polypeptide chains ($M_r = 72000$) with a variable region (V_H) as in normal immunoglobulins (see Figs. 7b and 7c).

4. Implications and Applications

Attempts to combine the results of chemical structural analyses and the biological observations of H-2 antigens do not yet yield a comprehensive picture. The most important recent results can be easily summarized by considering structure and function in isolation from each another.

As far as structure is concerned, the current state of knowledge allows one to postulate a molecular model as a working hypothesis. This model describes the number of subunits, their interactions and their orientation on the cell surface. Furthermore, sequence analyses demonstrate genetic relationships between the K and D products with the histocompatibility antigens of other species (man) and even with immunoglobulins. In order to derive structural rules one needs the total amino acid sequence of the heavy chains of the histocompatibility antigens. Only by this approach can the localization of the antigenic determinants and the molecular principles of polymorphism be elucidated.

Knowledge of the primary structure of β_2-microglobulin revealed evolutionary relationships to immunoglobulins. This has not led to any progress with regard to the function of the histocompatibility antigens. It is open to discussion whether β_2-microglobulin could be a general acceptor for a T cell receptor. It is conceivable that the T cell receptor has a constant binding site (C region) for the β_2-microglobulin and a variable region (V region) for the antigenic site on the heavy chain of the H antigen or the antigenic determinant of a hybrid complex. On the other hand, β_2-microglobulin could also bind a complement component to trigger the disintegration of the target cell[67].

In 1959 *Thomas*[68] wrote that nature had not invented H antigens in order to make the life of the transplant surgeon difficult. Recent results show that the rejection of foreign cells and the elimination of the body's own abnormal cells are subject to similar rules. The examples of abnormal cells cited (virus-infected cells, tumor cells) appear so frequently during the long lifetime of a vertebrate organism and their effects are so strong that a pressure for an evolutionary selection to create and maintain such a defense system seems to be justified. This system seems to have developed from rejection systems of simple multicellular organisms. In sponges, for example, a high degree of specificity in cell-cell contact has been shown. In organisms of this type which live closely packed together in a confined environment, this principle is extremely important for the preservation of biological individuality. In addition, transplantation immunity including memory effects has been demonstrated in simple multicellular organisms such as corals[38]. In vertebrates the danger lies not so much in the mixing of cells from different individuals, but rather in the alteration of the cells within one organism by virus infections, tumor formation and somatic mutations. A teleological basis for the presence and functioning of such a system can be easily imagined.

The discussion as to whether a one- or two-receptor model operates in T lymphocytes may end in a compromise. Firstly, there could be two types of variable gene products which are clonally distributed on the T cells. The first variable gene product, the H-2 antigen receptor, is very strongly selected for the recognition of syngeneic H-2 products. The number of clones needed for H-2 recognition is thus greatly reduced. The statistical problems involved in the existence of two variable receptors on one cell would then be easier to resolve. However, the second variable gene product, the neoantigen receptor, still requires a broad diversity.

Secondly, it can be argued that two variable receptor proteins are linked together in the form of two subunits in a bivalent receptor (Fig. 7b). A bivalent T cell receptor of this type would also explain the unresolved problem of the molecular association between H antigens and neoantigens, since the T cell receptor itself produces this association. In this model it would be very easy to imagine the function of the β_2-microglobulin as being that of a contact protein for a T cell receptor.

Thirdly, two variable but physically separate T cell receptors can be pulled together by submembranous contractile elements as a result of binding to an H-2 antigen-neoantigen hybrid complex on the surface of the target cell (Fig. 7c). This process could trigger a signal which initiates the proliferation of the competent T cell. The triggering of signals for cell division and differentiation of lymphocytes by the binding of extracellular substances to cell surface proteins is already known in several systems[69].

Most of the current serological and cell immunological findings as well as the "cocapping" and "lysostrip" experiments outlined above point rather to a one-receptor model.

The immune defense system has reached a high degree of complexity. In such complex systems the susceptibility to errors increases rapidly. The control of errors and quality is only satisfactorily effective if all elements of the system are intact. In this respect the immune system resembles the central nervous system which compensates for the loss of active elements in the aging process with memory cells. This principle operates very effectively in common bacterial and viral infections. In old age, tumor cell transformations are perhaps no longer recognized with certainty because of the absence of competent memory cells and the much less frequent formation of tumor cells. No further evolutionary progress can be expected because reproduction stops in old age and the present increase in life-span no longer affects selection.

The experiments described above and their discussion make it clear that neither chemistry nor biology can answer the most important questions concerning this area of research. The medical importance of histocompatibility antigens has so far been limited mainly to the problems of organ transfer. Long term successes have only been achieved in special cases (*e.g.* in kidney transplantations). The understanding of the functions of the histocompatibility antigens in the immune

surveillance of abnormal cells is not sufficient to develop a therapy which makes active use of the immune surveillance system. With precise molecular data it will be possible to use biological methods to successfully deal with diseases due to defective regulatory cell mechanisms. Chronic viral diseases and associated defective defense reactions (*e.g.* possibly multiple sclerosis and cancer) belong to this category. A new type of immunotherapy will perhaps soon be possible by using killer cells cultured *in vitro* which are specifically directed against individual cancer cells. After the great success of chemically and bacteriologically synthesized drugs this could be the beginning of an era of scientifically based cell therapy.

A large number of the experiments described were carried out in Dr. G. M. Edelman's laboratory at the Rockefeller University, New York. The author thanks Dr. G. M. Edelman as well as the members of his department—Drs. B. A. Cunningham, R. J. Milner, J. W. Schrader, K. Reske and J. A. Ziffer—for their generous support and stimulating discussions without which this report could not have been written.

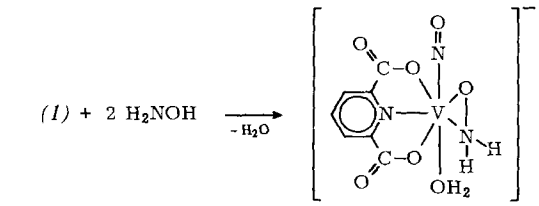
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Dipicolinato(hydroxylamido-*O*,*N*)(nitrosyl)aqua-vanadate—A Nitrosyl Complex of Vanadium with "side on" Coordinated Hydroxylamine[**]

By *Karl Wieghardt*, *Udo Quilitzsch*, *Bernhard Nuber*, and *Johannes Weiss*[*]



Vanadium(V) undergoes reduction with hydroxylamine in alkaline or acidic aqueous solution; depending upon the reaction conditions N_2, N_2O, and NO (as well as NH_3) may be formed[1]. A vanadium(V)-hydroxylamine 1:1 complex has been shown to exist in acidic solution[2] but so far has not been isolated.

Reaction of five-coordinated *cis*-dioxo(dipicolinato)vanadate(V) ion *(1)*[3] with hydroxylammonium chloride in weakly acidic solution (25 °C) affords a colorless neutral complex *(2)*, which on the basis of its analytical and IR spectroscopic data can be formulated as μ-oxo-bis[oxo(dipicolinato)(hydroxylamine-*N*)vanadium(V)].

(1) *(2)*

In alkaline solution *(1)* reacts quantitatively with hydroxylamine (1:2) without evolution of gas (!) to give deep-red solutions. Addition of solid KCl or CsCl yields air stable crystalline potassium and cesium salts, respectively. The IR spectra of these salts show the characteristic bands of the coordinated dipicolinato ligand (dipic)[3] and a strong band at 1530 cm^{-1} which we assign to a ν(N=O) vibration.

(3)

The structure of the anion *(3)* was determined by X-ray spectroscopy (Fig. 1). $Cs[V(dipic)(H_2NO)(NO)(H_2O)]\cdot 2H_2O$ crystallizes in the orthorhombic space group D_{2h}^{11}-Pcmb with $a = 839.4(3)$, $b = 884.3(2)$, $c = 1936.1(6)$ pm, $Z = 8$. Refinement with structure factors of 1260 observed independent reflections $[I > 2.58\sigma(I)]$ converged to an unweighted R value of 5.9 %. The positions of the H atoms could not be determined because of the poor quality of the crystals (platelets).

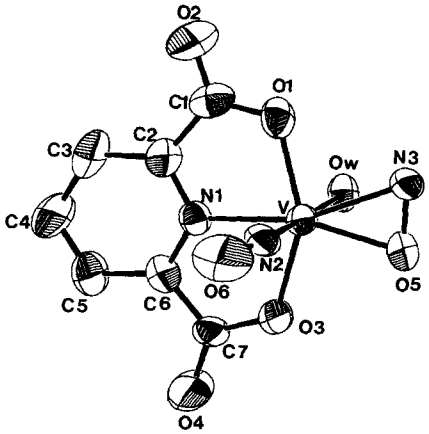


Fig. 1. Structure of the complex anion *(3)* in $Cs[V(dipic)(H_2NO)(NO)(H_2O)]\cdot 2H_2O$ (without H atoms). Important bond lengths [pm] and angles [°]:

V—N1	211.0(14)	V—O1	207.9(17)	N2—O6	119.6(23)
V—N2	169.3(17)	V—O3	210.5(14)	N3—O5	141.7(26)
V—N3	205.4(17)	V—O5	201.5(12)	V—Ow	217.2(16)

V—N2—O6	175.7(16)	N2—V—Ow	178.0(8)
N3—V—O5	40.7(7)	O1—V—O3	148.4(5)
V—N3—O5	68.1(8)	V—O5—N3	71.1(9)

The central vanadium atom is surrounded by a distorted pentagonal-bipyramidal array of tridentate dipicolinate ligands, a bidentate hydroxylamido ligand and—in the axial positions—a nitrosyl and an aqua ligand (the formal coordination number is 7) (Fig. 1). The hydroxylamido ligand is most probably coordinated as $H_2N—O^-$[5]. The nitrosyl group is almost linearly coordinated, and the V—N2 bond length is relatively short. Analogous bonding has been reported for the $[V(CN)_6NO]^{4-}$ ion[4]. The H_2NO^- ligand is coordinated "side on" *via* the O- and the N-atom, the N3—O5 distance corresponds to that of the usual N—O single bond length.

The smooth reaction course in alkaline medium and the lack of formation of gaseous reaction products are considered to be indicative of an intramolecular transfer of two electrons from *N*-coordinated hydroxylamine to V^V (formally, V^{III} and $NO^{\ominus}$ are formed). This is supported by the following experiment: Reaction of the V^{III}-complex *(4)* with hydroxylamine in alkaline solution likewise affords *(3)*:

$$[(\text{dipic})\text{V}(\text{OH}_2)_3]^+ + 3\ \text{H}_2\text{NOH} + 2\ \text{OH}^- \longrightarrow (3) + \text{NH}_3 + 5\ \text{H}_2\text{O}$$
(4)

However, in this case NH_3 is also formed, for the $NO^{\ominus}$ ligand must now be formed by disproportionation of the hydroxylamine to ammonia and hyponitrous acid.

Procedure

(2)·H_2O: $[H_3NOH]Cl$ (2.8 g) is added in small amounts to a solution of $Cs[V(O)_2(dipic)]\cdot H_2O$[3] (8 g) in 100 ml water (25 °C). A colorless, crystalline precipitate is formed, which is separated by filtration and washed with alcohol and ether (5.1 g).—The IR and Raman spectra show an intense ν(V=O) band at 980 cm^{-1}.

K*(3)*·3H_2O: A solution of $[H_3NOH]Cl$ (1.2 g) and KOH (2.4 g) in water (10 ml) is added to a solution of $K[V(O)_2(dipic)]$[3] in water (30 ml). The mixture becomes dark-red in color on warming (40 °C). After 15 h at 2 °C orange-colored crystals are filtered off and washed with alcohol and ether (3 g).—The cesium salt can be precipitated as red crystals by treatment of an aqueous solution of the potassium salt with solid CsCl.

*(4)*Cl·2H_2O: An aqueous suspension (30 ml) of pyridine-2,6-dicarboxylic acid (3.5 g) and vanadium trichloride (3.1 g) is treated with 15 ml conc. HCl and heated to 50 °C. Complete dissolution of the violet suspension takes place, giving a dark green solution. On cooling to 5 °C yellow crystals of the desired product precipitate which are filtered off and washed with alcohol and ether (5 g).

All the complexes gave correct elemental analyses [V, C, H, N (K, Cs, Cl)].

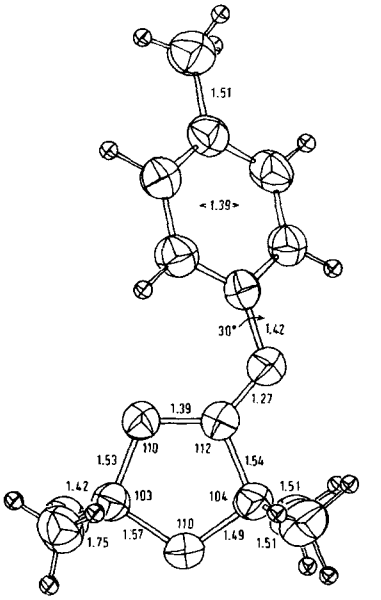
Reactions of Methanesulfonyl Azide with Ketenimines (a Revision)[**]

By *Gerrit L'abbé, Chih-Chou Yu, Jean Paul Declercq, Gabriel Germain*, and *Maurice Van Meerssche*[*]

In a previous article, two of us reported that *N*-aryldimethylketenimines react with methanesulfonyl azide at room temperature to give products which were characterized as alkylidenediaziridines *(1)*[1].

(a), X = H; *(b)*, X = CH_3; *(c)*, X = Br

However, X-ray diffraction analysis of the product with X = CH_3 has shown that our compounds are in fact 4-arylimino-2,5,5-trimethyl-4,5-dihydro-1,2λ⁶,3-oxathiazol-2-ones *(2)* (Fig. 1).



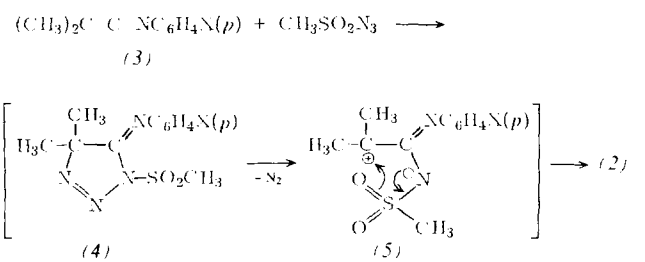


Fig. 1. Molecular structure of *(2b)* with the important bond lengths [Å] and angles [degrees]. The oxathiazoline ring is planar. Compound *(2b)* crystallizes monoclinically in space group $P2_1/a$ with $a = 32.057$, $b = 5.764$, $c = 7.039$ Å; $\beta = 96.49°$; $Z = 4$. The structure was solved by the MULTAN 77 program [2a] and refined with the X RAY 72 system [2b] to $R = 0.043$ for 1361 reflections (SYNTEX $P2_1$ diffractometer; $Mo_{K\alpha}$ radiation, $2\theta_{max} = 47°$).

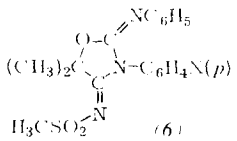
The spectroscopic properties of this unusual ring system[3] are compatible with structure *(2)* [IR (KBr): *ca.* 1640 ($\nu_{C=N}$), 1290, 1160 and 1050 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 1.7$ and 1.8 ($2CH_3$ at C-5); ^{13}C-NMR ($CDCl_3$) of *(2a)*: $\delta = 98$ and 162 (C-5 and C-4 in the hetero ring), 149, 123, 124 (C-1, C-2, and C-4 in the phenyl ring)[4]; MS $[M - CH_3SO_2]^+$ and $[CH_3SO_2]^+$ as intense signals].



(3) *(4)* *(5)*

Mechanistically, the reaction probably involves triazoline *(4)*[5,6] and the zwitterion *(5)*. Although this mode of decomposition is known for acyl azides[7], it is without precedent for sulfonyl azides[5]. The possible intermediacy of a nitrene is completely excluded on the basis of the mild reaction conditions (room temperature).

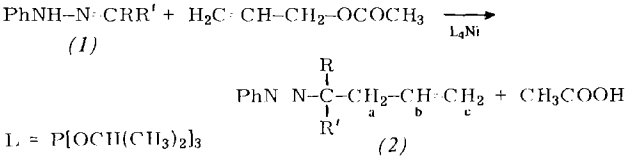
Catalytic Allylation of Phenylhydrazones[**]

By *Ugo Bersellini, Gian Paolo Chiusoli*, and *Giuseppe Salerno*[*]



During the course of our studies on insertion reactions into transition metal-carbon bonds[1] we found that allylnickel complexes, formed *in situ* by the oxidative addition of an allylic ester to nickel(0), are particularly effective for the insertion of chelated double bonds[2] and alkynes[3] into certain transition metal-carbon bonds. Substituted hydrazones have recently been reported to react with dienes in the presence of nickel or palladium complexes to give alkylation products at the carbon or the nitrogen[4, 5]. Although bis(π-allyl)nickel or palladium are probably the intermediates, reaction of hydrazones with allylnickel halides give only low yields of *N*-alkyl derivatives. We observed, however, that phenylhydrazones *(1)* react catalytically with allylic acetates in THF (at reflux under nitrogen) to give azo compounds *(2)* (formulated here for the simplest allyl compound). Examples are listed in Table 1.

Phenylhydrazones of both aldehydes and ketones appear to be reactive. Benzophenone, however, is practically unreactive probably for steric reasons. Table 1 reports yield and turn-over numbers (molecules of azo derivatives formed per molecule of nickel complex).

Yields and turn-over numbers drop to lower values on passing to higher homologs of the allylic groups. Thus, reaction of 2-butenyl acetate with formaldehyde *N*-phenylhydrazone *(1a)* affords *(3a)* in 20% yield only (turn-over

[*] Dr. U. Bersellini, Prof. G. P. Chiusoli, Dr. G. Salerno

(1) (2)

Table 1. Reaction of phenylhydrazones *(1)* (1 mmol) with allyl acetate (1 mmol) in THF (10 ml) to give azo compounds *(2)*; catalyst: tetrakis(triisopropyl phosphite)nickel(0) (0.05 mmol); 70°C, 15 h.

	R	R'	Yield [a] [%]	mol *(2)*/mol L_4Ni
(a)	H	H	51.0	10.2
(b)	H	C_6H_5	62.5	12.5
(c)	H	*n*-C_4H_9	58.5	11.7
(d)	—$(CH_2)_5$—		51.0	10.2
(e)	CH_3	CH_3	35.0	7.0

[a] Based on phenylhydrazone *(1)* employed; unconverted *(1)* was recovered almost completely except in the case of *(1a)* (75%).

number = 2). Interestingly, the branched isomer is formed selectively (98%) instead of the linear one.

$$PhN{=}N{-}CH_2{-}CH(CH_3){-}CH{=}CH_2 \quad (3a)$$
$$\qquad\quad a \qquad\quad b \quad c$$

Other donor solvents behave in the same way as THF. In toluene or hexane however, *N*-substitution products of type *(4)* predominate (formulated for allyl acetate).

$$RR'C{=}N{-}N(Ph){-}CH_2{-}CH{=}CH_2 \quad (4)$$

On using tetrakis(triphenylphosphane)nickel(0) in toluene, *C*-alkylated products are formed, but the reaction loses its catalytic character.

When tetrakis(triphenylphosphane)palladium(0) is used instead of the nickel complexes, the catalytic attack at the nitrogen predominates. Thus, reaction of 40 mol of formaldehyde *N*-phenylhydrazone *(1a)* and 40 mol of allyl acetate per mol of Pd complex in THF (75°C, 20 h) affords *(4a)*, R = R' = H, in 68% yield (turn-over number 27).

Ligand and substrate effects were studied on the nickel complexes under the conditions set out in Table 1. An excess of phenylhydrazone *(1)* leads to an enhanced catalytic effect, the number of molecules of product per molecule of nickel complex varying from 1.9 to 7.7 on passing from an excess of 5 to one of 12 mol of formaldehyde *N*-phenylhydrazone *(1a)* per mol of nickel complex. The corresponding yield increases from 38.0 to 64.2%, but begins to drop to lower values (51%) if a higher excess of phenylhydrazone (20 mol *(1a)*/mol L_4Ni) is used, while the catalytic effect continues to improve (see Table 1). If, however, an excess of triisopropyl phosphite is used (40 mol/mol L_4Ni) the yield does not decrease any more and 25 mol *(2a)*/mol L_4Ni are obtained (excess of *(1a)* 50 mol/mol L_4Ni).

An analogous tendency was observed with acetone *N*-phenylhydrazone *(1e)*. Thus the phosphite in excess helps to maintain the catalytic cycle. The series of decreasing efficiency of ligands appears to be the following: triisopropyl phosphite ≃ diisopropoxy(phenyl)phosphane > triethyl phosphite > trimethyl phosphite ≃ triphenyl phosphite > triphenylphosphane.

Experimental

Allyl acetate and phenylhydrazone *(1)* (prepared and stored under nitrogen) are dissolved in THF or in other ethereal

or amidic solvents and placed in a Schlenck tube under nitrogen together with tetrakis(phosphite) nickel complexes. After warming at 70°C for several hours with stirring, the products *(2)* are separated by distillation, chromatographed and identified by elemental analysis, mass spectrum, and IR and ^{1}H-NMR spectra (Table 2).

Table 2. Characteristic ^{1}H-NMR data of compounds *(2a)*—*(2e)* and *(3a)* [in $CDCl_3$, TMS int.; a, b, c see formulas *(2)* and *(3)*].

formula $Cs_4[Nb_4O_{12}]$ in which Nb^{5+} exhibits coordination number (C.N.) 5 towards O^{2-}[2].

Since literature data on the properties of $RbTaO_3$[3] undoubtedly warranted re-examination and it was questionable regarding the still unknown structure whether a perovskite variant with C.N. 6 exists—as previously suggested[4]—or a structure analogous to that of $CsNbO_3$ with C.N. 5 were more likely, we have prepared single crystals of $RbTaO_3$ [intimate mixture of $RbO_{0.65}$ with Ta_2O_5 (Merck analytical grade). Rb:Ta = 1.05:1; sealed Ni bomb, 1000°C, 21 d] in the form of water-clear thin platelets.

Crystals of $RbTaO_3$ are monoclinic with $a = 9.58_9$, $b = 8.50_5$, $c = 8.13_5$ Å, $\beta = 94.8_7°$ in C2/m; $d_X = 6.32$, $d_{pyc} = 6.37$ g·cm^{-3}. Diffraction data were collected using a four-circle automatic diffractometer [PW1100, $4° \leq \theta \leq 33°$, Mo-Kα], and the structure was determined using Patterson, Fourier, and least-squares techniques. For 1014 of the 1296 *hkl* data $R = 9.9\%$ (with no correction being made for the marked absorption due to the platelet shape of the crystal). The atomic positional and thermal parameters of the anisotropic refinement (O^{2-} isotropic) along with their standard deviations are listed in Table 1.

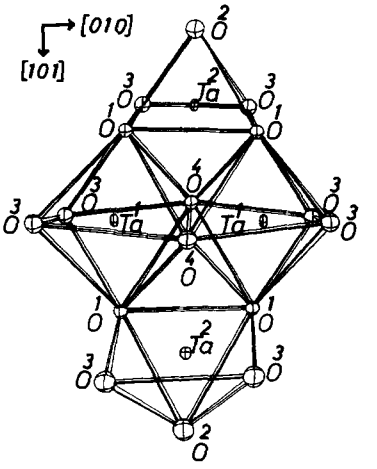

Fig. 1. Perspective diagram of the constituent structural groups $[Ta_4O_{8/1}O_{8/2}]$ in $RbTaO_3$.

Table 1. Atomic positional and thermal parameters of $RbTaO_3$ (standard deviations in brackets).

Atom	Position	x	y	z	U_{11}	U_{22}	U_{33}	U_{23}	U_{13}	U_{12}

The isotropic temperature factor is defined as: $\exp[-8\pi^2 V \sin^2\theta/\lambda^2]$,

the anisotropic as: $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$

Coordination Number 5 and 6 in $RbTaO_3$: $Rb_{4\infty}^2[Ta_4O_{12}]$[1]

By *Michael Serafin* and *Rudolf Hoppe*[*]

In a structural analysis of $CsNbO_3$, we unexpectedly found isolated cluster-like structural units commensurate with the

A complex layer structure is present:

Primary structure: Ta^1 is surrounded by a distorted octahedral array of six oxygen atoms [Ta—O = 1.92_6 (2×), 1.98_3 (2×), 2.05_0 (2×) Å], and Ta^2 by a distorted tetragonal-pyramidal arrangement of five O atoms [1.80_7 Å; 1.96_0 (2×), 2.00_3 (2×) Å].

Secondary structure: groups containing two Ta^1 atoms and two Ta^2 atoms bonded *via* common oxygens and the two coordination octahedra of Ta^1 linked together *via* a common pair of O^4 atoms; of the four O^1 atoms each adjacent pair

[*] Prof. Dr. R. Hoppe, Dipl.-Chem. M. Serafin
Institut für Anorganische und Analytische Chemie der Universität
Heinrich-Buff-Ring 58, D-6300 Lahn-Giessen (Germany)

forms a basal edge of one of the two pyramids, which in turn joins the pyramid to the two octahedra (see Fig. 1). O^2, as apex of a pyramid, belongs only to Ta^2. O^3 atoms, occupying the two remaining corner points of each of the mentioned coordination polyhedra, complete the secondary structural unit.

Tertiary structure: Four O^3 atoms, as $O_{8/2}$, couple the Ta_4O_{12} groups mentioned previously in accordance with the formula $[\{(O^4_{2/2}Ta^1)_2O^1_4(Ta^2O^2_{1/1})_2\}O^3_{8/2}]$ such that Ta^1 of one of the Ta_4O_{12} units is connected by O^3 with Ta^2 of one of the other units and *vice versa*. Each of the groups is coupled *via* two O^3 atoms with a total of four other groups such that a strongly puckered layer is formed.

Quaternary structure: Identical layers of the above type are stacked in the [001] direction, translated by length *c*.

An unusual difference is observed in the coordination of the two crystallographically different Rb atoms: Rb^1, with C.N. 8 [2.71_4, 2.81_6; and 2.88_2 (2×), 3.09_8 (2×), and 3.13_4 (2×) Å] couples the apex of a pyramid of one group with four groups of another layer; Rb^2, with C.N. 4 [2.76_1 (2×), 2.88_9 (2×) Å], on the other hand, couples two groups each of two layers in a quasi-tetrahedral arrangement. Two each of these tetrahedra have a common edge.

We have calculated the Madelung part of the lattice energy (MAPLE[5]) of $RbTaO_3$ [4815 kcal/mol] and compared it with MAPLE values for other oxotantalates, since the structure of Ta_2O_5 is still uncertain. The comparison shows that the value obtained by difference [9057 kcal/mol] for Ta_2O_5 from MAPLE ($RbTaO_3$) is equal to the mean value [9055 kcal/mol] obtained for Ta_2O_5 from other oxotantalates.

$RbTaO_3$ hydrolyzes immediately on exposure to water. Previous reports of solubility data of $RbTaO_3$ are thus incorrect[6].

Extremely High Electronegativities[**]

By *Dieter Lentz* and *Konrad Seppelt*[*]

It would appear inconceivable for an atom present in a molecule to have an electronegativity greater than that of a fluorine atom. And yet studies on compounds containing $OSeF_5$ and $OTeF_5$ ligands[1] have led us to the conclusion that these groups actually do have higher electronegativity values than fluorine, at least in the sense of the electron pair repulsion model (VSEPR theory)[2].

IF_5 reacts with the ligand transfer agent $B(OTeF_5)_3$ to give $FI(OTeF_5)_4$ with retention of the square-pyramidal molecular structure, the remaining fluorine atom occupying the axial position [eq. (1)]. Attempts to accomplish complete substitution were unsuccessful [eq. (2)]. The completely substituted species $I(OTeF_5)_5$ could only be obtained by oxidation of $I(OTeF_5)_3$[3] [eq. (3)].

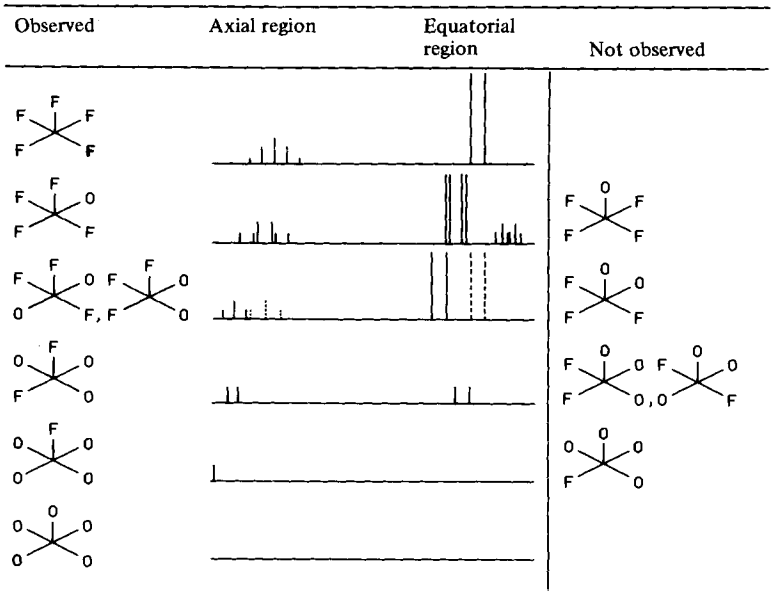

Fig. 1. ^{19}F-NMR spectra of $IF_x(OSeF_5)_{5-x}$ and $IF_x(OTeF_5)_{5-x}$: the signals of F_5SeO and F_5TeO groups (symbolized by O) have been omitted from the schematic representation.

$$IF_5 + B(OTeF_5)_3 \xrightarrow[-BF_3]{20\,^\circ C} FI(OTeF_5)_4 \quad (1)$$

$$FI(OTeF_5)_4 \xrightarrow[-TeF_6]{80\,^\circ C,\ B(OTeF_5)_3} O{=}I(OTeF_5)_3 \quad (2)$$

m. p. 83 °C, subl. 70 °C/10^{-2} mbar

[*] Priv.-Doz. Dr. K. Seppelt, Dipl.-Chem. D. Lentz
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

$$I(OTeF_5)_3 + Xe(OTeF_5)_2 \xrightarrow[-Xe]{20\,^\circ C,\ h\nu} I(OTeF_5)_5 \qquad (3)$$

m. p. 89—94 °C, subl. 65 °C/10^{-2} mbar

The square-pyramidal arrangement of the ligands in $I(OTeF_5)_5$ is confirmed by the appearance of two different ^{19}F-NMR patterns in the intensity ratio 1:4.

$I(OTeF_5)_5$ dissolves in IF_5 to form numerous exchange products belonging to the series $F_xI(OTeF_5)_{5-x}$, whose selenium analogs $F_xI(OSeF_5)_{5-x}$ could be prepared by ligand transfer with $F_2OPOSeF_5$:

$$IF_5 + I(OTeF_5)_5 \rightarrow F_xI(OTeF_5)_{5-x} \qquad (4)$$

$$IF_5 + F_2OPOSeF_5 \xrightarrow[-POF_3]{} F_xI(OSeF_5)_{5-x} \qquad (5)$$

Structural studies on these mixed-substituted compounds by ^{19}F-NMR show that the axial position of the square pyramid is always occupied by a fluorine atom (Fig. 1). Assignment is facilitated by the fact that axial and equatorial fluorine resonance signals occur in different regions and exhibit characteristic coupling constants.

According to the rules of electron pair repulsion (VSEPR theory), the axial position is occupied by the less electronegative ligand, as already found for OCH_3 and C_nF_m[4, 5].

Hence we conclude that the $OSeF_5$ and $OTeF_5$ ligands are more electronegative than fluorine. This also explains why only $FI(OTeF_5)_4$ is formed in reaction (1), because the extremely electronegative ligand will avoid the axial position if possible. Steric effects cannot account for preferential occupation of the equatorial position since crystal structure studies on the very similar compounds *trans*-$F_2Te(OTeF_5)_4$ and $Te(OTeF_5)_6$ rule out mutual hindrance of the $OTeF_5$ groups[1b,c]. Kinetic effects can be discounted since the substitutional behavior is unchanged after several weeks reaction or heating.

In order to better quantify this qualitative observation of extremely high electronegativity, the group electronegativities of the model compounds POF_2—$OTeF_5$, POF_2—$OSeF_5$, POF_3, POF_2Cl, *etc.* were correlated in known manner with the P=O stretching frequencies, ^{31}P-NMR signals, and P—F coupling constants. In all three cases, electronegativities approximately equal to that of fluorine were found for $OSeF_5$ and $OTeF_5$[6].

This abnormal electronegativity can be interpreted by the inductive effect of five fluorine atoms per ligand. Moreover, as shown for the derivatives F_5SOSF_5, $F_5SeOSeF_5$, and $F_5TeOTeF_5$, a pronounced withdrawal of electrons at the oxygen, probably into the d orbitals of the chalcogens, also becomes effective and is especially favored by the contracting action of the five fluorine atoms on these orbitals[1a].

Xenon Tetrakis(pentafluoroorthotellurate), $Xe(OTeF_5)_4$[**]

By *Dieter Lentz* and *Konrad Seppelt*[*]

The chemistry of tetravalent xenon has hitherto been limited to XeF_4, which on hydrolysis is converted into the highly unstable compound $XeOF_2$[1]. Since the $OSeF_5$ and $OTeF_5$ groups appear to have an electronegativity resembling that of fluorine[2], it seemed logical to synthesize corresponding derivatives containing these ligands. $Xe(OSeF_5)_2$ and $Xe(OTeF_5)_2$ are already known as the most stable covalent derivatives of XeF_2[3].

We have indeed succeeded in preparing stable $Xe(OTeF_5)_4$—the first compound containing xenon(IV) bound only to oxygen:

$$XeF_4 + B(OTeF_5)_3 \xrightarrow[-BF_3]{0\,^\circ C} Xe(OTeF_5)_4$$

The dark yellow crystalline product melts with decomposition at 72 °C, but can be sublimed *in vacuo* at 50 °C. Its composition and structure were determined by elemental analysis, and by mass [m/e = 859, $Xe(OTeF_5)_3^+$; 618 $Xe(OTeF_5)_2^+$; and other fragments], Raman [127 (90), 145 (88), 230 (60), 241 (81), 297 (3), 309 (19), 320 (7), 335 (9), 418 (100), 649 (27), 662 (91), 709 (40), 721 (24), 750 (16), 782 (11), 827 (3) cm^{-1} (%)]. ^{19}F-NMR [AB_4 spectrum, $\delta_A = 47.2$, $\delta_B = 39.4$, $J_{AB} = 188$ Hz], and ^{129}Xe-NMR spectroscopy [$\delta = 4694$ rel. to Xe, $J_{^{129}Xe\text{-}F} = 61 \pm 1$ Hz, $J_{^{129}Xe\text{-}^{125}F} = 1005 \pm 15$ Hz].

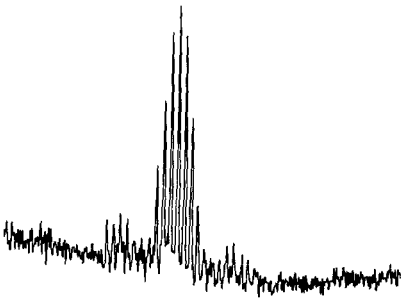

Fig. 1. ^{129}Xe-NMR spectrum of $Xe(OTeF_5)_4$, solution in perfluorobutanesulfonyl fluoride.

Tetravalency is confirmed above all by the ^{129}Xe-NMR spectrum (Fig. 1). The chemical shift closely resembles that in XeF_4[4a], whereas compounds of divalent xenon have signals in other characteristic regions[4]. Coupling with the tellurium isotope ^{125}Te and the 16 equatorial fluorine atoms proves the existence of the compound.

The driving force of decomposition according to

$$Xe(OTeF_5)_4 \xrightarrow{72\,^\circ C} Xe(OTeF_5)_2 + F_5TeO{-}OTeF_5$$

$$XeF_4 \xrightarrow{ca.\ 450\,^\circ C} XeF_2 + F_2$$

is the strong peroxide bond in $F_5TeOOTeF_5$[5]; in contrast, the analogous decomposition of XeF_4 occurs at much higher temperatures owing to the weak bond present in molecular fluorine[6].

The analogous selenium compound $Xe(OSeF_5)_4$ has not yet been prepared because the required ligand transfer agent $B(OSeF_5)_3$ is not yet available.

Procedure

XeF_4 (1.5 g, 7.2 mmol) is transferred into a quartz trap under argon. To this compound is condensed perfluoro-*n*-hexane (10 ml) and $B(OTeF_5)_3$ (8.8 g, 12.1 mmol) in a dynamic vacuum. The mixture is warmed to $-78\,^\circ C$; evolution of gaseous BF_3 increases as the mixture is warmed to room temperature. All volatile components are subsequently removed at room temperature in an oil-pump vacuum. The residue is $Xe(OTeF_5)_4$, yield 7.2 g (92%).

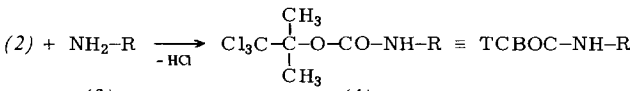
The 2,2,2-Trichloro-*tert*-butyloxycarbonyl Group (TCBOC)—An Acid- and Base-Resistant Protecting Group Removable under Mild Conditions[**]



By *Heiner Eckert, Monika Listl*, and *Ivar Ugi*[*]

β-Haloalkoxycarbonyl protecting groups[1-6] are important because they can be removed selectively. The protecting groups 2-chloro-[2], 2-bromo-[3,4], 2-iodo-[4], and 2,2,2-trichloroethoxycarbonyl[5], and also 2-bromo-*tert*-butyloxycarbonyl[6] all show some degree of base lability which limits their preparative scope. However, we have discovered that the 2,2,2-trichloro-*tert*-butyloxycarbonyl group (TCBOC) is so stable towards acids and bases that conditions are fulfilled for its wide application.

The TCBOC group can be introduced by means of the stable and distillable chloroformate *(2)*, which is readily accessible from 2,2,2-trichloro-*tert*-butanol (chloretone) *(1)* and phosgene in dichloromethane or pyridine. Chloretone itself is an inexpensive commercially available reagent.

(1) *(2)*

(3) *(4)*

NH_2–R = amino acid or peptide ester

Table 1. Yields of TCBOC-protected components in the synthesis of tetrapeptide *(4f)*.

Reaction		Yield [%]
(3a) → *(4a)*	TCBOC-Val-OH	82
(4a) → *(4b)*	TCBOC-Val-Ala-OMe	90
(4b) → *(4c)*	TCBOC-Val-Ala-OH	82
(4c) → *(4d)*	TCBOC-Val-Ala-Phe-O*t*Bu	67
(4d) → *(4e)*	TCBOC-Val-Ala-Phe-OH	82
(4e) → *(4f)*	TCBOC-Val-Ala-Phe-Phe-O*t*Bu	94

Reaction of *(2)* with the amino acids or peptide esters *(3)* can be accomplished under the usual Schotten-Baumann conditions. Thus, on treatment with *(2)*, valine *(3a)* affords the TCBOC-protected amino acid *(4a)* in good yield (see Table 1). Subsequent synthesis of the tetrapeptide *(4f)* by the DCCD/HO-Su method[1] proceeds without difficulty (apart from the problems of separation encountered in product work-up after linkage by this method); the excellent crystallization properties of the TCBOC-protected products warrant particular mention. The pronounced hydrophobic behavior of the TCBOC group endows the compounds *(4)* with good solubility in organic solvents such as dichloromethane. The group is easily recognized in the ^{1}H-NMR spectrum by virtue of a characteristic singlet at $\delta = 2.0$.

Table 2. Stability of the N-terminal TCBOC group towards acidic and basic reagents.

		Conditions	Stability of the C-terminal group	Stability of the TCBOC group
(4g)	TCBOC-Val-OMe	0.1 N NaOH/20 °C/2 h	+	+
(4g)	TCBOC-Val-OMe	1 N NaOH/40 °C/2 h	−	(+) [a]
(4b)	TCBOC-Val-Ala-OMe	0.1 N NaOH/20 °C/2 h	−	+
(4g)	TCBOC-Val-OMe	TFA [b]/20 °C/2 h	+	+
(4d)	TCBOC-Val-Ala-Phe-O*t*Bu	TFA [b]/20 °C/1 h	−	+

[a] 40% of TCBOC-Val-OH are formed.
[b] TFA = trifluoroacetic acid.

The TCBOC group proves to be inert on alkaline hydrolysis of the methyl ester *(4b)* to give *(4c)*, and on acidic cleavage of the *tert*-butyl ester *(4d)* to give *(4e)* (see Table 2).

Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] Fragmentations with Supernucleophiles, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 6: [8].

CoPc = Cobalt phthalocyanine

Removal of the TCBOC group can be accomplished with the supernucleophilic cobalt(I)-phthalocyanine anion in methanol or acetonitrile[3, 7, 8] and with zinc in glacial acetic acid (see Table 3); the yields of amine component are 66—94%. N-Terminal deprotection by lithium cobalt(I)-phthalocyanine also proceeds smoothly in the case of benzyl esters.

Table 3. Removal of the TCBOC group from compounds *(4)* by lithium cobalt(I)-phthalocyanine in methanol (method A) or acetonitrile (method B) or with zinc in glacial acetic acid (method C) at 20 °C.

	(4)	Method	Reaction time	Yield of *(3)* [%]
(4g)	TCBOC-Val-OMe	A	1 min	87
(4h)	TCBOC-Val-OCH_2Ph	A	1 min	93
(4d)	TCBOC-Val-Ala-Phe-O*t*Bu	B	1 h [a]	94
(4g)	TCBOC-Val-OMe	C	3 h	66
(4d)	TCBOC-Val-Ala-Phe-O*t*Bu	C	3 h	73

[a] The actual deprotection reaction only takes 5 min.

Experimental

Synthesis of *(2)*: Anhydrous chloretone *(1)* (178 g, 1.0 mol) dissolved in anhydrous dichloromethane (400 ml) is treated at −20 °C with phosgene (140 ml, 2.0 mol). Pyridine (105 ml, 1.5 mol) in dichloromethane (70 ml) is added dropwise at −20 °C and the mixture is then stirred for 12 h at 20 °C. Subsequent washing of the ether solution at 0 °C with water (caution: vigorous evolution of gas owing to liberation of excess phosgene), 2 N sulfuric acid, and water followed by distillation affords 214 g (89%) of *(2)*, b. p. 77—81 °C/12 torr.

Synthesis of *(4a)*: Valine (11.7 g, 0.1 mol), dissolved in water (200 ml) and 1 N sodium hydroxide solution (250 ml), is treated with diethyl ether (100 ml) and then emulsified at 0 °C with *(2)* (33.8 g, 0.14 mol) in dioxane (140 ml) for 1 h. The aqueous phase is washed with diethyl ether, acidified with 5 N hydrochloric acid, and extracted into ethyl acetate. After washing with water, compound *(4a)* (26 g, 82%) crystallizes from the extract; the product is recrystallized from hexane; m. p. 102 °C.

Deprotection of *(4d)* (method B): A solution of lithium cobalt(I)-phthalocyanine[3, 7, 8] (2.5 g, 2.8 mmol) in acetonitrile (15 ml), phenol (600 mg, 6 mmol), and *(4d)* (500 mg, 0.84 mmol) are stirred together at 20 °C under N_2 for 1 h. Water (20 ml) and 1 N HCl (2 ml) are added to the dark green mixture; the dark blue precipitate is centrifuged off, and the residue is washed with 1% citric acid and water. The supernatant liquors (pH 4.0) are washed with ether, rendered alkaline with Na_2CO_3 and extracted with ethyl acetate. Evaporation of the extract affords *(3d)* (310 mg, 94%) (identification by ^{1}H-NMR, IR).

Deprotection of *(4d)* (method C): Compound *(4d)* (595 mg, 1.0 mmol) is dissolved in 95% acetic acid (10 ml) and zinc dust (*ca.* 1 g) is added portionwise over 3 h to the stirred solution. Zinc is then filtered off, washed with water, and the filtrate and washings washed with ether. After rendering alkaline with caustic soda solution and extraction with ethyl acetate, *(3d)* (286 mg, 73%) is obtained from the extract by evaporation (identification by ^{1}H-NMR, IR).

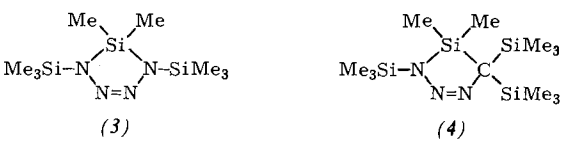
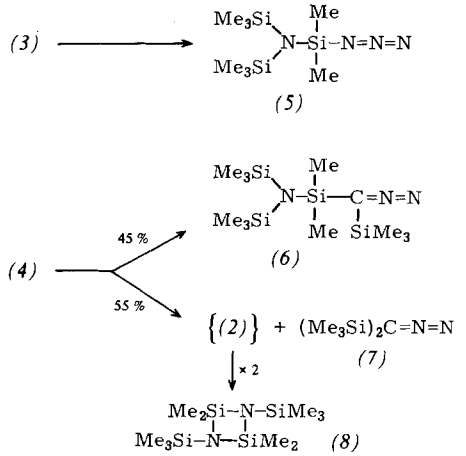
Preparation and Some Reactions of Dimethyl(trimethylsilylimino)silane, $Me_2Si{=}NSiMe_3$[1]



By *Nils Wiberg* and *Gerhard Preiner*[*]

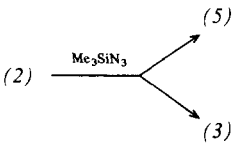
Having synthesized the silaethene *(1)*[2], we have now found a facile entry to iminosilane *(2)*—a representative of the poorly characterized, highly reactive compounds containing a Si=N double bond which have not yet been isolated[3].



(1) *(2)*

Our study was prompted by observation of differing behavior on thermolysis of the "isosteric" heterocycles *(3)* and *(4)*:

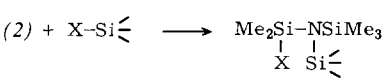
(3) *(4)*



While thermolysis of *(3)* at 180 °C leads quantitatively *via* isomerization to the aminosilyl azide *(5)*[4], compound *(4)* (readily accessible from *(1)* and Me_3SiN_3; metastable below −5 °C)[2, 5] is not converted exclusively into *(6)* (analogous to *(5)*); fragmentation also occurs, affording the iminosilane *(2)*, which dimerizes to *(8)* in the absence of a trapping reagent, and the diazomethane derivative *(7)*[5].

(5) *(6)* *(7)* *(8)*

[*] Prof. Dr. N. Wiberg, Dipl.-Chem. G. Preiner
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)



Evidence for the intermediacy of *(2)* is provided (i) by the insensitivity of the yields of *(6)* and *(7)* to addition of a trapping agent for *(2)*[6], and (ii) by the fact that the product yields according to

are independent of the source of *(2)*[7].

Like *(1)*[2], *(2)* shows an, albeit considerably lower, tendency to undergo *cycloaddition* to multiple bond systems. Thus *(2)* reacts with itself or with benzophenone in a [2+2] cycloaddition. Unlike *(1)*, however, *(2)* does not react with bis(trimethyl)diazene to form four-membered rings. Moreover, [2+3] cycloaddition of *(2)* and trimethylsilyl azide to give *(3)* plays only a minor role, especially at low temperatures (0°C)[8], whereas *(1)* reacts quantitatively with Me_3SiN_3 to form *(4)*. Dienes which can form Diels-Alder adducts with *(1)* could not formerly be subjected to [2+4] cycloaddition with *(2)*.

On the other hand, the tendency to undergo *insertion* into single bonds of type $\geqslant$Si—X according to

appears to be greater for *(2)* than for *(1)*. Thus *(2)* and trimethylsilyl azide give *(5)* in high yields, whereas the silaethene *(1)* does not insert at all into the Si—N bond of Me_3SiN_3. Trimethylsilyl chloride also reacts with *(2)* mainly according to the above equation (slight dimerization of *(2)* occurs), but only to a limited extent with *(1)*. Hexamethylcyclotrisiloxane still gives an eight-membered ring with *(2)* (dimerization of *(2)* is the principal reaction), but not with *(1)*[9].

Procedure

BuLi (0.79 mmol) in diethyl ether (2 ml), and then Me_3SiN_3 (91 mg, 0.79 mmol) in diethyl ether (1 ml) are added dropwise to $TosOSiMe_2$—$CBr(SiMe_3)_2$[2] (370 mg, 0.79 mmol) dissolved in a mixture of diethyl ether (5 ml) and tetrahydrofuran (5 ml) cooled to −110°C. The reaction mixture is first warmed to −55°C, whereupon *(4)* and insoluble TosOLi are formed, and then—after addition of the desired reactant for *(2)*—to room temperature.

[5] Corresponding heterocycles metastable up to about 35°C are obtained from *(1)* and organyl azides (*e.g.* R=Ph, tolyl); they decompose by isomerization and fragmentation like *(4)*.
[6] The trapping agent does not react directly with *(4)*.
[7] According to our findings, *(2)* is also formed by thermolysis (*ca.* 90°C) of the [2+2] cycloadduct [2] accessible from *(1)* and $Me_3SiN{=}NSiMe_3$.
[8] At higher temperature (90°C), *(3)* is formed in about 20% yield alongside *(5)*.
[9] *Note added in proof* (April 15, 1978): The efficacy of compounds $\geqslant$SiX as trapping agents for *(2)* increases along the series $(Me_2SiO)_3 \ll Me_3SiNMe_2 < Me_3SiOMe < Me_3SiCl < Me_3SiN_3$.

Chiral Polysiloxanes for Resolution of Optical Antipodes[**]

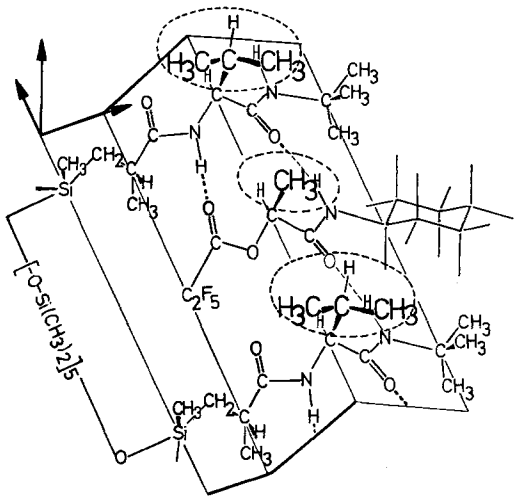
By *Hartmut Frank, Graeme, J. Nicholson*, and *Ernst Bayer*[*]

Enzymes and receptors are responsible for the specific reactions and recognition of optical antipodes in nature. In the case of synthetic drugs too, one enantiomer is usually more active than the other. Proteins can thus undergo selective interaction with enantiomers from an enormous variety of substances. We have attempted to impart nature's enantiomeric selectivity to synthetic polymers with amino acid groups.

In order to study such interactions between optically active substrate and an amino acid or peptide group as active site, we have synthesized polymeric organosiloxanes to which an active site, *e.g.* an L-amino acid, is linked with dicyclohexylcarbodiimide in the final synthetic step. Introduction of this site at an earlier stage proved unsatisfactory owing to the danger of racemization. Suitable polymeric backbones are copolymers of poly[(2-carboxylpropyl)methylsiloxane], octamethylcyclotetrasiloxane, and hexamethyldisiloxane; an amino acid or peptide group is linked as amide to the terminal carboxylic group.

The individual chiral centers must be separated by a siloxane chain of certain length to achieve optimum interaction and viscosity of the polymer.

The polymer-substrate interaction has been studied by gas chromatography. There is still no stationary phase of wide applicability for the gas chromatographic resolution of enantiomers. Not all enantiomeric pairs of natural amino acids can be separated with the low-molecular phases developed for amino acids by *Gil-Av*[1].



The new polysiloxanes with covalently bound amino acid or peptide groups can be used as stationary phases between 70 and 240°C. They effect direct separation of optical antipodes from widely diverse classes of compounds such as amino acids[2], hydroxy acids, alcohols, amines, and biphenyl derivatives without any need for preparation of diastereomers.

D- or L-Amino acids or their peptides can be bound as chiral centers to the organosiloxane. *N-tert*-Butyl-L-valinamide joined to the carboxyl group of the copolymeric organosiloxane by a peptide linkage has proved of great value for optical resolutions (Scheme 1).

Glass capillaries are coated by known methods[4] with this phase, which we designate Chirasil-Val[3], containing 0.86 mmol L-amino acid/g of polymer. The compounds are converted into the volatile *N,O*-bis(pentafluoropropionyl) derivatives[5] prior to gas chromatography, which is then performed under the conditions given in Figure 1. In all the cases examined so far, the D enantiomer is eluted from an L-amino acid phase before the L form.

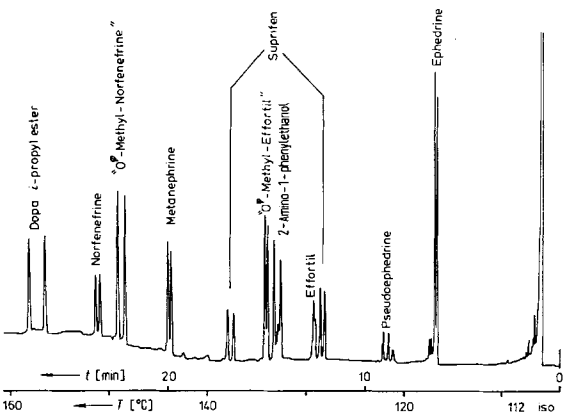
Scheme 1

The structure of the diastereomeric association complex is illustrated for *N*-cyclohexyl-*O*-pentafluoropropionyl-L-lactamide which elutes after the D enantiomer and whose association complex with Chirasil-L-Val is more stable than the complex with the D enantiomer. As in the pleated sheet structure of β-keratin, this conformation (Scheme 1) permits formation of the maximum number of hydrogen bonds. The space-filling isopropyl and methyl groups on the asymmetric carbon atom of the "receptor" and the "substrate", respectively, and the C-terminal alkylamide groups fit together as stacked layers and stabilize the structure by van der Waals forces. No such stacking is possible when the substrate has the D configuration; mutual hindrance of the isopropyl and methyl groups leads to a less stable association complex and earlier elution. The significance of the dimethylsiloxane units is also apparent from a model; they keep the L-valinamide units at a distance and prevent formation of intramolecular hydrogen bonds which would give the polymer a quasicrystalline structure.

Chirasil-Val has been used for determining the racemization of natural amino acids, for purity checks on glycols and biphenyl derivatives, and for separation of enantiomeric biogenic amines and hydroxy acids. The separation factors for optical antipodes expectedly increase with decreasing separation temperature. Figure 1 shows a chromatogram of some substances used as drugs whose enantiomeric composition can now be established conveniently and rapidly.



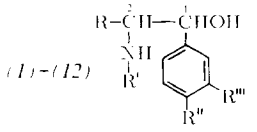


Fig. 1. Gas chromatographic separation of the enantiomeric pairs of drugs and metabolites as *N,O*-per(pentafluoropropionyl) derivatives on Chirasil-Val. 20 m × 0.3 mm glass capillary, hydrogen at 0.3 bar as carrier gas, temperature of injection block and detector 250 °C.

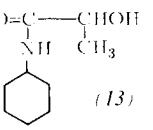

Apart from practical analytical aspects, considerable importance attaches to studies on interaction as a function of structure. Table 1 lists the separation factors of the enantiomers of some 2-amino-1-phenylethanols which occur naturally and are used as drugs. The following substituent effects are observed:

a) Separation factors are small for alkylated amino groups (R′ = alkyl). Since there is no hydrogen atom left for hydrogen bonding after derivatization, "three-point attachment"[6] is impossible and the diastereomeric association complex is less stable [norephedrine *erythro-(12)* → ephedrine *erythro-(3)*; norfenefrine *(9)* → etilefrine *(1)*].

b) Replacement of a hydrogen atom at C-2 by a methyl group (R = CH_3) increases the difference in stability of the diastereomeric complexes. In the case of the "parallel"

[a] Examined as the *O*-pentafluorpropionyl derivative.

complex, the methyl group is directed away from the isopropyl side chains of the valine groups; in the diastereomeric complex they hinder each other to such a degree that optimum approach of the *N*-proton of the substrate and the carbonyl group of valine is impossible [*(6)* → norephedrine *erythro-(12)*; synephrine *(7)* → *p*-hydroxyephedrine *(5)*].

c) The influence of substitution in the phenyl ring is less clear-cut. A *m*-hydroxyl group has a deleterious effect upon the separation of the two antipodes. A *p*-hydroxyl group favors a stereospecific association of the secondary amines [ephedrine *erythro-(3)* → *p*-hydroxyephedrine *(5)*; *(2)* → metanephrine *(4)*], but is unfavorable with primary amines. In the former case, "two-point attachment" is probably stabilized by participation of the carbonyl of the *O*-acyl group to give a "third point"; in primary amines this would lead to competition between two association conformations.

Analogies become apparent on comparison of the observed effects with biological activities. As in gas-chromatographic systems, the differences in the sympathomimetic effect between the D and the L form are greater when C-2 bears an additional methyl group ($R = CH_3$). While the difference in the dose/action curve consists merely in a shift of the concentration for the enantiomers of norepinephrine, an additional lowering of the maximum efficacy of the L enantiomer compared to that of the D enantiomer is observed with the corresponding 2-methyl compound cobefrin (and all other 2-methyl compounds)[7]. As in gas chromatography, where interaction of the amino acid residues with secondary amines is lower, these compounds also exhibit lower activities than primary amines in some biological systems[8].

The use of such polymeric stationary phases facilitates investigation of the interaction between two optically active molecules over a wide range of temperature. We are now one step closer to the synthesis of "tailored" chiral matrices, and the requirements for the stereospecificity of catalyst systems can be better examined. At the same time, these organosiloxanes represent yet another example of the imitation of the properties of biopolymers by synthetic polymers[9].

Stable L-(+)-Ascorbic Acid Radical Anions

By *Hartmut B. Stegmann, Klaus Scheffler*, and *Paul Schuler*[*]

The great biochemical significance of L-(+)-ascorbic acid has induced numerous authors to undertake ESR studies on the radicals formed on oxidation[1]. The reactivity of the radicals requires their generation by methods permitting maintenance of an adequate steady concentration of paramagnetic particles in the ESR cavity. However, side reactions also occurred and mixed spectra were observed.

On studying paramagnetic ion pairs with organometal cations[2] we found that the half-lives of paramagnetic anions can be considerably extended by complexation. We have therefore examined the oxidation of L-(+)-ascorbic acid in the presence of diarylthallium hydroxides.

Immediately after mixing, equimolar mixtures of R_2TlOH and ascorbic acid in pyridine as solvent show distinct ESR signals which reach maximum intensity after *ca.* 3 h. The concentration of the radicals formed by autoxidation can be greatly increased by addition of lead dioxide without giving rise to any further changes in the ESR spectra. The hyperfine structure (cf. Fig. 1) comprises four triplets, corresponding to coupling with two protons which are equivalent within the linewidth, with a single proton, and with the magnetic thallium nuclei.

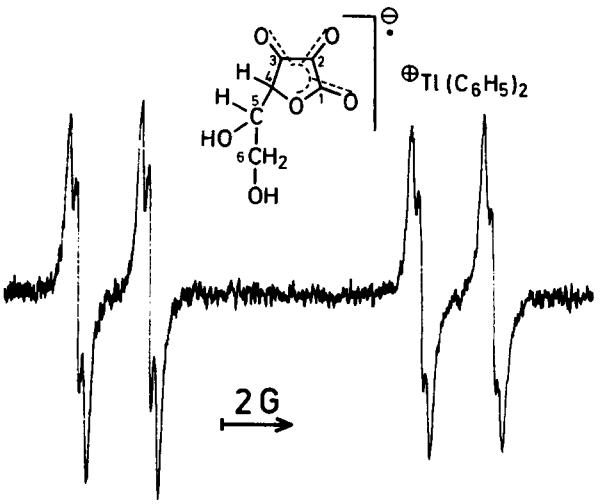

Fig. 1. ESR spectrum of the L-(+)-ascorbic acid radical anion-diphenylthallium complex in pyridine at room temperature.

We assigned the proton coupling constants (Table 1) by analogy with earlier studies[11]. The fact that the greatest coupling constant is due to the thallium nuclei follows (i) from the unusually large temperature dependence and (ii) from the pronounced substituent effect (Table 1).

Table 1. ESR data of paramagnetic ascorbic acid-diarylthallium complexes.

	$R_2Tl^{\oplus}$ R=	$a_{C_6}^{H_2}$ [G]	$a_{C_4}^{H_1}$ [G]	a_{Tl} [G]	g	ΔH [G]
(1)	C_6H_5	0.245	2.10	9.95	2.0051	0.15
(2)	$C_6H_3Me_2$-2,5	0.250	2.06	5.19	—	0.13
(3)	$C_6H_2Me_3$-2,4,6	0.270	2.4	6.5	2.0050	0.2
(4)	C_6F_5	—	2.0	61.75	—	1.0

The complexed radical anions are very stable. Thus, the half-life of *(1)* is of the order of days. In order to establish whether there is a quantitative relation between ascorbic acid concentration and peak-to-peak signal intensities, we have conducted preliminary studies on *(1)* at a modulation amplitude of 800 mG and a microwave output of 2 mW. Under these conditions a linear dependence of the signal intensity upon the concentration was detected, provided that comparable oxidation conditions were used. The experimental values were reproducible within 10%. This precision and the sensitiv-

[*] Prof. Dr. H. B. Stegmann, Priv.-Doz. Dr. K. Scheffler, P. Schuler
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen 1

ity of detection can be enhanced considerably, particularly by cation variation, thus permitting quantitative determination of L-(+)-ascorbic acid.

Mineralization of Chlorofluorocarbons in the Sunlight of the Troposphere

By *Siegmar Gäb, Johannes Schmitzer, Hans-Willi Thamm*, and *Friedhelm Korte*[*]

Rowland and *Molina*'s hypothesis[1] that chlorofluorocarbons (CFC's) destroy the ozone layer of the atmosphere is the topic of lively discussion[2]. One of the premises of this hypothesis, the infinite tropospheric lifetime of CFC's, has been questioned on the basis of recent experimental findings. Thus studies performed by *Ausloos et al.* showed that irradiation of perhalogenated CFC's with long wavelength UV light ($\lambda > 300$ nm) in the presence of quartz sand and C_2H_6 gives chlorinated ethanes (major product: C_2H_5Cl)[3]. Our own work on the oxidative degradation of persistent chlorohydrocarbons by heterogeneous photolysis[4] suggested that FHC's are also decomposed under these conditions.

For our investigations we chose silica gel (Kieselgel 60, Merck) as adsorbent since the silicon dioxide surface can be regarded as representative of many natural dusts and sands[5], permitting a qualitative analogy with atmospheric conditions. Measurements of the adsorption of CCl_2F_2 on various samples of natural Sahara sand (Libya Desert Soil, Algadones Dune Sand) and synthetic materials (Aerosil 200, Kieselgel 60) reveal only a slight influence of chemical composition of the sample upon the surface coverage. The adsorption isotherm measured for Kieselgel 60 corresponds to the average value from the isotherms of the two natural dusts[6].

We were able to detect formation of mineralization products (CO_2, CO, and HCl) both on irradiation of the CFC's (CCl_2F_2 and CCl_3F) adsorbed on silica gel with UV light from a high-pressure Hg lamp and on exposure of the sample to natural sunlight at ground level. The decomposition rates listed in Table 1 show a significant dependence upon the wavelength range of the incident UV light. In contrast to irradiation through Pyrex glass (P), irradiation through quartz glass (Q) resulted in the formation of Cl_2 and enhancement of the decomposition rate, possibly by a homogeneous photolysis running in parallel[7].

Even on considering the values measured in sunlight (S), the magnitude of the effect in the troposphere can only be roughly estimated so that any conclusions regarding tropospheric lifetimes are surrounded by some uncertainty. This is due mainly to the inhomogeneous energetic nature of the surface of the adsorbent, which leads to a rise in adsorption energy with decreasing partial pressure of CFC's[6]. A possible related effect on the decomposition rate of CFC's has yet to be studied in detail. Thus at the present stage we consider predictions of the decomposition rate under tropospheric conditions to be premature owing to the need to extrapolate over several orders of magnitude (partial pressure of $CFC_{reactor}$: partial pressure of $CFC_{troposphere} \approx 10^8$). Comparison with other classes of compounds serves for preliminary evaluation. Thus it could be shown that the photooxidative decomposition of CFC in the above simulation model clearly lies below that of chlorinated C_2, C_3 olefins (easily degradable) and is comparable with that of several methyl- and chlorine-substituted benzenes (poorly degradable)[4d].

Table 1. Photochemical decomposition of CCl_2F_2 and CCl_3F, adsorbed on silica gel [a].

		Mineralization products [%] [e]			
		CO_2	CO	Cl_2	HCl
CCl_2F_2	(Q) [b]	18.0	<1.0	10.6	3.2

	(S)	23.4	+	–	9.4

[a] Gaseous CFC (8 mmol) was passed into the evacuated reactor containing Kieselgel 60 (Merck) (200 g) with continuous mixing of adsorbent and gas phase. Oxygen was then passed in until atmospheric pressure was reached.
[b, c] Irradiation with a Hg high pressure lamp (HPK 125 W, Philips): [b] 48 h through quartz glass; [c] 144 h through Pyrex glass.
[d] Exposure to natural sunlight was performed for 170 h between September 7 and 28, 1977 (54 h overcast, 31 h cloudy, 85 h almost cloudless).
[e] The percentages were calculated from the ratios of the experimental amounts to the theoretically possible amounts; +, product formation; –, no product formation.

Experimental

UV irradiation was performed in a sealed rotating reactor drum with constant mixing of carrier with the adsobed phase and the gas phase[4b]. While the light source for the laboratory experiments was located in a half-closed Pyrex or quartz glass tube which projected into the reactor along its rotation axis, exposure to natural sunlight was through the wall of a quartz reactor. After irradiation, the reactor was flushed for *ca.* 12 h with O_2 and the gas stream first passed through 0.1 N NaOH to absorb CO_2 and Cl_2. The CO was trapped as CO_2 in NaOH after catalytic oxidation of the gas stream[8]. HCl was obtained by stirring the silica gel with aqueous NaOH. Quantitative determination of the mineralization products was performed by acidometric (CO and CO_2), iodometric (Cl_2), and potentiometric titration (HCl).

Methylene Chloride as a Reagent for Cyclizations with SO_3 as HCl Trapping Agent[**]

By *Herbert W. Roesky, Minoru Aramaki*, and *Lothar Schönfelder*[*]

Owing to its inertness, methylene chloride is usually employed as solvent and not as reactant. To our knowledge methylene chloride has hitherto not been observed to react with amides or amines at room temperature with concomitant loss of hydrogen chloride. We have now found that such reactions can indeed readily take place in the presence of sulfur trioxide as HCl trapping reagent. When fluorosulfonamide *(1a)* or trifluoromethane sulfonamide *(1b)* is allowed to react with "SO_3 in CH_2Cl_2" the corresponding 1,3,5-tris(sulfonyl)-1,3,5-triazacyclohexane *(2)* and chlorosulfonic acid are formed.

(2a), R = F
(2b), R = CF_3

The products *(2a)* and *(2b)* are crystalline white products, m.p. 217 and 211°C, respectively. The six-membered ring structure of the molecules manifests itself in the spectroscopic data: The mass spectrum of *(2a)* shows the molecular ion at $m/e = 333$ (3%) along with fragments at 222 $(FSO_2NCH_2)_2$ 20%, 111 FSO_2NCH_2 20%, 113 FSO_2NHCH_3 100%. ^{19}F-NMR: $\delta = -54.8$, quintet; ^{1}H-NMR: $\delta = 5.5$, quartet, $J_{HF} = 1.5$ Hz. The mass spectrum of *(2b)* likewise shows a trimer at $m/e = 483$ with a relative intensity of 2%. The ^{19}F-NMR spectrum shows only one signal, $\delta = 77.6$ (rel. $CFCl_3$ ext.)[1].

Experimental

SO_3 (0.3 mol) is added dropwise to a suspension of *(1)* (0.1 mol) in methylene chloride (0.25 mol). A weakly exothermic reaction takes place with formation of a white precipitate. After 24 hours' stirring, excess CH_2Cl_2 and SO_3 are removed by evaporation in a vacuum and the solid product isolated by filtration. *(2a)* can be purified by recrystallization from a mixture of CH_3CN and CCl_4, *(2b)* from CH_3CN; yields: 75% and 42% respectively.

Contamination of Amines with *N*-Nitrosamines[**]

By *Bertold Spiegelhalder, Gerhard Eisenbrand*, and *Rudolf Preussmann*[*]

During studies on trace analysis of carcinogenic nitrosamines in the environment[1], we have discovered that commercially available secondary and tertiary amines are contaminated with the corresponding nitrosamines. Concentrations in samples from various manufacturers varied between 0.03 and 53.0 mg/kg. The results of 35 determinations are shown in Table 1. Only in exceptional cases were other nitrosamines present; presumably, their occurrence is due to contamination with other amines.

Table 1. Contamination of secondary and tertiary amines with the corresponding dialkyl-*N*-nitrosamine.

Amine investigated	Concentration [mg/kg]	$\bar{X}$ [a]	n [b]
Dimethylamine solution	0.65—17.3	6.72	6
Dimethylamine hydrochloride	0.21		1
Diethylamine	0.1—7.3	1.78	6
Dipropylamine	1.9—13.0		2
Diisopropylamine	0.25—0.39		2
Dibutylamine	0.3—2.95	1.34	6
Diisobutylamine	8.35		1
Dipentylamine	0.31—2.6	1.4	3
Dihexylamine	0.4		1
Piperidine	1.6—2.1		2
Pyrrolidine	3.65—53.0	25.65	4
Triethylamine	0.03 [c]		1

[a] $\bar{X}$ = average value from several samples. [b] n = number of samples from different sources. [c] Diethylnitrosamine.

For analysis, a sample of the amine (0.5—1 g) is steam distilled at reduced pressure. After acidification with 2N H_2SO_4, the distillate is extracted with dichloromethane. Nitrosamine could be separated from the concentrated extract by gas chromatography (5 m steel column, $\frac{1}{8}$" i.d., 13% Carbowax 20 M TPA on Gas Chrom Q, oven temp. 205°C) and determined with a nitrosamine-specific chemiluminescence detector (TEA detector)[2] (sensitivity better than 0.0001 mg/kg). The identity of the nitrosamines was confirmed on combination of gas chromatography and high-resolution mass spectrometry (Varian MAT 311A) at a resolution of $R = 15000$ by precision measurement of the mass of the molecular ion.

The occurrence of even slight amounts of the extremely carcinogenic nitrosamines[3] in commercial material make protective measures imperative during their handling, especially in view of their volatility. Just a single dose of 1.25 mg/kg body weight produces malignant tumors in rats[4]. Moreover, the nitrosamines can appear in the reaction products of such amines, *e.g.* in drugs and pesticides[5]. Hence safety precautions

Ternary Rhenium Sulfides with $[Re_6S_8]$-Clusters

By *Manfred Spangenberg* and *Welf Bronger*[*]

We have been able to synthesize ternary sulfides of general composition $A_xM_yS_z$, where A = alkali metal and M = transition metal, with the elements:

Mn	Fe	Co	Ni	Cu
			Pd	Ag
			Pt	

In all cases, X-ray crystallographic investigations on single crystals gave collective structures in which chain or layer arrays of transition metal atoms are separated from alkali metals by their sulfur environments[1]. Experiments aimed at the preparation of analogous compounds with the usual platinum metals and with gold met without success, but we were able to synthesize the corresponding rhenium compounds. Alkali metal carbonates react with elemental rhenium in an H_2S atmosphere at 800 °C. After *ca.* 20 h well-formed lustrous bluish black crystals (red in transmitted light) of the compounds $Cs_4Re_6S_{13}$, $K_2Re_3S_6$, and $Na_2Re_3S_6$ are obtained. Structure investigations on single crystals of the cesium and potassium compounds showed that the transition metal atoms are not coupled one- or two-dimensionally in layers or chains *via* the coordinated sulfur atoms—as previously reported—but that $[Re_6S_8]$-clusters occur as structural units. Six rhenium atoms form an almost regular octahedron with Re—Re distances of 2.61(1) Å. The eight sulfur atoms are arranged over the octahedron surface. Further S atoms or S_2 groups couple the $[Re_6S_8]$ units *via* the Re atoms. The alkali metal atoms are intercalated in the interstices of these skeletal structures.

Figures 1 and 2 reproduce schematically the linkages of the $[Re_6S_8]$-clusters in two different structural types. For the different stoichiometries there are thus the following formulas:

$Cs_4Re_6S_{13} \triangleq Cs_4[Re_6S_8]S \quad S_{2/2}(S_2)_{3/2}$
$K_2Re_3S_6 \triangleq K_4[Re_6S_8]S_{4/2}\,(S_2)_{2/2}$

[*] Prof. Dr. W. Bronger, Dipl.-Chem. M. Spangenberg
Institut für Anorganische Chemie der Technischen Hochschule
Templergraben 55, D-5100 Aachen (Germany)

According to previous findings $Na_2Re_3S_6$ is isotypic with the corresponding potassium compound (cf. also Table 1). We have also been able to synthesize a rubidium compound, which is currently under investigation.

Table 1. Measured values of the monoclinic unit cells of ternary rhenium sulfides. The lattice constants *a*, *b*, *c*, are in Å units and β in degrees (standard deviations 0.01 Å and 0.1°, respectively).

	a	*b*	*c*	β	Space group
$Cs_4Re_6S_{13}$	13.72	17.68	10.13	100.8	$P2_1/n$
$K_2Re_3S_6$	16.53	9.69	11.85	91.07	C2/c
$Na_2Re_3S_6$	16.10	9.52	11.61	91.03	C2/c

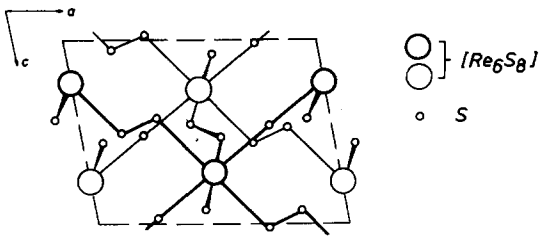

Fig. 1. $Cs_4Re_6S_{13}$: Structure of the $\{[Re_6S_8]S\ S_{2/2}\ (S_2)_{3/2}\}^{4-}$ skeleton. The mass centers of the $[Re_6S_8]$ clusters symbolized by thick circles are each shifted about *b*/2 relative to those represented by thin circles.

Cluster compounds containing M_6 units have so far not been reported in the chemistry of rhenium. $[M_6X_8]$ structural units, in particular with M = Mo or W and X = halogen, have

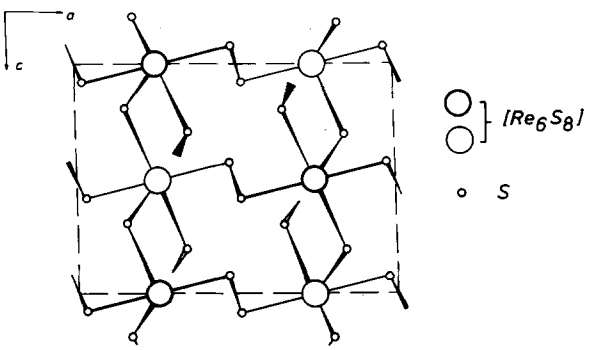

Fig. 2. $K_2Re_3S_6$: Structure of the $\{[Re_6S_8]S_{4/2}\ (S_2)_{2/2}\}^{4-}$ skeleton. The mass centers of the $[Re_6S_8]$ clusters symbolized by thick circles are each shifted about *b*/2 relative to those represented by thin circles.

been observed. In the so-called Chevrel phases, which have attracted interest because of their superconducting properties, $[Mo_6S_8]$ clusters are found to be characteristic structural units[2].

Synthesis of 1,2-Diazepin-3-one Derivatives by Reaction of Alkynes with the N=N Group Coordinated to $Fe_2(CO)_6$[1]

By *Bärbel Ulbrich* and *Horst Kisch*[*]

Complexes of type *(2)* contain a reactive diazene group which can undergo thermal and photochemical reactions with alkynes to form tricyclic organoiron compounds *(3)*[2]. We now wish to report the transformation of these "double addition products" into the hitherto unknown[3] 1,2-dihydro-1,2-diazepin-3-one derivatives *(4)*.

Starting from the 1-pyrazolines *(1a)* or *(1b)*, the corresponding complexes *(3)* can be prepared in 40—50% yield[2]. Oxidative decomposition of, *e.g.*, *(3a)* with bromine in glacial acetic acid/methylene chloride gives 2 mol of CO per mol of *(3a)* and, after column chromatography, a 60% yield[4] of colorless crystals of *(4a)*. Elemental analysis and the mass spectrum (M^+ at $m/e=646$) confirm the composition; the IR spectrum (CCl_4) contains not only the ν(CO) band of the methoxycarbonyl groups at 1730 cm^{-1} but also an intense absorption at 1640 cm^{-1}, which agrees well with the ν(CO) value of 1650 cm^{-1} for a comparable benzodiazepinone[5]. The ^{1}H-NMR spectrum (CD_2Cl_2, 100 MHz) shows the singlets of the ester methyl groups at $\delta=3.25$ and 3.95, the multiplets of the pyrazoline ring protons at $\delta=3.3$—4.1, and those of the aromatic protons at $\delta=6.75$—7.4. Chemical proof of the two C=C double bonds was obtained for the isopropyl derivative *(4b)* synthesized in the same way: uptake of 2 mol of Br_2 per mol of *(4b)* at 0°C in $CHCl_3$ gives a tetrabromo compound which can be dehalogenated by Zn/dimethyl sulfoxide at room temperature to regenerate *(4b)*. The presence of an N—N bond is evidenced by the nuclear magnetic resonance data, and above all by the result of thermolysis of *(4a)* at 180°C: tetracyclone is accompanied by 1,1-dimethoxycarbonyl-2-phenylcyclopropane and 1,1-dimethoxycarbonyl-2-phenyl-1-propene, which are also formed on thermolysis of the free 1-pyrazoline *(1a)*[6].

The reaction sequence *(1)* → *(4)* provides the first demonstration that diazenes activated by transition metals can react with alkynes by C—N and C—C bond formation to give organic heterocycles. This should also be possible with other reactants such as alkenes or 1,3-dienes; use of other transition metal complexes could lead to the discovery of a catalytic variant of this new synthetic approach.

Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung
Stiftstrasse 34—36, D-4330 Mülheim-Ruhr (Germany)

Procedure

A solution of Br_2 (0.44 g, 2.76 mmol) in glacial acetic acid/methylene chloride (1:1, 50 ml) is added dropwise to a solution of *(3b)* (1 g, 1.38 mmol) in the same solvent system (50 ml). Excess Br_2 is removed by Na_2SO_3 and the organic product is washed with benzene (3 × 100 ml). After drying and evaporation, column chromatography on Florisil (60—100 mesh) gives some tetracyclone on elution with toluene/ether (2:1), and pure *(4b)* with CH_2Cl_2. Crystallization from CH_2Cl_2/MeOH at room temperature gives colorless crystals of *(4b)* (0.48 g, 57%), m.p. 110—116°C (dec.). Compound *(4a)* is accessible in like manner: 60%, m.p. 207—215°C (dec., lilac coloration).

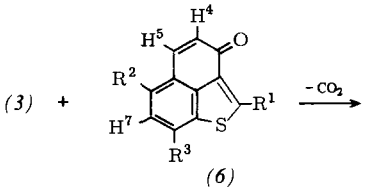
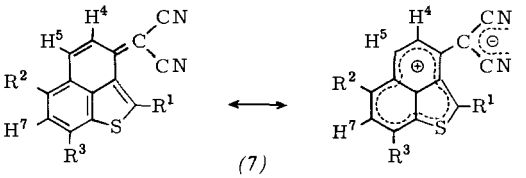
Dicyanoketene[**]

By *Richard Neidlein* and *Ernst Bernhard*[*]

Dedicated to Professor Adolf Butenandt on the occasion of his 75th birthday



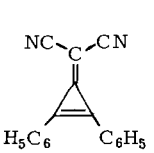
We have synthesized dicyanoketene *(3)*—previously unknown!—from 2,5-diazido-3,6-dicyano-1,4-benzoquinone *(2)* which in turn is formed under special conditions from 2,5-dichloro-3,6-dicyano-1,4-benzoquinone *(1)*[1] and sodium azide in tetrahydrofuran (yield 75%). Alkoxycarbonylcyanoketenes[2] are not accessible by an analogous route. The highly reactive ketene *(3)* could not be trapped by alcohols, amines, *etc.*, for these compounds react with *(2)* itself by substitution of the azide group, and only trapping reactions with polarized ketones were initially considered. Among other compounds, we used thiapseudophenalenones *(4)* and *(6a)*—*(6c)*.



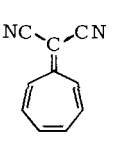
[*] Prof. Dr. R. Neidlein, Dipl.-Chem. E. Bernhard
Pharmazeutisch-Chemisches Institut der Universität
Im Neuenheimer Feld 364, D-6900 Heidelberg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

If *(2)* is subjected to thermal decomposition[3] in the presence of the thiapseudophenalenones *(4)*[4] and *(6a)—(6c)*[5], then dicyanoketene *(3)* reacts to form the otherwise inaccessible thiapseudophenafulvenes *(5)* and *(7a)—(7c)*;

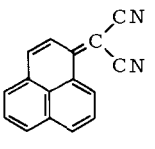


(6)



(7)

(a), $R^1 = R^2 = R^3 = H$; *(b)*, $R^1 = CH_3$; $R^2 = R^3 = H$; *(c)*, $R^1 = H$; $R^2 = R^3 = Cl$



the paramagnetic shift of the ^{1}H-NMR signals suggests polarization of these products.

(8)

(9)

(10)

The dicyanofulvenes *(8)*[6] (yield: 26 %), *(9)*[7] (yield: 20 %), and *(10)*[8] (yield: 37 %) which we obtained from dicyanoketene *(3)* and diphenylcyclopropenone, tropone, and phenalenone were identical with authentic material in their physicochemical and spectroscopic properties.

Experimental

Synthesis of (2): A 25 % aqueous solution of sodium azide (2.6 ml, 10 mmol) is added to a stirred solution of *(1)* (1.00 g, 4.40 mmol) in THF (20 ml) at −5 °C. The product is precipitated from the red solution by addition of ice-water (400 ml). The orange crystals are filtered off after a few minutes, the filter crucible being cooled with ice. The crystals are washed several times with cold ether, dried *in vacuo*, and stored in a refrigerator with exclusion of moisture, yield: 780 mg (74 %) of *(2)*; *IR* (KBr): 2240, 2210 (C≡N), 2155, 2100 (N_3), 1660 (C=O), 1560 cm^{-1} (C=C); UV (CH_3CN): $\lambda_{max} = 334$ nm ($\varepsilon = 25300$), 260 (17300), 226 (15000).

Synthesis of (5), (7a)—(7c), (8)—(10): A 0.25 mmol sample of *(4)*, *(6a)—(6c)*, diphenylcyclopropenone, tropone, or phenalenone and *(2)* (90.0 mg, 0.375 mmol) are refluxed in anhydrous benzene (25 ml) under N_2 for 4 h. The evaporated solution is applied to a silica gel PLC plate (PSC Kieselgel, "Merck") and developed with dichloromethane. The reddish fractions (yellow in the case of *(9)*) are extracted with dichloromethane (Soxhlet) and the solutions carefully evaporated. The physical data of *(5)* and *(7a)—(7c)* are listed in Table 1.

Azoalkanes by Anodic Oxidation of Anions of *N,N'*-Dialkylsulfamides[**]

By *Reinhold Bauer* and *Hartmut Wendt*[*]

Hypochlorite oxidation of ammonia, alkylsulfamides or geminal diamines is the usual reaction path to hydrazine, substituted hydrazines or azoalkanes, respectively[1]. The anodic oxidation of anions of primary and secondary amines in aprotic solvents opens another route to N—N-coupling products[2]. This electrochemical method can also be used for the anions of *N,N'*-dialkylsulfamides *(1)* and thus offers the possibility of carrying out anodic N—N-coupling in *protic solvents*, in a reaction which is easy to perform and which affords azoalkanes in about 90 % yield with attractive current efficiencies. Table 1 lists the anodic half-wave potentials of some sulfamides *(1)* and their monoanions *(2)*. The anions are generally oxidized in a one-electron step at potentials which are 600 to 800 mV more negative than the half-wave potentials of the corresponding sulfamides. Oxidation products are the azoalkanes *(4)*. Table 2 lists mass yields and current efficiencies for the potentiostatic oxidation of *(2)*.

Table 1. Anodic half-wave potentials of *N,N'*-dialkylsulfamides and their anions in methanol at a carbon electrode with 0.1 M *n*-Bu_4BF_4 as supporting electrolyte ($E_{1/2}$ [mV] measured *vs.* aqueous SCE).

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Table 2. Mass yields and current efficiencies for some reactions *(2)* → *(4)* in methanol at C- and Pt-electrodes.

RN=NR *(4)* R	Mass yields [%] Carbon	Platinum	Current yields [%] [a] Carbon	Platinum
n-Butyl	88	94	68	72
t-Butyl	81	84	63	62
Cyclohexyl	90	93	74	77
Adamantyl	78	79	61	60

[a] Assuming consumption of two electrons per molecule of azoalkane in accordance with equations (a) and (b).

A detailed investigation shows that the cyclic thiadiaziridine 1,1-dioxide *(3)* is formed as a primary oxidation product of the formal one-electron oxidation (being in fact a sequence of charge transfer, deprotonation and second charge transfer) [Eq. (a)]. In the case of the *N,N'*-diadamantyl derivative, after the electrolysis *(3)* could be isolated in small amounts (10%) besides the 1,1'-azoadamantane. The three-membered heterocycles with spatially less demanding *N*-alkyl groups slowly decompose in a well known thermal reaction to SO_2 and the azoalkanes *(4)*[3] [Eq. (b)].

(2) *(3)* *(1)* (a)

(4) (b)

Anodic oxidation of *N,N'*-dialkylsulfamides in the absence of base leads merely to fragmentation and not to N—N-coupling. Since azoalkanes can easily be converted into hydrazines by catalytic hydrogenation the described method provides access also to symmetrically substituted hydrazines[4]. This new anodic synthesis is based on direct anodic conversion of N-anions in protic solvents and avoids the use of chlorine or hypochlorite as oxidants.

Experimental

N,N'-dicyclohexylsulfamide (5.20 g, 0.02 mol) is dissolved in dry methanol (100 ml) and converted into the lithium salt by addition of an equimolar amount of Li-methoxide. This solution is oxidized at controlled potential at a carbon electrode in a divided cell at 273 K under a N_2 atmosphere. After consumption of 0.04 F the solvent is removed and the residue is extracted twice with 50 ml of *n*-pentane. Subsequent drying of the combined extracts over Na_2SO_4 and removal of the solvent by evaporation affords 2.73 g (90% mass yield and 74% current yield) azocyclohexane, m.p. 307 K (Ref.[5] 307.5 K). The product was identified by comparing its spectroscopic data (MS, IR, UV, ^{1}H-NMR with those of an authentic sample prepared according to the procedure of *Ohme et al.*[6].

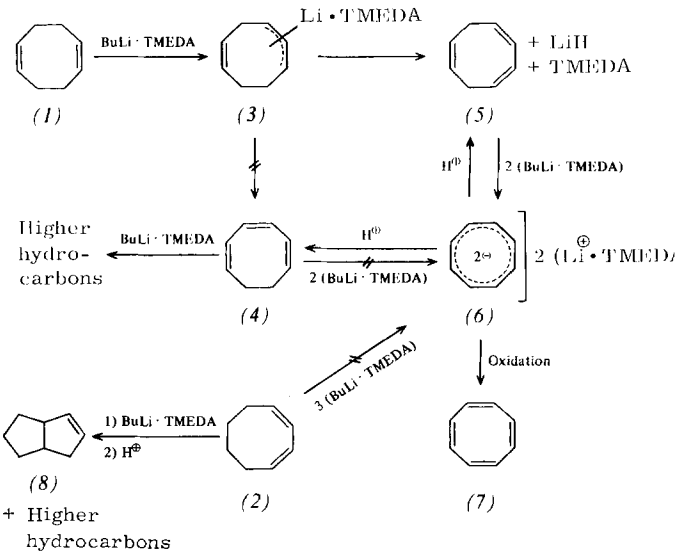
Facile Preparation of Cyclooctatetraene from 1,5-Cyclooctadiene by Metalation and Oxidation

By *Wolfgang Gausing* and *Günther Wilke*[*]



Metalation of olefins is attracting increasing interest; particular mention should be made of the formation of the trimethylenemethane dianion from isobutene[1] and of the cycloheptatrienyl trianion from various C_7-di- and tri-olefins[2]. 1,4-Cyclooctadiene is transformed into bicyclo[3.3.0]oct-2-ene by lithiation and protolysis[3].

We now wish to report the metalation of 1,5-cyclooctadiene *(1)*, of 1,3-cyclooctadiene *(2)*, and of 1,3,5-cyclooctatriene *(4)* and its 1,3,6 isomer *(5)*. The 1,5-diene *(1)* was expected to react with *n*-butyllithium-tetramethylethylenediamine[4] (BuLi·TMEDA) in the molar ratio 1:1 to give the allyl anion *(3)*. On protolysis of the product, however, we obtained not only *(1)* and its isomers but also the trienes *(4)* and *(5)* and hydrogen. The product apparently contained $Li_2(C_8H_8)$[5] and LiH.

Reaction of *(1)* with BuLi·TMEDA in a ratio of 1:3 gives LiH and crystalline $Li_2(C_8H_8)\cdot 2$TMEDA *(6)* in practically quantitative yield: the latter product affords cyclooctatetraene *(7)* in 90—95% yield (based on *(1)*) on oxidation with $CdCl_2$[5b, 6].

In an attempt to simplify this new synthesis of cyclooctatetraene for preparative purposes we have tried other metalation and oxidizing agents. A particularly suitable procedure proved to be the initial reaction of *(1)* with phenylsodium in the presence of TMEDA followed by oxidation with dry oxygen. Formation of *(7)* is accompanied by a mixture of sodium peroxide and hyperoxide[7].

The results of reactions of *(2)*, *(4)*, and *(5)* with *n*-butyllithium helped to elucidate the reaction mechanism: under the

[*] Prof. Dr. G. Wilke, Dipl.-Chem. W. Gausing
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr (Germany)

same conditions neither 1,3-cyclooctadiene nor 1,3,5-cyclooctatriene can be converted in significant amounts into *(6)*, 1,3,6-cyclooctatriene on the other hand reacts smoothly to give this product; addition of the BuLi-reagent to *(2)* and *(4)* does occur and in the case of *(2)* bicyclo[3.3.0]oct-2-ene *(8)* is formed. This suggests that *(1)* and BuLi·TMEDA initially form *(3)*, which is transformed into *(5)* by loss of LiH and TMEDA. Double metalation of *(5)* yields the intermediate *(6)*.

Procedure

Compound *(1)* (12 ml, 10.6 g, 98 mmol) is added to C_6H_5Na[8] (0.31 mol) in olefin-free pentane (150 ml) and TMEDA (95 ml), and the mixture is stirred under reflux for 20 h. A slow current of dry O_2 is then passed over the well stirred mixture at −5 °C for *ca.* 24 h. After filtration[7] the solution is vacuum distilled, freed from TMEDA with 5 N HCl, neutralized, and dried. GC analysis reveals 1.5 % (163 mg, 1.5 mmol) of *(8)* and 78.5 % (8 g, 76.9 mmol) of *(7)*, based on quantitatively consumed *(1)*. The remainder of *(1)* is present as oligomerization product in the distillation residue.

Benzenoid *versus* Annulenoid Aromaticity: Synthesis and Properties of Kekulene[1]

By *François Diederich* and *Heinz A. Staab*[*]

In 1965, first attempts to prepare the hydrocarbon *(1)* were reported[2]. Then, at the centennial of *Kekulé*'s benzene formula, this compound which may be regarded as a "superbenzene" on account of its planar cyclic conjugation and D_{6h} symmetry was given the name "kekulene"[2, 3]. *(1)* was of interest in connection with investigations to experimentally define benzenoid as against annulenoid aromaticity: on the one hand, *(1)* can be formulated as a combination of two [4*n*+2]annulenes—[18]annulene inside, [30]annulene outside—bridged by radial single bonds *(1a)*, and on the other, as a regular benzenoid system with a closed circle of angularly annellated benzene rings *(1b)*. Since *(1)*, in this respect a representative of a new class of aromatic compounds, has an intramolecular cavity containing hydrogen atoms it should be possible to decide by proton resonance whether an annulenoid diatropism in the macrocyclic system can compete successfully with ring-current induction within the benzenoid subunits.

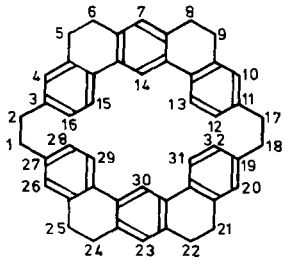
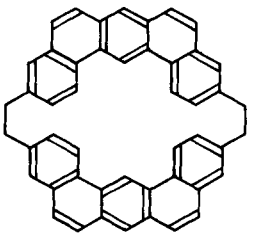
(1a) *(1b)*

In an attempt to synthesize *(1) via* a very involved and tedious route *Vögtle* and *Staab*[4] were able to show, on the basis of a mass spectrometric analysis, that the desired compound was probably formed, albeit in minute and unisolable amounts. Since preparation of *(1) via* such a route seemed impossible all further efforts were abandoned 10 years ago. Attempts by *Tenny et al.*[5] to prepare *(1)*, which they named '[12]coronaphene' apparently were likewise unsuccessful. Newly developed methods for C...C coupling in macrocyclic systems, especially by sulfur extrusion from dithia[3.3]phanes, prompted us now to resume our efforts to synthesize *(1)*.

The first steps of the synthesis followed, with minor modifications, those of the previously reported synthesis of 5,6,8,9-tetrahydrodibenzo[*a,j*]anthracene[4], whose bromomethylation according to the procedure used for 9,10-dihydrophenanthrene[6], led to the bis(bromomethyl) derivative *(2)*[7] in 50% yield. After conversion of *(2)* into the bis(mercaptomethyl) derivative *(3)*[7] [thiourea method; 75 % yield, m.p. 243 °C (corr.)], *(2)* and *(3)* were cyclized to 6,7,9,10,23,24,26,27-octahydro-2,19-dithia[3.3](3,11)dibenzo[*a,j*]anthracenophane[8] *(4)* [dilution apparatus of *Vögtle*; solutions of *(2)* and *(3)* in benzene (each 5.3 mmol in 3500 ml) added dropwise and simultaneously within 72 h into a boiling mixture of 1000 ml benzene, 1000 ml ethanol (95 %) and 4 g potassium hydroxide; 55 % yield]. *(4)*[7]: yellowish platelets, m.p. 291 °C (corr.); ^{1}H-NMR (360 MHz, $CDCl_3$): $\delta = 2.70$ (s, 16H, H-6,7,9,10,23,24,26,27), 3.82 (s, 8H, H-1,3,18,20), 6.73 (dd, $J = 8$ and 1.8 Hz, 4H, H-13,17,30,34), 6.91 (s, 2H, H-8,25), 6.94 (d, $J \approx 1.8$ Hz, 4H, H-5,11,22,28), 7.40 (d, $J = 8$ Hz, 4H, H-14,16,31,33), 7.83 (s, 2H, H-15,32).



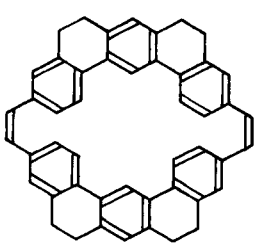
(2), X = Br
(3), X = SH



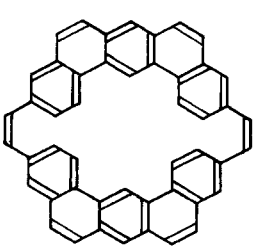
(4)

Irradiation of *(4)* in trimethyl phosphite (450 W Hg high-pressure lamp, 2 h, under N_2) led in 60% yield to 5,6,8,9,21,22,24,25-octahydro[2.2](3,11)dibenzo[*a,j*]anthracenophane *(5)*[7]: colorless needles, m.p. 462–464 °C. *(5)*, which had already been obtained in very unsatisfactory yield (1.5%) from *(2)* by a Wurtz reaction (phenyllithium, ether/benzene)[4], was dehydrogenated with 2,3-dichloro-5,6-

dicyano-1,4-benzoquinone (DDQ) [24 h, boiling benzene, 80 % yield] to *(6)*[7]: pale yellow needles, m.p. 490—495 °C (dec.); MS: $m/e = 608$ (M^+, base peak), 304 (70 %). The rigid steplike structure of the molecule is confirmed by the absorption of the methylene bridges and the upfield shift of the adjacent internal aromatic protons in the ^{1}H-NMR spectrum (360 MHz, $CDCl_3$, 45 °C) [$\delta = 2.69$ and 3.33 (each 'd', $J \approx 9$ Hz, for axial and equatorial H-1,2,17,18, resp.), 5.76 (dd, $J = 9$ and 2 Hz, 4H, H-12,16,28,32), 7.68 and 7.81 (AB, $J = 8$ Hz, 8H, H-5,9,21,25 and H-6,8,22,24), 7.72 (d, $J \approx 2$ Hz, H-4,10,20,26), 8.04 (d, $J = 9$ Hz, 4H, H-13,15,29,31), 8.31 (s, 2H, H-7,23), 9.56 (s, 2H, H-14,30)][9]. All attempts to achieve the internal ring closure in *(6)* and the dehydrogenation to *(1)* have so far remained unsuccessful.

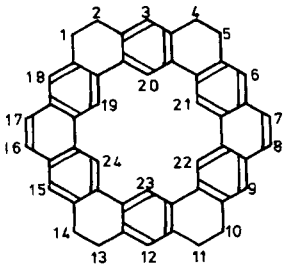


(5)



(6)

Subjection of the bis-sulfonium salt formed on reaction of the dithiaphane *(4)* with methyl fluorosulfonate (in methylene chloride, 95 % yield) to Stevens rearrangement (potassium *tert*-butoxide, tetrahydrofuran, 12 h, 20 °C, under N_2, 60 % yield), renewed methylation (methyl fluorosulfonate, methylene chloride, ≈ 90 % yield) and elimination (potassium *tert*-butoxide, tetrahydrofuran, 12 h, 20 °C, 9 % yield) afforded 5,6,8,9,21,22,24,25-octahydro[2.2](3,11)dibenzo[*a*,*j*]anthracenophanediene *(7)*[7]: pale yellow needles, m.p. 472 °C (dec.); ^{1}H-NMR (360 MHz, $CDCl_3$): $\delta = 2.883$ (s, 16H, H-5,6,8,9,21,22,24,25), 6.575 (dd, $J = 8.28$ and 1.68 Hz, 4H, H-12,16,28,32), 6.745 (s, 4H, H-1,2,17,18), 7.098 (d, $J = 1.68$ Hz, 4H, H-4,10,20,26), 7.114 (s, 2H, H-7,23), 7.365 (d, $J = 8.28$ Hz, 4H, H-13,15,29,31), 7.658 (s, 2H, H-14,30).—Dehydrogenation of *(7)* with DDQ (boiling benzene, 20 h, 66 %) yielded the dibenzo[*a*,*j*]anthracenophanediene *(8)*[7]: yellow needles, m.p. > 520 °C (subl.); MS: M^+ calc. for $C_{48}H_{28}$ 604.2191, obs. 604.2197; ^{1}H-NMR (360 MHz, [D_5]nitrobenzene, 80 °C): $\delta = 7.075$ (s, 4H, H-1,2,17,18), 7.119 (d, $J = 8.7$ Hz, 4H, H-12,16,28,32), 7.782 (br. s, 4H, H-4,10,20,26), 7.737 and 7.793 (AB, $J = 8.95$ Hz, 8H, H-5,9,21,25 and H-6,8,22,24), 8.141 (s, 2H, H-7,23), 8.602 (d, $J = 8.7$ Hz, 4H, H-13,15,29,31), 9.742 (s, 2H, H-14,30) [numbering of carbon atoms cf. formula *(5)*].



(7)

(8)

In contrast to *(8)*, an easy photo-cyclodehydrogenation was possible with *(7)* in which two *cis*-stilbene units are present: short irradiation (10 min, 300 W Osram-Ultra-Vitalux lamp) in benzene in the presence of iodine afforded the octahydro derivative *(9)*[7], the first compound with the carbon skeleton of kekulene, in 70 % yield: m.p. > 620 °C, pale yellow needles (from nitrobenzene), difficultly soluble in all solvents. MS: $m/e = 608$ (20 %, M^+), 607 (8), 606 (14), 605 (5), 604 (14), 603 (9), 602 (35), 601 (55), 600 (base peak, corresponding to *(1)*) and the doubly and triply charged ions therefrom at $m/e = 300$ (82) and 200 (7). ^{1}H-NMR (360 MHz, [D_5]nitrobenzene/arsenic trichloride, 1:3, 685 scans): $\delta = 3.11$—3.27 (AA'BB', 16H, H-1,5,10,14 and H-2,4,11,13), 7.26 (s, 2H, H-3,12), 7.74 and 7.77 (each s, 4H, H-7,8,16,17 and H-6,9,15,18), 9.19 (s, 2H, H-20,23), 9.67 (s, 4H, H-19,21,22,24).

(9)

Because of the low solubility of *(9)* the dehydrogenation with DDQ required rather drastic conditions (1,2,4-trichlorobenzene, 100 °C, 3 d). Kekulene *(1)* was formed in 80 % yield. With its extreme insolubility in solvents of all kinds, *(1)* is certainly outstanding among hydrocarbons of comparable molecular weight: for recrystallization, for example, 350 ml 1-methylnaphthalene at the boiling point (245 °C) dissolved 10 mg *(1)*, or 100 ml boiling 1,2,4-trichlorobenzene (b.p. 214 °C) about 1 mg *(1)*. Kekulene *(1)*[7], greenish-yellow microcrystals, m.p. > 620 °C, can be sublimed at 500 °C/10^{-3} torr. MS: M^+ calc. for $C_{48}H_{24}$ 600.1858, obs. 600.1878. In the mass spectrum, which is extraordinarily poor in fragment peaks, there appear besides the molecular peak $m/e = 600$ (100 %) the doubly and triply charged molecular ions at $m/e = 300$ (43 %) and 200 (7 %); above the molecular peak and its ^{13}C-peaks with intensities expected for C_{48} no further peaks are observed (up to $m/e = 2000$, temperature of the ionic source up to 400 °C)[10]. The complete dehydrogenation of *(9)* is also shown by the IR spectrum (KBr) in which the aliphatic ν(C—H) absorptions have disappeared; the spectrum shows only aromatic ν(C—H) absorptions (3007 and 3020 cm^{-1}) and, in accord with the high molecular symmetry, is very poor in vibration absorptions.

The electronic spectrum of *(1)* ($8 \cdot 10^{-7}$ molar solution in 1,2,4-trichlorobenzene) shows the following absorptions: λ_{max} 388 nm (lg ε 4.22), 347 (sh, 4.74), 326 (4.93). Solutions of *(1)* exhibit intense green fluorescence; in 1,2,4-trichlorobenzene a fluorescence emission is observed from about 400 to 550 nm with maxima at 420 and 435 nm (excitation at 365 nm). Under the same conditions a phosphorescence emission is observed around 590 nm with a half life of 0.6 s at −196 °C[11].

The extreme insolubility of *(1)* made the recording of a ^{1}H-NMR spectrum extraordinarily difficult. In the first usable spectra (80 MHz) of a saturated solution of *(1)* in [D_3]-1,3,5-trichlorobenzene at 215 °C after about 50000 scans three signals were observed reproducibly at $\delta = 7.94$, 8.37 and 10.45 in the intensity ratio of 2:1:1[12]. According to these results, there is no signal shifted strongly upfield as would be expected for the internal protons in the case of a synchronous induction of diamagnetic ring-currents in a double annulene system. On the contrary, intensity ratios and comparison with the ^{1}H-NMR data of compounds *(5)* to *(9)* lead to the

assignment of the signal at $\delta = 7.94$ to the twelve equivalent protons H-1,2,4,5,7,8..., of the absorption at $\delta = 8.37$ to the second group of equivalent external protons H-3,6,9,12,15,18 and of the signal at $\delta = 10.45$ to the six internal protons H-19,20,21,22,23,24 [numbering as in *(9)*]. The peculiar downfield shift just of the internal protons of *(1)* is taken as a strong experimental argument against the dominance of an annulenoid ring-current in the macrocyclic system and in favor of a strong coupling between the inner and outer perimeters according to the benzenoid formulation *(1b)*. This result is inconsistent with calculations of the diamagnetic anisotropy for *(1)* using the semi-classical approach of *Pauling*[13a]; it agrees qualitatively, however, with more recent MO calculations[13].

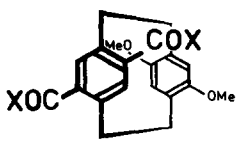
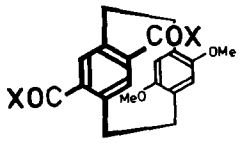
Attempts to Synthesize Zwitterionic Donor-Acceptor Cyclophanes: The Diastereomeric 12,15-Bis(dimethylamino)-[2](2,5)-*p*-benzoquinono[2]paracyclophanes[1]

By *Renate Reimann* and *Heinz A. Staab*[*]

Previous investigations of charge-transfer interactions in donor-acceptor cyclophanes[2] led to the question of the existence of 'paracyclophane-zwitterions' in which, as a consequence of an especially low ionization potential of the donor or a high electron affinity of the acceptor, an electron transfer from donor to acceptor occurs already in the ground state of the molecule. Such paracyclophanes for which the radical cation and the radical anion components would be fixed in close proximity and definite orientation were of interest regarding the interaction between the radical electrons: strong coupling should lead to a singlet (or a triplet?) ground state of the molecule, whereas with weak transanular interaction the single radical ion units of such a molecule should exist in doublet spin states. Furthermore, we wondered whether a zwitterionic structure of donor-acceptor cyclophanes would result in a crystal structure comprising stacked cyclophane moieties where the stacking axis is perpendicular or nearly perpendicular to the cyclophane planes and, therefore, the radical cation side of one cyclophane directly faces the radical anion side of the neighboring molecule. For such lattice structures peculiar anisotropic crystal properties (*e.g.*, changes in electrical conductivity) might be expected.



As an effort aimed in this direction we synthesized the donor-acceptor cyclophanes *(1)* and *(2)* in which *p*-benzoquinone as acceptor is combined in pseudo-*ortho* and pseudo-geminal orientations with the especially strong donor *N,N,N',N'*-tetramethyl-*p*-phenylene diamine (TMPD). The zwitterions *(1a)* and *(2a)* corresponding to *(1)* and *(2)*, respectively, would include as components the semiquinone radical anion and the 'Wurster's Blue' radical cation, both of which are known as relatively stable radical ions. Although, in intermolecular CT complexes of TMPD, the formation of radical ions apparently requires acceptors with higher electron affinity (*e.g.*, chloranil)[3], due to the specific interactions in [2.2]paracyclophanes, no definite conclusions could be drawn regarding the stability of the zwitterions *(1a)* and *(2a)* as against *(1)* and *(2)*.



For the syntheses of *(1)* and *(2)*, after the failure of more direct synthetic routes, we had to adopt the multi-step course starting from the diastereomeric 4,7-dimethoxy-12,15-dimethoxycarbonyl[2.2]paracyclophanes *(3)* and *(4)* which had already been synthesized as donor-acceptor cyclophanes previously[11].

Hydrolysis of *(3)* (potassium hydroxide, methanol; 24 h, 97 % yield) afforded the dicarboxylic acid *(5)*[4] (dec. > 320 °C), which on reaction with sulfinyl chloride (chloroform/dimethylformamide; 85 % yield) gave the dichloride *(7)*[4] (m.p. 152 °C). Treatment of *(7)* with sodium azide in acetone/water afforded the diazide *(9)*[4] (dec. > 90 °C, 85 % yield). Subsequent Curtius reaction of *(9)* (boiling toluene, 2 h) led to the diamino derivative which, on account of its extraordinary instability, without further purification and characterization was methylated with methyl iodide/potassium carbonate (methanol, 20 °C, under argon) to pseudo-*ortho*-4,7-dimethoxy-12,15-bis(dimethylamino)[2.2]paracyclophane *(11)*[4] (colorless crystals, m.p. 98 °C, overall yield 31 %).

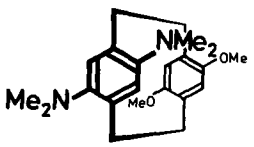
(3), X = OMe
(5), X = OH
(7), X = Cl
(9), X = N_3



(4), X = OMe
(6), X = OH
(8), X = Cl
(10), X = N_3

Analogously, in the pseudogeminal series, starting from (4) we obtained the dicarboxylic acid (6)[4] (dec. >320°C, 94.5% yield), the dichloride (8)[4] (m.p. 214°C; 88% yield), and the diazide (10)[4] (dec. >114°C; 81% yield). Curtius reaction of (10) and immediate subsequent methylation yielded the pseudogeminal bis(dimethylamino) derivative (12)[4] (pale yellow crystals, m. p. 181°C, overall yield 11%).—For all pairs of diastereomers of the two series the assignment to the pseudo-*ortho* and pseudogeminal structures, respectively, is confirmed by comparison of ^{1}H-NMR data; particularly characteristic is the transannular substituent effect of the methoxy groups which, for the aromatic protons in pseudogeminal positions of the neighboring ring, results in a downfield shift[5].

(11)

(12)

In the following reaction steps the ether cleavage in (11) and (12) and the oxidation to the benzoquinone had to be accomplished under reaction conditions under which the TMPD part of the molecule is not affected. According to model experiments with mixtures of TMPD and hydroquinone dimethylether, this could be achieved by demethylation with methyl magnesium iodide [(11): 190°C, 50 min; (12): 195°C, 75 min] and oxidation with silver oxide in ether. After chromatography on silica gel from toluene/methanol (10:1) and recrystallization from pet. ether (40—60) (1) was obtained in 15.5% yield, and (2) in 18% yield.—(1)[4]: black crystals, m.p. 183°C; MS: M^+ calc. for $C_{20}H_{24}N_2O_2$ 324.1838, obs. 324.1844; ^{1}H-NMR ($CDCl_3$): $\delta = 2.0$—3.7 (m, 8H), 2.67 (s, 12H), 5.93 (s, 2H), 6.14 (s, 2H).—(2)[4]: black crystals, m.p. 204°C; MS: M^+ calc. for $C_{20}H_{24}N_2O_2$ 324.1838, obs. 324.1828; ^{1}H-NMR ($CDCl_3$): $\delta = 2.0$—3.7 (m, 8H), 2.68 (s, 12H), 5.80 (s, 2H), 6.13 (s, 2H).

(1) and (2) show unusually broad absorption bands which extend from about 450 nm through the whole visible region into the near infrared. Long-wavelength initial absorptions and absorption maxima are strongly solvent-dependent and, in general, show a bathochromic shift with increasing polarity of the solvent; a strict correlation with dielectric constants or dipole moments of the solvent is, however, not observed. In the whole region of the long-wavelength absorption the absorption intensity of the pseudogeminal compound is higher by a factor of about 10 than that of the pseudo-*ortho* isomer [(1): $\lambda_{max} = 545$ nm ($\varepsilon = 147$), in cyclohexane; $\lambda_{max} = 595$ nm ($\varepsilon = 160$), in methylene chloride; (2): $\lambda_{max} = 531$ nm ($\varepsilon = 1670$), in cyclohexane; $\lambda_{max} = 577$ nm ($\varepsilon = 1930$), in methylene chloride]. The solvent-dependence of the absorption maxima as well as the orientation dependence of the absorption intensities, similar to those of [2.2]paracyclophane quinhydrones[6], indicate that the long-wavelength absorption is to be assigned to a CT-transition from a less polar ground state to a more polar excited state. On the other hand, the 'Wurster's Blue' radical cation derived from 4,7-bis(dimethylamino)[2.2]paracyclophane, which has been synthesized for comparison[7], shows absorptions in the same wavelength region [$\lambda_{max} = 585$ nm, in 1,2-dichloroethane]. Hence, on the basis of the absorption spectra alone an unambiguous distinction between (1)/(2) and the corresponding zwitterions (1a)/(2a) is rather difficult. ESR measurements on (1) and (2) in the solid state and on (2) in solution in 1,2-dimethoxyethane between 20 and 70°C[8], as well as the regular line-width of the ^{1}H-NMR absorptions of (1) and (2), exclude *para*magnetic ground states of zwitterionic structures. The problem of the existence and electronic structure of cyclophane-zwitterions of the type (1a) and (2a) needs, however, further investigation including the synthesis of TMPD-[2.2]paracyclophanes with stronger acceptors than *p*-benzoquinone.

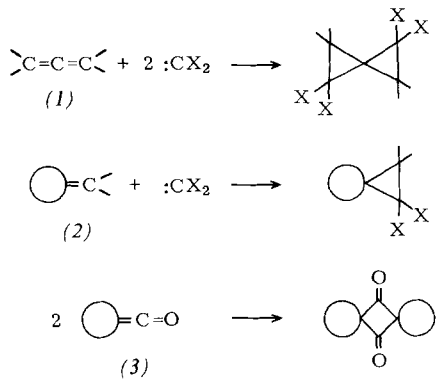
The chemistry of macrocyclic inclusion complexes—cryptates—is the topic of a review by *J.-M. Lehn*. The ligands (cryptands) characteristically have three-dimensional cavities which can take up, *e.g.*, alkali and alkaline earth metals. Cylindrical macrotricyclic compounds such as *(1)* are known to

(1)



(2)

form complexes with one or two metal ions, *e.g.* Na^+; in the 1:1 complexes the cation appears to be preferentially located in one of the rings or on one side of the cavity. Spherical macrotricyclic compounds such as *(2)* form very stable complexes with alkali metal ions and the ammonium ion. Diprotonated *(2)* contains a H-bonded H_2O molecule in the cavity; tetraprotonated *(2)* can take up a halide ion. [Cryptates: The Chemistry of Macropolycyclic Inclusion Complexes. Acc. Chem. Res. *11*, 49—57 (1978); 82 references]

BOOK REVIEWS

Methodische Fortschritte im medizinischen Laboratorium. Band 4: Diagnostik hämorrhagischer Diathesen (Methodological Advances in Medical Laboratories. Vol. 4: Diagnosis of Hemorrhagic Diatheses). Edited by *A. Englhardt* and *H. Lommel* together with *L. Róka* and *W. G. A. Ohler*. Verlag Chemie, Weinheim—New York 1977, 1st Edit., 203 pp., bound, DM 58.—.

The growing importance of blood-clotting disorders in various diseases and the continuing progress in the therapeutic treatment of the blood-coagulation system make it universally essential to have up-to-date information on the physiology and pathophysiology of coagulation and on the procedures available for its physiological investigation. The editors have succeeded in conscripting a group of experts for this book. The work contains seven chapters: 1) Principles of hemostasis and analytical coagulation diagnostics; 2) Formulation of indications for the analysis of hemostasis; 3) Hereditary and acquired coagulopathies; 4) Thrombocytic coagulation disorders; 5) Anticoagulation; 6) Quality control in physiological methods of investigating coagulation; and 7) Coagulation

diagnostics with chromogenic peptide substrates. An Appendix (p. 190) names suppliers of reagents and automatic equipment for coagulation analysis.

The book can be recommended without hesitation. It will assuredly soon find its place in reference libraries of even the smaller medical departments, in appropriate clinics, and in intensive-care units. Hospital doctors, anesthetists, surgeons, and clinical chemists concerned with the diagnosis and treatment of hemorrhagic diatheses will all use this book with advantage.

Friedrich Willig [NB 414 IE]

Metal Ions in Biological Systems. Vol. 6: Biological Action of Metal Ions. Edited by *H. Siegel*. Marcel Dekker, Inc., New York—Basel 1976. xiii, 453 pp., numerous figs., bound, Sfr. 130.—.

Under the title "Biological Action of Metal Ions" are collected aspects as diverse as the participation of metal ions in enzyme catalysis, the occurrence of vanadium in animate nature, and the effects of Ca^{2+} on regulation of muscle activity.

In Chapter 1 *J. Chlebowski* and *J. E. Coleman* discuss the function of zinc in zinc metalloenzymes. A clear and stringent definition of the term "zinc metalloenzymes" enables the authors to concentrate the discussion on a few well studied enzymes (carboxypeptidase A and B, thermolysin, alkaline phosphatase, carboanhydrase, superoxide-dismutase, alcoholdehydrogenase, aldolase, aspartate-transcarboxylase, transcarboxylase, and DNA-polymerase). This special section is preceded by a very good discussion of the techniques for investigating metalloenzymes by all the modern physicochemical methods applicable in this field, *e.g.* absorption, CD, ESR, and NMR spectroscopy. Anyone interested in metalloenzymes can draw stimulation from this section in particular. The literature is cited up to 1973 and is continued by a section "Recent Developments" up to 1976.

Chapter 2 *(W. R. Biggs* and *J. H. Swinehart)* deals with the occurrence of vanadium in plants and animals. Because of the general ignorance of the function of this metal ion in biochemistry, pride of place is given to the consideration of the vanadium content of plants and animals. Correspondingly, further sections are concerned, for example, with the uptake and uptake processes, mainly by comparison of different species, and they give no clues on the molecular level. The most recent references are from 1973.

Chapter 3, by *P. W. Schneider*, is devoted to the chemistry of nitrogen fixation. This extremely clear and precisely written review shows the present state of knowledge in the field of the molybdenum and iron proteins that are present in nitrogenase. Comparison with the inorganic-organic complexes of the transition metals leads to a far-reaching discussion of the nitrogen-reduction mechanism. Here too references are up to 1973.

Chapter 4 *(D. W. Darnall* and *E. R. Birnbaum)* deals with the stabilizing influence of calcium on the conversion of trypsinogen into trypsin. As both the primary sequence and the spatial structure of trypsin and trypsinogen are known, statements can be made on a molecular plane about the effect of calcium on this process, although no generalizations are permissible. References are dated up to 1973 and taken up to 1975 by an addendum.

In Chapter 5, *K. S. Rajan, R. W. Colburn,* and *J. M. Davis* describe the participation of metal chelates in the accumulation and transport of neurotransmitters. Much space is given to the hypothesis that ternary complexes of ATP-metal ion and neurotransmitters (amines) constitutes the basis for the transport of these biologically active amines through the lipid matrix. Since it is now certain that proteins take part in many transport processes, any theory postulating transport through biological membranes solely by chelate formation seems unlikely. Here too the references are supplemented by an addendum up to 1976.

In the last Chapter *F. N. Briggs* and *R. J. Salora* make an attempt to give a comprehensive review of the role of calcium in regulation of muscle contraction. It is indeed tempting to treat the role of calcium in terms of electromechanical coupling, regulation of actomyosin-ATPase, and regulation of the calcium-transport ATPase in a single review article, yet the authors must leave a few gaps. For example, new developments in the phosphorylation of troponin are not considered, although they have been known since 1974 and 1975 *inter alia* from *Perry*'s school. Similar remarks apply to the phosphorylation of myosin. The older literature, in particular, is reviewed in detail (347 references up to 1973).

The heterogeneity of the article makes it clear that "bioinorganic chemistry" cannot be regarded as an independent branch of science, as the editors claim in the Foreword.

Ludwig Heilmeyer [NB 417 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

Analytical Applications of NMR. By *D. E. Leyden* and *R. H. Cox*. Vol. 48 of the series "Chemical Analysis. A Series of Monographs on Analytical Chemistry and its Applications". Edited by *P. J. What Do We Know about the Metal-Metal Bond?

By Heinrich Vahrenkamp[*]

Dedicated to Professor Heinrich Nöth on the occasion of his 50th birthday

Almost all main group and subgroup metals are able to form metal-metal bonds. The bond order ranges from weak interaction to a quadruple bond, and the degree of aggregation from a dinuclear entity to a three-dimensional network. In spite of numerous physicochemical studies, not all aspects of the metal-metal bond are understood. The ability of metal-metal linked polynuclear complexes to serve as a reservoir for missing or excess electrons enables them to react both with nucleophilic or reducing reagents and with electrophilic or oxidizing reagents. The intermediate position occupied by clusters between simple complexes and the bulk metal is of theoretical and practical significance.

1. Introduction

Two extreme answers can be given to the question posed in the title. One is: So much that compounds containing metal-metal bonds have already been treated in about 70 reviews and monographs cited in this article[1–62]. The other answer is: So little that the significance of metal-metal interactions is still uncertain even in the simplest compounds, as is illustrated by the fact that the Cs—Cs distances in cesium fluoride are 20% shorter than in cesium metal[63] and that careful analysis of X-ray measurements on the complex $[Fe(CO)_2C_5H_5]_2$ showed there to be zero electron density midway between the two iron atoms[64]. Both answers prompted the author to write this article and to give it the chosen title.

The development of the chemistry of metal-metal bonds is intimately connected with X-ray crystal structure analysis. The availability of large scale computers and automatic diffractometers led to a breakthrough in both fields during the past decade. Even the concept of a "metal-metal bond" could only become popular some 20 years ago, once some crystal structure analyses had demonstrated its existence in solid-state and molecular compounds[65–69] for which rather adventurous structural proposals had only recently been voiced[70, 71]. Finally, the use of Fourier series for determining atomic positions in crystals was first demonstrated for Hg_2Cl_2 50 years ago, the metal-metal bond of which was then viewed merely as a curiosity[72].

We now know that almost all metallic elements participate in metal-metal bonding and that d elements are particularly good at doing so. The bond orders range from very weak interaction, such as in $Cr_2Cl_9^{3-}$[73] to the quadruple bond, as in $Cr_2(\eta\text{-}C_3H_5)_4$[74]. The estimated and experimental bond energies cover the range between almost 0 (monomer-dimer equilibrium[42]) to over 300 kcal/mol[75]. Complete transition from the metallic state to isolated mononuclear complexes or metal ions has been accomplished in compounds with more or less extended metal-metal linkages. The metal-metal bond has indeed become "textbook chemistry"[76]; however, there are many aspects yet to be elucidated.

The sheer volume of available material precludes a description of all compounds containing metal-metal bonds. The last attempt to do so for the transition metals dates from 1967[5], and the last attempt to cover all transition metal clusters was made in 1971[32]. In this present article, an attempt

[*] Prof. Dr. H. Vahrenkamp
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

is made to highlight points of a general nature and to examine aspects of systematics, structure, and bonding as well as reactivity and applicability of compounds with metal-metal bonds. The examples are selected with the aim of providing the best possible entry to the extensive literature.

2. Classification

The lightest metal lithium (in $[LiCH_3]_4$[77]) and the heaviest natural metal uranium (in $U_6O_4(OH)_4(SO_4)_6$[31]) undergo metal-metal interactions. The number of compounds with metal-metal bonds formed by the metals lying between these two extremes varies; a maximum occurs in the middle of the transition metal series, and that is where the main emphasis of this article lies. The early main group metals[78] and the lanthanoids[79,80] form a few compounds of this type, while the post-transition elements[13,81] form many; combination with transition metals[6,12] provides a means of forming stable metal-metal bonds for all metallic elements.

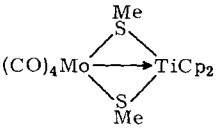
The conditions for the occurrence of metal-metal bonds have often been discussed[5,14,31,32,47,51]. The conclusions reached comply with chemical experience, but are only qualitative and do not necessarily follow from theoretical considerations. The situation is clearest in the large number of polynuclear complexes in which the tendency to achieve an 18-electron configuration is met by covalent bonding with other metal atoms. In many other cases, the metal-metal bond is a compromise adopted in the absence of other bonding partners. Examples are the electron-deficient compounds[78], the lower halides of Nb, Ta, Mo, W, and Re[19,31,34,62], and the metallocenes of the early transition metals[82,83]. However, structural constraints can also give rise to metal-metal bonds. Thus the crystal lattice of the bonding partners in many solids imposes spatial proximity of metal atoms[20,51,59,84,85], and the geometrical requirements of bridging ligands can lead to the contact of two metal atoms[18,23,26]. It is immaterial whether two identical or two different metal atoms interact with each other.

2.1. Units Containing Two Metal Atoms

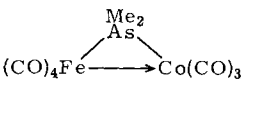
Most of the compounds considered contain two linked metal atoms[1-62]. All kinds of metal-metal interaction are encountered in dinuclear compounds, with bridging ligands frequently contributing to the stabilization of unusual kinds of bonding and bond orders.

2.1.1. Single Bonds

In organometallic compounds, any two molecular fragments which each need one electron to complete the inert gas configuration will generally be able to combine. The product is usually a dinuclear compound with a metal-metal single bond involving main group and/or subgroup elements. An analogous rule can be formulated for solid state chemistry which states that transition metal ions with d^1 configuration can approach pairwise in the crystalline network. However, this rule is not always obeyed and M_2 units with a single bond are also encountered among other d-electron configurations.

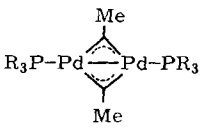


In addition to the large number of systems which can be described in this way, there are others requiring formulation with donor-acceptor metal-metal bonds[86-88]. Unequivocal cases are, *e.g.*, *(1)*[89] and *(2)*[90]; and *(3)*[91] and *(4)*[92] are also best formulated in these terms.

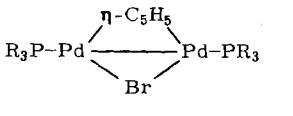


(1)

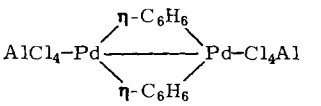
(2)



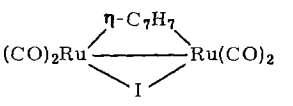
(3)



(4)



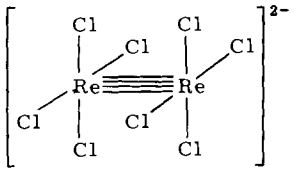
The metal-metal single bond in complexes can be bridged by up to four ligands; in solids it can "reach through" between a maximum of four anions in the lattice. The commonest examples are the linkage of ML_6 octahedra *via* shared edges (two bridging atoms) or *via* shared faces (three bridging atoms)[17,22,26,51]. Even ligands normally occupying terminal positions can act as bridges in dinuclear complexes. Examples are the allyl ligand in *(5)*[93], the cyclopentadienyl ligand in *(6)*[94], benzene in *(7)*[95], and the cycloheptatrienyl ligand in *(8)*[96]. Numerous unusual organic double bond systems likewise owe their existence to stabilization in a dinuclear complex[46].



(5)

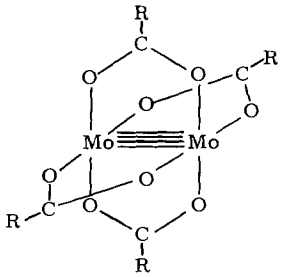
(6)

(7)



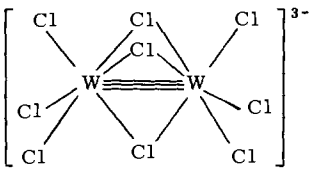
(8)

2.1.2. Multiple Bonds



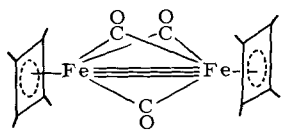
Bond orders of 2, 3, and 4 between metal atoms are no longer unusual. Examples are encountered most frequently in units containing two metal atoms. While the chloro complexes and acetates of some heavy transition metals were the first to exhibit metal-metal multiple bonds[15,16], the phenomenon has meanwhile been observed for most transition metals and classes of compounds.

The elements showing the greatest tendency to form multiple bonds are chromium, molybdenum, tungsten, and rhenium. Apart from the meanwhile classical compounds *(9)*—*(11)*[14] and their derivatives[15,16], there are numerous other similar units of stoichiometry M_2X_8 (quadruple bond) and M_2X_6 (triple bond). X may stand for alkyl[97], allyl[74], dialkylamino[98], alkoxy[99], and halogen[100].

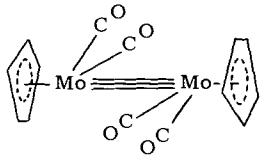


While metal-metal multiple bonds are rare in solid state chemistry[5,51,59], a large number of organometallic complexes with such bonds have recently been found. A condition for the stability of these compounds is that the M_2 unit

(9)

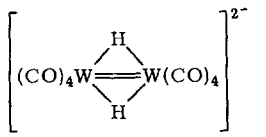


(10)

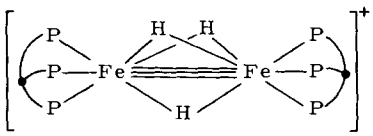


(11)

be protected by numerous or bulky ligands, as demonstrated particularly well by pentamethylcyclopentadienyl complexes[33]. Compounds *(12)*[101] and *(13)*[102] are two typical examples.

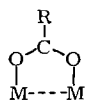


(12)

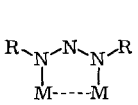


(13)

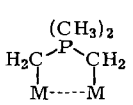
The necessary crowding in the ligand sphere also explains why bridging H atoms having very modest spatial requirements go so well with metal-metal multiple bonds; up to four such bridges may occur[103]. Double and triple bonds are observed [cf. *(14)*[104] and *(15)*[105], respectively]. A valid alternative to the double bond formulation in *(14)* is a formulation analogous to diborane with two WHW three-center bonds.



(14)



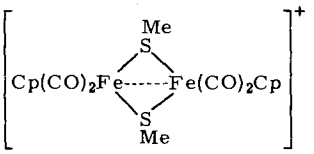
(15)



Bidentate ligands with three atoms in the bridge are able to force two metal atoms relatively close together. As a result, metal-metal multiple bonds are favored in carboxylates[5, 16, 18], triazenides[106], and derivatives of trimethyl(methylene)phosphorane[107] [cf. *(16)*—*(18)*]. In compounds of Cu[I][108], Ag[I][109], and Au[I][110] this leads to some degree of ambiguity because they can also be formulated without metal-metal bonds on the basis of their electronic structure, although the metal-metal distances are very short in some cases.

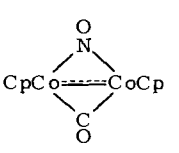
(16)

(17)



(18)

2.1.3. Weak Interactions



In many solids displaying a tendency to undergo metal-metal bonding, the attractive forces between the metal atoms are insufficient to displace them significantly from the centroids of their anion polyhedra. The result of this balance of forces is the weak metal-metal interaction in numerous compounds of stoichiometry $MHal_2$, MO_2, MOHal, and $M'_3(M_2Hal_9)$[5, 51, 59]. The structures and magnetic moments of such compounds indicate M_2 units with metal-metal bond orders of zero to two, depending upon the metal, anion, and stoichiometry. The usual relation between electronic structure and bond order is invalidated by stereochemical factors in these compounds.

This phenomenon is hardly encountered in organometallic complexes. Although the metal-metal distances can admittedly be varied between wide limits by the influence of bridging ligands (see Section 3.1), uncoupling of the two metal atoms, and hence paramagnetism given an even number of electrons, is only seldom observed[5, 17]. In contrast, inorganic dinuclear complexes with chalcogen and halogen bridges display a highly varied magnetochemistry which can be rationalized in part by weak metal-metal interactions[23, 26, 35]. In particular, the chemistry of Cu[II][7, 25] and Cu[III][18, 29] is rich in structural and magnetic anomalies.

Still anomalous and yet unequivocally definable are the half-integral bond orders found in some organometallic dinuclear complexes. There are one or three electrons too few for both metal atoms to achieve an 18-electron configuration. Such complexes are formed on use of ligands with an uneven number of electrons or by redox reactions. Complexes

(19)

(20)

(19)[111] and *(20)*[112, 113] having metal-metal bond orders of one-half and one-and-a-half, respectively, represent these rather atypical compounds.

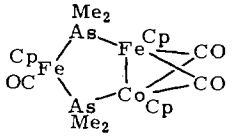
2.2. Aggregates

The commonest form of aggregated systems containing several linked metal atoms are clusters; however, individual metal-metal bonds or several of them may also occur in chains, rings, and cage-like structures. It cannot usually be predicted whether aggregates or simple systems with metal-metal multiple bonds will be formed. The number of bonding partners seems to be an important criterion (see Section 2.1.2). Large numbers of ligands or anions favor multiple bonding, small numbers promote aggregation.

2.2.1. Short Chains of Metal Atoms

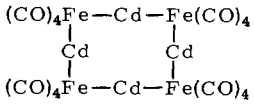
Arrangement of a few transition metal atoms in a short chain is relatively uncommon. It is hardly observed in solid-state compounds and inorganic complexes; only organometallic chemistry provides a few isolated examples. The simplest

cases are linear homoatomic systems such as *(21)*[114] or L_nMX_2 derivatives such as *(22)*[115].



$[(CO)_5Mn—Mn(CO)_4—Mn(CO)_5]^-$ *(21)* $(CO)_5Mn—Pd(py)_2—Mn(CO)_5$ *(22)*

Under suitable electronic conditions bent structures also occur[116,117], leading almost as far as arrangement of the metal atoms in an equilateral triangle[118]. Unusual bridging ligands[119] and donor-acceptor metal-metal bonds[120] are also found in these trinuclear complexes. The chain arrangement of four transition metal atoms has so far only been described for complex *(23)*[121], which is probably only a short-lived intermediate[122].



$Cl—Os(CO)_4—Os(CO)_4—Os(CO)_4—Au—PPh_3$ *(23)*

2.2.2. Rings and Cages

Linkage of two transition metal atoms *via* a chelate ligand to form a ring system is very common [cf. *(16)—(18)*]. Three and four metal atoms are joined together in rings containing four to eight members. Compounds *(24)*[123] and *(25)*[124] are typical examples. The structural chemistry of rings containing four metal atoms is of great variety; all

(24)

(25)

possibilities between zero and four metal-metal bonds are represented[10].

Numerous cage-like polynuclear complexes combine the bonding tendencies of the main group elements (as bridging ligands) and the transition metals (as polynuclear complex units). This relation is seen most clearly in polynuclear sulfur complexes[55]; however, other combinations of main group elements and transition metals also exhibit the full range of possibilities, from the pure cage structure without metal-metal interaction to the complete aggregation of metal atoms to form clusters. Polynuclear complexes with four metal atoms[17,125-127] provide the clearest illustrations.

The relationship between the bonding in polyhedral boranes and transition metal clusters[58] explains why structural units of these two classes of substances can be combined together. Incorporation of M_2, M_3, and M_4 units into the cage structure of boranes and carboranes[128] is accordingly a rapidly developing area of chemistry. The structures of two such cages are shown in order to demonstrate the scope of such reactions (Fig. 1).

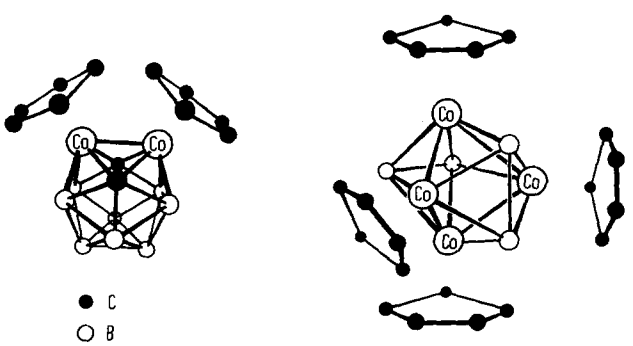


Fig. 1. Structures of $(CpCo)_2C_2B_8H_{10}$ [128] (left) and $(CpCo)_4B_4H_4$ [129] (right).

2.2.3. Clusters

Clusters of main group[13] and transition metals[10,11,28,56] have recently been reviewed and details are therefore readily available. The enormous structural variety of clusters still frequently resists systematization. The principal general points to be noted are: in addition to the well known arrangements of metal atoms as triangles, tetrahedra, and octahedra, many other geometries occur; clusters comprising up to 18 metal atoms have been found whose coordination resembles that in the bulk metal; clusters occur in solids and in inorganic and organometallic complexes; and the number of electrons and bond orders in clusters can deviate appreciably from the values expected by simple rules. Clusters provide the clearest demonstration that aggregates of several metal atoms are only partly governed by the rules discovered in the study of units containing two metal atoms, and that in some respects they already exhibit the cooperative phenomena of extended metal atom arrangements.

2.3. Extended Arrangements

In the region between metallic and ionic bonding and between metallic and covalent bonding we find compounds with infinitely extended arrangements of metal atoms. These compounds can be classified as "dilute metals" with the metal atoms linked in a kind of three-dimensional network, "two-dimensional metals" with layer-type linkage, and "one-dimensional metals" with chain-like linkage of the metal atoms. Practical interest in the optical and electrical properties of such compounds has greatly stimulated their study in recent years.

2.3.1. Chain Structures

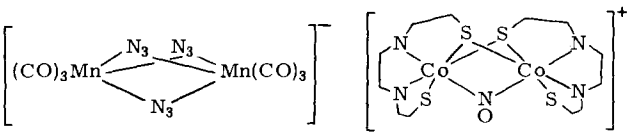
The chain structures include the only extended metal atom arrangements that can still be described by means of covalent metal-metal bonds. These are stoichiometrically pure, square-planar d^8 complexes which are stacked with short metal-metal bonds in their crystals. They include $[Ir(CO)_3Cl]_x$[130] and similar iridium compounds[131] in which each iridium atom achieves an 18-electron configuration by two metal-metal bonds.

Normally, however, d^8 complexes crystallize without pronounced metal-metal interaction[36,43]; only partial oxidation leads to mutual approach of the metal atoms, especially in the platinum complexes, with all its drastic physical consequences which can only be described in terms of a band model[36,44,54,132]. Optical, electrical, magnetic, and structural properties attributable to a one-dimensional infinite linkage of metal atoms are also found for polymeric ligand-bridged complexes, for crystalline $A^+MX_3^-$ compounds, and for some metal trihalides[24,30]. Finally, many Zintl phases[133] and transition metal sulfides[85] and phosphides[84] have long been known to contain chains of metal atoms in their crystals.

2.3.2. Layers and Three-Dimensional Networks

Numerous metal sulfides, selenides, phosphides, and arsenides have metallic properties because the modest electron affinity of the heavy chalcogen and pentel[*] atoms permit electron delocalization, *i.e.* metallic interaction. The structures of these compounds frequently indicate extended metal atom linkages[84, 85, 133]. Two- and three-dimensional metal-metal interactions are also being increasingly observed in halides and oxides of metals in formally low oxidation states[24, 59]. A classical example of metal atom layers is Ag_2F[59], and a recent one is found in the lanthanoid monochlorides[80]. Sc_7Cl_{10}[79] represents a transition between two-dimensional and three-dimensional linkage. And the alkali metal suboxides Rb_6O and Cs_7O[134] are excellent examples of "dilute metals", with ionic regions embedded in a metallic network.

As the extension of metal-metal interactions increases, the resemblance to metals becomes closer and closer. This also means that statements concerning electron balance and bond order become meaningless once the basic premises of localizable and covalent bonds no longer apply.



3. Studies on the Nature of the Bond

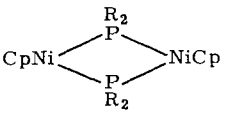
Classical experimental data in the chemistry of metal-metal bonds are interatomic distances and magnetism. However, these data do not always permit unequivocal delineation, and they do not adequately account for energetic information. In spite of the complicated nature of most of these compounds, the significance of other experimental and calculation methods of chemistry is therefore increasing in this field too. They are still mainly limited to units containing two metal atoms.

3.1. Bond Lengths

It is generally agreed that metal-metal bonds should be considered when the metal atom distances are of the same order as in the metal. The variability of metal-metal distances *(vide infra)*, however, precludes any definition of covalent metal atom radii and conclusions based solely on bond lengths. For instance, the metal-metal distances in complexes *(26)*[135] and *(27)*[136], for which the 18-electron rule predicts *no* metal-metal bonding, are shorter than in complexes *(28)*[69] and *(29)*[137] of the same metals *with* metal-metal bonding. Contradictions of this kind are encountered above all in the chemistry of univalent copper[7, 25].

The metal-metal bond defines a relatively flat energy minimum as a function of the interatomic distance. This fact is just as apparent in the structures of polynuclear complexes as in the flexibility of many bulk metals and the fluctuation of the metal atoms in individual clusters[138]. For this reason, the identification of a metal-metal bond requires the comparative study of two compounds of similar stereochemistry. The drastic change in geometry on going from *(30) without* metal-metal bonding to *(31) with* metal-metal bonding constitutes proof of the structure-determining power of this bond[139].

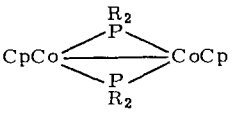
(26), Mn–Mn = 2.89 Å



$(CO)_5Mn$–$Mn(CO)_5$

(28), Mn–Mn = 2.93 Å

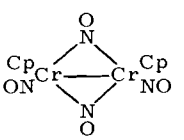
(27), Co–Co = 2.77 Å



$[(CN)_5Co$–$Co(CN)_5]^{6-}$

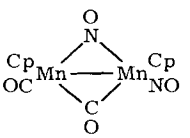
(29), Co–Co = 2.80 Å

(30), Ni–Ni = 3.36 Å



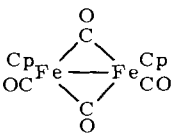
R = C_6H_5

(31), Co–Co = 2.56 Å



R = C_6H_5

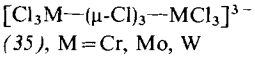
Variability of the metal-metal bond lengths is especially clear in complexes with bridging ligands which keep the metal atoms together even in cases of weak interaction. Thus the Fe—Fe distances in bridged dinuclear complexes having an Fe—Fe bond lie between 2.37 and 3.05 Å[17], and the influence of bridging atom radii and the number of ligands on the metal-metal distances can be followed systematically[17, 140]. On the other hand, the complexes *(32)*—*(34)*[141] in which the bond lengths do not differ significantly show the stereochemistry of the ligand system to exert a greater influence on these bond lengths than the differing radii of the metal atoms.



(32)

Cr–Cr = 2.61 Å

(33)

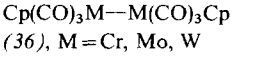


Mn–Mn = 2.57 Å

(34)

Fe–Fe = 2.53 Å

In cases of strong metal-metal interactions (*i.e.* generally with heavy transition metals) a compromise is often observed between the steric requirements of the coordination partners and mutual attraction of the metal atoms. Complexes *(35)*[73] and *(36)*[142] demonstrate how the bond between the metal atoms increases with increasing atomic weight. The optimum short metal-metal distance is achieved in none of these cases and one therefore speaks of "submaximum overlap".



(35), M = Cr, Mo, W

Cr—Cr = 3.12 Å

Mo—Mo = 2.66 Å

W—W = 2.41 Å

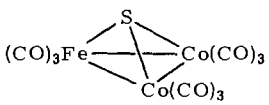
(36), M = Cr, Mo, W

Cr—Cr = 3.28 Å

Mo—Mo = 3.24 Å

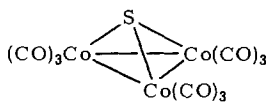
W—W = 3.22 Å

The numerous dimeric metal carboxylates[5, 16, 18] and metal dioxides with distorted rutile structure[5, 59, 68] are also ligand-bridged systems and likewise fail to show good correlations between metal-metal distances and bond orders. Conversely, series of complexes shown by other measurements to have different bond strengths often display constant metal atom distances[143, 144]. On its own, X-ray structure analysis is not very informative here; however, its advanced application, electron-density determination[64, 145], could provide more information in the future.



[*] Group V elements. See IUPAC Nomenclature of Inorganic Chemistry, Rule 1.21, and the Section entitled "Collective Names for Groups of Elements".

3.2. Magnetism



A decrease in magnetic moment from the value for isolated metal atoms in their coordination sphere is the quickest indication of a metal-metal bond. It applies almost without exception to organometallic complexes in which the metal-metal bond is nearly always associated with diamagnetism. It is only of limited validity for more "inorganic" transition metal compounds, in which diamagnetism is more often the exception then the rule and in which the reduced magnetism often comes about by superexchange *via* bridging atoms. Many metal dioxides[5, 59, 68] and carboxylates[5, 16, 18] again serve as examples for the latter effect: slight paramagnetism, temperature independent paramagnetism, antiferromagnetism, and ferromagnetism in the case of CrO_2, all occur.

Detailed papers have been published on the theory of magnetism in systems with two coupling metal atoms[26, 35, 146], on the application of the theory to complexes[23] and solids[20], or to the description of individual classes of compounds, especially copper carboxylates[18, 29]. Of great importance to the theme being discussed is the fact that there is no direct relation between magnetic coupling and the bonding interaction between two metal atoms.

NMR and ESR investigations on the nature of the metal-metal bond are sparse. The finest result was obtained in a single crystal ESR study of the paramagnetic complex *(38)* which was diluted with the isostructural diamagnetic complex *(37)*[147]. It was found that the unpaired electron of *(38)*

(37)

(38)

occupied an antibonding A_2 orbital formed from metal d-orbitals; this provides experimental proof of the metal-metal bond character of the highest occupied orbitals in such complexes.

3.3. Electronic Structure

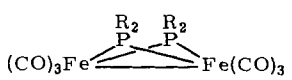
A theory of metal-metal bonding must correctly reproduce the observed structural and magnetic data. In more sophisticated form, it should also interpret the electronic spectra of polynuclear complexes or solids which have recently been studied in great detail[148, 149], and among which only the absorption for the $\sigma \rightarrow \sigma^*$ transition of single bonds[150, 151] and the $\delta \rightarrow \delta^*$ transition of quadruple bonds[152] can be assigned with comparative ease.

The simplest starting point is the 18-electron rule, the noble gas rule of transition metal chemistry. It governs organometallic compounds and permits ascertainment of the number of metal-metal bonds in a complex by a simple counting procedure. Systems with an odd number of electrons are rare in such cases, and only few heavy and late transition metals form 16-electron complexes.

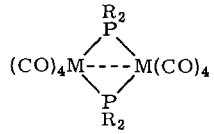
Of similar qualitative nature and value is the skeletal electron counting method of the Wade rules[58], which was developed from the bonding theory of polyhedral boranes and links the electronic structure of organometallic clusters with their geometrical structure. In the modified form due to *Johnson*[153], the method can reproduce the shape of clusters having up to eight metal atoms[56]. An attempt at further simplification lies in the purely geometrical consideration of the space within a closely packed arrangement of ligands. Such a geometrical approach can indeed predict the shape of many clusters, independently of the bonding between the metal atoms in this space[154, 155]. The "theories" mentioned thus far do not forecast energies, but otherwise possess considerable predictive value.

Simple MO methods attempting to provide an illustrative picture of the nature of metal-metal interaction are restricted mainly to energy estimates with the aid of the symmetry properties of the metal atomic orbitals. In many cases they nevertheless afford correct correlations between the number and nature of the metal-metal bonds in complexes and clusters and the electronic configuration of the participating metal atoms. The decisive simplification consists in the complete separation of metal-ligand and metal-metal bonding. Thus, it could be shown for the structural units $Mo_3O_8^{4-}$[156], $Mo_6Cl_8^{4+}$[157], $Nb_6Cl_{12}^{2+}$ and $Ta_6Cl_{12}^{2+}$[157, 158], $Re_3X_{12}^{3-}$[157, 159], and $Re_2X_8^{2-}$[75, 160] that in each case all metal-metal bonding MOs are completely occupied by electrons. Statements about the symmetry and energy of the HOMOs in ligand-bridged dinuclear complexes were obtained analogously[161]; however, these statements did not stand up to quantitative scrutiny[162]. Finally, the predicted HOMO-LUMO nature of the metal-metal bonds of organometallic clusters could be confirmed by the ESR spectra of the complexes *(38)* and corresponding Se and Te compounds[147] and by the distinct structural differences of the Fe_4S_4 compounds *(39)*—*(41)*[163].

(39)



(40)



(41)

Quantitative semiempirical MO procedures, preferably the extended Hückel method (EH), are progressing towards a description of the energetics of the metal-metal bonds. This concerns the theory of magnetic interactions[146] just as much as the assignment of UV and PE spectra[164]. EH calculations have also provided a quantitative basis for the skeletal electron counting method as applied to polyhedral clusters[165] and accounted for the variation of metal-metal distance and ligand geometry in the bridged complexes *(42)*[166].

(42)

(43), M = Mn, Cr

The complicated nature of the systems preclude *ab initio* MO calculations in transition metal chemistry. Their predictive power is almost equalled, however, by two modern methods. The parameter-free approach of *Fenske* and *Hall* unequivocally demonstrated the HOMO-LUMO character and σ type of the metal-metal bonds in ligand-bridged dimers such as *(42)*[167] and *(43)*[162]. The SCF-X_α-SW procedure has also provided a very detailed description of the strong

metal-metal bonds in $Mo_2X_8^{4-}$ compounds[168,169] and the weak metal-metal bonds in the dimer $[Rh(CO)_2Cl]_2$[170] and in the tetramer *(40)*[171].

3.4. Bond Energies

Thermochemical determination of metal-metal bond energies is difficult. There are so many assumptions and simplifications to be made that the values obtained are very uncertain. Accordingly, indirect methods are still used today.

Such a method, *viz.* estimation of orbital energies, gave the highest energy value for cleavage of a chemical bond, 366 kcal/mol for the Re—Re quadruple bond of $Re_2Cl_8^{2-}$ *(9)*[75] which was subsequently reduced to 115–130 kcal/mol after a careful spectroscopic analysis[148]. Likewise indirect are determinations by way of mass spectrometric appearance potentials[172] or recombination kinetics after flash photolysis[173], which gave 25 and 36 kcal/mol for D(Mn—Mn) in $Mn_2(CO)_{10}$, as against a calorimetric value[174] of 16 kcal/mol. The values of D(Co—Co) in $Co_2(CO)_8$[174–176] also vary.

More direct information is available from equilibrium measurements in the gas phase[177] or from thermochemical measurements[174,176]; the error margin is 20—50% even in the most favorable case. The most consistent values include those recorded as activation energies of reactions proceeding *via* cleavage of the metal-metal bond[150,178]. For instance, 37 kcal/mol are required for cleavage of the Mn—Mn bond in $Mn_2(CO)_{10}$.

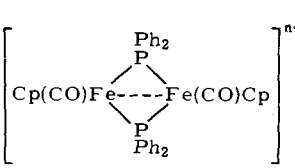
All determinations of metal-metal bond energies confirm the trend already discovered in the chemistry of these compounds[10,14,51] and in their mass spectra[38,179]: bonds between metals of the first transition series are extremely weak while considerable bond strengths are encountered with the heavier transition metals, and an increase in electron density at the metal atoms lowers the strength of the bond between them.

3.5. Vibrational Spectra

A convenient source of information about metal-metal bond energies should be vibrational frequencies or force constants, especially since it has been demonstrated[150,164] that these data can be correlated with the indirectly determined metal-metal bond strengths. Unfortunately, the low frequency metal-metal vibrations usually lead to very low IR intensities, and the colored substances often decompose on Raman measurements with laser light. On the other hand, the totally symmetric metal-metal stretching vibrations occasionally acquire very high intensities due to the resonance Raman effect, thus facilitating their assignment.

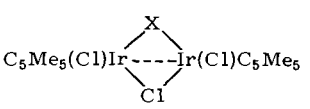
Metal-metal single bonds in dinuclear complexes exhibit vibrational frequencies of 150—250 cm^{-1}, corresponding to force constants of 0.5—1.5 mdyn/Å[41,53,180–182]. Frequencies and force constants show the familiar trend of increasing bond strength on going from the lighter to the heavier metals. The same applies to linear trinuclear complexes[115,183]. In these simple compounds the force constants can be calculated approximately by neglecting the ligands; this is impossible with polynuclear compounds owing to extensive coupling between metal-metal and metal-ligand vibrations[41,53].

Multiple bonds between metals appear at distinctive frequencies in the vibrational spectra. Thus a Fe—Fe double bond has a force constant of 2.7 mdyn/Å[184], and the triple and quadruple bonds in Mo and Re compounds have force constants of 3.5—4.5 mdyn/Å and vibrational frequencies of 270—400 cm^{-1}[181,185,186]. Assignment and evaluation of vibrational frequencies is more difficult in the case of clusters; however, conclusions concerning bond strengths correspond to those drawn from other measurements[41,53,181].



Some special applications of vibrational spectroscopy warrant mention. The most recent estimates of dissociation energies of metal-metal quadruple bonds were obtained by the Birge-Sponer approximation from overtone analysis of the corresponding Raman spectra[148]. Assignment of the $\delta \rightarrow \delta^*$ transition in the electronic spectra of complexes containing quadruple bonds was confirmed by the resonance Raman effect[187]. However, unequivocal information about bonding of the metal atoms in copper(II) acetate could not be obtained from the vibrational spectra either[181].

3.6. Variation of the Number of Electrons



The greater the number of metal atoms linked together, the greater will be the readiness of the relevant bonds to accept unusual numbers of electrons. The excess or deficient electrons are distributed over the clusters. That this essentially amounts to variation of metal-metal interaction has been demonstrated above all for transition metal clusters containing sulfur[55]. This also provides a rational explanation for the various overall oxidation states of niobium, tantalum, molybdenum, and tungsten in octahedral M_6-halogen compounds and for the existence of paramagnetic organometallic clusters[32,56].

At the same time, polynuclear complexes become accessible to a topical method of study, *viz.* electrochemistry. Numerous electrochemical oxidations and reductions have been carried out with metal-metal linked systems in recent years[42,188]: trinuclear[189–192] and tetranuclear transition metal complexes[55,193–195] proved to be especially suitable for such studies, as did complexes with multiple bonds[196]. The effect on the metal-metal bond complied with expectation in all cases.

The resulting effects are even clearer in the few dinuclear complexes which are able to take up and release electrons reversibly[111,197,198]. This is the reason why organometallic complexes with odd numbers of electrons, such as *(19)* and *(20)*, are very rare. Experiment[188] and theory[162] concur in showing that the acquisition of two electrons means the destruction of a metal-metal bond, and *vice versa*. Accordingly, the Fe—Fe distance in complexes *(44)*[199] is 3.49 Å for $n=0$,

(44), n = 0,1,2

(45), X = H, Cl

3.12 Å for $n=1$, and 2.78 for $n=2$, and analogously in complexes *(45)*[200] 3.77 Å for X=Cl and 2.90 Å for X=H. Two electrons are removed by the oxidation process in *(44)*, and by replacement of the three-electron ligand Cl by the one-electron ligand H in *(45)*.

3.7. Cooperative Phenomena

Deep color, conductivity, and unusual magnetic properties are the physical manifestations of the transition from covalent metal-metal bonding to metallic bonding in solids (cf. Section 2.3). In this article we shall consider only the phenomena observed with infinite one-dimensional systems.

In keeping with their structure, compounds containing chains of metal atoms exhibit anisotropy in many of their physical properties. The practical potential of these compounds has prompted intensive research into such properties. Surveys have been published of optical, NMR, and ESR spectra, conductivity and superconductivity, magnetism, Mössbauer spectra, dielectric constants, and diffraction of X-rays and neutrons[21, 24, 30, 44, 54, 61]. Furthermore, the structures[24, 30, 54, 201] and theory of bonding[24, 30, 44, 61, 132, 202] of one-dimensional metals have also been studied.

Among the one-dimensional systems, significant metal-metal interactions probably occur only in the polymeric d^8 complexes. This is especially true of partially oxidized species in which all the metal atoms are equivalent, although the oxidation numbers do not have integral values. Metallic properties embracing even superconductivity are to be expected in some cases; however, distortions of the chains of metal atoms are often observed, partly in connection with the Peierls instability, which transforms the metallic conductors into semiconductors or insulators at low temperatures.

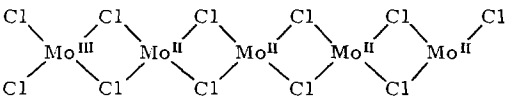
4. Chemistry of Metal-Metal Bonds

Owing to the large number of types of compounds with metal-metal bonds, it is impossible to present generally valid schemes for their synthesis or reactions. Many reactions leading to formation or breaking of metal-metal bonds are still discovered by chance. Compared with other classes of compounds, the systematic preparative chemistry of metal-metal bonds is still underdeveloped.

4.1. Synthesis

A number of conditions indicated by chemical experience have to be fulfilled for metal-metal bonds to be formed. These include relatively low oxidation states of the metals, suitable bonding partners, suitable coordination sphere, and frequently also the presence of heavy transition metals. If the metal and bonding partner are then chosen in such a way that the resulting hypothetical mononuclear species has an odd number of electrons, dimerization to form a metal-metal bond become likely. Examples of such predictable compounds are the carbonyl complexes of transition metals with an odd number of electrons[3] and the halides of the d^1 ions[19, 51].

A systematic entry to metal-metal bonds common in organometallic chemistry consists in metathetic reaction of a metal-halogen compound with an anionic metal complex. Innumerable hetero-dinuclear complexes, especially main group metal-transition metal compounds have been prepared in this way[3, 5]. The combination of two neutral complexes to form donor-acceptor metal-metal bonds also belongs to this kind of nucleophilic attack on a metal center (cf. Section 2.1.1).



Less systematic, but no less versatile, are reactions involving elimination of bonding partners from mononuclear compounds. This method is commonly used to prepare M_2 units from carbonyl complexes or metal halides[19]. Well known examples are the formation of $Fe_2(CO)_9$ from $Fe(CO)_5$ and the formation of $[Nb_2Cl_8]_x$ from $NbCl_5$. The method of elimination must be chosen such that the desired compound does not undergo further reaction. The success rate of such reactions is enhanced if the two metal atoms are previously linked *via* a bridging ligand[203, 204]. In favorable cases, elimination can also lead to multiple bonds[33, 101, 102].

Bridging atoms can themselves induce formation of metal-metal bonds. For this to happen, bonding partners must be present or generated in the reaction system which are capable of linking together several metal atoms. In this connection, detailed studies have been performed on the PR_2 and SR groups[22], the H atom[28], and the acetylene ligand[5, 205] which stabilize many dinuclear species. Sulfur atoms have proved particularly effective in linking three metal atoms, thereby supporting cluster formation[1, 55].

The synthesis of aggregated systems is possible, in principle, by the same methods as for dinuclear units. Clusters or polymers are formed with suitable metals if a multiply unsaturated species is constructed in the presence of a substoichiometric amount of bonding partner or on simultaneous elimination of several bonding partners. In the case of halogen clusters of Nb, Ta, Mo, W, and Re this is accomplished by reduction of higher halides, which can be controlled to give the desired oxidation state or cluster form[19, 51]. The large clusters of gold[56], nickel[206], and platinum[207] are formed by reduction from simple halogen or carbonyl complexes of these metals.

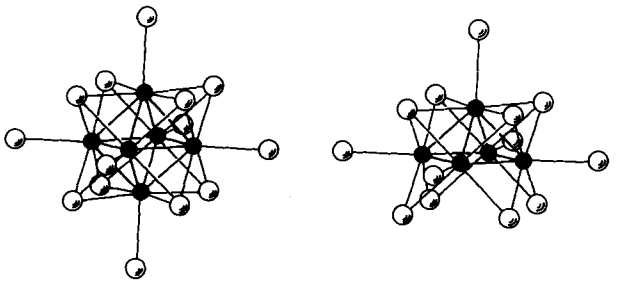
Among the carbonyl complexes, elimination of CO groups is the commonest method of aggregation. It can be induced thermally, photochemically, or chemically, and the shape of the resulting cluster cannot be predicted[11, 34, 56]. Impressive examples are seen in the synthesis of osmium carbonyl clusters containing up to eight osmium atoms by pyrolysis of $Os_3(CO)_{12}$[153] and the preparation of hydride clusters by pyrolysis of carbonyl complexes in the presence of hydrogen[28, 208]. Hetero-clusters can also arise by co-aggregation of two metal carbonyl species[56].

The mode of formation of clusters cannot usually be stated; kinetic studies are available in only two cases. They suggest that transformation of $Co_2(CO)_8$ into $Co_4(CO)_{12}$ proceeds *via* elimination of CO to give $Co_2(CO)_7$ and $Co_2(CO)_6$ which then dimerizes[209]. In the reduction of molybdenum halides

(46)

to Mo_6 clusters there are indications that a Mo_5Cl_{11} chain *(46)* is initially formed which then coils up to give the

$Mo_5Cl_{13}^{2-}$ cluster which has been isolated. Addition of another Mo_1 unit then gives the final product $Mo_6Cl_{14}^{2-}$ (Fig. 2)[210a].



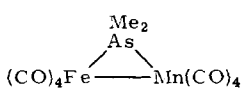


Fig. 2. Structures of the $Mo_6Cl_{14}^{2-}$ (left) and $Mo_5Cl_{13}^{2-}$ clusters (right) [210b].

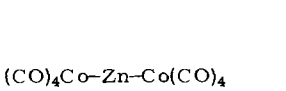
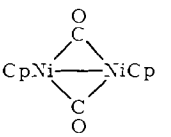
As the number of known compounds with metal-metal bonds increases, so also do the number of transformations of such compounds by substitution and the number of analogous syntheses with other bonding partners. In favorable cases, the carbonyl groups of polynuclear complexes[3, 211] and clusters[56] can be replaced by two-electron donors. The same applies to the halogen ligands in octahedral halogen clusters[212] and in dinuclear complexes with quadruple bonds[16]. The synthetic methods employed, especially for "one-dimensional metals", are usually the same, *viz.* conproportionation or partial oxidation, and the physical properties are modified by systematic variation of the bonding partners[24, 30, 213, 214].



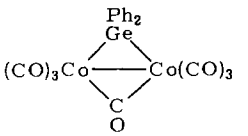
4.2. Reactions

Thorough studies of the reactions of complexes with metal-metal bonds have been limited to rearrangements and ligand substitution[3, 5, 10, 16, 32, 39, 50, 56]. Reactions directly affecting the metal-metal bond, which we shall consider in this article, have only recently attracted attention. The "softness" and variability of the metal-metal bond permits nucleophilic and electrophilic attack, homolytic and heterolytic cleavage, oxidation and reduction, the boundaries between the various reaction types often being poorly defined.

The most frequently observed reaction of the metal-metal bond is its nucleophilic degradation. This is promoted by the fact that bonding of a metal atom to a ligand nearly always liberates more energy than bonding of a metal atom to another metal atom[10, 51]. The longest known examples are seen in the disproportionation of polynuclear carbonyl complexes under the influence of hard bases[211]; however, phosphanes, acetylenes, and even CO cleave metal-metal bonds in carbonyl complexes of light transition metals[10, 32, 205, 211], the "large" clusters[11] being particularly sensitive to CO. In ligand-bridged complexes such as *(47)*, reversible cleavage by CO clearly demonstrates the weakness of the metal-metal bond[204, 215, 216]. And the tendency of complexes such as *(48)* to undergo ionic cleavage in polar solvents also correlates with the strength of their metal-metal bonds[42, 115]. The sensitivity of polynuclear complexes towards nucleophiles also raises problems in their CO substitution reactions.



(47)



(48)

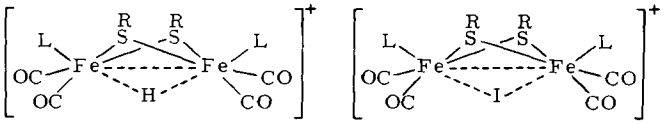
In many cases, nucleophilic attack is preceded by rupture of the metal-metal bond. This can be established by kinetic studies of the reaction course. Thus the Ni—Ni bond is broken prior to reaction of *(49)* with acetylenes[217], and the Co—Co bond prior to reaction of *(50)* with CO, phosphanes[218], or acetylenes[219]. The same applies to decomposition of $Co_4(CO)_{12}$ with acetylenes[205] and of $Ru_3(CO)_{12}$ with CO or phosphanes[220]. Even the racemization of phosphorus-bridged trinuclear complexes[221] and substitution of CO groups by phosphanes in $Mn_2(CO)_{10}$[150] proceed *via* intermediate cleavage of the metal-metal bond.

(49)

(50)

Surprisingly, even the quadruple bond of M_2X_8 compounds of molybdenum[222] and rhenium[223–225] is broken in the presence of suitable ligands. In these cases, however, the initial reaction step appears to be addition or substitution rather than cleavage of the metal-metal bond.

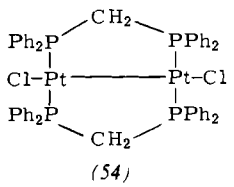
Further evidence for the weakness of the metal-metal bonds of the light transition metals is provided by numerous insertions of tin halides, SO_2, metals of the second subgroup, and acetylenes[42, 226, 227]. Insertion of $SnCl_2$ into *(51)* is preceded by homolysis of the Co—Co bond[228] *(vide supra)*.



$$Bu_3P(CO)_3Co—Co(CO)_3PBu_3 \quad (51)$$

The most effective means of inducing homolysis of metal-metal bonds is photolysis. The relationship between light absorption and light-induced cleavage has been thoroughly investigated for carbonyl complexes[34, 60], and monomeric complex fragments have been identified as the photolytic primary products[173, 229]. These short-lived fragments were identified by ESR spectroscopy after trapping with nitrosodurene, *i.e.* after transformation into the stable nitroso radicals[230]. Typical chemical reactions of the fragments are abstraction of halogen atoms from chlorohydrocarbons to form organometallic halides[60, 231] or addition of potential ligands to give substituted carbonyl complexes[34, 60]. A photooxidation has been described for the complex $[CpFeCO]_4$[232].

The variations in the electron complement described in Section 3.6 also affect the metal-metal bond. The most drastic effect is cleavage of the dinuclear carbonyl complexes to form carbonylmetalate anions on chemical or electrochemical reduction[3, 188]; the slightest effect is observed on addition or removal of an electron in some clusters[17, 42, 56]. The redox chemistry of transition metal clusters has also attracted recent attention (see Section 5), not least because of its biochemical significance.



The discovery that the occupied orbitals of highest energy in the compounds under consideration are those accounting for metal-metal interactions suggests that metal-metal bonds should be nucleophilic. Accordingly, some electrophiles do indeed add to metal-metal bonds. The protonation of

clusters[10, 28] is well known; however, protonation of metal-metal bonds in dinuclear complexes is by no means rare[233–235] even though many of the known complexes with H-bridged metal-metal bonds (see Sections 2.1.2 and ref. [5]) are not formed in this way. The electrophile $HgCl_2$, which frequently forms donor-acceptor metal-metal bonds, is also capable of adding to a bond between two metal atoms[236]. Oxidative cleavage of metal-metal bonds by halogens[3, 42, 237] also seems to start with an electrophilic attack. Ionic intermediates with positively charged halogen bridges are often postulated in this connection; their resemblance to the protonated compounds is illustrated by structures *(52)*[234] and *(53)*[237].

(52) L = PR_3 *(53)*

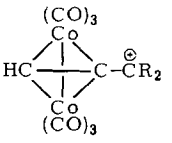
Addition of CO to *(54)*[238] is an example of the uncommon addition of nucleophiles to metal-metal bonds without subsequent reaction. Nucleophilic cleavage *(vide supra)* is the rule: the addition of CO, phosphanes, acetylenes, allenes, and halogens to the Mo≡Mo triple bond of *(13)* is no exception[102, 239], appearing as an addition only because a Mo—Mo single bond is retained. Some of the resulting complexes are also obtained by CO substitution from $[Cp(CO)_3Mo]_2$, which itself is transformed into *(13)* on loss of CO[102].

(54)

$Cp(CO)_2Mo{\equiv}Mo(CO)_2Cp$

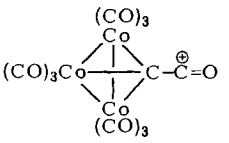
(13)

5. Systems Possessing Practical Potential



Economically the most important compound having covalent metal-metal bonds is $Co_2(CO)_8$, 25000 tons of which are employed per annum in oxo synthesis plants[240]. However, since the catalytically active species in the oxo synthesis does not contain a Co—Co bond it is outside the scope of this article. The use of other metal-metal linked compounds in engineering and the sciences is still insignificant, yet some of these hold promise of practical application in stoichiometric or catalytic organic reactions, in electronics, or in biology.

Properties of importance in this context—stabilization and activation of substrates—are also found in many metal-metal bonded complexes, and especially in clusters. Clusters show analogies with both polyfunctional mononuclear compounds and with the surfaces of metals. The following phenomena are of prime importance:



1) Polynuclear complexes can bind to unsaturated organic molecules[5, 32, 39, 46, 56]. The complexes can offer several bonding sites and form vacant coordination sites not only by substitution of ligands[39, 56], but also by cleavage of metal-metal bonds[241, 242].

2) Oxidative addition of substrates to polynuclear complexes appears to be favored by the proximity of two metal atoms. Many examples of unusual addition of H_2 and C—H bonds support this statement[28, 39, 56, 243].

3) Polynuclear complexes can act as reservoirs for excess or missing electrons[50, 56]. The two cobalt-stabilized carbocations *(55)*[244] and *(56)*[52] which can be isolated as salts are the clearest examples of this behavior.

(55)

(56)

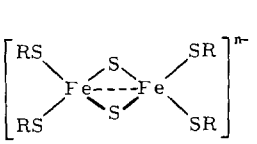
4) Many unsaturated organic compounds bound to polynuclear compounds exhibit fluxional behavior. This leads to contacts between metal and ligand atoms which are not linked together in the rigid structure[245]. Reaction sites can be made to approach each other in this way.

5) CO groups and H atoms are also highly mobile on the surface of polynuclear complexes. They behave essentially in the same way on clusters[4, 28, 39] as on clean metal surfaces[246, 247]. In particular, $Fe_3(CO)_{12}$ fluctuates so strongly that localized bonds between iron atoms and CO groups cannot be formulated[248, 249]. In clusters containing hydrogen as ligand[28, 250] the fluctuation of the H atom is comparable with the diffusion of hydrogen through metals with regard to mechanism and activation energy.

6) The similarity between clusters and metal surfaces is substantiated by the physical finding that ligand-free clusters containing only few metal atoms have practically the same electronic work functions as the clean metals[251].

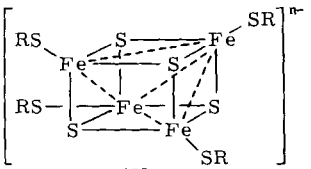
This knowledge has already been utilized in some stoichiometric and catalytic reactions. The cobalt-modification of organic compounds exemplified for *(55)* and *(56)* has led to an independent branch of chemistry dealing with acetylene-dicobalt[205] and methinyltricobalt complexes[52]; diverse organic reactions have been promoted by processes involving organometallic dinuclear complexes[252, 253]. Catalysis by clusters has been observed in isomerizations, hydrogenations, oligomerizations, and carbonylations of olefins and acetylenes; catalytically active intermediates have been isolated in several cases and it has usually been established that the clusters and not their fragments are the active species[39, 56, 205, 240, 242, 254–256]. A process for production of hydroquinone from acetylene, CO, and H_2 with $Ru_3(CO)_{12}$ as catalyst appears to have been developed to an industrial scale[240]. The renaissance of coal chemistry is also reflected in this area: it has recently been discovered that $Ru_3(CO)_{12}$ catalyzes the water gas shift reaction (a) at low temperature[257] and that $Ir_4(CO)_{12}$ is a useful catalyst for the Fischer-Tropsch synthesis (b)[258]. The cluster is not destroyed in either case.

$$CO + H_2O \rightleftarrows CO_2 + H_2 \quad (a)$$



$$nCO + (2n+1)H_2 \rightarrow C_nH_{2n+2} + nH_2O \quad (b)$$

Possible uses of "one-dimensional metals", *viz.* compounds containing chains of metal atoms, lie in their postulated superconductivity and in the fact that in the ideal case they represent minute electrical conductors with their own insulation[21, 36, 44, 61]. Nevertheless, in spite of the large number



of chemical and physical studies[24, 30] the desired high-temperature superconductivity has yet to materialize, and their use as current carriers is limited by the difficulty of obtaining ideal crystals of sufficient size.

Biochemical stimuli for the study of complexes with metal-metal bonds result from the observation that biological redox systems often involve enzymes containing several metal atoms[259]. Since polynuclear complexes readily take up and release electrons (Section 3.6) it appears justifiable to assume that the active sites of the enzymes concerned are aggregates of metal atoms. Nature employes mainly iron, molybdenum, and copper for electron transfer purposes.

The best studied species are the ferredoxins and related redox enzymes. They contain the Fe_2S_2 unit *(57)* or the Fe_4S_4 unit *(58)*[260] as redox centers, these moieties having meanwhile been isolated from biological material by chemical methods[261]. *(57)* and *(58)* exist in various oxidation states, the iron atoms being equivalent in each case. Prior to and since this discovery, a large number of organometallic Fe_4S_4 and Fe_2S_2 clusters have been prepared and their redox properties investigated[42, 55]. Nevertheless, the special properties of the natural or artificial systems *(57)* and *(58)* have not yet been approximated by other systems.

(57)

(58)

The copper-containing centers in oxidases and similar enzymes are less well known[262]. The occurrence of spin-paired Cu^{II}-Cu^{II} units can be taken as proved. In enzymes and model compounds alike[263], the nature of the Cu—Cu interaction appears just as complicated as in inorganic Cu_2 complexes[18, 29].

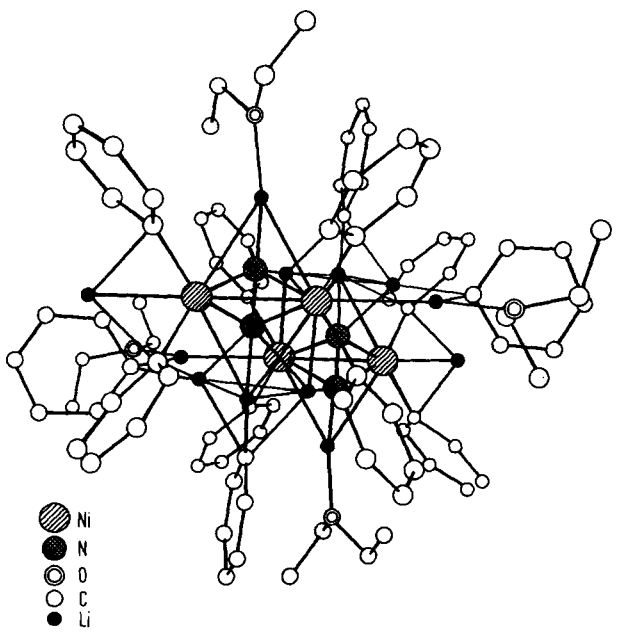


Fig. 3. Structure of the complex $[\{(PhLi)_3Ni\}_2N_2(Et_2O)_2]_2$ [267].

The greatest economic significance of metal enzyme-catalyzed reactions lies in the field of nitrogen fixation which occurs on molybdenum-containing centers[264, 265]. There has been no lack of attempts to identify the active molybdenum species or to imitate it with dinuclear complexes with and without metal-metal bonds[55, 264, 266], and yet, apart from the fact that reduction equivalents are provided by Fe_4S_4 units[261], no information has been gained about polymetallic units. However, since six reduction equivalents are required to convert the N_2 molecule into ammonia, polynuclear dinitrogen complexes are often synthesized in experiments on nitrogen reduction by metal complexes. One of the most involved results of such work, *i.e.* the compound $[\{(PhLi)_3Ni\}_2N_2(Et_2O)_2]_2$[267] (Fig. 3), closes this survey. Figure 3 once again demonstrates the validity of the introductory statement that main-group metals and subgroup metals can form metal-metal bonds among themselves and with one another.

6. Outlook

This article, which covers the literature up to the middle of 1977, is intended to throw some light on the interesting properties and the significance of the metal-metal bond. Some distinct trends should be noted: now that the existence of metal-metal bonds has been established in numerous chemical environments, preparative and structural research is concerned with larger and larger units of ever-increasing degree of aggregation. In the simple compounds, on the other hand, the ligand systems are becoming more and more diversified. Thus interest can shift from synthesis and characterization of metal-metal bonds to their reactions and effects of their ligands. Substitutions and redox reactions of polynuclear complexes and the cleavage of metal-metal bonds possess considerable synthetic potential which has hardly been utilized. Compared with bulk metals, polynuclear complexes containing metal-metal bonds are simplified models which greatly facilitate studies on the basic processes of chemisorption and substrate mobility. Compared with mononuclear complexes, on the other hand, the specific features of metal chemistry—stabilization and activation of ligands—are more pronounced. This versatility and its potential utilization justify the chemistry of the metal-metal bond.

Tetrahedral Carbonylcobalt Clusters

By Günter Schmid[*]

Dedicated to Professor Heinrich Nöth on the occasion of his 50th birthday

A variety of general methods is available for the synthesis of tetrahedral heteronuclear cobalt clusters of type $(CO)_9Co_3E(L)_n$ (E = hetero element). The size of E has a limiting effect on the existence of such complexes. No compounds $(CO)_9Co_3E(L)_n$ have so far been prepared in which the covalent radius of E exceeds 1.30 Å. Elements such as In, Sn, Pb, Sb, or Bi do not fit into the tetrahedral Co_3E cluster unit and form open complexes $E[Co(CO)_4]_n$ ($n = 3, 4$). Structural variations among the heteronuclear clusters are encountered in the presence or absence of carbonyl bridges between the cobalt atoms: hetero atoms E bearing several ligands L favor bridging, whereas those bearing only one ligand or none at all permit terminal bonding of all the CO groups.

1. Introduction

The concept of "cluster compounds" has been variously defined since intensive research into this class of compounds began. Since the term "cluster" is also employed in astronomy, biology, solid state physics, nuclear physics, mathematics, and even in music, a precise definition of the word as used in this article is called for.

F. A. Cotton[1] defined metal clusters as species "containing a finite group of metal atoms which are held together entirely, mainly, or at least to a significant extent, by bonds directly between the metal atoms even though some non-metal atoms may be associated intimately with the cluster".

[*] Prof. Dr. G. Schmid
Fachbereich Chemie der Universität
Universitätsstrasse, D-4300 Essen 1 (Germany)

In contrast, polynuclear complexes are compounds without metal-metal bonds. Hence $(CO)_5Mn—Mn(CO)_5$, for example, numbers among the cluster compounds, a situation which prompted *Chini* to classify such species as "open" (*e.g.* $Mn_2(CO)_{10}$) and "closed" clusters (*e.g.* $Fe_3(CO)_{12}$ or $Rh_6(CO)_{16}$)[2]. Other authors reserve the term cluster for compounds containing at least three metal atoms in direct contact or even in a cyclic array[3–5]. Subdivision into "open" and "closed" clusters has not been generally accepted. Instead, "open complexes" are usually taken to be polynuclear compounds devoid of direct interaction between the coordination centers (see Fig. 1).

In compliance with current practice and the principal points made in previous proposals, the cluster concept should be understood in the following sense: a cluster represents a group of three or more atoms, each one of which is linked to at least two of the others by chemical bonds. Hence it follows that each atom is part of at least one ring. Furthermore, this definition is not restricted to metal clusters. There are indeed many examples of cluster compounds containing not only metals but also non-metal atoms. The subconcept of a "heteronuclear cluster" is employed when the cluster unit is composed of various elements—in contrast to homonuclear clusters.

This article surveys our present knowledge of heteronuclear, tetrahedral cobalt clusters of the type $(CO)_9Co_3E(L)_n$; the heteroelement E can bear n ligands L.

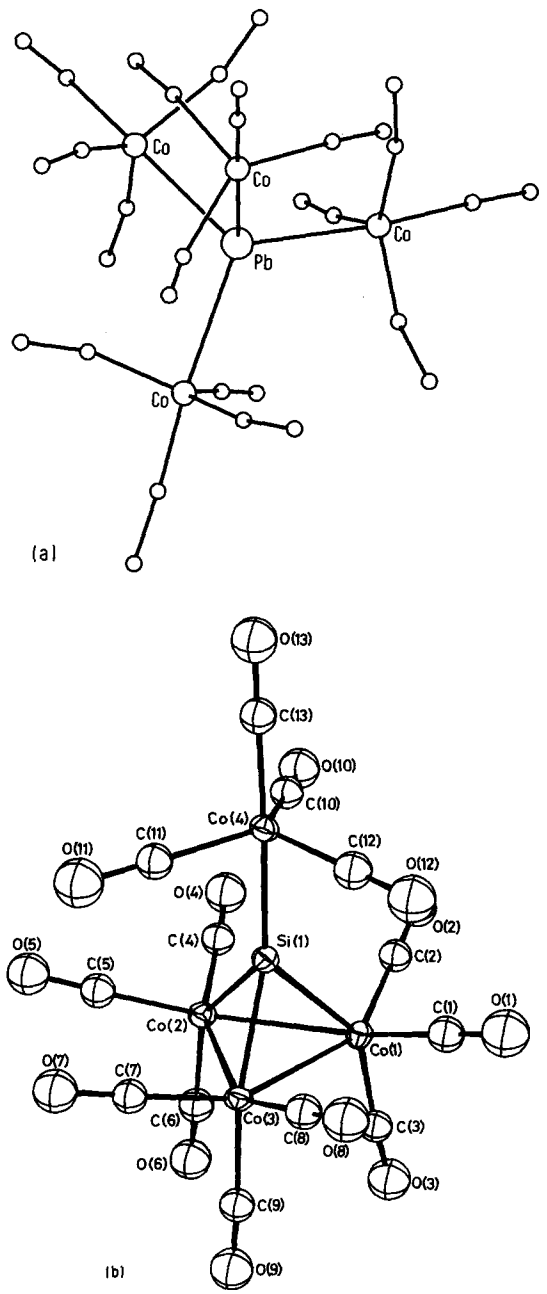

Fig. 1. Examples of (a) an open complex, $Pb[Co(CO)_4]_4$ [6], and (b) a cluster, $(CO)_9Co_3Si—Co(CO)_4$ *(10)* (see Table 2) [7].

2. Methylidyne Clusters

The oldest example of these heteronuclear carbonylcobalt clusters is methylmethylidynenonacarbonyl-*triangulo*-tricobalt which was prepared by *Cotton*[8] in 1958 and subjected to X-ray structure analysis by *Dahl* in 1967 (Fig. 2)[9]. The structure of the compound is determined by interaction of the sp^3-hybridized orbitals of the apical C atoms with suitable orbitals of the cobalt atoms. All the atoms are electronically and coordinatively saturated so that the cluster group $(CO)_9Co_3C$ always exhibits diamagnetism.

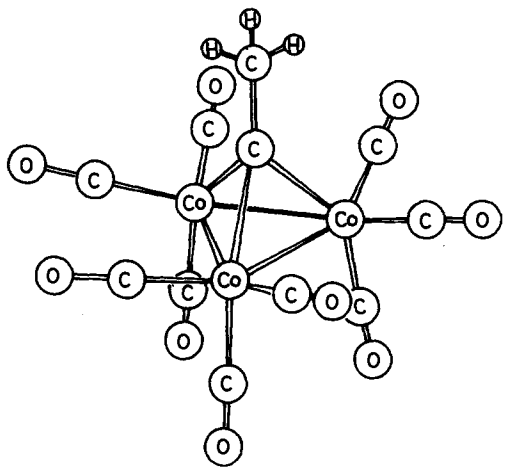

Fig. 2. Structure of $(CO)_9Co_3C—CH_3$ [type *(1)*, see Table 2] [9].

Carbon-containing clusters incorporating the μ_3-CL group are usually designated as methylidyne clusters. The ligand L can be varied almost at will; thus clusters are known with L = H, halogen, alkyl, arylalkyl, aryl, halo-alkyl or -arylalkyl, formylalkyl, and oxoalkyl[10–13] and other groups. The "organic chemistry" of the μ_3-C atom has been studied extremely thoroughly, but will not be considered in the present context.

The dark red to black methylidyne clusters are unusually stable towards air and dissolve in organic solvents. The particular stability of the Co_3C cluster unit is also manifested in the mass spectra, the Co_3C^+ fragment generally appearing at high intensity. The structure of the Co_3C tetrahedron is simple and readily understandable: the three cobalt atoms are linked by single bonds oriented at angle of 60° to each other. The $Co—C_{ap}$ distances also correspond to single bonds. The tetrahedral environment of the apical C atom is distorted because the Co—C—Co angles are *ca.* 80° on average. All the methyli-

dynenonacarbonyltricobalt clusters examined so far comply with these structural principles. A detailed account of bonding will be presented in Section 5.

3. Which Hetero-Elements Can Be Incorporated into the Co_3E Tetrahedron?

Apart from carbon, many other main group and subgroup elements might be considered as candidates for the hetero element E in the Co_3E cluster unit. One of the aims of this article is to examine which elements can be incorporated, and which cannot. The principal elements to be considered are listed in Table 1. Those elements which have already been incorporated into the cluster unit are indicated by a plus sign. A minus sign means that preparative studies gave negative results or have not yet been completed. No studies have yet been reported for the other elements.

Table 1. Compilation of the most important chemical elements that are potential hetero atom candidates E in $(CO)_9Co_3E(L)_n$. The + sign denotes: Co_3E cluster known; −: investigations negative or not yet complete; no sign: not examined.—The covalent radii [Å] [a] are given under the symbols for the elements.

							B+ 0.82	**C+** 0.77	N 0.75	O 0.73
							Al+ 1.18	**Si+** 1.11	**P+** 1.06	**S+** 1.02
Ti− 1.32	V 1.22	Cr 1.18	Mn 1.17	**Fe+** 1.17	**Co+** 1.16	**Ni+** 1.15	Ga 1.26	**Ge+** 1.22	**As+** 1.20	Se+ 1.16
Zr 1.45	Nb 1.34	**Mo+** 1.30	Tc 1.27	**Ru+** 1.25	**Rh+** 1.25	Pd 1.28	In− 1.44	Sn− 1.41	Sb− 1.40	Te− 1.36

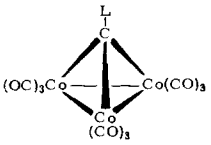
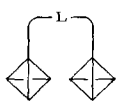
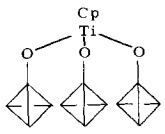
[a] Partly contradictory values are given for the covalent radii of the elements in the literature. The values used here should therefore not be regarded as absolute values; instead, it is the relative size of the elements which is of interest. The relative sizes are the same in nearly all literature sources. The values of the covalent radii used in this article are taken from the "Table of Periodic Properties of the Elements", Sargent-Welch Scientific Company, Skokie, Illinois (USA).

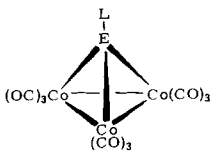
The most important heteronuclear cobalt clusters of type $(CO)_9Co_3E(L)_n$ can be seen from Table 2.

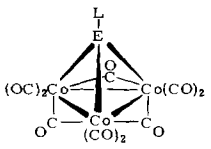
The methylidyne clusters of type *(1)* have been synthesized in large numbers thanks to the almost unlimited variability of the ligands L. Compounds of type *(2)*—*(6)*, in which the ligand L contains an oxygen atom at the point of linkage with the methylidyne C atom, also belong to the class of methylidyne clusters ("oxomethylidyne clusters"). Only few examples of this type of compound could be listed in Table 2.











In many respects, sp^3-hybridized boron atoms resemble sp^3-hybridized carbon atoms. Thus, the existence of the boron-containing cluster $(CO)_9Co_3B—NEt_3$ *(7)* is not surprising. Attempts to synthesize the amine-free compound $(CO)_9Co_3B$ failed, apparently because the angular distortion would be too large for sp^2-hybridized boron. The reported preparation of the analogous aluminum compound $(CO)_9Co_3Al$ *(15)*[26], containing only trivalent aluminum is therefore surprising. This series of heteronuclear clusters is continued by E=S *(8)*[21,22], Se *(11)*[24], P *(9)*[23], and As *(12)*[27]. Such clusters can be expected for sulfur and selenium as well as for phosphorus and arsenic. However, the compound $(CO)_9Co_3P$ is unstable: it trimerizes with displacement of CO to give $[(CO)_8Co_3P]_3$[27]. The long-sought silicon- and germanium-containing cluster compounds *(10)*[7] and *(13)*[28] could be confirmed only very recently.

Among the transition metals, iron, ruthenium, osmium, rhodium, and nickel, as well as molybdenum and tungsten, have also been incorporated into the Co_3E tetrahedron, as has cobalt itself which forms the well-known cluster $Co_4(CO)_{12}$. Compounds $(CO)_9Co_3Co(CO)_3$ $(=Co_4(CO)_{12})$ and $(CO)_9Co_3Fe(H)(CO)_3$ *(14)*, as well as $(CO)_9Co_3Rh(CO)_3$ *(16)* and $(CO)_9Co_3Ru(H)(CO)_3$ *(17)* are isoelectronic.

Let us now consider the problem of the "non-existence" of some nonacarbonyltricobalt clusters. In spite of the incomplete experimental work, Table 1 reveals that only atoms up to a certain covalent radius are apparently capable of forming Co_3E tetrahedra. No case has yet been found in which a heteroelement with a covalent radius of more than 1.30 Å could be incorporated in the Co_3E tetrahedron. Numerous studies with, say, indium, thallium, tin, lead, antimony, bismuth, or titanium all proved unsuccessful. The futile syntheses of $(CO)_9Co_3SnL$ and $(CO)_9Co_3PbL$ clearly demonstrate that the systems avoid cluster formation, yielding instead the open complexes $Sn[Co(CO)_4]_4$ and $Pb[Co(CO)_4]_4$ (cf. Fig. 1a)[34]. Antimony and bismuth also give open complexes $(Sb[Co(CO)_4]_3$ and $Bi[Co(CO)_4]_3)$[34]. Cluster formation would involve linkage of three cobalt atoms with loss of CO. This fails to occur either on heating or on UV irradiation. Instead of the desired cluster formation, complete decomposition to CO and the metals is observed. The clusters $(CO)_9Co_3Si—Co(CO)_4$ *(10)* and $(CO)_9Co_3Ge—Co(CO)_4$ *(13)* are sublimable, being thermally stable up to 50 °C.

Tin and lead have covalent radii of 1.41 and 1.47 Å, respectively, and accordingly large Co—Sn and Co—Pb distances. Cluster formation requires the three Co atoms to approach close enough for interaction to occur. For a constant Co—Co distance this means that the Co—E—Co angle must be all the smaller the larger E becomes. Beyond a given maximum distortion, which is of course also dependent upon other increments such as the degree of hybridization, cluster formation becomes impossible, particularly since the Co_3 triangle can hardly be deformed. The Co—Co—Co angle is almost exactly 60° in all compounds. The recognizable limit of r_{cov} (E) is 1.30 Å

Table 2. The most important cobalt clusters of type $(CO)_9Co_3E(L)_n$, arranged in the order of increasing covalent radius of E. The Co_3C tetrahedra of the polynuclear complexes *(4)*—*(6)* are represented in simplified fashion. Some of the structures have been confirmed by X-ray structure analysis (see footnotes), the others being proposals.

Cpd.		E	L	Synthesis [a]	Ref.

[a] Syntheses A–E, see Section 4. [b] The structure of *(1)*, L = CH_3, has been confirmed by X-ray analysis (see Fig. 2). [c] Structure confirmed by X-ray analysis. [d] See Fig. 4a. [e] See Fig. 4b. [f] See Fig. 6. [g] See Fig. 1b. [h] See Fig. 7.

as already mentioned. Thus titanium (r_{cov} = 1.32 Å) already appears unsuitable for formation of the Co_3Ti cluster: all attempts at synthesis have so far failed. For example, reaction of $(\eta\text{-}C_5H_5)TiCl_3$ and $NaCo(CO)_4$ in toluene affords the open complex $(\eta\text{-}C_5H_5)Ti[OCCo_3(CO)_9]_2Co(CO)_4$ (Fig. 3). This complex contains two oxymethylidyne clusters bonded to the titanium atom which arise in hitherto unexplained manner. The third and fourth valences of titanium are occupied by a η-cyclopentadienyl and a $Co(CO)_4$ group. This shows that Ti—Co bonds are indeed stable.

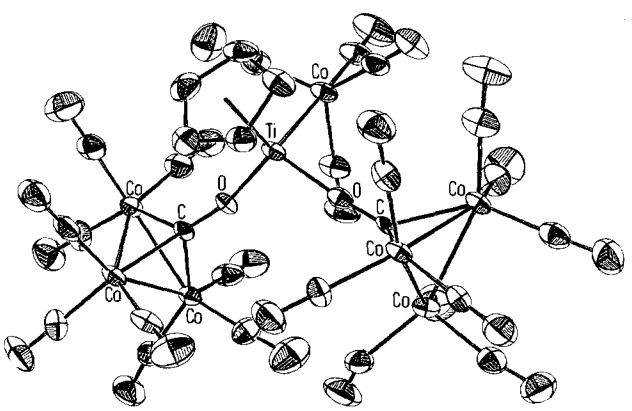

Fig. 3. Structure of $(\eta\text{-}C_5H_5)Ti[OCCo_3(CO)_9]_2Co(CO)_4$ [35].

4. Syntheses

Several pathways are available for the synthesis of tetrahedral heteronuclear cobalt clusters. The synthetic procedures A—E (cf. Table 2) will now be considered (X = Halogen, H).

A $\quad Co_2(CO)_8 + X_mEL_n$

B $\quad \begin{cases} [(CO)_9Co_3CO]^- + X_mER_n, \\ \text{replacement of R in } (CO)_9Co_3COER_n \end{cases}$

C $\quad [(CO)_4Co]^- + X_mEL_n$

D $\quad$ Thermolysis/photolysis of $(CO)_4Co—EL_n$

E $\quad$ Others

4.1. Method A

Method A is the method of choice for synthesis of methylidyne clusters of type *(1)*:

$$4X_3CL + 9Co_2(CO)_8 \rightarrow \underset{(1)}{4(CO)_9Co_3CL} + 6CoX_2 + 36CO \qquad (a)$$

X = Halogen

The first methylidyne cluster (L = CH_3) was prepared in this way (Fig. 2). The whole spectrum of methylidyne clusters becomes accessible by variation of L. Surprisingly, methylidyne clusters are also formed on reaction with element halides

X_mER_n with E = B, Al, Si, or Ti, which display Lewis acid character. Examples are found for compounds of type *(2)* and *(3)* in Table 2. They are all oxymethylidyne clusters, *i.e.* species containing μ_3-CO moieties. Figures 4a and 4b show the structure of a compound of type *(2)* and one of type *(3)*.

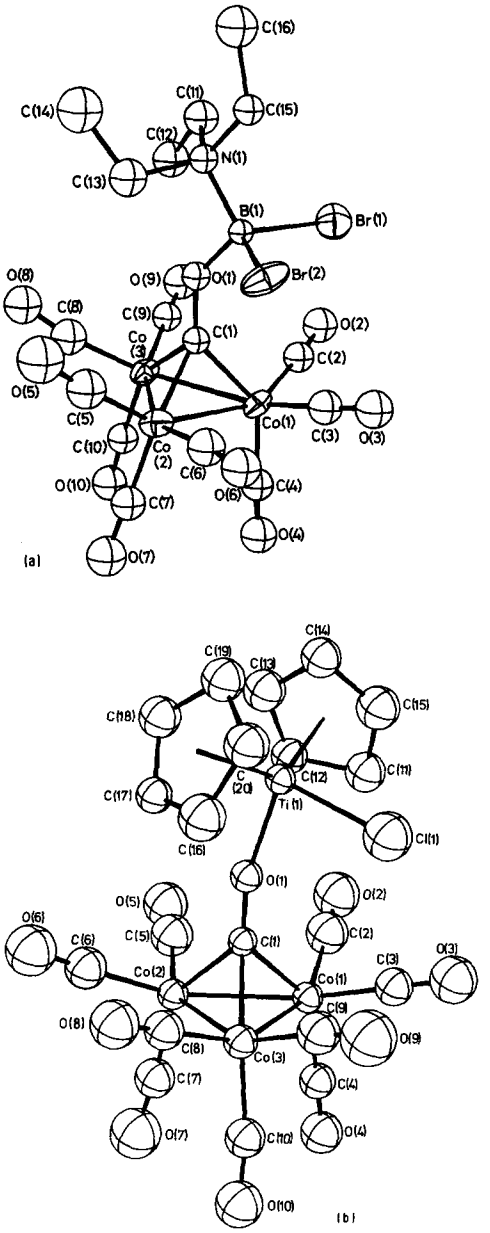

Fig. 4. Structures of the oxymethylidyne clusters (a) $(CO)_9Co_3COBBr_2 \cdot NEt_3$ [type *(2)*] [17] and (b) $(CO)_9Co_3COTi(Cl)(\eta\text{-}C_5H_5)_2$ [type *(3)*] [18].

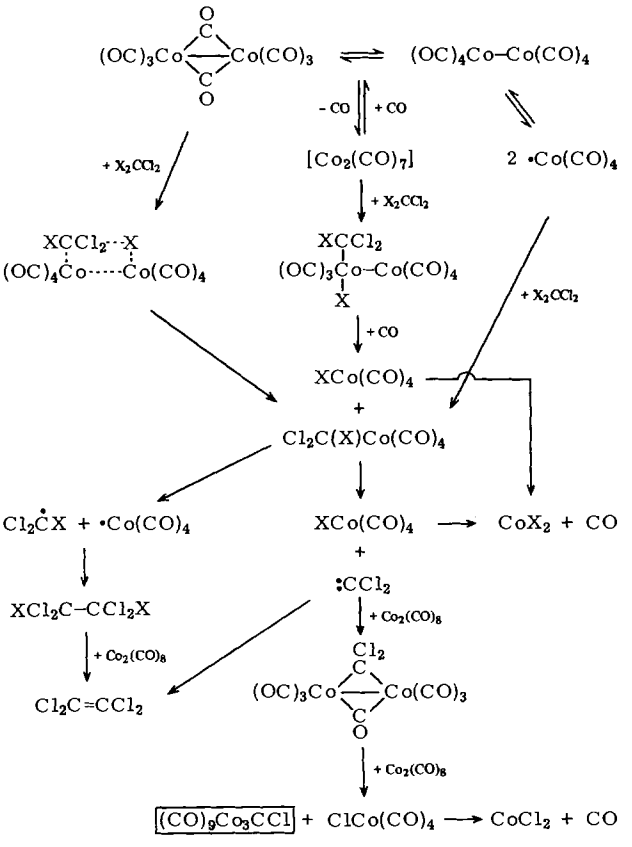
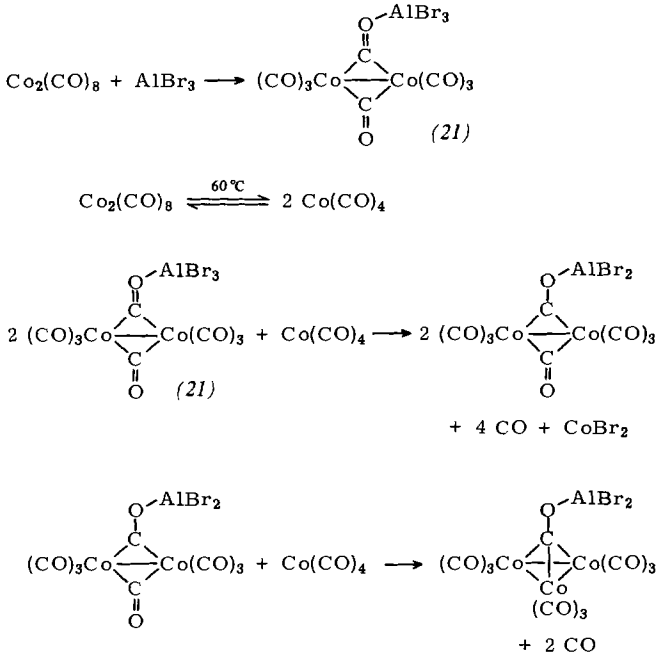


Equations (b) and (c) show the idealized reaction courses:

$$4Et_3N \cdot BBr_3 + 7Co_2(CO)_8 \rightarrow 4(CO)_9Co_3COBBr_2 \cdot NEt_3 + 2CoBr_2 + 16CO \quad (b)$$

$$4(\eta\text{-}C_5H_5)_2TiCl_2 + 7Co_2(CO)_8 \rightarrow 4(CO)_9Co_3COTi(Cl)(\eta\text{-}C_5H_5)_2 + 2CoCl_2 + 16CO \quad (c)$$

Reactions (b) and (c) follow a completely different course from (a). While the C atom of X_3CL is incorporated into the tetrahedral cluster according to reaction (a), E is transferred from X_mER_n into a component of the ligand L in $(CO)_9Co_3CL$ ($L = OB(halogen)_2 \cdot NEt_3$, $OAl(halogen)_2 \cdot NEt_3$, $OSiR_3$, $OTi(Cl)Cp_2$, *etc.*). The μ_3-CO group therefore comes from the octacarbonyldicobalt.



For reactions between $Co_2(CO)_8$ and chlorinated hydrocarbons in nonpolar solvents, *Haszeldine et al.*[36] proposed a mechanism involving carbenes as reactive intermediates: Both the reaction of $Co_2(CO)_8$ with CCl_4 and the reaction with $CBrCl_3$ or CBr_2Cl_2 afford not only the methylidyne cluster $(CO)_9Co_3CCl$ but also tetrachloroethylene. If the reaction is carried out with CCl_4 in the presence of excess cyclohexene, the yield of $(CO)_9Co_3CCl$ falls from 41 to 29%. In addition 7,7-dichloronorcarane can also be detected. Similar findings have been reported for the reactions of $Co_2(CO)_8$ with $CBrCl_3$ or CBr_2Cl_2 in the presence of cyclohexene. The basic reaction steps on formation of $(CO)_9Co_3CCl$ from $Co_2(CO)_8$ and X_2CCl_2 are shown in Scheme 1.

Scheme 1.

Starting from the known equilibrium between bridged and unbridged $Co_2(CO)_8$ the dichloromethane derivative X_2CCl_2 can attack in three possible ways: 1) X_2CCl_2 is added oxidatively to $(CO)_4Co—Co(CO)_4$ *via* a four-center mechanism; 2) X_2CCl_2 likewise undergoes oxidative addition but only to one Co atom; 3) oxidative addition only takes place after homolysis of $Co_2(CO)_8$ to $Co(CO)_4$ radicals. The $XCo(CO)_4$ formed in each case is known to be unstable, decomposing to CoX_2 and CO. The crucial step is formation of dichlorocarbene from $Cl_2C(X)Co(CO)_4$. Some of the carbene dimerizes to tetrachloroethylene, and some inserts between the two Co atoms of $Co_2(CO)_8$. Formation of the Co—C bonds is then followed by renewed reaction with $Co_2(CO)_8$ to give $(CO)_9Co_3CCl$ as final product.

In contrast, completely different reactions must take place on formation of oxymethylidyne clusters. Of decisive importance for the overall reaction course in the present case of reaction with X_2CCl_2 and of X_mER_n with $Co_2(CO)_8$ are the initial interactions. While oxidative addition of carbon to cobalt occurs in the former case, the compounds X_mER_n (E = B, Al, Si, Ti) act as Lewis acids in the second case, interacting with the oxygen atom of a bridging carbonyl group. Isolation or spectroscopic detection of primary products such as $(CO)_8Co_2 \cdot AlBr_3$ *(21)*[14] demonstrates that the initial reaction steps are due to Lewis acid-base interactions. Similar interactions can also be assumed to occur in other Lewis acid element halides such as $XSiR_3$ or $(\eta\text{-}C_5H_5)_2TiCl_2$. Scheme 2 shows a possible mechanism for the reaction of $AlBr_3$ with $Co_2(CO)_8$ which has not been proved in every detail but should be broadly valid and also apply to other Lewis acids.

Scheme 2.

Although the amine adducts $X_3B \cdot NEt_3$ and $X_3Al \cdot NEt_3$, which no longer exhibit Lewis acid properties, are used for the synthesis of $(CO)_9Co_3COEX_2 \cdot NEt_3$ (E = B, Al) [type *(2)*], the adducts undergo partial dissociation at 60 °C (*i.e.* at the reaction temperature) into NEt_3 and EX_3. Homolysis of $Co_2(CO)_8$ into $Co(CO)_4$ radicals is also feasible under the reaction conditions.

4.2. Method B

The synthesis of some oxymethylidyne clusters is also possible by method B, which starts from an existing $(CO)_9Co_3CO$ skeleton. The boron and silicon compounds $(CO)_9Co_3COBH_2 \cdot NEt_3$[37] and $(CO)_9Co_3COSiR_3$[37] (R = CH_3, Ph) were obtained for the first time by this method *via* the alkali metal compounds $[(CO)_9Co_3CO]M$. The synthesis of the first ester containing the cluster group $(CO)_9Co_3C$ (Fig. 5) was accomplished by reaction of $[(CO)_9Co_3CO]Li$ with acetyl bromide[38]:

$$[(CO)_9Co_3CO]Li + BrCOCH_3 \rightarrow (CO)_9Co_3CO{-}COCH_3 + LiBr \quad (d)$$

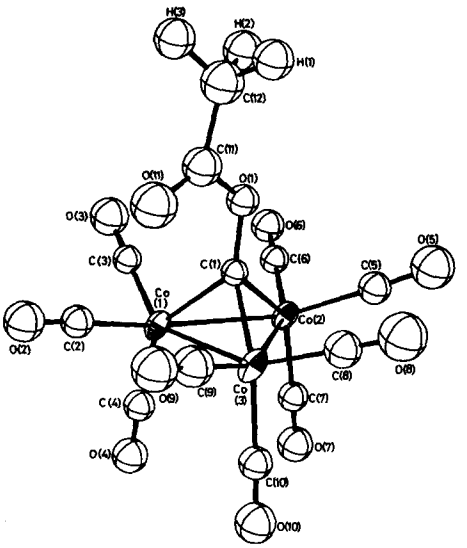


Fig. 5. Structure of $(CO)_9Co_3CO{-}COCH_3$ [38].

Method B also permits the synthesis of a variety of transition metal derivatives of types *(3)*, *(4)* (cf. Fig. 6), *(5)*, and *(6)*.

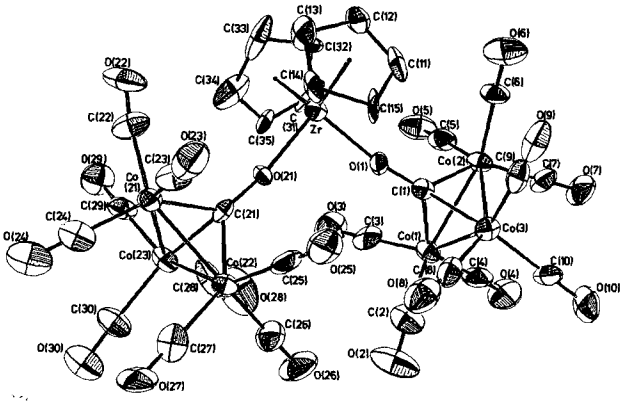

Fig. 6. Structure of $[(CO)_9Co_3CO]_2Zr(\eta\text{-}C_5H_5)_2$ and the analogous hafnium compound [type *(4)*] [19].

In some cases replacement of groups R in $(CO)_9Co_3COER_n$ compounds gave compounds accessible with difficulty, if at all, by other methods: *e.g.*, $(CO)_9Co_3COBr_2 \cdot NEt_3$ by fluorination of the analogous bromine compound with $AgBF_4$[7] and compounds *(5)* by hydrolysis of compounds *(3)*[19]:

$$2(CO)_9Co_3COE(Cl)Cp_2 + 2\,NaOH \rightarrow \underset{(3)}{} \underset{(5)}{[(CO)_9Co_3COECp_2]_2O} + 2\,NaCl + H_2O \quad (e)$$

(5)

E = Ti, Zr, Hf

4.3. Method C

Reaction between the carbonylcobaltate ions $[(CO)_4Co]^-$ and element halides is of broad scope (method C). It generally leads to formation of cobalt-element bonds, a prerequisite for the formation of heteronuclear cluster compounds $(CO)_9Co_3E(L)_n$. Numerous methylidyne clusters of type *(1)* which are also accessible by method A can be prepared by

method C. In recent years, particular attention has been focused on syntheses of heteronuclear clusters with elements E other than carbon. Thus, once the first methylidyne clusters had been synthesized, the search began immediately for homologous silanetriyl clusters $(CO)_9Co_3SiL$; and syntheses of compounds containing boron, aluminum, germanium, phosphorus, and arsenic appeared as the obvious next step. As discussed in Section 4.1, halogen compounds of boron and aluminum, and also silicon react with $Co_2(CO)_8$ to give oxymethylidyne clusters. If interactions between Lewis acids and the O atom of a bridging carbonyl group are prevented by use of $[Co(CO)_4]^-$ then the desired complexes can indeed be obtained by method C. Formation of clusters is presumably preceded by generation of open complexes:

$$SiI_4 + 4[Co(CO)_4]^- \rightarrow Si[Co(CO)_4]_4 + 4I^- \quad (f)$$

$$Si[Co(CO)_4]_4 \rightarrow (CO)_9Co_3Si{-}Co(CO)_4 + 3CO \quad (g)$$

(10)

The possible intermediacy of $(CO)_9Co_3Si{-}I$ receives some support from mass spectrometric studies; this would mean that the cluster is formed from the open complex $[(CO)_4Co]_3$-SiI. Corresponding proposals are also possible for the synthesis of compounds of boron *(7)*, aluminum *(15)*, germanium *(13)*, phosphorus *(9)*, and arsenic *(12)*, particularly since the open complexes of the homologs indium, $In[Co(CO)_4]_3$, tin and lead, $M[Co(CO)_4]_4$[6], and antimony and bismuth, $M[Co(CO)_4]_3$[34] are isolable. It is nevertheless surprising that $Co_2(CO)_8$ can also react with PX_3 and AsX_3[27]. These halides do not react to give methylidyne clusters but form P- or As-containing clusters. Apparently the Lewis acidity of these halides towards the bridging carbonyl oxygens in $Co_2(CO)_8$ is not large enough, so that P—O and As—O interaction fails to occur. This is impressively demonstrated by experiments in which the reactions of $[(CO)_9Co_3CO]Li$ with halophosphanes were studied. Surprisingly, eq. (i) applies instead of eq. (h)[39]:

$$[(CO)_9Co_3CO]Li + ClPPh_2 \not\rightarrow (CO)_9Co_3COPPh_2 + LiCl \quad (h)$$

$$[Co(CO)_4]^-Li^+ + ClPPh_2 \rightarrow Ph_2PCo(CO)_4 + LiCl \quad (i)$$

The origin of $[Co(CO)_4]^-$ in ethereal solutions of $[(CO)_9Co_3$-$CO]Li$[40] is still unclear; however, equilibration appears a possibility especially since evidence has been obtained in favor of a species $Co_2(CO)_6$ in solution[41]:

$$[(CO)_9Co_3CO]^- \overset{Solv.}{\rightleftharpoons} [Co(CO)_4]^- + Co_2(CO)_6(Solv.)_n \quad (j)$$

Solv. = solvent

On the other hand, it cannot be ruled out that $Li[Co(CO)_4]$ is already formed on production of $[(CO)_9Co_3CO]Li$. Whatever the reason may be, the finding that $ClPPh_2$ selects the second component from a solution containing $[(CO)_9Co_3$-$CO]Li$ and $Li[Co(CO)_4]$ shows that phosphorus avoids bonding to the oxygen, preferring interaction with cobalt instead. The same most likely applies to arsenic.

4.4. Method D

Formation of compounds *(19)* (Fig. 7) and *(20)* has been well studied[33]:

$$(CO)_3CpECl + [Co(CO)_4]^- \rightarrow (CO)_3CpE{-}Co(CO)_4 + Cl^- \quad (k)$$

$$3(CO)_3CpE{-}Co(CO)_4 \rightarrow (CO)_9Co_3E(CO)_2Cp + 4CO + [(CO)_3Cp{=}E]_2 \quad (l)$$

(19), (20)

E = Mo, W

Although the actual cluster formation in method D proceeds as shown in eq. (l), the decisive step is formation of the Co—E bond according eq. (k). The "open" intermediates postulated for boron, aluminum, silicon, or phosphorus can be isolated here. This substantiates the proposed reaction course of cluster formation according to method C.

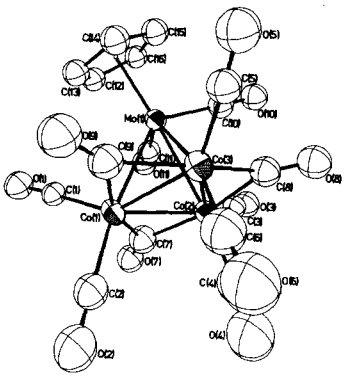

Fig. 7. Structure of $(CO)_9Co_3Mo(CO)_2(\eta\text{-}C_5H_5)$ *(19)* [33].

4.5. Other Methods

The syntheses of some cluster compounds with transition elements and with sulfur and selenium as hetero atoms do not fit into the series of methods mentioned.

These methods are designated as "E" in Table 2. $(CO)_9Co_3S$ *(8)* can be prepared just as well from $Co_2(CO)_8$ and sulfur in hydrocarbons as from $Co_2(CO)_8$ and CoS or H_2S. Relatively high yields are even obtained with thiophenol and $Co_2(CO)_8$. The homologous selenium compound *(11)* is formed from H_2Se and $Co_2(CO)_8$ in hexane at 150 °C and 100 atm[10].

Some cluster compounds of type $(CO)_9Co_3E(H)(CO)_3$ [*(14)*, E = Fe; *(17)*, E = Ru; *(18)*, E = Os] are formed in a highly complicated way. Thus $Fe(CO)_5$ and $Co_2(CO)_8$ in acetone react to give $[Co(CH_3COCH_3)_3][FeCo_3(CO)_{12}]_2$, which affords the iron compound *(14)* with conc. HCl or H_2SO_4[25]. It is isoelectronic with the known compound $Co_4(CO)_{12}$. The ruthenium compound *(17)* is formed analogously or from $Co_2(CO)_8$ and $[Ru(CO)_3Cl_2]_2$[31], while the osmium compound *(18)* is obtained from Na_3OsCl_6, CO, and $Co_2(CO)_8$[32].

5. Chemical Bond and Structure

Many attempts have been made to describe the chemical bond in metal clusters. *Dahl et al.* have developed a highly detailed concept of the bonding in heteronuclear clusters of the type $(CO)_9Co_3E$ on the basis of LCAO-MO models[24], which will now be briefly considered. Assuming the Co_3E tetrahedron to have ideal C_{3v} symmetry, the metal orbitals

available for metal-metal bonding can be constructed as shown in Figure 8. For this purpose each Co atom is placed at the origin of a system of Cartesian coordinates. The positive z-axes are directed towards the centroid of the triangle, the y-axes are perpendicular to the angular surface, and the x-axes are situated in the Co_3 surface.

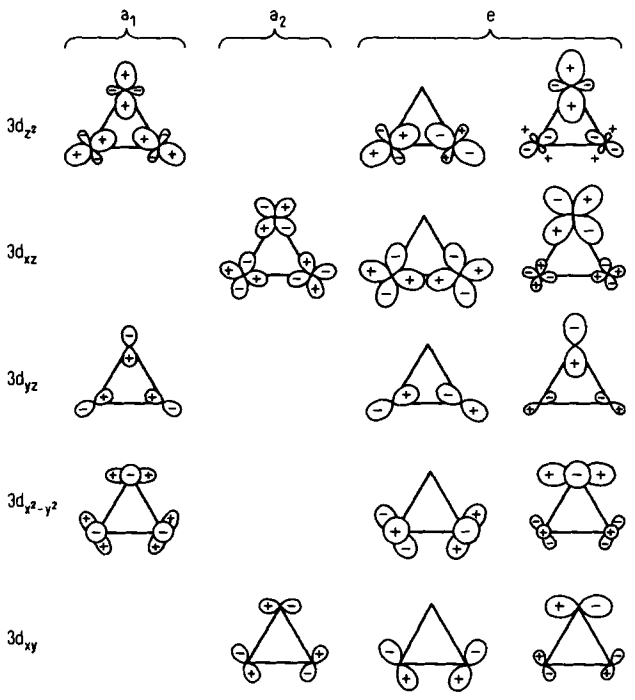

Fig. 8. Overlapping of 3d orbitals of three Co atoms in the Co_3 triangle.

This model reproduces the bonding in a greatly simplified, but qualitatively correct manner. Combinations of the three 4s- and nine 4p-orbitals possess the correct symmetry for formation of σ bonds, both to the CO groups and to the hetero atom E. Ignorance of the extent of mixing precludes our stating the energetic sequence of the Co_3 orbitals.

Table 2 shows that there are two types of compounds $(CO)_9Co_3E(L)_n$, which differ in the arrangement of the CO groups. Carbonyl bridges occur if the hetero element is a transition metal. (The structure of the Co_3Mo cluster *(19)* is confirmed—see Fig. 7—the correctness of the structural proposals *(14)*, *(16)*—*(18)*, and *(20)* is assumed; *(15)* *(vide infra)* is a special case.)

The problem of the formation of carbonyl bridges in carbonylmetal compounds is still unsolved. To this day, there is no firm experimental evidence for one or the other concept.

It is readily appreciated that the reason for the occurrence of carbonyl bridges in the $Co_3E(L)_n$ system must be sought in the nature of E or the EL_n group because the remainder of the tetrahedron, the Co_3 plane, is not subject to change. In the compounds $(CO)_9Co_3E(L)_n$ without carbonyl bridges, *e.g. (7)*—*(13)*, the three terminal CO groups of each cobalt atom can adopt an almost ideal mutual arrangement, thus minimizing repulsion (Fig. 9a). However, if the hetero atom itself bears three CO groups, as is the case in the complexes with E = Fe, Co, Rh, Ru, and Os, then perturbing interactions will occur between these three CO groups and a total of six upward-directed CO groups of the three cobalt atoms ($3 \times C^1$, $3 \times C^2$). As a result, C^2 is folded down into the Co_3 plane. In the direction of E, C^1 can adopt an orientation between two of the three terminal CO groups of E (Fig. 9b). In this way the two CO groups of all four metal atoms of the cluster adopt an overall distorted icosahedral arrangement.

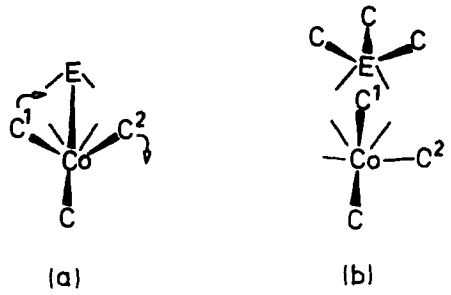

Fig. 9. Representation of the geometrical situation in (a) unbridged and (b) bridged complexes $(CO)_9Co_3E(L)_n$.

This idea does not explain why complexes such as $Ir_4(CO)_{12}$ do not contain bridging carbonyl groups. In this case, however, the size of the metal atoms probably also plays a role, the increasing metal-metal bond lengths on going from metals of the 1st to those of the 2nd and 3rd transition metal periods gradually prevents formation of CO bridges. This is especially apparent on comparison of homologous compounds such as $Fe_3(CO)_{12}$ with $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ as well as $Co_4(CO)_{12}$ with $Ir_4(CO)_{12}$: bridged structures exist for iron and cobalt and non-bridged structures for the larger elements Ru, Os, and Ir.

Purely steric effects thus appear to be responsible for the formation of CO bridges. Electronic effects are not expected to play any predominant effect, although a slight gain in energy will be associated with CO bridge formation: A *pentahapto* bonded C_5H_5 ring will still cause an inversion process in the sense of Figures 9a and 9b, as seen for the example of $(\eta\text{-}C_5H_5)NiCo_3(CO)_9$[42]. On the other hand, ligands attached to the carbon, boron, silicon, or germanium do not hinder the terminal arrangement of the CO groups. The compound $(CO)_9Co_3Al$ *(15)* is an exception, for which a structure with CO bridges has been proposed[26]. This proposal should be re-examined.

6. Summary and Outlook

The present article was intended to summarize the present state of knowledge in the field of tetrahedral heteronuclear cobalt clusters of the type $(CO)_9Co_3E(L)_n$. Owing to their simple and readily comprehensive structures, the compounds are very suitable for systematic investigations. Failure to synthesize Co_3E with a series of certain main group and subgroup elements was attributed to geometrical factors. Thus the covalent radius of E has a crucial effect on the existence of the cluster. Further studies should enable us to test this hypothesis.

Another important finding resulting from the systematic study of these complexes concerns the presence or absence of carbonyl bridges in the Co_3 plane. The reasons are probably to be sought in the steric requirements of $E(L)_n$. This could be of general validity for carbonylmetal compounds. The complexes $(CO)_9Co_3E(L)_n$ possess, as the first carbonylmetal compounds, a directing group $E(L)_n$ which can promote or suppress

bridge formation. This assumption also requires substantiation by further preparative and structural studies.

The author's own studies reported in this article were kindly supported by the Deutsche Forschungsgemeinschaft (SFB 127—Structure and Chemical Bonding) and by the Fonds der Chemischen Industrie. Thanks are also due to Dr. Volker Bätzel, Dr. Roland Boese, Dr. Jennifer Burt, Dr. Günter Etzrodt, Dr. Bernd Stutte, Dipl.-Chem. Klaus Bartl, and Dipl.-Chem. Werner Kruppa for their assistance.

The Distribution of Charge in Complex Compounds

By Joseph Chatt and G. Jeffery Leigh[*]

The charges on metal atoms and ligands in complex compounds of transition metals may be calculated theoretically or measured empirically, but there is no reliable method of doing either. This review is concerned mainly with two experimental methods, dipole moment measurement and X-ray photoelectron spectroscopy, applied to tertiary phosphane and such complexes of the heavier transition metals. It is concluded that the charge is rarely greater than $\pm 0.3e$ and that some so-called neutral or positive ligands, *e.g.* N_2 or NO^+, may carry more negative charge in a complex than formally anionic ligands such as H^-. Small ligands of high formal charge, *e.g.* O^{2-}, NR^{2-}, and N^{3-}, appear to carry no more negative charge than Cl^-, but monoanionic ligands vary greatly in their capacity to contribute to the dipole moments. The ligands NO, CO, PF_3, CH_3^-, and H^- are all nearly neutral to slightly negative, whereas pyridines, tertiary phosphanes, *etc.* are the most strongly positively charged.

1. Introduction

We have been interested for some time in the way in which charge is partitioned between the various partners (metal and ligands) in a metal complex. There is no direct way of measuring the absolute charge on an atom in a compound, but there are a variety of ways in which information bearing on it can be arrived at by calculation or empirically; also there is a large amount of chemical experience which is summed up by rules of thumb, such as the Pauling Electroneutrality Principle which suggests that the charge on an atom in a complex will generally lie between +1 and −1, whatever the formal charges.

It is, of course, possible to calculate charges at atomic centers if the appropriate wave functions (or molecular orbital coefficients) are known. Thus charge distributions can be calculated from any measurable property that can be related to wave functions or molecular orbital coefficients. In practice,

[*] Prof. Dr. J. Chatt, Dr. G. J. Leigh
Agricultural Research Council, Unit of Nitrogen Fixation
The University of Sussex
Falmer, Brighton BN1 9QJ (England)

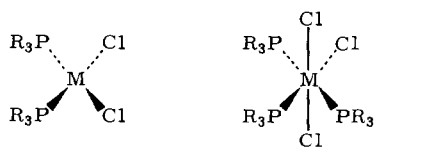
the correlation with wave functions is not easy, and calculations of charge distributions are not often related to empirical measurements. Further, calculations involving transition metal complexes are often suspect. One is thus left with empirical methods for more accessible and reliable determination of charge distribution.

The experimental techniques which give information about charge distribution can be conveniently considered under a variety of headings. There are those which look directly at atomic nuclei, nuclear quadrupole resonance (NQR) and the Mössbauer effect. In NQR the quadrupole coupling constants may be related to the occupancy of p- or d-orbitals, and this, in turn, is affected by the ionic/covalent character of the various bonds. NQR evidence supports the idea of electron transfer by π-bonding to d-orbitals in complexes of early transition elements. The Mössbauer isomer shifts are also related to charge density at the nucleus, and depend upon metal oxidation state, coordination number, and spin state. However, the precise interpretation in terms of charge distribution is very difficult. The Mössbauer quadrupole splitting is also difficult to interpret in these terms.

A second set of empirical techniques investigates the electronic energy levels. Included in this heading are UV and X-ray photoelectron spectroscopy, X-ray spectroscopy, and electronic spectroscopy in various forms. Of these spectroscopic methods we shall discuss only X-ray photoelectron spectroscopy in any detail. The information concerning charge distribution contained in data obtained using any of these spectroscopic techniques is often not easily accessible.

Finally, we have techniques which measure electron distribution throughout a whole molecule. Foremost is X-ray structure analysis, which is, however, generally of too low a resolution to enable us to look at minor variations in valence-electron distribution. Magnetic resonance techniques are also amenable but the data are again often not easily analyzed. Nevertheless, ESR spectroscopy provided early evidence of electron transfer from the p-orbitals of chloride ligands into the d-orbitals of the later transition metals in high oxidation states as in $[IrCl_6]^{2-}$. Magnetic neutron diffraction promises to be of great value in determining the distribution of unpaired electrons, but is unlikely to be of general availability. There is, however, a further, much older technique which has been comparatively ignored in recent years. The dipole moment of a molecule is a gross measure of its electrical asymmetry. Whereas the dipole moment of a complex compound has often been taken as a criterion of its stereochemistry, the significance of the moment as a measure of charge distribution has been much less frequently considered. The purpose of this review is to discuss the extent to which a relatively new technique (XPS) and a relatively old technique (dipole moment measurements) can give information regarding the charge distribution in complex compounds.

2. Measurement of Dipole Moments



The dipole moment of a complex can be considered as the vector sum of components operating along the axes of the complex. The values for single axial moments (group moments) can be elucidated by suitable choice of complex, and Table 1 gives a list of calculated P—M—Cl group moments based on a simple vectorial analysis[1,2]. There is a slight dependence on whether the phosphanes are aromatic or aliphatic, but nevertheless the narrow range of group moments, 6.8 ± 0.9 D, implies that the charges on P and Cl are approximately constant. The significance of this constancy will be discussed below. However, there is a problem in converting these group moments to individual charges as reflected by a point-charge model. This is that individual bond moments cannot be easily determined. Even where the dimensions of the molecule are known, there is of course still no guarantee that a point charge model is an accurate representation, but it is difficult to use a more complete model and we shall therefore use the simpler one.

Table 1. Dipole moments and P—M—Cl group moments [D] for various complexes.

Complex	Observed dipole moment	Ref.	P—M—Cl group moment
cis-$[PtCl_2(PEt_3)_2]$	10.7	[41]	7.6
mer-$[RuCl_3(PEt_2Ph)_3]$	6.9	[42]	6.9
mer-$[RhCl_3(PEt_2Ph)_3]$	7.3	[43]	7.3
mer-$[RhCl_3(PEt_3)_3]$	7.0	[43]	7.0
mer-$[ReCl_3(PEt_2Ph)_3]$	6.3	[28b]	6.3
mer-$[IrCl_3(PEt_3)_3]$	6.9	[44]	6.9
cis-$[RuCl_2(Et_2PCH_2CH_2PEt_2)_2]$	9.8	[45]	7.0
cis-$[RuCl_2(Ph_2PCH_2CH_2PPh_2)_2]$	9.5	[45]	6.8
cis-$[OsCl_2(Et_2PCH_2CH_2PEt_2)_2]$	9.3	[45]	6.6
cis-$[OsCl_2(Ph_2PCH_2CH_2PPh_2)_2]$	8.3	[45]	5.9

Chatt et al. analyzed the dipole moments of a large series of compounds on the basis that a metal-halogen bond moment is 2—3 D. Even though the grounds for selecting this value were shown to be wrong[1], the general self-consistency of the analyses leaves no doubt that, to a first approximation, this magnitude of the moment is correct and can be applied to a wide range of complexes. It is not clear, however, what it means in terms of charge distribution.

Dipole moments can, however, be further analyzed. Let us assume that a pair of ligands such as a tertiary phosphane and a chloride in a *trans*-arrangement carry a charge x and y, respectively. It is not, in fact, as we shall show below, justified to assume that the charges are constant, but it does seem to be the case for complexes of the Third Transition Series. Thus in *cis*-$[PtCl_2(PEt_3)_2]$, the charge on the platinum will be $-2(x+y)$. Now consider *mer*-$[MCl_3(PR_3)_3]$. In this case the charge on the metal should be $-3(x+y)$. However, the observed moment of the complex is still equal to the group moment P—M—Cl because of the symmetry.

cis-$[MCl_2(PR_3)_2]$ *mer*-$[MCl_3(PR_3)_3]$

This group moment can only be equal to that inferred from a square planar complex if $2(x+y)=3(x+y)$, *i.e.* if $x+y=0$. Since the group moments are indeed consistent it follows that in the chloro-tertiary phosphane complexes, where there are equal numbers of PR_3 and chloride ligands, the

charges on the phosphane and on the chloride are equal and opposite. Considering the appropriate bond lengths leads to charges of +0.3 e and −0.3 e on phosphorus and halide, respectively[1].

Having thus established some magnitudes, it is possible to extend the charge assessment as follows. In Table 2 are presented some Cl—M—CO group moments. Where the Cl—M—CO group moments can be inferred directly from the molecular moment due to the axial symmetry, then it is found consistently that Cl—M—CO has a value of 2—3 D. This implies that CO is a weak donor, considerably less so than a tertiary phosphane, and it may even be withdrawing charge, as it is believed to do in $[Ni(CO)_4]$. Other data in Table 2 suggest that CO and NO carry about the same charge and that the H ligand in hydrido-complexes is slightly positive. Thus, it has been suggested that the halide ion in a *trans* position to a hydride, as in *trans*-$[PtClH(PEt_3)_2]$, has become more negative or ionic, a manifestation of the *trans* effect of the hydride[3].

By this kind of analysis, it has been possible to infer something about charge separation and charge location in highly dipolar compounds[2].

To obtain good dipole moment data it is necessary to have non-labile, non-ionic, complexes without a center of symmetry and soluble in an inorganic solvent, preferably a non-polar one such as benzene. This has tended to focus attention on the tertiary phosphane and such complexes of the heavier transition metals, particularly of Group VIII. Within this limitation, the dependence of dipole moments on the formal charges and types of ligands, and the gross inferences from them concerning charge distribution have been evaluated and summarized[2], and will be listed here.

2.1. Dependence of Dipole Moment on the Metal

The group moment P—M—Cl is generally 6—7 D. The aliphatic phosphanes tend to produce apparently slightly higher group moments than the more electronegative aromatic phosphanes. The exact metal involved is not of any significance.

2.2. Dependence on So-called Electrically Neutral Ligands

"Good" electron donors, *e.g.* tertiary phosphanes, arsanes, stibanes, pyridines and amines, *etc.*, give analogous complexes of almost equal moments. "Poor" donors, *e.g.* good back-bonding ligands such as CO and PF_3, give complexes analogous to those of the good donors but with moderate moments. Thus *cis*-$[PtCl_2(PEt_3)_2]$ has a moment of 10.7 D, but *cis*-$[PtCl_2(CO)_2]$ has a moment of 4.65 D, close to the value expected from the Pt—Cl contributions alone. Generally such ligands as CO, PF_3, N_2, and even the so-called NO^+, appear to be negative, neutral or only slightly positive in their complex compounds. It follows that whereas the metal atom in *cis*-$[PtCl_2(PEt_3)_2]$ is about neutral, in a complex such as *cis*-$[PtCl_2(CO)_2]$ it should be considerably more positive. Also quite high charge separation is found in complex compounds containing only "neutral" ligands, *e.g.* $[Ni(CO)_2\{o\text{-}C_6H_4(PEt_2)_2\}]$ has a moment of 5.4 D.

2.3. Dependence on Anionic Ligands

Axially symmetrical complexes of type *trans*-$[PtXY(PEt_3)_2]$ where X and Y are different monovalent, anionic ligands can have considerable dipole moments, *e.g.* when X = H and Y = NCS the moment is 7.4 D, *i.e.* higher than the R_3P—Pt—Cl group moments. The negative contribution to the moments increases in the order H < Me < Ph < Cl < Br < I < NO_3 < NCS. If the Pt—H bond is arbitrarily given a contribution of zero to the moment the others contribute Me, 0.8; Ph, 1.6; Cl, 4.2; Br, 4.5; I, 4.9; NO_3, 6.8; NCS, 7.3 D. Even allowing for disparity in the sizes of the anions they obviously carry very different negative charges. Note that the contributions of the Cl, Br, and I ligands to the M—X bond moments are the reverse of those expected on

Table 2. Dipole moments and group moments [D] involving Cl, CO, NO, and H ligands in various complexes.

Complex	Observed dipole moment	Ref.	Group moment		Relation of dipole and group moments
trans-$[RhCl(CO)(PEt_2Ph)_2]$	2.4	[46]	Cl—M—CO	2.4	Equivalent
trans-$[IrCl(CO)(PEt_2Ph)_2]$	2.1	[47]	Cl—M—CO	2.1	Equivalent

the basis of relative electronegativities; they may possibly be rationalized as the effect of roughly constant absolute charges and increasing atomic radii.

2.4. Dependence on the Formal Anionic Charge

It might be expected that if a chloride ligand were replaced by formally more negatively charged ligands, such as oxide, nitride, or an organo-imide (RN^{2-}), a greater M—X bond moment would result. In fact, such complexes as *trans*-$[ReCl_3X(PR_3)_2]$ (X = Cl or O) have almost identical dipole moments. Such comparisons indicate that the Cl^-, the O^{2-}, and N^{3-} ligands make about the same contribution to the dipole moment. To obtain stable oxo-, imido-, and nitrido-complexes it is necessary to have central atoms such as rhenium in high oxidation states; then covalency is so strong that the bonds to the polyvalent anions are essentially triple in character and no more dipolar than the M—Cl bond.

In summary, dipole moments indicate that good electron donors such as amine and tertiary phosphanes in heavy transition metal complexes of type $[MCl_nL_n]$ carry considerable positive charge (≈ 0.3 e), the chloride ligands about equal negative charge, and the metal zero charge. Poor donors, *e.g.* good back-bonders such as CO, are about neutral overall under similar circumstances. This requires the metal to carry positive charge balancing that on the chlorine atoms. The contribution of monovalent anionic ligands to total charge separation in a complex varies considerably and will be a function of the size as well as the absolute charge on the ligand atom. The formal charge on the anionic ligand appears to be of no consequence so far as the dipolar quality of the M—X bond is concerned; Cl^-, O^{2-}, and N^{3-} as ligands make about equal contributions to the M—X bond moments.

3. X-Ray Photoelectron Spectroscopy

Because dipole moments measure overall separation of charge, inferences concerning absolute charges on atoms or groups can only be approximate and general. However, some of the inferences are confirmed by XPS data as detailed below.

From the beginning of XPS studies attempts have been made to relate measured binding energies to atomic charges[4]. This has never been entirely satisfactory, as evidenced by the calculations of charge which are still appearing[5]. It is evident that for the highest precision XPS measurements should be made in the gas phase, and for some complex compounds this is now possible. For example, it has been shown that the carbon atoms in volatile metallocenes have binding energies in the range 289.82, $[Co(C_5H_5)_2]$ to 290.17 eV, $[Mn(C_5H_5)_2]$, and the corresponding charges have been estimated as -0.3 e and $+0.1$ e per carbon atom[6]. The uncertainties in the binding energy measurements are estimated to be ± 0.05 eV, whereas measurements made on solids, which include the majority of complex compounds, normally have an experimental uncertainty of at least ± 0.3 eV.

The measured binding energy of an electron in a solid compound is the sum of contributions from several sources. To a first approximation we can divide these into effects due to atoms, ions, or molecules other than those due to the particular atom under study, and effects due to the atom being ionized. The former group of effects are generally classified as the Madelung contribution. The latter is a function of atomic charge, oxidation state, *etc.* The most superficial analyses of changes in binding energy generally ignore the Madelung contribution, and attempt to correlate binding energy directly with charge. This appears to be justified for the purpose of comparing binding energies of the same atoms in series of complexes of analogous types, as indicated by the consistency of the inferences which can be made from the observations.

3.1. Tertiary Phosphanes as Ligands

Tertiary phosphanes are normally believed to be π-bonding ligands—that is, they place charge onto a metal as a consequence of the partial transfer of the lone-pair electrons, and they receive charge back from metal d- or dp-hybrid orbitals into the empty 3d-orbitals of the phosphorus. In such circumstances, the total charge on the phosphorus will be the sum of these two opposing effects. One of the first endeavors of researchers using XPS has been to discover how P(2p) binding energies depend upon coordination. In fact, the results are not clear cut, and the P(2p) binding energy for PPh_3 is itself not precisely defined. The $P(2p_{3/2})$ binding energies for PPh_3, Ph_3PO, $[NiCl_2(PPh_3)_2]$, $[PdCl_2(PPh_3)_2]$ and $[CdCl_2(PPh_3)_2]$ have been reported[7] to be 131.9 ± 0.4, 132.9 ± 0.1, 131.6 ± 0.3, 131.7 ± 0.1, and 131.6 ± 0.2 eV, respectively (internal C(1s) as standard, 285.0 eV). These values seem to indicate that there is not much difference in charge between free and complexed triphenylphosphane. Independently, the $P(2p_{3/2})$ binding energies for $[MnCl(CO)_4(PPh_3)]$ and $[RhCl(CO)(PPh_3)_2]$ have been determined to be 131.2 and 131.6 eV, respectively (internal C(1s) apparently standard at 285 eV)[8]. The value for free triphenylphosphane was found to be 130.6 eV in this study. The reason for the discrepancy between the two results is not clear, but this kind of occurrence is common in XPS comparisons. Nevertheless, triphenylphosphane appears to carry the same charge as the free phosphane in all these complexes, and this is considerably less positive than in Ph_3PO; it is not clear whether phosphorus in the complexes is neutral or positive.

In an extension of this work, the complexes $[PdX_2(PPh_3)_2]$ (X = Br, Cl, I, or CN) have been studied. The $P(2p_{3/2})$ values are 131.8 ± 0.1, 131.8 ± 0.2, 131.6 ± 0.2 and 131.9 ± 0.2 eV, respectively (C(1s) graphite internal as reference)[9]. This constancy of energy is explained by a balancing of σ and π effects, which are in fact different for each X. Also the Pd(3d) energies do not vary significantly, which indicates a remarkable balancing of charges. This is consistent with the dipole moment measurements.

A considerable range of Pt complexes has also been investigated. These include a series of related triphenylphosphane complexes containing Pt^0 and Pt^{II} of general formula $[Pt(PPh_3)_2L]$, (L = $(PPh_3)_2$, PPh_3, Ph_2C_2, CO_3, O_2, CO, $C_2(CN)_4$ or Cl_2)[10]. The $P(2p_{3/2})$ binding energies were found to be essentially constant (*ca.* 131.6 ± 0.2 eV) despite the changes in Pt oxidation state and the wide variations of ligand type L. The Pt(4f) binding energies varied considerably over a range of about 2 eV. It was assumed, perhaps unwisely, that the metal atom in $[Pt(PPh_3)_2(PPh_3)_2]$ carries zero charge.

This is difficult to prove. Nevertheless, it does seem that any change in charge resulting from changes in L and in metal oxidation state is restricted to Pt and L. The phosphorus apparently achieves the same condition regardless of coordination circumstances when bound to Pd or Pt.

As a consequence of these considerations, it has been considered that PPh_3 places no charge on a metal to which it coordinates, as in, *e.g.*, $[MoCl_2(NO)_2(PPh_3)_2]$[11]. Since it is, however, a neutral molecule, and a bond is formed between PPh_3 and a metal, neutrality must imply equal and opposite σ- and π-effects. It now seems probable, in accord with the inference from dipole moments, that there is actually an overall *positive* charge on the phosphorus and that it is constant in these complexes[12]. The figure of 131.9 eV quoted above for free PPh_3 may be too high owing to oxidation of the measured sample[13]. The general indication is that, with the heavier transition elements, phosphorus in phosphane ligands *seems* to reach the same condition regardless of where it is coordinated. We shall return to this later.

An attempt has been made to settle the question of charge by use of infrared as well as XPS spectroscopy[12]. It was found for a series of benzene derivatives C_6H_5X that the intensity of ν(CH) is linearly related to C(1s) electron binding energies. The intensity of ν(CH) has been shown elsewhere to parallel the electron density on the aromatic ring. Implicit in this study, however, is a rejection of the idea normally axiomatic for crude XPS that internal C(1s) is immutable at 285.0 eV. In this case it was necessary to use a further external standard (Pt). The authors conclude that C(1s) in PPh_3 is 284.9 eV (cf. C(1s) in C_6H_6 is 284.5 eV and in $[PtCl_2(PPh_3)_2]$ is 285.3 eV). This is taken to indicate a small but real net flow of negative charge from PPh_3 to Pt. Further, it would seem that the overall charge donated from the aromatic rings on a single PPh_3 is 0.14 electrons. What the phosphorus itself donates is not clear. However, two points are apparent: (a) that C(1s) is not constant, but because the shifts are within the normal limits of experimental error, C(1s) = 285.0 eV is not a bad approximation, and (b) that even where P($2p_{3/2}$) does not change upon coordination (*e.g.*, PPh_3, 131.3 ± 0.3 eV, $[Hg(PPh_3)_2I_2]$, 131.3 ± 0.3 eV)[13] it does not *necessarily* mean that there is no overall phosphane-to-metal charge transfer. In fact, we are inclined to believe that there is. The P($2p_{3/2}$) binding energy, particularly when referenced against internal C(1s), takes no account of electron donation from the organic substituents which may change C(1s) and leave P($2p_{3/2}$) unaffected. Further, if we suppose that C(1s) does increase, indicating charge donation, by, for the sake of argument, 1 eV, then P($2p_{3/2}$) referenced to it could also increase by 1 eV but appear unchanged. The apparent constancy of the P($2p_{3/2}$) binding energies may indicate a constant C(1s)—P($2p_{3/2}$) separation within experimental error, rather than a constant charge on the phosphorus and may be consistent with the donation of negative charge from phosphorus.

There has been no wide-ranging study of the effect of changing "organic" substituents on the donor power of phosphorus, but for the heavier transition elements at least there is no sign of any systematic change: PEt_3 and PMe_2Ph seem substantially the same. Thus, for $[MCl_4(PEt_3)_2]$ (M = W, Re, Os, Ir, or Pt) and $[MCl_4(PMe_2Ph)_2]$ the P($2p_{3/2}$) binding energies fall within the ranges 131.5 ± 0.3 eV and 131.9 ± 0.2 eV (internal C(1s) standard). Considering the errors, these are identical[14]. Further, for a range of complexes $[ReCl_x(N_2)_y(PMe_2Ph)_{6-x-y}]$ ($x = y = 1$; $x = 2$, 3 or 4, and $y = 0$) P($2p_{3/2}$) is within the range 131.7 ± 0.4 eV. Evidently, nothing conclusive can be gleaned from these figures, although dipole moments show consistently that aromatic phosphanes give slightly less dipolar complexes than the aliphatic.

In a range of twenty four molybdenum complexes, generally of molybdenum(0) but with various phosphanes, P($2p_{3/2}$) was found to vary between extreme limits of 129.1 and 131.3 eV (external standard, Au)[15]. If the two extremes are excluded, the range is only 129.5 to 130.6 eV. At least one interpretation of these numbers is that generally the phosphorus reaches the same electronic condition in its complexes regardless of where it coordinates. This may be less true when phosphanes are coordinated to nickel. In that case P($2p_{3/2}$) apparently depends both upon the substituents on P and upon the metal oxidation state (*e.g.* $[Ni\{PPh(OEt)_2\}_4]$, 131.2; $[Ni\{PPh(OEt)_2\}_2(CN)_2]$, 132.3; $[Ni\{P(OMe)_3\}_4]$, 132.2; $[Ni(PPh_3)_3]$, 131.3 eV: all ± 0.3 eV, internal C(1s) = 285.0 eV)[16, 17]. Once errors are included the variations are less impressive than at first sight, and there are always reservations concerning photo-damage, particularly with First Transition Series elements. If there is a real difference between the phosphanes in nickel complexes on the one hand and in molybdenum and the heaviest metal complexes on the other, it could be explained on the basis that nickel is by far the least polarizable and it cannot so easily satisfy the charge requirements of its ligands.

3.2. Chlorine as a Ligand

The XPS method would seem to be ideal for distinguishing between the various types of chlorine (bridging, terminal, axial, equatorial, *etc.*) which can be found in metal complexes. Whether the technique can reliably do so is actually not clear. In octahedral complexes, no easy distinction can be made between facial and meridional chlorines[14]. It would seem unequivocal that the charge on a "free" chloride ion, as in a KCl lattice, should be greater than in a complex, as in $K_2[PtCl_4]$[18]. It was reported very early that the Cl($2p_{3/2}$) binding energies were 201.2 and 200.7 eV, respectively. This difference is hardly significant[19]. A study of bridging and terminal chlorines in platinum complexes led to the conclusion that the binding energy for $Cl_{bridging}$ is lower than for $Cl_{terminal}$ (*e.g.*, *trans*-$[Pt_2Cl_4(PnPr_3)_2]$, $Cl_b = 197.0$, $Cl_t = 198.2$ eV)[20]. This is not what one might expect intuitively, since a bridging chlorine, with two donor bonds, should be more positive than a terminal one. In $[Mo_2Cl_{10}]$, however, apparently the converse is true[19]. In clusters and systems containing metal-metal bonds $Cl_b > Cl_t$, but the differences are often close to the significant limits[21]. In fact all three situations $Cl_b \approx Cl_t$, $Cl_b < Cl_t$, and $Cl_b > Cl_t$ occur and the significance of these observations is doubtful.

None of these results gives a direct idea as to how much charge a chlorine atom in a complex might take up. However, an indirect approach is possible. There is a linear relationship between metal binding energy and formal oxidation state for complexes $[MCl_x(PMe_2Ph)_y]$ ($x = 2$, 3 or 4; $x + y = 6$)[1, 21]. This kind of relationship is intuitively attractive. To a first

approximation, the slope of these lines for M = W, Re, Os, and Ir appears to be 1.4 eV/unit oxidation state. Rough calculation suggests that the change of charge on the metal upon oxidation by one unit of oxidation state is nearer 0.1 electrons than 1.0 electrons[23]. In this context, "oxidation" means the exchange of a tertiary phosphane for a chlorine atom; the net effect of this is to change the binding energy by 1.4 eV.

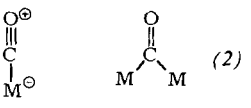
It is possible to apportion this binding energy change to the effects of individual ligands. Thus comparison of the five-coordinate species $[ReCl_2N(PEtPh_2)_2]$ and $[ReCl_2(NO)(PMePh_2)_2]$ with the six-coordinates species $[ReCl_2N(PMe_2Ph)_3]$ and $[ReCl_2(NO)(PMe_2Ph)_3]$ respectively shows that the addition of a phosphane ligand is tantamount to the reduction of the metal by three quarters to one unit of oxidation state[1]. The addition of a chlorine atom apparently raises the metal binding energy by less than 0.5 eV. Experimental errors in binding energy measurements are such that this does not necessarily conflict with the equal and opposite charges on phosphorus and chlorine implied by the dipole moment measurements. Appropriate comparisons of the above sort allow the following inferences to be made[1, 22]. Ligating nitrogen oxide (even "NO^+", carbon monoxide, and dinitrogen are electron withdrawing in the order $NO > CO \approx N_2$. Nitrido-ligands carry less real charge than NO. Chlorine atoms are apparently roughly neutral to slightly electron withdrawing, but chloride ions are definitely electron donating. Hydrido ligands carry very little negative charge, and the metal atoms in polyhydrido complexes of very high formal oxidation state carry charges considerably less than the oxidation states might suggest[23]. Thus, the Os^{IV} in $[OsH_4(PMe_2Ph)_4]$ $[Os(4f_{7/2}) = 50.5\,eV]$ is about as positive as Os^{II} in $[OsCl_2(PMe_2Ph)_4]$ $[Os(4f_{7/2}) = 50.7\,eV]$. Pure metals often have binding energies which are consistent with complexes in oxidation states as high as +II. This may be a result of the enormous differences in structure (and hence Madelung term) between a metal and its complexes[23].

3.3. Charges on Metals in Complexes

Attempts have been made to correlate metal binding energies directly with charge on the metal. The charge is usually calculated by approximate methods, such as CNDO, Hückel, and Pauling methods. There is no independent verification of these charges, which appear to be roughly linearly related to binding energies. Thus, in a series of chromium complexes the charge was calculated (extended Hückel) to vary from zero (Cr metal) through *ca.* 1.5 ($[Cr(CO)_6]$) to *ca.* 2.5 ($[CrO_4]^{2-}$)[24]. For molybdenum, calculations indicate that it varies (Pauling) from zero (Mo metal and $MoSe_2$) through *ca.* 1 ($MoCl_5$) to 1.6 (MoO_3)[24]. For nickel, the calculated charges (Pauling) vary from zero (Ni metal) through *ca.* 0.5 ($NiCl_2$) to 1.3 (NiF_2)[16]. The linearity of the binding energy/charge relationships is comforting. The absolute values of the calculated charges are probably not very significant.

Sherwood[25] has attempted to calculate binding energies in chromium compounds on the basis of the various methods of estimating charge. He concludes that Cr in $[Cr(CO)_6]$ probably has a gross positive charge (*ca.* 1.9), carbon is just negative and oxygen considerably negative, consistent with calculations for other carbonyls (*e.g.*, $[Ni(CO)_4]$[26]). Apparently CNDO charges give calculated binding energies in better agreement with experiment than the Pauling methods[25]. The CNDO charges are presumably therefore better approximations to the truth.

The calculated charges show rough parallels with metal oxidation state. In certain very restricted circumstances (*e.g.*, where the changes from one compound to another in a series involves the exchange of the same neutral ligand with the same anion) the parallel may be close. In general, it is dangerous to assume any relationship between metal charge and metal oxidation state. Thus, Cl and O atoms apparently have the same overall electron withdrawing effect on molybdenum[27]. Consequently the metal binding energies in complexes $[MoCl_2O_2L_2]$, $[MoCl_3OL_2]$, and $[MoCl_4L_2]$ (L = neutral ligand) are about equal, despite the fact that the molybdenum oxidation states are VI, V, and IV. This accords with the evidence from the dipole moments of rhenium complexes[28] which is also supported by XPS measurements[29].



3.4. Carbon Monoxide as a Ligand

3.4.1. Terminal Carbon Monoxide

The charge on CO in metal carbonyls has long been a favorite topic of organometallic chemists. An early XPS study on $[Cr(CO)_6]$, $[Fe(CO)_5]$, and $[Ni(CO)_4]$ suggested an overall electron transfer from metal to ligand[30]. (In contrast, the cyclopentadienyl rings in ferrocene were reckoned to be slightly positive[26].) The bulk of the negative charge transferred to the CO was assumed to reside on the carbon, but this conclusion rests heavily upon the reference used for C(1s). Another XPS study on these carbonyls (and $[W(CO)_6]$) came to a similar conclusion[31], and this is now supported by calculation[26]. Thus, in $[Ni(CO)_4]$ as compared with CO, the charge on C decreases from +0.371 e to +0.234 e, and that on O increases from −0.371 e to −0.350 e. The total charge on nickel was calculated to be +0.466 e. In $[Cr(CO)_6]$ the charges on chromium, carbon, and oxygen were calculated as +0.703 e, +0.233 e, and −0.349 e, respectively. Our XPS studies also show that CO is an overall electron acceptor[1].

3.4.2. Bridging Carbon Monoxide

Carbon monoxide can bind to metals in at least three ways, the most usual being *via* the carbon atom. Much more rarely it can bind *via* oxygen, but frequently it can bind (*via* carbon) between metals (bridging) as well as terminally. It was deduced from the spectra of gaseous $[Mn(COMe)(CO)_5]$ and $[Co_4(CO)_{12}]$ that the binding energies O(1s) in bridging carbonyls are lower than in terminal ones[32]. This accords with the authors' simple valence bond representations of the

(1) *(2)*

two bonding types [see *(1)* and *(2)*], but in view of the above discussion it is difficult to accept that oxygen in a terminal carbonyl is really positive.

3.5. Nitrogen Oxide as a Ligand

Nitrogen-containing compounds have been studied intensively by XPS since the technique was first introduced. Correlations of charge with N(1s) binding energies have been attempted (see, for example, reference [33]). The charge calculated depends very much upon the method of calculation. Thus extended Hückel charges on nitrogen range from +2.6 ($NaNO_3$) to −1.7 (KSCN). The corresponding CNDO charge for $NaNO_3$ is +0.4[31]. These are not, however, the only attempts to calculate binding energies (see, for example, reference[34]). Nevertheless, it has remained tempting to use XPS to investigate the binding of NO to metals, particularly in an attempt to distinguish straight and bent forms (so-called "NO^+" and "NO^-").

It is not surprising that NO in negative ions generally carries a negative charge as in the series $[M(CN)_5(NO)]^{n-}$ (M = Mn, Cr, M, or V) although in $[Fe(CN)_5(NO)]^{2-}$ it appears to be positive[35]. The substitution method[1] seems to show that NO, even in neutral complexes, is electron withdrawing, and more strongly so than CO. A study of an extended series of metal nitrosyls suggested that bent nitrosyls (NO^-) have relatively low N(1s) binding energies whereas straight nitrosyls (NO^+) can have higher or lower N(1s) depending upon the extent of π bonding[36]. A study involving $[MoCl_2(NO)_2(PPh_3)_2]$ was taken to show that the two NO groups together remove about 0.14 electrons from the molybdenum[11]. The quantitative interpretation may be wrong, but the qualitative conclusion is probably correct. Finally a study of iridium complexes led to the startling conclusion that "NO^+" in $[IrH(NO)(PPh_3)_3]^+$ carries more negative charge than "NO^-" in $[IrCl(CO)(NO)(PPh_3)_2]^+$[37]. There is no doubt that both ν(NO) and N(1s) are unreliable for distinguishing the two kinds of NO coordination, but they can be distinguished[38] using a method which is equally applicable to sulfoxide complexes[39]. The *difference* between N(1s) and O(1s) is 132±1 eV for straight nitrosyl ligands and 128±2 eV for bent ones. Although NO^- may carry greater positive charge than NO^+, the difference in binding energies appears characteristic of the structural type.

4. Conclusions

Both dipole moment measurements and XPS provide data concerning charge distribution in complex molecules. Where they can be easily interpreted, the data are in general agreement and sufficient data are now available to allow an appreciation of gross charge distribution. Surprising factors are that both the so-called neutral and anionic ligands vary considerably in their abilities to acquire positive or negative charges respectively. This is so marked that there is a complete gradation from the strong capacity of such ligands as the tertiary phosphanes and pyridines to carry positive charge through intermediate ligands (CH_3^-, CO, H^-, N_2, NO^+, and PF_3) around zero charge, to those with a strong capacity to carry negative charge, such as halide, O^{2-}, N^{3-}, and $RCOO^-$. This appears to accord with general chemical experience. It explains such observations as that $[PtMe_2(PEt_3)_2]$ oxidatively adds methyl iodide whereas $[PtI_2(PEt_3)_2]$ does not[40], because the platinum atom in the former is more negatively charged than in the latter where the negative charge has been passed on to the iodine ligands. For the same reason, polyhydride tertiary phosphane complexes behave much more like metal(0) complexes than do the corresponding chlorides. The actual charges carried by the metal and ligand atoms in complex compounds are considerably closer to zero than are implied by their formal oxidation states; it appears that they are rarely, if ever, outside the range ±0.5 e and more often around ±0.3 e for complexes between good electron donors and acceptors[*].

Hemoglobin—An Inspiration for Research In Coordination Chemistry

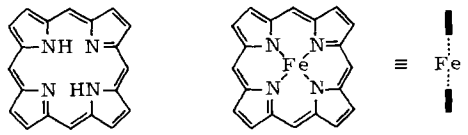
By Johann Walter Buchler[*]

Dedicated to Professor Heinrich Nöth on the occasion of his 50th birthday

Hemoglobin transports oxygen in the blood and is responsible for its red color. Being one of the most closely studied proteins, it is entitled an "honorary enzyme". This admirable natural substance invites chemists to copy it, imitate it, and vary or modify it. The first means a total synthesis of the original molecule, but such reproduction does not increase our knowledge of its function. In the case of imitation, the biochemical effect of the "original" (*i.e.* hemoglobin) is achieved in full or in part with simpler molecules of similar structure, *i.e.* with models. Research is here directed at the function of hemoglobin. In the case of variation or modification the original molecule is changed to various extents, which reveals the factors underlying its action. In all three cases—reproduction, imitation, and modification—hemoglobin serves as an inspiration for research. The aim of the present review is to summarize recent investigations inspired by hemoglobin in the field of coordination chemistry. A brief outline of the coordination chemistry of the porphin system serves as an introduction.

1. Introduction: The Coordination Chemistry of the Porphin Ligand

Porphin [$H_2(P)$; *(1)*], which forms the parent substance of all porphyrins[1], contains four pyrrole rings linked into a macrocycle by methine bridges (see Fig. 1 and Table 1). Of the four inner nitrogens, two that are diagonally opposite each other carry labile protons that can be split off with bases. The resulting porphin dianion $(P)^{2-}$ has four pairs of free electrons pointing inward. Owing to its aromatic character, this ion forms a rigid, planar, closed, quadridentate chelate ligand system whose center can be occupied by metal ions of suitable size[2–8]. This process, called metalation, is shown in reaction (a) for the important Fe^{II} ion. This reaction, which is generally slow because of the rigidity of the porphin system, follows a complicated mechanism, since many bonds have to be broken and formed in its course[5, 6].



$$\underset{(1)}{H_2(P)} + Fe(OAc)_2 \underset{HCl}{\overset{HOAc,\ 110°C}{\rightleftharpoons}} \underset{(2)}{Fe(P)} + 2HOAc \qquad (a)$$

[*] Prof. Dr. J. W. Buchler
Institut für Anorganische Chemie der Technischen Hochschule Templergraben 55, D-5100 Aachen (Germany)

The character of a rigid, closed chelate also explains the remarkable stability of porphyrin complexes. Thus, a formation constant of at least 10^{16} has been reported for a Zn^{II} porphin, related to the Fe^{II} porphin[5c]. Nevertheless, many metal ions can be abstracted from porphyrin complexes with the aid of strong acids. Thus, dilute hydrochloric acid is sufficient for such demetalation in the case of the Fe^{II} ion in the reverse of reaction (a).

The formation of the planar chelate Fe(P) *(2)*, an "inner complex salt" in the classical sense, by no means exhausts the possibilities offered by this system in coordination chemistry. In compound *(2)* the four nitrogens of the porphin ligand occupy the corners of a square, seen from the side in A (Figs. 1 and 2). This square in *(2)* can form the base of a pyramid B after the addition of a neutral donor ligand L, while after the addition of two donor molecules it can form the equatorial plane of a more or less tetragonally distorted octahedron C (Fig. 2). In the complexes B and C, formed in reaction (b), the donor molecules L act as "axial" ligands.

$$\underset{A}{Fe(P)} \overset{L}{\rightleftharpoons} \underset{B}{Fe(P)L} \overset{L}{\rightleftharpoons} \underset{C}{Fe(P)L_2} \qquad (b)$$

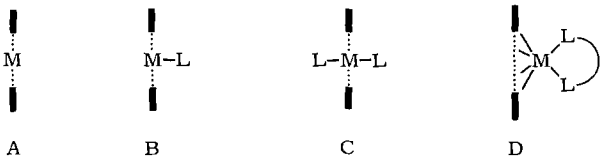
(1), $H_2(P)$ (2), Fe(P) A

Fig. 1. Formulas of porphin (1), the unsubstituted parent substance of all porphyrins, and of porphinatoiron (iron porphyrin) (2), the parent substance of all hemes.

Table 1. Abbreviations.

General symbols

M: central metal ion, L: axial donor ligand (neutral or anionoid), X: monovalent anion, $H_2(P)$: unsubstituted porphin (1)



Special symbols

a) Hemoglobins
[Hb]: monomeric hemoglobin, [Mb]: myoglobin

b) Metal-free porphyrins (examples)
H_2(proto): protoporphyrin-IX [cf. (3a)],
H_2(meso-DME): mesoporphyrin-IX dimethyl ester [cf. (3d)],
H_2(TTP): *meso*-tetra(*p*-tolyl)porphyrin [cf. (6j)],
H_2(OEP): octaethylporphyrin [cf. (7a)];
H_2(Pc): phthalocyanine

c) Organic solvents or axial ligands or their corresponding acids
Py: pyridine, Hlm: imidazole, 1-MeIm: 1-methylimidazole, 2-MeIm: 2-methylimidazole, THF: tetrahydrofuran, DMF: dimethylformamide, MeCN: acetonitrile, PR_3: triorganylphosphane, HOAc: acetic acid, H(acac): 2,4-pentanedione (acetylacetone)

While the d^6 electron configuration of the Fe^{II} ion favors the formation of coordination type C, which is very common also with other central metal ions, the d_{z^2} orbital of metal ions with configurations d^7, d^8, and d^9, which is partly or fully occupied and lies in the axial direction, repels axial donor ligands, so that coordination type A predominates in the case of Co^{II}, Ni^{II}, Cu^{II}, and ions that are isoelectronic with these and are in the same groups of the periodic table[3-9].

A B C D

Fig. 2. The most important coordination types of metal porphyrins A: square [see (2)]; B: square pyramid; C: distorted octahedron (*trans* configuration); D: *cis* configuration in the addition of bidentate chelate ligands L⌒L (See Section 7.1).

As will be seen later, the possibility of adding on axial ligands is in fact essential for the biological function of iron porphyrins.

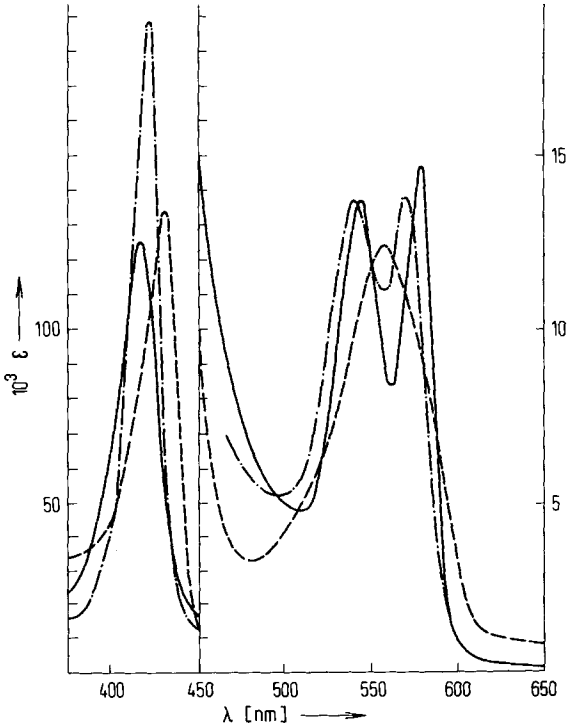
After *Richard Willstätter*'s[10] and *Hans Fischer*'s[1,11] significant contributions and the blossoming of organometallic chemistry after 1950, all metals and boron, silicon, germanium, and phosphorus have now been inserted into the porphyrin system[3-9]. Research in this field makes extensive use of physical and instrumental techniques[3,4], particularly X-ray structure analysis[12] and electron spin resonance spectroscopy[13]. As a result of this work, the coordination chemistry of metal porphyrins has grown into a separate field of coordination chemistry. This field is treated systematically in the appropriate sections of recent monographs and reviews[3-7].

The intensive work on porphyrins, illustrated by the publication of 44 articles in the Journal of the American Chemical Society in 1975 alone, stems from the great interest of chemists in heme proteins responsible for the transport of molecular oxygen in the body and for a wide variety of oxidation processes[14]. Yet this area itself is not so popular among chemists at present. The present review will treat hemoglobin as an inspiration for the chemistry of metal porphyrin complexes, without discussing the other heme proteins.

2. The Main Characteristics of Hemoglobin and Myoglobin

Human hemoglobin is a globular protein with a molecular weight of 64500, which gives the erythrocytes their red color (see Fig. 3) and enables them to transport oxygen[14-17]. The structure of hemoglobin with various axial ligands has been determined on single crystals by X-ray crystallography at a resolution of 2 Å[18]. Hemoglobin consists of four associated peptide chains (two α- and two β-chains), and its composition in the ligand-free state can be written as $[Fe(proto)G]_4$, where G is the apoenzyme globin and Fe(proto) is the coenzyme heme (3a), the latter being the iron(II) chelate of protoporphyrin IX (see Table 2).

Myoglobin has a molecular weight of 17000 and takes up oxygen in the muscle cells on its way to the mitochondria, thus accelerating its diffusion. In composition and structure it differs only slightly from one of the subunits of hemoglobin, specifically in the globin component, and can therefore be represented as [Fe(proto)G] (see above).



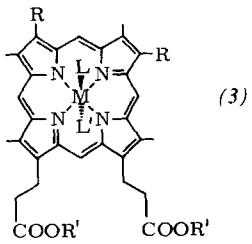


Fig. 3. Electronic absorption spectrum of oxyhemoglobin $[Hb{\cdot}O_2]_4$ (—), deoxyhemoglobin $[Hb]_4$ (– –), and carbonylhemoglobin $[Hb{\cdot}CO]_4$ (–·–) at pH 7 and 20°C (see Fig. 4). The longest-wavelength absorption maximum is called the "α band" (after [15]).

(3)

Table 2. Composition of metal porphyrins *(3)* of natural origin. (For abbreviations see Table 1.)

	M	L	L'	R	R'	Abbreviation
(3a)	Fe	—	—	$CH=CH_2$	H	Fe(proto)
(3b)	Fe	Cl	—	$CH=CH_2$	H	
(3c)	Fe	—	—	$CH=CH_2$	CH_3	Fe(proto-DME)
(3d)	Fe	—	—	C_2H_5	CH_3	Fe(meso-DME)
(3e)	Fe	—	—	H	CH_3	
(3f)	Fe	Hlm	Hlm	C_2H_5	H	
(3g)	Fe	—	—	$CH=CH_2$	C_2H_5	
(3h)	Co	Py	—	$CH=CH_2$	CH_3	
(3i)	Co	—	—	$CH=CH_2$	H	Co(proto)
(3j)	Yb	acac	—	C_2H_5	CH_3	

The term hemoglobin is also used nowadays in the broad sense as a generic name for all heme proteins that add on oxygen reversibly and transport it[16]. It is very confusing for outsiders that in physiological chemistry the abbreviations Hb and Mb are used for ligand-free hemoglobin and myoglobin, irrespective of their state of association, while there are also some hemoglobins that consist of a single peptide chain[16]. In contrast, the state of association will always be specified here, with the aid of the following abbreviations in square brackets:

human hemoglobin	$[Hb]_4 = [Fe(proto)G]_4$
hemoglobin subunit	$[Hb] = [Fe(proto)G]$
myoglobin	$[Mb] = [Fe(proto)G]$

Buse has given a protein chemist's account of the structure and function of hemoglobin, with special reference to the globin component[16]. Changes in the quaternary and tertiary structure (allosterism) are brought about by "allosteric effectors", low-molecular substances reacting with the protein. Allosterism is the basis of *e.g.* the Bohr effect (the pH-dependence of the overall oxygenation equilibrium shown [reaction (c)], with hydrogen ions as the effectors) and of the "cooperative" nature of the oxygen uptake, where the bound oxygen itself acts as an effector; a condition for this is an association of the subunits, *e.g.* to $[Hb]_4$. Contrary to expectation, there is much less driving force behind the first step of the oxygen uptake [reaction (d)] than behind the last step [reaction (e)], which ensures that the bound oxygen is released more easily in an oxygen-deficient medium a long way from the lungs. Finally, $[Hb]_4$ also takes care of about 60% of the reverse transport of CO_2 formed in cell respiration back to the lungs, but heme itself is not involved in this[14–16]. These effects cannot be discussed here in further detail.

$$[Hb]_4 + 4O_2 \rightleftarrows [Hb \cdot O_2]_4 \quad (c)$$

$$[Hb]_4 + O_2 \rightleftarrows \{[Hb]_3[Hb \cdot O_2]\} \quad (d)$$

$$\{[Hb \cdot O_2]_3[Hb]\} + O_2 \rightleftarrows [Hb \cdot O_2]_4 \quad (e)$$

The characteristics of hemoglobin that are considered essential by inorganic chemists will merely be outlined here, with what might seem ludicrous brevity, by representing the fundamental chemistry of a monomeric hemoglobin [Hb] in Fig. 4, this scheme referring both to a single subunit of human hemoglobin and to myoglobin [Mb].

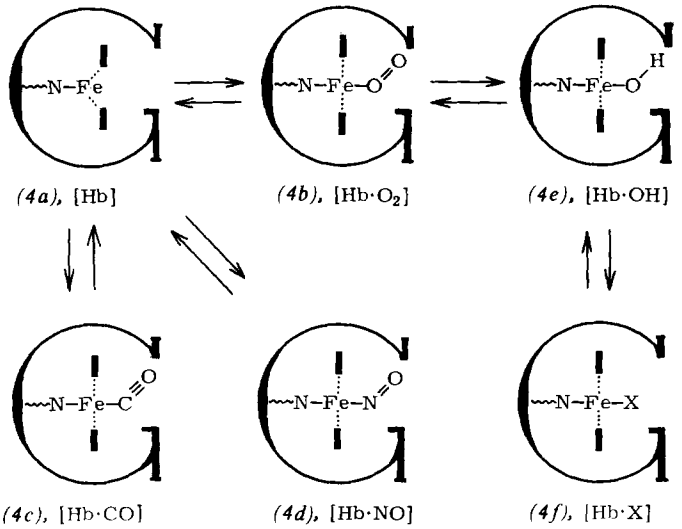

Fig. 4. Schematic representation of the essential chemistry of a hemoglobin unit [Hb] or myoglobin ([Mb] is then used instead of [Hb]). The letter G symbolizes the protein component, *i.e.* globin.

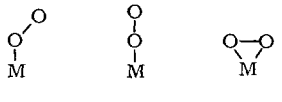
2.1. The Coordination Chemistry of Hemoglobin

In deoxyhemoglobin $[Hb]_4$ [cf. *(4a)*], the iron(II) ion is pentacoordinated (type B, Fig. 1), has an effective magnetic moment $\mu_{eff} = 5.4$ B.M.[19], and protrudes from the plane of the protoporphyrin[12,18] by about 50—60 pm. The heme component Fe(proto) *(3a)* is held in the "pocket" of the globin by van der Waals forces and the dative coordinate bond of the nitrogen atom shown in *(4a)*. This nitrogen belongs to the imidazole part of what is called the "proximal" histidine, which is not absolutely essential for fixing the heme in the globin but has a fundamental effect on the binding of ligands and probably also transmits the allosteric effects. "Distal" histidine, which is on the opposite side of the heme disk and is not shown in *(4a)*, cannot form a coordinate bond with the iron in heme because it is too far away; distal histidine is not essential for the binding of O_2, but seems to influence the entry of the ligand to the site of the bond formation[17,18].

Under physiological conditions (37 °C), $[Hb]_4$ reacts with molecular oxygen to give oxyhemoglobin $[Hb \cdot O_2]_4$ [cf. *(4b)*, while with carbon monoxide and nitric oxide it forms respectively carbonylhemoglobin $[Hb \cdot CO]_4$ [cf. *(4c)*] and nitrosylhemoglobin $[Hb \cdot NO]_4$ [cf. *(4d)*]. These reversible reactions cause characteristic changes in the visible spectra (Fig. 3). The association constants (K_{ass}) for the equilibria of the monomers have approximately the following relative magnitudes at comparable pH:

$$K_{ass}(4a) \rightleftarrows (4b) : K_{ass}(4a) \rightleftarrows (4c) : K_{ass}(4a) \rightleftarrows (4d)$$
$$= 1 : 4 \times 10^2 : 5 \times 10^{15} \text{ [15]}$$

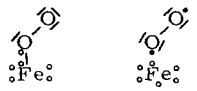
The binding of CO or NO is therefore favored over the uptake of O_2. This is true for $[Hb]_4$, [Mb], and numerous



other heme proteins in the Fe^{II} form, and is the reason for the high toxicity of CO and NO. Since $[Hb \cdot CO]_4$ and $[Hb \cdot NO]_4$ dissociate much more slowly than $[Hb \cdot O_2]_4$[20], a chain-smoker can easily render 10% of his hemoglobin useless, owing to the carbon monoxide in the smoke[21]. The adducts $[Hb \cdot O_2]_4$ and $[Hb \cdot CO]_4$ are diamagnetic, while $[Hb]_4$ is not, and $[Hb \cdot NO]_4$ has an unpaired electron. The adducts are therefore in the low-spin state[19].

In the crystalline product, and to a small extent also under normal metabolic conditions in the blood, the oxygenation of $[Hb]_4$ to $[Hb \cdot O_2]_4$ is followed by oxidation to "methemoglobin" $[Hb \cdot OH]_4$ [(cf. *4e*)], which carries an OH on each Fe^{III} ion, and these OH groups can be protonated to give an aquo complex called "acid methemoglobin". With anions X^- (X = F, OAc, CN, N_3 etc.), $[Hb \cdot OH]_4$ gives a series of other ferrihemoglobins $[Hb \cdot X]_4$ [cf. *(4f)*], whose magnetic moments show a pure high-spin state for X = OH or F, an intermediate spin state for $X = N_3$, and a low-spin state for X = CN[19]. In the blood $[Hb \cdot OH]_4$ is constantly reduced again to $[Hb]_4$ by the "repair enzyme" methemoglobin-reductase[22]. When a dangerous level of $[Hb \cdot OH]_4$ has built up in the blood ("methemoglobinemia") under abnormal metabolic conditions, such as nitrite poisoning, $[Hb \cdot OH]_4$ can be converted back into $[Hb]_4$ by an intravenous injection of redox mediators such as methylene blue or toluidine blue[21]. Incidentally, sperm-whale metmyoglobin [Mb·OH] was the first protein whose crystal structure was determined by X-ray crystallography[23].

All the X-ray structure analyses[18] so far carried out on carbonylhemoglobins point to the presence of a bent Fe—CO unit with an Fe—C—O angle of about 145°. This is unusual in complexes and was first found by *Huber* in his work on the [Hb·CO] of the insect *Chironomus thummi*[24]. Otherwise a bent M—C—O unit has so far been found only in a single carbonyl complex, namely in $Mn_2(AsMe_2)(CO)_6C_5H_5$; the bent shape of a terminal Mn—CO group is attributed to steric hindrance due to neighboring groups[25]. Distal histidine in globin is likewise so oriented that it is in the way of a CO or CN ligand attached to the iron normally to the porphin plane; as a result, either the Fe—C—O unit is bent, as in *(4b)*, or the Fe—C—O axis is tilted from the perpendicular line of the porphin plane, but one cannot yet distinguish between these possibilities. On the other hand, bent diatomic or triatomic ligands, such as azide or hydroxide, fit better into the heme pocket[18]. Figure 4 shows these aspects and thus anticipates the results for $[Hb \cdot O_2]_4$ and $[Hb \cdot NO]_4$ to be discussed in Sections 2.2 and 4.



2.2. Nature of the Dioxygenyliron Group in Oxyhemoglobin

The structure and the distribution of the valence electrons in the dioxygenyliron unit in $[Hb \cdot O_2]_4$ or $[Mb \cdot O_2]$ have long been the subject of lively dispute[26–32], but this cannot be described here in detail. Unfortunately, it has not yet been possible to investigate the oxygenated forms by X-ray crystallography, because autoxidation to $[Hb \cdot OH]_4$ takes place during the lengthy process of data collection. In addition, the resolution of the structure analysis is not high enough to allow the determination of the space coordinates of the atoms next to iron with the accuracy that can be achieved with low-molecular complexes.

E F G

Therefore, in the case of a hemoglobin a decision is not yet possible between the three conceivable configurations of the FeO_2 unit in *(4b)*, namely the bent monodentate (E), the linear monodentate (F), or the bidentate arrangement (G). The bent structure E selected in Figure 4 was proposed by *Pauling* as long ago as 1949[26]. The form G, first discussed by *Griffith* in 1956[27], would be a π-complex of Fe^{II} or a peroxo complex of Fe^{IV}. There are no examples of the linear arrangement F in inorganic chemistry.

H K

The experiments described in Sections 5 and 6 show that the synthetic O_2 adducts of mononuclear iron(II) and cobalt(II) complexes have a bent structure of type E, so that the latter is also likely for *(4b)* itself. The adducts of O_2 (like O_2 itself) cannot be formulated unambiguously with valence signs. *Pauling* has suggested formula H[26], in which the iron is divalent, and which explains the apparent diamagnetism of the adduct. Formula K, introduced by *Weiss*[28], shows $[Fe(proto)O_2 \cdot G]$ as a neutral complex of the hyperoxide ion $[O_2]^-$. (In these formulas circles denote d electrons of iron, and points and lines denote valence electrons and valence electron pairs of dioxygen.) In the case of the structure K it is difficult to understand how the two unpaired electrons at the Fe^{III} ion and the terminal O atom can couple to form a diamagnetic system. The latest and very accurate measurements of the magnetic susceptibility show that $[Hb \cdot O_2]_4$ exhibits residual paramagnetism, whose temperature dependence between 3 and 30 K indicates an exchange interaction with a coupling constant of $J = 12$ K between the two ($S = {}^1/_2$) systems of an Fe^{3+} ion and an O_2^- ion[29].

Formula K gives a correct description of some other properties of *(4b)* and is therefore preferred at present. For example, the weak light absorption in the near infrared region at 900—1100 nm that is observed with *(4b)*, *(4e)*, and *(4f)* but not with *(4a)* and *(4c)* points to the presence of Fe^{III} in the first set of hemoglobin derivatives, *i.e.* in *(4b)*, *(4e)*, and *(4f)*. Furthermore, the IR spectrum of $[Hb \cdot O_2]_4$ and $[Mb \cdot O_2]$ exhibits an O—O stretching vibration with a frequency of about 1100 cm^{-1}, characteristic of the coordinated hyperoxide ion[30a–30c]. Besides, when Cl^- reacts with $[Hb \cdot O_2]_4$ in an aqueous solution, it is possible to detect the hyperoxide ion (or HO_2 radical) that is displaced from the heme in a nucleophilic substitution [reaction (f), with X = Cl]. This explains the continuous formation of methemoglobin in the blood mentioned above. The hyperoxide released here is also made harmless by enzymatic means. Other methemoglobins $[Hb \cdot X]_4$ [cf. *(4f)*, with $X = N_3$, SCN, OCN, F]

can also be prepared directly by an exchange of the anions according to reaction (f)[30d, 30e].

$$[Hb \cdot O_2]_4 + 4X^- \rightarrow [Hb \cdot X]_4 + 4O_2^- \quad (f)$$

According to recent quantum-mechanical *ab-initio* calculations, the Pauling configuration F has as much as 55 kcal·mol^{-1} less energy than the Griffith configuration G. However, the calculated electroneutrality of the O_2 ligand points to a predominance of the electron configuration H[31]. The calculations involve a great deal of simplification, NH_3 being used as the base *trans* to the O_2 molecule; this might not take sufficient account of the contribution of imidazole to the π-bonds, which has been observed experimentally[17].

The special effect of the porphyrin and the globin components can be seen by comparing the behavior of the Fe^{II} ion in hemoglobin and in water at pH 7: in hemoglobin there is a rapid reversible oxygenation, while in water there is an extremely slow and irreversible autoxidation (it is considerably faster in an alkaline medium). This difference is explained to some extent by the syntheses in which hemoglobin is modified and imitated and which will be discussed later, after the following notes concerning a reproduction of hemoglobin.

3. Copying: Remarks on the Total Synthesis of Hemoglobin

The total synthesis of a natural product, *i.e.* its nonenzymatic reproduction *in vitro*, does not explain its mode of operation but provides us with the necessary methods for modifying and imitating the molecule and thus for discovering the way it acts in nature. With the total synthesis of hemin *(3b)*, and thus also heme *(3a)*, *Hans Fischer* succeeded in 1929 in "copying" or reproducing the coenzyme of hemoglobin[33]. However, it is easier to extract hemin *(3b)* from blood than to synthesize it. For this, the blood is first treated with citrate to bind the calcium ions and to make it uncoagulable by suppressing fibrin formation. The erythrocytes are then made to burst (hemolysis) by producing an osmotic shock with water. After centrifuging, $[Hb \cdot OH]_4$ is obtained in the aqueous phase if the work is carried out in air. Globin is denatured and precipitated by the addition of strontium chloride and acetone[34]. The intact globin can be isolated with dilute hydrochloric acid in acetone at $-20°C$[15]. Hemin remains in solution in both cases. The process is as shown in reaction (g).

$$[Fe(proto)OH \cdot G] + HCl \underset{\text{reconstitution}}{\overset{\text{cleavage}}{\rightleftharpoons}} [Fe(proto)Cl] + G + H_2O \quad (g)$$

(4e) = [Hb·OH] *(3b)*

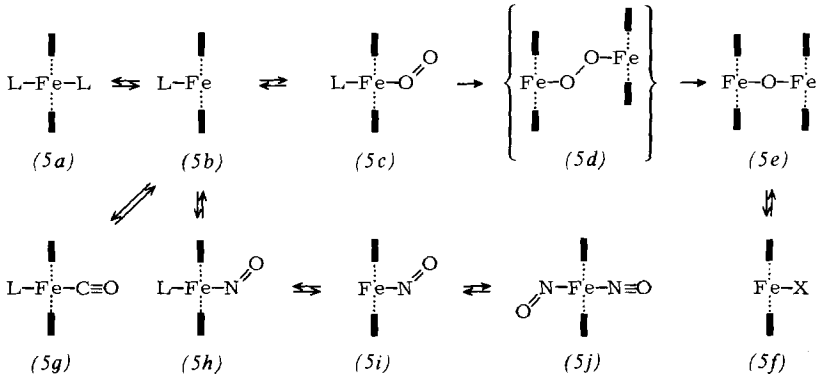
"Reconstitution", *i.e.* the recombination of heme *(3a)* and intact globin, was first achieved by *Hill* and *Holden* in 1926[35]. The overall process starts with the reversal of reaction (g), after which the resulting [Hb·OH] *(4e)* is reduced to complete [Hb] *(4a)* (see also Section 4). In a weakly alkaline medium (pH 7.2—8.0), the equilibrium in reaction (g) lies entirely to the left[15].

A total synthesis of the apoenzyme has not yet been described, but it seems feasible at the present state of protein research. The modification of globin is provided *in vivo* by the existence of many species-specific globin variants or mutants, which exhibit characteristic deletions or substitutions in their amino-acid sequence, leading to changes in the function of the molecule[15, 16, 36].

4. Variation I: Removal of the Globin Component—Coordination Chemistry of Heme and Hemin

The modification of the globin component on the basis of mutants occurring in nature belongs to the field of protein chemistry[16, 36]. Although this field is also instructive for inorganic chemists, we shall discuss here only one modification, namely the complete elimination of globin. Figure 5 shows the essential chemistry of heme *(3a)*, which exists preferentially as a complex $Fe(P)L_2$ [reaction (b)] when mixed with donor-solvent molecules L such as THF, DMF, and pyridine. These hemochromes (earlier called hemochromogens) *(5a)*, carbonylhemes *(5g)*, and hemins *(5f)* have long been known[1], whereas the other species were first isolated and characterized spectroscopically in the last decade.

Owing to the strongly polar carboxyl groups and the labile vinyl groups, it is not practical to use protoheme *(3a)*, which can be obtained from the blood *via* hemin *(3b)*. It is better to convert it into the dimethyl ester [Fe(proto-DME)] *(3c)*



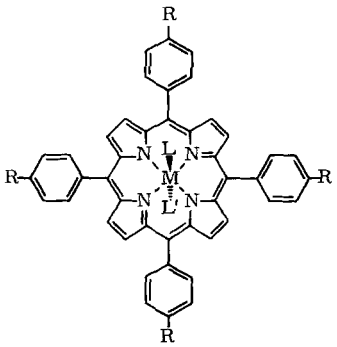


Fig. 5. Schematic representation of the essential chemistry of the heme Fe(P), especially iron(II) protoporphyrin Fe(proto) *(3a)* or the corresponding derivative of tetraphenylporphyrin Fe(TTP) *(6a)*, or octaethylporphyrin Fe(OEP) *(7a)*. The coordination types are designated as *(5a)*—*(5j)*.

or to hydrogenate it further to the mesoporphyrin derivative [Fe(meso-DME)] *(3d)*. The labile vinyl groups are often eliminated completely, and the dimethyl ester of deuteroporphyrin-IX *(3e)* is used for further work. To avoid these steps and the asymmetric arrangement of substituents which leads to complicated spectra, one can use either cheap tetraphenylporphyrin [H_2(TPP)], which can be prepared from pyrrole and benzaldehyde in a single step[3,4,37], or octaethylporphyrin [H_2(OEP)], which is expensive but is the most convenient to use. The incorporation of iron in reaction (a) or with the aid of iron(II) 2,4-pentanedionate[9,38] gives the heme Fe(TPP) *(6a)* or Fe(OEP) *(7a)* (see Tables 3 and 4). In solution, all hemes are very sensitive to air and are readily autoxidized to hemins *(5f)*, which are usually isolated after the insertion of iron. A very convenient way to incorporate the iron, described by *Hans Fischer*[1], is to use $FeCl_3$ in boiling glacial acetic acid and sodium acetate. The porphin is dissolved out of an extraction thimble in the course of about a day, and the chlorohemin Fe(P)Cl [*(5f)* with X = Cl] crystallizes on cooling.

(6l)	Ru	H	CO	Py

More care is needed for the introduction of iron into the much more labile H_2(proto), *i.e.* into the iron-free *(3a)*. For this, a solution of H_2(proto) in pyridine is combined with a solution of $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ in maximum-purity glacial acetic acid in the absence of air and the mixture is heated to 80°C for 1 h. The resulting Fe(proto) *(3a)* is oxidized by air in the cold and is converted into hemin *(3b)* by treatment with HCl[2,3,34b].

After treatment with reducing agents, such as sodium dithionite, hydrazine, chromium(II) 2,4-pentanedionate, $NaBH_4$, or palladium/calcium hydride, the required neutral ligands L, such as pyridine or 1-methylimidazole (1-MeIm), are added to the hemin solutions, the solvent is evaporated, and the solid hemochromes *(5a)* are isolated[1-4]. These hemochromes react with carbon monoxide and nitric oxide, giving the similarly crystallizable carbonylhemes *(5g)*[1-4,39] and

nitrosylhemes *(5h)*[40-43], respectively. In nitrosylhemes *(5h)*, only the ligand L *trans* to the nitrosyl group can be easily split off, giving *(5i)*. This has recently also been observed with $[Hb \cdot NO]_4$[40b,40c]. X-Ray crystallographic analysis has elucidated the structures of the carbonylheme Fe(TPP)CO(Py) *(6b)*[39g] and nitrosylhemes Fe(TPP)NO *(6c)* and Fe(TPP)NO(1-MeIm) *(6d)*[41]. Unlike $[Hb \cdot CO]_4$, the Fe—C—O group is linear and oriented normally to the porphin plane. According to *Scheidt*, the Fe—N—O unit is bent, the Fe—N—O angle being 149° in *(6c)*[41b] and 140° in *(6d)*[41c]. These angles agree with the assumption that nitric oxide is basically a neutral ligand here. The donor action of the imidazole system in the *trans* position in *(6d)* imparts a partial anionoid character to the NO, as can be seen from the widening of the angle on going from *(6c)* to *(6d)*. Since Fe(proto-DME)NO(1-MeIm) (dissolved in 1-methylimidazole, $\nu_{NO} = 1618\,cm^{-1}$) and $[Hb \cdot NO]_4$ ($\nu_{NO} = 1615\,cm^{-1}$) exhibit virtually the same NO frequency, it can be assumed that the FeNO unit has a bent configuration in $[Hb \cdot NO]_4$ as well[40b].

The complexes of the type *(5a)*, *(5g)*, and *(5i)*, which are fairly stable in the solid state in air, readily undergo autoxidation in solution, particularly in the absence of an excess of ligands. As expected, *(5a)* and *(5g)* are diamagnetic, while *(5i)* has an unpaired electron and takes on a further NO reversibly at −196°C to form the dinitrosyl complex *(5j)*[42].

Like the reversible reactions of $[Hb]_4$, the conversions of globin-free hemes start from a pentacoordinate species of type B, such as *(5b)*[43], these compounds being formed mainly by the dissociation of the hexacoordinate complexes *(5a)*. When a sterically hindered axial ligand like 2-methylimidazole (2-MeIm) is used, *(5b)* can also be prepared in the crystalline state. Thus, *Collman et al.* have isolated Fe(TPP)(2-MeIm) *(6e)*[44], and even managed to crystallize the bare heme

Fe(TPP) *(6a)* with the established square geometry A[45]. However, *Hans Fischer et al.*[1] and *Caughey*[46] had prepared such bare hemes before; for example, Fe(proto-DME) *(3c)* or Fe(OEP) *(7a)* are also formed when the hemochromes *(5a)* are heated in high vacuum[40b,46].

It has only recently been found that the reversible oxygenation is not restricted to $[Hb]_4$ and [Mb]. Thus, the existence of oxygen adducts *(5c)*, formed analogously to *(4b)* (see Figs. 3 and 4), has been demonstrated for a number of hemes, such as *(3c)*[47], *(3d)*[48], and *(6a)*[39c], with the aid of low-temperature absorption spectroscopy in solution at −50°C. When heated to room temperature, these adducts undergo autoxidation to the binuclear iron(III) complexes *(5e)* at a rate that depends on the solvent used[46a]. It is generally assumed that the autoxidation starts with an attack of a second heme *(5b)* on the dioxygen complex *(5c)*, as a result of which a μ-peroxo complex *(5d)* is formed. This might then change into *(5e)* by symmetrical cleavage to (P)Fe=O and by the further reaction of this iron(IV) species with excess iron(II) porphyrin *(5b)*. In this series of reactions *(5b)* → *(5c)* → *(5d)* → *(5e)*, the axial ligands L are lost. The NMR spectroscopic monitoring of the autoxidation of Fe(P) [P = *meso*-tetra(*o*-tolyl)porphyrin] into (P)Fe—O—Fe(P) in toluene at −30°C does indeed indicate an intermediate, which is probably the μ-peroxo complex *(5d)*[49].

The end products of the autoxidation, the μ-oxo-bis(iron(III)-porphyrins) *(5e)*, are identical with hematins, to which the formula Fe(P)OH [*(5f)*, with X = OH] was previously ascribed. The approximately linear Fe—O—Fe bridges present in them according to crystal structure analyses[12,50] cause an antiferromagnetic interaction between the two Fe^{III} ions, which leads to magnetic moments that are abnormally low at room temperature and disappear altogether at −250°C[50,51]. Unlike $[Hb \cdot OH]_4$ [cf. *(4e)*], mononuclear globin-free hydroxoiron(III)porphyrins *(5f)*, with X = OH, do not exist as isolable substances. Attempts to obtain them by the alkaline hydrolysis of a hemin Fe(P)X *(5f)* are invariably followed by condensation to *(5e)* according to reaction (h) (but see Section 8).

$$\underset{(5f)}{2\,Fe(P)X} \underset{2\,HX}{\overset{2\,OH}{\rightleftharpoons}} 2\,Fe(P)OH \underset{+\,H_2O}{\overset{-\,H_2O}{\rightleftharpoons}} \underset{(5e)}{(P)Fe{-}O{-}Fe(P)} \qquad (h)$$

The binuclear nature of hematins would have certainly been noticed before if the elementary analysis had been extended to oxygen[9,38].

The last remarkable phenomenon to be mentioned here is the reverse reaction of the hemin type *(5f)* with electrochemically produced hyperoxide ions to form the dioxygen adduct *(5c)* in reaction (i), observed by *Hill* in DMF at −50°C[52]. This reaction is the reversal of the formation of methemoglobin in reaction (f) and is a further indication of the hyperoxide character of the bound O_2 molecule.

$$Fe(proto\text{-}DME)OClO_3 + O_2^- + DMF \rightarrow Fe(proto\text{-}DME)DMF \cdot O_2 + ClO_4^- \qquad (i)$$

It appears from all this that the iron ion in hemoglobin has, pictorially expressed, two "garments": under the globin "cloak", it wears the red "gown" of porphyrin.

Each plays a part in affecting the reactivity of the iron ion. First of all, the inner envelope ensures that the formation of insoluble polynuclear hydroxo and μ-oxo-iron(III) complexes, which is dangerous in the biological medium (aqueous system, pH ≈ 7, air) is restricted to the formation of binuclear μ-oxo complexes *(5e)*, which readily decompose according to reaction (h). The contribution of the porphyrin ligand to this is an acceleration of the exchange of the axial ligands on the Fe^{III} ion. As a result, the solvent exchange in DMF is faster with the complex ion $[Fe(TPP)(DMF)_2]^+$, which probably exists in it, than with the cation $[Fe(DMF)_6]^{3+}$[53]. A labilization of the axial ligands is also assumed for the Fe^{II} porphyrin system, because Cr^{III}, Co^{III}, and Ru^{II} porphyrins also have rates of substitution that are not normally expected for inert complexes of these ions with d^3 or d^6 configuration[54,55]. This labilization, which was first noted by *Fleischer*[54] and is very important for the rapid establishment of the oxygenation equilibrium (c), is attributed to the additional π-acceptor function of the porphinate ligand, which is brought about by the delocalized π-electron system and which becomes effective when the central metal ions possess occupied d_{xz} or d_{yz} orbitals, from which some of the electron density can diffuse to the unoccupied e_g (π*) molecular orbitals of the porphyrin system[2-4]. This removes the degeneracy of the d_{xz}, d_{yz}, and d_{xy} orbitals that leads to the inert character of systems in the d^3 or d^6 configuration. This type of information comes mainly from studying porphyrin complexes with central metals other than iron (see Sections 6 and 7).

However, globin, which forms the second envelope of hemoglobin, constitutes an effective system only in the blood. Porphyrin has conferred the above-mentioned reaction advantages on the iron ion, but—owing to its own hydrophobic nature—has not made this ion water-soluble at all; this can only be done by combination with globin, which has a hydrophilic periphery, making dissolution in water possible. On the other hand, the hydrophobic inside space of globin shelters heme properly. The low dielectric constant of this inner medium makes it difficult for the dioxygen adduct to dissociate into a hyperoxide ion and methemoglobin in reaction (f). However, this shell has another, and quite fundamental, effect in that it inhibits the attack of a second heme on the already oxygenated heme and thus also the step *(5c)*→*(5d)* (Fig. 5), which starts the irreversible autoxidation of heme in a nonpolar medium. The longer life of oxyhemoglobin *(4b)* in comparison with dioxygenylheme *(5c)* is thus due to an inhibition of the subsequent reactions of oxygenation, which is confirmed by the investigations described in Section 5.

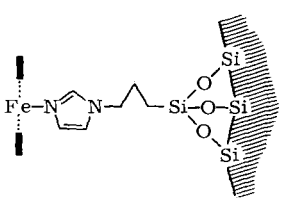
As mentioned before, globin is also responsible for the cooperative effects. Besides, it is worth mentioning that the oxidation potential of the iron(II) ion in [Mb] (0.05 V) is very close to zero, and thus the driving force behind the autoxidation to [Mb·OH] is relatively small[15,56]. Finally, globin provides as an axial ligand an imidazole group that can act simultaneously as a σ-donor, π-donor, and π-acceptor, and thus it facilitates the addition of dioxygen, and also carbon monoxide, in the *trans* position. Whereas the σ-donor/π-acceptor effect is well known[17,56b], the important π-donor effect has only emerged from recent analyses of the *cis*- and *trans* effects, which were carried out on metal porphyrins but which will not be discussed here[39c,57].

5. Imitation of Hemoglobin: Iron-containing Myoglobin Models

A complete simulation of all the functions of hemoglobin by a given metal complex calls for numerous characteristics, of which it suffices to mention the following:

1) The formation of an O_2 adduct *(5c)* from *(5b)* should be reversible.

2) The adduct *(5c)* should be stable in a liquid phase, *i.e.* in solution, at 37°C, so that it can be transported in a pipeline system of conduits.

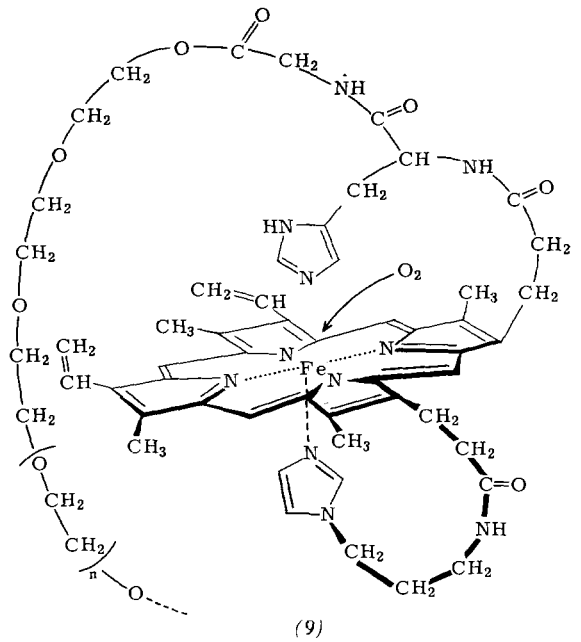


3) The adduct *(5c)* should be incorporated in a water-soluble protein, for only then can blood serve as a transport medium, and the adduct would not be excreted by the kidneys[14a]. (It is not taken into account here that $[Hb \cdot O_2]_4$ is in turn incorporated in the erythrocytes, which also impedes excretion.)

4) It should be possible to adjust the affinity of *(5b)* for oxygen to the prevailing physiological and biological conditions (different O_2 partial pressures), which means that it should be possible to control the system through allosterism.

The first requirement is fulfilled even by solid model substances, while the second calls for a soluble species. The third and fourth requirements are of a typically physiological nature. The designation "myoglobin models" is intended to indicate that one cannot expect a simulation of the cooperative effects.

5.1. The Concept of Immobilization



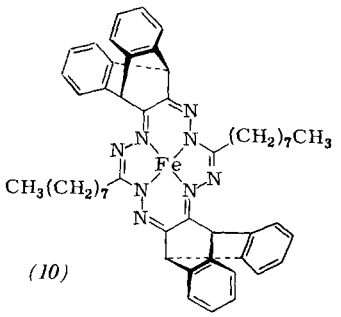
The first attempts to imitate hemoglobin by the use of iron porphyrins date back about 20 years. Thus, *Corwin* and *Bruck*[58a] studied the oxygen uptake of the solid imidazole-hemochrome Fe(meso)(HIm)$_2$ *(3f)* at room temperature. At 60—65°C the adduct suffered a loss of weight in vacuum, corresponding to the binding of 1 mol of O_2 per mol of hemochrome. This indicated a reversibility of the O_2 addition. Using carbon monoxide, 1-phenethylimidazole, the diethyl ester of Fe(proto) *(3g)*, and polystyrene, *Wang*[58b] obtained a carbonylheme of type *(5g)* embedded in polystyrene. Elimination of the CO with an inert gas left behind a heme assumed to be of type *(5b)*, which was capable of taking up O_2 reversibly, as was indicated by the visible spectrum typical of *(5c)* and *(5b)* in the presence and the absence of O_2, respectively. Both these studies were based on the concept of "immobilization" of the heme. When in the solid state or bound to a matrix, the heme molecules are not sufficiently mobile to form the μ-peroxo complex *(5d)*.

(8)

Returning to the concept of immobilizing heme, *Basolo et al.*[59] have recently obtained a heme with the partial formula *(8)*, fixed in a silica gel matrix. For this purpose, 3-chloropropyl groups were first introduced on the silica gel surface with 3-chloropropyltrimethoxysilane, and the chlorine in these 3-chloropropyl groups was then replaced by the imidazole group. This was followed by the addition of Fe(TPP) *(6a)* as the heme component, and the resulting heme, fixed on the silica gel, was finally brought into the active form of type *(5b)* denoted by *(8)* by drying at 250°C in high vacuum. System *(8)* is capable of chemisorption of molecular oxygen that is weak at room temperature, strong at −78°C, and irreversible at −127°C. No autoxidation to the μ-oxo complex of type *(5e)* was observed. Carbon monoxide is also taken up at room temperature and is only given off again at 160°C in a current of helium.

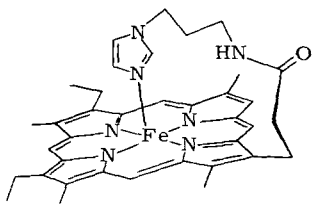
It has also been possible to immobilize heme in solution by fixing Fe(TPP) *(6a)* as the heme component on partially quaternized poly(4-vinylpyridine)[60a]. The heme-polymer adduct thus obtained was stable to oxidation in a mixture of DMF and water, but it absorbed oxygen, which could be displaced from it by CO as in the case of *(4b)* and *(5c)*. However, no reversible binding of O_2 was observed, and the identification of the presumed adduct of type *(5c)* is incomplete.

(9)



Much more sensational is *Bayer* and *Holzbach*'s publication about synthetic heme polymers, describing *e.g.* the preparation of the macromolecule *(9)*[60b]. In *(9)*, the heme carries not carboxyl groups as in *(3a)* but amide functions, coming from 3-(1-imidazolyl)propylamine and terminal histidine groups, two of which complete a chain of polyethylene glycol bis(glycine ester) with an amide-type bond. Besides the immobilization of heme in the polymer coil, other concepts were also involved here, which have already been worked out on low-molecular myoglobin models, such as the fixing of an imidazole residue on the heme to simulate the proximal histidine [cf. *(11)*]; the distal histidine has also been simulated (see Section 5.2).

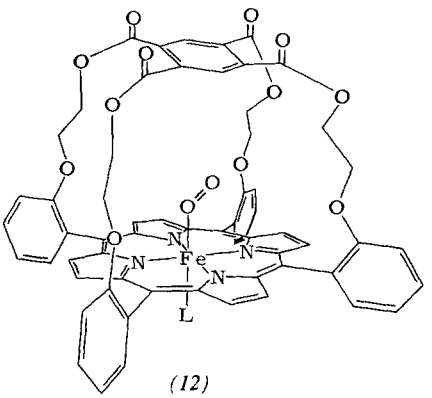
In fact, the macromolecule *(9)* resembles $[Hb]_4$ in many respects: It can go through a number of oxygenation cycles in aqueous solution and gives an S-shaped oxygen sorption isotherm. In view of the binuclear nature of this heme complex, this second effect, which points to a cooperative character,



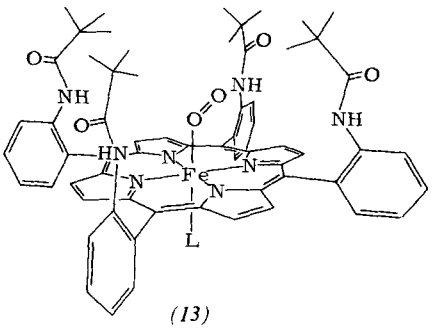
is not entirely unreasonable [formula *(9)* shows only one heme terminus of the polymer chain completed by two heme units], but the visible spectra of *(9)* in various ligand states indicate that the species are not uniform, and further experimental details need to be reported.

5.2. Monomolecular Myoglobin Models

The model substances described in Section 5.1 have the short-coming that the heme envelope in them is by no means "tailor-made". Therefore, we cannot expect the heme package to have a long life in these systems. Another idea is to link heme firmly to its envelope by introducing steric hindrance on heme itself with the aid of bulky substituents strongly bonded through C—C bonds. In 1973—75 numerous authors competed to be the first to prepare such monomolecular soluble myoglobin models.



(10)



(11)

Baldwin and *Huff*[61] described in 1973 the first synthetic iron(II) complex *(10)*, which is a rigid macrocyclic chelate similar to heme but can be oxygenated reversibly only at low temperatures. *Chang* and *Traylor*[62] were the first to show with the peripherally modified heme *(11)* that globin-free hemes can also be reversibly oxygenated at low temperatures. The coordination type B is stabilized in *(11)* on account of the chelate effect, because the imidazole ligand is firmly connected with one of the porphyrin side chains. However, the stabilization of type B, *i.e.* of the complex *(5b)* analogous to deoxyhemoglobin *(4a)*, is not necessary for reversible oxygenation, since the usual hemes *(3c)*, *(3d)*, and *(6a)* also give the reaction *(5b)* ⇄ *(5c)* at −50 °C[39c, 47, 48] (see Section 4). Nevertheless, heme *(11)* and related systems are still useful for studying the reaction mechanism and the bonding of small molecules in detail[63], though this will not be discussed here.

The first systems that can be reversibly oxygenated at room temperature were prepared by *Baldwin*[64], *Collman*[65–67] and their associates; these are *Baldwin*'s "capped heme" *(12)* (crown heme[6]) and *Collman*'s "picket fence heme" *(13)*. Both of these have been given the formula *(5c)*, which is analogous to *(4b)*. The globin pocket is in these compounds to some extent fused with the porphyrin system. One of the sides of the porphyrin disk is covered by bulky substituents in such a way that no irreversible autoxidation can take place as long as the other side is occupied by axial ligands, such as 1-methylimidazole, that favor reversible oxygenation. It has thus been possible to carry out "several" cycles of reversible oxygenation at 25 °C with *(12)* and *(13)* [at least three with *(12)*] without any notable irreversible oxidation taking place. After the addition, the oxygen was cleaved off from *(12)* by freezing and the application of vacuum, and from *(13)* by flushing with nitrogen. The dioxygenyl complexes *(12)* and *(13)* have even been isolated as pure solid substances.

(12)

(13)

For *(13)*, crystal structure analysis has indicated structure E, *i.e.* a monodentate, bent dioxygen chain bound to the iron atom[66], although it should be mentioned that this analysis did not have the accuracy attainable nowadays, owing to the mediocre quality of the crystals and the disordered arrangement of the bound oxygen molecule. After initial difficulties, the typical IR bands of the FeO_2 system have been detected (at 1159 cm^{-1}), and the magnetic data and the Mössbauer spectra of *(13)* agree with those of $[Hb \cdot O_2]_4$, so that the Pauling structure E is also valid for $[Hb \cdot O_2]_4$[66, 67].

The sterically hindered porphyrin ligands in *(12)* and *(13)* were prepared by conventional methods of organic chemistry[37]. The key compound forming *(12)* was the pyromellitate tetrakis[2-(2-formylphenoxy)ethyl]-1,2,4,5-benzene tetracarboxylate, which condensed with pyrrole to give the *meso*-substituted porphyrin that gave the heme component in *(12)* after the incorporation of iron[64]. The decisive step in the synthesis of *(13)* was the chromatographic separation of the atropo-isomers of α,β,γ,δ-tetrakis(2-aminophenyl)porphyrin. The isomer that had all the amino groups on the same side of the porphyrin disk was acylated with pivaloyl chloride and converted into the heme component *(13)* by the incorporation of iron[65, 66].

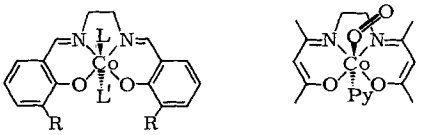
However, *(12)* and *(13)* have a limited lifetime in solution, because the detachment of the imidazole ligand can start an autoxidation and μ-oxo complex formation at the lower, unprotected side of heme. In hemoglobins, however, the axial ligand *trans* to the O_2 molecule, the proximal histidine, is also supplied by the enveloping globin [*(4b)*, *(4c)*]. The

number of cycles can be raised to 200 by making use of immobilization, *i.e.* by the reversible formation of *(13)* in the solid state. The thermodynamic data for this reaction show a remarkable agreement with those of myoglobin[67b].

The use of a rather aprotic medium is important for a long life of the dioxygen complex, as can be seen from the fact that, when the pivaloyl amide groups in *(13)* are replaced by the more strongly acidic *p*-toluenesulfonamide groups, the corresponding O_2 adduct cannot be detected[66]. The presence of unsubstituted imidazole in the solution has the same effect[48, 64].

The synthesis of the sterically hindered hemes *(12)* and *(13)* has stimulated many other laboratories engaged in porphyrin synthesis to prepare further porphyrins with bulky side chains or side chains bonded like cyclophane[68], but these variants have not yet supplied coordination chemists with any fundamentally new results.

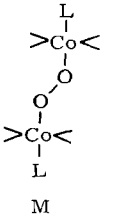
None of the models discussed here fulfils all the requirements for a perfect imitation of hemoglobin. They possess only the first two necessary characteristics, *i.e.* reversible adduct formation and transportability. In contrast, the well characterized model substances *(12)* and *(13)* are not soluble in water and have a low molecular weight, so that they would be removed from the blood by renal ultrafiltration and are therefore unsuitable as blood substitutes, not to mention the allosteric effects, which must be absent in the case of a monomolecular model. Nevertheless, the synthesis and structure analysis of such model substances are highly instructive and fruitful for hemoglobin research and for preparative coordination chemistry.



6. Variation II: Coboglobin and Other Metalloglobins

In the description of work aimed at imitating the biological function of hemoglobin in the previous section we deliberately ignored the publications dealing with the reversible oxygenation of metal complexes containing neither iron nor porphyrin ligands. The aim was to adhere closely to the original example, although basically any reversibly oxygenable metal complex is an imitation of hemoglobin at the simplest level. The whole field of reversible oxygenation of metal complexes is very large and is covered comprehensively in many reviews, some of them giving even the more recent results[56, 69–71], so that we shall deal here only with data of direct relevance to our topic.

We shall examine in this section the possibility of varying the central metal in hemoglobin, *i.e.* examine which other metals can be incorporated in hemoglobin instead of iron without suppressing its main biological function, *viz.* the transport of oxygen. According to *Vaska*, only certain complexes of manganese, copper and all Group 8 metals react with molecular oxygen[71]. Besides iron, only cobalt (which lies next to iron and has one more d electron) forms complexes that bind O_2 in a demonstrably monodentate manner. In the case of manganese this arrangement is not yet certain. All the others hold the O_2 in a bidentate manner as in G and can, in a simplified way, be regarded as peroxo complexes. There is no question here of an imitation of $[Hb \cdot O_2]$, because of their structural and electronic difference from it, even if they can take up oxygen in a reversible manner.



6.1. Development of Coboglobin

A cobalt(II) chelate—salcomin *(14a)*, first prepared by *Pfeiffer* in 1933[72]—was incidentally the first reversibly oxygenable metal complex known[73]. However, a complex does not have to be a planar chelate to be capable of reversible oxygenation, as has since been proved by many investigations[70]. Most adducts are diamagnetic μ-peroxodicobalt(III) complexes of type M, which are much more stable than the corresponding iron complexes *(5d)*. *Calderazzo*[74] first described the preparation of a mononuclear 1:1 chelate complex *(14b)* in 1969. *Basolo* and *Hoffman*[69] studied at the same time the formation of the analogous complex *(15)* at 0°C in DMF. The ESR spectra of *(15)* and of numerous similar

	R	L	L'
(14a)	H	–	–
(14b)	OMe	O_2	Py

(15)

M

compounds have been ascribed to the Co^{III} hyperoxide species having structure E. This has been proved correct by the determination of the crystal structure of *(15)*[75] and of a large number of corresponding adducts[69–71].

It was now an obvious step to the porphyrin system, and *Walker*[76] and the teams of *James* and *Ibers*[77] discovered almost simultaneously, by electronic absorption spectroscopy and ESR spectroscopy, the reaction (j) with various cobalt(II) porphyrins Co(P)L such as *(3h)* and *(6f)*, proceeding to a small extent at room temperature and readily at temperatures below −20°C.

$$Co(P)L + O_2 \rightleftarrows Co(P)L(O_2) \qquad (j)$$

In the presence of an excess of base, there is autoxidation to the cobalt(III) species in this case as well. These experiments established the analogy with iron-porphyrin chemistry (see Sections 2, 4, and 5), and the results obtained with the two systems mutually confirmed each other.

This analogy between iron and cobalt received its ultimate demonstration in the work of *Hoffman et al.*, who "reconstituted" coboglobins from Co(proto) *(3j)* and globins by methods described in connection with the heme Fe(proto) *(3a)* (see Section 3). These cobalt analogs of myoglobin [CoMb] or hemoglobin $[CoHb]_4$ show an amazing similarity to [Mb] or $[Hb]_4$. Thus, both these analogs take up oxygen reversibly at room temperature! However, the formation constant of the "original", $[Mb \cdot O_2]$, is almost a hundred times higher than that of $[CoMb \cdot O_2]$. Furthermore, $[CoHb]_4$ too exhibits allosteric effects such as the Bohr effect (see Section 2) and the cooperative behavior in the O_2 uptake, although to a smaller extent[78]. The cobalt analog of *(13)* has also been found in the meantime; the equilibrium mixture contains about 25% of this adduct besides the starting material (type B) in toluene at room temperature[79].

Although coboglobin has a much lower affinity to oxygen, it surpasses its "original" in one respect of ecological interest: it does not take up carbon monoxide. Therefore, living organisms that have coboglobin instead of hemoglobin should be capable of existing in an atmosphere containing more CO, since the latter would be only physically dissolved in their blood. Besides, Co^{II} porphyrins also give only a limited reaction with CO. *Wayland et al.* have shown that Co(TPP) *(6g)* takes up CO in reaction (k) only at very low temperatures and only in the absence of a nitrogen or phosphorus donor[80]. Since coboglobin contains a nitrogen donor in the form of the proximal histidine, it is inert to carbon monoxide.

$$Co(TPP) + CO \rightleftharpoons Co(TPP)CO \qquad (k)$$

In contrast, Co(TPP) and coboglobin add on nitric oxide to the same extent[78,80]. The additional electron in the d_{z^2} orbital of the Co^{II} ion evidently repels CO, but pairs off with an unpaired electron of the radical-molecule O_2 or NO; Co(TPP)NO is diamagnetic, contains a bent Co—N—O unit, and is isoelectronic with the corresponding FeO_2 system[81].

6.2. Other Metalloglobins

As mentioned at the beginning of this section, according to *Vaska* not only Co^{II} but also Mn^{II} might function as a central metal ion in place of the Fe^{II} ion in hemoglobin. In fact, the reversible oxygenation of Mn(TPP)Py *(6h)* in reaction (l) has recently been detected at low temperatures[82]. On the other hand, Cr(TPP)Py *(6j)* adds on oxygen irreversibly, presumably with the formation of a hyperoxide complex[83].

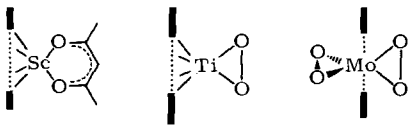
$$Mn(TPP)Py + O_2 \rightleftarrows Mn(TPP)O_2 + Py \qquad (l)$$

Since the relatively large high-spin Mn^{II} ion in Mn(TPP) is not coplanar with the porphyrin system[82c] and reaction (l) follows the stoichiometry given, it is concluded that pyridine is replaced by O_2 in a frontal attack. Accordingly, the "manganoglobins" $[MnHb]_4$ and [Mn·Mb] prepared by several teams cannot add on oxygen, since in the reconstituted system the O_2 would have to displace the relatively immobile proximal histidine[84–86]. However, manganoglobins are still interesting: $[MnHb]_4$ exhibits a Bohr effect and, when binding NO, the allosteric cooperative effects known for $[Hb]_4$[86]. Unlike O_2 and CO, the NO[87,88] can therefore be bound, because only the particularly strong π acceptor NO can effect a transition of the Mn^{II} ion into the low-spin state during the addition. In this state the Mn^{II} ion is smaller and capable of assuming the octahedral configuration C, as for example in Mn(TPP)NO(L) (L = 4-methylpiperidine)[87], which must also be present in $[MnHb \cdot NO]_4$. The constitution of $Mn(TPP)O_2$ formed in reaction (l) is still unclear. *Basolo* suspects a peroxo complex of Mn^{IV} (structure G)[82b], while *Lever*[89] assumes the formula of a hyperoxomanganese(III) complex (structure E) for his O_2 adduct obtained from manganese(II)-phthalocyanine Mn(Pc).

The metalloglobins obtained by "reconstitution" from Cu(proto) or Zn(proto)[84,90] are unsuitable as O_2 carriers, since Cu^{II} and Zn^{II} normally cannot donate any more electrons. In addition, Cu^{II} porphyrin has a fully occupied d_{z^2} orbital, which allows only a weak interaction with axial ligands (see Section 1). This also rules out nickel porphyrins for reconstitution. On the other hand, pentacoordinate Zn^{II} porphyrins are known[12]. In fact, the optically excited triplet state has been detected in $[ZnHb]_4$ and [ZnMb] by ESR spectroscopy, and differences have been noted between the porphyrin-globin interaction here and that in hemoglobin and myoglobin[90].

Even a lanthanoid porphyrin, Yb(meso-DME)(acac), with the composition *(3j)*, has recently been reconstituted with apomyoglobin. Being a shift reagent, the paramagnetic ytterbium ion should facilitate the analysis of the NMR spectra of globin[91]. However, since *(3j)* very probably has a different structure from that shown in *(3)* (see Section 7.1), the results cannot be simply applied to myoglobin itself.

7. Variation III: Exotic Metal Porphyrins



The idea of varying the central metal in hemoglobin can be taken further, but we shall mention here only two types of metal porphyrins, namely the complexes of some d-electron-deficient ("early") transition metals, and the ruthenium and osmium derivatives, with the heavier central atoms from the same group in the periodic table as iron, examples being the carbonylmetal porphyrins *(7c)* and *(7d)*, which are analogous to carbonylheme *(7b)* but much more stable. From a chemical point of view, these are "exotic" metal porphyrins, which cannot be prepared by the usual methods such as reactions (b), and have been reported only recently[3–9]. Though equally interesting, the porphyrin derivatives of technetium and rhenium[7], and of rhodium[92], are less relevant here, because the first two contain two metal ions per porphyrin ligand (like the alkali metal porphyrins[2–6]) and therefore do not belong to any of the coordination types presently under discussion, while the rhodium derivatives are more suitable as models for vitamin B_{12} than for hemoglobin. This incidentally also applies to cobalt porphyrins, which form a great variety of alkyl-metal and aryl-metal derivatives.

The early transition metals give unusual coordination geometries in their oxidation states being sometimes normal, while osmium porphyrins display a larger variety of oxidation states and axial ligands than their iron or ruthenium analogs.

7.1. Unusual Coordination Geometries

Figure 2 shows the coordination types A—C, which are "normal" for the porphyrin system. In principle, besides the *trans* arrangement, a *cis* configuration D is also possible in the presence of two axial ligands L. According to *Schneehage*, the scandium porphyrins[38] can be obtained from tris(2,4-pentanedionato)scandium $Sc(acac)_3$ and the corresponding porphyrin in molten imidazole by reaction (m), an example being Sc(OEP)(acac)[9,93]. On the basis of the IR and NMR spectra, the *cis* configuration N has been chosen for these scandium complexes.

$$Sc(acac)_3 + H_2(OEP) \rightarrow Sc(OEP)(acac) + 2\,H(acac) \qquad (m)$$

N P Q

Initial IR-spectroscopic work[9, 93, 94], followed by X-ray structure analysis (Fig. 6)[95], has demonstrated on bis(acetato)-zirconium(IV)porphyrin and bis(acetato)hafnium(IV)porphyrin of formula M(OEP)(OAc)$_2$ (M = Zr, Hf) that porphyrin complexes with a metal ion can also have a coordination number higher than 6 (in this case 8). This high coordination number had already been established by *Lux* and *Hoppe*[96] for sandwich-type phthalocyanine derivatives such as U(Pc)$_2$, and it is also typical of hafnium and thorium porphyrins such as Hf(OEP)(acac)$_2$[97] and Th(TPP)(acac)$_2$[98]. Prompted by this work, other authors demonstrated the coordination number 7, again with *cis*-axial ligands, in the case of two niobium(V) porphyrins, namely the complexes Nb(TPP)O(OAc)[99] and $Nb_2O_3(TPP)_2$[94, 99, 100]. It seems that this unusual geometry can exist only in the presence of a transition metal ion of the acceptor class A ("hard acid", early transition metal) and a bidentate chelate ligand L⌒L, for which acetate and 1,3-diphenyl-1,3-propanedionate have been used besides 2,4-pentanedionate.

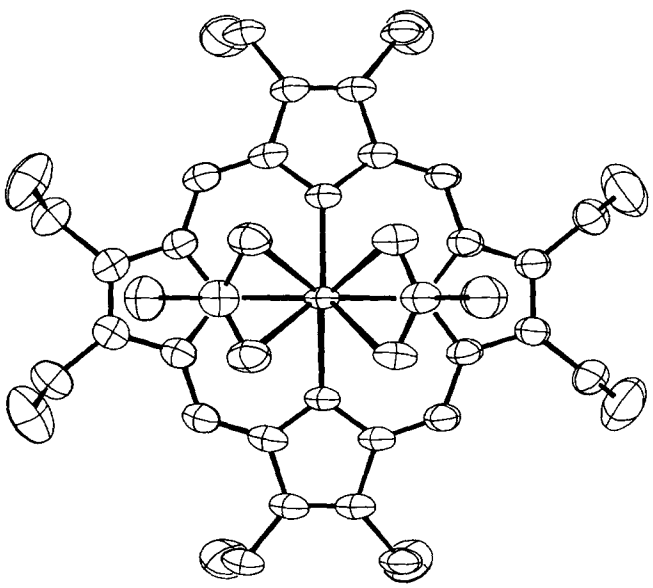


Fig. 6. Results of crystal structure analysis of an octacoordinate hafnium(IV) porphyrin Hf(OEP)(OAc)$_2$ [95]. Two of the pyrrole nitrogens are hidden under the two carboxyl carbons of the acetate groups; the four nitrogens of the porphyrin ligands and the four oxygens of the acetate ions form a distorted square antiprism. The Hf^{IV} ion lies 100 pm above the porphyrin plane.

If the "bite" is reduced, *i.e.* if the distance between the L atoms in the chelate Ligand L⌒L is decreased, then not only relatively large ions like Sc^{III}, Zr^{IV}, and Nb^{V} but also smaller ones like Ti^{IV} and Mo^{VI} can enlarge their coordination sphere in the porphyrin system. According to *Fournari*[101] and *Weiss*[102], peroxide groups with a bidentate linkage can smoothly replace double-bonded oxygen in these complexes—as also in many oxo complexes—by the action of hydrogen peroxide, *e.g.* in reaction (n).

$$\underset{(7e)}{TiO(OEP)} + H_2O_2 \rightarrow \underset{P}{TiO_2(OEP)} + H_2O \qquad (n)$$

X-Ray crystallographic investigations have shown that the peroxotitanium(IV) porphyrin TiO_2(OEP) has configuration P[101], which corresponds to D or N. Particularly remarkable is the bis(peroxo)molybdenum(VI) compound Mo(O$_2$)$_2$(TPP) with configuration Q, which has also been proved by X-ray crystallography.

The complex is obtained from oxomolybdenum(V) porphyrins[9, 93, 103, 104] described before, by oxidation and ligand exchange as in reaction (n)[102]. This complex is the *trans* analog of octacoordinate zirconium porphyrins (Fig. 6). The two peroxide ligands are staggered (S_4 symmetry) when the molecule is viewed normally to the porphyrin surface and are ecliptic to the N atoms of the porphyrin system.

P and Q are the first examples of porphyrin complexes that exhibit structural elements of the Griffith configuration G of the dioxygenyliron system. The complexes can be formally regarded as mono- or bis(dioxygen) adducts of Ti(OEP) or Mo(TTP), but these derivatives of Ti^{II} and Mo^{II} are as yet unknown, and O_2 cannot be detached from P and Q. It is strange though that P and Q have come to light just now as more and more arguments are being found against the presence of G in [Hb·O$_2$].

According to the IR spectra, the lanthanoid porphyrins such as Yb(meso-DME)(acac) mentioned in Section 6.2 also possess bidentate pentanedionate ligands and therefore exist in a *cis* configuration D, like the scandium porphyrins whose discovery prompted the synthesis of the lanthanoid derivatives[91]. This is understandable in view of their large ionic radii; even heptacoordinated species like Yb(meso-DME)(acac)H$_2$O must be considered. However, a *cis* configuration of the axial ligands lead to the formation of a metalloglobin with a rather unnatural conformation in reconstitution experiments with apoglobins, even if the proximal histidine adds on to the lanthanoid ion at all.

7.2. An Increased Variety of Axial Ligands in the Case of Osmium Porphyrins

Up to 1971 all the known methods of metal insertion failed to introduce osmium into the porphyrin system. Finally *Rohbock* succeeded in synthesizing the carbonylosmium(II) porphyrin Os(OEP)CO(Py) *(7d)*[105] by the dropwise addition

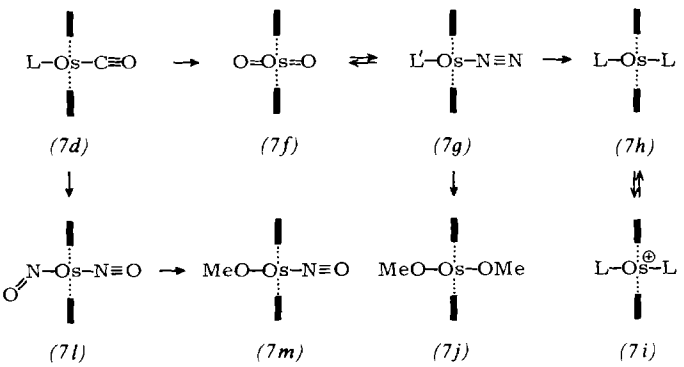

Fig. 7. Schematic representation of the essential chemistry of osmium porphyrins [Os(OEP) *(7)*; for *(7d)*, *(7f)*—*(7j)* also with Os(TTP) *(6j)*].

of a cold solution of osmium tetroxide in diethylene glycol monomethyl ether to a solution of octaethylporphyrin in the same solvent, kept at about 200 °C. The CO ligand was formed by oxidation and decarbonylation of the primary hydroxy groups of the solvent; pyridine was added at the crystallization stage. Figure 7 shows the essential chemistry of osmium porphyrins, based on *(7d)*. The fundamental differences from the chemistry of iron porphyrins (Fig. 5) are as follows:

1) Osmium can have more oxidation states (+2, +3, +4, and +6) than iron (+2 and +3) in compounds stable in air.

$$\underset{(7d)}{Os(OEP)CO\cdot Py} \xrightarrow[CH_2Cl_2/MeOH]{CH_3CO_3H/H_2O} \underset{(7f)}{OsO_2(OEP)} \qquad (o)$$

trans-Dioxoosmium(VI) porphyrin *(7f)*[106], which can be prepared from *(7d)* with peracetic acid in dichloromethane/methanol/H_2O as shown in reaction (o), was the first example of the highest oxidation state of a metal that can be achieved in a porphyrin; *(7f)* is an important starting material for further reactions (Fig. 7).

2) The adducts of Os^{II} porphyrins formed with small π-acceptor molecules are much more stable than those of the Fe^{II} analogs. This can be explained by the stronger π-donor character of the Os^{II} ion and the consequently reinforced metal-ligand back-donation, because its occupied 5d orbitals extend further out and penetrate through the π^* molecular orbitals of the ligands better than do those of the Fe^{II} ion. As a result, the carbonylosmiumporphyrin *(7d)*, for example, is so stable that it can be vaporized at about 200 °C in the high vacuum of a mass spectrometer, and the molecular ion can be detected[105]. The replacement of Fe^{II} by Os^{II} in hemoglobin is therefore pointless, because the "osmoglobin" would absorb even traces of carbon monoxide, and would gradually become irreversibly poisoned.

3. Owing to the stronger "penetration" of the d orbitals into the π^* level of the porphyrin ligand on the one hand and of the axial ligands on the other, the spectroscopic effects (*cis* and *trans* effects[39b, 57]) accompanying the changes in the axial ligands are much more pronounced with Os^{II} porphyrins than with Fe^{II} porphyrins, where they are just outside the accuracy of the measurements. In this connection, Os^{II} porphyrins permit a much more accurate study of the electronic interactions[107], the results of which can be applied to Fe^{II} porphyrins.

The strong d_π donor action of the Os^{II} ion *e.g.* in Os(OEP)CO(THF)[105] is also manifested in the very low frequency of the CO stretching vibrations, namely $\nu_{CO} \approx 1900\,cm^{-1}$. According to *Chatt*'s rule, in the case of such low values one can expect the existence of dinitrogen derivatives that are isosteric with the CO complexes and in which the N_2 molecule is accordingly bonded end-on[108]. *Smith* indeed obtained the first isolable dinitrogen complex of a metal porphyrin by reducing the dioxoosmium(VI) complex *(7f)* with hydrazine hydrate in THF as shown in reaction (p). The resulting Os(OEP)N_2(THF) *(7g)* can be kept in the solid state in air for a few days, but undergoes rapid autoxidation in solution, re-forming the Os^{VI} porphyrin *(7f)*; in methanol,

$$\underset{(7f)}{Os(OEP)O_2} + N_2H_4 + THF \rightarrow \underset{(7g)}{Os(OEP)N_2(THF)} + 2H_2O \qquad (p)$$

the autoxidation stops at the tetravalent osmium stage, with the formation of the bismethoxide $Os(OEP)(OMe)_2$ *(7j)*[109]. This again shows the labilizing effect of the porphyrin system on the axial ligands, discussed in Section 5. The dinitrogenpentaamminoosmium(II) cation $[Os(NH_3)_5N_2]^{2+}$, which has been known for a long time, is much more stable not only in the salt-like solid state but also in solution[110]. Accordingly, the displacement of the coordinated N_2 molecule, so far the only reaction of *(7g)*, could be used for preparative purposes as shown in reaction (q)[109, 111].

$$\underset{(7g)}{Os(OEP)N_2(THF)} + 2L \rightarrow Os(OEP)L_2 + N_2 + THF \qquad (q)$$

L = 1-MeIm, Py, MeCN, PR_3

This gave "osmochromes" such as $Os(OEP)Py_2$ *(7h)*, which are analogous with the hemochromes *(5a)* and are otherwise difficult to obtain. Like the hemochromes, these can be oxidized electrochemically into cationic complexes—"osmichrome salts", such as $[Os(OEP)Py_2]PF_6$ *(7i)*[111]. In comparison with the hemochrome/hemichrome system, however, the osmochrome/osmichrome system is much more resistant to substitution of the axial ligands and can therefore be characterized better. As in the case of iron porphyrins, this gives an opportunity to increase our knowledge of the mode of action of cytochromes[57].

Two further dinitrogen complexes, Os(OEP)N_2(DMF) *(7k)*[111] and Os(TTP)N_2(THF) *(6k)*[112], have recently been isolated. The order of the frequencies of the NN stretching vibrations [$\nu_{NN} = 2035\,cm^{-1}$ *(7k)* < $2042\,cm^{-1}$ *(7g)* < $2050\,cm^{-1}$ *(6k)*] shows that, as a donor ligand in the *trans* position, dimethylformamide increases the Os—N back-donation, probably because of its π-donor action, which is more pronounced than that of THF[57, 77] (*trans* effect), while the tetra(*p*-tolyl)porphyrin ligand in *(6k)* decreases the Os—N back-donation (*cis* effect) owing to its π-acceptor capacity, which is greater than that of the octaethylporphyrin system.

A strong *trans* effect has also been found in the case of the nitrosyl complexes *(7l)* and *(7m)*[107]. While the dinitrosyl complex $Os(OEP)(NO)_2$ *(7l)*, which can be prepared from the carbonyl derivative *(7d)* in an aprotic medium, decomposes with evolution of NO when heated to above 100 °C, the nitrosylmethoxo derivative Os(OEP)NO(OMe) *(7m)*, which is obtained by reacting *(7l)* with methanol, can be vaporized without decomposition in the high vacuum of a mass spectrometer, giving a molecule-ion. The dinitrosyl complex *(7l)* can be chromatographed and crystallized at room temperature, unlike its iron analog *(5j)* (Fig. 5), which has been detected only at −196 °C; this shows again how much the replacement of Fe^{II} by Os^{II} stabilizes adducts formed between small molecules and the metal porphyrin system. The diamagnetism and the IR spectrum of *(7l)* point to a rare *trans* arrangement of both NO species, caused by the porphyrin system.

Another *cis* effect exerted on the visible spectrum embodies the "rule of bathochromism" (see below), which serves to identify the adducts of small molecules to metal porphyrins and can be worked out particularly well in the case of the osmium porphyrins, because of the particularly pronounced effects in their case[57]. On going from hemochromes to car-

bonylhemochromes [sequence *(5a)* → *(5b)* → *(5g)*, Fig. 5], there is a 10—14 nm bathochromic shift in the absorption maximum with the longest wavelength ("α band", Fig. 3). In contrast, the corresponding shift is by 30—33 nm in the carbonylosmium porphyrins *(7d)* and osmochromes *(7h)*[57]. The greater is the π-acceptor capacity of the axial ligand, the greater is this shift. Accordingly, there is a bathochromic shift of the α-band in the series Os(OEP)Py_2 *(7h)*, 510 nm < Os(OEP)N_2(THF) *(7g)*, 523 nm < Os(OEP)CO(Py) *(7d)*, 540 nm < Os(OEP)NO(OMe) *(7m)*, 567 nm, corresponding to the series Py < N_2 < CO < NO^+ along which the π-acceptor strength increases[107]. If this rule is applied to the α bands of hemoglobins [Hb] (555 nm), [Hb·CO] (569 nm), [Hb·O_2] (577 nm, Fig. 3), and [Hb·NO] (575 nm), we find that the electron delocalization to the π-acceptor ligands is found to be about the same for NO and O_2 and in either case greater than with CO. This rule also holds for cobalt(II)-porphyrins[77]. *Gouterman* has provided the theoretical basis of this rule by molecular-orbital calculations by the iterative extended Hückel method[113].

The replacement of iron by osmium in hemoglobin to prepare an "osmoglobin" seems highly problematic and troublesome, because the very drastic reaction conditions used for the incorporation of osmium cannot be applied with the labile protoporphyrin system, and besides they lead to the extremely stable CO complex. However, in principle it is now possible to prepare an "osmoglobin". The possibility cannot be altogether excluded that it might function as an N_2 carrier.

7.3. Ruthenium Porphyrins and Their Comparison with Iron and Osmium Porphyrins

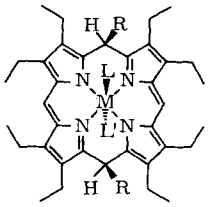
Ruthenium porphyrins were first synthesized by *Fleischer*[114] in 1969 and were then further investigated mainly by *Tsutsui*[7, 55a, 55b], *Holm*[55c], and *Whitten*[115, 116]. However, their axial-ligand chemistry is underdeveloped in comparison with iron and osmium porphyrins[6]. Only the carbonyl complexes *e.g.* Ru(TPP)CO(Py) *(6l)*[117], the ruthenochromes, *e.g.* Ru(OEP)Py_2 *(7n)*[113, 118], and the nitrosylmethoxide complex Ru(OEP)NO(OMe) *(7p)*, which also obey the "rule of bathochromism"[113], have been properly characterized. The bathochromic shifts of the α bands in the series Ru(OEP)Py_2 *(7n)*, 521 nm < Ru(OEP)CO(Py) *(7c)*, 549 nm < Ru(OEP)NO(OMe) *(7p)*, 572 nm lie between the corresponding values for the compounds of the Fe^{II} and Os^{II} series. The CO frequencies decrease from Fe(OEP)CO(Py) *(7b)*, 1967 cm^{-1} through Ru(OEP)CO(Py) *(7c)*, 1925 cm^{-1} to Os(OEP)CO(Py) *(7d)*, 1902 cm^{-1}. Both results show that the back-donation ability of the central metal ion and thus also the bond strength for small π-acceptor molecules increase along the series: Fe^{II} < Ru^{II} < Os^{II}.

As regards their redox behavior, however, ruthenium porphyrins occupy a surprising position: the half-wave potentials of the metal(II/III) state, determined by cyclic voltammetry with respect to a calomel electrode, rise in the series Os^{II} < Fe^{II} < Ru^{II}, *i.e.* Os(OEP)Py_2 *(7h)* −0.37 V[111], Fe(OEP)Py_2 *(7q)* −0.15 V[57, 119], Ru(OEP)Py_2 *(7n)* −0.02 V[57, 115, 119]. This effect, which is also exhibited by the carbonyl derivatives, agrees with theoretical results based on molecular-orbital calculations[113].

The relatively high Ru^{II}/Ru^{III} redox potentials mean that Ru^{II} porphyrins have a correspondingly weaker driving force for autoxidation, and they should therefore be interesting candidates for reversible oxygenation (see the closing remarks in Section 4). Indeed, recent results indicate that a labile bis(acetonitrile)ruthenochrome, Ru(OEP)$(MeCN)_2$ *(7r)*, is capable of undergoing reversible oxygenation even at room temperature[120]! However, the dioxygen adduct of *(7r)*, postulated only on the basis of spectrophotometric and presumably also gas-volumetric findings, does not obey the "rule of bathochromism": its α band shows an appreciable hypsochromic shift with respect to that of the carbonyl complex. This does not mean that this adduct does not exist, but it conflicts with a monodentate bent bonding state of its RuO_2 unit according to Pauling's model E. It is possible that we are faced here with a peroxoruthenium(IV) system of configuration G, which according to the results given in Section 7.1 for metal porphyrins can no longer be disregarded and which, according to *Vaska*[71] is to be expected anyway for ruthenium, together with the ability of liberating O_2 again at room temperature. The product of autoxidation of *(7r)*, which is slower than oxygenation, has not yet been identified. Owing to the more highly negative redox potential[57] the kinetically more stable Os^{II} analog Os(OEP)$(MeCN)_2$ *(7s)* merely undergoes irreversible autoxidation to OsO_2(OEP) *(7f)*[111].

The existence of nitrogen-carrying ruthenium porphyrins[116, 120], postulated on the basis of spectrophotometric findings only, should be viewed with skepticism since such compounds also do not obey the "rule of bathochromism" and purportedly exist as *trans* ligands in the presence of pyridine or other N-donors. (The latter also applies in the case of the previously discussed, but still unknown Fe(proto-DME)N_2(Py)[121].) Since even dinitrogenosmium(II) porphyrins are cleaved by any other N-donor[109, 112, 113], such behavior would be all the more likely in the case of the more labile Fe^{II} and Ru^{II} analogs which must therefore be regarded—on the basis of experimental evidence thus far—as doubtful species.

On the whole, what has been said about an osmoglobin (Section 7.2) applies also to ruthenoglobin.



8. Variation IV: Iron Porphodimethenes

The final variation to be presented is the porphodimethene system, a further, not only sterically but also electronically modified porphinoid ligand system akin to an α,γ-dihydroporphyrin. The synthesis of the configuratively important carbonyl(α,γ-dimethyloctaethylporphodimethenato)pyridineosmium(II) *(16a)*[122] might serve as example for the synthesis of such complexes (see Table 5) by *Puppe*'s reductive methylation of porphin complexes[123] according to reaction (r).

$$\underset{(7d)}{\text{Os(OEP)CO(Py)}} \xrightarrow[2.\ 2\,\text{MeI}]{1.\ 2e^{\ominus}} \underset{(16a)}{\text{Os(OEPMe}_2\text{)CO(Py)}} \qquad \text{(r)}$$

On the basis of crystal structure analysis by *Scheidt*, the molecule *(16a)* carries the two newly introduced methyl groups in a *syn*-axial position to the carbonyl group, like a chimney on the tetrapyrrole system, which is folded like a roof, with

the pyridine molecule suspended under the ridge of the roof (Fig. 8). Like the further structure analyses of nickel(II)- and titanylporphodimethenes[124], this picture immediately prompts one to try—as is being done now by *Lay*—to introduce bulky substituents somehow at the iron center in place of the methyl groups, in order to obtain myoglobin models of the type described in Section 6.

(16)

Table 5. Examples of porphodimethenes $M(OEPR_2)LL'$ *(16)*.

	M	R	L	L'
(16a)	Os	Me	CO	Py
(16b)	Fe	Me	Py	Py
(16c)	Fe	t-C_4H_9	OH	
(16d)	Fe	Me	O/2 [a]	

[a] μ-Oxo complex of type *(5e)*.

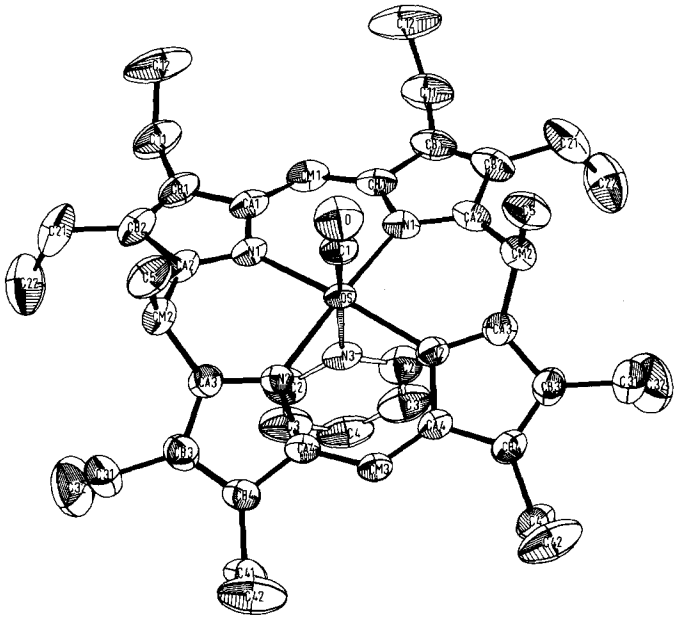


Fig. 8. Results of crystal structure analysis of a metal porphodimethene complex $Os(OEPMe_2)CO(Py)$ *(16a)* [d(Os—C) = 183, d(C—O) = 115, d(Os—N_{Py}) = 223, d(Os—$N_{(P)}$) = 207 pm].

However, it is very difficult to investigate the iron porphodimethenes, for two reasons:

1) Reductive ring alkylation does not work with Fe^{II} porphyrins, so that the iron porphodimethenes must be synthesized in a different, complicated way, which is of no interest to us here[125].

2) The double interruption of the porphyrin chromophore leads to much less informative visible spectra, which sometimes exhibit only a broad band at about 460 nm (this band is reponsible for the orange color of the porphodimethenes). For this reason, the complexing reactions corresponding to those shown in Figure 5 cannot be monitored spectrophotometrically as in the case of Figure 3.

3) The decreased aromaticity lowers the π-acceptor capacity of the porphinoid ligands and may thus make the oxygen uptake irreversible[126] by lowering the redox potential at the porphodimethene-hemochrome [*(16b)*, −0.30 V with respect to a calomel electrode[119]].

However, with the isolation of the di-*tert*-butylporphodimethene complex *(16c)*, the first mononuclear hydroxoiron(III) complex with a porphinoid ligand system has been prepared in substance. The constitution of this complex has been ascertained by chemical analysis, IR spectrum ($\nu_{OH} = 3661\ cm^{-1}$), magnetic measurements ($\mu_{eff} = 5.7$ B.M.), ESR spectrum ($g_\perp = 5.83$), and the Mössbauer spectrum[127]. In the porphodimethene complex *(16c)* condensation with the iron hydroxide group into a binuclear complex occurring in the step *(5f)* → *(5e)* (Fig. 5) is inhibited on both sides: at the top by the bulky *tert*-butyl groups, and at the bottom by the roof-like folding of the ligand surface, which does not even allow the formation of a greatly over-extended Fe—O—Fe bridge.

On the other hand, *(16d)*, a μ-oxo complex of α,γ-dimethylporphodimethene corresponding to type *(5e)*, is easy to prepare[125]. IR spectra and magnetic measurements[51b] indicate that axial methyl groups impair its Fe—O—Fe bridge, but this is not sufficient to prevent condensation.

Owing to its similarity to [Mb·OH] [cf. *(4e)*], the hydroxide *(16c)* can be regarded as a "partial metmyoglobin model", partial because there is no proximal histidine *trans* to the OH group. An accurate analysis of the physical properties of *(16c)* might be useful in the continuing investigation of the physics of metmyoglobin[19e].

This review was written while the author held a visiting professorship at Munich Technical University in the summers of 1976 and 1977. The manuscript was read critically by Professor Fuhrhop and Professor Gersonde. His own work, summarized in Section 7 and 8, was made possible by effective contributions from the colleagues mentioned in the text and the literature, by generous financial support from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie, and by the fact that Professor Inhoffen and Professor Pommer (BASF) generously supplied a large sample of the expensive octaethylporphyrin. The author wishes to express his gratitude here to all these research workers and institutions.

Chemical Ionization—A Mass-Spectrometric Analytical Procedure of Rapidly Increasing Importance

By Wilhelm J. Richter and Helmut Schwarz[*]

The mode of ionization of a molecule has a strong influence on its behavior in the mass spectrometer and thus on the information that can be obtained from its mass spectrum. In chemical ionization a reagent gas, *e.g.* methane, is first ionized by electron impact. The ions formed in ion-molecule reactions, in particular $[CH_5]^+$, $[C_2H_5]^+$, and $[C_3H_5]^+$, then react "chemically" with the substrate M in fast acid/base type reactions to form ions of the type $[MH]^+$, $[M(C_2H_5)]^+$, *etc.*, which subsequently fragment to various extents. Alternatively, chemical ionization can be effected by charge exchange, in that ions of a reagent gas, *e.g.* $[He]^{+\bullet}$, react with the substrate M to form molecular ions $[M]^{+\bullet}$. Chemical ionization can thus be conducted in a more or less mild fashion and the extent of the fragmentation can be controlled over a very wide range.

1. Introduction

Given the use of a suitable instrument, the versatility of mass spectrometry[**] permits the investigation of a wide variety of problems ranging from investigations of primarily scientific character to investigations of practical and highly topical significance. Studies of the kinetic, thermodynamic, and chemical behavior of ions in the gas phase, including studies of extremely fast to relatively slow reactions on the picosecond to millisecond time scale, exploration of surface properties of solids, structure elucidation of unknown substances, as well as detection and quantitative determination of known substances are but a few examples to which mass spectrometry can be successfully applied[1]. Mass spectrometry qualifies especially for analytical applications because of its very high sensitivity (present detection limits about 10^{-14} g) and because of the wealth of information afforded, quite unattainable by any other routine method of instrumental analysis for minute sample size. As judged by the number of published papers and instruments in use, analytic chemistry represents the principal field of application of the method. Mass spectrometry is almost indispensable for trace analysis, especially in the environmental, biological, and medical sciences. In depth, its potential and scope are demonstrated by geochemical, paleontological, archeological, and cosmochemical studies—*e.g.* in the Apollo and Viking projects.

In analytical applications the reliable determination of molecular weights (when using high-resolution instruments also the determination of molecular formulas), along with correlation of fragmentation with structural features are often the main objectives. In conventional ionization by electron impact, limitations or difficulties may arise because the sample has to be ionized in the gas phase, yielding molecular ions $[M]^+$ often insufficiently stable to permit detection. Further limitations may arise because insufficiently volatile or thermally labile compounds can pyrolyze or isomerize before ionization takes place and because isomerization can also occur after ionization.

In recent years it has become possible to overcome these disadvantages to a considerable degree by an extension of the methodology. So far as the correlation of fragments with structural features is concerned, collisional activation (CA) mass spectrometry[2] and other techniques[3] now make it possible to verify structures of ions. Thus conclusions can be drawn from fragments on a much better-founded basis regarding the structure of molecular ions and, hence, also about the structure of intact molecules. In the determination of molecular weights of intact substrates there have even been several breakthroughs, represented by three new techniques: 1) Field desorption mass spectrometry (FD), developed by *Beckey* and his associates[4a], especially in its variant of cationization[4b-4d]; 2) the still very recent development of ionization by radioisotopes (californium-252 source)[5]; and 3) the method of chemical ionization (CI)[*] developed by *Munson* and *Field*[6], which constitutes the subject of the present article. The first two of these procedures allow very mild ionization of the substrate, *i.e.* ionization with little excess energy transfer; owing to the suppression of fragmentation, well-defined molecular ions are produced, or their adducts with protons or alkali-metal ions. The two processes truly extend the area of application of mass spectrometry in that, unlike electron-impact ionization (EI), they permit the study of intact compounds that do not volatilize without decomposition. Chemical ionization (CI) shares only the advantage of mild ionization; yet, in contrast to the FD techniques, the amount of fragmentation can be controlled within a wide range, whereby the proportions of information about molecular weight on the one hand and structure on the other can be adapted,

[**] Abbreviations: amu, atomic mass units; CD, charge exchange; CI, chemical ionization; EI, electron-impact ionization; FD, field desorption; FI, field ionization; GC, gas chromatography; ICR, ion cyclotron resonance; MS, mass spectrometry; PA, proton affinity; RE, recombination energy; SIM, selected ion monitoring; TIC, total ion current.

[*] The term "chemical ionization" (CI) is not synonymous with chemi-ionization. Chemi-ionization achieves ionization of a substrate by interaction with electronically excited neutral particles [8].

almost at will, to requirements by varying the experimental conditions. Chemical ionization is therefore often an alternative to electron-impact ionization, whereas the two other modes of ionization represent more or less complementary techniques.

In accordance with its special merits and promise[*] for modern mass-spectrometric analysis, chemical ionization has been discussed in several earlier reviews[1b, 7] sometimes placing emphasis on special aspects of the topic; in the present article we can thus concentrate on some of the more recent viewpoints and results after first describing the principles of the phenomenon.

2. Physicochemical Aspects

2.1. Production of the Ionizing Plasma and Ionization of the Substrate

When electron-impact ionization of a compound, *e.g.* methane, is carried out at *ca.* 1×10^{-3} bar in contrast to the usual high-vacuum conditions (*ca.* 10^{-9} bar), the molecular ions and fragments produced [eq. (a)] can react further in rapid ion/molecule reactions[9] with neutral methane molecules as a result of the diminished mean free path. Concentrations of "secondary" and "tertiary" ions are thus built up [eq. (b)—(h)], in dependence on the pressure, temperature, and instrumental parameters that determine the residence time of the charged particles in the collision chamber (ion source). At this operating pressure of about 1×10^{-3} bar 95% of the total ion current is carried by the following species: $[CH_5]^+$ (48%), $[C_2H_5]^+$ (41%), and $[C_3H_5]^+$ (6%).

$$CH_4 + e^- \rightarrow [CH_4]^{+\bullet}, [CH_3]^+, [CH_2]^{+\bullet}, [CH]^+, [C]^{+\bullet}, [H_2]^{+\bullet}, [H^+] \quad (a)$$
$$[CH_4]^{+\bullet} + CH_4 \rightarrow [CH_5]^+ + CH_3^\bullet \quad (b)$$
$$[CH_3]^+ + CH_4 \rightarrow [C_2H_5]^+ + H_2 \quad (c)$$
$$[CH_2]^{+\bullet} + CH_4 \rightarrow [C_2H_4]^{+\bullet} + H_2 \quad (d)$$
$$[CH_2]^{+\bullet} + CH_4 \rightarrow [C_2H_3]^+ + H_2 + H^\bullet \quad (e)$$
$$[CH]^+ + CH_4 \rightarrow [C_2H_2]^{+\bullet} + H_2 + H^\bullet \quad (f)$$
$$[C_2H_5]^+ + CH_4 \rightarrow [C_3H_7]^+ + H_2 \quad (g)$$
$$[C_2H_3]^+ + CH_4 \rightarrow [C_3H_5]^+ + H_2 \quad (h)$$

If such a "methane plasma" contains as an additive a second compound M in a concentration smaller by orders of magnitude (generally 1: $<10^{-4}$), it will be converted into ions not directly by primary electron impact (a physical process), but by ion/molecule reactions with the above species (*i.e.* by chemical processes). Not only can the $[CH_5]^+$[**] and the $[C_2H_5]^+$ ions function as Brønsted acids with respect to M in proton-transfer reactions [eqs. (i) and (j)], but also the $[C_2H_5]^+$ ion can function as a Lewis acid [eq. (k)] in the formation of collision-stabilized complexes. In the formation of the ions $[MH]^+$ and $[M(C_2H_5)]^+$ ("quasimolecular ions" $[QM]^+$)[***], methane at a pressure of *ca.* 1 mbar (the usual CI working pressure) thus acts as a "reagent gas", the compound M as a CI substrate.

$$[CH_5]^+ + M \rightarrow [MH]^+ + CH_4 \quad (i)$$
$$[C_2H_5]^+ + M \rightarrow [MH]^+ + C_2H_4 \quad (j)$$
$$[C_2H_5]^+ + M \rightarrow [M(C_2H_5)]^+ \quad (k)$$

Besides this acid/base type of substrate ionization, which is often used in practice and which invariably involves "closed shell" ions, in chemical ionization in the widest sense[*], another type of ion/molecule reactions is of importance, in which the substrate is ionized by charge exchange (CE). Such CE processes correspond to the redox-reaction type and, like electron-impact ionization, lead to "true" molecular ions, *i.e.* to species with "open shell" character [eq. (l)]; they occur particularly with reagent gases that contain no H atoms (noble gases, N_2, NO, O_2, CO).

$$[He]^{+\bullet} + M \rightarrow [M]^{+\bullet} + He \quad (l)$$

Like electron-impact ionization, acid/base and also redox-type ionization find a counterpart in the formation of negative ions. Whereas "negative CE" (NCE) occurs by resonance capture of thermal electrons, such as are present in a nitrogen plasma (electron attachment), in "negative CI" of the acid/base type (NCI), proton transfer occurs in analogy to the positive mode (but in the opposite direction) together with formation of addition complexes. Reagent anions such as $[CH_3O]^-$ (*e.g.* from CH_3ONO as the reagent gas [(eq. (m)][11a]) or $[Cl]^-$ (from the substrate itself by dissociative electron addition [eq. (n) and (o)][11b, 11c]) now function as Brønsted or Lewis *bases*, respectively.

$$[CH_3O]^- + R{-}H \rightarrow [R]^- + CH_3OH \quad (m)$$
$$e^- + R{-}Cl \rightarrow [Cl]^- + R^\bullet \quad (n)$$
$$[Cl]^- + R{-}Cl \rightarrow [RCl_2]^- \quad (o)$$

2.2. Energetics of Ionization and Fragment Formation

2.2.1. Thermodynamic Factors

The contributions of processes (i)—(k) to the total ionization of a substrate are in the first place determined by the structure of the substrate and the nature of the reagent gas selected. In general, only exothermic ion/molecule reactions proceed at high rates[9]. In the acid/base case this fundamental condition for chemical ionization is always fulfilled for proton transfer [eqs. (i) and (j)] if the proton affinity (PA)[**] of M exceeds that of the conjugate base (*e.g.* CH_4 or C_2H_4) of the relevant reagent ion ($[CH_5]^+$ or $[C_2H_5]^+$). The PA values of some common reagent gases are listed in Table 1.

[*] The growing importance of chemical ionization can be recognized, by the fact that as few as about 30 papers appeared on this topic in the period from 1966 to 1971 [7i] but more than a thousand up to 1976. We are grateful to Dr. *H.-M. Schiebel*, Technical University of Braunschweig, for his assistance with the literature search.

[**] For the structure of the ion $[CH_5]^+$ and some homologous carbonium ions see [10].

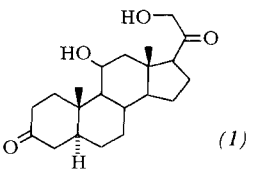
[***] Although this description is, strictly speaking, incorrect [1b, 74], it is retained here for convenience.

[*] Some authors restrict the term "chemical ionization" to this acid/base type of reaction [eq. (i)—(k)] and regard charge-exchange processes [eq. (l)] as a separate type of ionization. Common to both types of ionization is the occurrence of ion/molecule reactions.

[**] Proton affinity (PA) is defined as the standard enthalpy ΔH^0 of the reaction $[MH]^+ \rightarrow M + [H]^+$. For a comprehensive collection of PA values and critical comments on the methods of measurement see [7h] and [12b—12d].

Table 1. Protonating reagent gases, principal reagent ions, and proton affinity (PA) of corresponding conjugate bases (chemical ionization (CI)) [7, 12b, 12d].

Reagent gas	Brønsted acid	PA (kcal/mol)
H_2	H_3^+	101
CH_4	CH_5^+	126
H_2O	H_3O^+	169
CH_3OH	$CH_3OH_2^+$	182
i-C_4H_{10}	t-$C_4H_9^+$	193 (i-C_4H_8)
NH_3	NH_4^+	201



A first consequence of this energy requirement is that some degree of selectivity as to effective ionization of the substrate can be achieved by the choice of the reagent gas. Thus, chemical ionization with NH_3 as the reagent gas $[CI(NH_3)]$, unlike universally protonating chemical ionization with CH_4 $[CI(CH_4)]$, causes no protonation to $[MH]^+$ ions neither in saturated nor non-conjugated unsaturated ketones (PA values $< 200\,kcal \cdot mol^{-1}$[7h, 12]); yet it causes formation of their precursors, *i.e.* of collision-stabilized complexes $[M(NH_4)]^+$, in which (endothermic) H^+-transfer is not completed. However, owing to the increase in proton affinity as a result of conjugation α,β-unsaturated ketones afford high yields of $[MH]^+$ ions under these conditions[13]. A second, no less important consequence of the energetics of the ionization process is that the exothermicity (difference between the PA values of the substrate and of the conjugate base of the reagent ion) controls to a considerable degree the stability of the $[MH]^+$ ions and thus the extent of decomposition into ions of smaller mass with loss of neutral particles (CI fragmentation). In this way, energy-rich reagent ions such as $[H_3]^+$ or $[CH_5]^+$ afford *e.g.* highly excited $[ROH_2]^+$ ions by protonation of alcohols ROH, which, in general, have a much higher proton-affinity than the corresponding reagent-gases (H_2 or CH_4); consequently, these excited ions often decompose completely with loss of water molecules into $[R]^+$ fragments. If, however, $[H_3O]^+$ ions are used for the ionization, (H_2O as reagent gas) relatively stable and thus detectable $[ROH_2]^+$ ions are obtained owing to the smaller PA difference between H_2O and ROH. As mentioned above, this possibility of controlling the fragmentation by appropriate choice of the reagent gas, together with adjustable selectivity, endows the method with a degree of freedom that is of great value in many analytical applications.

A similar situation is encountered in the ionization of substrates by charge exchange (CE). Here too, the reactivity of the initially formed $[M]^{+\bullet}$ ions can be controlled by a suitable choice of the ionizing agent. In this case the energy content of the molecular ions $[M]^{+\bullet}$ is determined[14] by the difference between the recombination energy (RE) of the reagent ions (in eq. (l) of $[He]^{+\bullet}$) and the ionization potential (IP) of M, the latter being in the range 7—12 eV for most organic compounds[14] (RE values for some typical CE reagent gases are listed in Table 2). Correspondingly, when helium is used complete fragmentation often results, while heavier noble gases tend to give molecular ions that fragment to a much smaller extent.

Table 2. Redox type reagent, recombination energy (RE) (ionization by charge exchange (CE)) [12a].

Reagent gas	RE [eV]
He	24.6
Ne	21.5
Ar	15.7
N_2	15.6
Kr	14.0
Xe	12.1

How such energy effects can be used to advantage, and how these two types of chemical ionization can be effectively combined is illustrated in Figure 1. It shows the combined CE/CI spectrum of 4,5α-dihydrocorticosterone *(1)* obtained with a two-component reagent gas system[15] (Ar/H_2O; cf. Section 4.2.1)[15a]. On the one hand, the mild protonation by the weak Brønsted acid $[H_3O]^+$ ($m/e = 19$) leads to $[MH]^+$ ions of remarkable stability for an ROH-type compound (*ca.* 50% relative intensity in spite of the repeated subsequent loss of H_2O) as reliable indicator of molecular weight. On

(1)

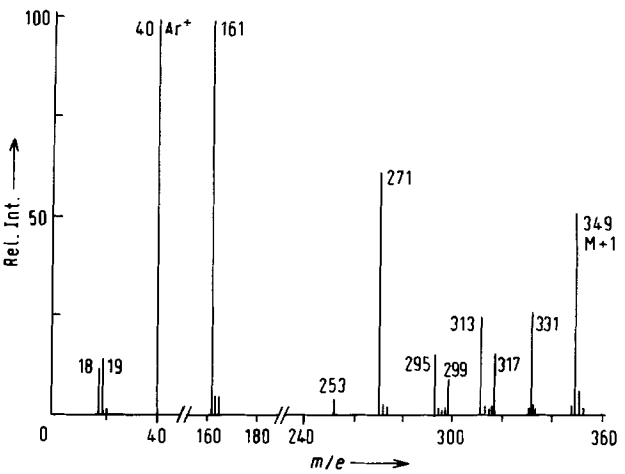


Fig. 1. CE/CI(Ar/H_2O) spectrum of 4,5α-dihydrocorticosterone *(1)*.

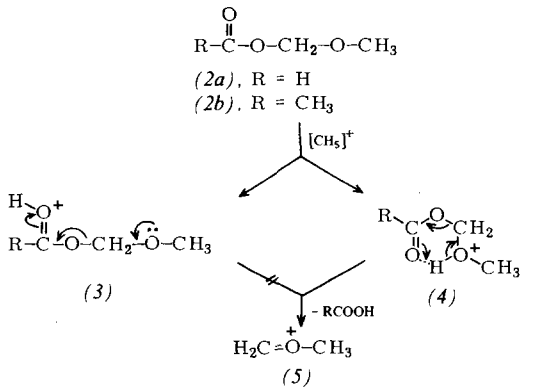
the other hand, $[Ar]^{+\bullet}$ ions ($m/e = 40$), act mainly as an aggressive agent of the redox type, simultaneously producing highly unstable $[M]^{+\bullet}$ molecular ions (barely 2% are recorded as such). These latter yield valuable information about the structure because of their marked fragmentation, whose course resembles that observed on electron impact.



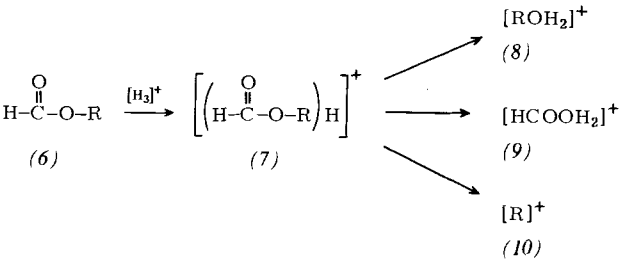
2.2.2. Kinetic Factors

For a given substrate, not only the exothermicity of the ionization process but also the reaction temperature (here in chemical ionization the temperature of the reagent gas) is decisive for the extent of fragmentation, since this temperature provides contributions to the internal energy of the ionized particle. In electron-impact ionization the internal energy of the ions formed in the high vacuum cannot be represented by a Boltzmann distribution, which would be the prerequisite

for an exact mathematical description and formal kinetic treatment of the temperature-dependence of the spectra[*]. In sharp contrast to this, in chemical ionization the large number of collisions of ions with excess reagent gas (the number of collisions lies between 1×10^2 and 2×10^3[7j], depending on pressure, temperature, and residence times of ions in the source) usually permits equilibrium to be sufficiently established in order to assume a Boltzmann distribution of the internal energies of the ions. According to *Field*[7j, 17], the kinetic parameters, *i.e.* activation energy and pre-exponential factor (frequency factor) ν, can consequently be obtained by studies of the temperature-dependence of the fragmentation.

2.3. Special Investigations

The possibility of determining the kinetic parameters of a fragmentation process experimentally is, of course, very valuable for the investigation of fundamental aspects of reaction mechanisms. Thus, it has been shown[18] that the elimination of RCOOH from the $[MH]^+$ ions of methoxymethyl esters *(2)* (Scheme 1) occurs by the same mechanism as their acid-catalyzed solvolysis[19]. From the relatively low values of the frequency factors [$\nu = 4.5 \times 10^9$ and $6.5 \times 10^8\ s^{-1}$ for *(2a)* and *(2b)*, respectively] one can conclude that the rate-determining step is not a simple bond fission [*(3)* → *(5)*] but a rearrangement by way of a relatively highly ordered transition state [*(4)* → *(5)*]. For the methylthiomethyl ester analogous to *(2)* no such strict correspondence of the kinetics of ester fission in the gas and in the condensed phase was observed[20].



Scheme 1. Fragmentation of methoxymethyl esters *(2)* under CI conditions.

The CI-induced decomposition of benzyl and *tert*-amyl acetate with loss of acetic acid from $[MH]^+$ ions has also been investigated in kinetic detail[17, 21]. $[C_7H_7]^+$ and $[C_5H_{11}]^+$ ions are formed with almost identical activation energies (12.3 and 12.4 kcal × mol^{-1}, respectively), whereas ν for the formation of $[C_7H_7]^+$ is smaller by an order of magnitude than that for the formation of $[C_5H_{11}]^+$. This difference can be accounted for by assuming that, in contrast to *(2)*, the *tert*-pentyl ester decomposes by simple bond fission [analogous to *(3)* → *(5)*], whereas in the transition state of the benzyl ester, rotation around the Ph—CH_2 bond will be restricted as a result of its partial double bond character (stabilization of the incipient carbenium center by π-participation); the reduced number of rotational states of the activated complex is reflected in a somewhat lower frequency factor ν.

The same processes are, however, also of interest because of their temperature effects. When benzyl acetate is protonated with a weak Brønsted acid, *e.g.* $[C_4H_9]^+$ (isobutane as the reagent gas, isobutene as the conjugate base of the reagent ion), then at $T = 37\,°C$ one observes almost exclusively $[MH]^+$ ions. At $T = 196\,°C$, however, the concentration of $[MH]^+$ is considerably reduced and the fragment $[C_7H_7]^+$ now provides the base peak of the spectrum. When $[CH_5]^+$ is used as the protonating agent, only a minimal temperature effect is, however, observed ($[C_7H_7]^+$ is the base peak in the entire temperature range). This contrasting behavior is ascribed to the fact that decomposition of the protonated benzyl ester is a weakly endothermic reaction and can thus occur sufficiently rapidly only on additional *thermal* activation; in protonation by $[CH_5]^+$, a supply of additional thermal energy is unnecessary because of the strong exothermicity of the process (*chemical* activation).

An informative study of the influence of the reagent gas on the nature and the importance of competing fragmentation processes was carried out by *Harrison et al.*[22]. These authors were able to show, again for protonated esters, that—in loose analogy to the quasi-equilibrium theory (QET) governing EI—a process with a relatively high activation energy is kinetically favored if a) the internal energy of the precursor ion considerably exceeds the activation energy and b) the process has a high frequency factor ν (*simple* bond fission). The authors showed that on ionization of *(6)* (Scheme 2) with $[H_3]^+$ (H_2 as the reagent gas) the ion $[R]^+$ *(10)* is formed as the main fragment in an energetically rather demanding but entropically favored process (except when $R = CH_3$). When a weaker Brønsted acid is used the ion *(10)* will be suppressed since condition a) is no longer fulfilled, and the formation of *(8)* and *(9)* will be favored.

Scheme 2. CI fragmentation of alkyl formates *(6)*, R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, *sec*-C_4H_9.

Finally, it should be mentioned that in chemical ionization structural features of the transition state of S_N2 reactions[23] can be revealed. *Dougherty et al.* and *Brauman* demonstrated which inherent properties[24] (structure of the transition state $[Y \cdots R \cdots X]^-$, nucleophilicity of $[Y]^-$, degree of substitution of R) contribute to the energy and entropy factors of the reaction investigated [eq. (p)]. On comparison of the results with data for the reaction carried out in the condensed phase the authors indirectly established solvent effects.

$$[Y]^- + R{-}X \rightarrow [Y \cdots R \cdots X]^- \rightarrow Y{-}R + [X]^- \qquad (p)$$

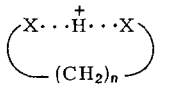
[*] The fact that also under EI conditions temperature can considerably influence the extent of fragmentation was emphasized by *Spiteller* [16].

3. The Chemistry of Chemical Ionization

3.1. Classification of Principal Reaction Types[*]

If we neglect the special cases of charge exchange (CE) and "negative" chemical ionization (NCI, NCE), then, owing to the absence of radical reaction centers, most of the behavior of chemically ionized substrates can be ascribed to but a few general modes of reaction such as are familiar from condensed phase ion chemistry. To a first approximation, in which only changes in the relative positions of atoms are considered, we can distinguish the following types of processes: 1) addition reactions, 2) heterolysis, 3) rearrangement, 4) elimination reactions, and 5) replacement (substitution).

3.1.1. Addition Reactions



Irrespective of the nature of the newly formed bond, we may consider, for example, the formation of collision-stabilized complexes (described in Section 2.1) of the substrate M with reagent ions (in general with an electrophile $[E]^+$) as an *intermolecular* addition [eq. (k)]. Besides the "classical" electrophiles $[C_2H_5]^+$ and $[C_3H_5]^+$ of the methane plasma, $[i\text{-}C_4H_9]^+$ ions from isobutane, $[NO]^+$[14b,25], $[SiMe_3]^+$[26], and recently $[Li]^+$[27] are of importance. Relatively long-lived adducts are obtained through formation of regular two-electron bonds from substrates with nucleophilic centers (π-electrons of multiple bonds, functional groups X with lone electron pairs). If these centers are basic heteroatoms (*e.g. in* X), this is also true for the adducts $[M(NH_4)]^+$ mentioned above, in which partial bonds are responsible for complex formation (hydrogen bonds $M\cdots H\cdots NH_3$ and perhaps further H-bonds in chelate-like structures when M contains additional basic centers), and for the $[M_2E]^+$ cluster ions[28] that arise under certain conditions (relatively long ion extraction times, high partial pressure of M). Common to all these stable adducts is their analytical significance for reliable molecular weight determination of unknown compounds (cf. Sections 5.1.1 and 5.1.2).

As opposed to these long-lived products of addition reactions, short-lived collision complexes can be recognized only indirectly, due to their rapid decomposition into fragments of often unexpected composition. Formation of complexes of this type with X-substituted arenes by $[CH_5]^+$ and $[H_3]^+$, *i.e.* strong Brønsted acids, was demonstrated only recently[29]. In both cases HX was eliminated from these complexes. In the net result, this corresponds to the unexpected substitution of X by CH_3 or H [eqs. (q) and (r)].

$$[CH_5]^+ + FC_6H_4R \rightarrow [(FC_6H_4R)CH_5]^+ \rightarrow [(CH_3C_6H_4R)H]^+ + HF \quad (q)$$

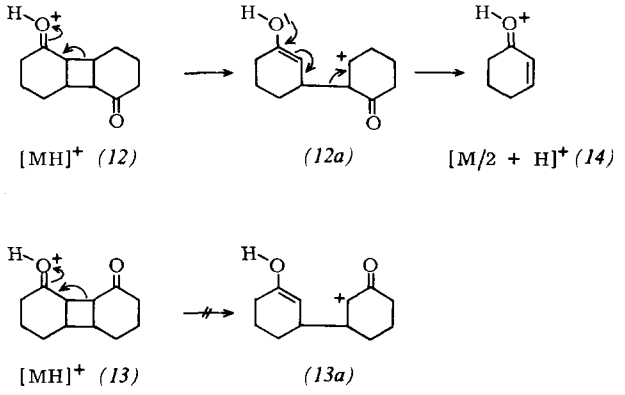
$$[H_3]^+ + FC_6H_4R \rightarrow [(FC_6H_4R)H_3]^+ \rightarrow [(C_6H_5R)H]^+ + HF \quad (r)$$

Hydrogen bonding, for example, in $[MH]^+$ ions of specific bifunctional compounds can be regarded as an *intramolecular* addition reaction, *i.e.* as counterpart to the formation of bimolecular adducts $[ME]^+$ and $[M_2E]^+$. Corresponding formation of cyclic structures *(11)* from α,ω-diamines[30] and α,ω-dimethoxyalkanes[31] is, *e.g.*, reflected in the proton affinities (which are higher than those of analogous monofunctional compounds) and also by strongly negative protonation entropies. Both *ab initio* calculations[32] and the correlation of thermochemical data with the ring sizes of *(11)* suggest linear geometry of the $(X\cdots H\cdots X)$ bonds.

(11), X = NH_2, OH, OCH_3, OAc, SH; $n > 2$

In conformationally mobile systems macrocyclic structures of the type *(11)* can be formed with up to 49 ring members[33]; as is to be expected, with short-chain diols the entropically favored ring formation does not take place if triple bonds or *trans*-double bonds are present[34]. Consequences of the formation of such internal adducts for fragmentation are discussed in Section 3.1.5.

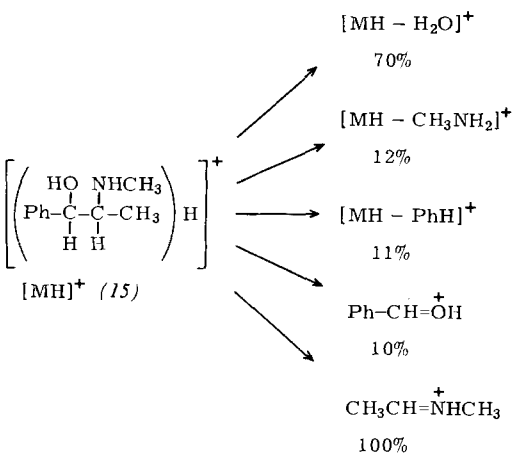
3.1.2. Heterolysis



Whereas addition reactions can occur both intermolecularly or intramolecularly, heterolysis must, by definition, be an intramolecular reaction. Effecting the simple cleavage of a bond, heterolysis is the counterpart of an addition reaction. The most simple, though not directly observable case of heterolysis would be the reversal of eq. (k); such a reaction is, in principle, possible on thermodynamic grounds, since dissociation and recombination energies are equal; in practice, the reverse reaction is largely prevented by stabilizing collisions with neutral molecules of the reagent gas. Heterolytic decomposition of $[MH]^+$ ions (M = RX) is, however, very often directly observable; examples in Section 2.3 are the $CI(H_2)$-induced decomposition of the *O*-protonated alkyl formates *(7)* to form the alkyl ions *(10)* (Scheme 2) or of protonated *tert*-amyl acetate in the temperature study discussed. In general, the extent of heterolytic fission of protonated RX compounds [eq. (s)] under standard conditions (same reagent gas, same temperature, same residue R) is, to a first approximation, inversely proportional to the ionization potential of X and to the basicity of HX[7j,35]. The $[R]^+/[RXH]^+$ ratios thus increase within a series of compounds RX in the order $X = NH_2 < SCH_3, OCH_3, COOH < CN < SH < OH < I, Br, Cl$. Quantitative predictions from the CI spectra are, however, often thwarted by the fact that heterolysis of $[MH]^+$ ions overlaps with heterolysis of $[ME]^+$ adducts. For example, $[C_6H_{11}]^+$ is formed from protonated cyclohexanol in chemical ionization with $i\text{-}C_4H_{10}$, but also in part by the decomposition of $[M(C_4H_9)]^+$ ions by loss of H_2O or C_4H_9OH, respectively[36].

$$[R{-}X{-}H]^+ \rightarrow [R^+] + H{-}X \quad (s)$$

Heterolysis of C—X bonds in onium ions can be considered along with the subsequent fission of further C—C bonds, as can occur under special conditions in (formal) carbenium ions. Examples of this special case of heterolysis (usually referred to as β-cleavage) are provided by the $CI(CH_4)$ analysis of the photodimers *(12)* and *(13)* of cyclohexenone (Scheme 3), as reported by *Field et al.*[37]. An abundant $[MH]^+$ ion is observed for both isomers, but only *(12)* gives an intense $[M/2+H]^+$ fragment *(14)*. It is assumed that *(12)* decom-

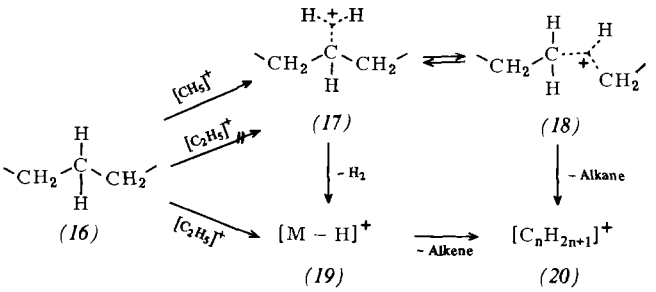


[*] An attempt at a detailed classification is given in [7j].

poses promptly to *(14)* by double β-cleavage *via* a β-oxocarbenium ion *(12a)* as an intermediate; with *(13)* an analogous genesis is likely to be quenched at this intermediate stage, since the corresponding α-oxocarbenium ion *(13a)* represents an energetically unfavorable intermediate. This case illustrates how chemical ionization permits constitutional isomers to be readily differentiated. As in this very example, this is often not possible on electron-impact ionization.

Scheme 3. Different CI fragmentations of constitutionally isomeric photoproducts *(12)* and *(13)* from 2-cyclohexen-1-one. Reagent gas: CH_4.

When several functional groups are available for protonation a certain multiplicity of fragments may result from the parallel occurrence of various possible heterolytic processes; frequently, this multiplicity reflects the gross structural features of the substrate more evenly and completely than is the case with electron-impact ionization, in spite of the latter's numerous competitive and consecutive fragmentation paths. An illustrative example is provided by a simplified consideration of the competing primary heterolyses of ephedrine (Scheme 4) (these are actually likely to proceed in a more complex manner, presumably because of neighboring group participation; cf. Section 3.1.5)[38].



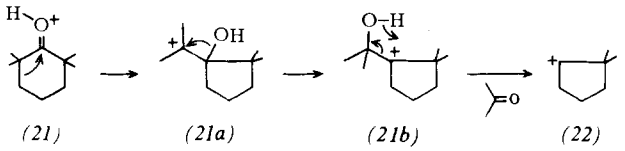
Scheme 4. CI fragmentation of ephedrine: diverse reactions as a consequence of protonation at different sites. Reagent gas: CH_4.

3.1.3. Rearrangements

This type of reaction, more complex than the preceding ones, arises formally from the combination of bond cleavage with bond formation. An intermolecular variety of H-rearrangement can again be encountered in substrate ionization, effecting the usual proton transfer by Brønsted acids [eq. (i) and (j)]. Abstraction of a hydride ion by Lewis acids [eq. (t)] can be regarded, in a way, as its counterpart. This latter process is often considered as a primary ionization event along with protonation and adduct formation, although, according to their masses, the resulting $[M-H]^+$ ions already represent fragments; moreover, it is not immediately possible to differentiate hydride abstraction from decomposition of short-lived $[MH]^+$ ions (cf. Section 3.3.1) through loss of H_2, *i.e.* from a true fragmentation process.

$$[C_2H_5]^+ + R{-}H \rightarrow [R]^+ + C_2H_6 \qquad (t)$$

It was shown by an ion cyclotron resonance (ICR) experiment[*][39a–39c] that both hydride abstraction *and* H_2-loss from $[MH]^+$ ions take place in the chemical ionization of alkanes with CH_4 as reagent gas. The study revealed that $[C_2H_5]^+$ reacted exclusively as a hydride-acceptor as in eq. (t), and not as a proton donor according to eq. (j) (which would be possible on thermodynamic grounds). In contrast, $[CH_5]^+$ was, however, found to furnish extremely unstable carbonium ions *(17)* and *(18)* by protonation of the alkane *(16)* (Scheme 5); these ions decompose quantitatively with



Scheme 5. CI fragmentation of *n*-alkanes with partial structure *(16)*.

loss of H_2 or smaller alkane molecules ("dissociative ionization"[7a]) to yield $[M-H]^+$ *(19)* and various $[C_nH_{2n+1}]^+$ ions *(20)*. At the same time, the alkyl ions *(20)* also arise from *(19)* by (formal) loss of alkene molecules, presumably as a result of β-cleavage (cf. Section 3.1.2); extensive C/H rearrangements precede this terminal step[30].

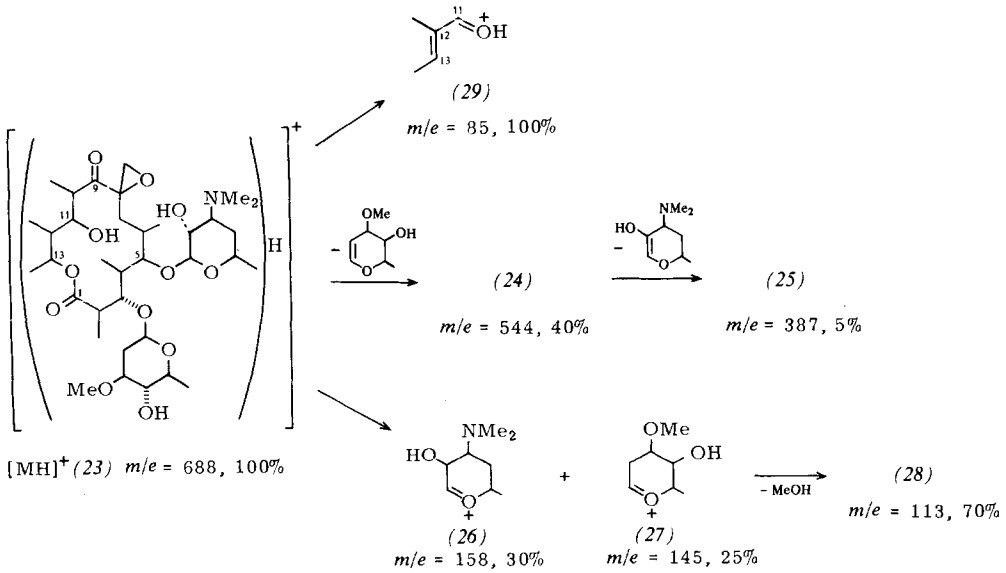
The fact that in the protonation of C—C and C—H bonds [*(16)→(17), (18)*], and also in hydride abstraction [*(16)→(19)*] the attack by $[CH_5]^+$ or $[C_2H_5]^+$ occurs largely statistically at every bond (random-attack concept)[6], causes saturated hydrocarbons to undergo a multiplicity of competing degradation reactions, which is unusual for chemical ionization. This more or less E1-like variety of fragmentation processes is in distinct contrast to the behavior of functionalized molecules (*e.g.* RX in Section 3.1.2); in these the primary ionization process is governed by ion/dipole interactions, causing a strictly localized attack of the reagent ion and thus correspondingly localized subsequent decomposition.

[*] In the case of competing reaction channels, it is possible to show conclusively which products of ion/molecule reactions arise from which ionic precursors by performing a double resonance experiment. As an integrating method of measurement mass spectrometry with conventional chemical ionization cannot disclose individual processes; for a review cf. [39d, 39e].

The chemistry of carbenium ions in solution leads one to suspect that in chemical ionization, too, intramolecular rearrangements will neither be rare nor be limited to H-transfer. With unlabeled compounds, skeletal rearrangement is usually hard to spot unless it involves rearrangement of groups containing hetero-atoms whose dislocation is readily apparent from fragment mass or competition. This applies, for example, to the CI(CH_4)-induced decomposition of 2,2,6,6-tetramethylcyclohexanone. The $[MH]^+$ ion *(21)* of this compound, formally corresponding to a carbenium ion, undergoes

(21) *(21a)* *(21b)* *(22)*

Scheme 6. CI(CH_4)-induced skeletal rearrangements of the Wagner-Meerwein type in cyclohexanone derivatives with a high degree of α-alkylation.



a dominant fragmentation process in which acetone is ejected as a neutral particle; this can be plausibly explained by ring contraction to *(21a)* with subsequent migration of the hydroxyl group [*(21a)*→*(21b)*] (Scheme 6). In *cis*- and *trans*-2,6-dimethylcyclohexanone the analogous process can likewise be observed, though with ejection of acetaldehyde being much less pronounced[40].

3.1.4. Elimination Reactions

In chemical ionization, elimination reactions have in common with heterolyses that saturated or unsaturated neutral particles are lost from ionized substrate. However, elimination is more complex in that bond rupture is formally combined with intramolecular rearrangement. The rearranged entity is often an H atom. In heterolysis [eq. (s)] the neutral molecule to be lost is already present as a leaving group: in elimination this neutral molecule must first be formed in a reactive intermediate or transition state.

We have encountered examples of elimination reactions in the preceding sections. The methoxymethyl esters *(2a)* and *(2b)* decompose after protonation following elimination routes, by way of *(4)*, and not by heterolysis *via (3)*. In the decomposition of $[MH]^+$ ions *(7)* the heterolysis to *(10)* is only the "high-temperature" path; under milder conditions elimination becomes prevalent in this case as well. In the decomposition to *(8)* and *(9)*, elimination processes even occur in two ways (1,1- and 1,2-elimination). In general, eliminations (like heterolyses) are of great diagnostic value for structural analysis; in useful extension of EI fragmentation, they frequently disclose several elements of the overall structure simultaneously rather than spotlighting one particular detail. Since protonated hetero-atoms (onium centers) often provide similarly favored reaction sites, substituents at these centers are mostly better recognized in CI than in EI spectra; in the latter, one single cleavage process may dominate fragmentation entirely. This is illustrated by the CI(i-C_4H_{10})-induced decomposition of the macrolide antibiotic oleandomycin (Scheme 7)[7g]. By elimination processes the protonated molecule loses both sugar constituents in succession [*(23)*→*(24)*→*(25)*]; thereby not only these moieties are disclosed but also the intact macrolide ring as the structural core. Heterolyses of the protonated glycosidic bonds yield the oxonium ions *(26)* and *(27)*, thus providing valuable complementary findings. A diagnostically especially important fragment is *(29)*: it is formed by elimination (opening of the lactone ring in a manner similar to a McLafferty rearrangement) and, after protonation of the carbonyl group in position 9, by heterolytic β-cleavage (similar to a retroaldol fission). This process also occurs with other macrolides containing a 14-membered ring, *e.g.* with erythromycin B[7g], from which an ion with $m/e=99$ results due to the presence of a 13-ethyl substituent. This fragment is thus suitable for an approximate localization of substituents within the ring section encompassed (C-11 to C-13). Decomposition of these compounds on electron impact is characterized by complete disintegration of the basic structural units; only residual structures of the amino-sugar components are recognizable (due to the strong fragmentation-inducing effect of the Me_2N substituent).

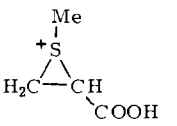
Analogously, a direct insight is often obtained into the way subunits are linked in oligomeric molecules, as is often revealed

Scheme 7. CI(i-C_4H_{10})-induced heterolyses and elimination reactions in oleandomycin.

only by extensive chemical degradation. The CI-fragmentation of peptides can serve as an example representative of many other potential applications to the analysis of natural products (*e.g.* nucleosides[41] or oligosaccharides[42]). The principal advantage of chemical ionization over electron-impact ionization for peptide-sequence analysis—a classical[43] and yet also recent[44] objective of mass spectroscopy—lies in the fact that both *N*-terminal ions and *C*-terminal ions are produced simultaneously [eq. (u)][45]. Unless very special derivatization is employed[*], electron-impact ionization affords only ions of the former kind.

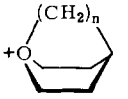
$$[(R{-}\underset{\underset{O}{\|}}{C}{-}NH{-}R')H]^+ \rightarrow [R{-}C{\equiv}O]^+ \text{ and } [H_3N{-}R']^+ \qquad (u)$$

In CI, the *C*-terminal ammonium ions are thereby formed by elimination (ejection of a neutral aminoketene molecule); for the genesis of the *N*-terminal acylium ions the question of involvement of elimination or heterolysis (cf. Scheme 1) remains unresolved. Since, in principle, protonation can occur at every single peptide bond, two series of fragments are produced which, owing to the redundancy of their information, should permit the deduction of the amino-acid sequence even when isobaric fragment ions interfere. Thus, there is little need to resort to high-resolution mass spectrometry.



3.1.5. Substitution Reactions

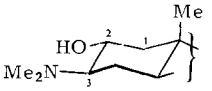
According to the formalism used, substitution reactions in chemical ionization consist of a combination of two simple steps: the displacement of a leaving group in the substrate by a nucleophile amounts to a heterolysis associated with the addition of the nucleophilic reagent [eq. (v)]. As outlined in Section 3.1.2, in a substrate of type RX the formation of potential leaving groups is a direct consequence of ionization at X. Depending on the external or internal origin of the nucleophile Y: (reagent gas or functional groups within the substrate), again an intermolecular and an intramolecular mode (S_N2 or S_Ni type) are conceivable.



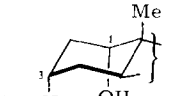
$$Y: + [R{-}X{-}H]^+ \rightarrow [R{-}Y]^+ + H{-}X \qquad (v)$$

It is uncertain whether direct intermolecular substitution, *i.e.* a process corresponding exactly to the S_N2 type, plays a role in chemical ionization [eq. (p) and Section 2.3]. In their net results, occasionally observable hydrolyses like those of trimethylsilyl and perfluoroacyl derivatives on use of H_2O or other insufficiently dried reagent gases, fall into this category, as do the ammonolyses[46] and transesterification reactions[47] of esters on use of NH_3 or CH_3OH. However, detailed investigation of such reactions of the ionized substrates with the reagent gas itself, *e.g.* the hydrolysis of aliphatic dimethyl α,ω-dicarboxylates in dependence on the number of carbon atoms in the chain (3—12)[47], compel one to assume more complex pathways, namely elimination of HX from $[RXHY]^+$-adducts with neighboring group participation by the second ester group instead of direct HX/Y-substitution in $[RXH]^+$ ions.

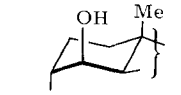
In contrast to this intermolecular mode, intramolecular substitution in chemical ionization is relatively well documented. S_Ni reactions are reflected, for example, in protonated open-chain bifunctional molecules in heterolytic processes that are absent or unimportant in monofunctional analogs under comparable conditions. $[MH]^+$ ions of simple amino acids, for instance, undergo no appreciable ejection of NH_3, in sharp contrast to those containing additional functionalities; thus, *S*-methylcysteine is readily converted into a cyclic sulfonium ion *(30)* by an S_Ni reaction[48]. Analogous reactivity was observed with a series of polyamines under CI conditions[49], which is paralleled by their EI behavior[50]. The formation of bicyclic oxonium ions of structure *(31)* must be interpreted along similar lines[51].



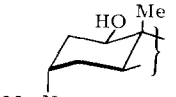
(30)



(31), n = 1, 2



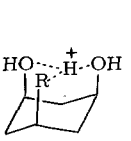
More direct indications of interactions of the S_Ni type can, of course, be expected for stereochemical effects[52a]. Marked reactivity differences may thus be exhibited by polyfunctional alicyclic systems, depending on the spatial arrangement of the substituents. An elegant study of 1,3-, 2,3-, and 3,4-difunctionalized steroidal amino alcohols was reported by *Longevialle et al.*[52b]. These authors found that in all compounds in which intramolecular H bridges between the substituents were sterically possible [*e.g.* in *(32)* and *(33)*], there was no ejection of H_2O from $[MH]^+$; such ejection was prominent when the leaving group was not hydrogen-bonded and S_Ni attack was configurationally favored [*e.g.* in the 3,4-diaxial or 1,3-equatorial/axial *trans*-compounds *(34)* and *(35)*]. Furthermore, proportions of specific conformations of the protonated forms were estimated from the $[MH]^+/[MH-H_2O]^+$ ratio. The results showed surprisingly good agreement with IR-spectroscopic measurements.



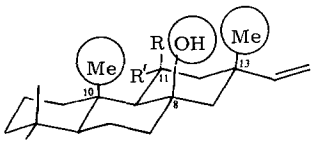
(32)

(33)

(34)



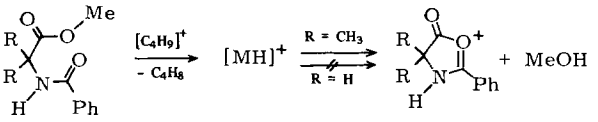
(35)



The fact that H-bond formation in bifunctional molecules (cf. Section 3.1.1) can also block sterically unhindered S_Ni reactions follows from investigations of open-chain compounds. In the $CI(CH_4)$ spectrum of *n*-decanol, $[MH]^+$ ions are completely missing, mainly due to the loss of H_2O[6]; in the $CI(CH_4)$ spectrum of 1,10-decanediol *(11)*, X = OH, $n = 10$, the $[MH]^+$ ions retain as much as 60% relative intensity[33].

[*] Reduction of the polypeptide chain to polyamino alcohols by *Biemann*'s method [43, 44] with $LiAlH_4$ intentionally generates optimum conditions for a uniform formation of *C*- and *N*-terminal fragments.

As shown by investigations of alicyclic diols and triols[53], alkyl effects play an additional role. In general, in compounds of the type *(36)* the loss of water from $[MH]^+$ is quite



(36)

(37), R = OH, R′ = H (11β-OH)
(38), R = H, R′ = OH (11α-OH)

sensitive to the configuration of the group R. For the $[MH]^+/[MH-H_2O]^+$ ratio, the case R = OH provides the upper and $R=CH_3$ the lower extreme value. Alkyl effects may prevent the formation of linear H-bonds for example in the diterpenediols *(37)* and *(38)*; this effect may be so marked that the spatial arrangement of the hydroxyl groups is no longer of importance for the extent of loss of water[54]. Apparently, the space-filling by the 10β- and 13β-methyl groups of *(37)* precludes the formation of such a bridge; in *(38)* it is ruled out in any event for configurational reasons. Indirectly, cooperative effects of this type may also be of importance for the behavior of open-chain compounds.

As a result of a geminal dialkyl effect[55], the ejection of methanol from the $[MH]^+$ ions of, *e.g.*, α-(benzoylamino) acid methyl esters is strongly dependent on additional α-substitution: in *(39)* the amount of loss of CH_3OH is considerable (25% relative intensity, $[MH]^+$ = base peak), in *(40)* it is not even detectable[56] (Scheme 8).

(39), R = CH_3
(40), R = H

(41)

Scheme 8. Loss of CH_3OH from protonated α-benzoylamino acid methyl esters in dependence on α-alkylation (alkyl effect).

4. Instrumental and Methodological Aspects

4.1. Instrumentation for Chemical Ionization

As far as instrumental aspects are concerned, the only essential difference between chemical ionization (CI)[*] and electron-impact ionization (EI) lies in the manner in which ions are produced. Mass separation and detection are based on the same principles in both techniques. Conventional EI mass spectrometers can thus be modified for CI or combined EI/CI operation[**] with little effort. No loss of resolution was observed for high-resolution instruments adapted to CI operation[59, 71]. Modifications are required (they are already taken care of in commercial instruments) to allow the ion source to be operated at a working pressure of around 1 mbar (in EI instruments *ca.* 10^{-6} mbar) through fairly gas-tight construction[*]; suitably high pumping capacities have to maintain the necessary minimum vacuum (10^{-4} to 10^{-5} mbar) outside the ion source for operation of a heated cathode[**] as well as in the analyzer to avoid collisions of ions with residual gas. Pump performances of 600 to 1200 $l \cdot s^{-1}$ at the source housing and differential pumping of the analyzer are thus necessary. In magnetic field instruments, in which the ion source is held at high potentials (acceleration voltage in the kV range), precautious must also be taken for electrical insulation of the reagent gas, which will become conducting at the prevailing pressures[7i, 7k, 59]. The technical simplicity of chemical ionization is also borne out by the fact that the same sample-introduction techniques are used for analysis of single substances as in electron-impact ionization. As in EI, in CI mass spectrometry the combination with gas chromatography (GC) leads to a major broadening of the scope of the technique, since analyses of complex mixtures become possible (cf. Section 5.1).

Technically, combination of gas chromatography with CI mass spectrometry is simpler than that with its EI counterpart—at least as far as the level of performance of monogas systems[58, 63, 64] is concerned. The reagent gas, usually CH_4, can be passed through the gas chromatograph and thus serve at the same time as a carrier gas. Because of the "high" pressure required in the ion source, molecular separators or split systems become unnecessary, *i.e.* can be replaced in favor of direct connections which operate largely without loss of sample and with minimum failure and maintenance requirements[58, 63]. Gas chromatograms are obtained by recording total ion current (TIC) representative of the sample[***]. Independent optimization of separation and reagent gas properties is made possible in the dual gas concept[****] by which different carrier and reagent gases are employed. In order to avoid interference with the separation process, the reagent-gas is admixed with the carrier gas flow only shortly before entering the ion source[65–68]. On introduction of capillary-GC/CI mass spectrometry with typically low carrier gas flows (*ca.* 1 ml/min) relative to that of reagent gas (20 to 30 ml/min) this concept could be realized in its "purest" form, *i.e.* without compromising the versatility of CI operation by major carrier gas contributions (Fig. 2)[65, 67–70].

For packed columns with considerably higher carrier gas flow (30—50 ml/min) either the carrier gas (noble gas, N_2)

[*] Since the working pressure is significantly higher in chemical ionization than in electron-impact ionization, the term "high-pressure" ionization is occasionally used.

[**] In principle, every CI source becomes an EI source as soon as the flow of reagent gas is interrupted. Unless special modifications are made [57] the sensitivity in the EI mode considerably decreases, however, because of the smaller aperture dimensions. The simultaneous or alternative operation of a combination of an independent CI and EI source has been advocated [58], and at least one such dual source is commercially available.

[*] The number and the dimensions of the source apertures into the housing are much smaller than in EI sources. The electron entrance and ion exit apertures have together an area of only 1—2 mm^2.

[**] For primary ionization of the reagent gas other principles than the customary emission of thermal electrons are available (corona discharge, use of radioisotopes such as ^{63}Ni). Plasmas of aggressive reagent gases (*e.g.* O_2, NO) are produced by gas discharge [60—62].

[***] The total ion current (TIC) signal cannot be sampled before mass separation, as is possible in GC/EIMS under certain conditions (helium as the carrier gas, 20 eV ionization energy), since it is predominantly due to unused reagent ions. In dynamic spectrometers, total ion current representative of the sample can be conveniently obtained after mass separation by integrating the single ion currents over preselected mass ranges, *i.e.* with exclusion of reagent ions, in rapid scan cycles (0.1 s). In magnetic field instruments this is less easily achieved.

[****] First described for (non-chromatographic) direct analysis [63].

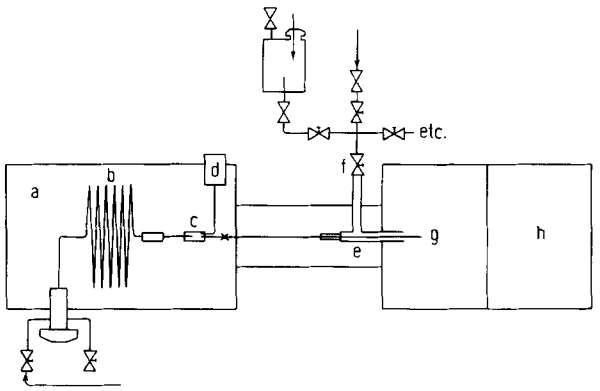


Fig. 2. Block diagram of a GC/CIMS system in typical dual gas operation (cf. [71]). Principal components: a) gas chromatograph with Grob injector, b) capillary GC column, c) split systems for dual FID/TIC recording, d) flame ionization detector (FID), e) coaxial interface, f) reagent gas inlet, g) mass spectrometer, h) dedicated computer.

is modified[*] in the desired manner by addition of appropriate amounts of a reagent gas (*e.g.* i-C_4H_{10} or NO)[66], or most of it is removed in molecular separators or flow dividers before the reagent gas is added. In the former case the full sensitivity of the system is retained at the expense of some flexibility in the choice of the CI conditions[**]; in the latter case complete flexibility of the experiment is retained as in capillary-GC/CI mass spectrometry, yet at the expense of sensitivity owing to unavoidable losses of material on pressure reduction.

4.2. Methods of Chemical Ionization

4.2.1. Choice of the Reagent Gas

The choice of the reagent gas is of decisive importance for the achievement of the analytical purpose. This choice determines not only the type of ionization (redox or acid/base type)[***], but also the exothermicity of the ionization process. As noted before, these two factors largely shape the information to be derived from the CI spectrum. According to the magnitude of the difference (Δ) between the recombination energy or the proton affinity of the reagent gas and the substrate, the result will range between extremes of high ionization selectivity, reduced fragmentation, and thus low substrate specificity (low Δ value) on the one hand, and high substrate specificity, extensive fragmentation, and low selectivity as a result of universal ionization (large Δ value) on the other. Control of selectivity and fragmentation is important not only for the analysis of multicomponent systems, in which it allows discrimination of disturbing components, but also for structural analyses of isolated, single compounds that contain several functional groups distinguished by different proton affinities[70, 15c].

In this connection it is worth mentioning experiments with binary reagent gas systems, including partially modified systems (addition of modifying gas $<10\,\%$)[15d] such as Ar/H_2O[15a], He/H_2O[15b], and many others[15d]; mild protonation is generally used to provide stable $[MH]^+$ ions, while strongly exothermic charge exchange[14b] produces highly reactive $[N]^{+\bullet}$ ions that decompose very much in an EI-like fashion. In this way one attempts to combine the advantages of chemical ionization with those of electron impact (cf. also Fig. 1). In single-compound analysis there may be real advantages to such a "hybrid" concept; in the analysis of complex mixtures by GC/CIMS, however, a sequential approach by independent, yet correlatable[71] single experiments with only one reagent gas at a time (a "puristic" concept) may frequently be preferable[65, 67, 70, 100].

4.2.2. Selected Ion Monitoring

This recording technique, which was initially developed and proposed for EI mass spectrometry under the name of "mass fragmentography"[72][*], has today acquired similar importance for CI mass spectrometry, especially in GC/CIMS analysis. In this technique the usual recording of complete spectra (*i.e.* repetitive scanning of wide—largely empty—mass ranges) during a separation process (*e.g.* fractional evaporation or GC/MS) is abandoned; instead, during the same period of time only a few selected masses are monitored continuously by rapid switching rather than sweeping electric or magnetic fields. Thus, for these few ions deadtimes are reduced by several orders of magnitude, with the result that detection limits are lowered dramatically from the nanogram down to the lower picogram level (some 10^{-12} g). Since this detection principle is independent of the mode of the ion production, it lends itself immediately to GC/CIMS analysis.

5. Analytical Applications

5.1. Analysis of Organic Compounds

This Section intends to point out applications of chemical ionization that are characteristic of both the analytical objective (determination of structure, identification, detection, quantitative determination) as well as of the fields in which it is chiefly applied (biomedical field, environmental sciences). For more complete presentations the literature should be consulted[1b, 7n].

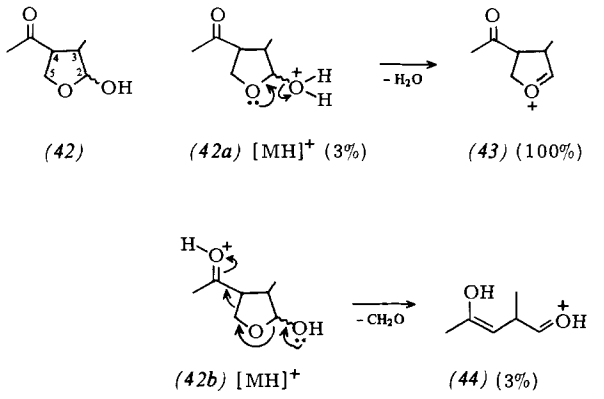
Of the advantages CI may offer over EI mass spectrometry for analytical purposes reliable molecular weight information and the possibility of controlling fragmentation are of prime importance. This is true not only for structural analysis but also for the identification of known, yet unexpected compounds present as minor components in mixtures. The detection and quantitative determination of expected, known compounds in the presence of unknown constituents or ballast material may likewise profit from control of fragmentation behavior. Pronounced $[MH]^+$ ions and deliberately suppressed frag-

[*] Addition of approximately 10 % reagent gas to the carrier gas [15d] usually suffices to moderate the latter's "hard" charge-exchange (CE) character (addition of NO), or to modify it to a CI reagent (addition of i-C_4H_{10}).

[**] In this case, the carrier gas serves only as an inert collision gas [63], which is essential to maintain CI conditions.

[***] Depending on the substrate (differences between recombination energy and proton affinity), one reagent gas can act both ways simultaneously: in the typical acidic CH_4 plasma $[C_2H_4]^{+\bullet}$ and $[C_2H_5]^+$ ions are potential charge-exchange (CE) reagents [7j].

[*] After considerable terminological uncertainty [74] (the synonyms "multiple ion monitoring", "multiple ion detection", "selective ion recording", "specific ion plotting" and many more were in use; cf. also [73a]) the acronym SIM ("selected ion monitoring") seems to have found wide acceptance [73].



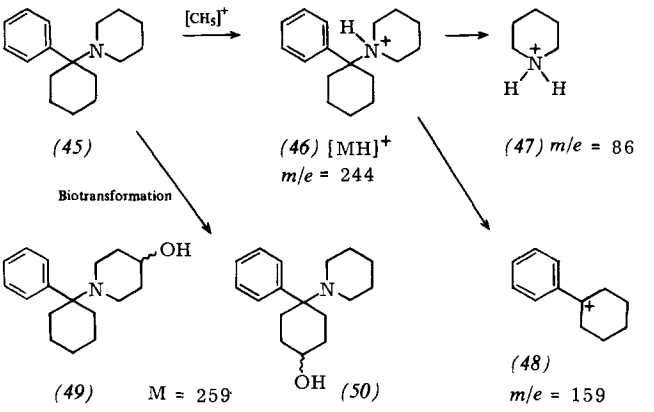
mentation are, of course, important non-instrumental prerequisites for high detection sensitivity, as is essential in trace analysis since they reduce the risk of spectral interference by foreign substances (which will also fragment to lesser degrees, and hence be more readily detected than in EI mass spectrometry). The ease of suppressing interferences, the greater reliability in qualitative applications, and the higher accuracy in quantitative work by measurement in the less disturbed region of highest possible mass (thus excluding systematic errors) are direct advantages. The control of ionization also results in great flexibility as to the selectivity desired; its optimization frequently permits the complete exclusion of disturbing accompanying materials from ionization, and thus a reduction of background in favor of lower detection limits. In these respects, electron-impact ionization is rather inflexible[*].

Finally, in structural analysis and identification, the great versatility of chemical ionization allows for the use of a series of reagent gases, in order to probe, step by step, for specific structural evidence[70]. This extension to multiple analyses of one and the same sample is certainly justified in the analysis of complex mixtures by GC/CI mass spectrometry; the expenditure of work is then economized when the structural characterization of more than only a few compounds is required, and when difficult problems of correlation can be avoided by keeping the GC parameters constant[65,67,70,71] throughout the series of GC/CIMS runs. It also has to be kept in mind that other ways are currently unavailable if one attempts to compensate for the lack of structural information otherwise provided by other spectroscopic means.

5.1.1. Elucidation of the Structure of Unknown Compounds

Chemical ionization, like electron-impact ionization, will frequently allow solution of only part of a complex structural problem. In any case, its most likely minimum contribution will be the determination of the molecular weight and, when using high-resolution instruments, the determination of the elemental composition. This information alone is especially valuable because of its high reliability[**]. However, the greater simplicity and better predictability of CI fragmentation, which is often complementary in character to that of EI mass spectrometry, and in particular its better correlation with structural elements will make its extensive evaluation highly attractive in structural work. Little effort has as yet been made in exploiting this feature in practice.

The situation is illustrated by the determination of the constitution of the antibiotic botryodiplodin *(42)* (Scheme 9). In view of the poor reproducibility of the EI behavior of the compound (tautomerizable five-membered ring lactol structure with an anomeric center at C-2), recourse was made



(42) *(42a)* $[MH]^+$ (3%) *(43)* (100%)

(42b) $[MH]^+$ *(44)* (3%)

Scheme 9. CI(CH_4)-induced decomposition of botryodiplodin *(42)*.

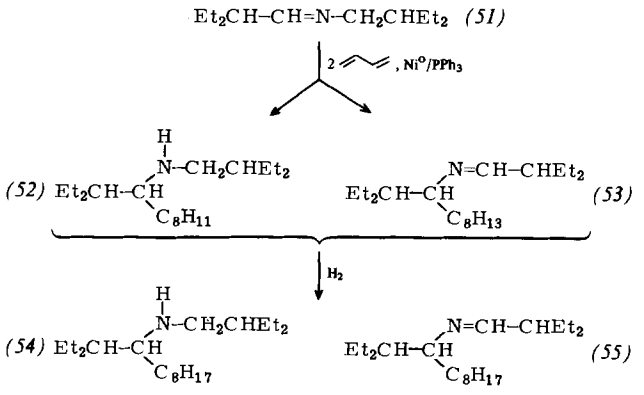
to chemical ionization[76] (incidentally, this was the first application of CI to structure analysis). Although the intensity of the $[MH]^+$ ions was relatively low due to excessive decomposition of *(42a)* into *(43)*—(as usual at that time, methane was used as the reagent gas) the molecular weight and empirical formula could be determined. Indication of a β-oxygenated carbonyl system with no substituent at C-5 was afforded by the loss of $CH_2{=}O$ from the $[MH]^+$ ion [*(42b)*→*(44)*]. This type of fragmentation is similar to the retroaldol decomposition of oleandomycin [*(23)*→*(29)*, Scheme 7]; since double β-cleavage occurs, it can also be considered as a Grob fragmentation[77] in the gas phase[78,79]. From the above and the results of ^{1}H-NMR analysis, structure *(42)* was finally arrived at in which only the stereochemistry at C-3 and C-4 remained unestablished.

(45) *(46)* $[MH]^+$ *m/e* = 244 *(47)* *m/e* = 86

(49) M = 259 *(50)* *(48)* *m/e* = 159

Scheme 10. CI fragmentation and biotransformation of phencyclidine *(45)*. *(45)* with a perdeuterated phenyl group affords an ion with *m/e* = 249 instead of *(46)*, and an ion with *m/e* = 164 instead of *(48)*. *(47)* remains unshifted.

As a result of their small absolute amount and low degree of enrichment, compounds "isolated" from physiological fluids often cannot be subjected to parallel spectroscopic investigations like those used for *(42)*. Structural characterization of drug metabolites is clearly such a case. Work of this kind is admittedly easier than that on natural products because the structure of the starting material is known and the biotransformation is almost invariably confined to the molecular periphery[*]. Determination of the structure of two metabolites



[*] The attempt to achieve selective ionization in EI by reducing electron energy to below the ionization threshold of individual classes of compounds is known to cause a prohibitive loss in sensitivity.

[**] As in the EI method, limitations arise from the necessity to vaporize the sample without thermal decomposition. However, pyrolysis is easier to recognize in CI than in EI spectra, particularly when more than one product, *i.e.* several quasimolecular ions (cf. footnote [*] on p. 436), as is the case with certain quaternary nitrogen compounds [75]. If in this latter case only one pyrolysis product is formed, the presence of a covalent compound can be simulated (*e.g.* in the phospholipid dioleylphosphatidylcholine $ROP(O)(O^-)OCH_2CH_2NMe_3^+$ by intramolecular methylation to the covalent $ROP(O)(OMe)CH_2CH_2NMe_2$ [7g]).

[*] In principle, skeletal changes are not entirely excluded. Cases of ring contraction (7-ring → 6-ring) are known, *e.g.* from the biotransformation of 5*H*-dibenz[*b,f*]azepine-5-carboxamide (carbamazepine) [80].

of the local anesthetic phencyclidine *(45)* can serve as an example (Scheme 10)[81]. GC/CIMS analysis (packed column, monogas system with CH_4 as universal gas) of a silylated crude extract from human urine showed, besides unchanged parent drug *(45)*, two GC peaks whose spectra corresponded to trimethylsilyl derivatives of isomeric monohydroxy metabolites *(49)* and *(50)* ($[MH]^+$: $m/e=332$). Marked losses of trimethylsilanol in both cases ruled out substitution of aryl positions. Comparison of these spectra with the fragmentation of the parent compound [larger structural elements are revealed in a manner typical of chemical ionization: *(45)* → $[MH]^+$ → *(47)* by elimination of phenylcyclohexene; *(45)* → $[MH]^+$ → *(48)* by heterolysis with loss of piperidine] rapidly permitted the substitution region to be narrowed down to one of the saturated rings in both cases. Silylated *(49)* decomposed to silyloxy-*(47)* ($m/e=174$) and unchanged *(48)*, while silylated *(50)* decomposed to silyloxy-*(48)* ($m/e=247$) and unchanged *(47)*. The complementary nature of EI and CI is borne out by the fact that in the EI mass spectra $[M]^{+\bullet}$ ions were much less intense than $[MH]^+$ ions in CI, but that the EI fragmentation allowed an exact placement of the hydroxyl group in one of the two metabolites *(50)*. The structural proposals *(49)* and *(50)* were subsequently confirmed by synthesis.

A similar situation may arise in structural investigations of hard-to-separate reaction mixtures from preparative organic chemistry; admittedly sample sizes are mostly larger and sample compositions less complex than when analyzing biological materials. Although the starting materials are known, the variety and number of the products may be large enough to thwart their isolation and application of conventional methods for structure elucidation or confirmation. As the following example shows, multiple GC/CIMS analysis with variation of the reagent gas[65,67,71] can be of help in such cases. The sample studied originated from a co-oligomerization experiment with butadiene and the Schiff base *(51)* (Scheme 11). Under Ni(0)-ligand catalysis, among other products, 2:1 adducts mainly of the types *(52)* and *(53)*[82] were formed.

Scheme 11. Co-oligomerization of 1,3-butadiene with the Schiff base *(51)* under nickel(0)-ligand catalysis with subsequent hydrogenation.

Figure 3[83] shows the gas chromatogram of a distillation fraction after (incomplete) hydrogenation to *(54)* and *(55)*. The difficult separation of the components 3/4 and 5/6 required the high resolution of glass capillary columns in the GC/CIMS experiments. Gross structural characterization of the important components sufficed for an evaluation of the oligomerization experiments, and was achieved by employing the reagent gas sequence $CH_4/i\text{-}C_4H_{10}/CH_3OD$. Isobutane invariably gives $[MH]^+$ ions as the base peaks and thus reveals molecular weights, which are hard to obtain by electron-impact ionization in the case of secondary aliphatic amines *(54)*. Methane,

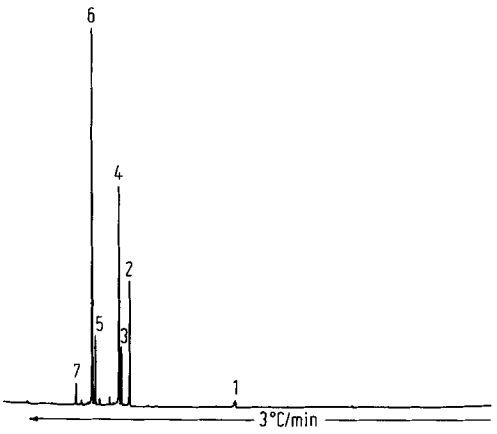


Fig. 3. CI(CH_4)-total ion current-gas chromatogram (TIC-GC) of a partially hydrogenated reaction mixture obtained by co-oligomerization of butadiene with the Schiff base *(51)* under Ni(0)-ligand catalysis (glass capillary column, 20 m × 0.3 mm, SE-54). Components of the mixture: 1) $H_2NCH(C_8H_{17})CHEt_2$, 2) and 3) $Et_2CH{-}CH{=}N{-}CH(C_8H_{17})CHEt_2$ *(55)*, 4) $Et_2CHCH_2NHCH(C_8H_{17})CHEt_2$ *(54)*, 5) $Et_2CH{-}CH{=}N{-}CH(C_8H_{13})CHEt_2$ *(53)*, 6) $Et_2CH{-}CH{=}N{-}CH(C_8H_{15})CHEt_2$, 7) $Et_2CHCH_2NHCH(C_8H_{15})CHEt_2$ (see Scheme 11).

besides confirming the $[MH]^+$ findings, furnished distinct structural information based on fragmentation similar to that of electron-impact ionization: pronounced $[M-H]^+$, $[M-C_5H_{11}]^+$, and $[M-C_8H_{17}]^+$ ions indicate which substituents occupy α-positions with respect to the N atom in the secondary amines and Schiff bases. CH_3OD, like D_2O[84], is an efficient reagent gas for the determination of the number of exchangeable H atoms (two in component 1, one in 4 and 7, none in 2, 3, 5, and 6); in the present case it serves as a probe for the recognition and distinction of primary and secondary amines in the presence of Schiff bases[69,85].

5.1.2. Identification and Detection of Known Substances

A certain minimum of structural characterization is normally required when there is no specific clue as to the identity of the compound in question, *i.e.* there is only an indication of the class to which the compound belongs. If additional complications arise from hard-to-separate mixtures, from a low degree of enrichment, or from small sample quantities, then, for reasons given above, chemical ionization will be the method of choice.

The widespread abuse of drugs provided a challenge to the exploratory application of the new technique for the identification of these materials in clinical analysis. Direct sample introduction, applied to crude extracts of gastric contents, urine, or blood was performed at the National Institutes of Health by a group centered around *Fales* and *Milne* some years ago, as a means of simple rapid screening[*][88]. The

[*] The potential of GC/MS for this field was clearly recognized [86], but instruments then available operated relatively slowly and were generally reserved for non-routine problems [87].

procedure consisted in taking a series of CI(i-C_4H_{10}) spectra during evaporation of the sample and searching them for $[MH]^+$ ions[*]; visual comparison ($[MH]^+$ as search parameter) against the 48 reference spectra then available made it possible to identify rapidly at least the most often abused drugs. The spectrum of a gastric extract (Fig. 4) illustrates an overdose case in which five constituents [*(56)—(60)*]

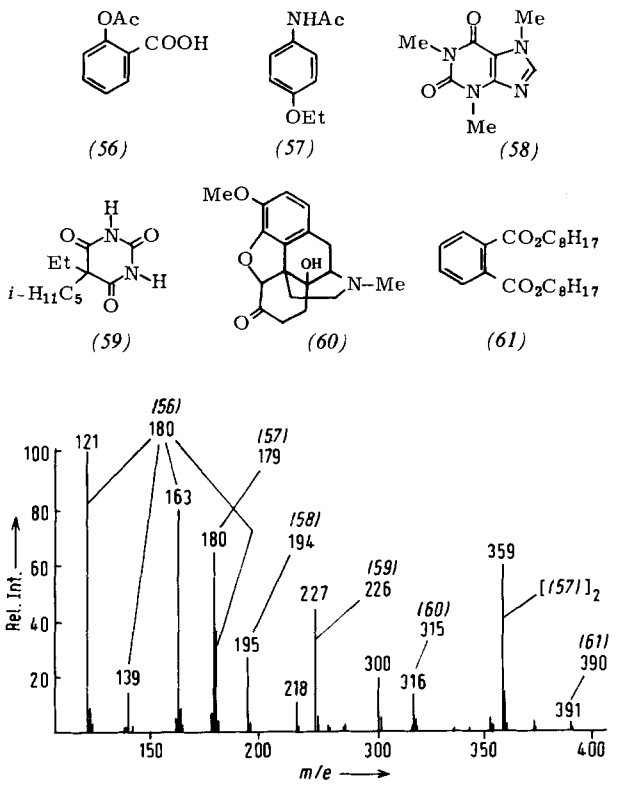

Fig. 4. CI(i-C_4H_{10}) spectrum of an extract of gastric contents after drug abuse (overdose of Percodan). *(56)*, acetylsalicylic acid (aspirin); *(57)*, phenacetin; *(58)*, caffeine; *(59)*, amytal; *(60)*, oxycodon; *(61)*, dioctyl phthalate.

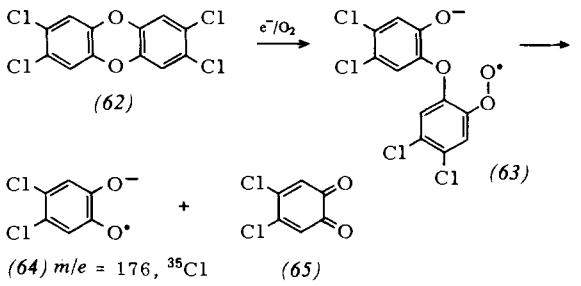
of the preparation Percodan, even in spite of pronounced fragmentation of one component [aspirin *(56)*], could be identified[88]. While contaminants, *e.g.* the ubiquitous dioctyl phthalate *(61)*, barely interfere, the formation of cluster ions of the type $[M_2H]^+$ (cf. Section 3.1) by phenacetin *(57)* is to some extent a disadvantage; cluster formation of this kind is a consequence of high momentary sample pressure which is not always easy to avoid, yet fortunately readily recognized.

In forensic medicine common "street drugs" and narcotics such as heroin can be similarly identified by direct analysis of the confiscated material as such[89]. Diluents and current "narcotic substitutes" are simultaneously identified, and this often enables the investigating authorities to draw conclusions as to the origin of the material[**].

In the past years the increasing spread of technically more sophisticated GC/MS/computer systems, and the resulting automation of spectra comparisons, have replaced much of the initial skillful improvisation in this field. Importance still attaches to direct analyses in cases in which thermal lability or low volatility excludes the use of GC/MS analysis in spite of derivatization. Examples are the identification of LSD[90], or of explosives for which chemical ionization with H_2O as reagent gas has proven valuable[91]. The general trend toward automated identification is reflected in the inclusion of CI spectra in larger general collections of mass spectra, and also in the growth of specific collections of CI reference spectra for drug identification to currently 450 compounds (including the main metabolites and customary associated substances)[92]. An approach developed at the Batelle Institute in Columbus, Ohio, is based on a GC/CIMS analysis of crude extracts; a monogas system operating with packed GC columns and methane as the carrier/reagent gas is used[90, 92]. For compounds of equal molecular weight (which serves as the main search parameter) fragmentation provides sufficient distinguishing criteria. Because of the dependence of CI fragmentation on experimental parameters, strict standardization of the conditions is, of course, necessary.



Detection sensitivities very much greater than in the preceding examples are required for analyses of trace components, while at the same time, high substance specificity must be maintained. This applies particularly to the detection of trace components in very complex mixtures. A breakthrough in this direction (detection limits in the lower picogram range and less) was achieved by the technique of selective ion monitoring (SIM), described in Section 4.2.2[72]. A result of general interest, relying on this technique, is the detection of traces of nicotine in the urine of non-smokers[93]. This analysis, which required an extremely high detection sensitivity and very narrow selectivity of ionization, was performed by *Horning et al.* These authors developed a special version[94, 95] of chemical ionization using reagent gases at atmospheric pressure (API) in an "open" ion source; the detection limits of such a system are in the upper femtogram range (1 fg = 10^{-15} g). In a typical experiment a benzene extract of the urine is injected directly into the source flushed with N_2 at atmospheric pressure, and the solvent vapor also acts as a highly selective CE reagent gas ($[C_6H_6]^{+\bullet}$ ions). The presence of nicotine in urine was evidenced by the SIM profile of $m/e = 162$ ($[M]^{+\bullet}$). Surprisingly, the alkaloid was also detected in the urine of all *non*-smokers tested: the nicotine levels of these apparently "passive smokers" were *ca.* 5% of the average content for smokers examined at the same time.

"Negative chemical ionization" (NCI and NCE; cf. Section 2.1) has opened up some interesting and highly topical possibilities for the detection of traces of special compounds. This applies particularly to 2,3,7,8-tetrachlorodibenzo[1,4]dioxin (TCDD), which recently made the headlines. The molecule of *(62)* is remarkably stable in every respect but, after the formation of a radical-ionic adduct *(63)* with O_2 (reagent gas in a Townsend ion source), it decomposes readily into an ionic fragment *(64)* (Scheme 12).

By means of this fragment, *(62)* can be detected in extremely low concentration (a 2×10^{-12} g sample gave a signal/noise ratio of over 50:1 on the SIM trace[96]) and, owing to the specificity of the process and the relatively low mass of the fragment, can be easily differentiated from other wide-spread

[*] The presence of several $[MH]^+$ ions (*e.g.* when combined preparations were ingested) causes irregular changes of the intensity profiles within a series of subsequently recorded spectra, in contrast to the presence of CI fragments.

[**] For detailed analysis, the GC/CIMS version is, of course, likewise recommended; in this context, the use of He/NO (10/1) as a moderated CE reagent gas has been reported [66].

Scheme 12. Decomposition of 2,3,7,8-tetrachlorodibenzo[1,4]dioxin *(62)* after negative chemical ionization (NCE) with O_2 as the reagent gas.

polyhalogenated compounds which are hard to separate by present techniques.

5.1.3. Quantitative Analysis[*]

Here too, direct introduction of the sample with fractionating evaporation may be of certain interest as the simplest mode of analysis when, for example, only one or a few main components of a simple mixture are to be determined quantitatively. A typical case in which derivatization and GC/CIMS analysis proved hardly worthwhile has been reported by *Fales et al.*[97]. These authors were concerned with the quantitative determination of phenylthiohydantoin (PTH) derivatives of amino acids which they obtained in decreasing purity in the course of a sequential Edman degradation of sperm whale myoglobin, *i.e.* in admixture with PTH derivatives of the amino acids next in the sequence. After identification of all the PTH-amino acids present by means of a preliminary CI run, quantitative determination was successfully achieved by the addition of the corresponding C_6D_5 derivatives in known amounts as internal standards (isotope dilution analysis). This permitted the identification of the chief component in the mixtures obtained at every single step (in contrast to visual inspection of spectra beyond step 20), and thus the deduction of the correct sequence of the protein chain. The concentrations of the PTH derivatives were obtained from the relative intensities of the $[MH]^+$ ions from the sample and standard in the very simple CI(i-C_4H_{10}) spectra.

For quantitative determination of very low concentrations in multicomponent mixtures, GC/MS with the use of selective ion monitoring (SIM) is, of course, much more effective. The GC/CIMS combination is a very promising alternative to GC/EIMS[98] because of the advantages mentioned above, especially the lower susceptibility to interference by material co-eluted with the sample. As in the direct-introduction mode, an internal standard is added in a known amount (depending upon the expected concentrations) to the original medium, *e.g.* blood plasma, before isolation and clean-up (generally by extraction) of suitably enriched fractions. As with the above phenylthiohydantoins, the current practice is to use standards multiply labeled with stable isotopes of high isotopic purity[95b]. Multiply deuterated or ^{13}C-labeled standards with at least 3 amu mass difference from the unlabeled substrate are particularly suitable, because they preclude overlap in the simultaneous recording of selected $[D_0]/[D_n]$ mass pairs even in the presence of the $[MH]^+/[M]^{+\bullet}/[M-H]^+$ peak groups in CI(CH_4) spectra (should CH_4 be unavoidable as reagent gas).

A typical case of pharmacokinetic investigations is the quantitative determination of phencyclidine *(45)* (Scheme 10) (already mentioned in Section 5.1.1) as unchanged parent drug in blood and urine[81]. The derivative with a perdeuterated phenyl group is the internal standard and CH_4 is the carrier and reagent gas (monogas system). As mentioned above, only the two main fragments *(47)* ($m/e=86$) and *(48)* ($m/e=159$) are prominent apart from $[M]^{+\bullet}$ and $[MH]^+$ ($m/e=243$ and 244; relative intensity 100 and 50%, respectively)[*]. Unlike *(48)*, fragment *(47)* contains no heavy isotope in the case of the $[D_5]$-derivative and, thus, cannot be used as a reference mass. The mass pairs $m/e=243/248$ and 159/164 are, therefore, used for selective ion monitoring. The recording of two ions characteristic of the compound, together with practically identical retention of the substrate and the added standard provides sufficient compound specificity and is nearly equivalent to a duplicate analysis by independent routes. Interference at one of the two selected masses (*e.g.* by metabolites) would result in a discrepancy between the two values found.

By establishing two calibration curves for the two selected mass pairs with known amounts ($[D_0]/[D_5]$ intensity ratios are plotted against increasing amounts of the $[D_0]$ compound), the necessary linearity of response is ascertained for the required concentration range; unknown concentrations can then be interpolated directly. The versatility of chemical ionization and its special advantages in the field of pharmacological chemistry are amply demonstrated by a multitude of further reports on the quantitative determination of drugs such as methadone (and its metabolites)[99], phenformin[100], morphine[98], quinidine and lidocaine[101], tolbutamide (and its metabolites)[102], several barbiturates and hydantoins[103], and also of endogenous substances such as purine and pyrimidine bases and nucleosides (as permethylated derivatives)[104].

5.2. Analysis of Inorganic and Organometallic Compounds

The advantages of chemical ionization outlined in Section 5.1, and the complementary nature of chemical ionization and electron-impact ionization naturally apply also to inorganic and organometallic substrates; however, little information is so far available on this topic[105, 106]. Borohydrides, as an example, have been investigated in some detail; in CI(CH_4) mass spectrometry they always yield intense $[MH]^+$ ions when terminal BH groups are present; in contrast $[M-H]^+$ fragments result from compounds containing terminal BH_2 groups[107]. Among the organometallic compounds there is apparently a more or less pronounced tendency to undergo redox reactions in accordance with eq. (l), depending on the nature of the metal, the ligand, and the reagent gas[108]. Such charge-exchange reactivity has been utilized to detect, for example, molecular ions from thermally very labile arsolanes[109].

[*] Aspects of quantitative analysis by means of mass spectrometry have recently been reviewed by *W. D. Lehmann* and *H.-R. Schulten*, Angew. Chem. *90*, 233 (1978); Angew. Chem. Int. Ed. Engl. *17*, 221 (1978).

[*] $[M]^{+\bullet}$ ions often occur with high intensity in CI(CH_4) spectra of aryl-substituted compounds or arenes (low values of ionization potential or recombination energy) as a result of charge-exchange processes.

This article and the investigations of chemical ionization carried out at the Technical University of Berlin were kindly supported by the following Institutions: Technische Universität Berlin (Research Area "Massenspektrometrie" FPS 5/1), Fonds der Chemischen Industrie, and Gesellschaft von Freunden der Technischen Universität Berlin. We are also indebted to CIBA-GEIGY AG, Basel, for similar support.

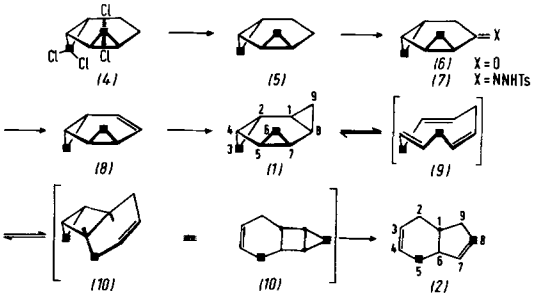
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Thermolysis of *endo,exo*-Tetracyclo[6.1.0.0^{2,4}.0^{5,7}]-nonane (*trans*-Tris-σ-homobenzene)[**]

By *Werner Spielmann, Dieter Kaufmann,* and *Armin de Meijere*[*]

Whereas all the hitherto known structural analogs of *cis*-tris-σ-homobenzene undergo [2+2+2] cycloreversions at 60 to 200°C to form derivatives[1] of *cis,cis,cis*-cyclonona-1,4,7-triene, the unsubstituted *trans*-tris-σ-homobenzene *(1)* is stable under these reaction conditions[2]. In contrast, its 3,3,6,6,9,9-hexamethyl derivative rearranges reversibly to hexamethyl-*trans*-tricyclo[4.3.0.0^{7,9}]non-3-ene above 120°C[3]. The ease of this reaction, suspected to involve a [$_\sigma 2_s + _\sigma 2_a$] process[3], could be attributable to the molecular geometry which is determined to some extent by the steric effect of the methyl groups[4].



We have now found that the parent hydrocarbon *(1)* also undergoes a rearrangement at 380—400°C in a flow apparatus (contact time 10—75 s), which is *ca.* 75% uniform. The major product isolated by gas chromatography is shown by its ^{1}H- and ^{13}C-NMR spectra (Table 1) to be *trans*-bicyclo[4.3.0]nona-3,7-diene *(2)*. On catalytic hydrogenation (2 mol hydrogen) it affords *trans*-bicyclo[4.3.0]nonane *(3)*, the ^{1}H-NMR spectrum of which (Table 1) differs substantially from that of the *cis* isomer. The overall reaction of *(1)* obeys

(1) *(2)* *(3)*

first order kinetics; the activation parameters are $E_a = 175.7 \pm 3.8$ kJ mol^{-1}, $\log A = 13.39$ ($\Delta H^{\ddagger}_{298} = 173.2 \pm 3.8$ kJ mol^{-1}, $\Delta S^{\ddagger} = 3.14$ J mol^{-1} K^{-1})[5].

More detailed information about the mechanism of the major reactions comes from an examination of the [3,6-^{12}C$_2$]-labeled hydrocarbon *(1b)* prepared by a new method. Addition of dichlorocarbene (from $^{12}CHCl_3$) to 1,3-cyclohexadiene

led to *(4b)* (68% yield), which on reduction with $LiAlH_4$ in diglyme gave the hydrocarbon *(5b)* (73%). Compound *(5b)* was oxidized on silica gel with ozone to the ketone *(6b)* (44%)[6]; the tosylhydrazone *(7b)* (78%) of this ketone was treated with methyllithium in ether to give the olefin *(8b)* (78%), which could be cyclopropanated by the Simmons-Smith method to form *(1b)* (45%). Unlabeled *(1)* was obtained analogously.

Table 1. ^{1}H- and ^{13}C-NMR data.

^{1}H-NMR δ_{TMS} (signal shape, rel. int.)		
(1)	*(2)*	*(3)*
1.23–0.87 (m, 5H)	5.78 (s, 2H)	2.00–1.18 (bm, 9H)
0.79 (mc, 2H)	5.67 (m, 2H)	0.92 (bs, 7H)
0.51 (mc, 2H)	2.54–1.56 (bm, 8H)	
0.27 (mc, 1H)		
0.07 (mc, 2H)		

^{13}C-NMR δ_{TMS} (rel. int.)			
(1a)	*(1b)*	*(2a)*	*(2b)*
11.05 (2.1)	11.05 (1.6)	134.68 (1.0)	134.68 (1.0)
10.81 (1.0)	—	131.22 (1.2)	—
9.45 (2.0)	9.45 (1.0)	128.26 (1.2)	128.26 (1.3)
8.06 (2.0)	8.06 (1.6)	127.15 (1.1)	127.15 (1.4)
7.59 (1.7)	7.59 (1.9)	46.85 (1.1)	46.85 (0.9)
		44.49 (1.1)	44.49 (1.3)
		37.22 (1.2)	37.21 (1.6)
		31.11 (1.4)	31.11 (0.6)
		30.89 (1.2)	30.87 (0.6)

Thermolysis of *(1b)* gave a bicyclononadiene *(2b)*, the ^{13}C-NMR spectrum of which contained no signal for C-8 and the signals for C-2 and C-5 were only half as strong as in the spectrum of *(1a)*. If *(2b)* were formed by a [$_\sigma 2_s + _\sigma 2_a$] cycloaddition between the C-2/C-4 and C-5/C-7 bonds[7] of *(1b)* the ^{12}C label should appear in the ratio 50:75:75 at C-8, C-2, and C-5. The 100:50:50 distribution actually found rather indicates a mechanism in which primarily all three cyclopropane rings open—stepwise or synchronously as a [$_\sigma 2_s + _\sigma 2_s + _\sigma 2_s$] process—to give *cis,trans,trans*-1,4,7-cyclononatriene *(9)*. A [$_\pi 2_s + _\pi 2_a$] cycloaddition between the two strained *trans* double bonds[8] then leads to *(10)*, which rearranges to *(2)* with retention of the characteristic *trans* linkage.

Only the final step of this sequence is irreversible; in the hexamethyl derivative of *(1)*, in which the $+I$ effect of the methyl group probably lowers the energy of the first, presumably rate-determining transition state, this last step does not occur and the reversibility of the first two becomes obvious from the equilibrium position of the overall reaction[3].

Thus it has been demonstrated that the thermal rearrangement, at least of unbridged[9] *trans*-tris-σ-homobenzenes, is also partly determined by the same [2+2+2] cycloreversion that is characteristic of the *cis* isomers[1]. The value of the activation energy found for *(1)* provides grounds for believing that *(10)* and maybe even *(9)*[10] could be isolable under flash-pyrolysis conditions.

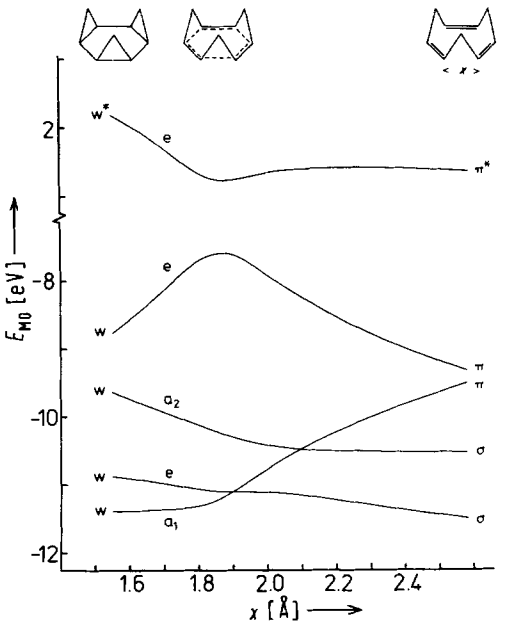
Rearrangement of Tris-σ-homobenzenes to 1,4,7-Cyclononatrienes[**]

By *Jens Spanget-Larsen* and *Rolf Gleiter*[*]

Thermal isomerization of *cis*-tris-σ-homobenzenes to π isomers is regarded as a $[\sigma 2_s + \sigma 2_s + \sigma 2_s]$ cycloreversion[1, 2]; the geometry of the transition state is assumed to resemble that of the corresponding trishomobenzene ("trishomoaromatic"). With the aim of substantiating this classification, based on stereoelectronic, kinetic, and thermochemical criteria, and of characterizing such reactions in greater detail, we have calculated (MINDO/3[3]) part of the multidimensional potential energy surface for the carbocyclic cases (I—III).

In the case of (I) the calculation was performed with variation of all geometrical parameters without symmetry constraints (see Tables 1 and 2). It qualitatively reproduces the structural parameters expected for *(1a)*[4] and known for *(1c)*[5], the estimated H_f values (269.1 and 191.3 kJ mol^{-1}[1a]), and the activation energy ($E_a = 100$—126 kJ mol^{-1}[2, 6]) extrapolated from numerous model reactions. According to the correlation diagram (Fig. 1) the highly symmetrical transition state *(1b)*, which is consistent with a concerted reaction course, is already reached on elongation of the cyclopropane C—C bond to 1.9 Å.



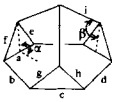


Fig. 1. Orbital energies *(1a)* as a function of the length x of the bonds broken during reaction (I). The symmetry is C_{3v} (w = Walsh orbital).

Table 1. Calculated bond lengths [Å] and bond angles according to MINDO/3. Values refer to C_{3v} symmetry for *(1a)*—*(1c)* and *(2a)*—*(2c)*, and to C_s symmetry for *(3a)*—*(3c)*; the symmetry plane passes through *a* and *d*.

Table 2. Calculated heats of formation (H_f) and activation energies (E_a) according to MINDO/3.

	H_f [kJ/mol]	E_a [kJ/mol]	E_a^{el} [eV]	E_a^{core} [eV]
(1a)	221.0	151.9	70.18	− 68.60
(1b)	372.9	−263.3	229.70	−232.42
(1c)	109.6			
(2a)	445.3	223.0	70.05	− 67.75
(2b)	668.3	−338.5	231.33	−234.82
(2c)	329.8			
(3a)	211.8	202.5	72.48	− 70.39
(3b)	414.3	−180.8	159.66	−161.53
(3c)	233.5			

C_{3v} and C_s symmetry was assumed for the calculations on (II) and (III), respectively. The structural data calculated for *(2c)* and *(3c)* agree well with those obtained experimentally[7] or from force field calculations[8]. The slight difference of 22 kJ mol^{-1} in the H_f values of *(3a)* and *(3c)* is remarkable. This suggests that *(3a)* should be accompanied by a detectable amount of *(3c)* in equilibrium (III) at elevated temperatures[9]. The predicted activation energies are too high, but do reproduce the correct trend, *i.e.* that *(1a)* has a lower kinetic stability than *(2a)* and *(3a)*.

Interestingly, the electronic component of the activation energy E_a^{el} (Table 2) is higher for (I) than for (II). Only the energy term for core-core interaction is responsible for the lower activation energy of (I) (Table 2). The lower stability of *(1a)* compared with *(2a)* and *(3a)* can be partly explained by a decrease of the interaction between the CH_2 groups in the transition *(1a)*→*(1b)*. The shortest H···H distance between the CH_2 groups increases from 2.75 Å in *(1a)* to 2.91 Å in *(1b)*. No such decrease in nonbonded interactions is observed in (II) and (III).

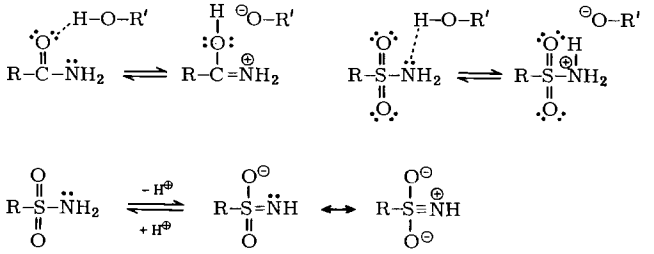
^{15}N-NMR Investigation of Solvent Effects on Sulfonamides[1]

By *Hans R. Kricheldorf*[*]

Two surprising effects have been observed in the ^{15}N-NMR spectra of poly(tauryl-ε-aminocaproyl)[1]: Firstly, the sulfonamide signal in caustic soda (pH = 13.5) appears about 13 ppm further downfield than in trifluoroacetic acid, while the carboxamide signal is shifted upfield; secondly, the signal intensity is reduced to *ca.* ¼ of its original value. We have now examined these solvent effects more closely on methanesulfonamide, which besides being readily soluble in many solvents has the added advantage that a onefold deprotonation at the NH_2 group influences the relaxation time T_1 and thus also the signal intensity only slightly. No ^{15}N-NMR signals can be observed at pH ≥ 10, but one is observed in the pH range 1.0—8.5. On addition of 3 mol % EDTA a signal also appears at pH ≥ 10 which has the same intensity as that at pH < 8.5. It therefore follows that the reduction in signal intensity in alkaline medium is mainly caused by paramagnetic cations. The traces of such ions in tap water do not suffice to influence the neutral sulfonamide group, but in the case of sulfonamide anions, which are better ligands they can lead to "signal nulling"[2].

The chemical shifts of methanesulfonamide in water at various pH values show the course of a titration curve with the anionic branch at low field. The turning point lies at pH = 10.4 to 10.6 and δ = −279 if the maximum value of the chemical shift in the alkaline range is taken to be −273.5 (cf. Table 1). The larger downfield shift in 8 N caustic soda can arise from the very high concentration of electrolyte. In organic solvents the direction of the chemical shift is analogous to the aqueous medium. Thus, the signals of various sulfonamides in dimethyl sulfoxide, which can function only as an acceptor for hydrogen bonds, are always found at lower field than in acidic, protonic solvents. Hence, in the case of sulfonamides the solvent effects are in direct contrast to a simple electron density shift correlation and also in contrast to the behavior of carboxamides, which exhibit downfield shifts of up to 30 ppm with increasing solvent acidity[3].

Table 1. ^{15}N-NMR shift δ (ppm upfield rel. $NO_3^{\ominus}$ ext.) of methanesulfonamide in various solvents.



Water at pH	δ	Solvent	δ
1.0— 1.1	−284.4	Dimethyl sulfoxide	−281.3
4.0— 4.1	−284.4	Acetone	−285.6
6.4— 6.5	−284.6	Methanol	−287.1
8.5— 8.6	−284.5	Formic acid	−286.3
10.0—10.1	−283.2 [a]	Trifluoroacetic acid	−289.0
11.1—11.2	−273.5	Dimethyl sulfoxide [b]	−281.7
11.7—11.8	−273.6	Trifluoroacetic acid [b]	−289.3
12.3—12.4	−273.5	Dimethyl sulfoxide [c]	−293.2
8 N caustic soda	−271.8	Trifluoroacetic acid [c]	−297.3

[a] Broad signal; sharp signals in all other measurements. [b] *N-tert*-Butylmethanesulfonamide. [c] Methanesulfonanilide.

A qualitative interpretation of these findings must take into consideration that in the ^{15}N nucleus, as in the ^{13}C nucleus, the paramagnetic term of the shielding constant (σ_p) dominates. Though this means that the electron density has an influence on the chemical shift, other factors are also of importance, *e.g.* the degree of delocalization of n- and π-electrons, and thus their excitation energies, and the anisotropy of the electron density distribution. It is known from ^{1}N-NMR investigations[4] that carboxamides are attacked at the oxygen atom during hydrogen bond formation and protonation. The delocalization of the N-electrons is thereby enhanced, the anisotropy increased, and the absolute electron density decreased. In the case of sulfonamides, however, the hydrogen bridges attack at the nitrogen atom[3] and thus effect a delocalization of the electron pair, until in the limiting case of protonation an sp^3 hybridized N atom with largely isotropic electron density distribution is formed. In contrast to the carbonyl

[*] Dr. H. R. Kricheldorf
Institut für Makromolekulare Chemie der Universität
Stefan-Meier-Strasse 31, D-7800 Freiburg (Germany)

group, the sulfonyl group can delocalize two electron pairs; hence, deprotonation in the case of sulfonamides leads to increased anisotropy, as does protonation in the case of carboxamides. As in many other cases, the influence of the absolute electron density on the chemical shift would appear here also to be only of secondary importance[5].

Apart from their theoretical significance, the solvent effects can be of analytical utility in the case of amides, for they permit simple identification of sulfonamide signals besides the signals of carboxamides, urethanes and urea derivatives, which usually appear in the same spectral region.

Experimental

All ^{15}N-NMR spectra were recorded with an FT instrument (Bruker WH-90) at 21 kG (=9.12 MHz) [1 K data points to 200 Hz spectral width, pulse interval 2.54 s, pulse width 30 µs (*ca.* 30—40° depending upon the solvent), 3500—4000 pulses]. 2.8 g (≈30 mmol) of methanesulfonamide was dissolved in 10 ml of solvent and, in the case of alkaline solutions, 300 mg EDTA were added. The measurements were carried out in 20 mm sample tubes with a coaxial 5 mm capillary which contained D_2O as "lock". Isotope enriched NH_4NO_3 in D_2O (5 mm capillary) was used as reference standard. All amides of natural isotopic composition were measured.

Various Adducts of Isothiocyanates to the λ^5-Phosphazene Group of an Azaphosphole[1]

By *Alfred Schmidpeter* and *Thomas von Criegern*[*]

A phosphazene group incorporated into a five-membered ring as in the 1,2λ^5-azaphospholes *(1)* exhibits a considerably greater readiness to undergo cycloaddition than in the acyclic case[2]. Thus, on treatment with alkyl, aryl, and acyl isothiocyanates *(2)*, compounds *(1a)* and *(1b)* give stable [2+2] cycloadducts which can be isolated in crystalline form. Methyl isothiocyanate *(2a)* is found to add *via* the CN bond to give *(4)*, and the other isothiocyanates studied *(2b)*—*(2e)* *via* the CS bond to form *(6)*. The products are homogeneous as shown by their IR spectra. Compounds *(6)* contain the hitherto unknown 1,3,2λ^5-thiazaphosphetidine ring.

In solution, the situation shifts somewhat in favor of *(4)*. While the equilibrium still lies completely on the side of *(4)* for R=CH_3, and completely on the side of *(6)* for R=$(C_6H_5)_2PS$ and C_6H_5CO, there is considerable rearrangement of *(6)* to *(4)* when R=C_6H_5 and $(CH_3)_2PS$.

X	R		*(4)* : *(6)*
CH_3	C_6H_5	0.8 M $CDCl_3$	60 : 40
CH_3	$(CH_3)_2PS$	0.9 M C_6H_6	20 : 80
CH_3	$(CH_3)_2PS$	1.0 M $CDCl_3$	45 : 55
CH_3	$(CH_3)_2PS$	1.0 M $(CH_3)_2SO$	40 : 60

Ring closure and the resulting pentacoordination of the bridgehead phosphorus is established both for *(4)* and for *(6)* by the upfield shift of δ^{31}P (solution in $CDCl_3$) = −30 to −50 and −20 to −40, respectively. In benzene the shifts are generally at still higher field and in dimethyl sulfoxide at lower field. This dependence is particularly pronounced in adducts with electron-withdrawing groups R (δ^{31}P shift of about 20). It is interpreted as being due to slight participation of the zwitterionic forms *(3)* and *(5)*, which are favored by polar solvents. *(3)* and *(5)* are obviously separated from each other by a rotational barrier. Only at temperatures of 70 to 90 °C does the rearrangement *(3, 4)*/*(5, 6)* become fast enough for coalescence of the ^{1}H(PCH_3) signals of the two isomeric adducts. Rearrangement is intramolecular and does not proceed *via* reverse dissociation such as *(6)* ⇄ *(1)* + *(2)* ⇄ *(4)*. This follows from the failure of added azaphosphole *(1a)* to participate in coalescence.

A third isomeric adduct is observed on reaction of *(1a)* with *(2a)* and with *(2e)* in benzene: 1-dimethylthiophos-

[*] Prof. Dr. A. Schmidpeter, Dipl.-Chem. T. von Criegern
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

phinoyl- and 1-benzoyl-azaphospholium thiocyanate *(7c)* and *(7e)*, respectively. They are formed to the extent of about 2/3 as a result of kinetic control and are prevented from undergoing fast subsequent reaction by their sparing solubility in benzene. In chloroform solution *(7c)* is transformed, *via* regeneration of *(1a)* and *(2c)* (observable by NMR spectroscopy) into a solution of an equilibrium mixture of *(4)*, *(6)*; the same reaction also occurs somewhat slower in benzene suspension.

7-Methyl-5,7-diaza-1-phosphabicyclo[3.2.0]hept-2-ene-6-thiones (4) and 7-thia-5-aza-1-phosphabicyclo[3.2.0]hept-2-en-6-imines (6)

The yellow color of a concentrated solution of *(1)* in $CHCl_3$ or CH_2Cl_2 largely or completely disappears on addition of an excess of isothiocyanate *(2)*. The cycloadducts *(4)*, R = CH_3, or *(6)*, R = C_6H_5, $(CH_3)_2PS$, $(C_6H_5)_2PS$, C_6H_5CO, precipitate as colorless crystals, either spontaneously or on addition of *n*-pentane.

2,2-Dimethyl-1-dimethylthiophosphinoyl- and -1-benzoyl-1,2-azaphospholium thiocyanates (7)

On addition of an equimolar amount of the isothiocyanates *(2c)* or *(2e)* to a solution of *(1a)* (10 mmol) in benzene (250 ml), a voluminous colorless crystalline precipitate of *(7c)* or *(7e)* is immediately formed. Only *(7e)* can be recrystallized without decomposition from acetonitrile.

$(CO)_5Cr \cdot SFeCo_2(CO)_9$: An Organometallic Donor-Acceptor Complex[**]

By *Felix Richter* and *Heinrich Vahrenkamp*[*]

While the sulfur ions in the solid state structures of metal sulfides are usually surrounded by four or six metal ions, six-coordination of sulfur by metals is unknown in the covalent complexes, and four-coordination of the sulfur atoms is very rare[1]. This could be rationalized by assuming that in a covalent tetrahedral SM_4 arrangement two of the four metal-sulfur bonds must formally be donor-acceptor bonds, which would lead to accumulation of positive charge at the sulfur. Opposing evidence comes from the observation that complexes with SM_3 structural units release electrons very readily[2]; this is explainable in terms of accumulation of negative charge density as a result of linkage of the sulfur atom to three electropositive metal atoms. In the case of complex *(1)*[3] with a formal donor-acceptor (sulfur-metal) bond, the former argument would predict the absence of Lewis base properties whereas the latter argument would predict the complex to have good Lewis base properties.

(1)

(2)

Our experiment supports the latter alternative. *(1)* reacts with a solution of $(CO)_5Cr \cdot THF$ to give the new tetranuclear complex *(2)*. The composition of *(2)* is confirmed by elemental analysis and an EI mass spectrum. Its IR spectrum in the CO region (in cyclohexane: 2108 w, 2071 m, 2059 s, 2040 m, 2033 w, 1989 m, 1963 cm^{-1} s) can be reconstructed by combination of the spectrum of *(1)*[3] and the two typical bands of a $(CO)_5CrL$ complex. The structure suggested was confirmed by X-ray methods[4] (cf. Fig. 1). *(2)* is the first complex we know to have a sulfur atom linked to three different metal atoms.

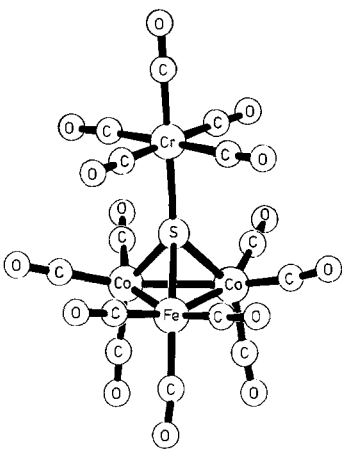

Fig. 1. Molecular structure of the tetranuclear complex *(2)*. Bond lengths: Co—Co and Fe—Co = 255.7 ± 0.3 pm, Co—S and Fe—S = 214.5 ± 0.5 pm, Cr—S = 235.1 pm. The Fe and Co atoms were assigned arbitrarily.

As in the structure of *(1)*[5a], the iron and cobalt atoms of *(2)* are indistinguishable by crystallography. Moreover, the donor complex *(1)* is almost unchanged in *(2)*: the metal-metal bond lengths are equal, and the metal sulfur bonds are shortened by only 1 pm. On the other hand, the Cr—S bond in *(2)* is significantly shorter than in other $(CO)_5CrL$ complexes containing sulfur ligands[6]. Both results can be interpreted by assuming the S→Cr σ donor function to induce a comparably strong S←Cr π acceptor function, which strengthens the Cr—S bond and balances the electronic requirements of the "ligand" *(1)*.

The organometallic Lewis base *(1)* is much less reactive than the isoelectronic compound $PCo_3(CO)_9$[7], which even reacts with itself at room temperature. The reason is probably that the HOMO in *(1)* does not correspond to the sulfur lone pair[5b]. This fact and the bond delocalization apparent from the structure and the IR spectrum of *(2)* justify the conclusion that the cluster *(1)* is an electron reservoir with properties similar to $RCCo_3(CO)_9$[8].

Procedure

A solution of *(1)* (280 mg, 0.6 mmol) in *n*-hexane (25 ml) is added to a solution of $(CO)_5Cr$ (0.6 mmol) in tetrahydrofuran (8 ml) generated by irradiation. The mixture is immediately

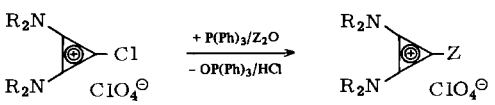
S_E Reactions on the C_3^+-Ring: π-Attack[**]

By *Robert Weiss* and *Claus Priesner*[*]

All substitutions on the aromatic cyclopropenylium ion discovered so far are either variants of classical nucleophilic aromatic substitution[1] or 4z exchange reactions[2]. We now report the first example of an electrophilic aromatic substitution in this system.



The hypothetical σ complex *(1)* possesses the unusual structure of an α,β-dicarbenium ion[3], suggesting *a priori* that electrophilic substitution at the C_3^+ ring requires the assistance of two strong donor groups according to *(2)*.

(1) *(2)*

E^+ = Electrophile, X = Donor substituent

If the readily accessible[1] cyclopropenylium salt *(3)* is subjected to redox hydrolysis with $P(Ph)_3/H_2O$ or $P(Ph)_3/D_2O$, then the substitution product *(4a)* or *(4b)* can be isolated in practically quantitative yield under mild conditions (CH_2Cl_2, *ca.* 20°C).

(3) *(4a)*, Z = H; *(4b)*, Z = D

R = *i*-C_3H_7

Compound *(4a)* has apparently already been obtained *via* another route by *Yoshida et al.* and has been repeatedly mentioned[4], but without citation of characteristic data. Compound *(4b)* was formerly unknown.

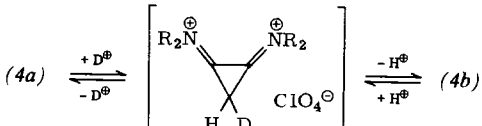


Table 1. Characteristic data of bis(diisopropylamino)cyclopropenylium perchlorate *(4a)* and its 3-deuterio derivative *(4b)*. Only end absorption is observed in the UV spectrum (CH_2Cl_2).

	M.p. [°C]	IR (KBr) [cm^{-1}]	^{1}H-NMR [a] τ	^{13}C-NMR [a] δ
(4a)	201—203 (dec.)	3105 (m) 2950 (m) 1895 (m) 1880 (m) 1570 (s)	2.6 (s, 1H) 6.1 (mc, 4H) 8.53/8.63 (d, $J=10$ Hz)	C-1,2 133.7 C-3 99.0
(4b)	203—205 (dec.)	2950 (m) 2350 (m) 1895 (m) 1880 (m) 1570 (s)	6.1 (mc, 4H) 8.53/8.63 (d, $J=10$ Hz)	

[a] In $CDCl_3$, rel. to TMS as internal standard.

The incomparably large upfield shift of the single ring proton in the ^{1}H-NMR spectrum of *(4a)* (cf. Table 1) shows that C-3 cannot be far removed from electroneutrality. The ^{13}C resonance frequency of this ring atom ($\delta=99.0$) even suggests a negative charge of −0.15 units[5]. Electrophilic attack at this ring site therefore appears feasible, even though the energy content of the corresponding σ-complex must be regarded as the decisive parameter. The transformation of *(4a)* into *(4b)* in acidic solution represents a model for such a reaction. No H/D exchange could be observed on the action of D_2O, CF_3CO_2D, or 50% D_2SO_4 on *(4a)*. However, the pure deuteration product *(4b)* could be isolated within a few minutes by dilution of a solution of *(4a)* in conc. D_2SO_4 with D_2O and extraction with CH_2Cl_2[6]. The reverse process *(4b)* → *(4a)* could also be accomplished in a corresponding manner and could also be detected in the mass spectrum of *(4b)*[2b, 10b].

The observed reaction conditions for this H/D exchange rule out a dissociation-recombination mechanism *via* a cyclopropenylidene intermediate[7] and are compatible only with electrophilic attack on the cyclopropenylium π-system according to the following scheme[8]:

(5)

Direct spectroscopic detection of a σ-complex *(5)* has not yet been possible; the steady state concentration of such a species, derived from the still unknown cyclopropanedione, should therefore be very low under our reaction conditions.

Both the π-electron distribution deduced from the NMR data of *(4a)* and the reaction behavior discussed above are in accord with a pronounced vinamidinium character[9] of this cyclopropenylium system. Although expected in principle[10a], the extent to which the 2π-aromatic C_3^+-ring loses its integrity under the perturbing influence of two strong donor groups is nevertheless surprising. Preliminary studies have shown[2b, 10b] that other electrophiles can also substitute the H atom attached to the ring of *(4a)*. Since the development of more effective alternative methods such reactions are of limited practical significance.

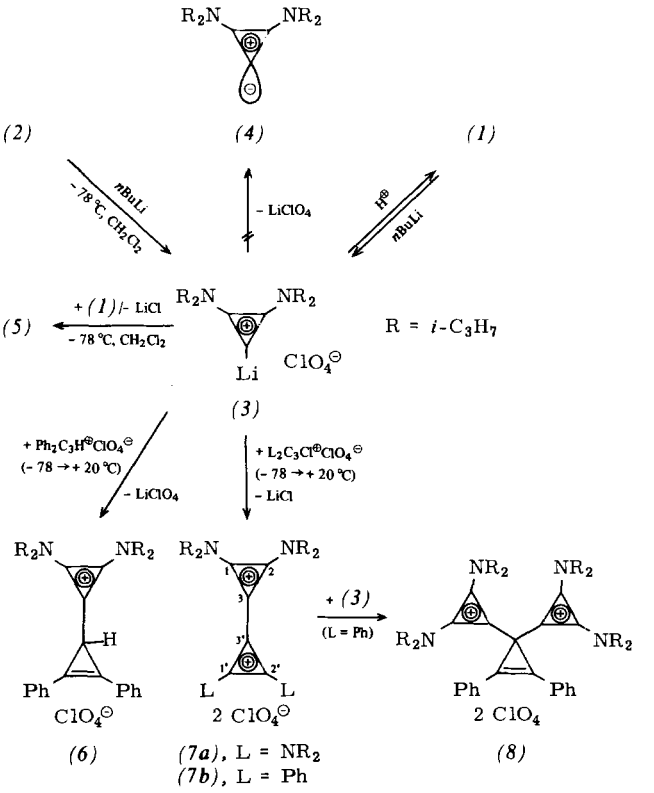
S_E Reactions on the C_3^+-Ring: σ-Attack[**]



By *Robert Weiss, Claus Priesner*, and *Hilmar Wolf*[*]

We have demonstrated[1] for the cyclopropenylium salt *(1)* that the C_3^+-ring can in principle undergo electrophilic aromatic substitution.

(1) R = *i*-C_3H_7 *(2)*

However, such S_E reactions with the optimally stabilized π-system of *(1)* require relatively drastic conditions and are limited to the strongest electrophiles. In connection with studies on "coupled three-membered rings"[2], we wished to use cyclopropenylium derivatives as electrophilic components. These relatively weak electrophiles do not react with *(1)*. Replacement of the H atom attached to the ring of *(1)* by a more electrofugic group should facilitate S_E reactions on the activated σ-skeleton of the aromatic system. We now report the first halogen/lithium exchange on the C_3^+ ring of *(2)* and syntheses with the metallocyclopropenylium system *(3)* obtainable in this way [Scheme 1].

Scheme 1.

Addition of equimolar amounts of *n*-butyllithium in *n*-hexane to the readily accessible[3a] chlorine compound *(2)* in anhydrous dichloromethane[3b] at −78 °C gives a yellow solution from which the dehalogenation product *(1)*[1] can be isolated quantitatively by addition of water and subsequent thawing. This reaction demonstrates that quantitative halogen/metal exchange[4b] is possible for *(2)* as it is for haloacetylenes[4a]. The lithium derivative *(3)* is a possible reactive intermediate[5]; its generation is favored by two factors: on the one hand, the bond between the three-membered ring and the halogen is susceptible to S_N attack[4a] at the halogen owing to sp hybridization, and on the other the alternative nucleophilic attack at position 3 of the C_3^+-ring is greatly hindered owing to the cyanine character of *(2)*[1]. CH_2Cl_2 solutions of the resulting organometallic species remain homogeneous down to −40 °C, *i.e.* under the reaction conditions employed, no "free" cyclopropenylidene *(4)* is present, which is reported by *Yoshida* to arise from *(1)* and *n*BuLi[6a], since its formation would be accompanied by precipitation of a molar equivalent of $LiClO_4$ which is insoluble in CH_2Cl_2. Deposition of lithium salts is, however, observed in a series of S_E reactions with *(3)* (cf. Scheme 1). Thus reaction of *(3)* with the weak electrophile *(1)* at −78 °C is accompanied by precipitation of $LiClO_4$. The salt-like reaction product *(5)* isolated pure in 65 % yield is shown by analytical data to formally correspond to a 1:1 adduct of *(1)* and *(4)*, whose structure could not be completely elucidated. Spectroscopic data confirm that *(5)* contains an intact cyclopropenylium system [m.p. 151 °C (dec.); IR (KBr): 1905 (m), 1630 (s), 1535 (vs), 1465 (m), 1370 (m) cm^{-1}].

Remarkably, *(5)* is formed as the sole product (65 % yield) even when a CH_2Cl_2 solution of *(3)* is warmed from −78 °C to room temperature. The reaction does not start until the temperature has risen above −40 °C; precipitation of lithium salt and a brown coloration are observed. Compound *(3)* and the solvent probably afford *(1)* and $LiCHCl_2$ *via* a metala-

[**] Functional *cyclo* C_3-Derivatives, Part 5. Also: Reactions of Coupled Three-Membered Rings, Part 9. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Parts 4 and 8: Ref. [1] and [2a], respectively.

tion equilibrium; recombination of *(3)* and *(1)* then yields the adduct *(5)*.

Reaction of *(3)* with the considerably more electrophilic 1,2-diphenylcyclopropenylium perchlorate instead of *(1)* gives the cyclopropenylcyclopropenylium salt *(6)* (cf. Scheme 1) whose spectroscopic data reveal the structural features of the two three-membered ring subunits [m.p. 181 °C (dec.); IR (KBr): 1900 (w), 1835 (m), 1535 (vs), 1440 (w), 1375 (w) cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 1.28$ (mc, 24H), 3.33 (s, 1H), 3.85 (mc, 4H), 7.72 (mc, 10H); ^{13}C-NMR ($CDCl_3$): $\delta = 131.5$ (C-1,2), 113.5 (C-3), 109 (C-1',2'), 15.7 (C-3')].

As high-energy derivatives of the hardly investigated $C_6H_5^+$ series, compounds of type *(6)* warrant synthetic and theoretical interest[7]. The only stable representative obtained so far is the perphenylated analog[8]. The procedure presented in this communication provides a flexible[9] entry to high-energy isomers of phenyl cations[7b] so that corresponding series of rearrangements[7a] can now be studied on a broad basis.

In the same way, *(3)* and *(2)* give an 85% yield of the triafulvalene dication salt *(7a)* which was recently synthesized by *Yoshida et al.*[6b] from *(1)*, *(2)*, and *n*-BuLi. Our procedure is superior with regard to yields and convenience, and in particular disposes of the need for *(1)* as a precursor of *(3)*[10]. In the interests of further simplification, *(2)* can be subjected to a Wurtz reaction with only 0.5 equivalent of *n*-BuLi (cf. *Experimental*). Moreover, *(7a)* is also accessible by oxidative coupling of *(3)*, *e.g.*

$$2\,(3) \xrightarrow[CH_2Cl_2,\ -78\text{ to }20\,^\circ C]{+I_2/-LiI} (7a)$$

(7a) belongs to the $C_6H_4^{2+}$ series, which may provide a new entry to the $C_6H_5^+$ and C_6H_6 series with their great potential for rearrangement[2, 7a].

An attempt to synthesize the unsymmetrical dication system *(7b)* gave 3,3-dicyclopropenyliocyclopropene *(8)* in 60% yield as the sole product [m.p. 151 °C (dec.); IR (KBr): 1890 (w), 1805 (m), 1550 (vs), 1450 (w), 1380 (w) cm^{-1}; ^{1}H-NMR: $\delta = 7.67$ (mc, 10H), 4.0 (mc, 4H), 3.43 (mc, 4H), 1.40/1.50 (d, 24H, $J = 10$ Hz), 1.14/1.24 (d, 24H, $J = 10$ Hz); UV (CH_2Cl_2): $\lambda_{max} = 330$ nm ($\varepsilon = 16600$)]. The spectroscopic data show that the second attack of *(3)* on *(7b)* occurs regiospecifically at position 3'. The UV spectrum of *(8)* is especially characteristic of a 1,2-diphenylcyclopropene derivative[8].

The first representative of the 3,3-dicyclopropenyliocyclopropenes raises interesting questions regarding electronic interaction between the cyclic subunits.

Experimental

n-BuLi (1 mmol; *ca.* 0.7 ml of a 20% solution in *n*-hexane) is added dropwise at −78 °C to a solution of *(2)* (740 mg, 1 mmol) in anhydrous CH_2Cl_2 (20 ml). The mixture is allowed to warm slowly to room temperature, LiCl is filtered off, and the product precipitated with Et_2O. The analytically pure product still contains CH_2Cl_2 (1:1 adduct) which can be removed at 80 °C *in vacuo*. Yield: 590 mg (88%) of *(7a)*, m.p. 295 °C (dec.). The substance is identical with an authentic sample[6b].

Structural Elucidation of Diastereoisomeric 1,3,6-Trioxacyclooctane Systems by Simultaneous Relaxation and Double Resonance Experiments[**]

By *Klaus Bock, Bernd Meyer*, and *Joachim Thiem*[*]

Reaction of methyl-β-D-cellobioside with benzylidene halide in pyridine[1] leads to a mixture of four methyl benzylidene-β-D-cellobiosides[2] which, after acetylation, can be resolved by various methods of separation into methyl penta-*O*-acetyl 4',6'-*O*-benzylidene-β-D-cellobioside (34%) and three isomeric methyl tri-*O*-acetyl-di-*O*-benzylidene-β-D-cellobiosides *(1)*—*(3)*[3]. Attempts to elucidate the structures of *(1)* and *(2)* by conventional NMR spectroscopic techniques have so far met without success. Interpretation of the NMR spectra in $CDCl_3$ and in C_6D_6 and normal double resonance investigations enabled assignment of only a limited number of structural units and location of a 4',6'-benzylidene moiety.

On measurement of the T_1 values by the inversion recovery method[4] some of the signals in the complex multiplets show sufficiently different spin-lattice relaxation times (see Table 1) that individual signals can readily be observed at zero crossover point of the other signals. However, since both carbohydrate rings have a β-D-*gluco* configuration with only axial ring protons, assignment of the signals from the coupling constants alone was impossible. We therefore decided to carry out simultaneous inversion recovery and double resonance measurements on the products. In this way it was possible to assign couplings to protons normally superposed by multiplets.

The spectra obtained for one experiment on using this approach in the case of *(1)* are shown in Figure 1. At a delay of 0.33 s between 180° and 90° pulses all the proton signals of the multiplet at δ = 3.60 (4'-H, 5'-H, 3-H), apart from that for 3-H, display zero intensity (see Fig. 1b), thus leaving the 3-H signal unsuperposed and clearly discernable. Irradiation of 2-H during the inversion recovery measurement (Fig. 1c) allows undisturbed observation of the effect at 3-H. Using this new technique we have been able to completely assign the NMR spectra of compounds *(1)* and *(2)*.

The results show that both *(1)* and *(2)* have an unusual structure in which the second benzylidene ring additionally binds the two β,1→4-glycosidically linked glucose rings *via* the atoms C-3 and C-2', while the remaining three acetoxy groups are sited on C-2, C-6, and C-3'. We are therefore dealing with a 1,3,6-trioxacyclooctane system. While the absolute configuration of all ring atoms in the saccharide is known, an assignment for the chiral acetal C-atom in the eight-membered ring (C-7) is still lacking.

On measurement of the nuclear Overhauser effect (NOE), irradiation of 7-H of *(1)* leads to distinct enhancement in intensity of only the 2'-H signal. When the same experiment is carried out on *(2)* the signal intensity of 3-H is enhanced. Saturation of 3-H in *(2)* expectedly gives a distinct nuclear

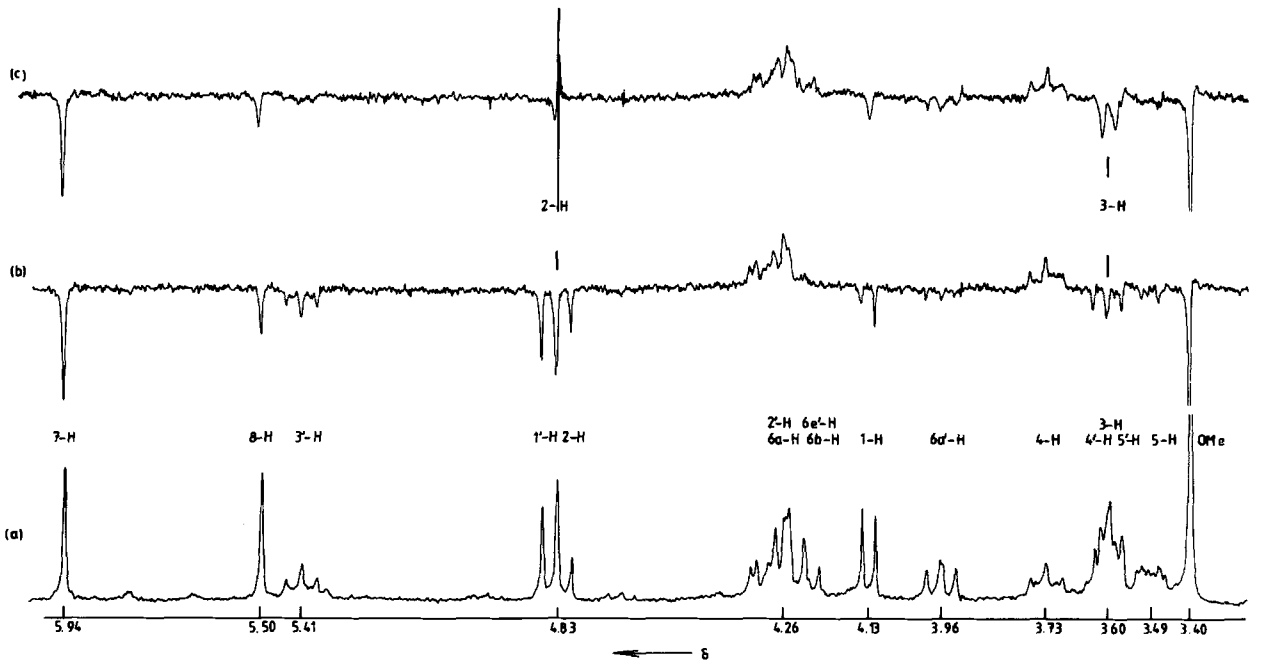

Fig. 1. a) Section from the 270-MHz ^{1}H-NMR spectrum of *(1)* in $CDCl_3$ ($c = 0.03$ mol/l, $T = 294$ K) from δ = 3.40—5.94; b) inversion recovery ($\tau_1 = 0.33$ s); c) inversion recovery as in (b) in combination with double resonance experiment at the frequency of 2-H.

Table 2. ^{1}H-NMR coupling constants J [Hz] of compounds *(1)* and *(2)*.

Cpd.	1,2	2,3	3,4	4,5	5,6a	5,6b	6a,6b	1',2'	2',3'	3',4'	4',5'	5',6a'	5',6e'	6a',6e'
(1)	8.2	9.2	7.8	9.8	4.2	2.6	—	8.8	9.8	9.4	9.4	10.3	4.8	10.3
(2)	8.0	9.9	8.8	9.5	—	—	—	8.8	9.5	9.5	9.5	10.4	5.2	10.4

Overhauser effect at 7-H and a still noticeable effect at 1'-H. Hence compound *(1)* has C-7-(*S*) chirality, while *(2)* is the (*R*)-diastereomer.

As can be deduced from the coupling constants (Table 2) the non-reducing glucose ring in *(1)* and *(2)*, which together with the condensed 1,3-dioxane ring forms a *trans*-trioxadecalin system, is present in a $^4C_1$ chair conformation. Only the $J_{1'2'}$ coupling constant (8.8 Hz) is greater than in normal disaccharides, presumably as a result of the condensed eight-membered ring. The reducing glucose ring also shows a definite $^4C_1$ chair conformation; but only in the case of *(1)* is a noticeably reduced transdiaxial coupling constant ($J_{3,4}$ = 7.8 Hz) observed.

According to studies with Dreiding models the 1,3,6-trioxacyclooctane structural unit in both *(1)* and *(2)* can be present in rigid twisted conformations or flexible "tub-chair" conformations, while butterfly ("tub-tub") or crown ("chair-chair") conformations[5] can be ruled out. Determination of the relative positions of the β,1→4-linked saccharides revealed the torsion angles 1'-H, C-1', C-4, O-4 (θ_1) and C-1', O-4, C-4, 4-H (θ_2) of $\theta_1 = 120°$ and $\theta_2 = 30°$[6]. Measurements on a model of the "tub-chair" conformation gave for *(1)* $\theta_1 \approx 0°$ and $\theta_2 \approx 150$—$180°$, consistent with an highly stretched molecule. In the case of *(2)* the corresponding torsional angles are $\theta_1 \approx 150$—$180°$ and $\theta_2 \approx 0°$, resulting in a sickle-shaped molecule, as confirmed by X-ray structure analysis[7].

Thus, in each case the eight-membered ring system of the isomers *(1)* and *(2)* assumes a "chair-tub" or a "tub-chair" conformation, determined by the fixed chair conformations of the saccharide molecules.

The First Oxostannate(II): $K_2Sn_2O_3$[1]

By *Rolf Michael Braun* and *Rudolf Hoppe*[*]

The amphoteric nature of $Sn(OH)_2$ has long been known. And yet no hydroxo- or oxostannate(II) of defined structure has so far been detected. At the end of a 25-year search we have now obtained the first single crystals of $K_2Sn_2O_3$ [1.1 $KO_{0.48}$ + SnO; under argon, sealed alumina cylinder, 550°C, 24 h (powder) or 7 d (single crystals)].

As a powder $K_2Sn_2O_3$ is deep yellow, while the platelet-shaped single crystals of hexagonal habit are brownish yellow. Hydrolysis takes place immediately on exposure to air, yielding black SnO. Dilute mineral acids readily dissolve the sample, leaving no residue.

$K_2Sn_2O_3$ forms trigonal-rhombohedral crystals, space group $R\bar{3}—C_{3i}^4$, with $a = 6.00_1$, $c = 14.33$ Å, $c/a = 2.39$, $Z = 3$. If c/a were $\sqrt{6} \approx 2.45$ the unit cell would show pseudo-cubic geometry, corresponding to the $K_2Pb_2O_3$ type[2]. $R = 4.7_2$ % [four-circle diffractometer data, Philips PW 1100, 348 *hkl*, $4° \leq \theta \leq 32°$; Mo-Kα; K^+ and Sn^{2+} refined anisotropically, not corrected for absorption (cf. Table 1)].

Table 1. Positional parameters [$\times 10^4$] and anisotropic temperature factors [$Å^2 \times 10^4$] of $K_2Sn_2O_3$ (standard deviations in parentheses).

Atom	x	y	z	$U_{11} = U_{22} = 2U_{12}$	U_{33}	$U_{23} = U_{13}$
K^1	0	0	7445(20)	183(10)	160(50)	0
K^2	0	0	2380(20)	220(10)	120(20)	0
Sn^1	0	0	0	106(5)	135(20)	0
Sn^2	0	0	4802(1)	79(4)	80(20)	0
O	1685(20)	3380(20)	618(10)	380(2)		

The anisotropic temperature factor has the form: $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$

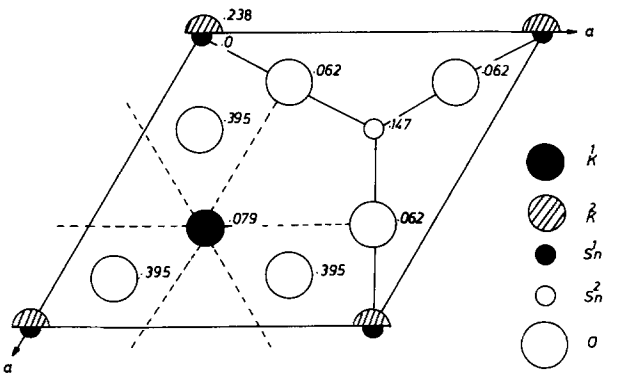

Fig. 1. Partial projection of crystal structure of $K_2Sn_2O_3$ along [001]; heights given in units of *c*.

Commensurate with $KSnO_{3/2}$, we are dealing with a perovskite variant in which half of the anions are missing in a regular manner. Unlike $KPbO_{3/2}$, however, in which the spatial network of the $PbO_{3/2}$ skeleton is retained, the present compound unexpectedly has a layer structure in which $Sn^{2+}—O_3^{2-}—Sn^{2+}$ layers are stacked parallel to the base in a rhombohedral sequence (cf. Fig. 1). Thus K^+ is partly in a distorted octahedral environment ($K^2—O$: 2.82_5 (3×), 3.07_7 (3×) Å) and partly in a hexagonal planar environment ($K^1—O$: 3.00_6 (3×), 3.01_2 (3×) Å). The Sn—O distances are 1.96_6 (Sn^1) (3×) and 2.09_9 (Sn^2) (3×) Å. The lone pair electrons of Sn^1 and Sn^2 are directed towards K^1 which thereby acquires the coordination number 8 (hexagonal bipyramid).

The *primary structure* is thus determined by the presence of two kinds of SnO_3 groups of symmetry C_{3v}, and the *secondary structure* by the fact that these groups are linked to form $Sn^1O_3Sn^2$ double layers; stacking of these layers along [001] is responsible for the *tertiary structure*. K^2 and K^1, which join the layers respectively *via* O^{2-} and *via* the Sn^{2+} lone pair electrons, are arranged between the layers.

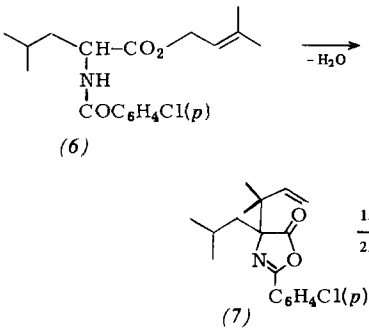
α-Amino Acids as Nucleophilic Acyl Equivalents: Synthesis of Ketones and Aldehydes by Means of Oxazolin-5-ones[**]

By *Rainald Lohmar* and *Wolfgang Steglich*[*]

Oxidative degradation of α-amino acids to aldehydes, CO_2, and ammonia and its reversal, the Strecker amino acid synthesis, demonstrate that the C-2 atom of the amino acids is a carbonyl equivalent. *Stork et al.*[1] exploited this relationship for the synthesis of aldehydes and ketones by alkylation of *N*-benzylideneglycine ethyl ester. The substitution products were subsequently hydrolyzed, reduced with $LiAlH_4$, and cleaved with periodate.

We found that the 2-oxazolin-5-ones *(2)*, which are readily accessible from α-amino acids or their *N*-acyl derivatives *(1)*, are particularly suitable as nucleophilic acyl equivalents. They can be substituted in position 4 by reaction with alkyl, benzyl, and allyl halides, as well as other electrophilic reagents, to give 2-oxazolin-5-ones *(3)*[2] which after hydrolysis to α,α-disubstituted *N*-acyl amino acids *(4)* afford the ketones *(5)* on oxidation with lead(IV) acetate[3] in hexamethylphosphoric triamide (HMPT)/tetrahydrofuran (THF) at 0—20°C (Table 1).



(1) *(2)* *(3)* *(4)* *(5)*

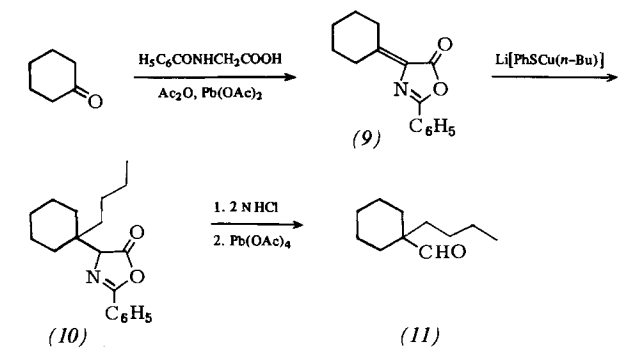
[a] Internal temperature of furnace on bulb-tube distillation. [b] From ethyl acetate. [c] Chromatographed on silica gel (CCl_4 eluent). [d] Semicarbazone, m.p. 69°C. [e] Rearranges on heating to 2-(*p*-chlorophenyl)-2-(1,1-dimethylallyl)-4-isobutyl-3-oxazolin-5-one [4a]. [f] Based on *(6)*. [g] Based on *(9)*. [h] Semicarbazone, m.p. 168—170°C.

Since 4-allyl substituted oxazolinones *(3)* are also accessible by dehydration of *N*-acyl amino acid allyl esters *via* Claisen rearrangement of the intermediate 5-allyloxyoxazoles[4], the scope of the new ketone synthesis is considerably enhanced. Thus, *N*-(*p*-chlorobenzoyl)leucine 3-methyl-2-butenyl ester *(6)* reacts with $PPh_3/C_2Cl_6/NEt_3$ in acetonitrile[5] at 0°C to give the oxazolinone *(7)*[6], which, after ring opening[7], can be oxidized to give the ketone *(8)* in good yield.



(6) *(7)* *(8)*

Allyl hippurates can react further to give 5-chlorooxazoles; in this case it is better to use the corresponding *N*-acylaminomalonic ester as starting material[8].

Oxidative cleavage of oxazolinones also permits a facile synthesis of aldehydes from carbonyl compounds according to

$$R^1R^2C{=}O \rightarrow R^1R^2R^3C{-}CHO$$

For example, cyclohexanone reacts with hippuric acid/acetic anhydride/lead(II) acetate[9] according to *Erlenmeyer* to form 4-cyclohexylideneoxazolinone *(9)*, which smoothly affords the oxazolinone *(10)*[11] on treatment with lithium phenylthio-*n*-butylcuprate[10]. After ring opening, *(10)* can be oxidized to the aldehyde *(11)* in 61 % yield.

[**] This work was supported by the Ministry of Science and Research of North Rhine-Westphalia and by gifts of chemicals from BASF.

Procedure

Hydrolysis of *(3)*: Crude *(3)* obtained by alkylation[2] of *(2)* (50 mmol) is stirred overnight in ether (100 ml) with 30% caustic soda (20 ml). After hydrolysis (TLC check) the aqueous phase is acidified with 2 N HCl and extracted with $CHCl_3$. The organic phase is washed with water, dried, and evaporated down. The residue is recrystallized from ethyl acetate. Alternatively, *(3)* can be hydrolyzed overnight with 2 N HCl (10 ml) in acetone (30 ml). After stirring with saturated $NaHCO_3$ solution (500 ml) and light petroleum (100 ml), the aqueous phase is acidified and worked up as above (concerning the hydrolysis of oxazolinones subject to strong steric hindrance, such as *(7)*, see ref. [7]).

Lead(IV) acetate oxidation: To a stirred solution of *(4)* (10 mmol) in HMPT (4 ml) and anhydrous THF (24 ml) at 0°C is added lead(IV) acetate (4.65 g, 10.5 mmol). As soon as the initially vigorous evolution of CO_2 subsides, the ice bath is removed and the mixture is allowed to warm up to 20°C. Once the reaction is complete (amount of CO_2, TLC check) the resulting *N*-acylketimine is hydrolyzed by addition of water (60 ml) and oxalic acid dihydrate (13 g) or 20% hydrochloric acid (50 ml) [*(5b)*, *(8)*] and the mixture is stirred for 2 h with light petroleum (40—60°C) (30 ml). The organic phase affords the carbonyl compound on drying and evaporation; it is purified by vacuum distillation or filtration through a silica gel column (CCl_4 as eluent).

$Ce_4O_4S_3$: A Mixed-Valence Cerium Oxide Sulfide

By *Winfried Wichelhaus*[*]

According to *Marcon*[1], oxide sulfides $M_4O_4S_3$ exist for M = Ce, Np, and Pu. These compounds are reported to contain the metals as M^{3+} and M^{4+} ions and to crystallize in a pseudohexagonal superstructure of Ce_2O_2S. The conditions for synthesis and the crystal structure have not yet been reported.

The author's own systematic studies on oxide sulfides of rare earth metals showed that single crystals of $Ce_4O_4S_3$ can be prepared by reaction of CeO_2 with Ce_2S_3 in a NaCl/KI melt. The crystal structure was solved from four-circle diffractometer data (499 reflections with $I > 2\sigma(I)$) and refined to $R = 0.031$ for isotropic temperature factors. $Ce_4O_4S_3$ forms orthorhombic crystals, space group Pbam (no. 55), with $a = 6.856$, $b = 14.558$, $c = 3.984$ Å; $Z = 2$; $d_{calc} = 6.073$, $d_{exp} = 6.04$ g/cm³. The atoms occupy the positions listed in Table 1.

Table 1. Positional parameters and temperature factors of $Ce_4O_4S_3$.

Atom	Position	x	y	z	B [Å²]
Ce(1)	4 g	0.2180	0.1618	0	0.39
Ce(2)	4 h	0.2880	0.4225	½	0.32
S(1)	2 c	0	½	0	0.48
S(2)	4 h	0.0126	0.2812	½	0.39
O(1)	4 g	0.3746	0.3762	0	0.69
O(2)	4 h	0.1351	0.0694	½	0.48

The structure of $Ce_4O_4S_3$ contains $[Ce_4O_4]^{6+}$ units one-dimensionally linked along [001] and joined by common S^{2-} ions. It cannot be described as a superstructure of Ce_2O_2S[2] which would contain layers of $[Ce_2O_2]^{2+}$ and S^{2-}

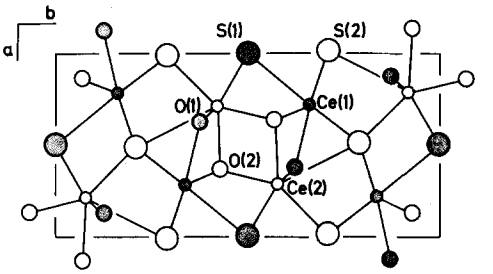

Fig. 1. Crystal structure of $Ce_4O_4S_3$; solid circles for $z = 0$, open circles for $z = ½$.

The Ce in $Ce_4O_4S_3$ occupies two crystallographically distinct positions. These differ significantly in their coordination by anions; distances {number}: Ce(1)—O = 2.42—2.46 Å {3}, Ce(1)—S = 2.98—3.05 Å {5}; Ce(2)—O = 2.17—2.38 Å {4}, Ce(2)—S = 2.79—3.34 Å {4}. Assignment of valence is possible on the basis of the shortest bond lengths. $Ce_4O_4S_3$ is the first reported mixed-valence oxide sulfide of rare earth metals, containing both Ce^{3+} [Ce(1)] and Ce^{4+} [Ce(2)]. In agreement with its formulation as $Ce^{III}Ce^{IV}_2O_4S_3$, it exhibits paramagnetic behavior ($\theta = -42$ K; $\mu_{exp}/\mu_B = 2.48$, based on Ce^{3+}). The compound is a semiconductor. Isotypic oxide sulfides $Ln^{III}M^{IV}_2O_4S_3$ could be prepared by replacement of Ce^{3+} by Ln^{3+} (Ln = Gd—Lu, Y) and of Ce^{4+} by M^{4+} (M = Zr, Hf): *e.g.* $Y_2Zr_2O_4S_3$ with $a = 6.520$, $b = 14.196$, $c = 3.680$ Å[3].

Experimental

CeO_2 (860.6 mg, 5 mmol), Ce_2S_3 (940.6 mg, 2.5 mmol), and S (80 mg) were melted together with a eutectic mixture of NaCl/KI (5 g) in an evacuated quartz ampoule (i.d. 15 mm, *l* 100 mm). The horizontal ampoule was heated in a two zone furnace (600—550°), the reactants being located in the higher temperature zone. After several days' heating, black needles of $Ce_4O_4S_3$ were formed. Relatively large single crystals were found in the colder part of the ampoule. The solidified melt was dissolved in water, filtered, and the residual cerium oxide sulfide freed from excess S by washing with CS_2. $Ce_4O_4S_3$ decomposes above 730°C *in vacuo* with separation of S; highly pure Ce_2O_2S is formed. The reaction is reversible.

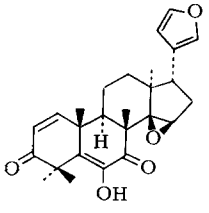
Toonacilin and 6-Acetoxytoonacilin, Two Novel B-*seco*-Tetranortriterpenoids with Antifeeding Activity[**]



By *Wolfgang Kraus*, *Wolf Grimminger*, and *Gisela Sawitzki*[*]

Several types of shrubs and trees of the Meliaceae family are rarely attacked by insects; extracts from the leaves or fruits of these plants can be used as pesticides for the protection of other plant varieties[1]. So far, azadirachtin[2] from *Azadirachta indica* A. Juss and meliantriol[3] from *Melia azederach* L. are already known to be active anti-feeding principles. Extracts from leaves of *Toona ciliata* M. J. Roem. *var. australis* exhibit a strong antifeeding and insecticidal activity on the moth *Hypsipyla grandella* Zeller (Lep., Pyralidae)[4] and the Mexican bean beetle *Epilachna varivestis* Muls. (Coleoptera, Coccinellidae)[1]. The latter is known as a virulent pest in soybean plantations in America. We report here on the isolation and structural elucidation of two novel compounds from the bark of *Toona ciliata* which act as feeding repellents to *Epilachna varivestis*[5].

The two compounds, for which we have suggested the names toonacilin *(1)* and 6-acetoxytoonacilin *(2)*, are the first B-*seco*-tetranortriterpenoids with an intact Ring A which are related to cedrelone *(3)*.

(1), R = H
(2), R = OAc

(3)

Isolation: After repeated column chromatography on silica gel the ether extract from 20.8 kg of powdered bark[6] yielded 12 g of a fraction containing toonacilin. From methanolic solution there first precipitated 1 g of a 1:1 mixture of crystals of *(1)* and *(2)* (prisms, m.p. 151—152 °C). After concentration by evaporation, the mother liquor afforded 7 g of pure *(1)* (needles, m.p. 118—119 °C, $[\alpha]_D^{20} = +69°$ ($CHCl_3$, $c = 1$ g/100 ml)). Preparative high-pressure liquid chromatography of the mixed crystals followed by crystallization from methanol gave 335 mg of pure *(2)* (prisms, m.p. 215 °C, $[\alpha]_D^{20} = +42.5°$ ($CHCl_3$, $c = 1$ g/100 ml)).

Structure of toonacilin (1): High resolution of the M^+ signal gave the mass 554.25097, thus indicating the empirical formula $C_{31}H_{38}O_9$ (calc. 554.25159); *R* value 13. The ^{1}H-NMR spectrum [in $CDCl_3$, δ referred to TMS = 0] shows four methyl groups (0.97, 3H; 1.01, 3H; 1.09, 6H), two acetoxy groups (1.79 and 1.99), one methyl ester group (3.65), one *exo*-methylene group (5.21 and 5.39, $J_{gem} = 1.0$ Hz), an isolated six-membered ring enone system (6.18 and 7.24, d, $J_{AB} = 10.4$ Hz) and a furan ring (6.16, 7.12 and 7.31). It follows from signals at δ = 5.34 and 5.36 that the two acetoxy groups are bound to secondary C atoms in a vicinal *cis* arrangement. The broad singlet at δ = 3.94 indicates an ether function. The ^{13}C-NMR spectrum (Table 1) shows three quaternary C atoms (δ = 41.9, 44.7, 46.0). The remaining ^{13}C-NMR signals were completely assigned by selective ^{1}H-^{13}C decoupling (IR and mass spectra, see Table 2).

From these structural units and assumption of biogenesis by oxidative ring opening of a 14,15-epoxymeliacane[7] [*(3)* or a precursor thereof] toonacilin was assigned the structure *(1)*. An isomeric C-*seco* structure can be be ruled out since the ^{1}H-NMR signal for H^{17} in *(1)* (δ = 2.94) is hardly shifted compared to that in *(3)*. The base peak in the mass spectrum (*m/e* = 209), formed by scission of the C^9—C^{10} bond, likewise provides evidence for structure *(1)*. The configuration at C^5, C^9, C^{11}, and C^{12} followed from decoupling experiments in the 360-MHz ^{1}H-NMR spectrum[8].

Table 1. ^{13}C-NMR data of compounds *(1)* and *(2)* (23 MHz, $CDCl_3$, δ rel. to TMS = 0).

Table 2. IR- and MS data of compounds *(1)* and *(2)*.

(1), IR (KBr): 3165, 3145 (furan), 3082 (=CH_2), 3037 (=C—H), 1766, 1745 (ester carbonyl), 1688 (α,β-unsaturated six-membered ring ketone), 1504 (furan), 1247 (C—O), 881 and 874 cm^{-1} (furan and =CH_2)

(1), MS: m/e = 554 (3.8%, M^+), 494 (7.6%), 476 (2.2%), 434 (9.2%), 346 (9.8%), 345 (8.7%, Ring-C-D fragment), 225 (39%), 209 (100%, Ring-A fragment), 208 (78%), 177 (40%), 121 (52%)

(2), IR: essentially the same as the spectrum of *(1)*

(2), MS: m/e = 612 (2%, M^+), 552 (2.6%), 492 (2.5%), 432 (1.5%), 345 (5.9%, Ring-C-D fragment), 267 (74%, Ring-A fragment), 225 (32%), 207 (100%, Ring-A fragment −60), 175 (18%), 137 (34%), 121 (15%)

Structure of 6-acetoxytoonacilin (2): From the greater mass of *(2)* compared to that of *(1)* (a difference of m/e = 58), an additional acetoxy signal at δ = 2.21, a —CH—O signal at δ = 5.31, and the simplification of the H^5 signal in the ^{1}H-NMR spectrum with hardly any other alteration in the pattern of the signals, it was concluded that *(2)* must be the acetoxy derivative of *(1)*. The structure and stereochemistry of *(2)* were confirmed by X-ray structural analysis (Fig. 1).

Ring Contraction in the Reaction of Cationic $C_5H_5Mo(CO)_2$ Chelate Complexes with Methyllithium

By *Henri Brunner, Heinrich Schwägerl, Joachim Wachter, George M. Reisner*, and *Ivan Bernal*[*]

A stereospecific phenyl addition at the azomethine carbon has been proposed to occur in the reaction of C_6H_5Li with $[C_5H_5Mo(CO)_2NN']PF_6$ (NN' = Schiff base derived from 2-pyridinecarbaldehyde and (*S*)-1-phenylethylamine)[1]. It has now been shown that reaction of CH_3Li with $[C_5H_5Mo(CO)_2NN']PF_6$ surprisingly results in a contraction of the five-membered chelate system present in the complex[2]. The rearrangement, which has been proved by IR, ^{1}H- and ^{13}C-NMR spectra as well as X-ray structure determination, involves several steps which can formally be considered as exchange of CH_3 for H at the azomethine carbon, addition of H to the imine nitrogen, cleavage of the Mo—N(pyridine) bond, and formation of a Mo—C bond to give a three-membered ring.

(1)

(2) *(3)*

R = CH_3, C_6H_5, $CH(CH_3)_2$, $CH_2C_6H_5$, $CH(CH_3)C_6H_5$

The cationic pyridinecarbaldimine complexes *(1)* react with excess CH_3Li to give the neutral compounds *(2)* and *(3)*. A strong N—H stretching vibration in the IR spectrum corresponds in the ^{1}H-NMR spectrum to a N*H*—C*H* coupling in the *N*-alkyl group of *(2)* and *(3)* and a N*H*—C*H* coupling within the three-membered ring of *(3)*, both of which collapse on addition of D_2O. In the complexes *(2)* the methyl substituent introduced gives a singlet. The structural relationship of both types of complexes *(2)* and *(3)* also is apparent from the similar ^{13}C-NMR spectra.

Compound *(2)* with R = $CH(CH_3)C_6H_5$ forms orange monoclinic crystals (space group $P2_1/a$) with cell constants a = 17.053(9), b = 11.185(5), c = 11.011(3) Å, β = 104.48(3)°; V = 2033.5 Å^3, d_{calc} = 1.44 g·cm^{-3}, Z = 4. From 6364 measured reflections ($Mo_{K\alpha}$ radiation, λ = 0.71069 Å) 3268 were used for the refinement of the structure (R value 5.4%). The dominant structural feature of the molecule is a η^2-aminomethylene ligand with *trans* arrangement of the large pyridyl and 1-phenylethyl substituents. In accord with exclusive for-

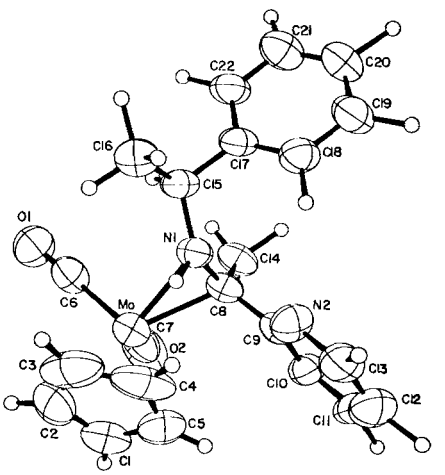

Fig. 1. ORTEP plot of *(2)*, R = $CH(CH_3)C_6H_5$. Bond lengths: Mo—N1 2.178(8), Mo—C8 2.223(12), C8—N1 1.418(16), Mo—C6 1.933(12), Mo—C7 1.932(13), Mo—Cp 2.348—2.407, C—C(phenyl and pyridyl ring) 1.381—1.415, C—N(pyridyl ring) 1.356(17), and 1.344(13) Å. Bond angles: N1—Mo—C8 37.6(4), N1—Mo—C6 92.3(4), C6—Mo—C7 78.4(6), C7—Mo—C8 78.9(5), Mo—N1—C8 72.9(6), Mo—C8—N1 69.5(6)°.

Houston, Texas 77004 (USA)

mation of the *trans* structure, the NMR spectra of *(2)* and *(3)* each exhibit only one set of signals.

Compounds *(2)* and *(3)* correspond to a previously described complex type[3]; distances and angles in the three-membered ring of *(2)* are comparable with those in $(CO)_4MnCH_2NR_2$[4].

Procedure

To a suspension of *(1)* (5.6 mmol) in THF (100 ml) is added dropwise at room temperature $LiCH_3$ (11.2 mmol) in diethyl ether. The reaction is completed by 30 minutes' heating under reflux. On chromatography over SiO_2 with benzene $[C_5H_5(CO)_3Mo]_2$ is first eluted, then *(2)*, and on addition of some ether also *(3)*. The products were recrystallized from ether/pentane at −35 °C. Yields of *(2)* and *(3)* are 3—23%, depending on the substituents R.

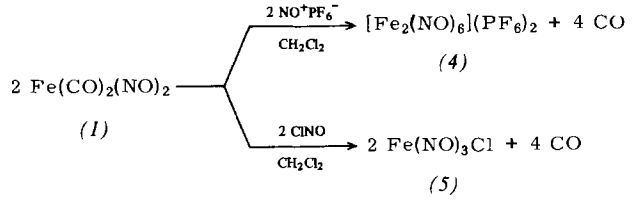
$[Fe_2(NO)_6]^{2+}$, A Binary Nitrosyliron Cation[**]



By *Max Herberhold* and *Reinhard Klein*[*]

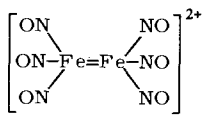
In the isoelectronic series of tetrahedral carbonyl(nitrosyl)-iron complexes $[Fe(CO)_{4-n}(NO)_n]^{n-2}$ ($n=0$—4), the cationic members *(2)* and *(3)* have so far not been reported:

$Fe(CO)_4^{2-}$ $Fe(CO)_3(NO)^-$ $Fe(CO)_2(NO)_2$ *(1)*

$\{Fe(CO)(NO)_3^+\}$ *(2)* $\{Fe(NO)_4^{2+}\}$ *(3)*

We attempted the preparation of *(2)* by reaction of the neutral complex *(1)* with $NO^+PF_6^-$ and found that even less than an equimolar amount of the nitrosyl salt effects cleavage of both CO ligands from the complex, leading to formation of the deep-green salt $[Fe_2(NO)_6](PF_6)_2$ *(4)*. This oxidation of *(1)* corresponds formally to the known[1] formation of the mononuclear complex $Fe(NO)_3Cl$ *(5)* from *(1)* and nitrosyl chloride.

The new compound *(4)* is also obtainable by removal of halide from *(5)*:



$$2\,(5) + 2\,AgPF_6 \xrightarrow[CH_2Cl_2]{} (4) + 2\,AgCl$$

[*] Prof. Dr. M. Herberhold, Dipl.-Chem. R. Klein
Anorganisch-chemisches Institut der Technischen Universität
Lothstrasse 17, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Particularly noteworthy, however, is the reaction of iron powder with $NO^+PF_6^-$ in nitromethane, which also leads to *(4)* without passage of NO gas.

We assume that the cation of the green salt *(4)* has a binuclear structure in which the iron atom achieves a noble gas configuration:

This structure is in agreement with the experimental findings on nitromethane solutions of *(4)*:

1. The ^{1}H-NMR spectrum reveals diamagnetism.
2. The equivalent conductivity ($\Lambda_e = 148 \pm 2\,cm^2/\Omega \cdot mol$ of a 10^{-3} M solution at −25.5 °C) lies within the range (150—180 $cm^2/\Omega \cdot mol$) typical for 2:1 electrolytes[2].
3. The Mössbauer spectrum[3] of a frozen solution ($\delta = 0.33$ mm/s, $\Delta E_Q = 0.49$ mm/s rel. to Fe metal; −196 °C) is reconcilable with only one sort of iron atoms.
4. The IR spectrum gives no indication of the presence of bridging nitrosyl ligands. The pattern of the two NO stretching absorptions corresponds to that expected for terminal nitrosyl groups (A+E). However, it remains unclear whether the NO ligands of both $[Fe(NO)_3]$-cation halves have D_{3d} (staggered) or D_{3h} (eclipsed) symmetry.

The salt *(4)* is stable only below −20 °C. It can be handled in polar solvents not having coordinating properties (CH_2Cl_2, $CHCl_3$); it is readily soluble in nitromethane. On addition of tetraalkylammonium halides, $NR_4^+X^-$, characteristic ν(NO) bands[4] of $Fe(NO_3)X$ (X = Cl, Br, I) appear in the IR spectrum. Phosphanes react with *(4)* to give adducts of the type $[Fe(NO_3)L]PF_6$ which behave like 1:1 electrolytes (*e.g. (6)*, L = PPh_3: $\Lambda_e = 82\,cm^2/\Omega \cdot mol$ in CH_3NO_2 at −25.5 °C).

Table 1. IR spectra in nitromethane solution (in cm^{-1}).

$Fe(CO)_2(NO)_2$	*(1)*	ν(NO) 1805 s, 1765 s;	ν(CO) 2095 s, 2043 s
$[Fe_2(NO)_6](PF_6)_2$	*(4)*	1937 w, 1828 s	
$Fe(NO)_3Cl$	*(5)*	1898 w, 1790 s	
$[Fe(NO)_3PPh_3]PF_6$	*(6)*	1919 m, 1828 s	
$[Fe(NO)_3PMe_3]PF_6$	*(7)*	1917 m, 1824 s	

Cationic nitrosylmetal complexes are of interest for investigations of catalysis[5]. Hexanitrosyldiiron(2+) is the first example of a binary nitrosylmetal cation.

Experimental[6]

(4): $NO^+PF_6^-$ (0.77 g, 4.4 mmol) is added to a solution of $Fe(CO_2)(NO)_2$ (0.52 g, 3 mmol) in dichloromethane (20 ml) and the mixture stirred for 2 h (evolution of gas), cooled to −30 °C, and filtered under N_2 pressure through a cold (−30 °C) frit. The dark-green residue consisting of *(4)* and unchanged $NO^+PF_6^-$ is washed with CH_2Cl_2 (2 × 30 ml) and the combined washings and filtrate slowly cooled to −78 °C. The dark-green fibrous needles which crystallize out are washed several times with pentane (−40 °C) and dried for 3 h at −78 °C/10^{-2} torr. Yield 0.08—0.10 g (*ca.* 10%).

(6): $NO^+PF_6^-$ (0.35 g, 2 mmol) is added portionwise to a stirred solution of *(1)* (0.34 g, 2 mmol) in nitromethane (20 ml) at −30 °C. When evolution of CO has ceased (after *ca.* 5 min), a cold (−30 °C) solution of triphenylphosphane (0.54 g, 2 mmol) in nitromethane is added dropwise to the mixture. On subsequent addition of cold toluene lustrous green leaflets of *(6)* crystallize out which are then washed at −30 °C with

toluene and pentane, recrystallized from CH_3NO_2/Et_2O, and finally dried in a high vacuum; dec. pt. 118°C (in N_2-filled capillary tubes). Yield 80–90%.

The trimethylphosphane complex $[Fe(NO_3)PMe_3]PF_6$ *(7)* is formed in an analogous way, dec. pt. 143°C.

γ-Sultenes and 1,3-Oxazolidinethiones by 1,3-Dipolar Cycloaddition of Thioketene *S*-Oxides to Azomethines[**]

By *Ernst Schaumann, Jörn Ehlers*, and *Ulrich Behrens*[*]

Thioketenes undergo [2+2] cycloadditions with azomethines to give β-thiolactams[1]. The analogous β-thiolactam *S*-oxide structure is ruled out for the 1:1 adduct of thioketene *S*-oxide *(1b)*[2a] and the azomethine *(2a)* because, in contrast to independently synthesized compounds *(3)*[2b], the product fails to show a *S*-oxide band in the IR spectrum. The spectroscopic data (Table 1) are in accord with the structure of a 1,2,4-oxathiazolidine *(4)*, *i.e.* a representative of the still largely unknown[3] cyclic esters of sulfenic acid (sultenes). Thus *(1)* surprisingly reacts as a 1,3 dipole[4a]. Although a dipolar resonance structure has been considered in the description of the ground state of other thiocarbonyl oxides[4b], it has not previously been detected in reactions.

(3) *(1)* *(2)* *(4)*

(1a), *(4a)*-*(6a)*: $R^1 = CH(CH_3)_2$, $R^2 = C(CH_3)_3$
(1b), *(4b,c)*-*(6b,c)*: $R^1 + R^2 = -C(CH_3)_2-(CH_2)_3-C(CH_3)_2-$
(2a), *(4a,b)*-*(6a,b)*: $R^3 + R^4 =$ 
(2b), *(4c)*-*(6c)*: $R^3 = CH_3$, $R^4 = C_6H_5$

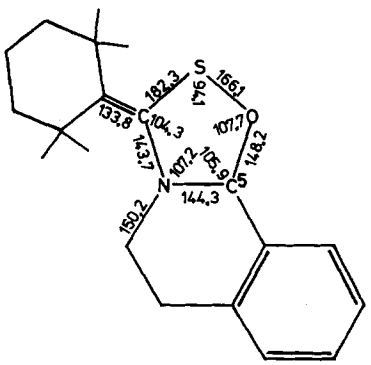
[**] This work was supported by the Fonds der Chemischen Industrie.

Table 1. Reaction conditions, yields, and principal IR bands of *(4)*, *(6)*.

	T [°C]	Reaction time	Solvent	Yield [%]	M.p. [°C]	IR (KBr) [cm⁻¹]
(4b)	25	1 d	Ether	70 [a]	97—98 [b]	1575(C=C)
(6a)	25	12 h	Ether	58 [c]	103—105	1485(Thioamide-B)
(6b)	40	6 h	None	72 [c]	96—97	1480(Thioamide-B)
(6c)	55	10 d	None	48 [c]	94—95	1485(Thioamide-B)

[a] *(4b)* crystallizes from a small volume of diethyl ether. [b] On melting *(4b)* undergoes partial conversion into *(6b)*. [c] Isolated by preparative layer chromatography on silica gel (Kieselgel PF 254, eluent dichloromethane/light petroleum or ethyl acetate/light petroleum).

X-Ray structure analysis[5] of *(4b)* confirms the proposed structure (cf. Fig. 1). The bond lengths in the C—S—O—C moiety largely correspond to the values already measured for an open chain sulfenic ester, while the angles at the sulfur and the nitrogen are *ca.* 6° smaller[6]. The oxathiazolidine ring exists in an envelope conformation, with C-5 deviating from the plane of the other ring atoms (±8 pm).



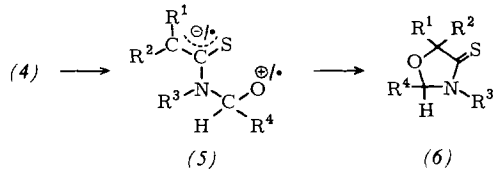


Fig. 1. Principal bond lengths [pm] (standard deviation 0.7 pm) and angles [°] (standard deviation 0.4°) in γ-sultene *(4b)*.

The oxathiazolidines *(4a)* and *(4c)* cannot be obtained in pure form by reaction of *(1a)* with *(2a)* or of *(1b)* with *(2b)* because rearrangement to the 1,3-oxazolidine-4-thiones *(6)* competes with formation of *(4)*.

(4) *(5)* *(6)*

The structure of the isomerization products has been proved by X-ray analysis in the case of *(6c)*[7]. The crystalline product *(4b)* is also unstable in solution, rearranging *via* rupture of the SO bond with a half-life of 14 h (at 52°C in $CDCl_3$) to *(6b)*; a 1,5 dipole or 1,5 diradical *(5)* is assumed as intermediate. Rearrangement of the sultenes *(4)* is apparently favored by the absence of neighboring groups with hetero atoms, in contrast to other heterocycles with the SO structural unit[3b,8], which precludes stabilization by no-bond resonance[9].

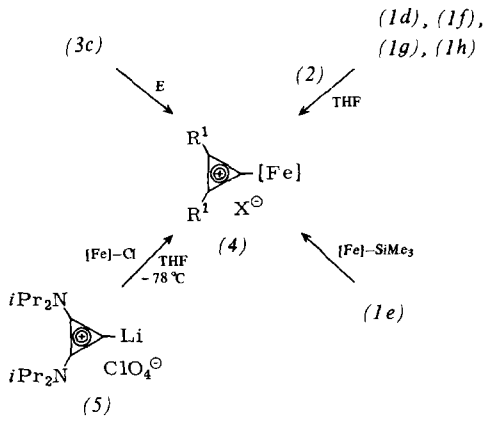
σ-Dicarbonylcyclopentadienyliron Derivatives of Cyclopropenes and Cyclopropenylium Salts[**]

By *Rudolf Gompper* and *Ekkehard Bartmann*[*]

We have synthesized dicarbonyl(η-cyclopentadienyl)(1,2,3-triphenylcyclopropenyl)iron *(3a)* as a potential masked cyclopropenyl anion from triphenylcyclopropenylium salts *(1a)* and sodium dicarbonyl(cyclopentadienyl)ferrate *(2)*[1]. However, *(3a)* does not react as a cyclopropenyl anion with electrophiles[1]. In order to establish whether cyclopropenyl-[Fe]

(1) *(2)* *(3)*



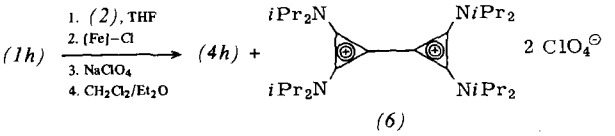
(1a), R^1, R^2 = Ph, $X=BF_4$, Br
(1b), R^1 = tBu, R^2 = Me, $X=ClO_4$
(1c), R^1 = Ph, R^2 = H, $X=ClO_4$
(1d), R^1 = tBu, $R^2=OCH_3$, $X=FSO_3$ [2]
(1e), R^1 = Ph, R^2 = Cl, $X=BF_4$
(1f), R^1 = Ph, $R^2=OCH_3$, $X=FSO_3$
(1g), $R^1=Et_2N$, R^2 = Cl, $X=ClO_4$
(1h), $R^1=iPr_2N$, R^2 = Cl, $X=ClO_4$

(3a), R^1, R^2 = Ph
(3b), R^1 = tBu, R^2 = Me
(3c), R^1 = Ph, P^2 = H

[Fe] = [Fe(C5H5)(CO)2]

derivatives act as synthetic equivalents of cyclopropenyl anions we have now prepared the derivative *(3b)* [yellow crystals; ^{1}H-NMR (CS_2): $\delta=1.18$ (s, 18H), 1.49 (s, 3H), 4.67 (s, 5H)] from *(1b)* and *(2)*. Compound *(3b)* is highly decomposable; it reacts similarly to *(3a)* with iodine in dichloromethane at −70 °C to form di-*tert*-butyl(methyl)cyclopropenylium pentaiodide (67 %) and [Fe]-I (*ca.* 60 %). *Green et al.*[3] obtained only dimers from *(1b)* and *(2)*.

Reaction of *(1c)* and *(2)* gives a 45 % yield of dicarbonyl(η-cyclopentadienyl)(2,3-diphenylcyclopropenyl)iron *(3c)* [IR (CS_2): 3063, 3055, 2840 (CH), 1995, 1937 (C≡O), 1782 cm^{-1} (cyclopropene); ^{1}H-NMR (CS_2): $\delta=2.63$ (s, 1H), 4.59 (s, 5H), 7.15—7.5 (m, 6H), 7.55—7.8 (m, 4H)]. It is much more stable than *(3b)* but less so than *(3a)*. The reactions of *(3c)* differ considerably from those of *(3a)*. All the electrophiles E tested so far (trityl tetrafluoroborate, $HOEt_2^+BF_4^-$, HCl, Br_2, I_2, $SbCl_5$, $(MeO)_3C^+BF_4^-$) give almost exclusively dicarbonyl(η-cyclopentadienyl)(σ-2,3-diphenylcyclopropenylidene)iron salts *(4c)* as pale yellow crystals [*(4c)*, $X=BF_4$: m.p. 185 °C (dec.); IR (KBr): 2045, 2005 (C≡O), 1368, 1330, 1310, 1288 cm^{-1} (three-membered ring); ^{1}H-NMR (CD_3CN): $\delta=5.55$ (s, 5H), 7.9 (mc, 6H), 8.3 (mc, 4H). *(4c)*, $X=ClO_4$: m.p. 183 °C (dec.). *(4c)*, X = Br: m.p. 175—180 °C (dec.). *(4c)*, $X=SbCl_6$: m.p. 188 °C (dec.)]. Compounds *(4c)* are structurally related with pentacarbonylchromium-[4a,5], pentacarbonylmolybdenum-[5], and palladium dichloride complexes[4b] of diphenylcyclopropylidene; the $PdCl_2$ complex of bis(diisopropylamino)cyclopropylidene can be transformed into a metallocyclopropenylium salt by treatment with antimony pentachloride[4c].



(5)

(4c), R^1 = Ph; *(4d)*, R^1 = tBu, $X=BF_4$
(4g), $R^1=Et_2N$, $X=ClO_4$; *(4h)*, $R^1=iPr_2N$, $X=ClO_4$

The complex salt *(4c)*, $X=BF_4$, is also obtained in *ca.* 50% yield on heating *(1e)* with dicarbonyl(cyclopentadienyl)(trimethylsilyl)ferrate[6] in dichloromethane or chloroform.

Other complex salts *(4)* arise from *(2)* and *(1d)*, *(1f)*, *(1g)*, or *(1h)*. In the case of *(1g)* and *(1h)*, some [Fe]—Cl is added on completion of reaction to remove excess *(2)*, followed by $NaClO_4$; in the case of *(1d)* and *(1f)* workup is performed with $HOEt_2^+BF_4^-$ [*(4d)*: 51 %, yellow crystals; m.p. 189—192 °C (dec.), IR (KBr): 2042, 2000 (C≡O), 1484, 1464, 1370, 1330 cm^{-1} (three-membered ring); ^{1}H-NMR ($CDCl_3$): $\delta=1.49$ (s, 18H), 5.41 (s, 5H), *(4g)*: 60 %, pale yellow crystals; m.p. 108—109 °C (dec.); IR (KBr): 2035, 1973 (C≡O), 1880, 1520, 1380, 1289 cm^{-1} (three-membered ring); ^{1}H-NMR ($CDCl_3$): $\delta=1.33$ (t, 12H), 3.55 (mc, 8H), 5.25 (s, 5H). *(4h)*: 8 %, light yellow crystals; m.p. 178—179 °C (dec.); IR (KBr): 2040, 1980 (C≡O), 1846, 1490, 1375, 1346, 1322 cm^{-1} (three-membered ring); ^{1}H-NMR ($CDCl_3$): $\delta=1.41$ (d, 24H), 4.15 (mc, 4H), 5.26 (s, 5H)]. Better yields (*ca.* 60 %) of *(4h)* than are obtained with *(1h)* and *(2)* [product also free from *(6)*] are achieved with dicarbonyl(cyclopentadienyl)iron chloride and the carbenoid *(5)*[7b] described by *Yoshida*.—The complex salts *(4)* are stable towards mineral acids.

Apart from the major product *(4h)* (42 %), reaction of *(1h)* with *(2)* affords the dication salt *(6)* [*(6)*·½ CH_2Cl_2: m.p. 260 °C (decrepitation); ^{1}H-NMR (CH_3CN): $\delta=1.31$ (d), 1.43 (d), 4.00 (sept), 4.20 (sept), 5.47 (s, CH_2Cl_2)].

(6)

Triafulvalene dication salts such as *(6)* were first obtained by *Yoshida*[8], and independently by *Weiss*[9].

Procedure

Synthesis of *(3a)*: A solution of *(2)* in tetrahydrofuran (THF) (10 ml), prepared from dimeric dicarbonyl(cyclopenta-

[**] Donor/acceptor-substituted Aromatic Systems, Part 2.—Part *1*: [1].

dienyl)iron $[Fe]_2$ (1.7 g, 4.8 mmol) and 2% Na amalgam (*ca.* 17 g), was slowly added to a suspension of *(1c)* (2.6 g, 8.95 mmol) in THF (10 ml) cooled to −78 °C. After warming to −10 °C the solvent was removed in a high vacuum, the residue taken up in ether/dioxane 2:1 (15 ml), and the solution quickly filtered, after cooling to −10 °C, through a G3 frit. The filtrate was evaporated to dryness in high vacuum at −10 °C, the residue taken up in ether (10 ml), and the solution stirred for several hours at −40 to −70 °C. Cooling was continued and the yellow crystals were freed from supernatant liquor by means of an immersion frit, washed with ether, ether/hexane 1:1, and hexane (5 ml of each, cooled at −70 °C), and dried in a high vacuum. Yield 1.51 g (46%), m.p. 66—67 °C on rapid heating, decomposition.

Synthesis of *(4c)*, X = BF_4: A solution of [Fe]—$SiMe_3$[6] (2.5 g, 10 mmol) and *(1e)* (3 g, 9.6 mmol) in chloroform (50 ml) was refluxed for 1 h. After cooling to room temperature, the volatile components were removed in a high vacuum. The residue was taken up in CH_2Cl_2 (15 ml) and the resulting solution filtered. Ether (20 ml) was slowly added to the filtrate; the precipitate was recrystallized from CH_2Cl_2/ether. Yield 1.75 g (40%).

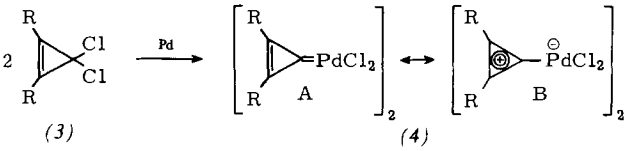
Coordinatively Unsaturated Transition Metal-Substituted Cyclopropenylium Systems[**]

By *Robert Weiss* and *Claus Priesner*[*]

We have examined the conditions under which coordinatively unsaturated transition metal-substituted species[1] *(1)* can exist.



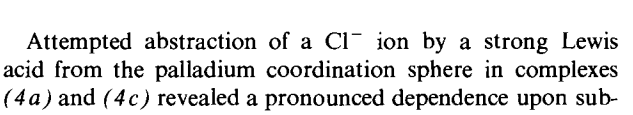
(1) *(2)*

ML_n = coordinatively unsaturated transition metal center

If the counterion $X^\ominus$ has ligand properties, it should be incorporated into the coordination sphere of M to form an electroneutral cyclopropenylidene complex *(2)*. With the aid of strong Lewis acids we have been able to transform compounds of type *(2)* into those of type *(1)*; the substituents R were found to exert a decisive influence.

We first synthesized complexes *(4a)*[2]—*(4c)* which are readily accessible in 60—70% yield from the dichlorides *(3)*[3] and Pd black according to *Öfele*[2].

(3) *(4)*



(a), R = C_6H_5; *(b)*, R = t-C_4H_9; *(c)*, R = $N(i\text{-}C_3H_7)_2$

The new carbene complexes *(4b)* and *(4c)* (Table 1) are orange-yellow, air-stable compounds showing considerable thermal stability, which, unlike *(4a)*, are readily soluble in polar solvents without pronounced donor character. Their IR spectra have the same habit as that of *(4a)* in the region of metal-halogen frequencies[2]. The IR and ^{1}H-NMR data of *(4b)* and *(4c)* are expectedly in accord with a large contribution from the resonance structure B.

Table 1. Characteristic data of the cyclopropenylidene complexes *(4b)* and *(4c)*.

	M.p. [°C]	IR (KBr) [cm^{-1}]	^{1}H-NMR δ	UV (CH_2Cl_2) λ_{max} [nm] (ε)
(4b)	225 (dec.)	1920 (m) 1480 (s) 1457 (s) 1396 (vs) 1383 (s)	1.47 (s) ($CDCl_3$, TMS)	
(4c)	185 (dec.)	1855 (m) 1500 (vs) 1455 (s) 1400 (m) 1374 (m)	4.0 (mc, 4H) 1.61/1.51 (d, J = 10 Hz, 24H) ([D_6-acetone, TMS)	325 (4100)

Attempted abstraction of a Cl^- ion by a strong Lewis acid from the palladium coordination sphere in complexes *(4a)* and *(4c)* revealed a pronounced dependence upon substituent R. Thus the action of $AgOSO_2CF_3$ on *(4a)* does not release AgCl, whereas AgCl is released gradually in the case of *(4b)* and instantaneously in the case of *(4c)*. No characteristic product of *(4b)* has been isolated; the desired reaction does, however, take place with *(4c)*.

R = i-C_3H_7 *(5)*

Compound *(5)* has so far only been isolated as amorphous material [m.p. >118 °C (dec.); IR (KBr): 1870 (s), 1525 (vs),

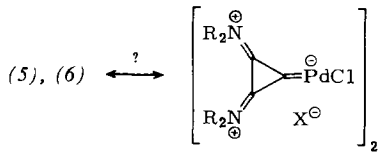
[**] Functional *cyclo*-C_3 Derivatives, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 5: [1a].

1464 (m), 1408 (m), 1380 (m), 1345 (s) cm^{-1}; ^{1}H-NMR (CD_3CN)[5]: $\delta = 3.93$ (mc, 4H); 1.52/1.42 (d, $J = 10$ Hz, 24H)]. The ionic formulation of *(5)* follows from the characteristic IR absorption bands of the anion at 1030, 1140, 1270 cm^{-1}. The fragment of highest mass number ($m/e = 237$) corresponds to demetalation with formation of the cation *(8)*.



The complexes *(4a)*—*(4c)* show a similar gradation of reactivity towards $SbCl_5$. Thus *(4a)* does not react at all, *(4b)* only reluctantly and in still unknown manner, but *(4c)* combines instantaneously and quantitatively to give the hexachloroantimonate *(6)* corresponding to *(5)*.

Compound *(6)* is a yellow, air-stable crystalline salt (m.p. 185°C (dec.)); its ^{1}H-NMR spectrum (CD_3CN[5]) resembles that of *(5)*. Apart from anion-induced differences, its IR spectrum is also similar to that of *(5)*. The presence of a discrete $SbCl_6^-$ ion is evidenced by an intense IR band at 340 cm^{-1} (ν_{as})[6].

To our knowledge, *(5)* and *(6)* are the first coordinatively unsaturated transition metal-substituted cyclopropenylium systems[7]. Such species are expected to undergo demetalating S_E reactions[1a]. We have been able to confirm this for two model reactions: thus *(6)* can be subjected to electrophilic chlorination by $SbCl_5$, giving *(7)*[4], and to protonolysis by conc. H_2SO_4[8], giving *(8)*[4].

It seems logical to attempt to correlate the increasing tendency of palladium to release Cl^- in the series *(4a)*—*(4c)* with the donor properties of R[9] and thus with the increasing weight of the polar resonance structure B. The ready formation of *(5)* and *(6)* might possibly be rationalized by assuming the three-membered ring in *(5)* and *(6)* to act as a four-electron donor according to the [3]radialene resonance structure[10] C. Hindered rotation of the NR_2 substituent has not yet been detected by ^{1}H-NMR spectroscopy, possibly owing to the coordinating properties of the solvent CD_3CN.

If the formulations *(5)* and *(6)* correctly represent the structural situation, then the compounds are formally tricoordinate d^8 complexes[11]. Such 14-electron systems play an important role in homogeneous catalysis[11].

Procedure

Synthesis of *(6)*: A well stirred suspension of *(3c)* (612 mg, 2 mmol) and pretreated[2] Pd black (212 mg) in anhydrous benzene (35 ml) is refluxed for 2 h. The new precipitate is extracted with CH_2Cl_2 and the carbene complex *(4c)* precipitated with ether; yield 520 mg (63 %) of analytically pure *(4c)*. $SbCl_5$ (297 mg, 1 mmol) in CH_2Cl_2 (5 ml) is added dropwise at room temperature to a stirred solution of *(4c)* (411 mg, 0.5 mmol) in CH_2Cl_2 (5 ml). A crystalline precipitate of *(6)* is rapidly formed. After 20 minutes' stirring, anhydrous CCl_4 (10 ml) is added and the salt *(6)* filtered off; yield 700 mg (94 %).

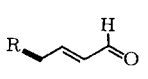
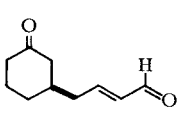
12	2-Cyclopenten-1-one [{—$(CH_2)_2$—CO—CH_2—}CH]		40	S		4.9 d (6.3)
13	2-Cyclohexen-1-one [{—$(CH_2)_3$—CO—CH_2—}CH]	only *(8b)*	48	S		4.92 d (6)
14	2-Cycloheptan-1-one [{—$(CH_2)_4$—CO—CH_2—}CH]		60	S		4.95 d (6)
15	Benzylideneacetophenone [$C_6H_5COCH_2CH(C_6H_5)$]		72	— [d]		4.8 m



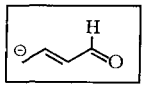
[a] According to ^{1}H-NMR, the 4-nitro-1-butene obtained is 74% deuterated in the β-position, and the 1-nitro-2-butene 83% deuterated in the γ position. [b] Mixture of diastereomers. [c] M.p. 66—68 °C. [d] M.p. 46—47 °C.

the allylic compound *(3)*[3] undergoes α,α double deprotonation to give *(5)*, whereas the homoallylic derivative *(4)*[4] yields dark red solutions of the α,β abstraction product *(6)*. This is shown by the reactions of *(5)* and *(6)* with *electrophiles*.



The C_3 nucleophile *(5)* reacts with acetone, cyclohexanone, benzaldehyde, and benzophenone at the α-nitro C atom to form nitro alcohols of type *(7)* [*(7a)*: E=$(CH_3)_2C(OH)$, 40%, b.p. 70 °C (bath)/0.3 torr, n_D^{20}=1.4588; *(7b)*: E=$(CH_2)_5C(OH)$, 60%, b.p. 90 °C (bath)/0.01 torr, n_D^{20}=1.4918; *(7c)*, E=$C_6H_5CH(OH)$, mixture of diastereomers, 70%, b.p. 120 °C/0.005 torr; *(7d)*: E=$(C_6H_5)_2C(OH)$, 53%, m.p. 75 °C]; their ^{1}H-NMR spectra show the multiplets expected for the vinyl groups[5].

The diene *(6)* affords the mixtures of the products *(8a)* and *(8b)* in the ratios and yields given in Table 1 (Nos. 1—11) on reaction with alkyl halides, aldehydes, or ketones. Separation can generally be accomplished by gas or column chromatography, and identification by the characteristic ^{1}H-NMR chemical shifts and coupling constants of the α-NO_2—CH_2 groups likewise listed in Table 1 [decoupling experiments with compounds *(8b)* give typical *trans* coupling constants of 13—17 Hz]. Interest attaches to the Michael additions (Nos. 12—15 of Table 1) which give the readily isolable products of δ attack on the π system *(6)*.



We have transformed three of the δ adducts *(8b)* into the α,β-unsaturated aldehydes *(9a)* and *(9b)* and into the

(9a), R = $CH(CH_3)_2$
(9b), R = $CH_2C_6H_5$

(10)

(11)

1,7-keto aldehyde *(10)*[7] by Nef reaction with $TiCl_3$[6] (Nos. 4, 6, and 13 in Table 1). Thus for synthetic purposes, *(6)* is not only a nitrobutadiene exhibiting umpolung [cf. *(2)*] but also a crotonaldehyde enolate equivalent [cf. *(11)*], which, unlike normal dienolates, preferentially reacts at the γ position to the carbonyl group and not at the α position.

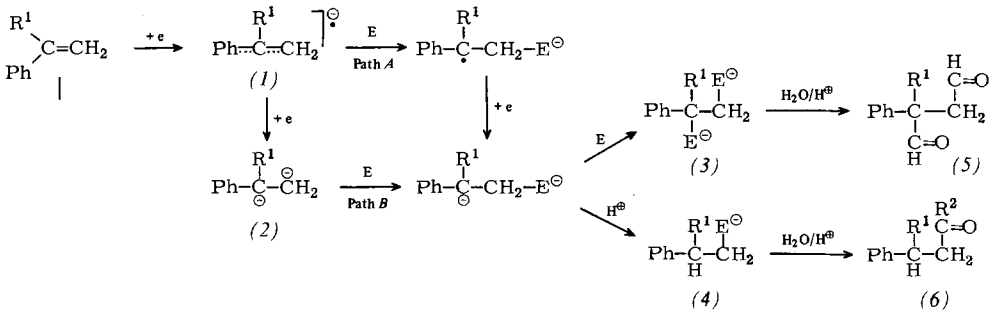
Cathodic Acylation of Aryl Olefins[**]

By *Rainer Engels* and *Hans J. Schäfer*[*]



Electrochemical reductive acylation has so far only been accomplished with activated olefins such as α,β-unsaturated carboxylic esters and nitriles[1]. We have now found that aryl olefins can be cathodically acylated, and in particular formylated (see Table 1).

Table 1. Products and yields of reductive acylation of aryl olefins.

Aryl olefin [a]	Electrophile	Product (current efficiency)
α-Methylstyrene	Acetonitrile	4-Phenyl-2-pentanone (68 %) [b]
α-Methylstyrene	*n*-Butyronitrile	2-Phenyl-4-heptanone (50 %) [b, c]
α-Methylstyrene	*i*-Butyronitrile	2-Methyl-5-phenyl-3-hexanone (54 %) [b]
Styrene	Acetonitrile	4-Phenyl-2-butanone (20 %) [d]
		1,4-Diphenylbutane (48 %) [d]
α-Methylstyrene	*N,N*-Dimethylformamide	2-Methyl-2-phenylsuccinaldehyde (86 %) [d, e]
		(91 %) [d, e, h]
Styrene	*N,N*-Dimethylformamide	Phenylsuccinaldehyde (82 %) [d, f]
		2,5-Diphenyladipaldehyde (12 %) [d, f, g]

[a] Electrolysis conditions: 20 mmol of aryl olefin and 40 mmol of $LiClO_4$ in 80 ml of anhydrous electrophile, diaphragm cell, platinum mesh cathode, current density *ca.* 10 to 30 mA/cm², current passed 20 mF.
[b] Determined by gas chromatography (5 % SE 30 on Chromosorb W).
[c] 2-Methyl-2-phenyl-3-hexanone (3 %) was detected as by-product.
[d] Isolated yield.
[e] Isolated as 4-methyl-4-phenyl-4,5-dihydropyridazine.
[f] Isolated as *O*-methyloxime derivative.
[g] Small amounts of 2-phenylpropanal appear as a further minor product.
[h] Reduction by lithium in *N,N*-dimethylformamide.

The reduction of the aryl olefins $Ph(R^1)C{=}CH_2$ at the cathode (directly or by deposited lithium) leads to radical anions *(1)* and/or dianions *(2)*[2] which can react by path A or path B with the electrophilic solvent E.

R^1 = H, Me
E = HCO–NMe_2, R^2–C≡N; *(3)*: $E^{\ominus}$ = –CH–NMe_2, *(4)*: $E^{\ominus}$ = –C=$N^{\ominus}$
R^2 = Me, *n*Pr, *i*Pr

The resulting anionized hemi-aminals *(3)*[3] and ketimines *(4)*[4] are subsequently hydrolyzed to the products *(5)* and *(6)*, respectively.

Procedure

α-Methylstyrene (2.36 g, 20 mmol) and lithium perchlorate (4.38 g, 40 mmol) are electrolyzed in anhydrous *N,N*-dimethylformamide (80 ml) at −10 °C in a diaphragm cell at a platinum mesh cathode (geometrical surface area 18 cm²) at a current density of *ca.* 25 mA/cm² until 20 mF have passed through the cell. The catholyte is added to a cold 80 % solution of hydrazine hydrate which has previously been acidified to pH 5 with conc. H_2SO_4, and the mixture is heated to 130 °C for 2 h. Bulb to bulb distillation (80—90 °C/0.1 torr) of the residue after the usual workup gives pure 4-methyl-4-phenyl-4,5-dihydropyridazine (1.48 g, 8.6 mmol) [^{1}H-NMR ($CDCl_3$): $\delta = 1.5$ (s, 3H), 4.5—4.65 (m, 1H), 6.2—6.4 (m, 2H), 7.1—7.4 (m, 6H); MS (70 eV): $m/e = 172$ (M^+, 4 %), 157 ($M^+ - CH_3$, 100 %)].

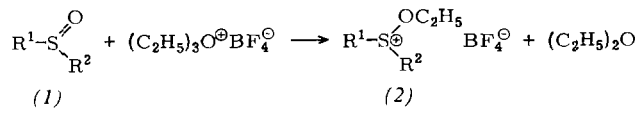
Synthesis of Donor-substituted Sulfonium Salts

By *Hans-Ulrich Wagner* and *Aviv Judelbaum*[*]

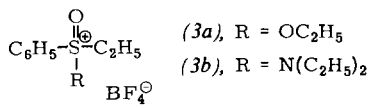


Despite their potential utility as synthetic intermediates, sulfonium salts of type *(A)* or *(B)* stabilized by donor substituents have hitherto not been isolated[1]. Only *N*-acyl derivatives of *(B)*[2] and a cyclic salt of type *(A)* stabilized with trifluoromethyl groups[3] have so far been described. *Kresze et al.* recently reported the synthesis of the related sulfonium salts *(C)*[4].

[*] Dr. H.-U. Wagner, Dipl.-Chem. A. Judelbaum
Institut für Organische Chemie der Universität
Karlstr. 23, D-8000 München 2 (Germany)

(A) (B) (C) R = Alkyl, Aryl

We have now found that the sulfonium salts *(2)* are accessible in almost quantitative yields by alkylation of the sulfinic acid derivatives *(1)* with triethyloxonium tetrafluoroborate in dichloromethane[5]. Characteristic examples are listed in Table 1.

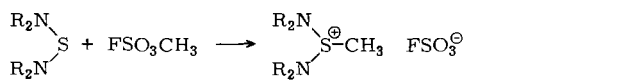


(1) *(2)*

Table 1. Some characteristic sulfonium salts *(2)*.

(2)	R^1	R^2	M.p. [°C]
(a)	C_6H_5	OC_2H_5	oil
(b)	C_6H_4-*p*-CH_3	OC_2H_5	28—30
(c)	C_6H_5	NH_2	oil
(d)	C_6H_5	NHC_2H_5	oil
(e)	C_6H_5	$NHCH(CH_3)_2$	oil
(f)	C_6H_5	$N(CH_3)_2$	18—19
(g)	C_6H_5	$N(C_2H_5)_2$	19—20
(h)	C_6H_5	$N[CH(CH_3)_2]_2$	139—141

The ^{1}H-NMR spectra of *(2a)* and *(2b)* show signals for *one* ABX_3 spin system for the protons of the ethyl groups[6] and thus afford evidence that the two ethoxy groups are equivalent, *i.e.* an alkylation of the sulfinate at the sulfur atom to give the salt *(3a)* can be ruled out. The given structure for the amino-substituted sulfonium salt *(2g)* could thus be demonstrated by the fact that the ^{1}H-NMR spectra of *(2g)*[7] and of the isomeric salt *(3b)* independently synthesized by us[8] are different.



(3a), R = OC_2H_5
(3b), R = $N(C_2H_5)_2$

That the three ligands of the sulfur atom in the sulfonium salts *(2)* must also be oriented pyramidally, as in the sulfinic acid derivatives *(1)*, is revealed in the ^{1}H-NMR spectra of those salts which bear diastereotopic groups: the signals of the ethyl groups of *(2a)*, *(2b)*, and *(2d)* appear as an ABX_3 system with a relative chemical shift of the AB part of 0.02 to 0.04 ppm. Correspondingly, the signals of the isopropyl groups of *(2e)* and *(2h)* appear as an AX_3Y_3 system with the larger relative chemical shift of the X_3Y_3 part of 0.20 ppm. Only in the case of *(2g)*[7] is the relative chemical shift too small to be recognizable in the spectrum.

The colorless salts *(2)* are stable towards air and water. Towards nucleophiles such as sodium hydroxide, triethylamine, or aniline they act as alkylating agents leading to re-formation of the sulfinic acid derivatives. Results of preliminary experiments on the nucleophilic substitution of the ethoxy groups of *(2)* are encouraging.

Regarding the synthesis of sulfonium salts of type *(C)* we have found that the salt *(5)* is obtainable by alkylation of the sulfur diamide *(4)* with methyl fluorosulfonate.

(4) *(5)* R = $CH(CH_3)_2$

Alkylation of *(4)* at one of the two nitrogen atoms can be ruled out on the basis of the ^{1}H-NMR spectrum of *(5)*[9]. The appearance of only one heptet signal for the CH fragments and of two doublet signals for the diastereotopic CH_3 groups indicates alkylation of *(4)* at sulfur to give the symmetrical sulfonium ion *(5)*.

Procedure

To a solution of the sulfinic acid derivative *(1)* (15 mmol) in anhydrous CH_2Cl_2 cooled to −20 °C is added 10 mmol $Et_3O^{\oplus}BF_4^{\ominus}$. The mixture is allowed to stand for 3 d at −20 °C (+20 °C in the case of *(2a)* and *(2b)*) and then the solvent is removed by distillation *in vacuo*. The oily residue is washed several times with anhydrous ether. The solid sulfonium salts *(2)* (Table 1) crystallize out on storage of the residues in a refrigerator; they can be purified by pressing on a clay tile.

(5) is obtained by slow dropwise addition of 10 mmol *(4)* to 10 mmol FSO_3CH_3 at 0 °C. After 1 d at 0 °C the reaction mixture is dissolved in CH_2Cl_2 and treated with activated charcoal. The salt *(5)* is precipitated from the solution by addition of ether. Repetition of this purification three times affords *(5)* as a colorless powder (m.p. 196—198 °C) in *ca.* 70 % yield.

Cyclooctenynes[**]

By *Hermann Petersen, Heinz Kolshorn*, and *Herbert Meier*[*]

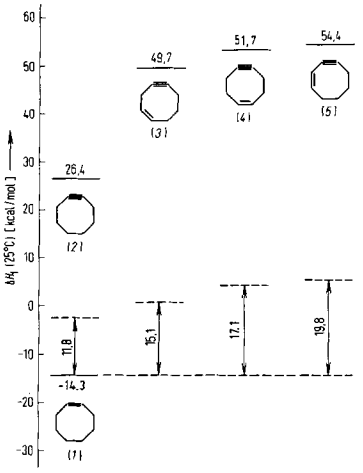
Linear arrangement of four carbon atoms on incorporation of a C≡C triple bond in a carbocyclic ring system is possible only from ten-membered rings onward. In smaller ring systems[1,2], such an arrangement leads to *geometrical ring strain*[1], defined as the sum of the individual deformation energies. Interaction between atoms not directly attached to each other induces additional deformations and hence also strain energies, which add to the sum total of *steric energy*.

The smallest stable cycloalkyne to have been isolated in pure form is cyclooctyne *(2)*[3]; ring strain and reactivity are enchanced when further sp^2 or sp carbon atoms are introduced into the eight-membered ring[4].

[*] Prof. Dr. H. Meier, Dipl.-Chem. H. Kolshorn, Dipl.-Chem. H. Petersen
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Figure 1 shows the enthalpies of formation ΔH_f of cyclooctene *(1)*, cyclooctyne *(2)*, and the three *cis*-cyclooctenynes *(3)*—*(5)* obtained by semiempirical quantum mechanical calculations[5] with complete optimization of geometry in each case[6].



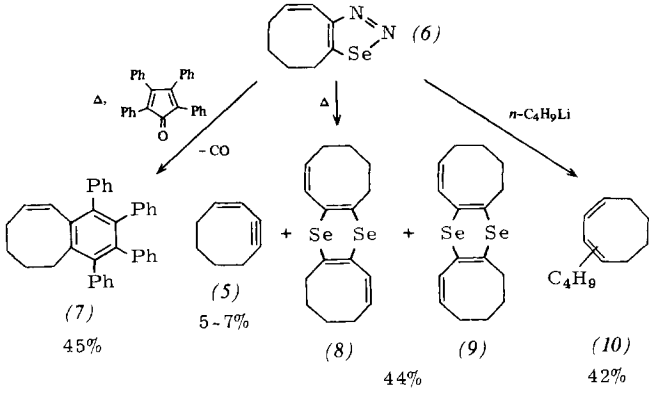


Fig. 1. Enthalpies of formation ΔH_f and strain energies E (dashed levels) of *(1)*—*(5)* calculated by the MINDO/2 procedure [5].

The ΔH_f values refer to the lowest energy conformations [symmetry (point group): *(1)*, *(3)*, *(5)* C_1; *(2)* C_2; *(4)* C_s]. Subtraction of the MINDO/2 value for the hydrogenation of an unstrained triple bond to a single bond (*e.g.* 2-butyne→*n*-butane) from the heats of formation of the enynes *(3)*—*(5)* and of the value for the hydrogenation to the *cis*-olefin (*e.g.* 2-butyne→*cis*-2-butene) from the enthalpy of formation of cyclooctyne *(2)* gives the excess enthalpies E (dashed lines). They constitute a direct measure of the ring strain. Since the non-bonding interactions in *(1)*—*(5)* are, to a first approximation, equal in magnitude, the values of E correspond to the geometrical strain. The value of 11.8 kcal/mol for cyclooctyne falls neatly in line with the values of 7—10 kcal/mol[7] determined experimentally from heats of hydrogenation and of 12.7[4] and 20.8 kcal/mol[8, 9] derived from force field calculations.

Compound *(5)*, with the conjugated system, is the most energy-rich of the *cis*-cyclooctenynes. Highly strained cycloalkynes can be readily prepared by fragmentation of the corresponding 1,2,3-selenadiazoles. We synthesized the selenadiazole *(6)* by reaction of the semicarbazone of *cis*-2-cyclooctenone with selenium dioxide (Method: [2d, 2f]). Thermolysis of *(6)* in xylene (130—140°C) leads to *(5)*, which was trapped *in situ* with tetraphenylcyclopentadienone (tetracyclone) as the bicyclic compound *(7)*.

Thermolysis (170°C) of neat *(6)* permitted isolation of *(5)*, which precipitates on the cold finger of the thermolysis apparatus at 70 torr. Column chromatographic separation of the residue afforded the 1,4-diselenins *(8)* and *(9)*. Fragmentation of *(6)* with *n*-butyllithium at −80°C also leads to *(5)*, which adds butyllithium and is subsequently converted on hydrolysis into *(10)*.—In similar experiments we have trapped *(3)* and *(4)* with tetracyclone.

Table 1. ^{13}C-NMR signals of cyclododecyne *(11)*, cyclooctyne *(2)*, *cis*-cyclododecen-3-yne *(12)*, and *cis*-cycloocten-3-yne *(5)* (δ values, $CDCl_3$, TMS internal).

	...—CH_2—	C≡≡C		—CH=CH—		Remaining
	α	sp	sp	sp^2	sp^2	C atoms
(11)	18.4	81.5		—		24.5, 24.9, 25.7, 26.3
(2)	20.8	94.4		—		29.7, 34.5
(12)	19.6	95.4	78.6	111.1	142.3	23.9, 25.1, 25.3, 26.4, 26.6, 26.8, 27.2
(5)	21.6	114.5	94.5	111.8	149.1	25.3, 32.9, 35.5

The highly reactive compound *(5)* is moderately stable at room temperature. Of the spectra recorded, we shall discuss here only the ^{13}C-NMR spectrum (Table 1). Comparison of the chemical shifts of cyclooctyne *(2)* and the unstrained cyclododecyne *(11)* shows that ring strain causes an overall downfield shift of the signals. Most pronounced is the effect on the signals of the sp carbon atoms ($\Delta\delta = 12.9$).

For comparison with *(5)*, we have prepared the unstrained *cis*-cyclododecen-3-yne *(12)* by thermolysis of the corresponding 1,2,3-selenadiazole. Ring strain causes a downfield shift of the signals also in the case of *(5)*, the sp carbon atoms once again being the most strongly affected ($\Delta\delta = 15.9$ and 19.1). The $\Delta\delta$ values can serve as a direct experimental measure of ring strain[2e].

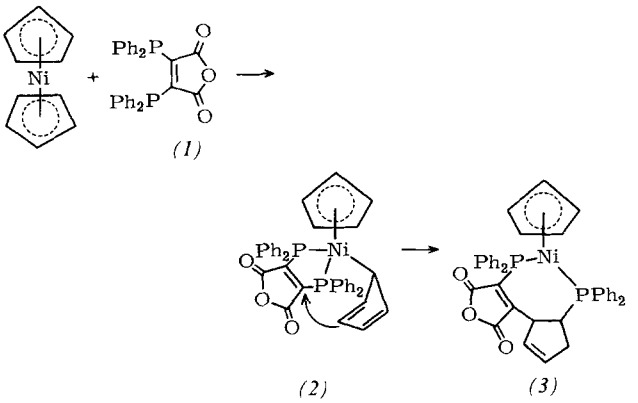
Unusual Reaction of Nickelocene with Bis(diphenylphosphino)maleic Anhydride



By *Walter Bensmann* and *Dieter Fenske*[*]

Nickelocene [bis(η^5-cyclopentadienyl)nickel, $NiCp_2$] reacts with potential mono- and bidentate phosphane ligands to form complexes obeying the noble gas rule. Organyl groups

[*] Priv.-Doz. Dr. D. Fenske, Dr. W. Bensmann
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

attached to the phosphorus can direct the reaction in various ways. Thus complexes of type $Ni(PR_3)_4$[1] are obtained with triphenylphosphane and tri-*n*-butylphosphane, and η^3-$CpNi(PPhBu_2)_2$[2] with di-*n*-butyl(phenyl)phosphane. With halonickel complexes of ethylenebis(diphenylphosphane) [diphos], $NiCp_2$ gives ionic compounds $[CpNi(diphos)]_2NiX_4$ (X = Cl, Br) or bridged complexes XCpNi(diphos)NiCpX (X = I, CN)[3].

We have now discovered a novel insertion of the C_5H_5 ligand into a P—C bond of the bisphosphane ligand on reaction of $NiCp_2$ with bis(diphenylphosphino)maleic anhydride *(1)*[4]:

The high yield (70%) of *(3)* suggests that the insertion reaction takes place within the coordination sphere of nickel. ESR measurements indicate formation, immediately upon addition of *(1)* to $NiCp_2$, of a triplet radical—presumably *(2)*—which is no longer detectable after 24 h. During this time the color of the solution changes from red to green and crystals of the diamagnetic compound *(3)* are precipitated.

X-Ray structure analysis of a single crystal of *(3)* showed a 1:1 adduct with benzene to be present: space group $P2_1/c$, $a = 1294.7(6)$, $b = 1983.9(16)$, $c = 1474.1(12)$ pm, $\beta = 94.42(3)°$, $d_{exp} = 1.28$, $d_{calc} = 1.31\ g\,cm^{-3}$, $Z = 4$, $\mu(Mo_{K\alpha}) = 6.4\ cm^{-1}$. Data collection: Syntex $P2_1$ diffractometer up to $2\theta = 40°$, 3539 reflections of which 2160 had $I > 1.96\sigma(I)$. Solution: heavy atom method, isotropic refinement of all positional parameters and isotropic temperature factors; $R_1 = 0.082$, $R_2 = 0.081$. Hydrogens could not be localized. As shown by Figure 1, a cyclopentadienyl group has inserted into one of the P—C bonds of the coordinated bisphosphane *(1)*. This ring then only has one double bond between C8 and C9; C6 and C7 are sp^3 hybridized. The C5 and C2 atoms are each surrounded by a planar arrangement of three carbon atoms; therefore they cannot bear any hydrogen atoms. The C5—C2 distance suggests a strengthening of the bond. The C2—C3 double bond of the anhydride ring is unusually long (145(2) pm). This ring becomes unsymmetrical as a result of C_5H_5 insertion (cf. Fig. 1).

The two C=O bond lengths (120 and 121 pm) are also lengthened relative to the values for diamagnetic metal complexes of *(1)*[4]; a similar lengthening was also observed in the paramagnetic complex *(1)*·$Co(CO)_3$[5]. The special bonding situation is even more apparent from a pronounced drop in the ν(C=O) frequency of *(3)* as compared with that for free *(1)* or its complexes with normal electron configuration[4, 5]. We attribute it to an electronic transition from nickel into a low-lying π^*MO of the ligand *(1)*.

The Ni—Cp distances of 210—216(2) pm lie in the same range as for other η^5-cyclopentadienyl complexes[6].

If the nickel of $NiCp_2$ is assigned the oxidation number zero, then a C_5H_5 group with an unpaired electron is inserted into the ligand *(1)* on formation of *(3)*. The resulting bisphosphane ligand of *(3)* should also contain a single electron. On the other hand, this ligand (as a donor of two electron pairs) and the remaining Cp ligand (as a five-electron donor) formally lead to the presence of 37 electrons on the Ni. As in the case of the complex *(1)*·$Co(CO)_3$ with a similar electron complement, one electron is apparently transferred from the metal into an antibonding πMO of the phosphane-substituted anhydride group [ν(C=O) in *(3)*: 1748 and 1692 cm^{-1}], which extends into the inserted cyclopentadienyl ring, leading to spin pairing with the single electron initially formally present there.

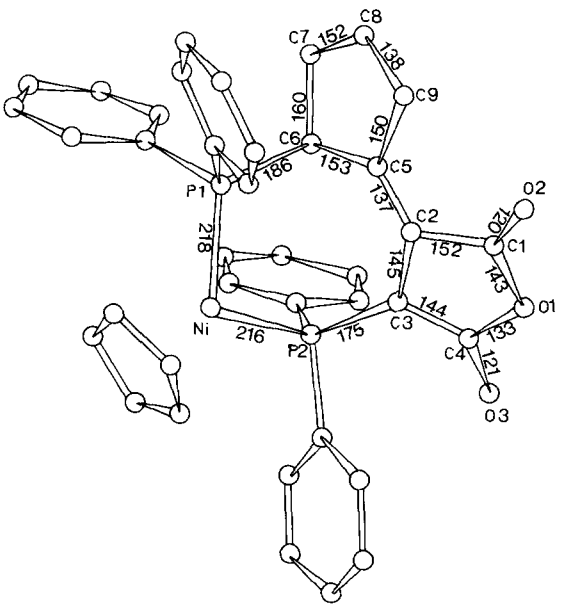


Fig. 1. Molecular structure of the complex *(2)* in its crystal (atomic distances in pm).

Experimental

(1) (1.0 g, 2.14 mmol) in benzene (60 ml) is added dropwise to nickelocene (0.38 g, 2.01 mmol) in benzene (30 ml). Cyclohexane is added after 24 h. Compound *(2)* is precipitated as green crystals within a few days.

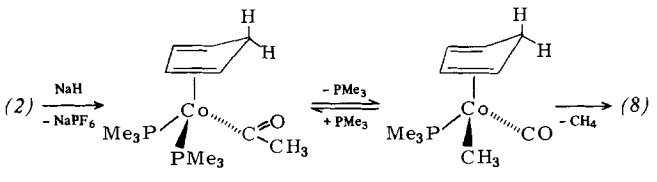
Reductive Elimination Reactions of Cationic Acylcobalt Complexes: Transformation of a Co^{III}—COR Bond into a Co^{I}—CO Bond[1]

By *Helmut Werner* and *Werner Hofmann*[*]

The cobalt compound $C_5H_5Co(PMe_3)_2$ *(1)*, which possesses a strongly nucleophilic metal atom and forms the hydrido complex $[C_5H_5(PMe_3)_2CoH]^+$ with weak protic acids such as H_2O or MeOH[2], reacts with acyl chlorides to give the cations $[C_5H_5(PMe_3)_2Co(COR)]^+$ which can be isolated as the hexafluorophosphates.

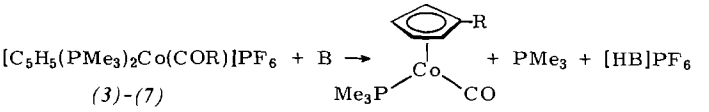


(2), R = CH_3
(3), R = C_6H_5
(4), R = p-$C_6H_4OCH_3$
(5), R = p-$C_6H_4CH_3$
(6), R = m-$C_6H_4CH_3$
(7), R = 3,5-$C_6H_3(OCH_3)_2$

The yellow, air-stable salts *(2)*—*(7)*, which were characterized by elemental analysis and IR and NMR spectra, are completely inert towards strong acids such as CF_3COOH. This suggests that, in contrast to comparable acylmetal complexes such as acylmetal carbonyls assumed to have a charge distribution $M^{\delta+}$—$COR^{\delta-}$, the cations $[C_5H_5(PMe_3)_2Co(COR)]^+$ contain an acyl group exhibiting umpolung[3].

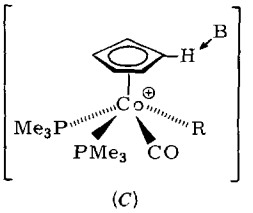
This is supported by the reactions of *(2)*—*(7)* with strong bases and nucleophiles, the product patterns being highly dependent upon the group R in the acyl moiety. Reaction of *(2)* and NaH in tetrahydrofuran affords *quantitatively* the neutral carbonyl complex *(8)*; moreover, one equivalent each of methane and PMe_3 are formed.

$$(2) + NaH \xrightarrow{THF} \underset{(8)}{C_5H_5Co(CO)PMe_3} + CH_4 + PMe_3$$



We assume the mechanism of this novel *reductive elimination* to involve initial attack on the cyclopentadienyl ring by the hydride ion to give the intermediate *(A)*. Dissociation of a Co—PMe_3 bond in this species and concomitant migration of CH_3 to the metal gives the carbonylmethyl complex *(B)*, which undergoes loss of methane to form the dicarbonyl(cyclopentadienyl)cobalt derivative *(8)*. Reaction of *(2)* and phenyllithium in ether consequently gives $C_5H_4PhCo(CO)PMe_3$.

[*] Prof. Dr. H. Werner, Dipl.-Chem. W. Hofmann
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)



The reversibility of the process *(A)*⇌*(B)* + PMe_3 confirms the result of the reaction of *(2)* with NaH in the presence of PEt_3 which gives not only *(8)* but also the corresponding triethylphosphane compound $C_5H_5Co(CO)PEt_3$ *(9)*.

The cations of the salts *(3)*—*(7)* with R = *aryl* react with NaH in THF basically in the same way as $[C_5H_5(PMe_3)_2Co(COMe)]^+$. Elimination of ArH and PMe_3 again gives *(8)*. In addition, the ring-substituted complexes *(10)*—*(14)* are also formed. We attribute this to the inevitable presence of base in the reaction system on use of commercial NaH in THF—the strong base B effects the side reaction mentioned. Reaction of the salts *(3)*—*(7)*, with for example DBU (1,5-diazabicyclo[5.4.0]undec-5-ene) in THF or acetone yields quantitatively the monocarbonyl complexes *(10)*—*(14)*.

(10), R = C_6H_5
(11), R = p-$C_6H_4OCH_3$
(12), R = p-$C_6H_4CH_3$
(13), R = m-$C_6H_4CH_3$
(14), R = 3,5-$C_6H_3(OCH_3)_2$

We rationalize the mechanism of this ring substitution, which likewise involves *reductive elimination*, as proceeding *via* initial interaction of base B with a proton of the ring to give an "acid-base adduct" from which a transition state (or labile intermediate) of composition *(C)* is formed, possibly with an η^3-cyclopentadienyl ligand. Subsequent fast migration of the aryl group R to the ring and elimination of HB^+ (and of PMe_3) leads to the reaction product. We recently described a similarly facile ring substitution, *i.e.* that of *(1)* to give $C_5H_4RCo(PMe_3)_2$ (R = *i*Pr, *t*Bu, $SiMe_3$, *etc.*)[4].

(C)

Reaction of the *acetyl* complex *(2)* with NaOH in THF at 25 °C gives the methyl compound $[C_5H_5(PMe_3)_2CoMe]PF_6$ *(15)*. The corresponding iodide is readily prepared by direct reaction of *(1)* with MeI[2]. *In the absence of base*, no elimination of CO takes place from the cation $[C_5H_5(PMe_3)_2Co(COMe)]^+$ even at elevated temperature. It therefore appears plausible that the formation of $[C_5H_5(PMe_3)_2CoMe]^+$ from $[C_5H_5(PMe_3)_2Co(COMe)]^+$ and OH^- proceeds *via* a transition state similar to *(C)*.

So far, we have observed initial attack at the *metal* or the *acyl carbonyl atom* only on reaction of *(2)* with methyllithium in ether. The sole products are *(1)* and acetone; no formation of *(8)* or *(15)* was detected.

$$(2) + MeLi \xrightarrow{Et_2O} (1) + Me_2CO + LiPF_6$$

Experimental

The salts *(2)*—*(7)* are stirred with an excess of NaH in THF for *ca.* 4 h at 50 °C. After removal of solvent, the residue

is extracted into pentane, and the compounds *(8)* and *(10)*—*(14)* are precipitated by cooling of the pentane solution to −78 °C. Yield almost quantitative.

The reaction of *(3)*—*(7)* with an excess of DBU in acetone at 50 °C requires *ca.* 1 h. The red-brown solution is allowed to react with NH_4PF_6 to remove the excess of base and the solvent then removed. The oily residue is extracted with ether and the corresponding products *(10)*—*(14)* isolated by precipitation from ether/pentane at −78 °C.

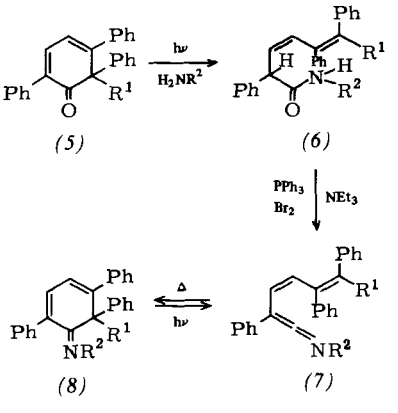
Dienylketenimines—An Entry to Linearly Conjugated Cyclohexadienimines

By *Heinz H. Eckhardt* and *Hartwig Perst*[*]

Whereas the chemistry of linearly conjugated cyclohexadienones has been thoroughly investigated[1], the properties of the analogous cyclohexadienimines have remained essentially unknown. This is probably due mainly to the lack of a general method for their synthesis; presumably this is also the reason why no *N*-alkyl and *N*-aryl derivatives have previously been described[2]. We have now discovered a novel entry to this series.



Just as dienylketenes *(1)* are able to give linearly conjugated cyclohexadienones *(2)*[3,4], dienylketenimines *(3)* should be capable of forming cyclohexadienimines *(4)*.

(1), (3) *(2), (4)*

(1), (2): X = O
(3), (4): X = NR

We first accomplished a reaction of this kind in the case of triarylated dienylketenimines *(7)*. In contrast to the frequently demonstrated dienylketene intermediates[3,4], the dienylketenimines *(7)* were previously unknown. *N*-Monosubstituted hexadienamides *(6)* represent potential precursors. These compounds are themselves readily accessible as trapping products of dienylketenes of type *(1)* *via* photochemically induced *cyclo/seco* isomerization of linearly conjugated cyclohexadienones *(5)* in the presence of primary amines[3-5]. Subsequent dehydration occurs smoothly with triphenylphosphane, bromine, and triethylamine in boiling dichloromethane[6]. While diarylketenimines are stable under these conditions[6], the expected dienylketenimines *(7)* cannot be isolated. Dehydration of *(6)* affords the cyclization products of *(7)*; we obtained the *N*-alkylated cyclohexadienimines *(8a)*—*(8e)*[7] in up to 80 % yield as colorless to pale yellow compounds[9].

(5) *(6)* *(8)* *(7)*

(5a), $R^1 = CH_3$
(5b), $R^1 = OCH_3$[8]
(5c), $R^1 = OCO{-}CH_3$[4]

(6)-*(8)*	R^1	R^2
(a)	CH_3	i-C_3H_7
(b)	CH_3	CH_3
(c)	OCH_3	i-C_3H_7
(d)	OCH_3	CH_3
(e)	$OCO{-}CH_3$	CH_3

The cyclohexadienimines *(8)* themselves provide an entry to dienylketenimines *(7)*. Thus, *(7a)* can be generated by UV irradiation of a solution of *(8a)* and can be detected together with unreacted *(8a)* in the IR [$\tilde{\nu} = 2000\,cm^{-1}$[6]; in 2-methyltetrahydrofuran (MTHF)] and in the ^{1}H-NMR spectrum [$\delta(CH_3) = 2.02$ (R^1), 1.26, $J = 7$ Hz (R^2), in [D_8]tetrahydrofuran ([D_8]THF)]. The lifetime of the dienylketenimine *(7a)* is highly solvent dependent: it is stable for several days in MTHF or [D_8]THF at room temperature; although also stable in [D_8]toluene at −60 °C, it regenerates *(8a)* within a few minutes above 0 °C.

Experimental

Synthesis of *(8a)*: A solution of isopropylamine (50 ml, 3 M in benzene) is added to a solution of compound *(5a)*[10] (2.0 g) dissolved in benzene (400 ml) and the mixture is irradiated (Hanau TQ 150 high pressure Hg lamp; photoreactor, Normag-Hofheim, Germany) at room temperature under nitrogen until decoloration is complete (*ca.* 22 min). After removal of solvent, *(6a)* can be crystallized with *n*-hexane and recrystallized from ethanol/*n*-hexane; yield 2.25 g (96 %) of *(6a)*, m.p. 88—90 °C.—A solution of bromine (1.8 g, 11 mmol) in dichloromethane (10 ml) is added under nitrogen to a solution of triphenylphosphane (2.9 g, 11 mmol) in anhydrous dichloromethane (40 ml), followed by addition of triethylamine (9 ml). To the resulting solution is added *(6a)* (2.25 g, 6 mmol). After heating (5 h under reflux) and removal of solvent, the residue is taken up in benzene (50 ml), filtered and dried over Na_2SO_4. The solution is concentrated, chromatographed over silica gel (activity II), eluted with benzene, evaporated down *in vacuo*, and *(6a)* (0.5—0.6 g, 22—27 %) is precipitated with *n*-hexane. The mother liquor is concentrated, the pale yellow oil made to crystallize with a small volume of methanol, and once again allowed to dissolve and precipitate from chloroform/methanol: the procedure affords (1.0—1.3 g of colorless *(8a)* 70—80 % based on reacted *(6a)*. M.p. 115 °C; MS: $m/e = 377$ (M^+, 92 %), 334 ($M^+ - C_3H_7$, 100 %); ^{1}H-NMR (C_6D_6): $\delta = 1.04$ (d, 6 H, $J = 7$ Hz, isopropyl-CH_3),

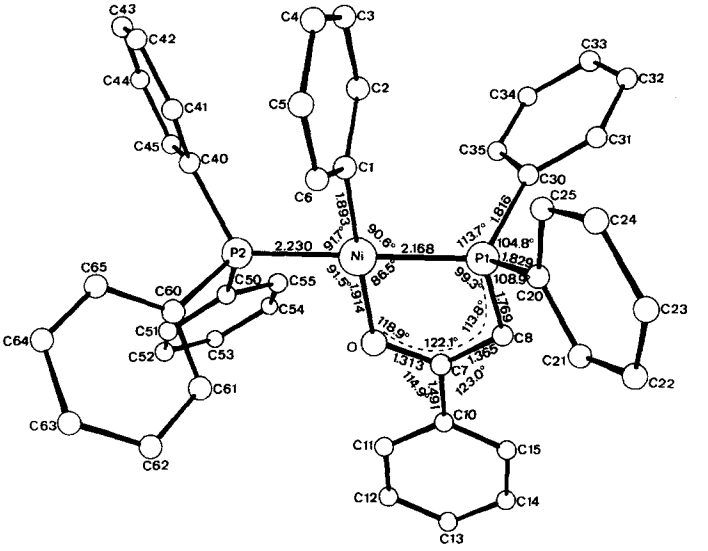
Novel Coordination of (Benzoylmethylene)triphenylphosphorane in a Nickel Oligomerization Catalyst[**]

By *Wilhelm Keim, Frank H. Kowaldt, Richard Goddard*, and *Carl Krüger*[*]

The oligomerization of ethylene to linear α-olefins is of substantial technical interest[1]. On reacting $Ph_3P{=}CH{-}CO{-}Ph$ with $Ni(PPh_3)_4$ or $Ni(cod)_2/Ph_3P$ [cod = 1,5-cyclooctadiene] in toluene we obtained a compound of the composition $C_{44}H_{36}OP_2Ni$ *(1)*, the first well defined and readily crystallizable complex, which converts ethylene in high selectivity and activity into α-olefins or also polyethylenes in the absence of cocatalysts such as are required *e.g.* by catalysts of the Ziegler type.

The structure of the complex *(1)* followed from spectroscopic data (^{1}H- and ^{13}C-NMR, IR, MS) and from a crystal structure analysis[2] (cf. Fig. 1). The nickel atom is surrounded in an almost square planar arrangement by a triphenyl moiety, a σ-bonded phenyl group and a bidentate ylide ligand bonded *via* O and P (deviations from planarity of $+0.07\,m^{-10}$ for C1, O; $-0.07\,m^{-10}$ for P1, P2). The bond lengths and angles in the planar PC_2ONi five-membered ring indicate a delocalized system with typical P—C and P—Ni bond lengths[3]. As in the triphenylphosphane coordinated *via* P2 to Ni, both the phenyl groups attached to P1 are oriented in a propeller-like arrangement. The Ni—Cl σ-bond is unusually short ($1.893\,m^{-10}$); in comparable Ni—Ph compounds[4] values of 1.96—$2.00\,m^{-10}$ are observed. This finding might be explained in terms of a strong electron affinity of the *O,P*-ligand. ESCA analyses confirm this assumption.



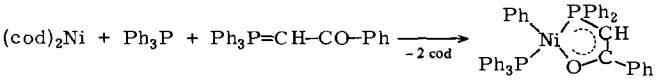


Fig. 1. Molecular structure of the complex *(1)* in the crystal.

The formation of *(1)* according to

(1)

proceeds *via* a novel type of phenyl rearrangement leading to a phenyl-metal bond. A 1,2-migration of a phenyl group in phosphorus ylides catalyzed by nickel compounds is already known[5].

Reaction of a toluene solution of the complex *(1)* with ethylene (50 bar) at 50 °C affords *n*-olefins which are up to 99 % linear and consist of up to 98 % of α-olefins. The olefins up to C_{30} analyzed by gas chromatography are present in a geometrical distribution. Activities of 6000 mol ethylene per mol of complex *(1)* are achieved. When the reaction of *(1)* with ethylene is carried out in *n*-hexane as suspension medium, however, high molecular linear polyethylene is formed.

Procedure

A solution of triphenylphosphane (26.2 g, 0.1 mol) and (benzoylmethylene)triphenylphosphane[6] (38 g, 0.1 mol) in toluene (900 ml) is added dropwise to a solution of bis(cyclooctadiene)nickel(0) (27.5 g, 0.1 mol) in toluene (600 ml) at 0 °C and the mixture stirred for 24 h at room temperature and a further 2 h at 50 °C. It is then evaporated to dryness in a vacuum at 50 °C. The toluene distilled over contains almost quantitatively the liberated 1,5-cyclooctadiene. The brownish-red crude reaction product is dissolved in toluene at 50—70 °C and treated with a small amount of *n*-octane. On cooling to 0 °C, 48.5 g (69 %) of compound *(1)* crystallizes out.

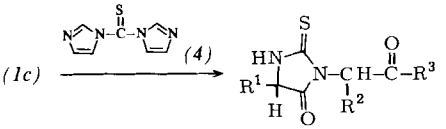
N-Terminal Cyclization of Peptides with *N,N'*-Carbonyldiimidazole or *N,N'*-Thiocarbonyldiimidazole

By *Franz Esser* and *Otto Roos*[*]

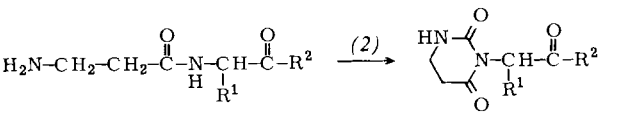
We have found that *N,N'*-carbonyldiimidazole *(2)*[1] reacts smoothly and without racemization under very mild conditions with C-terminally protected peptides to give hydantoin peptides of type *(3)* [*(3c)* and *(3d)* after removal of the benzyl protecting group]. This cyclization can also be carried out on a solid phase[2].



(1) *(3)*

	R^1	R^2	R^3
(3a)	*(S)*-$CH_2CO_2CH_2Ph$	*(S)*-CH_2Ph	NH_2
(3b)	H	*(S)*-3-Indolylmethyl	Met-Gly-NH_2
(3c)	*(S)*-3-Indolylmethyl	*(S)*-CH_2—$CH(CH_3)_2$	Asp-Phe-NH_2
(3d)	*(R)*-3-Indolylmethyl	*(S)*-CH_2—$CH(CH_3)_2$	Asp-Phe-NH_2

The significance of the procedure lies in the fact that it provides a convenient entry to such modified peptides which are of interest for the study of structure activity-relations of peptide hormones. Previous methods[3] required relatively drastic conditions and their scope is therefore very limited.



By analogy with the hydantoins *(3)*, thiohydantoins *(5)* are obtained by reaction with *N,N'*-thiocarbonyldiimidazole *(4)*.

(1c) *(4)* *(5)*

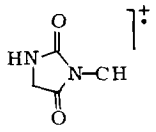
R^1 = *(S)*-3-Indolylmethyl, R^2 = *(S)*-CH_2-$CH(CH_3)_2$
R^3 = Asp(CH_2Ph)-Phe-NH_2

Peptides *(6)* containing an N-terminal β-amino acid cyclize with *(2)* to form 2,4-pyrimidinediones *(7)*.

(6) *(7)*

R^1 = *(S)*-CH_2Ph, $R^2 = NH_2$

Characteristic data for six selected products are compiled in Table 1. Ring formation is readily seen in the ^{13}C-NMR spectra. The expected signals (Table 1)[4] are accompanied by a typical shift of the C_α signals of the second amino acid unit relative to the corresponding signals of the open-chain compounds. Diastereomers such as *(3c)* and *(3d)* can be unequivocally distinguished. The expected molecular ions were observed in the mass spectra of *(3a)* and *(7)*, and the species *(8)* containing the hydantoin ring could be detected as key fragment in the case of *(3b)*[5].



That the compounds synthesized were indeed N-terminally cyclized structures and not ureas of type *(9)* was proved as follows: For example amino acid analysis of *(3c)* revealed a Trp:Leu:Asp:Phe ratio of 0.27:0.46:1.01:1.0 on acidic degradation[6] and a ratio of 0.99:0.95:0.97:1.0 on alkaline hydrolysis[7]. The incomplete regeneration of the first two amino acids on acid hydrolysis can only be rationalized by

Table 1. Selected data of compounds produced.

	Reactant	Product	Method	Yield [%]	M.p. [°C] (dec.)	R_f [d]	$[\alpha]_D^{20}$ (*c* = 1, DMF)	^{13}C-NMR [e]

(9)

assuming their participation in a hydantoin ring which is completely degraded only in an alkaline medium. Conversely, this method is suitable for identification of the first two amino acids of a peptide of unknown sequence, resembling the method tried by *Wessely*[3d].

Experimental

(3c) by classical method (A): A solution of H-Trp-Leu-Asp(CH_2Ph)-Phe-NH_2·HCl (2 g, 2.9 mmol) in anhydrous dimethylformamide (DMF) (50 ml) was neutralized with triethylamine and added dropwise over 30 min at room temperature to a solution of *(2)* (0.55 g, 3.6 mmol) in DMF (50 ml) with exclusion of moisture. The mixture was left to stand overnight, stirred into an approximately tenfold volume of water, and the white precipitate was isolated. After dissolution in methanol, precipitation by dropwise addition to water, and drying, the hydantoin peptide benzyl ester was obtained (1.9 g, 94 %). A solution of this ester in glacial acetic acid was treated with H_2 in the presence of Pd/C as catalyst; yield 1.05 g (64 %) of *(3c)*.

(3c) by the solid phase method (B): Boc-Phe-OH, Boc-Asp(CH_2Ph)—OH, Boc-Leu-OH, and Boc-Trp-OH were successively linked by standard procedures[2] to 15 g of a 2% divinylbenzene-crosslinked benzhydrylamine-polystyrene resin (Pierce, USA). The resin was then treated for 2 h with a solution of *(2)* (13 g, 80 mmol ≙ 16 equiv. based on Boc-Phe loaded resin) in DMF (150 ml) at room temperature. The hydantoin peptide was subsequently cleaved from the dried resin by liquid HF in the presence of 10 % of anisole (1 h at 0 °C)[2]. After removal of HF and anisole the product was extracted with glacial acetic acid, the solvent removed, the residue taken up in methanol, decolorized with activated charcoal, and precipitated by addition of ether; yield 2.9 g (94 % based on Boc-Phe loaded resin) of *(3c)*. HPLC: content of *(3d)* <0.4 %.

3d-Orbital Participation in Sulfur Diimides[**]

By *Richard Bartetzko* and *Rolf Gleiter*[*]

Whenever sulfur compounds exhibit unexpected physical or chemical properties, an expansion of the electron octet to a decet (participation of 3d orbitals in bonding) is invoked[1]. The relatively high stability of sulfur diimides *(1)* and their frequent occurrence as structural components of organic and inorganic compounds[2] have led to their formulation with tetravalent sulfur *(1a)*[3] although the ground state can just as well be described in terms of resonance between the charged forms *(1b)*↔*(1c)*.

zines *(2)* and *(3)*[4] as model substances for *(1)* with the corresponding spectra of the 2-methylnaphtho[1,8-*de*]triazines *(4)* and *(5)*[5], which cannot be formulated analogously to *(1a)*, shows the spectra to be almost superimposable (cf. Fig. 1 and Table 1).

The spectra were interpreted assuming (i) that the bands of the electronic spectra can be described as $\pi^*\leftarrow\pi$ transitions[8] and (ii) the validity of Koopmans' theorem ($-\varepsilon_j = I_{v,j}$). Within this framework, comparison of experimental data with calculated values (energy, intensity, direction of polarization; ionization potential and intensity) showed that the observed similarity between the spectra of *(2)*, *(3)* and those of *(4)*, *(5)* is due to analogous valence electron structures. Hence we conclude that valence structures with tetravalent sulfur can be neglected for *(1)*. In molecular orbital terms, this means that 3d orbitals are of no importance in the description of *(1)*, whether in the ground state or in excited states.

The transformation of ammonium cyanate into urea—discovered 150 years ago by *Wöhler*—is known to all chemists on account of its historical importance. Less well known, according to *J. Shorter*, is the fact that the question of its mechanism has still not been settled although discussions began 80 years ago. Any decision between the ionic (a) and

$$NH_4^{\oplus} + CNO^{\ominus} \rightleftharpoons CO(NH_2)_2 \qquad (a)$$

(b)

the molecular mechanism (b) appears impossible on the basis of conventional kinetic methods. [The Conversion of Ammonium Cyanate into Urea—A Saga in Reaction Mechanisms. Chem. Soc. Rev. 7, 1—14 (1978); 69 references]

[Rd 18 IE]

Pericyclic Reactions. Vol. I. By *A. P. Marchand* and *R. E. Lehr*. Academic Press, Inc., New York—London 1977. 1st Edit., xi, 286 pp., bound $ 28.00.

Twelve years after appearance of *Woodward* and *Hoffmann*'s equally fundamental and stimulating work, *Marchand* and *Lehr* present the first volume of "Pericyclic Reactions". Selected aspects of this type of reaction are set out and looked at critically in four chapters.

The first chapter, "Operational Criteria for Evaluation of Concertedness in Potential Pericyclic Reactions", written by *Lehr* and *Marchand*, is concerned with the experimental criteria that can lead to a statement whether or not a reaction course is concerted. As examples, kinetic and thermodynamic results, investigations of isotope effects, and labeling experiments illustrate the textual content.

The second Chapter, "The Möbius-Hückel Treatment of Organic Systems and Reactions and MO Following as a Technique in Organic Chemistry", written by *H. E. Zimmerman*, is fully in line with the intention laid down in the first sentence of the article: "The present chapter presents the author's approach to dealing with orbital-control of organic reactions". Correspondingly, for instance, *Fukui*'s name is not mentioned in the references. If this article is designed to give an insight into the theoretical background to pericyclic reactions, we cannot deny that this brilliantly written chapter has a certain onesidedness. It may be added that the Möbius-Hückel procedure is also known as the Evans-Dewar procedure.

W. M. Jones and *U. H. Brinker* contributed the third Chapter, "Some Pericyclic Reactions of Carbenes". The accent is placed on addition to multiple bonds, insertion into C—H bonds, and 1,2-rearrangement of carbenes, in which besides experiments the qualitative and quantitative theoretical approaches to these reactions are discussed. Rearrangement of vinylcarbenes to cyclopropenes is reviewed for the first time. Special weight is also laid on sections about carbene-carbene rearrangements and on ring-opening of cyclopropylidenes to allenes.

"Pericyclic Reactions of Carbanions" is the title of the fourth Chapter, by *S. W. Staley*. In this review of a topical and rapidly developing field are included the rotation barriers of unsaturated "carbanions" as well as the typical pericyclic reactions; this feature is especially welcome, since stereochemical investigations in these species depend far more than *e.g.* investigations in olefins on comparatively low rotation barriers. One can be excited to learn how investigations of the ion-pair character and of reversible electron-transfer processes will widen our knowledge of this field.

All in all, this is a volume of reviews of important areas for those familiar with the field. It also provides any interested chemist with an expert introduction.

Gernot Boche [NB 418 IE]

Chemie der Pflanzenschutz- und Schädlingsbekämpfungsmittel (Chemistry of Pesticides and Plant-Protection Agents). Edited by *R. Wegler*. Vol. 5. Herbicides. Technical editors: *R. Wegler* and *L. Eue*. Springer-Verlag, Berlin—Heidelberg—New York 1977. xxi, 752 pp., 6 figs., bound, DM 198.—.

In the Foreword the editor bases his purpose on the need to use chemicals for plant protection; the efforts to produce vegetable foods as cheaply as possible and in good quality have led to a remarkable expansion of the spectrum of active agents, a feature applying particularly to fungicides. Among the herbicides there have been no essentially new discoveries of active substances to report recently, and yet the number of preparations on the market has greatly increased. In countries engaged intensively in agriculture, herbicides now account for more than half of all plant-treatment agents by amount and by value.

The usual division into inorganic and organic herbicides is retained in the present book. There are short introductory chapters on the mode of action and application as well as on tests, and a list of the various names used for weedkillers in the literature, particularly in patents. Inorganic compounds are mainly suitable for total weed destruction, and are still widely used despite the fact that their importance has been diminishing for several years. The authors have therefore confined their treatment to a few pages. Much space is given, on the other hand, to a description of organic herbicides. They are classified according to active components, a typical formula being provided for the various active compounds. In each case there follows a collection of the more recent literature and valid patents. A review of the supplementary patents published in 1969 to 1976 is given in a separate Appendix of over 300 pages. In the authors' view a comprehensive knowledge of the patent situation constitutes the basis for decisions about new developments and investment in plant. In view of the large number of herbicidal compounds described, the concluding subject and compound index is a valuable addition to the book.

Unlike earlier volumes in this series, the herbicide volume is produced photomechanically, which means that the reproduction of the formulas has suffered somewhat. However, the editor sees a special advantage in the possibility of continuing supplements, and in view of the continuing development of the herbicide sector this must be accepted, though with reservations. The book fulfils its purpose of providing detailed information for specialists in the chemical industry and for phytopathologists.

Dieter Knösel [NB 409 IE]

The Chemical Physics of Surfaces. By *S. R. Morrison*. Plenum Press, New York—London 1977. xvii, 415 pp., numerous figs. and tables, bound, $ 47.40.

An ever-increasing interest in the physics and chemistry of solid surfaces is currently fostered by the recent investigations of the use of semiconductors for the conversion of sunlight into electrical or chemical energy. Corrosion, catalysis, and electrophotography are other examples in which electron transfer at solid surfaces plays a part.

The author has been at pains—and with success—to bring the physicist's predominantly energetic mode of consideration (band model and surface states) into harmony with the chemist's mainly atomistic picture (surface groups, active centers). At last, someone has pointed out that there is a difference between redox processes and Lewis acid-base reactions. Of course, Lewis base centers may occasionally donate single electrons. The first chapter reads like a good textbook and provides the chemist with an excellent introduction. With didactic skill of high order the principles are first described and discussed qualitatively, then treated formally and quantitatively. In the energy level diagrams the coordinates are clearly marked, which is a pleasant change. The text could, however, have been supported by more illustrations. The real structure of crystal surfaces is treated too briefly. The exposition of the experimental methods is comparatively short, and owing to the rapid development of this field it is not completely up

to date. Above all, a more detailed description of how to determine band edge energies and flat band potentials would have been welcome.

In line with the author's interests, the description of individual systems is dominated by semiconductors and ionic crystals, while metals are treated rather summarily. This part of the book contains a compressed review of recent literature; the last chapter, on heterogeneous catalysis, can naturally provide only a limited selection. The sections on solid/solution interfaces and on photoeffects on semiconductor surfaces are highly informative. The rich bibliography goes up to the end of 1975.

The book will undoubtedly prove extremely useful to the chemist who wants to work his way into problems of solid surfaces; his own background will enable him to go beyond the summary and the simplified descriptions in the field of chemistry. Pure physicists will find the book harder to digest.

Reflections on an Anniversary of Chemical Synthesis

By Gerhard Quinkert[*]

Dedicated to Sir Derek Barton on the occasion of his sixtieth birthday

The significance of chemistry as a science and as a branch of industry, as well as its role in the evolution of scientific thought during the past 150 years, are thoughts which come to mind while contemplating the development of organic synthesis.

1978 is an anniversary of chemical synthesis.

- 150 years ago *Wöhler* reported "Über künstliche Bildung des Harnstoffs" from ammonium cyanate[1];
- 100 years ago *Baeyer* delivered his famous speech "Über die chemische Synthese"[2];
- 50 years ago *Diels* and *Alder* added the cycloaddition bearing their names[3] to the existing armamentarium of synthetic methods.

Retracing the pathway leading from the events indicated up to the present day reveals the way in which chemical synthesis has evolved. In his searching study on "La logique du vivant"[4] *François Jacob* has taken note of the role organic chemistry played in the first part of the 19th century. The task of this discipline was to analyze. This branch of science had to identify the substances of life and to unravel their "metamorphosis" in the organs and organisms. Synthetic contributions were not expected. Only living organisms were thought to be able to build up the chemical materials of life, by means of some vital force.

It is nowadays common knowledge that

- there is no biological basis for a special position of organic chemistry,
- there is no purely chemical way of deciding whether a compound has been synthesized in a cell or in a chemist's laboratory.

It is *Wöhler*'s conversion of ammonium cyanate into urea which caused such a change of mind. This event of the year 1828 determined the date of birth of organic chemistry as a science[5] and is even recognized as a turning point in the history of human knowledge[2].

> Konnte man den Harnstoff künstlich darstellen, so gab es keine Schranke mehr zwischen organischer und unorganischer Welt und mit frohem Erstaunen sah man der experimentellen Forschung die Möglichkeit eröffnet, die zahllosen Stoffe des Pflanzen- und Tierreichs künstlich darzustellen, vielleicht sogar – wenn auch nur in später Zukunft – das große Rätsel zu lösen, welches wir Leben nennen[2]

Such a hope does not seem presumptuous. Meanwhile *Khorana* by synthesizing well defined nucleic acids contributed to the decipherment of the genetic code[6]. Shortly afterwards he succeeded in the chemical synthesis of a gene[7]. To raise the question about the chances of synthesizing a living cell is no longer a prerogative of science fiction literature. In a state of the art account of the life sciences it was stated:

> Those who are hopeful about synthesizing a cell in the foreseeable future have every reason to retain their optimism[8].

[*] Prof. Dr. G. Quinkert
Institut für Organische Chemie
Niederurseler Hang, D-6000 Frankfurt am Main (Germany)

Wöhler's artificial formation of urea released chemical synthesis from its dogmatic fetters. The resulting consequences for thought and action are emphasized up to our days. It is thus all the more surprising that popular accounts of the historic event are often marred by a lack of attention to chemical detail[9-11].

During the "Gründerjahre", a short period of history immediately following the Franco-German War, there was literally a fortune to be made from chemical synthesis. Ample funds for investment, an optimistic faith in progress, and universities which had for some time been devoted to research and cultivated a tradition of excellence were all to be found within the boundaries of Germany[12-14]. The world-wide political activities of various neighboring states and their "industrial revolutions" had passed this country by. When industrialization at last began to gather momentum, chemistry proved to be one of the main driving forces. The principal reason for this turn of events was the existence of a viable research establishment which rose to the task of synthesizing valuable substances from inexpensive raw materials. Once *Liebig* had introduced the chemical laboratory into German universities, it was these institutions which fostered technological development. They provided adequate numbers of well trained chemists who mastered the handiwork of research. Notable university scholars consolidated and extended the foundations of chemistry, yet never losing sight of the economic significance of synthetic chemistry which provided additional incentive for their investigations. Pure research in German universities has always provided fertile ground for applied research and technological development[15]. It is therefore hardly surprising that *A. von Baeyer* received the Nobel prize in 1905 "for his services in the advancement of organic chemistry and the chemical industry"[16]. The same expression was to be used once again five years later when the Nobel prize was awarded to *O. Wallach*[16].

The official citation on the award of the Nobel prize to *R. B. Woodward* in 1965, *i.e.* "for his outstanding achievements in the art of organic synthesis"[17], enjoys the same pointedness as those just mentioned. *Woodward*'s syntheses of natural products belong to the great cultural contributions of our age, and provide a measure of the potential of organic chemistry. A branch of science which can accomplish the synthesis of chemical compounds possessing extremely complex structures is clearly in a healthy state:

> The synthesis of substances occurring in Nature, perhaps in greater measure than activities in any other area of organic chemistry, provides a measure of the condition and powers of the science. For synthetic objectives are seldom if ever taken by chance, nor will the most painstaking, or inspired, purely observational activities suffice. Synthesis must always be carried out by plan, and the synthetic frontier can be defined only in terms of the degree to which realistic planning is possible, utilizing all of the intellectual and physical tools available[18].

If proof were ever needed of the fruitful interplay that can take place between theoretical chemistry and practical chemical synthesis[19], it would be forthcoming from the publication of the now famous Woodward-Hoffmann rules[20] in the same year as *Woodward* received the highest scientific honor for his synthetic work. The synthesis of natural products now plays a leading role in the development of structural organic chemistry and the study of organic reactions[21,22]. The full implications of this are apparent from the two syntheses of vitamin B_{12} due to *Woodward* and *Eschenmoser*[23-25] and to *Eschenmoser*[26,27]: the synthetic target is particularly complex in its constitution and stereostructure. Its vitamin function lent it additional attraction. Since the structure had been determined by X-ray diffraction, its synthesis had to be planned from the very outset as an expedition through chemical *terra incognita*. The gigantic task was solved in a new spirit. The synthesis of natural products had meanwhile been relieved of the burden of structural confirmation, and nothing stood in the way of designing a synthetic strategy such that it could accommodate hitherto unknown but desired reactions in the course of its execution:

> The execution of such a synthesis is not simply an experimental verification of a plan conceived in detail in advance. Rather, in its most important phases it is an inquiry, guided by a synthetic strategy, into the reactivity of structural types with respect to their potential as intermediates in a synthetic reaction sequence. What the synthetic target provides is stimulation and direction. Challenged by the necessity of moving toward a given structure, the synthesis often leads to problems that are complementary to those chosen in open-ended preparative research on reactivity[22].

As the significance of chemical synthesis has grown, so too has the need to make known the problems of planning and executing syntheses and to concentrate more on teaching approaches to their solution. The time is ripe for such a shift in emphasis. There has been a recent boom in the literature devoted to the compilation[28,29], classification, and comparison[30-36] of synthetic methods for complex chemical compounds. Books are also being published which concentrate on the strategy and tactics of synthesis[37-40]. Much of the initiative in the systematic development of a synthetic methodology has been provided by *Corey*:

> A sufficiently great number and variety of syntheses have now been completed to encourage attempts at setting down in a generalized form the process by which a synthetic chemist devises an original but valid synthetic route to a complicated structure. Such an effort surely is more than an intriguing theoretical exercise: it is a prerequisite to a deeper comprehension of Synthesis and the methodologies which are fundamental

to it, and it is likely to be a keystone in the rational development of Synthesis to still higher forms. For example, any technique for the automatic generation of synthetic schemes by a computer will require a complete and detailed definition of the elements of Synthesis and their mutual interaction, in a most general sense[41].

Discussions about computer planning of syntheses are very evident in the literature[42–51] and in practice[52–54]. Opinion is divided, but most chemists would agree that

even if the effort to devise an effective problem-solving computer program were to fail utterly, a deeper comprehension of the strategies, principles, and elements of chemical synthesis would be gained, the classification and organisation of basic chemical data according to the requirements of synthesis would be advanced, and new and more powerful methods of teaching chemical synthesis and solving synthetic problems would result[43].

Although many reactions are known for the construction of carbon atom skeletons and/or introduction of functional groups, the search for new synthetic methods continues—with considerable success. The systematic study of a given class of compounds or a selected kind of reaction still plays a major role. A prototype of such a study is the 50-year old Diels-Alder reaction[55]. Wherever a six-membered ring occurs as a partial structure, whether in the target compound itself or in a projected precursor, the Diels-Alder reaction springs to mind. Time and again this cycloaddition has been utilized in the synthesis of natural products, with overwhelming success especially in cases where its regio- and particularly its stereoselectivity could be exploited.

The successful synthesis of a gene or of vitamin B_{12} could create the false impression that there is no longer any need for further methods of specific structural modification. Compared with the synthetic capabilities of Nature, most of our laboratory procedures leave much to be desired, particularly on account of the extreme conditions often required and their frequently inadequate regio-, stereo-, and enantio-selectivities[56–58].

From Molecular Biology we know that Nature is capable of carrying out Syntheses which are thousands of steps in length with a yield and an optical specificity of 100% in each step. We are very far from any such feat. The best industrial syntheses may attain average yields of over 90% for a 30–40 step synthesis. It is clear, therefore, that the synthesis of natural products remains an objective of great scientific value and of great social and economic significance[59].

In this anniversary year, there is every reason to intensify our efforts in the field of organic synthesis: The directed synthesis of improved products having desired properties continues to have a powerful economic incentive. The discovery of new synthetic reagents and the development of new preparative methods are still urgent problems of pure chemical research. Last but not least, the character-forming influence that active participation in a synthetic project aimed at a complex target structure may have on young scientists should not be underestimated.

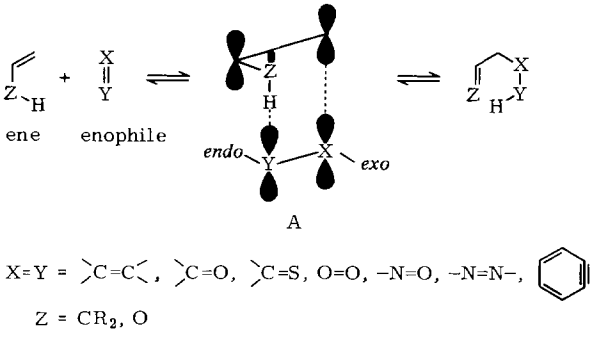
Intramolecular Ene Reactions in Organic Synthesis

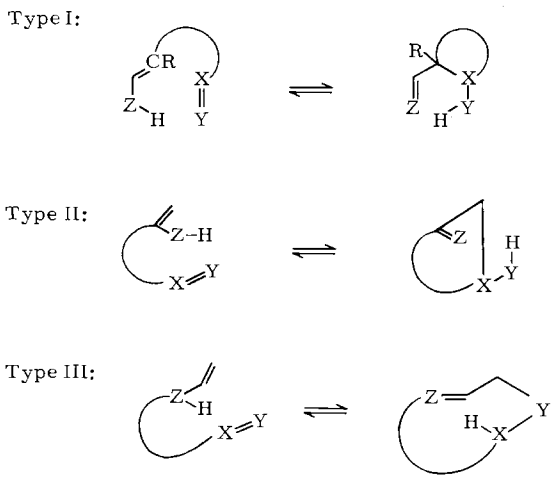


New synthetic methods (22)

By Wolfgang Oppolzer and Victor Snieckus[*]

Thermal cyclizations of appropriate dienes, enynes, enones and related unsaturated systems, some of them carried out on an industrial scale, demonstrate increasingly the preparative power of the intramolecular ene reaction. A variety of substituted, fused and bridged ring systems, including natural products, are thus easily accessible in a regio- and stereo-selective manner. Numerous examples are discussed systematically illustrating the possibilities, limitations, and common features of this cyclization reaction and its reverse ring-opening process.

1. Introduction



The ene reaction, first recognized and systematically investigated nearly 35 years ago by Alder[1], usually involves the thermal reaction of an olefin containing an allylic hydrogen (ene) with an electron-deficient multiple bond (enophile) to form a 1:1 adduct as illustrated in Scheme 1. Experimental evidence[2] and orbital symmetry considerations[3] are consistent with a concerted pathway involving a *supra-supra*facial *endo*- or *exo*-oriented interaction (see A). It thus resembles the Diels-Alder reaction[4] and [1,5] sigmatropic shifts[4,5], which are also considered to involve a cyclic 6e transition state. Recent calculations concerning the ene process[3] suggest that in the transition state A the C—X bond is more developed than the H—Y bond. (For related discussions regarding an unsymmetrical transition state in the Diels-Alder reaction see[6].) Mechanistic and preparative aspects of the ene reaction were comprehensively reviewed by *Hoffmann* in 1969[7] (see also[8]).

Scheme 1. The intermolecular ene reaction.

Early examples of the intramolecular ene reaction (Scheme 2) date back to the 1930's[9–11]; however, its synthetic utility has become recognized only recently parallel to the general interest in intramolecular [4+2][12–14] and [3+2][14,15] cycloadditions. Similar to the cycloadditions, the intramolecular ene process profits from entropic advantage and exhibits preparatively useful regio- and stereoselectivity. This applies to three different modes of thermally-induced cyclizations (and cycloreversions) (Scheme 2) in which the enophile is linked by an appropriate bridge, either to the olefinic terminal (Type I), the central atom (Type II), or the allylic terminal (Type III) of the ene unit.

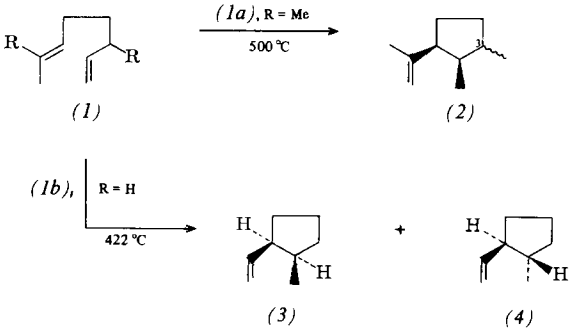
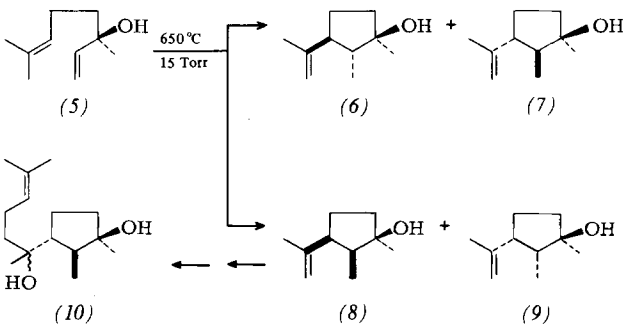
Scheme 2. Variants of the intramolecular ene reaction (Type I, Type II and Type III).



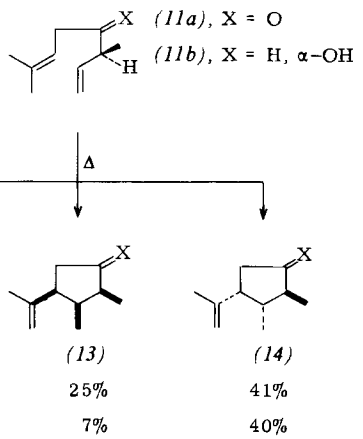
The aim of this review—in continuation of a review on intramolecular cycloadditions[14]—is to delineate the common characteristic features of the intramolecular ene reaction and to show, by selected examples, its scope, limitations, and utility in organic synthesis.

2. Type I Additions

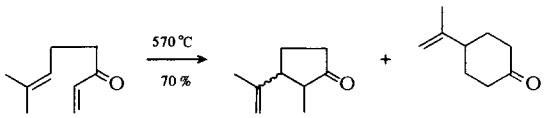


2.1. 1,6-Dienes

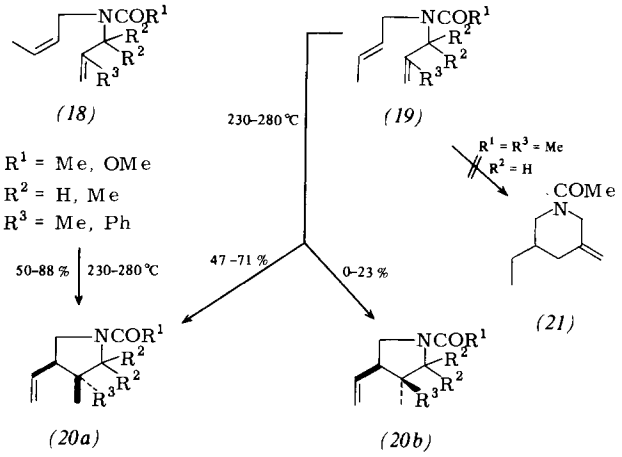
2.1.1. Acyclic 1,6-Dienes



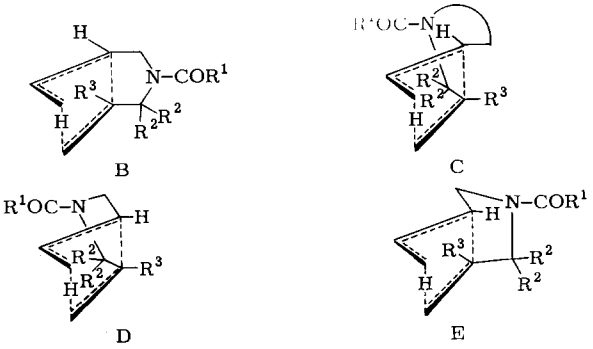
The majority of intramolecular ene reactions are concerned with the thermolysis of 1,6-dienes. In the first systematic study, *Huntsman* showed[16] that 1,6-dienes undergo cyclization to vinyl cyclopentanes, *e.g.* *(1a)*→*(2)*. This demonstrated the effective participation of nonactivated double bonds in the intramolecular ene process in contrast to the necessity for activated enophiles in the bimolecular counterpart. That this effect may be due to entropic factors is evident from the less negative entropy of activation ($\Delta S^{\neq} = -18$ cal K^{-1} mol^{-1}) for the reaction *(1a)*→*(2)* compared with that for intermolecular cases ($\Delta S^{\neq} = -30$ to -45 cal K^{-1} mol^{-1}[12b, 7]). Furthermore, this example illustrates the regioselectivity observed for numerous intramolecular ene reactions of 1,6-dienes in that predominant C—C bond formation occurs between the *closest* olefinic termini leading to five-membered rings. In addition, stereochemical selectivity was displayed in that cyclization of *(1a)* yielded a 4:1 mixture of the C(3)-epimers *(2)*[17] and also ring closure of *(1b)* gave *(3)* and *(4)* in the ratio 14:1[16].



The analogous thermolysis of linalool *(5)* to give the plinols *(6)*—*(9)* was first carried out by *Ikeda* in 1936[11] and more carefully investigated by *Ohloff* 30 years later[18]. Flash pyrolysis of *(5)* at 650°C under reduced pressure gave a 9:15:50:26 mixture of all four possible diasteriomeric plinols *(6)* to *(9)* in high yield, again indicating high regioselectivity but considerable loss of stereochemical control. In fact, a recent careful study has shown[19] that thermolysis of *(5)* under kinetically controlled conditions at lower temperature affords almost exclusively *(8)* and *(9)*. Thus, vapor phase pyrolysis (240 to 290°C) of the silylether of *(5)* (so as to avoid the partial dehydration occurring with *(5)*) showed the kinetic parameters $\Delta S^{\neq} = -18.7$ to -19.4 cal K^{-1} mol^{-1}, $\Delta H^{\neq} = 31.2$ to 31.8 kcal mol^{-1} and $\Delta G^{\neq} = 32.3$ to 32.9 kcal mol^{-1} for the formation of *(8)* and *(9)* which is favored over the formation of *(6)* and *(7)* by a difference $\Delta\Delta G^{\neq} = 2.2$ to 3.1 kcal mol^{-1}. Therefore the earlier observed formation of the products *(6)* and *(7)* at 650°C[18] may be attributed to the reversibility of the reaction at the higher temperature. The synthetic utility of such cyclizations is demonstrated[20] by the conversion of the main product *(8)* into the fungal sesquiterpene cyclonerodiol *(10)*.

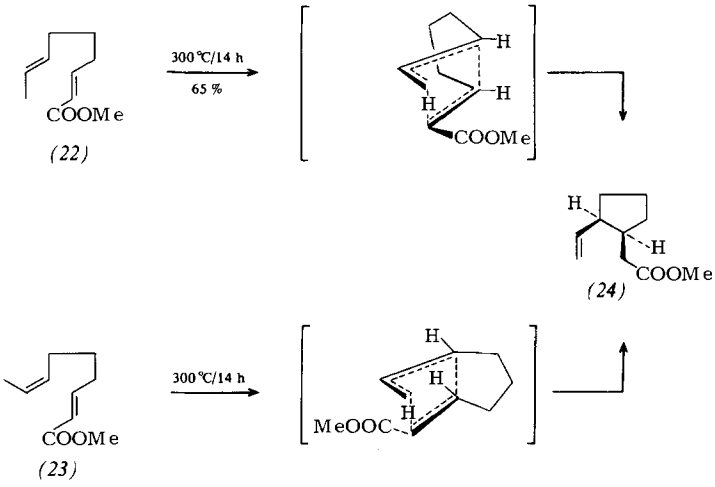


Thermolysis of the structurally similar dienes *(11a)* and *(11b)* likewise results in almost exclusive formation of cyclopentanes *(13)* and *(14)* with *cis* oriented adjacent isopropenyl and methyl groups at C-4 and C-3[21]. On the other hand, loss of regioselectivity was observed in the pyrolysis of the dienones *(15)*, leading to the cyclopentanones *(16a)* and *(16b)* together with the cyclohexanone *(17)* in the ratio 2:3:1[22]. At 570°C, partial interconversion of *(17)* and *(16)* was observed, again indicating the operation of a retro ene-process.

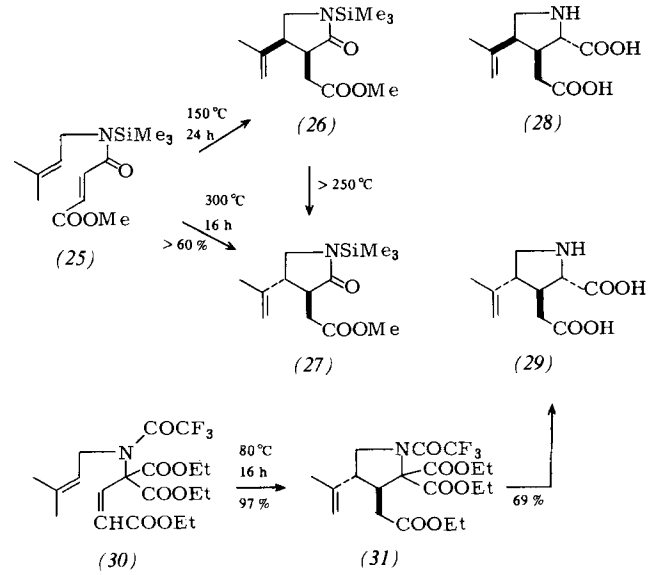


(15) (16a), cis (16b), trans (17)

The first systematic stereochemical investigation[23] of the intramolecular ene reaction dealt with the regioselective thermal cyclization of the *N*-allyl-*N*-(2-butenyl)amides *(18)* and *(19)* to afford the *cis*-substituted pyrrolidine derivatives *(20a)* in high yields. The *cis* dienes *(18)* reacted under kinetic control with 100% stereoselectivity whereas the *trans* dienes *(19)* furnished, in addition to *(20a)*, minor amounts of the *trans* isomers *(20b)*. Model considerations (Scheme 3) show that the observed stereochemical results are consistent with a *supra-supra*facial process. In the cyclization of the *cis* diene *(18)*, the *endo* transition state C appears to be highly strained thus favoring the exclusive formation of the *cis*-substituted pyrrolidine *(20a) via* the relatively unstrained *exo* transition state B.

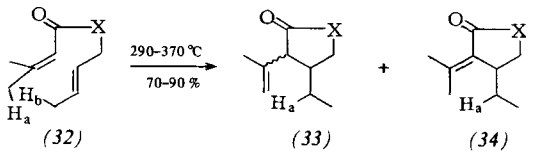


In the analogous cyclization of the *trans* diene *(19)*, preference of the *endo* transition state D over the *exo* transition state E is indicated. From these studies, it also appeared that not only the stereochemical outcome but also the rate of the intramolecular ene reaction of 1,6-dienes may be largely independent of the ene geometry.



Scheme 3. Transition states for the thermal cyclizations of the dienes *(18)* and *(19)*.

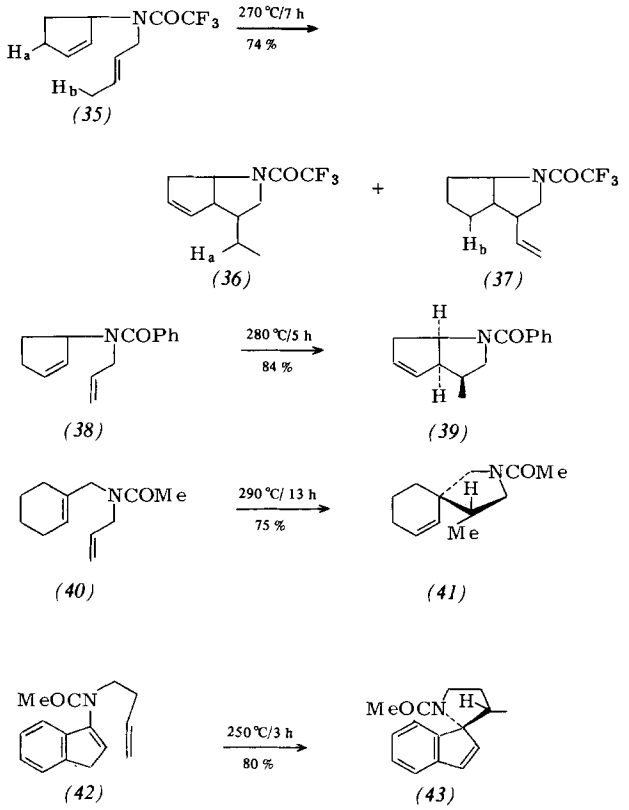
Similarly, at 300 °C, both the terminally carbonyl-conjugated *trans,trans* diene *(22)* and its *cis,trans* isomer *(23)* provided the *cis*-substituted cyclopentane *(24)* at the same rate thus indicating no preference for an *endo*-oriented methoxycarbonyl group in the transition state[24].



In an attempt to synthesize the natural anthelminthics, α-kainic acid *(28)* and α-allokainic acid *(29)*, cyclization of the readily available fumaric ester amide *(25)* was examined[25]. At 150 °C, the *cis*-pyrrolidone *(26)* was the exclusive product; on the other hand, thermolysis of the diene *(25)* or *(26)* at higher temperature furnished predominantly the thermodynamically more stable *trans* isomer *(27)*. This finding demonstrates the possibility of selectively synthesizing both *cis*- and *trans*-substituted five-membered rings under conditions of kinetic or thermodynamic control. The conversions *(26)* → *(28)* and *(27)* → *(29)* have not yet been realized; however, the natural amino acid *(29)* has been prepared in good yield from the simple precursor *(30)* in two synthetic operations[25]. The key step *(30)* → *(31)* proceeds in quantitative yield at surprisingly low temperatures (80 °C/16 h or 25 °C/3 months). Whether or not the exclusive formation of the *trans*-substituted pyrrolidine *(31)* is due to the reversibility of the reaction remains to be clarified.

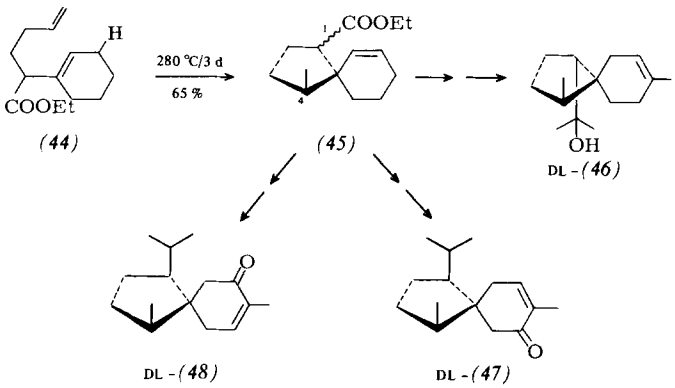
The analogous cyclizations of the diene amides, esters, and ketones *(32)* with carbonyl-conjugated ene units provide stereo

and double bond isomers *(33)* and *(34)* in good yields and thus indicate preference for H_a over H_b hydrogen transfer[26]. (An alternative explanation for this preference involves hydrogen transfer *via* a dienol intermediate by a Type II ene reaction.)



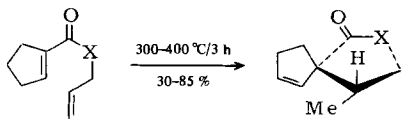
(32) *(33)* *(34)*

(a), X = NH, NR; *(b)*, X = O; *(c)*, X = CH_2



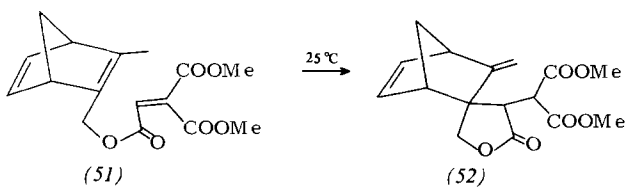
2.1.2. Cyclic 1,6-Dienes

Cyclic dienes in which one double bond is situated in the ring and the other in a side chain can likewise undergo intramolecular ene reactions. In contrast to the reaction *(32)* → *(33)* + *(34)* essentially no discrimination in the transfer of H_a and H_b was observed in the thermolysis of the cyclopentenylamide *(35)* to give the structural isomers *(36)* and *(37)*[23]. However, 1,6-dienes containing an endocyclic ene component and a terminal olefin as enophile unit, cyclize efficiently to single bicyclic products. Thus the highly stereoselective transformations *(38)* → *(39)*, *(40)* → *(41)*, and *(42)* → *(43)* illustrate nicely a simple route to fused or spiro bicyclic systems containing *cis*-related methyl- and vinyl substituents[23].

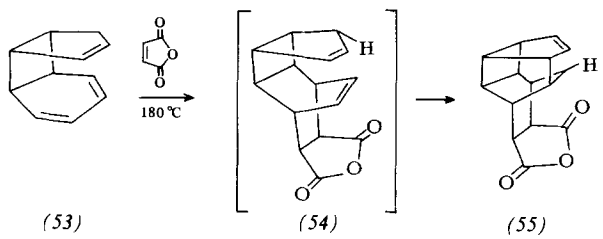


(35) *(36)* *(37)* *(38)* *(39)* *(40)* *(41)* *(42)* *(43)*

These stereochemical features, which are also observed in the thermal cyclization of open chain dienes (see Section 2.1.1), have been exploited in a flexible and stereoselective approach to spirosesquiterpenes[27]. Thus the readily available cyclohexenyl derivative *(44)* cyclizes at 280 to 290 °C exclusively to the C-1 epimeric *endo* products *(45)*. Their base-induced interconversion provides easy access to either 1,4-*trans* or 1,4-*cis*-substituted natural spiro[4,5]decanes[27d] such as β-acorenol *(46)*[27a], acorenone-B *(47)*[27b] and acorenone *(48)*[27c]. Similar stereoselective formation of spiro-lactams, -lactones, and -ketones *(50)* is observed on heating compounds *(49)* at high temperatures[26].



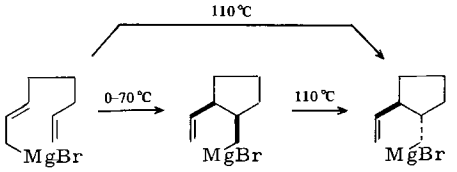
(44) *(45)* DL-*(46)* DL-*(48)* DL-*(47)*



(49) *(50)*

(a), X = NR; *(b)*, X = O; *(c)*, X = CH_2

Activation of the enophile component by three carbonyl groups as in *(51)* promotes smooth cyclization even at room temperature to give a single spirolactone *(52)*, the stereochemistry of which has not yet been elucidated[28]. The formation of three C—C bonds in a single synthetic operation is demonstrated[29] by the thermal addition of the triene *(53)* at 180 °C to maleic anhydride involving an ene reaction of the intermediate Diels-Alder adduct *(54)*. This simple approach to the cage compound *(55)* illustrates the general potential of combining pericyclic reactions in the synthesis of complex molecules.

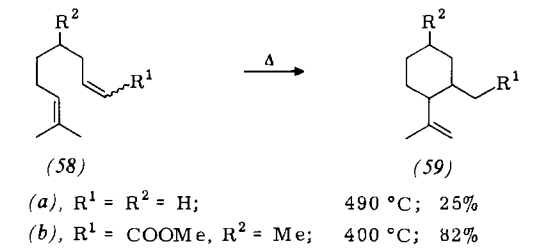


(51) *(52)*

(53) *(54)* *(55)*

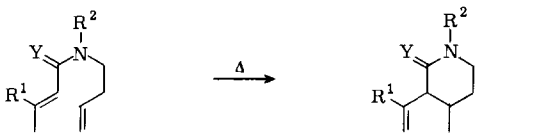
Intramolecular ene reactions involving the transfer of atoms other than hydrogen have rarely been observed. An interesting observation[30a,b] is the cyclization of the Grignard reagent

(56) which is readily available in one synthetic operation from butadiene. Even at temperatures between 0 and 70°C, highly selective cyclization to the *cis*-substituted cyclopentane *(57a)* is observed. At 110°C, *(57a)* as well as *(56)* isomerize to the more stable *trans* product *(57b)*, indicating the reversibility of the reaction *(56)* → *(57)* at higher temperatures. Reaction of the cyclic Grignard products *(57)* with a series of electrophiles[30a] provides access to variously functionalized 1,2-disubstituted cyclopentane derivatives in a stereoselective manner.



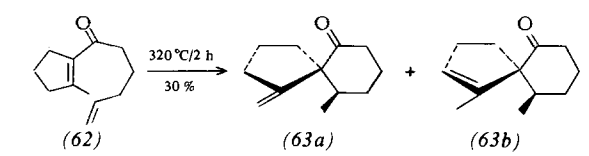
(56) *(57a)* *(57b)*

Analogous lithium transfer seems to occur in the cyclization of 3,7-dimethylocta-1,6-diene with nBuLi/TMEDA to give the allylic carbanion of 1,2-dimethyl-3-isopropenylcyclopentane[30c].



2.2. 1,7-Dienes

1,7-Dienes undergo the intramolecular ene reaction less readily than the corresponding 1,6-dienes. Thus the transformations *(58a)* → *(59a)*[31], *(60a)* → *(61a)*[23,26c] and *(62)* → *(63)*[26a] require higher temperatures and proceed in lower yields. Nevertheless, preparatively useful yields of six-membered ring products such as *(59b)* or *(61b)* may be obtained from 1,7-dienes containing carbonyl-activated enophile or ene components.



(58) *(59)*

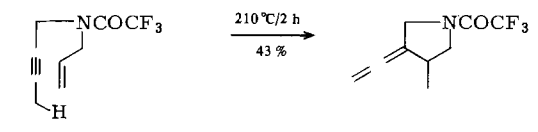
(62) *(63a)* *(63b)*



2.3. 1,6-Enynes and 1,2,6-Trienes

In contrast to dienes acetylenes generally participate in intramolecular ene reactions under considerably milder conditions. Thus, even on brief heating at 400°C, the enyne *(64a)* gives the cyclic 1,4-diene *(65a)* in good yield[32]. Cyclization of the enynes *(64b)*[23] and *(64c)*[26c] also proceeds easily at about 200°C to the pyrrolidine derivatives *(65b)* and *(65c)*, respectively, thus demonstrating smooth cyclization of an acetylenic enophile. Alternatively, an acetylenic ene component is involved in the thermal conversion of *(66)* under similar conditions into the allene *(67)*[23]. The quantitative transformation of dehydrolinalool *(68)* into *(69)*[33a] proceeds at 200°C with $\Delta S^{\neq} = -13.7$ cal K^{-1} mol^{-1} and $\Delta H^{\neq} = 28.7$ kcal mol^{-1}[19] (showing a significantly lower free energy of activation than the analogous reaction of linalool *(5)*). The reaction *(68)* → *(69)* has recently been exploited[33b] in the synthesis of the spirosesquiterpene, β-acoratriene *(72)*. The allylic alcohol in *(69)* serves as the reactive site for the introduction of the remaining carbon atoms of *(72)* *via* the intermediates *(70)* and *(71)*. Similar Claisen rearrangement *via* reaction of *(69)* with 1-ethoxy-1-propene provides easy access to the industrially important perfume ingredient *(82)*[33c].

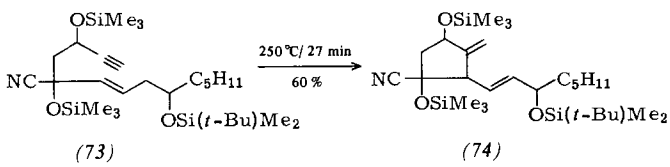
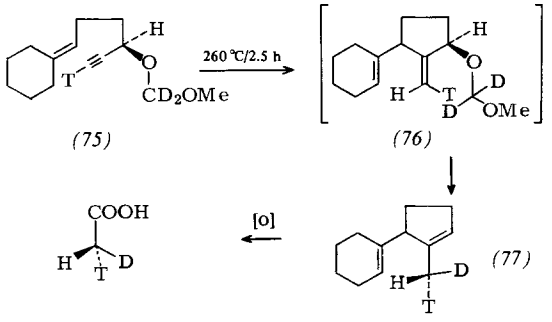
(66) *(67)*

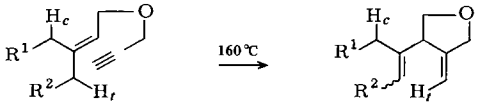


(68) *(69)*



(72) *(71)* *(70)*

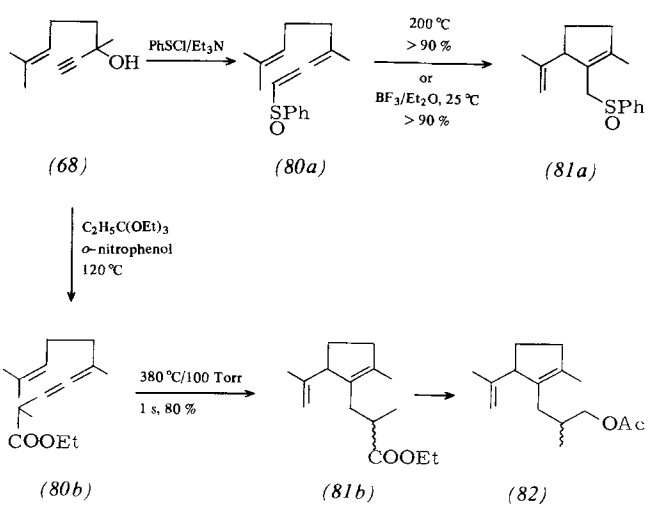
Similarly, cyclization of the multifunctionalized enyne *(73)* to *(74)* represents the key step in a total synthesis of prosta-



(73) *(74)*

glandins[34]. In an exceedingly elegant synthesis of chiral acetic acid[35], the *supra-supra* character of the ene reaction is utilized in the thermal cyclization of the enyne *(75)* to control the configuration of the exocyclic double bond in the transient product *(76)*. Intramolecular chirality transfer by a subsequent retro-ene reaction, *(76)*→*(77)*, generates the desired asymmetric center. Thus *(77)*, obtained from *(75)* in one synthetic operation, provides after Kuhn-Roth oxidation (*R*)-[^{2}H, ^{3}H]-acetic acid in high optical purity.

(75) *(76)* *(77)*



An interesting selectivity is displayed by the thermal cyclizations of the propargyl ethers of nerol *(78a)* and geraniol *(78b)* to *(79a)* and *(79b)*, respectively; in both cases transfer of H_t predominates over H_c-transfer[36a].

(78) *(79)*

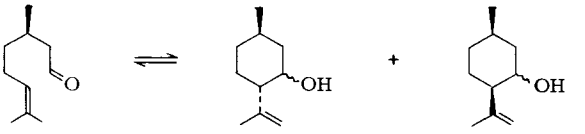
Recently, it has been shown[36b] that the sulfoxide *(80a)*, containing an allenic enophile unit, cyclizes quantitatively to the doubly functionalized cyclopentene derivative *(81a)*. Striking rate enhancement of this reaction can be achieved by Lewis acid catalysis. An industrial process, actually carried out on a scale of several 100 kg, involves efficient thermolysis of the allene *(80b)* (also readily prepared from *(68)*) to give *(81b)*, which is then converted into the odorant *(82)* (also accessible from *(69)*, *vide supra*)[36c].

(68) *(80a)* *(81a)*

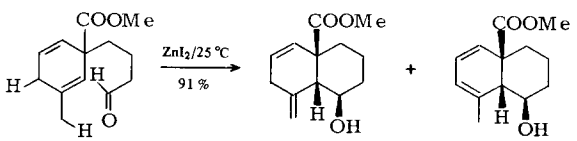


(80b) *(81b)* *(82)*

2.4. Enones

Intramolecular ene reactions of enones have been widely used in the synthesis of five- and six-membered ring systems. The carbonyl group serves either as the enophile or, *via* its enol tautomer, as the ene unit.

2.4.1. Hydrogen Transfer from Carbon to Oxygen (Carbonyl as Enophile)

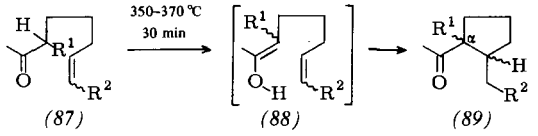


Although the acid-induced cyclization of citronellal *(83)*, observed as long ago as 1896[37], probably proceeds *via* cationic intermediates, the thermal transformation *(83)*→*(84)* at 350 °C, first reported 31 years later[9], may be described by an intramolecular ene mechanism. This mechanism is also implicated in the reverse process, which proceeds at 500 °C and reflects the delicate energy balance between *(83)* and *(84)*. Both the forward[9] and reverse[10] reactions were observed before the ene reaction was formulated as a general reaction principle.

(83) *(84a)* β-OH *(84b)* α-OH *(84c)* β-OH *(84d)* α-OH

180 °C/30h	49%	16%	4%	12%
$ZnBr_2$/5-10 °C/15 min	66%	4%	traces	
[$RhCl(PPh_3)_3$] 25 °C/15h	14%	41%	–	–

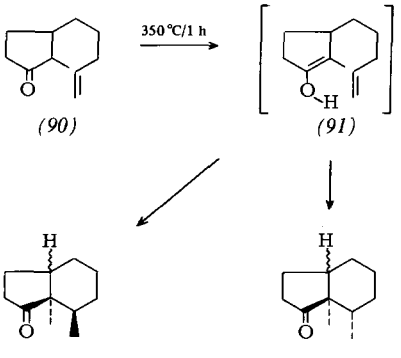
Because of its industrial importance the pyrolytic cyclization of citronellal *(83)* has been restudied in more detail[38a–c]. Heating of *(83)* at 180 °C leads to all possible stereoisomeric isopulegols *(84)*, the major isomer *(84a)* exhibiting *trans*-related hydroxyl and isopropenyl groups. This isomer is formed even more selectively from *(83)* at low temperature in the presence of 1 equiv. of $ZnBr_2$[38d]. On the other hand, when the reaction is catalyzed by tris(triphenylphosphane)rhodium chloride, *(84b)* is formed as the predominant isomer at 25 °C[39]. The analogous cyclization of the benzylimine derived from *(83)* in the presence of $SnCl_4$ at −25 °C[40] yields a similar product pattern as the uncatalyzed process of *(83)*. A related example is the synthesis of the eudesmane sesquiterpenes: the aldehyde *(85)*, readily available *via* reductive alkylation of *m*-toluic acid, smoothly isomerizes in the presence of zinc iodide catalyst to a 1:3 mixture of the bicyclic dienols *(86a)* and *(86b)*[41].



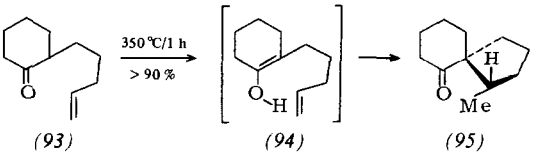
(85) *(86a)* *(86b)*

2.4.2. Hydrogen Transfer from Oxygen to Carbon (Enol as Ene-Component)

Monocyclization: By far the largest number of intramolecular enone cyclizations described to date involve hydrogen

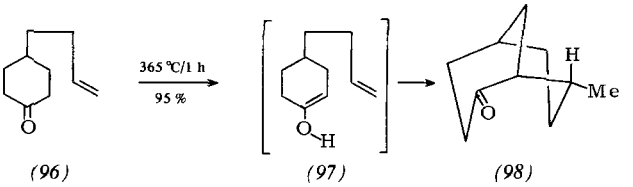


transfer from an enol intermediate to an olefinic enophile. As developed by *Conia et al.*, this method leads to an enormous variety of monocyclic, bicyclic, and bridged systems. A few selected examples will suffice here in order to discuss this principle within the framework of the intramolecular ene reaction (for a major review see [42]). Thus ε,ζ-unsaturated ketones *(87)*, on heating at 350—270°C on a Pyrex surface, furnish substituted cyclopentanes *(89)* in high yield[43]. In general, these reactions proceed by two successive steps: rate-determining tautomerization, *(87)* → *(88)*, followed by the actual cyclization process, *(88)* → *(89)*. The high temperatures and surface catalysis required for the first step somewhat limit the general applicability of this reaction. Subsequent enolization determines also the *trans* configuration of the products *(89a)* and *(89b)* containing available α-hydrogens. However, in analogy to cyclizations of 1,6-dienes, kinetic control favors a *cis* relationship between the hydrogen donor and hydrogen acceptor units in the product, as in *(89c)*.



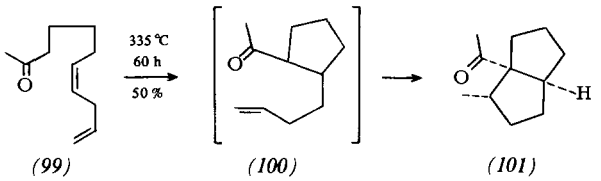
(87) *(88)* *(89)*

(a), $R^1 = R^2 = H$; R^1/H: *trans*; 84%
(b), $R^1 = H$; $R^2 = COOMe$; R^1/H: *trans*; 90%
(c), $R^1 = Me$; $R^2 = H$; R^1/H: *cis*; 90%

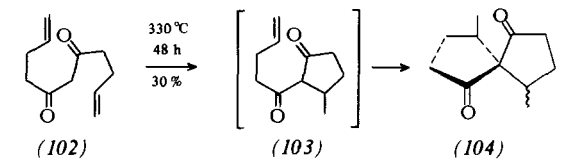


In the kinetically controlled pyrolysis of cyclic ketones the stereochemical outcome depends on whether the enol intermediate is fixed in the *trans* or *cis* configuration with respect to the enophilic bridge. Thus, in accord with model considerations, the "*trans*" enol intermediate *(91)* derived from *(90)* affords[44] a mixture of the stereoisomers *(92a)* and *(92b)*, whereas the *cis* enol *(94)* resulting from *(93)* provides[45] exclusively the spiro product *(95)* with *cis*-related methyl and carbonyl groups. Furthermore, bridged ring systems are easily accessible, as exemplified by the efficient thermal conversion of *(96)* into *(98)*[46].

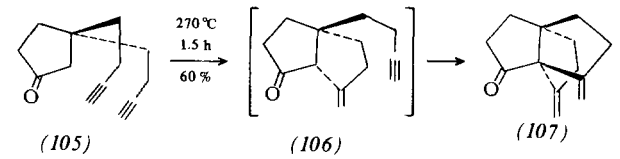
(90) *(91)* *(92a)* 17% *(92b)* 58%



(93) *(94)* *(95)*

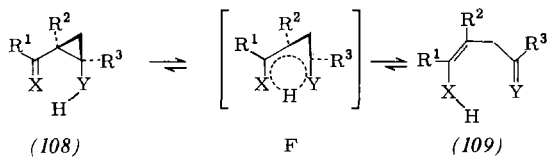


(96) *(97)* *(98)*



Double cyclizations: Elegant examples exploiting successive pericyclic reactions include the thermal conversions *(99)* → *(101)*[47], *(102)* → *(104)*[47], and *(105)* → *(107)*[48]. Thus a single synthetic operation involving two sequential ene reactions provides fused, spiro, and propellane systems.

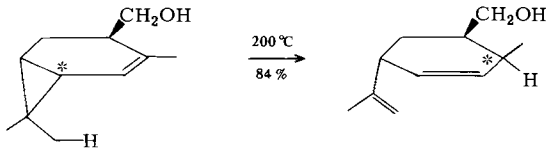
(99) *(100)* *(101)*



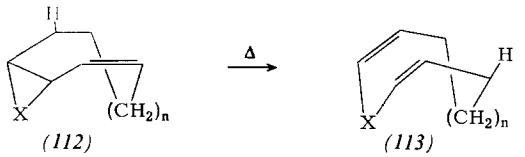
(102) *(103)* *(104)*

(105) *(106)* *(107)*

2.5. Retro-Ene Reactions



Ring strain effects clearly shift the equilibrium between *(108)* and *(109)* highly in favor of the diene (retro-ene process)[49]. In agreement with a concerted retro-ene mechanism (transition state F), cyclopropanes with *cis*-related hydrogen donor (Y) and acceptor (X) units cleave at significantly lower temperatures than the corresponding *trans* isomers.

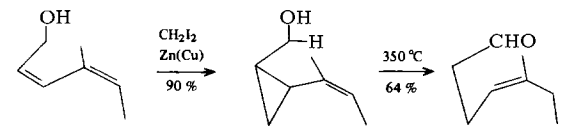


(108) F *(109)*

2.5.1. Hydrogen Transfer from Carbon to Carbon

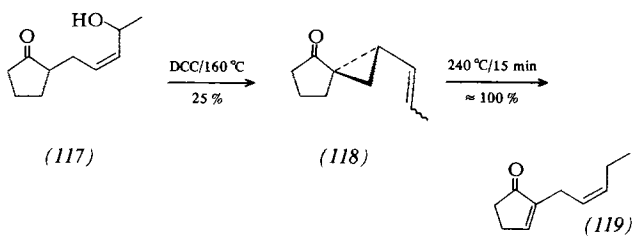
The suprafacial character of the retro-ene reaction is further demonstrated by the highly specific chirality transfer observed[50] in the conversion of the carene derivative *(110)* into the menthadiene *(111)*. The related ring enlargement reaction of the annelated cyclopropanes[51] and epoxides[52] *(112)* into dienes *(113)* implies transannular hydrogen transfer and concomitant cleavage of the C—C bond common to the two rings.

(110) (111)



(112) (113)

(a), X = $CHCH_2OH$; n = 2; 340°C; seconds

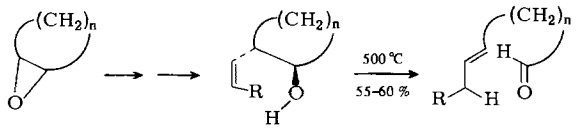


(b), X = O; n = 2; 195°C; 2 days

(c), X = CH_2; n = 1; 180-300°C; ?

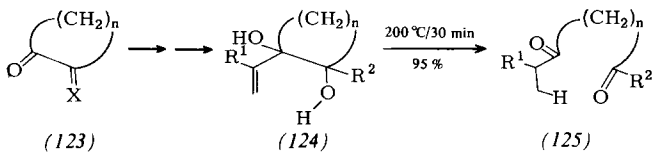
The earlier observations concerning the selective formation of (*Z*)-olefins *(109)* in the ring opening of the *cis*-alkylvinyl cyclopropanes *(108)*[49] have been elegantly exploited[53] in the stereoselective synthesis of the trisubstituted olefin *(116)*. This building block for the synthesis of Cecropia juvenile hormone was obtained by pyrolysis of the *cis*-cyclopropane *(115)* which was readily available from the dienol *(114)*.

(114) (115) (116)



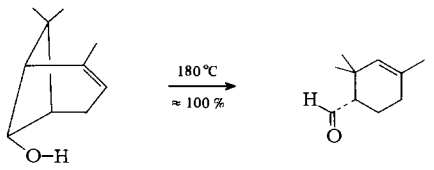
(117) (118) (119)

The synthesis of a jasmone precursor *via* the sequence *(117)*→*(118)*→*(119)* also illustrates the highly stereoselective (Z)-olefin formation in the retro-ene step *(118)*→*(119)*[54].



2.5.2. Hydrogen Transfer from Oxygen to Carbon

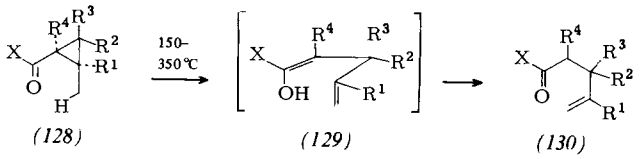
As mentioned earlier (Section 2.4), the equilibrium *(83)* ⇄ *(84)* is shifted to the side of the acyclic enone *(83)* at higher temperatures. Likewise, unsaturated aldehydes *(122)* with different chain lengths can be obtained by heating the β-hydroxyolefins *(121)* to 500°C[38a, 55a]. For example, *trans*-2-vinylcyclohexanols, prepared by acid treatment of 7-hydroxymethylbicyclo[4.1.0.]heptanes, on heating to 440°C for 2 min afforded stereoselectively (*E*)-ε,ζ-unsaturated carbonyl compounds[55b]. At considerable lower temperature, the unsaturated glycols *(124)* cleave readily to the energetically more favorable diketones *(125)*[56]. Loss of cyclobutane ring strain facilitates the related cleavage of *(126)* to the γ,δ-unsaturated aldehydes *(127)*[57].



(120) (121) (122)

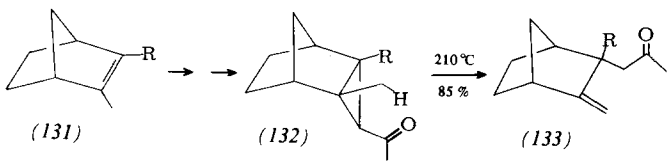
R = *n*-C_4H_9, *n*-C_5H_{11}, *n*-C_6H_{13}; n = 3, 4, 5

(123) (124) (125)



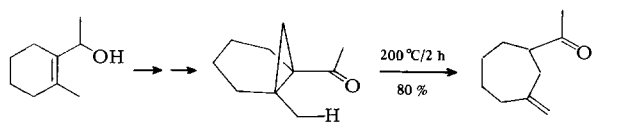
R^1 = H, Me; R^2 = H, Me, Et; n = 3, 10

(126) (127)



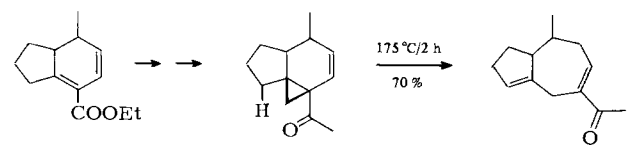
2.5.3. Hydrogen Transfer from Carbon to Oxygen

cis-Methylcyclopropane carbaldehydes, ketones, and esters *(128)* also undergo thermal ring opening to provide γ,δ-unsaturated carbonyl compounds *(130)* in good yields[49a, 49c, 58]. This conversion, proceeding *via* enol *(129)*, as well as the related transformation *(132)*→*(133)*[59], correspond to the retro-ene equivalent of the reaction *(87)*→*(88)*→*(89)* mentioned in Section 2.4.2. The analogous examples *(135)*→*(136)*



(128) (129) (130)

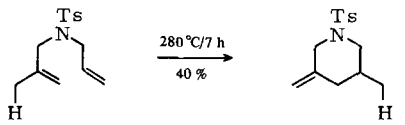
X = H, Alkyl, Aryl, OMe



(131) (132) (133)

R = H, Me

(134) (135) (136)



(137) (138) (139)

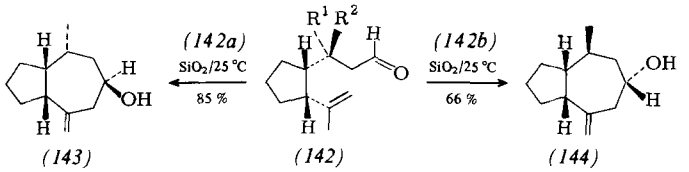
and *(138)*→ *(139)* represent interesting thermal ring enlargements[60]; thus, the annelated cycloheptane *(139)* is a potential precursor for the synthesis of hydroazulene sesquiterpenes.

3. Type II Additions

3.1. 1,6-Dienes

The Type II addition of dienes has hitherto received relatively little attention. This reaction occurs less readily than the corresponding Type I addition, as seen by the low conversion of *(140)* into *(141)*[61]. Likewise, the thermolysis of

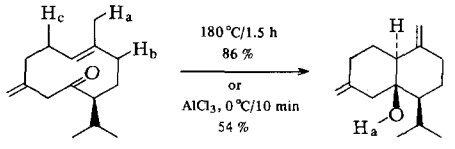
(140) *(141)*



(19), $R^1 = R^3 = Me$, $R^2 = H$, which offers internal competition between Type I [→ *(20)*] and Type II [→ *(21)*] modes also shows high preference for the former process.

3.2. Enones

The preparative utility of the Type II additions of enones can be illustrated with the aid of a few examples.

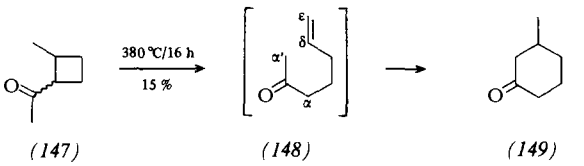


3.2.1. Hydrogen Transfer from Carbon to Oxygen (Carbonyl as Enophile)

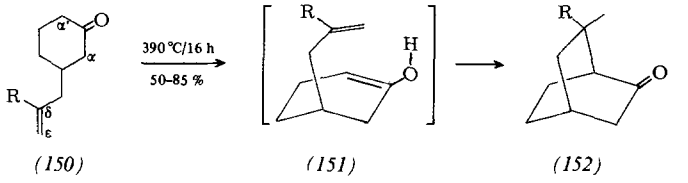
Hydroazulene derivatives are formed in high yield by silica gel catalyzed cyclizations of enones *(142a)* and *(142b)*[62]. The operation of an ene process appears to be responsible for the exclusive formation of *exo*-methylene products and for the high stereoselectivity; in both cases major isomers are formed, to which structures *(143)* and *(144)*, respectively, have been assigned[62a, 62b]. This approach to hydroazulenes has been exploited in the synthesis of the sesquiterpene

(143) *(142)* *(144)*

(a), R^1 = Me, R^2 = H; *(b)*, R^1 = H, R^2 = Me



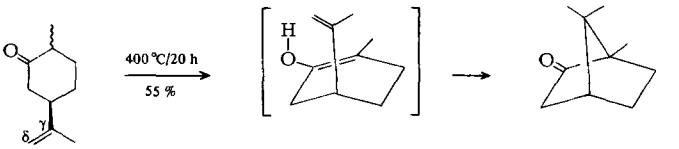
(145) *(146)*



(+)-kessanol[62d]. Recently, the analogous stereoselective cyclization of a δ,ε-unsaturated aldehyde to produce a methylenedecanol was also observed[62e]. In the thermolytic or Lewis acid-catalyzed cyclization of the ten-membered ring enone *(145)* to the decalin *(146)*[63], conformational factors appear to favor transfer of H_a (Type II addition) over transfer of H_b or H_c (Type I addition).

3.2.2. Hydrogen Transfer from Oxygen to Carbon (Enol as Ene Unit)

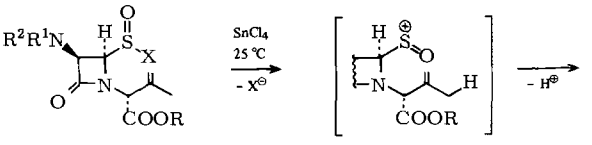
δ,ε-Unsaturated ketones with available α'-protons form cyclohexanones (Type II) rather than cyclobutyl ketones (Type I) because of ring strain. In fact, retro-ene reaction of *(147)* gives *(148)* which cyclizes *via* its α'-enol directly to *(149)* at higher temperatures[64]. Complicated bridged ring systems are accessible in an analogous manner by thermolysis of δ,ε- and γ,δ-unsaturated cyclic ketones, as shown by the conversions of *(150)* and *(153)* into the bicyclo[2.2.2]octanone *(152)*



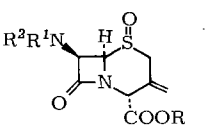
(147) *(148)* *(149)*

(150) *(151)* *(152)*

R = H, Me

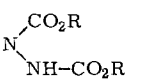


(153) *(154)* *(155)*



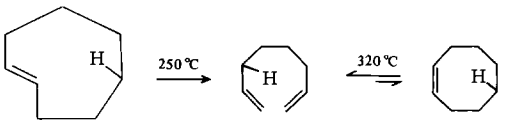
and camphor *(155)* respectively at 400 °C[65]. The relative configuration of *(152)* results from the *endo* transition state requirement in Type II additions.

3.3.3. Sulfinyl Cations and Nitroso Groups as Enophiles



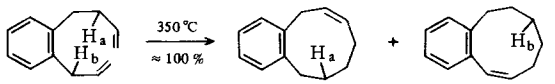
Although groups with hetero multiple bonds such as azo and nitroso groups may serve as effective enophiles in intermolecular ene reactions[7], their participation in intramolecular

(156) *(157)*



(158)

X = Cl, OH, S-*i*-Pr, NHPh, 



ene processes have rarely been tested. One of the few reports[66] describes the transformation of *(156)* derived from penicillin sulfoxide into the cepham *(158)*, presumably *via* the transient sulfinium ion *(157)*. An analogous cyclization of an unisolable aliphatic nitroso compound into a cyclic hydroxylamine has been described[67].

4. Type III Additions

The few cases of Type III reactions so far reported deal with the thermal equilibrium between medium-sized cycloalkenes and acyclic α,ω-dienes, the latter being favored at higher temperatures[7, 49a, 68]. For example, 1,7-octadiene *(160)* is obtained on heating *trans-* *(159)* or *cis*-cyclooctene *(161)*,

(159) *(160)* *(161)*

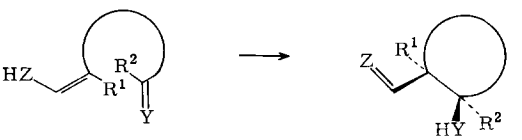
(162) *(163)* *(164)*

the more strained *trans*-isomer opening at lower temperature. In contrast, exclusive cyclization, *(162)* → *(163)* + *(164)*, was observed at 350 °C[69].

5. Discussion

The available evidence allows the following generalizations.

5.1. Entropic Assistance



Since the intermolecular ene process shows a high negative entropy of activation[2b, 7] it clearly should profit from intramolecularity, as is well known for other pericyclic reactions[14]. Accordingly, kinetic measurements of the transformations *(1)* → *(2)* and *(5)* → *(8)* + *(9)* show an activation enthalpy $\Delta H^{\neq} = 31.2$ to 31.8 kcal mol^{-1} and an activation entropy $\Delta S^{\neq} = -18.0$ to -19.4 cal K^{-1} mol^{-1}, whereas the intermolecular ene reactions of alkenes with maleic anhydride exhibit activation parameters $\Delta H^{\neq} = 18.0$ to 21.5 kcal/mol and $\Delta S^{\neq} = -36$ to -45 cal K^{-1} mol^{-1}[2b]. It thus appears that the effective participation of nonactivated enophiles in the intramolecular ene process is due to the less negative $\Delta S^{\neq}$ which compensates for the higher $\Delta H^{\neq}$ values. Intramolecularity also facilitates the ene reactions of activated enophiles as exemplified by the reactions *(30)* → *(31)* and *(51)* → *(52)*.

5.2. Direction of Addition

In 1,6- and 1,7-dienes and -enynes and the corresponding enones and dienols containing several allylic or propargylic hydrogens, preference for hydrogen transfer follows the order Type I > Type II > Type III [for an exception see the reaction *(145)* → *(146)*]. When the linking chain is shorter than three atoms, formation of three- to four-membered rings by the Type I pathway is thermodynamically disfavored thereby promoting the less strained Type II products, as illustrated by the transformations *(147)* → *(148)* → *(149)*, *(150)* → *(152)* and *(153)* → *(155)*. In most reactions of Type I and Type II, carbon-carbon bond formation occurs preferentially between the closest unsaturated centers. This preference, observed in the formation of five-, six- and seven-membered rings using nonpolarized enophiles may be ascribed to entropic factors consistent with an "unsymmetrical" transition state[3]. Thus, the development of the C—C-bond being more advanced in the transition state than H-transfer concords well with the regioselectivity which is also observed for other biradicaloid intramolecular processes. Steric repulsion probably favors C—C bond formation between terminal olefinic centers in Type III additions of α,ω-dienes to give medium-sized rings.

5.3. Stereochemistry

In systems where the ene and the enophile units are linked by three or four atoms, the highly ordered transition state may induce useful *endo-exo* discrimination avoiding nonbonding interactions between the bridge and substituents and/or bond angle deformation. For example, the Type I additions of systems containing the hydrogen donor site Z *cis* with respect to the enophilic chain (Scheme 4) exclusively lead to rings where the H-donor and H-acceptor sites Z and Y appear in a *cis* relationship, *e.g. (18)* → *(20a)*, *(23)* → *(24)*, *(38)* → *(39)*, *(94)* → *(95)*. Model considerations clearly show this selectivity to be derived from a strong preference for the *endo* over the *exo* transition state which would exhibit considerable angle strain (see also Scheme 3).

Scheme 4. Stereochemistry of Type I reactions involving "*cis*" enophiles.

For the same reason, Type II reactions can occur only in an *endo* manner when leading to five-, six- or seven-membered rings [see *e.g. (150)* → *(151)* → *(152)*]. The counterplay of kinetic *versus* thermodynamic control may influence the stereochemical outcome as seen in the thermolysis of *(5)*, *(25)* and *(56)*.

6. Concluding Remarks

Accumulating evidence points to the synthetic potential of the intramolecular ene reaction. Based on the given examples a set of rules have been derived, similar to those obtained for intramolecular cycloaddition reactions[14]. Particular mention should be made of the stereoselective construction of five-membered carbo- and heterocyclic systems including substituted, annelated, spiro-fused and bridged systems. The smooth intramolecular ene reaction involving magnesium transfer merits further application and suggests the use of other organometallic ene components. More attention could also be given to the Type II process using activated enophiles. Combination of an intramolecular ene process either with itself or with other pericyclic reactions offers additional fascinating possibilities. It appears possible that further mechanistic details of the ene reaction may be revealed through work on the intramolecular variant. In view of the continuing need for high yield and selective carbon-carbon bond forming cyclizations in the synthesis of natural products and other complex

molecules, further exploitation of this reaction is expected in the near future.

Some of our own work mentioned in this article was carried out at Sandoz Ltd., Basle, and some at the University of Geneva. The latter investigations were kindly supported by the Fonds National Suisse de la Recherche Scientifique, Sandoz Ltd., Basle, and Givaudan SA, Vernier. We are indebted to Hendrik Andres, Kumar Mahalanabis, Emil Pfenninger and Tarun Sarkar for their valuable contribution. One of us (V.S.) thanks the National Research Council of Canada and the Department of External Affairs, Ottawa for Travel Grants as well as the University of Geneva in aid of a Visiting Professorship in Geneva (1976—1977).

Organic Reactions at Alumina Surfaces

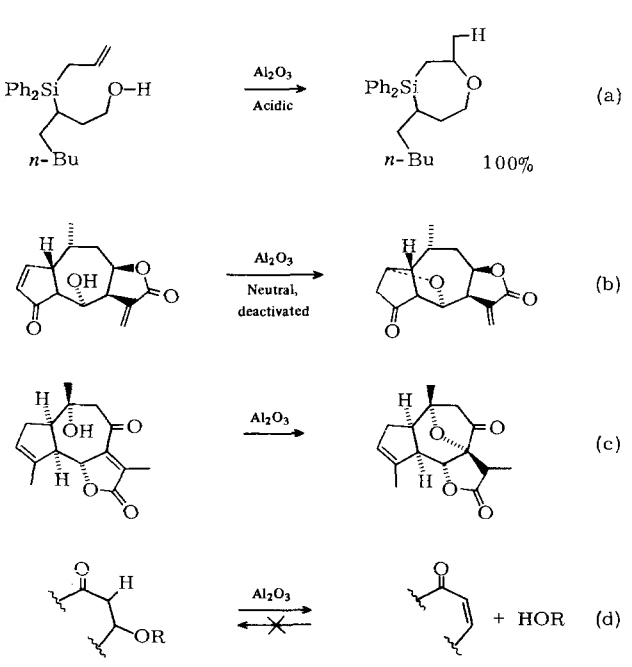
By Gary H. Posner[*]

New synthetic methods (24)

Recent examples are given to emphasize that alumina can cause many different and often unexpected chemical reactions of adsorbed organic molecules. Recent developments are summarized to publicize that reagent-doped alumina can be used deliberately to achieve some very mild and highly selective organic transformations. The scope and limitations of organic reactions at alumina surfaces are discussed, and the advantages of these heterogeneous reactions over the corresponding homogeneous ones are pointed out. The role of the alumina and future problems are discussed briefly.

1. Introduction

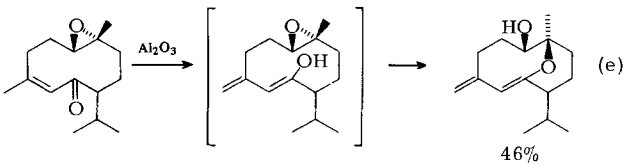
The main purpose of this article is two-fold: (a) to emphasize with recent examples the pronounced catalytic activity of γ-alumina in causing various adsorbed organic molecules to undergo many different types of often unanticipated chemical reactions[1] and (b) especially to publicize recent developments involving *deliberate* placement of different reagents on solid alumina and use of this doped alumina to cause diverse organic reactions heterogeneously at the alumina surfaces under unusually mild conditions. The examples given in the article were chosen to illustrate the most important results for organic synthesis, and they do not represent all literature reports on this subject. The nature of γ-alumina has been reviewed[2], and therefore it will not be discussed here at length; catalytically active γ-alumina as used for chromatography has both acidic and basic sites, and probably the synergistic effect of these two properties on organic molecules is the basis for the unusual mildness and selectivity of many of the chemical transformations discussed in the following sections.



Although a 1924 patent reported use of chemical reagents on porous carriers to achieve some highly selective and mild chemical operations[3], not until recently has interest been rekindled in this area, as shown by the dates of the following references: *Collins'* reagent[4] and silver carbonate[5] on Celite, chromic acid on an anion exchange resin[6] and intercalated in graphite[7], and chromyl chloride on silica-alumina[8] for alcohol oxidations; ozone on silica gel for oxidation of tertiary alkyl centers[9], for oxidation of arenes[10] and for oxidation of primary amines to their nitro derivatives[11]; thallium trinitrate on K-10 montmorillonite clay for oxythallation reactions[12]; alcohols on various zeolites[13] for reduction of small carbonyl compounds[14]; nitric acid on Celite for aromatic nitration[15], and $SbCl_5$ intercalated in graphite for substitution of bromine by chlorine[16,17].

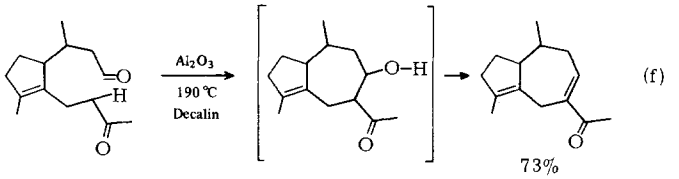
These heterogeneous organic reactions effected by reagents immobilized on porous solids are becoming very useful to chemists involved with laboratory-scale synthesis mainly for the following reasons: (a) they are often more selective than the corresponding homogeneous reactions, and therefore some heretofore impossible transformations are made possible; (b) they are usually milder than the corresponding homogeneous reactions thus allowing some highly sensitive molecules to be used as reactants; and (c) they are often operationally simpler to perform than the corresponding homogeneous reactions, with product isolation usually involving only filtration and solvent evaporation. Organic reactions at *alumina* surfaces also usually possess advantages (a)—(c).

2. Addition Reactions

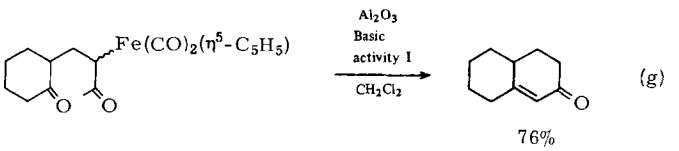


2.1. Intramolecular Addition of O—H Groups

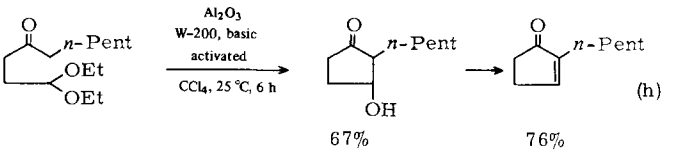
Alumina-induced intramolecular additions of hydroxyl groups across isolated [eq. (a)][18,21] and carbonyl-conjugated [eq. (b) and (c)][19,20] carbon-carbon double bonds have been reported. Intramolecularity is a critical feature of these reactions because no comparable alumina-promoted intermolecular additions of alcohols to alkenes or of alcohols to α,β-unsaturated carbonyl compounds have been observed. In contrast to this intramolecular OH *addition*, alumina in fact has been used to produce α,β-ethylenic ketones *via elimination* of alcohols from β-alkoxyketones [eq. (d); cf. Section 5.2].



[*] Prof. G. H. Posner
Department of Chemistry, The Johns Hopkins University
Baltimore, MD 21218 (USA)

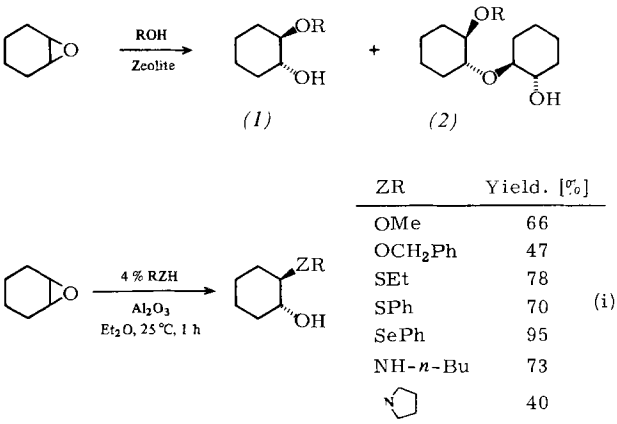


An unusual example has been published dealing with alumina-promoted ketone enolization and subsequent intramolecular addition of the enolic OH group across a transannular epoxide [eq. (e)][22].



2.2. Intramolecular Addition of Acidic CH Groups

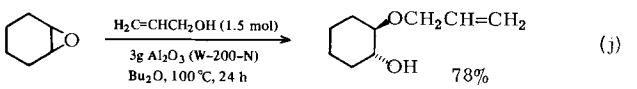
As shown in eq. (e), some forms of alumina are sufficiently basic to cause enolization of ketones. When a second carbonyl group is present in the same molecule, intramolecular addition of the carbon atom of the enol (or the enolate ion) to the nonenolized carbonyl group leads to a carbocyclization reaction. Equations (f) to (h)[23–25] illustrate application of this type of alumina-promoted intramolecular aldol condensation to mild and efficient construction of seven-, six-, and five-membered carbocycles.



2.3. Intermolecular Addition of OH and other Heteroatom-H Groups

Despite the sporadic reports of alumina catalyzing intramolecular addition of O—H groups, prior to 1974 no one had intentionally added an alcohol and an electrophile to alumina. In 1974, we began a systematic study aimed at using porous chromatographic alumina as a catalyst for intermolecular nucleophilic addition of various heteroatom-H (RZ-H) species to electrophiles. Of the electrophiles examined (olefins, ketones, epoxides), epoxides were the most promising. We have found that a stirred slurry of commercially available[26] Woelm, 200, neutral (W-200-N) chromatographic alumina (activity "super I" on the Brockmann scale)[27] catalyzes opening of a very wide variety of epoxides by only a few equivalents of RZ-H nucleophiles reproducibly and under exceedingly mild conditions (10 min to 1 h, 25 °C, diethyl ether solvent)[28]. Although our initial work was done with W-200-N alumina which we had activated at 400 °C under vacuum[29], we have recently found that W-200-N alumina used directly from the commercial can gives essentially the same results. Nucleophiles successfully incorporated under these conditions include alcohols, thiols, benzene selenol, amines, and acetic acid. Alumina impregnated with a few equivalents of these nucleophiles opens epoxides regioselectively at the less substituted epoxide carbon atom and stereospecifically *(trans)* to give the corresponding β-functionalized alcohols cleanly and in good yields[28].

Reactions of epoxides with active chromatographic alumina has been reported to give usually a mixture of products containing mainly allylic alcohols[30]. An aluminosilicate molecular sieve (zeolite) has recently been used for catalytic alcoholysis of cyclohexene oxide, giving a mixture of 1,2-cyclohexanediol derivative *(1)* and dicyclohexyl ether *(2)*[31]. In contrast, cyclohexene oxide reacts with Woelm-200-N alumina carrying 4 % of RZ-H to give the corresponding *trans*-2-functionalized cyclohexanols reproducibly in good yield as the only product [eq. (i)]. No allylic alcohol, 1,2-diol, or *cis*-isomer was detected. Several grams of epoxide have been successfully opened by this heterogeneous reaction on RZ-H doped alumina[28]. The yields given in eq. (i) refer to purified products.



ZR	Yield. [%]

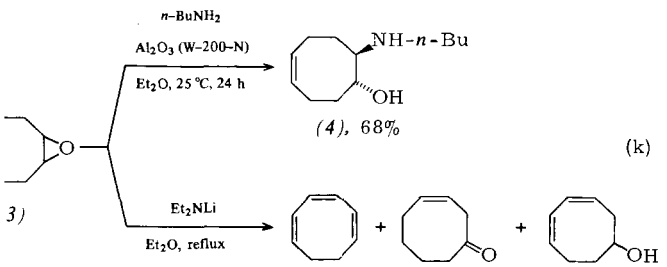
(i)

In several cases cyclohexene oxide reactions with RZ-H-doped alumina are superior to homogeneous methods for synthesis of the corresponding 2-RZ-cyclohexanols[28].

Typically, about 7.5 g of the W-200-N alumina per 1 mmol of epoxide is required for complete reaction at 25 °C. By operating with dibutyl ether as solvent at 100 °C for 24 h, however, we have recently been able to use only 3 g of W-200-N alumina to convert 30 g (≈ 300 mmol) of cyclohexene oxide [eq. (j)][32]. This type of *catalytic* reaction is very appealing for possible application to large-scale reactions.

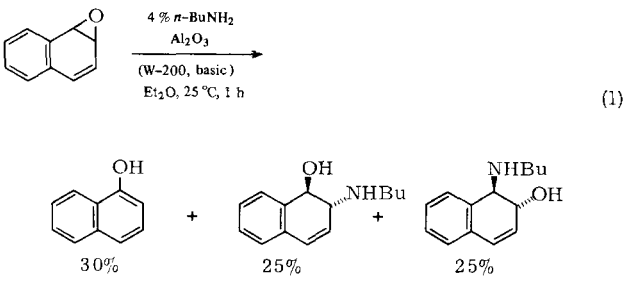
30g (0.3 mol)

The oxides of symmetrical 5-, 7-, 8-, and 12-membered cycloalkenes also undergo mild and selective opening by RZ-H doped alumina[28].



Medium ring (C_8—C_{12}) cycloalkene oxides are much less reactive than cyclohexene oxides and are difficult to open homogeneously to only 2-functionalized cycloalkanols; direct

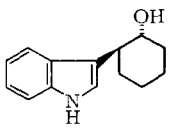
1,2-epoxide opening is usually accompanied by substantial amounts of side products derived from transannular interactions[33]. In sharp contrast to these homogeneous reactions, *no* products arising from transannular interactions were found in the RZ-H-doped alumina catalyzed opening of these medium ring cycloalkene oxides, and the yields of pure 1,2-opened products were reproducibly good. This mild and clean heterogeneous opening of medium ring epoxides by RZ-H-impregnated alumina appears to be the best method for stereospecific conversion of medium ring *cis*- or *trans*-cycloalkene oxides into the corresponding *trans*- or *cis*-2-substituted cycloalkanols, respectively.



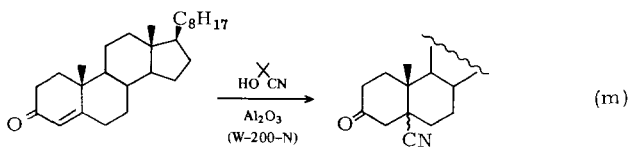
Oxides of symmetrical acyclic alkenes (symmetrically substituted oxiranes) also undergo clean nucleophilic *trans*-opening with RZ-H species on alumina, and unsymmetrically substituted oxiranes are cleaved with preferential attachment of the RZ unit at the less substituted epoxide carbon atom. For example, a regioselectivity of 6:1 was observed for an unsubstituted *versus* a mono- or di-substituted epoxide carbon atom on reaction with ROH on alumina[28].

Because it is often desirable to open an epoxide in the presence of some other functional group (*i. e.* chemoselectively), we have established that alcohols, nitriles, ketones, esters, and olefins are relatively stable to RZ-H-doped alumina for one hour at 25 °C[28].

1,5-Cyclooctadiene monoxide *(3)* has been reported to react with lithium diethylamide to give a mixture of cyclooctene derivatives [eq. (k)][34]. In contrast, *n*-butylamine-doped alumina produced analytically pure *trans*-amino alcohol *(4)* in 68% yield after column chromatographic purification. Likewise, in sharp contrast to homogeneous acidic solvolysis of the epoxide *(3)*, which gave bicyclic products in 20% yield, acetic acid-doped alumina gave no bicyclic products. These results and particularly those with epoxycyclooctane support the notion that nucleophilic opening of epoxides by RZ-H-doped alumina is a concerted and not a stepwise process[28].



RZ-H-doped alumina also catalyzes *trans*-opening of vinyl- and aryloxiranes, and of both K-region and non-K-region arene oxides[35]. Vinyloxiranes, such as 1,3-cyclopentadiene monoxide, undergo regiospecific attack by RZ-H species at the allylic carbon-oxygen bond to form homoallylic alcohols. Indene 2,3-oxide reacts with methanol-doped alumina to give *trans*-1-methoxy-2-indanol exclusively in 97% yield, with complete regiospecificity and stereospecificity. Amine-doped alumina is the only method now available for opening naphthalene 1,2-oxide (and probably other non-K-region arene oxides) by weak nitrogen nucleophiles [eq. (l)]. This result is especially significant because opening of arene oxides by weak nucleophiles is considered such a fundamental step in the expression of the toxicological effects of these systems[35].



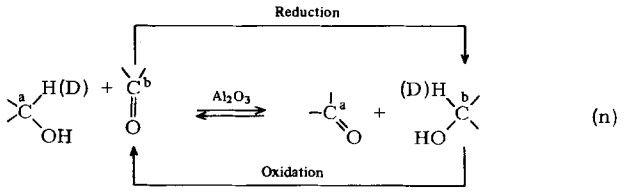
These epoxide openings effected by alcohols, thiols, benzeneselenol, amines, and acetic acid on commercial W-200-N alumina constitute a useful new synthetic method. This new procedure is characterized by its clean formation usually of only one product, by its practical aspects (direct use of commercially available alumina, room temperature conditions, multi-gram scale reactions, easy product isolation), by its high chemoselectivity, and by its stereospecificity.

2.4. Intermolecular Additions of Acidic C—H Groups

Attempts to form carbon-carbon bonds by placing cyclohexene oxide and 1-octyne, diethyl malonate, or nitromethane on alumina failed to produce any products derived from incorporation of the acidic doping agent[36]. We have two preliminary results, however, which are very encouraging. First, indole-doped alumina cleaved cyclohexene oxide after 10 min at 25 °C with formation of 2-(3-indolyl)cyclohexanol *(5)* in good yield[36]. Secondly, acetone cyanohydrin-doped alumina transferred the nitrile group in a conjugate fashion to carbon-5 of 4-cholesten-3-one [eq. (m)][37]. Further work along these lines may lead to a generally useful method for selective carbon-carbon bond forming reactions at alumina surfaces.

(5)

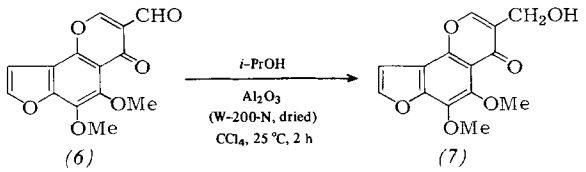
(m)



Addition of alumina-generated dihalocarbenes to olefins has been suggested as a simple and convenient method for preparation of dihalocyclopropanes[38].

3. Reduction-Oxidation Reactions

3.1. Reductions

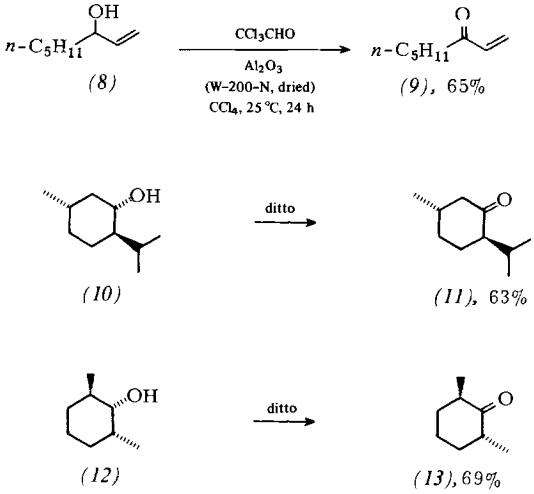


Alumina supporting various metals has been used as an hydrogenation catalyst for reduction of carbon-carbon double bonds[39], and sodium tetrahydridoborate impregnated on neutral alumina has been applied to reduction of carbon-oxygen double bonds especially in base-sensitive molecules[40]. A Cannizzaro-type disproportionation of an aldehyde into the corresponding alcohol and carboxylic acid has been

reported to occur at room temperature over Woelm-I-neutral alumina[41]. Carbonyl addition of a hydride ion derived from a secondary hydroxyl group has been found to occur over alumina *intra*molecularly[42] in the case of some keto alcohols and *inter*molecularly when both alcohol and carbonyl compound are present[43]. That this carbonyl reduction involves hydride (rather than, for example, hydrogen atom) transfer has been established by use of deuterium labeled compounds[44] and by use of cyclobutanol as the hydride donor [eq. (n)][45].

(n)

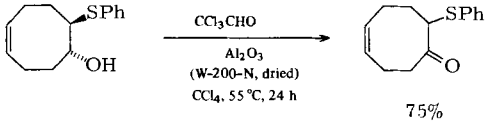
This Meerwein-Ponndorf-Verley (aluminum triisopropoxide) type carbonyl reduction at room temperature using 2-propanol over W-200-N vacuum-dehydrated alumina has been suggested as a general synthetic method[43a]. The most noteworthy features of this new heterogeneous procedure are as follows: 1) α,β-unsaturated aldehydes can be reduced cleanly to the corresponding allylic (*i.e.*, not saturated) alcohols; 2) aldehydes can be reduced even in the presence of some ketones; 3) many normally labile functional groups (*e.g.* nitro, alkoxycarbonyl, cyano, bromo, and iodo substituents) survive this alumina-based reduction method; and 4) the 2-propanol-alumina "reagent" can be stored in a sealed vial for at least eight months without loss of reducing activity. 2-Propanol on activated Woelm alumina is a reducing "reagent" with selectivity comparable to, or in some cases even greater than,



(6) (7)

that of the most sophisticated complex boron and aluminum hydride reducing agents[43a]. For example, chromone *(6)* suffered reduction of both the aldehyde group and the α,β double bond with the following reagents: $NaBH_4$, $NaBH_4/AlCl_3$, diisobutylaluminum hydride in tetrahydrofuran, and $NaB(CN)H_3$ in the presence of acid[43a]. Although polyfunctional chromone *(6)* was inert to aluminum triisopropoxide under homogeneous conditions, selective and effective aldehyde reduction occurred heterogeneously with 2-propanol on activated alumina to give allylic alcohol *(7)* in 80% crude yield (spectroscopically pure) and 55% yield of analytically pure material.

3.2. Oxidations



Room-temperature Oppenauer-type oxidation of secondary alcohols to ketones using trichloroacetaldehyde on activated Woelm alumina has also been suggested as a new synthetic method[46]. The most useful aspects of this heterogeneous procedure are its mildness, its tolerance of acid and base sensitive functional groups, and its chemospecificity.

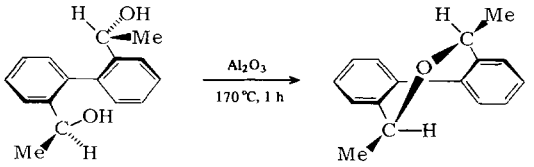
The mildness of chloral on activated Woelm-200-Neutral alumina is illustrated by: (a) oxidation of allylic alcohol *(8)* into vinyl ketone *(9)* which usually polymerizes at the slightest provocation; (b) oxidation of substituted cyclohexanols *(10)* and *(12)* to ketones *(11)* and *(13)* without epimerization to the thermodynamically more stable isomers; and (c) high-yield oxidation of cyclobutanol to cyclobutanone, which process is often accompanied by fragmentation[46b].

Such functional groups as primary iodides, benzylic chlorides, methyl esters, nitro groups, lactones and ethers survive this heterogeneous oxidation procedure[46a].

The chemospecificity of chloral on alumina is illustrated by: (a) oxidation of secondary but not primary alcohols; (b) oxidation of olefinic alcohols to the corresponding olefinic ketones; and (c) oxidation of β-hydroxy sulfides and selenides to the corresponding β-keto sulfides and selenides [*e.g.*, eq. (o)][46b]. Few other homogeneous reagents match this chemospecificity of chloral on activated alumina.

(o)

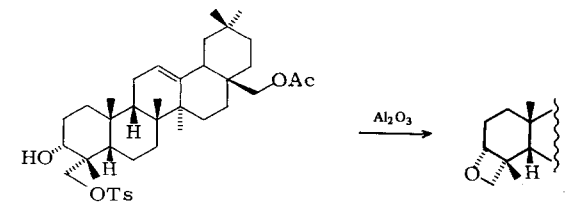
In contrast to the good reproducibility of all the alumina-based reactions on Woelm alumina discussed in this article, we have found that, contrary to our initially reported data, steroidal diol oxidation gives variable results[46c].



The main disadvantage of chloral on activated alumina for alcohol oxidation is the tediousness of the 400 °C vacuum-drying of the commercial alumina immediately before use. Use of W-200-N alumina without activation, however, led to much inferior results.

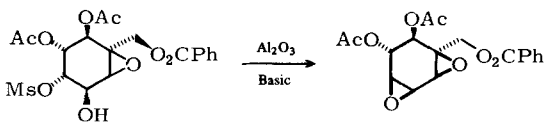
4. Substitution Reactions

4.1. Intramolecular Substitution by Heteroatom Nucleophiles



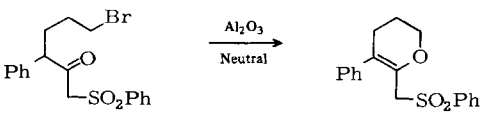
Kessler[47] reported that alumina promoted a stereoselective and concerted (*i.e.*, not ionic) intramolecular substitution of one OH group by a second OH group in the same molecule [eq. (p)]; it was suggested that the role of the alumina was

to facilitate removal of the first OH group as the new ether linkage was being formed.



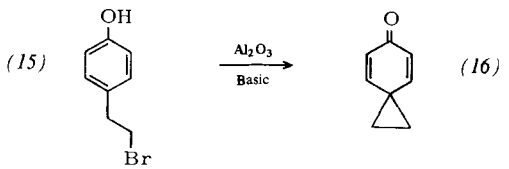
(p)

Intramolecular displacement of sulfonate groups by neighboring hydroxyl groups has also been reported, leading to four-membered (oxetane)[48] and three-membered (oxirane)[49] oxygen heterocycles [eq. (q) and (r)].



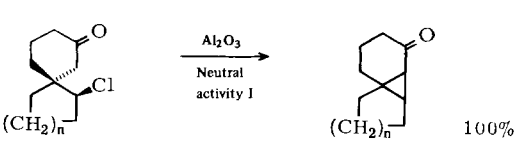
(q)

(r)



Cook and *Magnus*[50] showed that bromo ketone *(14)* was enolized by alumina and that intramolecular substitution of bromine took place exclusively with the enolic oxygen as nucleophile; no enolic *C*-alkylation occurred.

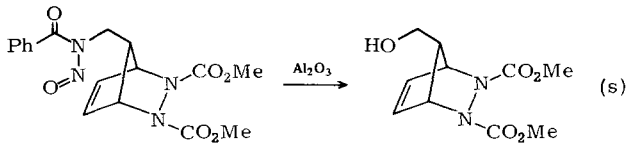
(14) 95%



4.2. Intramolecular Substitution by Nucleophilic Carbon Atoms

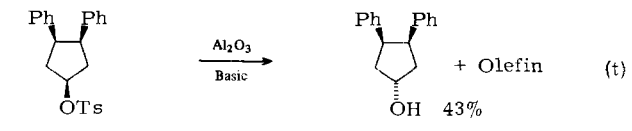
Baird and *Winstein*[51] showed that the unusually reactive spiro-dienone *(16)* was best prepared (albeit in low yield) by alumina-promoted intramolecular displacement of bromide ion from 4-(bromoethyl)phenol *(15)*.

(15) *(16)*



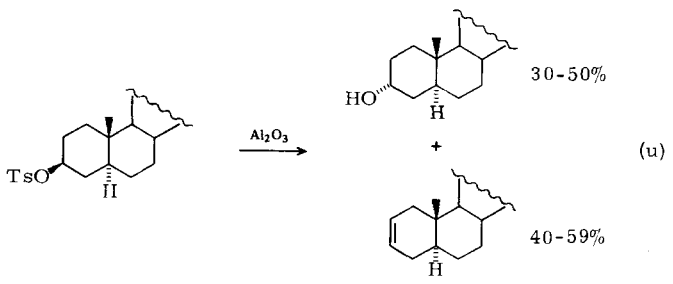
Ruppert and White[52] reported that the facile displacement of chloride ion from chloro ketones *(17)* was due to the stereoelectronically favorable relationship of the leaving group and the alumina-generated neighboring enolate ion.

(17), n = 1,2 100%



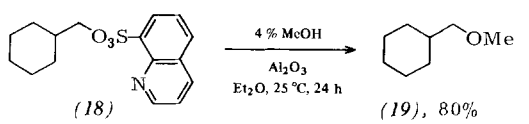
4.3. Intermolecular Substitution by Heteroatom Nucleophiles

Undesired reactions often occur during attempts to purify organic compounds by alumina chromatography[1]. Hydrolysis, for example, involves cleavage of the organic substance by nucleophilic hydroxyl groups on the alumina surface. Historically such alumina-promoted hydrolyses were considered undesirable and unintentional side-reactions; a recent example of an unexpected and unwanted hydrolysis is shown in eq. (s)[53].



(s)

Recently, however, alumina has been used *intentionally* for mild and selective hydrolysis of some organic molecules. *Johns* and *Jerina*[54] reported that steroidal primary acetates are selectively hydrolyzed on alumina, and *Barton* and coworkers[55] noted that enimides are conveniently hydrolyzed on alumina into enamides. Because carboxylate[56] and sulfonate ester hydrolyses on alumina have been shown to involve *O*-alkyl (rather than *O*-acyl or *O*-sulfonyl) cleavage, hydrolytic epimerization of alcohol derivatives on alumina has been used as a synthetic method in some cases [*e.g.*, eq. (t)[57] and (u)[58]]. The main synthetic limitation to this method, however, is the substantial amount of elimination (*i.e.*, olefin formation) concurrent with hydrolysis (cf. Section 5.3).



(t)

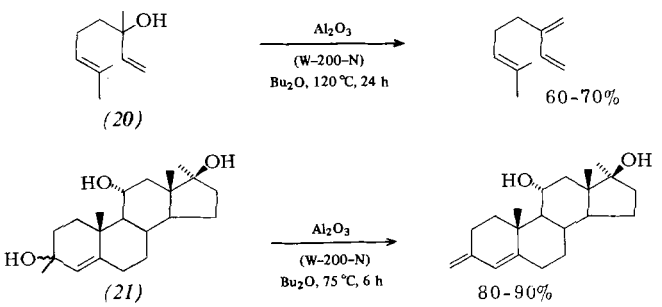
(u)

In the 1960's *Hodosan* and co-workers reported the first rational attempts to impregnate alumina with heteroatom nucleophiles and to use the doped-alumina for intermolecular substitution of some steroidal tosylates with stereochemical inversion of configuration. Steroidal nitrates, thiocyanates, and isothiocyanates were prepared[59]. More recently we showed that methanol-doped alumina converted L-1-methylheptyl tosylate into D-2-methoxyoctane (40 % chemical yield, 90—95 % net inversion of configuration) and converted the sulfonate ester *(18)* into methyl ether *(19)*[60].

(18) *(19)*, 80%

In 1974, *Hudlicky*[61] reported that a column of acidic alumina "soaked with a solution of benzyl chloride in chloroform containing hydrazoic acid" gave benzyl azide in good yield and under conditions substantially milder than those required in typical homogeneous reactions. We have observed similar substitution reactions of aliphatic and benzylic halides by amine-doped alumina [*e.g.*, eq. (v)][36b].

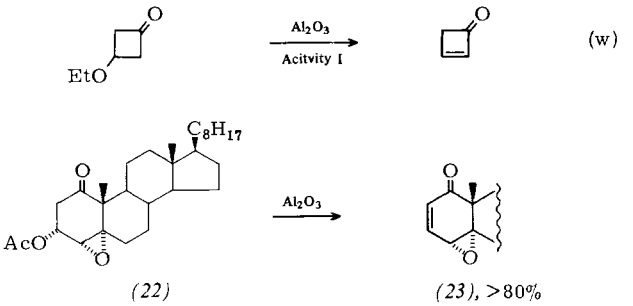
$$\underset{(1\ \text{Equiv.})}{PhCH_2Cl} \xrightarrow[Et_2O,\ 25\,^\circ C,\ 48\ h]{PhNH_2\ (3\ \text{equiv.}),\ Al_2O_3\ \text{neutral}} \underset{75\%}{PhCH_2NHPh} \qquad (v)$$



Radical substitution of H by Cl has been reported to occur selectively at the ω-position of octanoic acid adsorbed on neutral alumina[62].

5. Elimination Reactions

This section deals with alumina-promoted elimination of the following groups: H—OH, H—OR, H—OAc, H—OTs, H—halogen, and H—SO_2R.



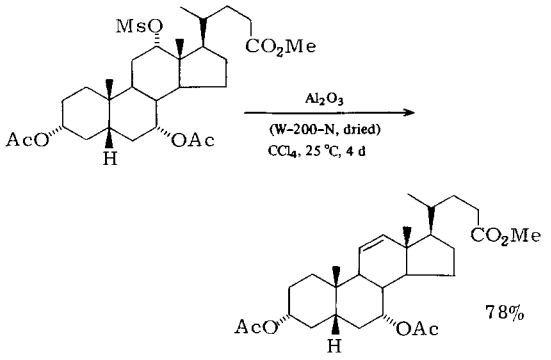
5.1. Elimination of H—OH from Alcohols

Pines and co-workers[63] have studied extensively alumina-induced gas phase dehydration reactions of many small alcohols containing less than 15 carbon atoms, and they have concluded that a carbonium ion mechanism seems to be followed in tertiary alcohol dehydration whereas a synchronous mechanism appears to be operative for secondary and primary alcohol dehydration. *Knözinger* has recently reviewed this subject[64], and two recent articles emphasize that non-Saytzeff elimination often predominates[65]. In 1961, *von Rudloff*[66] reported using alumina doped with pyridine or quinoline to effect dehydration of non-volatile terpene alcohols at ≥200 °C in the liquid phase. Although these conditions have been used in the synthesis of several different sesquiterpene natural products[67], they are not mild and they do not allow selective elimination of one alcohol group in a diol. We have found that linalool *(20)* and the steroidal triol *(21)* undergo mild, selective dehydration when heated in dibutyl ether solvent over commercial W-200-N alumina at 75—120 °C[68].

5.2. Elimination of H—OR and H—O_2CCH_3 from Ethers and Acetates

Ethers and carboxylate esters are normally stable toward alumina at room temperature. When the ether or carbonyl group is located β to a keto group, however, loss of H—OR or of HOAc to form an enone can occur even on alumina chromatography [*e.g.*, eq. (w)][69, 70]. Functionalized steroidal β-acetoxyketone *(22)* reacted chemospecifically on alumina to form epoxy conjugated enone *(23)*[71].

5.3. Elimination of H—OTs from Tosylates



Over the years, various researchers have noticed that alumina chromatography of steroidal sulfonates causes some elimination of the elements of H—OSO_2R to form steroidal olefins as well as some hydrolysis to form epimeric steroidal alcohols (cf. Section 4.3)[72, 73]. Because the hydroxyl groups on the alumina surface were the cause of the competing hydrolysis, activation (*i.e.*, dehydration) of the alumina suppressed sulfonate hydrolysis and favored olefin formation. For example, the amount of 1-methylheptyl tosylate hydrolysis (*i.e.*, 2-octanol) decreased from 30% to 10—15% to 0—7% as the activity of the alumina was increased from I to super-I (Woelm-200) to super-I-dehydrated (Woelm-200-vacuum dried at 400 °C); octene formation increased proportionately in this series[60b]. Olefins usually are the major or even exclusive products when cyclic secondary tosylates are stirred over unactivated commercial W-200-N alumina. Based on a systematic study, it was concluded that Woelm chromatographic alumina is especially useful for concerted olefin-forming dehydrosulfonation reactions in the following instances[60b]: 1) when stereoelectronic factors strongly favor elimination in one of two possible directions (*e.g.*, 3β-cholestanyl tosylate giving only 2-cholestene); 2) when elimination of a methine β-hydrogen atom does not occur because it would lead to a bridgehead double bond; 3) when the sulfonate is symmetrical and elimination in either direction produces the same olefin; 4) when a β-elimination is possible in only one direction because there are no β′ hydrogen atoms (*e.g.*, neopentylic sulfonates).

The major disadvantages of this heterogeneous olefin-forming procedure are as follows: 1) poor regiochemical control of olefin formation when two double bond positional isomers are possible; 2) poor stereochemical control when *cis*- and *trans*-alkenes are possible; 3) indirectness (*i.e.*, alcohol→ sulfonate→ olefin); 4) large amount of alumina required for complete reaction (5—7 g Al_2O_3 per mmol of sulfonate); and 5) the inconvenience of having to dehydrate commercial alumina in order to suppress completely hydrolysis of primary and acyclic secondary tosylates.

The major advantages of this sulfonate elimination procedure are as follows: 1) inertness of many acid and base sensitive functional groups (*e.g.*, carboxylic ester); 2) concerted elimination without skeletal rearrangement of some highly rearrangement-prone tosylates (*e.g.*, neopentyl); 3) convenience of using commercially available W-200-N alumina for elimination par-

ticularly of cyclic secondary sulfonates without any significant amount of hydrolysis; and 4) ease of product isolation (*i.e.*, filtration to remove alumina and evaporation of solvent).

The practical advantages of Woelm chromatographic alumina for introducing double bonds into polyfunctional and labile compounds will make this heterogeneous "reagent" useful to organic chemists, as suggested by eq. (x)[60b].

(x)

5.4. Elimination of H—X from Alkyl Halides

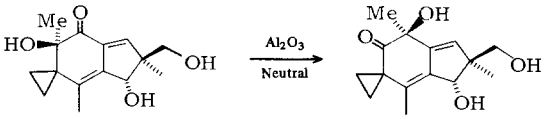
Although dehydrohalogenation over alumina occurs at elevated temperatures[74], most unactivated (*e.g.*, non-allylic) halides are stable to alumina at room temperature. In contrast to homogeneous liquid phase dehydrohalogenations in which alkyl fluorides are the *least* reactive halides, alkyl fluorides are most reactive toward alumina in heterogeneous elimination reactions[75]. For example, whereas 2-iodooctane is stable toward W-200-N-dehydrated alumina for 24 h at 25 °C, 1,1-difluorocycloheptane is converted into 1-fluorocycloheptene in good yield[60b].

5.5. Elimination of H—SO_2—R

β-Elimination of a sulfinic acid on alumina has been reported to occur in a system in which an α-proton is acidified by a nitro group ($RO_2S-\underset{|}{\overset{|}{C}}-CHNO_2$)[76], and α-elimination of *p*-toluenesulfinic acid from a tosylhydrazone on alumina has been suggested as an improved procedure for generation of α-diazo carbonyl compounds[77].

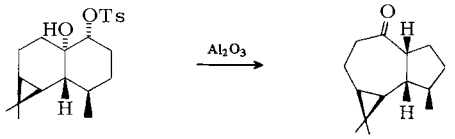
6. Abstraction of Acidic Hydrogen Atoms

Unactivated C—H groups of alkanes in the gas phase can be cleaved heterolytically by alumina with abstraction of H^+ and formation of the corresponding carbanion. A linear relationship between hydrogen exchange activity and hydrocarbon acidity has been observed[78].



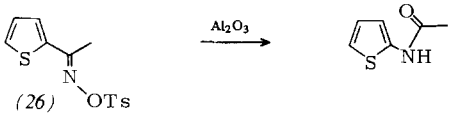
Carbonyl-activated C—H groups can be ionized by alumina to the corresponding enolate species even at room temperature. Some examples have already been given of how these alumina-generated enolate intermediates can react further in addition reactions (Section 2.2) and in substitution reactions (Section 4.2). Tritium has been introduced into keto steroids by room temperature chromatography on basic alumina previously treated with tritiated water; this heterogeneous alumina-promoted H/T exchange reaction provides pure, highly labeled ketones with remarkable economy of tracer[79]. Alumina-induced ketone enolization had also been used to epimerize C^9-H_β to C^9-H_α in an 11-keto steroid[80] and to isomerize a conjugated enone into its β,γ-unsaturated isomer in a sesquiterpene pseudoguaianolide[81].

Phosphonium-activated N—H groups can be deprotonated by basic alumina at room temperature to form ylides of the type $Ar_3\overset{\oplus}{P}-\overset{\ominus}{N}R$[82].

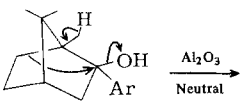


7. Skeletal Rearrangements

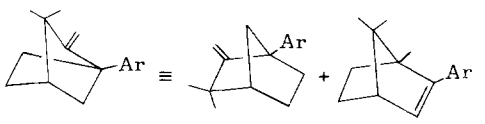
Alumina can act as a base, as an acid, or as a polar medium to cause molecular reorganizations in many different types of organic compounds[1].



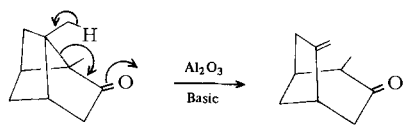
The following are a few illustrative examples. Intramolecular carbonyl addition of a neighboring methyl group in the keto alcohol *(24)* took place upon alumina chromatography[83]. Intramolecular substitution of OTs by a neighboring carbon atom in hydroxytosylate *(25)*[84] and by a neighboring thiophene group (*i.e.*, Beckmann rearrangement) of the *O*-tosyloxime *(26)*[85] occurred easily at room temperature on alumina.



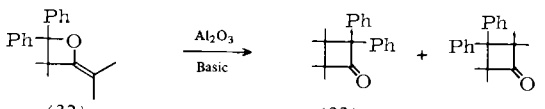
(24)



(25)



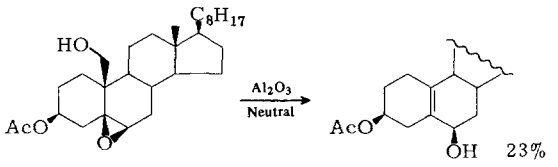
(26)



(27)

(28) *(29)*

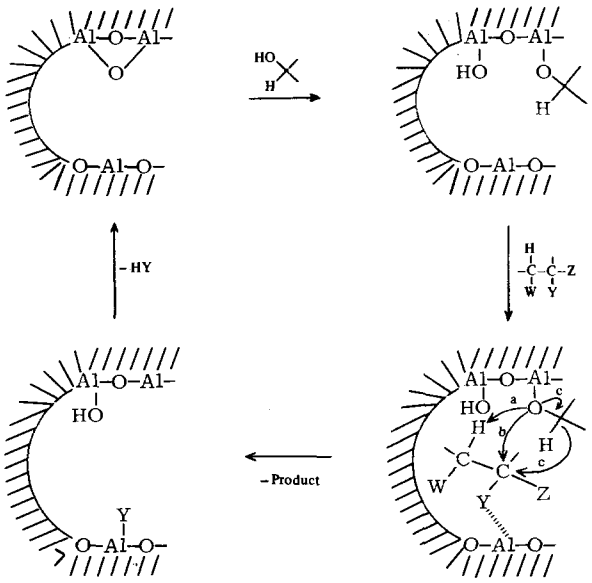
(30) *(31)*



(32) *(33)* *(34)*

Overall elimination of water from tertiary benzylic alcohol *(27)* on neutral alumina produced rearranged olefin *(28)* and unrearranged olefin *(29)* in 2:3 ratio[86]. Fragmentation of carvonecamphor *(30)* *via* enolization on basic alumina gave olefinic ketone *(31)* in good yield[87], and rearrangement of isopropylideneoxetane *(32)* formed cyclobutanones *(33)* and *(34)* in 78:22 ratio[88].

8. Decarboxylation Reactions



Crabbé[89] recently reported a convenient, new, and mild procedure for decarboxylation of even sensitive β-keto esters

using basic alumina in refluxing 1.5% aqueous dioxane. Loss of one carbon atom was also noted by *Morand* when the hydroxy epoxide *(35)* was exposed to alumina[90].

9. Role of the Alumina

Although much more mechanistic (*e.g.*, spectroscopic) work must be done before a detailed picture of the function of the solid support emerges, the alumina probably lowers the entropy of activation when a reactant and a reagent are adsorbed close to each other and in the proper orientation for chemical reaction[91]. Another important function of the alumina probably is to activate the reactant and/or the reagent[92]. Scheme 1 is proposed as a working model for the role of the alumina.

Scheme 1. Possible pathways of reactions on alumina.

Possibilities	Pathway	Type of reaction
Case I	a	rarely observed
W, Y = O; Z = H	b	addition
(epoxides)	c	not observed
Case II	a	enolization
W = H; Y, Z = O	b	rarely observed
(aldehydes and ketones)	c	reduction-oxidation
Case III	a	elimination
Y = OH, OR, OTs,	b	substitution
or halogen	c	not observed

Active alumina, having some strained Al—O—Al rings, is known from spectroscopic studies to cleave the heteroatom-H bonds of alcohols (*e.g.*, isopropyl alcohol is shown in Scheme 1) and of primary and secondary amines with attachment of the resultant alkoxide and amide groups to the alumina surface[93]. Because most of the reactions reported here proceed under such mild conditions, it seems reasonable to invoke also activation of the reactant by coordination of its heteroatom Y to one of the acidic aluminum atoms exposed on the alumina surface. Possible reaction pathways a, b, and c are considered for epoxides, carbonyl compounds, and good leaving groups beneath Scheme 1. Removal of HY from the alumina surface might then allow the alumina to work with high catalytic activity [see, for example, eq. (j)]. This picture of the role of alumina as a template and as an activator of reactant and reagent resembles current chemical models of the function of some enzymes.

10. Important Problems for Future Investigation

As the chemical community begins to recognize more fully the significant potential of alumina (and other solid supports) to effect some very mild and selective organic transformations, more work will probably have to be done in the following important areas: (a) understanding the physical and chemical properties of alumina surfaces and thus understanding the differences among aluminas from different commercial sources; (b) chemically and/or physically modifying the alumina surface deliberately to prepare a support having certain desired properties; (c) using alumina *catalytically*, especially in large-scale reactions; (d) forming carbon-carbon bonds *via* intermolecular reactions on alumina surfaces; (e) selectively protecting one functional group of a bifunctional molecule by selective adsorption to the alumina surface; and (f) modifying the reactivity of various known reagents by placing them on alumina.

I wish to thank publicly all of my co-workers whose names appear in the references for their many physical and intellectual contributions to our work on organic reactions at alumina surfaces. Special thanks go to Maurice Whalen, George Gurria, Al Runquist, and Donald Rogers for their very effective participation in, and stimulation of, this project. Financial support from the National Institute of Health (CA-16068) and the Research Corporation and a generous gift of alumina from ICN Pharmaceuticals and Woelm Pharma are gratefully acknowledged.

Ion Implantation into Semiconductors

By Christian Fritzsche[*]

Ion implantation is a method of introducing foreign atoms into solids that guarantees a high accuracy even with very small amounts and very short penetrations. It is basically a way of doping solids by bombarding them with accelerated ions, and its main application lies in the manufacture of semiconductor components. The action of implantation is closely connected with the accompanying radiation damage and its repair by annealing.

1. The Role of Irradiation Techniques

The methods used for introducing foreign atoms into solids are of fundamental importance in the production of semiconductor components. These methods are used for doping, which modifies the conductivity and the type of conduction (p or n), and dopability is essential for the industrial use of a semiconductor.

In the early days of semiconductor technology, doping was accomplished by alloying with the host material in a liquid phase. However, alloying does not permit a particularly exact localization of small p- or n-conducting regions. To make transistors for high frequencies, therefore, it was necessary to turn to diffusion as a doping method. It soon became possible to produce p-n junctions at vertical distances of about 1 μm and—by the additional use of masking techniques—in lateral dimensions with a width of less than 10 μm. Taken in conjunction with the characteristics of SiO_2 layers used for the masking, the diffusion technique also offered an excellent basis for combining many components into an integrated circuit on a semiconductor chip. This gave the work a new direction in the sense that silicon became the most important semiconductor material. Further miniaturization of the components and its prerequisite, the improvement of the doping technique, promised a much greater technical advance than efforts to use other semiconductors with better physical properties.

The limits of miniaturization still have not been reached, even though an entire processing unit of a computer can now be put on a single semiconductor chip. On the other hand, the limits have already been stretched for the use of techniques in which doping is controlled by small changes in the vapor pressure and high temperatures.

[*] Dr. C. Fritzsche
Institut für Angewandte Festkörperphysik der Fraunhofer-Gesellschaft
Eckerstrasse 4, D-7800 Freiburg (Germany)

It was suggested quite early to bombard semiconductors with ions or elementary particles for accurate doping. In 1954, *Shockley*[1] applied for a patent concerning ion implantation, *i.e.* the introduction of accelerated dopant ions into the host material. This technique makes it possible to modify the properties of the host material in the vicinity of the surface. Another early suggestion, this time for uniform doping of large penetration, was to bombard the material with neutrons[2] in order to bring about the nuclear transformation of the silicon into phosphorus[3]. The introduction of irradiation techniques was delayed because of difficulties in predicting three decisive factors: the cost of the new method and the possibilities of its development, the limits of the existing methods, and the economic advantages of the attainable improvements. For the development of ion implantation a theoretical background and experience in ion beam handling was already available from nuclear physics and the physics of elementary particles. The introduction of the method into semiconductor technology was paralleled by the further development of implantation devices. We shall therefore discuss the construction of an implantation apparatus together with the requirements that arise from the technology.

2. Technique and Applications of Ion Implantation

To incorporate foreign atoms into a solid by ion implantation, these atoms must first be ionized by an ion source and the ions must then be accelerated by an electric field. The ion source and the available accelerating voltage therefore determine the possible uses and largely also the cost of the apparatus. The accelerating voltage determines—together with the charge of the ion—the ion energy and thus its depth of penetration. Presently, practical considerations impose an upper limit of 400 kV on the accelerating voltage, for semiconductor technology is already so highly rationalized that the cost-benefit ratio of an implantation apparatus is now favor-

able only if the accelerating voltage is below this value. As a result, the attainable penetration is almost invariably less than 1 μm. This is not much, but ion implantation offers great advantages over the introduction of foreign atoms by diffusion. The depth of penetration can be controlled much more accurately *via* the accelerating voltage than by the use of constant vapor pressures and constant high temperatures, particularly when small penetration depths are required. In the case of diffusion, the temperature and the vapor pressure—or instead of the latter a fixed amount of starting material—also determine the amount of substance diffusing into the solid. In the case of ion implantation, on the other hand, the amount introduced is determined by the charge, and this is the greatest advantage of the method. From the point of view of measurement, the charge-to-mass ratio is high even for heavy ions, so that the measurement of the charge is free from problems even with amounts whose accurate weighing out would be a hopeless task. For example, by using a current of 1 μA, we can transfer as little as 3.3×10^{-9} g of phosphorus in 10 s.

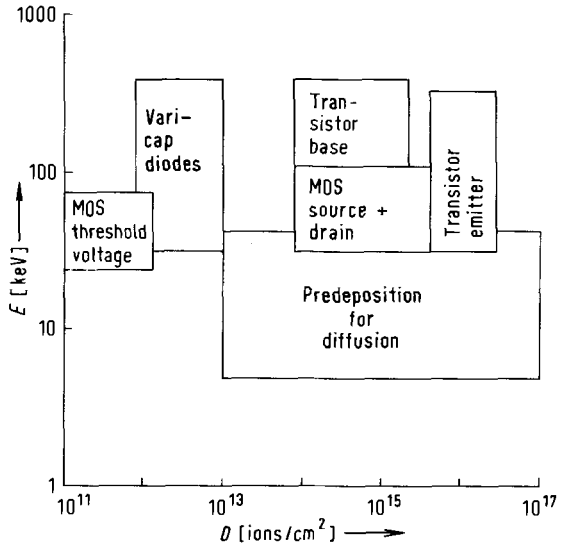

Fig. 1. Application field of ion implantation into semiconductors according to the dose D and the energy E (modified after [4]).

To show what this means for the duration of implantation and the required characteristics of the ion source, we shall first discuss the various technical applications according to the energy and the dose region, as illustrated in Figure 1. The dose is the number of ions implanted per cm^2 of the solid surface.

The smallest amount of ions is implanted for the control of the threshold voltage of MOS transistors[*]. Since this is one of the main applications of ion implantation at present, it will be briefly described here. In an MOS transistor the conductivity is controlled just below the surface with the aid of a control electrode (gate) insulated from the semiconductor. The dielectric strength and the dielectric constant of the layer insulating the control electrode permit only a limited charge accumulation, amounting to only 10^{12}—10^{13} elementary charges per cm^2 under reliable operating conditions. However, the threshold voltage at which the current flows through the transistor has to be considerably exceeded at this charge, which means that the doping must amount to 10^{11}—10^{12} atoms per cm^2. Another requirement is to control the dopant concentration to within a few percent. However, since the current flows only in an extremely thin zone below the surface, the material need be doped only to a depth of 100 nm at the most.

Therefore, to set the threshold voltage precisely, the doping must be controlled with great precision at a small depth, and it is easy to see that ion implantation is an ideal technique for this purpose.

In the other applications shown in Figure 1, ion implantation is used for making p-n junctions. Admittedly, the depths of penetration that can be achieved with energies of less than 400 keV are not always sufficiently great here, but even when one has to turn to diffusion, implantation can still be useful for first depositing an accurately controlled amount of the material that is to diffuse into the matrix. Since in the case of diffusion the implanted ions are distributed over a large vertical distance, a very high dose is needed to reach a certain concentration.

As Figure 1 shows, the various applications call for implantations in a very wide dose range of 10^{11}—10^{17} ions/cm^2. The dose D can be calculated with the aid of the formula:

$$D = It/qF$$

where I is the ion current, t is time, q is the ionic charge, and F is the surface area to be doped. Accordingly, for implanting a dose of 10^{14} ions/cm^2 over an area of 7.5×7.5 cm^2 in a few seconds an ion source supplying a current of about 200 μA is needed. This is asking a great deal, but it can be achieved with a few types of ions if a good source is used.

In such sources the ions are formed by collisions between electrons and atoms or between electrons and molecules containing the atoms to be ionized. The electrons are either drawn out from a cold cathode by the use of a high voltage (about 5 kV) (Fig. 2a), or they are emitted by a hot cathode and accelerated with about 70 V (Fig. 2b). The substance to be ionized must be either a gas, or it must be possible to vaporize it and to obtain a vapor pressure of more than 10^{-2} mbar at temperatures that can be reached in the source[5]. Therefore, ion sources to be used for making many different

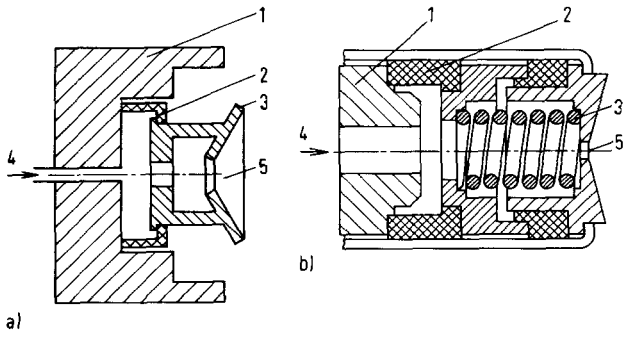

Fig. 2. Ion sources a) with a cold cathode and b) with a hot cathode: 1, anode; 2, insulator; 3, cathode; 4, gas inlet; 5, ion outlet orifice.

[*] MOS = metal oxide semiconductor. The combination of a metallically conducting layer and a semiconductor separated by an insulating layer differs from an ordinary capacitor mainly in that when the sign of the charge changes, the type of conduction near the semiconductor surface can also change.

types of ions are equipped with a small furnace from which the substance to be ionized is evaporated. Sources with hot cathodes are preferred in this case, but the cold-cathode types are more robust and more suitable for production purposes. The ion beam is drawn out (extracted) from an opening in the ion source by the use of a voltage of 20—40 kV.

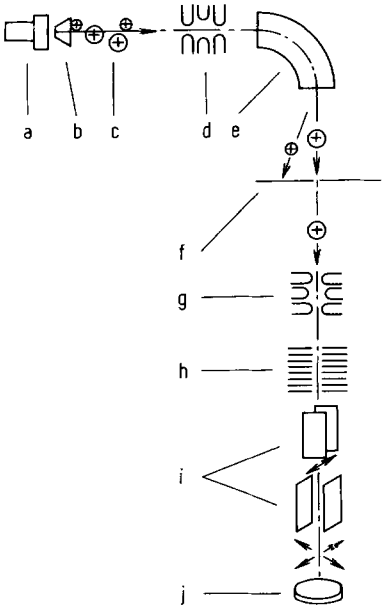

Fig. 3. Sketch of an implantation apparatus: a, ion source; b, extraction electrode; c, ion beam; d, lens; e, magnet; f, separating diaphragm; g, lens; h, accelerating electrodes; i, deflecting electrodes; j, target.

The overall construction of an implantation apparatus can now be easily understood from Figure 3. The ion source and the extraction have already been discussed. Since the source also contains some unwanted ions besides the required type, a mass separation is necessary, and this is carried out by deflection in a magnetic field. Mass separation is very valuable for scientific work, because it excludes the possibility of confusion with entrained impurities when minimal amounts are implanted. To be able to work with magnetic fields of less than 1 tesla, the ions are subjected to full acceleration only when they have passed beyond the separating magnet. For uniform implantation over large surfaces, the beam must sweep the surface. This is done either by electrical deflection of the beam or by mechanically moving the material to be doped, *i.e.* the target, with respect to the beam.

3. Penetration of Ions into Solids

Under the influence of accelerating voltages of up to 400 kV the ions reach velocities of up to 10^9 cm/s, *i.e.* 10000 km/s. What happens when ions traveling at such velocity enter the assembly of the electrons and the nuclei of atoms in the solid? It should be mentioned first of all that the ions very soon capture an electron and thus return to the neutral state, but they are still often called ions to distinguish them from the target atoms. To understand the implantation process it is important to know how the ions transfer their energy to the electrons and to the atomic nuclei of the target before finally coming to rest.

Owing to the small mass of electrons, the energy transfer to them is very different from that to the nuclei. Figure 4a shows the energy loss per unit distance of the path plotted against the energy in the case of both processes. The difference in the shapes of the curves can be explained as follows. The braking effect of the electrons on the ions resembles friction[*]. The energy loss is proportional to the velocity, and therefore decreases continuously as the energy itself decreases. The situation is different with the braking effect of the nuclei of the target atoms. This "nuclear" energy loss is calculated from the elastic collisions between charged particles. At high velocities the ion quickly traverses the electrical field of a target atom without much interaction, while at very low velocities there is little energy to transfer. In the case of intermediate velocities the transfer of energy from one nucleus to another reaches a maximum. As Figure 4a shows, the retardation by nuclei is virtually never negligible in comparison with retardation by the electrons in the energy range of interest for ion implantation. This has the following three important consequences:

1) The depths of penetration of individual ions show a large scatter, since the distance at which the ions fly past the nuclei of the target atoms is a matter of chance, and so is therefore the energy transfer. The distribution of the implanted ions is described by a mean depth of penetration (projected range) and a standard deviation. The projected range R_p for boron and phosphorus in silicon is plotted in Figure 4b *versus* the energy. The standard deviation depends on the energy and the ion-target combination and is smaller than the projected range by a factor of 1.5—4. The ranges and the energy losses have been calculated and published in tabular form for a large number of ion-target combinations[6–8].

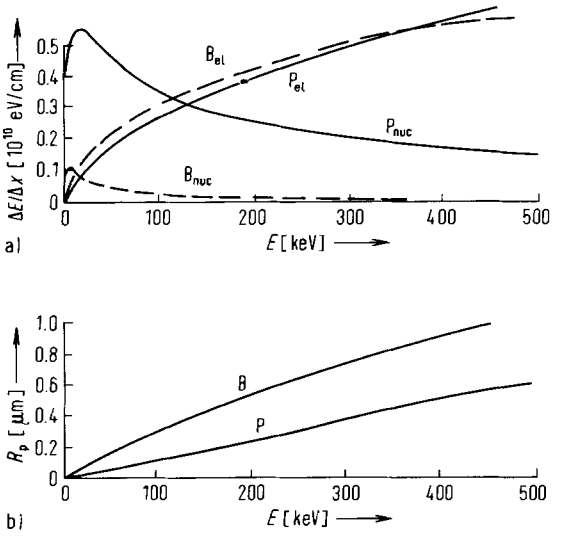

Fig. 4. a) Electronic (el) and nuclear (nuc) energy loss of boron and phosphorus ions in silicon per unit path ($\Delta E/\Delta x$) traveled; b) depth of penetration R_p of boron and phosphorus ions in silicon as a function of the ion energy E (data from [6]).

[*] It would be more accurate to compare it to electrical conduction. To determine the effect of all the electrons on the ion the relationship is reversed as it were, and the energy loss of the electrons is calculated for the case when they are scattered at an ion.

2) When nuclei collide the ions are deflected from their original direction, but this lateral spread is much smaller than the depth of penetration. For 200-keV phosphorus ions in silicon, the ratio is about 1 : 2.5, and it becomes even smaller as the energy is raised. Therefore, if the ions are implanted through a mask, the doped region has much sharper lateral boundaries than in the case of diffusion, where the lateral spread beyond the mask edge is equal to the depth of penetration.

3) Many target atoms are displaced from their sites in the crystal lattice by the nuclear collisions, causing radiation damage. Figure 4a shows that, as a phosphorus atom is being slowed down in a silicon target from 200 to 0 keV, an average energy of 0.4×10^{10} eV is transferred in nuclear collisions for each centimeter of its path. With a dose of 5×10^{14} ions/cm^2 this amounts to 2×10^{24} eV/cm^3. Since 1 cm^3 of silicon contains 5.1×10^{22} atoms, on average an energy of 40 eV is transferred per silicon atom at this dose. This is twice the energy needed to dislodge an atom that has been hit from its bonded position in the crystal lattice.

Although this simple explanation shows that ion implantation causes considerable radiation damage even at low doses, it is not suitable for quantitative estimates, because, as the dose is raised, some of the ions also collide with atoms that have already left their lattice sites, and because the atoms that have been hit only pass on some of their excess energy in nuclear collisions[9].

The transfer of energy to electrons is also involved in the occurrence of radiation damage. It causes ionization of the target atoms along the track of the ion, as a result of which, it seems, additional vacant sites arise in the crystals lattice in a region where a nuclear collision has already created a vacancy[10]. In any case, radiation damage occurring in the implantation of light ions is noticeably greater than it appears from the calculation of the nuclear energy loss. It is debatable whether the ionization of the target atoms alone leads to lattice defects in the case of semiconductors[11]. This problem is of scientific interest, because both the nature of the chemical bond and the concentration of conduction electrons must affect the course of atomic processes if the ionization facilitates the formation of defects.

4. The Effect of Nuclear Collisions

Figure 5 illustrates several possible courses of nuclear collisions. If an ion does not get close enough to a target atom, it will give up only a small proportion of its energy and change its direction only slightly. If it collides with it along a line pointing roughly to the center of the atom, it will give up much more energy to the atom than is needed to dislodge it from the lattice site. The target atom can then dislodge further atoms out of their sites in rapid succession, so that an imperfect lattice region is produced (case 1 in Fig. 5). At low energies the changes in direction are so marked that even after only a few collisions a target atom can fly out toward the surface and leave the solid (case 2). In the case of very high doses, this effect, known as sputtering, leads to a loss of the implanted ions as well. If the thickness s of the layer removed by sputtering reaches roughly the projected range R_p, the number of atoms retained in the target is already about 10 % less than the number of ions originally implanted[12]. Figure 6 shows that this can occur even at moderately high doses.

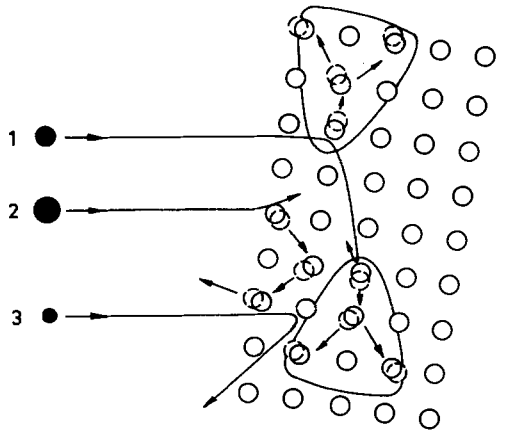

Fig. 5. Nuclear collision processes. Case 1, formation of radiation damage; case 2, sputtering; case 3, backscattering. It is customary to tilt the crystal with respect to the beam, otherwise some of the ions perform only collisions with a small angle of deflection and travel to excessively great depths along paths parallel to one of the crystal axes.

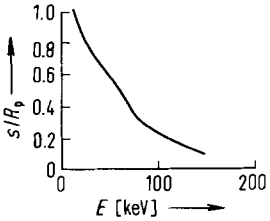

Fig. 6. Ratio between the thickness s of the layer removed by sputtering and the projected range or depth of penetration R_p, as a function of the ion energy E in the implantation of tellurium ions into GaAs at a dose of 5×10^{15} cm^{-2}.

As the dose is raised further, the concentration of the ions remaining in the target eventually reaches a limiting value, which in the case of strong sputtering is only a few atom-%. Therefore, simple chemical compounds can be prepared by implantation only when the target is not very susceptible to sputtering or the ions have a small mass.

Light ions transfer little energy to the nuclei of the target atoms and can be scattered back after an approximately central collision, so that they leave the surface altogether (case 3). Their energy then depends on the mass of the backscattering atoms and on the depth at which the back-scattering took place. The depth of backscattering in turn depends on the orientation of the crystal axis with respect to the ion beam, and on the disorder in the crystal. This is why measurement of the energy distribution of backscattered ions offers an extremely valuable method both for investigating radiation damage and for the chemical analysis of thin layers[13]. Some of the results discussed in the next section were obtained from the backscattering of H^+ and He^+ ions with initial energies of 0.3—2 MeV.

Collision with target atoms in the direction of greater depths of penetration (case 1 in Fig. 5) can lead to a special effect when the target is covered with a thin layer of another material, as in the case of a silicon target covered by an oxide layer or a layer of aluminum. If the layer thickness and the ion energy are so chosen with respect to each other that much

energy is transferred in nuclear collisions shortly before the interface has been reached, then a large number of atoms will migrate from the surface coating into the substrate. This effect is called recoil implantation. The atoms that migrate from the oxide layers are mostly oxygens, owing to their low atomic weight. Figure 7 shows by way of example the implantation of 100 keV arsenic ions into an oxide layer on a silicon substrate at a dose of $5 \times 10^{13}\,cm^{-2}$. The number of oxygen atoms introduced into the silicon per unit area by recoil implantation is plotted here against the thickness of the oxide layer. When the layer thickness is approximately the same as the projected range R_p, as many oxygen atoms are introduced into the silicon as there are arsenic atoms implanted into the oxide[14]. Oxygen is undesirable in the silicon, because it hampers the repair ("annealing") of radiation damage[15].

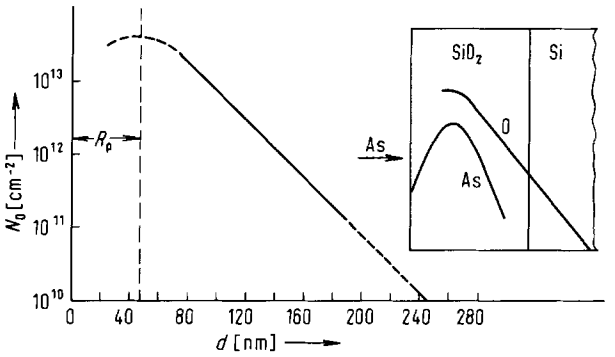

Fig. 7. Recoil implantation of oxygen from SiO_2 [14]. Primary ions: 100-keV As^+ at a dose of 5×10^{13} ions/cm^2. N_0 = number of oxygen atoms per cm^2 of silicon area, d = thickness of the oxide layer. Insert: distribution of arsenic and recoil-implanted oxygen when the oxide layer is sufficiently thick to mask against the implantation of arsenic ions.

Recoil implantation is useful if ions are to be introduced to a very small depth in a high but rapidly decreasing concentration, as for example in the case of solar cells[16]. The dopant is then applied as a thin layer onto the host and is bombarded with ions of the same or higher mass. Under favorable conditions, the number of ions introduced per unit area by recoil implantation may be fifty times as high as the dose of the primary ions.

Of the three consequences of nuclear collisions discussed above, *i.e.* radiation damage, sputtering, and recoil implantation, the first is of special importance, because it has a direct effect on the doping of semiconductors. This will be made clear in the following Section.

5. State of the Crystal Lattice after Implantation and the Doping of Semiconductors

5.1. Causes of Incomplete Doping

In most cases, ions are implanted into semiconductors for the purpose of doping. The function of the implanted ions is to act as donors or acceptors, *i.e.* to provide electrons or holes for conduction. If all the implanted ions turn into active donors or acceptors, then the number of additional charge carriers per cm^2 of surface area must be equal to the dose. However, electrical and optical measurements often indicate smaller numbers of additional electrons or holes, which may be due to the following causes:

a) The implanted ions may occupy lattice sites on which they do not become electrically active. For example, the usual doping agents for silicon must be located at substitutional sites, because on interstitial sites they remain inactive.

b) Some lattice defects may have been formed in the crystal that counteract doping either because they are electrically active themselves and are of the opposite type to the implanted ion, or because they form pairs with the implanted ions. For instance, a donor species may pair off with a vacancy in silicon to form an acceptor[17]. In compound semiconductors vacancies are available for pairing in at least two sublattices. The observed effects show a corresponding variety[18].

c) The implanted ions may diffuse to the surface and separate out there. The temperatures and times needed for annealing the radiation damage may be sufficient for a noticeable diffusion to occur.

The effect of radiation damage is not confined to the formation of electrically active defects (b), but extends to the occupation of lattice sites (a) and to diffusion (c). If we examine the way these phenomena depend on the type of the ions, the dose, and the target temperature, we find a bewildering array of effects. However, the main points already emerge from two important special cases: the formation and recrystallization of an amorphous layer, and the far reaching prevention of radiation damage by the use of high target temperatures.

5.2. Doping with Utilization of Radiation Damage

When the strongly disordered regions shown in Figure 5 (case 1) overlap with one another after the implantation of a large number of ions, an amorphous layer is formed. The disorder can then no longer be described by the number of individual defects. Figure 8a shows the disorder, determined by backscattering measurements, as a function of the dose[19]. The disorder reaches a saturation value at a dose that decreases with increasing ionic mass. In Figure 8b the disorder is expressed on the ordinate not in relative units but in the number of certain defects. Both the number and the type of the defects were determined from paramagnetic resonance[20]. The Si-G7 center (negative divacancy) was chosen as an example of defects, but other lattice defects behave similarly. The number of these centers at first increases with the dose, and at a fairly high dose centers exist whose resonance is independent of the direction. The increase in their number with a simultaneous reduction in the number of other centers indicates the change from discrete lattice defects to a fully disordered state. It is possible to show by electron diffraction or with a scanning electron microscope that an amorphous region is formed when the radiation damage reaches saturation[21–23]. The amorphous layer recrystallizes in contact with the crystalline substrate even at moderate temperatures (550—650 °C for silicon). Impurity atoms that can replace the atoms of the semiconductor in the crystal lattice mostly occupy a large proportion of these substitutional sites during recrystallization. This is why the formation of an amorphous zone can be very useful, as shown in Figure 9[24]. These curves indicate the number of conduction electrons under 1 cm^2 of the surface after the implantation of antimony into silicon and subsequent annealing at various

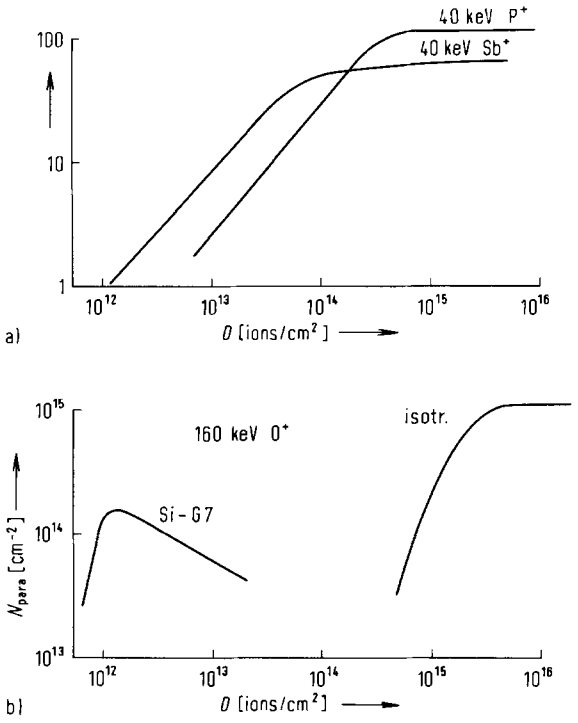

Fig. 8. Dose-dependence of radiation damage in silicon. a) Disorder determined by backscattering (relative units) [19]; b) number of paramagnetic defects N_{para} [20]. D = dose.

temperatures. If all the implanted ions turn into active donors, this number must be equal to the dose. With a dose of 1.5×10^{13} antimony atoms per cm^2 (curve b) no amorphous layer is yet formed. The proportion of active donors increases slowly with the annealing temperature and does not yet reach the maximum when this temperature is raised to 800 °C. With

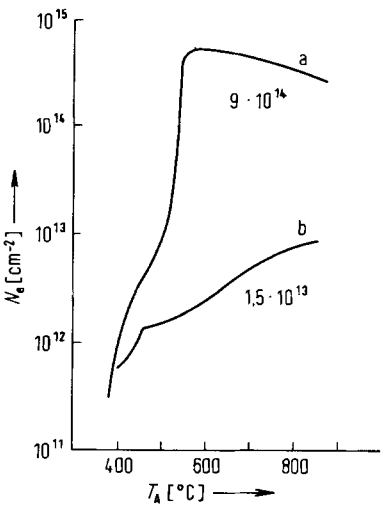

Fig. 9. Electrical activity of 40-keV antimony ions implanted into silicon [24]. N_e = number of electrons per cm^2; T_A = annealing temperature.

a dose of 9×10^{14} ions per cm^2 (curve a) the number of ions is well above the critical dose needed for the formation of an amorphous layer. As soon as the amorphous layer recrystallizes, the proportion of ions that function as active donors sharply increases to a maximum.

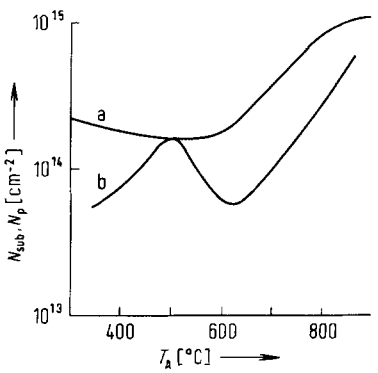

Fig. 10. Electrical activity of boron ions implanted into silicon. a) N_{sub} = number of boron atoms per cm^2 on substitution sites; implantation energy 56 keV, dose 1.2×10^{15} ions/cm^2 [29]; b) N_p = number of free charge carriers (holes) per cm^2; implantation energy 40 keV, dose 1.0×10^{15} ions/cm^2 [27]; T_A = annealing temperature.

In the case of phosphorus this sudden increase in the proportion of active species occurs even at a low dose[25, 26] as soon as the defects are repaired. Boron implantations commonly do not exceed the critical dose, and the proportion of active boron ions at a low dose does not increase either suddenly or monotonically but instead passes through a maximum and then a minimum. Comparison between electrical measurements[27] and backscatter measurement[28, 29] indicates that the processes mentioned under Point b) in Section 5.1 play an important role here. In fact, the electrical activity and the number of boron ions on substitutional sites vary differently with the annealing temperature (Fig. 10). To reach a high activity also with boron after a moderate annealing temperature, one can implant the ion of a heavy boron compound such as BF_2^+[30], formed from boron trifluoride in the ion source. Here a dose of 1×10^{15} ions/cm^2 already leads to the formation of an amorphous layer, in the recrystallization of which over 90 % of the boron atoms become electrically active[*].

5.3. Doping with Utilization of Self-annealing

The maximum electrical activity of the implanted ions cannot always be reached by the annealing of the amorphous layer. It may be better to suppress to a great extent the occurrence of radiation damage in the first place, by heating the target during implantation. The temperature needed for this is lower than the recrystallization temperature after implantation, because the collisions of ions rupture chemical bonds. When the bonds have re-formed, which takes about 10^{-9} s, the inside of the disordered region will be amorphous and its edges will be crystalline. Crystallization requires diffusion processes, and the higher the temperature of the target the faster these proceed within the 10^{-9} s period[32]. It should be mentioned that we are speaking here of a disordered zone along the path of a single ion and not of the whole amorphous layer, which arises from the aggregation of the individual zones only at a high dose.

[*] The high activity is not the only advantage of BF_2^+ implantation. The amorphous layer also prevents the migration of defects on annealing in oxidizing atmospheres and so enables the manufacture of implanted p-n junctions with low leakage currents [31].

Figure 11 illustrates the effect of this self-annealing during implantation in the case of GaAs, by showing how the disorder (determined by measuring the back-scatter of He ions) varies with the target temperature[33]. It can be seen that even temperatures of 100—200 °C greatly reduce radiation damage, and hardly any disorder is noticeable at 350 °C. Figure 12 shows the favorable effect of an elevated target temperature on the activity of selenium ions in GaAs[34]. The curves have been

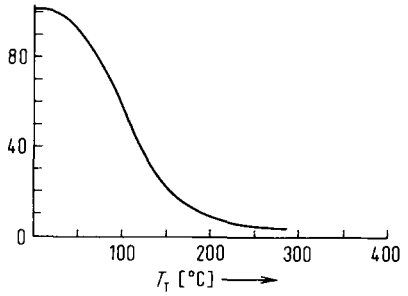

Fig. 11. Lattice disorder in GaAs (arbitrary units) [33] after the implantation of 40-keV tellurium ions at a dose of 5×10^{15} ions/cm^2; T_T = target temperature.

obtained by plotting the charge-carrier concentration against the depth in the target. The maximum is expected at 70 nm, and it does come there at 350 °C, with the concentration

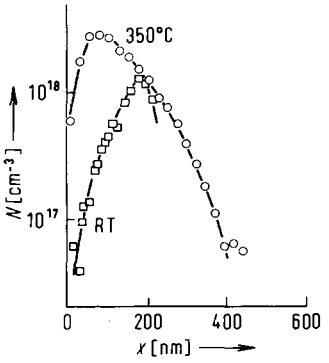

Fig. 12. Implantation profile of 400-keV selenium ions in GaAs for two target temperatures T_T [34] at a dose of 1×10^{14} ions/cm^2, after annealing at 900 °C. The depths of penetration do not agree with the theoretical value because the ions were implanted through a protective layer of Si_3N_4. RT = room temperature, N = density of free charge carriers, x = depth below the surface.

corresponding to an electrical activity of 80 %. When the implantation is carried out at room temperature, the activity decreases particularly in the region in which radiation damage is the most extensive. When doping PbTe it is also advisable to allow the radiation damage to "repair" already during the implantation. However, the self-annealing is so strong here that the target must be cooled with liquid nitrogen if an amorphous layer is to be obtained[35].

5.4. Residual Damage, Diffusion Losses, and Choice of Conditions of Implantation and Annealing

It seems to be a property of compound semiconductors in particular that in many cases heating to the highest technically practicable temperature is still not sufficient to abolish the effect of radiation damage on the electrical activity. Perhaps this can be explained by the high stability of defect pairs formed from a doping atom and a vacant site in the appropriate sublattice of the compound. The vacancies can be filled by implanting not only the dopant but also the component of the compound that corresponds to the vacancies, or by covering the semiconductor, prior to annealing, with a protective layer that contains this component.

A residual radiation damage remains also in elemental semiconductors after high-temperature annealing, but—unlike in many compound semiconductors—it is manifested not so much in a reduction of the electrical activity as in a reduced mobility[27, 36] and lifetime[37] of the charge carriers. This is because of the transformation of the original or primary defects into secondary defects, especially dislocations, which under unfavorable conditions do not disappear in silicon even at 1100 °C[38]. The type and the magnitude of the secondary defects depend on the conditions of implantation, the type of the ions used, the annealing temperature, and the atmosphere in which the annealing is carried out[39, 40]. However, they have significant disadvantages only when the dose exceeds 5×10^{14} ions/cm^2[41].

The reduction of the electrically active proportion of the implanted ions by outward diffusion may be mentioned here briefly. Ions that easily diffuse at the required annealing temperatures (*e.g.* Sb in Ge) must be implanted to a greater depth if one wants to prevent a significant part from diffusing

Table 1. Electrical activities of ions implanted into Si and GaAs as a function of the conditions of implantation and annealing (RT = room temperature).

Target	Ion	Electr. activity [%]	Dose [ions/cm^2]	Energy [keV]	Impl. temp. [°C]	Annealing temp. [°C]	Protective layer	Ref.
Si	B	100	10^{15}	40	RT	950	—	[27]
Si	B	100	10^{15}	40	−196	550	—	[27]
Si	Al	70	10^{13}	30	RT	650	—	[42]
Si	Al	30	10^{14}	30	RT	900	—	[42]
Si	P	90	5×10^{15}	280	RT	600	—	[26]
Si	As	100	3×10^{15}	280	RT	600	—	[26]
Si	Sb	50	5×10^{14}	30	RT	600	—	[42]
Si	Bi	10	2×10^{14}	40	RT	600	—	[42]
GaAs	Be	100	10^{14}	250	RT	900	Si_3N_4	[45]
GaAs	Zn	100	10^{15}	150	RT	850	SiO_2	[43]
GaAs	Cd	100	10^{14}	135	RT	850	Si_3N_4	[44]
GaAs	Si	70	10^{13}	400	RT	850	Si_3N_4	[32]
GaAs	S	100	2×10^{12}	350	RT	850	SiO_2	[46]
GaAs	S	16	10^{14}	1000	RT	825	Ga—SiO_2	[47]
GaAs	S	40	10^{14}	1000	360	825	Ga—SiO_2	[47]
GaAs	Se	66	10^{14}	400	350	900	AlN	[48]
GaAs	Te	26	10^{14}	400	350	900	AlN	[48]

out[41]. The diffusion may be promoted by the continuous formation of defects during the implantation (radiation-enhanced diffusion).

Recently, the annealing of radiation damage by laser irradiation has attracted considerable attention. The sudden and intense supply of energy by the laser obviously affects the lattice defects in an essentially different way from continuous heating in a furnace. Tellurium in GaAs could be incorporated almost completely at substitutional sites even for concentrations which exceed the known solubility more than tenfold[67]. However, the conductivity did not exceed that obtained by conventional doping. High electrical activity was also achieved for boron in silicon by laser annealing[68]. Irradiation at a sufficiently high energy per laser pulse apparently produces a liquid phase such that epitaxial crystal growth from the liquid can replace the recrystallization in the solid state[69]. Particularly for Si, the depth distribution of the ions after laser annealing does not correspond to the Gaussian distribution obtained by the implantation[68, 70]. The technical interest in laser annealing results both from the high electrical activity achievable in a relatively short time and from the possibility of confining the heating of the material to the implanted zone.

To sum up, the factors causing a reduction of the electrical activity and mentioned at the beginning of this section can be combated mainly by a suitable choice of the temperature during implantation and the annealing of radiation damage, but the results depend to a great extent on the dose, the depth of penetration, additional implantations, and the use of protective layers during annealing. The data in Table 1 show the electrical activity of implanted ions in Si and GaAs after implantation and annealing under various conditions.

6. Implantation into Silica Layers and Interfaces

One of the most important structures in semiconductor technology is the combination of a silicon wafer with a thin layer of silica. This layer can serve as a mask for diffusion and implantation processes, it stabilizes the silicon surface, and it is used in MOS transistors as an electrically insulating layer. We shall deal here only with the layers obtained by the thermal oxidation of silicon. The main effects in ion implantation are as follows:

In the case of implantation before oxidation: influencing the rate of oxidation through the implanted ions; and influencing the radiation damage through oxidation.

In the case of implantation after oxidation: radiation damage in the oxide; and recoil implantation of oxygen (see Section 4).

The effect of radiation damage on the rate of oxidation is only temporary, since the oxidation temperatures are well above the annealing temperature. Some doping elements have a direct effect on the oxidation rate. Antimony can accelerate the growth of the oxide layer by a factor of 6, but it must be implanted in a concentration of about 10^{21} ions/cm^3 for this to happen. When the oxidation extends beyond the implanted layer, the effect rapidly decreases[49, 50]. Implanted nitrogen can reduce the growth of the oxide layer by a factor of more than 10. It is assumed that nitrogen is pushed to the surface during the recrystallization of the silicon. The concentration thus rises until it is sufficient for the formation of an Si_3N_4 layer, which protects the silicon from oxidation[51].

As mentioned in Section 5, dislocations are formed when the radiation damage is annealed in silicon. In the case of thermal oxidation the dislocation loops can become so large that they can be seen under an optical microscope after chemical etching[52]. We must anneal the radiation damage before oxidation or ensure a slow oxidation if we want to avoid the undesirable effect of the radiation damage on the electrical characteristics of the components[53].

Oxide layers are often used to shield parts of a silicon surface from implantation, or the ions are implanted through an existing oxide layer. The radiation damage that then arises in the silica can be studied very easily by examining the optical properties of silica. Figure 13 shows by way of example

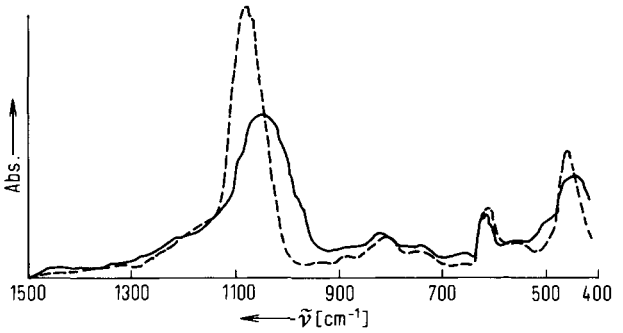

Fig. 13. Absorption spectra of SiO_2 layers [54] with implanted phosphorus (full line) and without it (broken line). The band at 620 cm^{-1} is due to the much thicker silicon substrate.

the IR spectra of two silica layers on silicon, one with and the other without implanted phosphorus ions. The result of the bond rupture due to implantation is that the band near 1100 cm^{-1} is shifted and the area under it is reduced. However, the original spectrum is re-established when the material is heated to 690 °C for 50 min[54]. Although thermally grown oxide layers are amorphous, they show saturation of radiation damage at a certain dose, similarly to crystalline materials. This indicates that amorphous layers are not structureless and that ion implantation results in a special type of disorder.

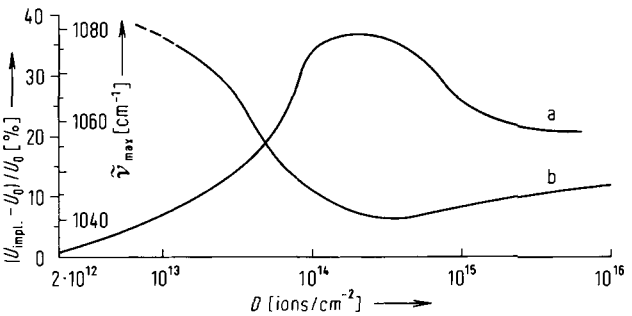

Fig. 14. Dose dependence of the change in the dielectric breakdown (a) and the position of IR absorption in silica implanted with phosphorus (b) [56]. U_0 = breakdown voltage without implantation. U_{impl} = breakdown voltage after implantation, $\tilde{\nu}_{max}$ = wave number of the principal band, D = dose.

The electrical properties of the boundary surfaces between silica and silicon, which are very important for MOS transistors, are not, it seems, directly connected with disorder in the oxide. Although the density of the surface states is raised

by the implantation of ions, it rapidly decreases again even at an annealing temperature of only 200 °C[55], *i.e.* well before the radiation damage in the silica has been repaired. In contrast, the implantation-induced increase in the dielectric strength[56] is clearly connected with the shift of the absorption band and thus with the disorder (cf. Fig. 14). The disorder makes the free path of the electrons shorter and thus reduces the probability that an electron will be accelerated until it reaches the energy needed for ionization on collision.

The effect of ion implantation on dielectric breakdown is of scientific rather than of practical interest, but it does show that ion implantation is not only a technological process but also a useful tool for scientific investigations, important examples of which have been collected by *Schulz*[57].

7. Miscellaneous Applications, Limitations, and Future Development of Ion Implantation

Besides the doping of semiconductors, ion implantation has many other possible applications of varying technical importance. The preparation of SiC, Si_3N_4, and SiO_2 by implantation into silicon is possible but has no prospects[58, 59, 54]. Other topics of research are the modification of the magnetic properties of garnet layers[60], the preparation of superconductors[61, 62], and the modification of friction and wear[63].

If we extend the diagram shown in Figure 1 to even higher doses and extremely low energies of between a few hundred electron volts and 40 eV, we come to the field of ion beam deposition of thin layers[64, 65], but this will not be discussed here because it is very different from ion implantation both as regards the apparatus used and the physical problems involved.

It should be pointed out that the fascinating advantage of ion implantation—its excellent reproducibility—does not mean an absolute accuracy of the dose and the depth of penetration. The accuracy is limited both by problems connected with the apparatus, the solution of which is very costly, and by insufficient knowledge of some side effects[66]. The beam deflection system alone introduces inaccuracies, because, at the same change in the angle, the area bombarded differs with the angle, particularly when the target is not normal to the beam. Yet with single crystals the target must be tilted with respect to the beam by about 7° to minimize deviations from the normal spatial distribution of the implanted ions. Such deviations are caused by ions whose paths largely run along definite preferred crystallographic directions, which makes a longer range possible. We have already mentioned the loss of ions through sputtering. It is often forgotten that light ions can be reflected at a target of high atomic weight. In the implantation of aluminum into cadmium mercury telluride, for example, this can introduce an error of up to 20 % into the dose. In unfavorable cases the fluctuations in the vacuum inside the beam guidance system and variations in the composition of the residual gas in the ion source can limit not only the accuracy but also the reproducibility. Charge variations and the decomposition of molecule-ions have an adverse effect on the uniformity of the depth of penetration and the beam deflection. Ions of the same mass such as CO^+, N_2^+, and $^{28}Si^+$ cannot be separated, and their proportions in the beam can be estimated only roughly from the intensity of the accompanying ions, in this case C^+, O^+, and N^+.

However, except for the error involved in the beam deflection angle, these sources of error are noticeable only in special cases. Ion implantation has proved to be an outstanding doping technique. Besides, the more widely it is used, the more attractive is its application for regulating the course of certain technical processes such as oxidation and etching. The need to make semiconductor components smaller and smaller and to combine more and more of them in integrated circuits calls for costlier apparatus not only for doping but also for masking and etching techniques. This trend must be taken into account when considering the future development of the implantation technique, and it can be assumed that ion implantation will not remain merely a complement of the diffusion technique but will instead lead to fundamental changes in technical concepts when all the innovations have been combined.

The author wishes to thank F. Friedrich and Dr. M. Schulz for reading through the manuscript and for valuable comments.

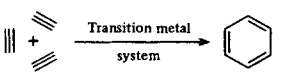
Cobalt-Catalyzed Pyridine Syntheses from Alkynes and Nitriles

New synthetic methods (23)

By Helmut Bönnemann[*]

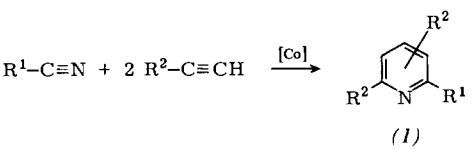


Soluble organocobalt catalysts permit selective formation of substituted pyridines under mild conditions in a single step: mono-, di-, and trisubstituted pyridines can be obtained at will in high conversions and high yields from nitriles and alkynes. Polynuclear derivatives such as bipyridines can also be prepared by this method.

1. Introduction

During the past 15 years, the use of homogeneous transition metal catalysts in olefin chemistry has made numerous useful hydrocarbons available from simple starting materials. The relation between the structure of the catalyst and its mode of action has, in many cases, been largely elucidated (cf. refs. [1, 2]). In contrast, relatively few investigations have been made on the metal-catalyzed syntheses of heterocycles[3]. This is understandable since many metal catalysts are blocked when hetero atoms such as nitrogen, oxygen, or sulfur are present in the substrate.

Starting from the discovery that the perturbing influence of polar groups on cobalt as the central atom of a homogeneous catalyst is apparently very slight[4], heterofunctional substrates were allowed to react in the presence of organocobalt catalysts.



Cyclotrimerization of alkynes to give benzene derivatives [eq. (a)] was adopted as a "model reaction" for systematic studies on the use of soluble cobalt catalysts in the synthesis of heterocycles.

(a)

Many variants of this long-known reaction have been studied. It is a typical metal-catalyzed organic reaction, proceeding with a wide range of transition metal systems such as carbonyls, metallocenes, and even simple salts (cf. refs. [5-8]). Cobalt was found to be one of the most effective catalyst metals for the reaction shown in eq. (a).

The very first attempts to use cobalt for the synthesis of heterocycles revealed that a C≡C bond could be replaced by a C≡N bond in the standard cyclization procedure [eq. (a)]: reaction of both alkynes and nitriles on cobalt catalysts

(b)

(1)

[*] Priv.-Doz. Dr. H. Bönnemann

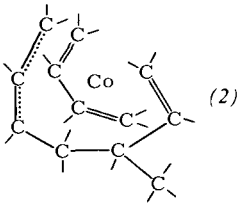
in homogeneous phase afforded a pyridine derivative of type *(1)* as the main catalytic product.

Delineation of the scope of this approach soon showed that eq. (b) provides a new general catalytic pathway to pyridine derivatives[9, 10].

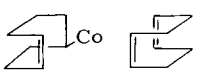


Before considering the preparative implications, let us first examine the nature of the catalysts.

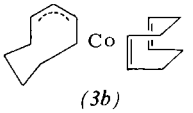
2. Survey of the Organocobalt Systems Employed

2.1. Organocobalt Complexes

A series of "ready-made" organocobalt complexes can be used for the synthesis of pyridines.



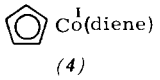
Reaction usually proceeds smoothly on *allylcobalt* systems. The preparation and properties of these species have been reported elsewhere[11]. A typical representative of this class of catalysts is butadiene(5-methylheptadienyl)cobalt *(2)*[12]. All the organic constituents of compound *(2)* are derived from butadiene.



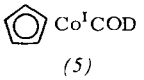
(2)

The red crystalline complex *(2)* is formed on reduction of a solution of cobalt(II) chloride and butadiene in ethanol at −30°C with $NaBH_4$. Two butadiene units combine to form a methyl-substituted C_7 chain which is bonded to the cobalt atom *via* the π-allylic system and the terminal vinylic group. Pure *(2)* is thermolabile and must be stored and handled below −30°C.

More suitable for practical applications in catalysis are the 1,5-cyclooctadiene(cyclooctenyl)cobalt complexes *(3a)* and *(3b)*. These compounds may be stored at 20°C and may be prepared by reduction of cobalt salts with triethylaluminum[13], metals[14] or electrochemically[15] in the presence of 1,5-cyclooctadiene (COD).



(3a)

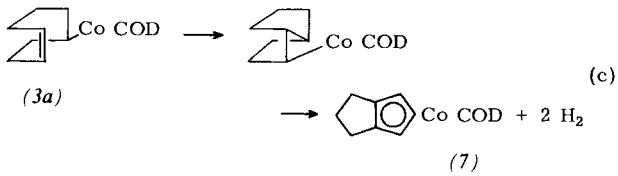


(3b)

The σ form *(3a)* and the π isomer *(3b)* show the same selectivity in pyridine synthesis.

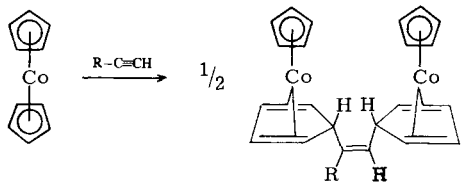
An important role in the catalytic reactions shown in eq. (b) is played by *cyclopentadienylcobalt(I) systems:* the π-cyclopentadienyl group confers considerable thermal stability upon the complex.

(4)



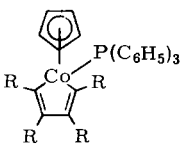
(5)

(6)



This class of compounds *(4)* containing a CpCo core complex *(6)* is considered to include *(7)*, which is obtained according to eq. (c) by intramolecular ring closure and elimination of hydrogen from *(3a)*. *(7)* can also be prepared from the π form *(3b)*[15].

(3a) (c) *(7)*

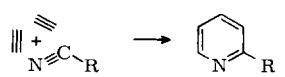


Diamagnetic cobalt(I) complexes with a central unit *(6)* stabilized by ene and diene systems are known in various guises[16–20] and are readily accessible. Our previous experience has shown that all systems containing a central unit of type *(6)* are effective catalysts for the pyridine synthesis, regardless of the kind of stabilizing olefinic ligand present.

This series of "ready-made" cobalt catalysts for the pyridine synthesis could be extended at will: the only basic requirement is that the complex ligands should be completely or partly displaceable from the metal by the nitrile or alkyne—the active cobalt(I) species is liberated and catalysis occurs. Cobaltocene can also be used in this way[21, 22]; an initial activating step, eq. (d), gives a system containing the essential core structure *(6)*[21].

(d)

Similar observations have been reported for the phosphane-modified cobalt(III) complexes *(8)*. *Yamazaki* and *Wakatsuki* obtained pyridine derivatives with the aid of such systems as early as 1973[23] while our work on phosphane-free systems was in progress.



(8)

The species *(8)* contains two acetylene molecules linked together at one end and joined *via* a cobalt atom at the other to form a five-membered ring. However, the Japanese authors report the synthesis of *(8)* to be troublesome, and subsequently they also adopted simple organocobalt complexes such as cobaltocene for use as catalysts[21, 23c].

2.2. Catalysts Generated *in Situ*

Synthesis of pyridines from alkynes and nitriles [eq. (e)] can be carried out advantageously in a one-pot reaction; the cobalt catalysts then being generated *in situ*[9, 10].

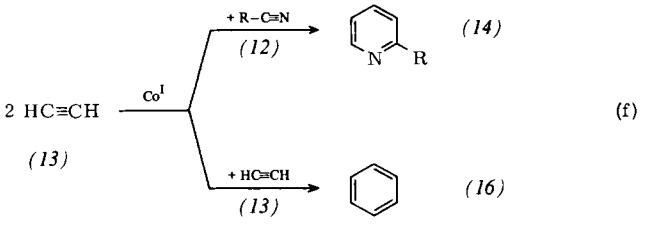
(13) + *(12)* *(14)* (e)

Prior to the initiation of catalysis, a small amount of a suitable cobalt salt is dissolved or suspended in the substrate

mixture and a solvent is added if required. The next step consists in activation with reducing agents, the anions being removed from the cobalt and the vacant coordination sites being occupied by substrate molecules. Metals of the 1st to 3rd Main Groups, and their hydrido or alkyl compounds, are especially suitable as reducing agents. If complex formation with the substrates is insufficient to stabilize the cobalt atom in solution, additional "stabilizers" can be introduced before the reduction step. Cyclic olefins (*e.g.* the chelating diolefin 1,5-cyclooctadiene) are particularly suitable as stabilizing agents. In contrast to the situation with Ziegler catalysts, the organometallic species serves merely as reducing agent. It is not an integral component of the catalyst and thus of no importance for the actual catalytic reaction. Examples are shown in Table 1.

Table 1. Catalysts for pyridine synthesis generated *in situ* [eq. (e)].

No.	CoX_n/Metal	No.	CoX_n/MH	No.	CoX_n/MR
(9a)	$CoCl_2$/Li [a]	*(10a)*	$CoCl_2$/LiH	*(11a)*	$CoCl_2/C_4H_9Li$
(9b)	$CoCl_2$/Na [b]	*(10b)*	$CoCl_2/LiAlH_4$	*(11b)*	$CoCl_2/C_2H_5MgX$
(9c)	$CoCl_2$/Mg [c]	*(10c)*	$CoCl_2/NaBH_4$	*(11c)*	$Co(acac)_3/(C_2H_5)_3Al$
(9d)	$Co(acac)_3$/Mg [c]	*(10d)*	$Co(OAc)_2$/ $Co(acac)_2$/ $Co(HCO_2)_2$ } $NaBH_4$	*(11d)*	$Co(acac)_2/(C_2H_5)_2AlOC_2H_5$



[a] Reduction in the presence of the nitrile *(12)*; the acetylene *(13)* is added subsequently. [b] Subsequent addition of the nitrile *(12)*. [c] Activated with iodine.

The cobalt salts, *e.g.* $CoCl_2$, can be used in hydrated form. Use of an inert atmosphere and additional stabilizing ligands such as phosphanes, is unnecessary. The system *(15)* has proved most valuable in the laboratory:

$$CoCl_2 \cdot 6\ H_2O/2\ NaBH_4 + \text{Nitrile/Alkyne} \qquad (15)$$

3. Catalytic Synthesis of 2-Substituted Pyridines

2-Substituted pyridines of type *(14)* are readily obtained in solution from carbonitriles *(12)* and acetylene *(13)* [eq. (e)] in the presence of "ready-made" organocobalt catalysts (Section 2.1). Whereas the nitriles *(12)* undergo practically exclusive conversion into the pyridine derivatives *(14)*, if no special precautions are taken[*] the alkyne component always undergoes some degree of conversion into benzene derivatives *(16)*. The ratio of heterocyclic to carbocyclic products (*i.e.* *(14)*:*(16)*) determines the preparative value of the synthesis and can be directed in favor of *(14)* by using an excess of the nitrile *(12)*.

(f)

[*] *Vollhardt*'s generalization that co-cyclization of monoacetylenes with nitriles leads to "complicated mixtures" [132] is not justified and is presumably based on a misinterpretation of the data published by us [10, 24] and *Wakatsuki* [21, 23].

If catalysis [eq. (f)] is conducted in the presence of a permanent excess of nitrile and the stoichiometric amount of alkyne is added at such a rate that the steady-state concentration of the C≡C bond remains as low as possible, the heterocycles *(14)* can be obtained in yields exceeding 90 % without significant formation of by-products *(16)*. About 1 mol-% of catalyst is first dissolved in pure nitrile to give a brown solution without deposition of metal; these solutions are drawn into a V4A autoclave. Acetylene is then added at 20 bar up to a pressure of 11 bar[*]. The autoclave is heated to 120—130 °C for 1 h, whereupon the pressure drops to *ca.* 9 bar. The pressure is then raised to *ca.* 16 bar and the acetylene consumed is continuously replaced. After *ca.* 2 h, the stoichiometric amount of acetylene has been consumed and the catalytic reaction [eq. (e)] is complete. This modified procedure readily affords 2-substituted pyridines *(14)* (Table 2). The catalyst systems *(3)*, *(5)*, or *(11)* produce 100 to 400 mol of *(14)* per mol of catalyst.

Table 2. 2-Substituted pyridines *(14)* obtained according to eq. (e). [Catalyst *(11)* or *(5)*; reaction temperature 120—130 °C; almost complete conversion; work-up by distillation.]

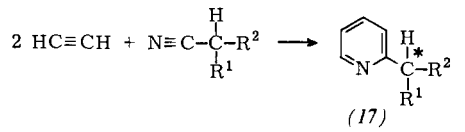
[a] Further IR and ^{1}H-NMR spectra are available for the major fraction.

As discussed for eq. (f), the product selectivity of the cobalt catalyst with respect to *(14)* or *(16)* can be influenced by a suitable choice of the nitrile/alkyne ratio. This result suggests that the product selectivity in eq. (f) might be controlled by further ligands complexed to the cobalt. Moreover, the catalytic reaction could possibly show a control effect in strongly polar solvents such as tetrahydrofuran, alcohols, or amines which can coordinate to transition metals. Several series of comparative studies show, however, that

[*] Special safety precautions must be observed on working with acetylene under high pressure (> 3 bar).

1) The product selectivity is independent of the catalyst type; compounds *(2)* to *(4)* and *(8)* to *(11)* were examined;
2) Phosphanes, arsanes, and Lewis acids have no effect[*];
3) Strongly coordinating solvents such as cyclic ethers, chlorohydrocarbons, amines, or alcohols lower the rate of eq. (f) but do not affect the product ratio *(14)*:*(16)*.



These observations justify the conclusion that the selectivity of the cobalt catalyst of eq. (f) is subject only to "substrate control".

In order to compare the turnover numbers (measured as number of mols of pyridine per mol of cobalt and hour) of soluble organocobalt catalysts we performed the standard reaction of eq. (e) at 130°C and 13 bar of acetylene under the same conditions but with various catalysts. The results of this comparative study are listed in Table 3.

Table 3. Efficacy of various catalyst types in reaction according to eq. (e) [130°C/13 bar acetylene, R = phenyl]. As soon as a drastic drop in acetylene uptake was observed catalysis was discontinued and the products worked up.

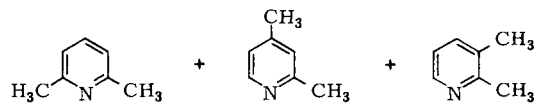
	Catalyst type	Conversion of RCN [%]	$\frac{\text{mol } (14)}{\text{mol CO}\cdot\text{h}}$
(10d)	$Co(OAc)_2/Co(acac)_2/Co(HCO_2)_2/NaBH_4$	93	595
(11c)	$Co(acac)_3/Et_3Al$	96	621
(11d)	$Co(acac)_2/Et_2AlOEt$	94	640
(15)	$CoCl_2\cdot 6H_2O/2\,NaBH_4$	94	590
(9a)	$CoCl_2$/Li	95	595
(5)	CpCo(COD)	97	618
(3b)	$C_8H_{13}Co(COD)$	94	580
(2)	$C_8H_{13}CoC_4H_6$	92	400
(8)	$Cp(R_4C_4Co)PPh_3$, R = phenyl	90	120
	Cp_2CO	92	12
	$CpCo(CO)_2$ [73]	40	2

Table 3 also clearly reveals the inhibitory action of carbonyl and phosphane groups on the catalysis [eq. (e)]. The best catalysts are systems reduced *in situ* as well as compounds containing the cyclopentadienylcobalt group.

(17)

(g)

The only method so far available for selective synthesis of 2-substituted pyridines, *i.e.* cobalt-catalyzed reaction of nitriles with acetylene [eq. (e)], has also acquired industrial importance. In this context, particular interest is attached to 2-picoline (2-methylpyridine) that is used mainly for the production of 2-vinylpyridine.



2-Vinylpyridine, which is also directly accessible from acetylene and acrylonitrile according to Table 2, is used as a terpolymeric grip promoter in the tire industry. Moreover, it is also employed as comonomer in the polymerization of acrylonitrile in order to improve the dyeing properties of acrylic fibers.

4. Catalytic Synthesis of Lutidines

Reaction according to eq. (e) can also be conducted as a co-cyclotrimerization by using two different alkynes [eq. (h)]. For instance, simultaneous reaction of acetylene, propyne, and acetonitrile in presence of catalyst *(5)* affords a mixture of dimethylpyridines (lutidines) *(18)* together with 2-methylpyridine and isomeric trimethylpyridines.

(h)

(18a) *(18b)* *(18c)*

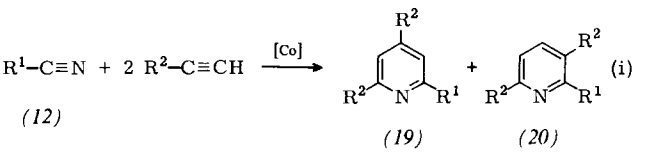
[a] According to gas chromatography. [b] Identified by ^{1}H-NMR spectroscopy, separated by gas chromatography.

Prompted by a preliminary report[74] of our new catalytic synthesis of 2-substituted pyridines, *Botteghi* applied the technique to the catalytic synthesis of analogous optically active derivatives[75]. Thus optically pure *sec*-butyl cyanide, which is readily accessible by classical methods, on cyclization with acetylene above 7 bar at 140°C with catalyst *(5)* affords the corresponding optically active 2-*sec*-butylpyridine *(17)* in over 90% yield. For example, (*S*)-(+)-*(17)* was obtained in 96% enantiomeric excess.



However, the catalytic reaction does not yield lutidines selectively: Table 4 shows that the yields of lutidines formed catalytically according to eq. (h) correspond to the statistically expected distribution.

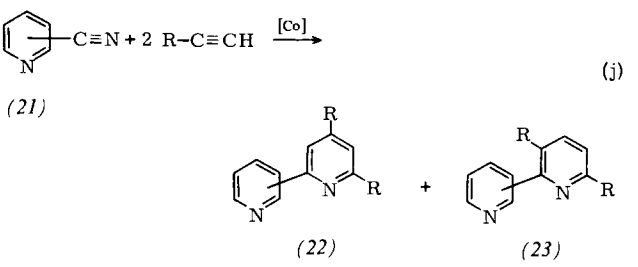
5. Catalytic Synthesis of 2,3,6- and 2,4,6-Trisubstituted Pyridines

A wide field of application of the one-step catalytic synthesis is found in the field of trisubstituted pyridines of types *(19)* and *(20)*. They can be prepared, with high catalyst turnover numbers, according to eq. (i) at *ca.* 130°C using cobalt com-

[*] Addition of more than two molecules of phosphane, arsane, and CO or isocyanide per cobalt atom merely blocks the catalyst.

plexes of type *(4)* or catalysts generated *in situ*, such as *(9)*, *(10)*, *(11)*, or *(15)*.

6. Catalytic Synthesis of Bipyridines



Polynuclear pyridine derivatives can also be synthesized in high yields using cobalt catalysts[24]. Starting from the readily available pyridinecarbonitriles *(21)*, reaction with terminal alkynes leads to the bipyridines *(22)* and *(23)* [eq. (j)].

Table 5. Trisubstituted pyridines *(19)* and *(20)* obtained according to eq. (i) [catalyst *(4)*, *(9)*—*(11)*, or *(15)*; reaction temperature *ca.* 130°C; work-up by distillation].

[a] On ^{1}H-NMR spectroscopic analysis, the isomeric ratio was determined from the intensity ratios of the signals characteristic for each of the structures. [b] Based on reacted alkyne, not optimized. [c] B.p. of mixture of isomers. [d] M.p. of mixture of isomers; purification by acid-base separation.

The catalytic reaction of terminal alkynes always leads to two isomeric pyridine derivatives: the symmetrically substituted type *(19)* is formed as the major product, while the asymmetric type *(20)* is formed in about 30% relative yield. The substituents R^1 and R^2 can be varied within wide limits and combined at will. The nitrile component may be an alkyl derivative of any length or an aryl compound. In this last case phenylpyridines are formed in a single step. This appears particularly remarkable because no single, general method was previously available for the production of phenylpyridines (cf., *e.g.*, [97]). The results obtained so far are summarized in Table 5.

Use of acetylene as the alkyne component gives the respective parent compound, *e.g.* 2,2′-bipyridine. Up to 350 catalytic cycles [eq. (j)] can be performed on a cobalt compound such

Table 6. Bipyridine derivatives *(22)* and *(23)* obtained according to eq. (j) [catalyst, *e.g.*, *(5)*; reaction temperature 120–130°C; almost complete conversion; work-up by distillation].

as *(5)*. Substituted alkynes give two positional isomers, with type *(22)* usually predominating. The bipyridines *(22)* and *(23)* bearing different substituents on the two rings, which were inaccessible by classical methods, could be of interest for the synthesis of transition metal bipyridine complexes. Some typical examples are shown in Table 6.

Particular industrial interest attaches to the new synthesis of 2,2'-bipyridines. The quaternization product of bipyridine and 1,2-dibromoethane is a commonly used herbicide.

7. Catalytic Reaction of α,ω-Dinitriles with Alkynes

The procedure corresponding to eq. (j) is also applicable to α,ω-dinitriles *(24)*. The bifunctional starting materials *(24)*

[a] 4-Amino-2,6-bis(cyanomethyl)-5-pyrimidinecarbonitrile is formed as a by-product in a yield of preparative interest.

containing any number of bridging members Z afford the bis(2-pyridyl) derivatives *(25)*, *(26)*, and *(27)*. The reaction proceeds stepwise: in the first step the monopyridyl derivatives *(28)* and *(29)* are formed; this is followed by reaction of the cyano group with further alkyne [eq. (k)].

As shown by Table 7, the otherwise rather inaccessible or unknown oligomethylenepyridines *(25)*—*(27)* can be prepared in good yield, without about 450 cyclization steps being achieved per cobalt atom of the catalysts *(5)* or *(14)*.

(l)

Table 8. ω-(2-Pyridyl)alkanonitriles *(28)* and *(29)* obtained according to eq. (k) at 25 % conversion of dinitrile *(24)* [catalyst, *e.g.* *(5)*; reaction temperature 80–90 °C; work-up by distillation].

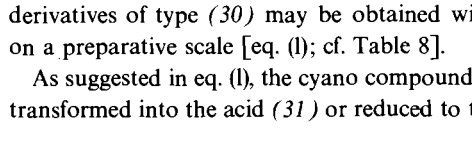
[a] Determined by ^{1}H-NMR spectroscopy. [b] B. p. of mixture of isomers.

If the catalytic reaction of eq. (k) is interrupted after *ca.* 25% of the dinitrile has been consumed then monopyridyl derivatives of type *(30)* may be obtained without difficulty on a preparative scale [eq. (l); cf. Table 8].

As suggested in eq. (l), the cyano compound *(30)* is readily transformed into the acid *(31)* or reduced to the amine *(32)*.

8. Catalytic Synthesis of Pentasubstituted Pyridines; Synthesis of Derivatives with Functional Groups

Pyridine derivatives having a higher degree of substitution can also be prepared catalytically [eq. (m)]. 2-Butyne or diphenylacetylene, for example, reacts with nitriles to give pentasubstituted pyridines *(33)* (Table 9).



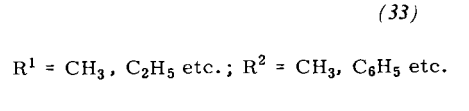
(m)

(33)

$R^1 = CH_3$, C_2H_5 etc.; $R^2 = CH_3$, C_6H_5 etc.

It has become apparent in the course of our studies that cobalt-catalyzed pyridine synthesis is by no means limited to carbonitriles. Even extensive modifications of the cyano components in the pyridine synthesis are tolerated by cobalt catalysts of types *(5)*, *(15)*, and *(4)*. Monomeric cyanamide[*] yields 2-aminopyridines *(34)* according to eq. (n) with the catalyst systems mentioned.

Aminopyridines of type *(34)* (Table 9) possess considerable preparative interest but can usually only be prepared by substitution of ready-made pyridine rings (cf. ref. [130]), in several steps.



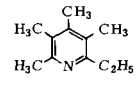
(n)

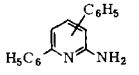
R = H, Alkyl, Aryl

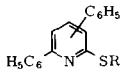
(34)

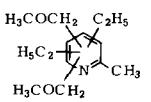
A catalytic cyclotrimerization reaction, using a modification of eq. (m), leads to pyridine rings having ether functions *(36)*. These are useful for pharmaceutical applications (Table 9).

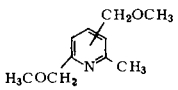
Alkyl thiocyanates can also be used as the cyano component; one-step reactions according to eq. (o) give alkylthiopyridines *(35)* which are otherwise accessible only with difficulty[135][*]. Although most of the Co^I systems are blocked within a few steps by deposition of free sulfur so that true catalysis according to eq. (o) cannot occur, use of catalyst *(5)* in toluene permits synthesis of *ca.* 40 to 50 mol *(35)*/mol *(5)*. Some of these results are compiled in Table 9.











(35) (o)

$R^1 = CH_3$, C_2H_5, $i\text{-}C_3H_7$; $R^2 = C_6H_5$, C_4H_9

Hong and *Yamazaki*[131] recently reported the catalytic reaction of acetylene derivatives with isocyanates and carbodiimides. Phosphane-substituted systems of type *(8)* and cobaltocene served as catalysts.

The reaction of isocyanates and alkynes according to eq. (p) can also be conducted with a similar degree of success

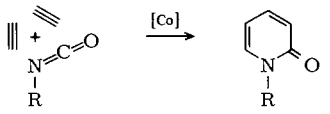


Table 9. Pyridine derivatives of type *(33)* [eq. (m)], *(34)* [eq. (n)], *(35)* [eq. (o)], and *(36)* [modification of eq. (m)] [work-up by distillation].

Product		Yield [%] [a]	B.p. [°C/torr] (M.p. [°C])	M^+ (*m/e*)	Product known according to ref.

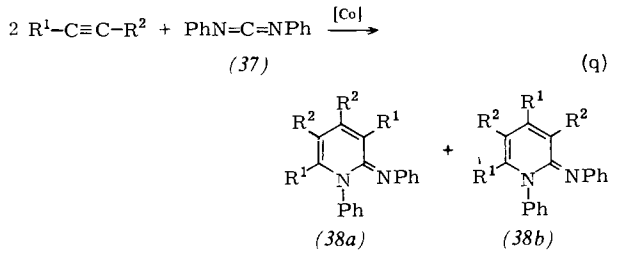
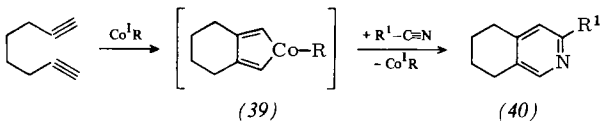
[*] Monomeric cyanamide is available in various grades from Süddeutsche Kalkstickstoffwerke AG, D-8223 Trostberg.



[*] This variant was developed by Dr. *G. S. Natarajan*, Nagpur University, India, 1974—1976 DAAD Guest Scientist at the Max-Planck-Institut für Kohlenforschung.

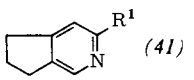
(p)

using our catalysts *(5)* and *(11)* to give 2-pyridones. About 200 catalytic steps take place per cobalt atom.



In the presence of complex *(8)* or of cobaltocene, the carbodiimides *(37)* react catalytically to form the imines *(38)* [eq. (q)][131].

(q)



(37) *(38a)* *(38b)*

A highly interesting variation becomes possible by reaction of acetylenes on $CpCo^{I}$(diene) systems *(4)* [eq. (r)]. 1,7-Octadiyne initially gives the non-isolable intermediate *(39)* containing a cyclohexane ring in an intramolecular process. In

(39) *(40)*

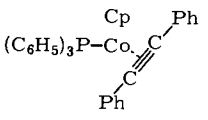
(r)

(41)

the presence of an excess of nitrile, a second ring closure takes place at the cobalt and leads to derivatives of tetrahydroisoquinoline *(40)* in *ca.* 60% yield. Compound *(41)* is obtained analogously from 1,6-heptadiyne.

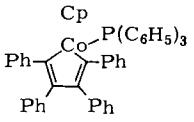
The annelated pyridines *(40)* and *(41)* are also obtained with $CpCo(CO)_2$ as catalyst[132].

9. Mechanism of the Cobalt-Catalyzed Pyridine Synthesis



The product formation using catalysts containing the $CpCo^{I}$ group as central moiety, can be rationalized in terms of a double reaction cycle (Fig. 1). The left-hand cycle (bold arrows) represents the principal reaction leading to pyridine as the catalytic reaction product; the right-hand cycle explains the formation of carbocyclic by-products.

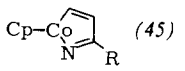
Both cycles start with a $CpCo^{I}$ complex *(6)* which initially coordinates an acetylene molecule to form *(42)*. This coordinatively unsaturated species can accept a further molecule of acetylene, under formation of a cobaltacyclopentadiene. This cobalt-containing intermediate, shown enclosed in a box, may be regarded as a junction between the pyridine and benzene cycles.



The product-forming step of the catalysis consists in insertion of a third triple bond. In the case of a nitrile molecule (left-hand cycle), the pyridine derivative *(14)* is formed catalytically *via (43)* while coordination of a third acetylene molecule (right-hand cycle) leads catalytically to benzene.

The phosphane-stabilized complexes *(44)*, reported by *Yamazaki et al.* in another context in 1970[133], can serve as model compounds for the intermediates shown in Figure 1.

(44a) can be compared with species *(42)*, while *(44b)* resembles the postulated intermediate *(43)* [cf. also catalyst *(8)*].



(44a)

(44b)

An intermediate of type *(45)* might be considered as an alternative to the central intermediate shown in Figure 1.

(45)

Results of kinetic studies[134], however, show that the rate of catalytic pyridine formation is independent of the concentration of nitrile in the reaction mixture. If the catalytic pyridine formation were to proceed *via* -containing intermediates of type *(45)*, then high nitrile concentrations would accelerate the catalytic reaction. The available experimental evidence

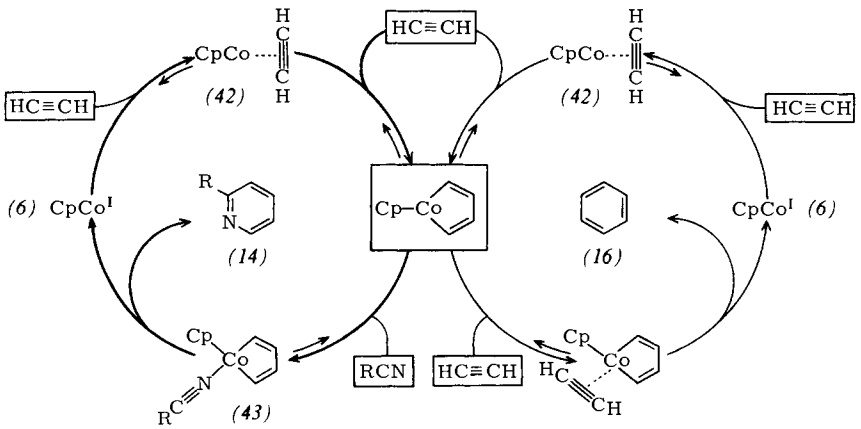


Fig. 1. Cobalt(I)-catalyzed reaction of alkyne and nitrile [cf. eq. (f)].

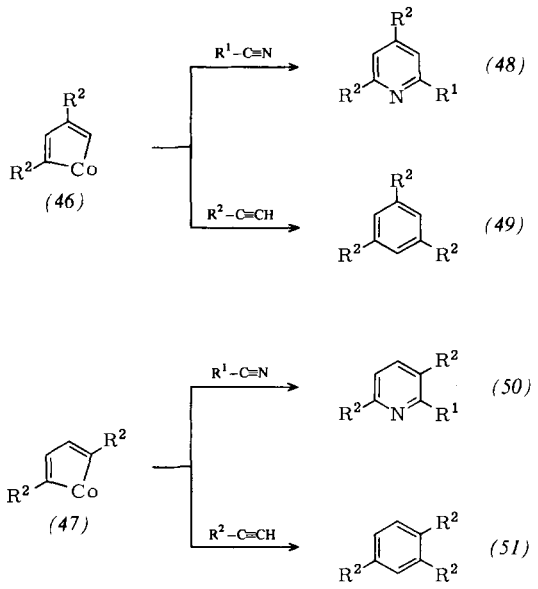
shows that this is not the case and intermediates of type *(45)* are thus highly unlikely.

Kinetic measurements also revealed that the reaction rates of both catalytic cycles show a quadratic dependence upon the acetylene concentration.



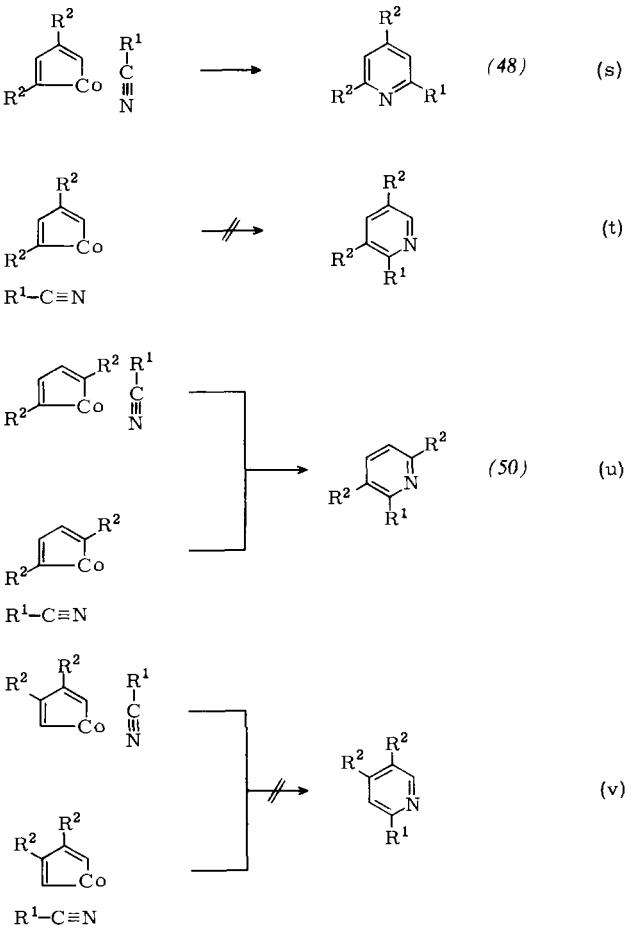
If a large steady-state concentration of acetylene is made available to the central intermediate shown in Figure 1, which is evidently formed in the rate-determining step of the catalysis, then the reaction is increasingly diverted into the right-hand cycle and benzene formation predominates.

Two characteristics of the catalytic reaction course appear to be important:

1) Cyclic alternation of the formal valency between cobalt(I) and cobalt(III);

2) cyclic alternation of the coordination numbers and coordination geometries of the central atom.

The formation of positional isomers in reactions involving terminal alkynes is readily explained by assuming the intermediacy of the cobalt-containing five-membered ring. Intermediate *(46)* results from head-to-tail linkage at cobalt and, after insertion of the third triple bond, affords compounds *(48)* and *(49)* with symmetrical substitution. Intermediate *(47)* results from tail-to-tail linkage of the alkynes to cobalt, and leads to the asymmetrically substituted products *(50)* and *(51)*.



$R^1 = C_2H_5$, $R^2 = CH_3$

The trisubstituted pyridines obtained by cobalt catalysis provide further information about the course of reaction at the cobalt. This is shown schematically in equations (s) to (v).

Insertion of the C≡N triple bond of the nitrile into the CoC bond evidently occurs in such a manner that the nitrogen atom initially interacts with the cobalt. This is supported in particular by the findings corresponding to eq. (s).

Products which would arise from intermediates with a vicinal substitution pattern (head-to-head linkage of the acetylenes [eq. (v)]) are not formed.

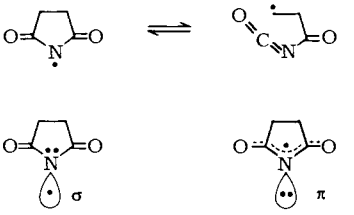
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

More about π- and σ-Succinimidyl Radicals: Ring Opening Reactions[**]

By *Philip S. Skell, James C. Day,* and *Joseph P. Slanga*[*]



Until recently[1-3] the reactions of the succinimidyl radical were virtually unknown, or unrecognized, with the exception of its intermediacy in the rearrangement of *N*-bromosuccinimide (NBS) to β-bromopropionyl isocyanate *(1)*, a reaction which had defied understanding[4].

NBS

(1)

The various parts of the puzzle are now accommodated by the hypothesis that succinimidyl radical undergoes rapid and reversible ring cleavage, and that trapping of the open-chain form leads to the β-halopropionyl isocyanate. Of the two types of succinimidyl radicals which have been recognized[2], the σ type undergoes this cleavage reaction while the π type does not.

The assemblage of experimental results which are to be accommodated by this hypothesis are summarized below.

1) Irradiation (or heating, with benzoyl peroxide initiation) in the presence of alkenes results in 25–90% yields of acyl isocyanate *(1)* for *N*-bromo- (NBS) and *N*-iodosuccinimide (NIS); no isocyanate is formed if *N*-chlorosuccinimide (NCS) is used, or any of the *N*-halophthalimides or *N*-haloglutarimides, despite the fact that the same H-abstractions, additions to alkenes, and additions to arenes are observed as for NBS and NIS.

2) Within large limits the above results are insensitive to changes in olefin concentrations (see also [4b]).

3) In the presence of large concentrations of alkenes (or benzene) no isocyanates are obtained; the succinimidyl moieties are found as succinimide (H-abstraction) and in 1,2-adducts to the olefin (or benzene)[3].

4) In the presence of Br_2 or I_2 no isocyanates are formed; only H-abstractions occur, among them abstractions which cannot be attributed to $Br^{\bullet}$ or $I^{\bullet}$.

5) One or more alkyl substituents on NBS have only a small effect on its reactivity in the presence of alkenes, as determined in competition reactions in which the rate of disappearance of the NBS derivatives is monitored[5]. However, the product is 100% isocyanate when the alkyl-substituted NBS is used, whereas under the same circumstances NBS itself gives 25–60% yields of isocyanate (and succinimide arising by H-abstraction). In the presence of alkenes the succinimidyl radicals are exclusively σ type.

6) On the other hand, in the reaction of *N*-bromo-3,3-dimethylsuccinimide with neopentane in CH_2Cl_2 in the presence of Br_2, no isocyanate formation is observed (absence of 2230 cm^{-1} band). The reaction products are neopentyl bromide, $BrCHCl_2$, and 3,3-dimethylsuccinimide. In the presence of Br_2 the succinimidyl intermediate is exclusively of π type. There seems to be no significant interconversion of σ and π types under these reaction conditions.

7) The percentage of NBS converted into isocyanate decreases with decreasing concentration of NBS, without affecting the relative rates of the competing processes.

In the presence of halogens the succinimidyl generation step ($X^{\bullet} + NXS$) is almost thermoneutral and thus can produce only the ground state, π radical[2], which does not correlate[6] with the ground state of the open-chain radical. On addition of alkene but no halogen, the alkene functions as a halogen scavenger and thus makes possible the generation ($R^{\bullet} + NXS$) of the σ radical[2], which does correlate[6] with the ground state of the open-chain radical. Thus, in the presence of halogen, π-succinimidyl radicals arise which can abstract hydrogen but do not form isocyanates; in the presence of alkenes, σ radicals are produced, leading to competition between ring opening and hydrogen abstraction.

σ-Succinimidyl is postulated to undergo a rapid, reversible ring-opening reaction; thus it is possible to explain all the observations.

Reactions of the σ-succinimidyl radical in H-abstraction and additions to alkenes or arenes are very fast, the rates being almost encounter-controlled[3]. NBS and NIS can trap the open-chain radical, the much less reactive NCS cannot; thus there is no ring-opened product from NCS. The rate constant k must exceed $10^8\,s^{-1}$.

With one or more alkyl substituents on the ring, open chain secondary and tertiary radicals can arise, which are more stable than the cyclic radical. Therefore, formation of open-chain radical is rapid; isocyanates are produced exclusively. The ring-opening rates k probably approach $10^{10}\,s^{-1}$, since H-abstractions by the σ-succinimidyl forms are not observed. On the other hand, in the presence of Br_2, the *N*-bromo-3,3-dimethylsuccinimide yields a π-succinimidyl which cannot undergo ring opening, and thus only H-abstractions are observed.

A critical test of this rationalization was obtained by demonstrating that in the NCS reactions (presence of alkene) in which succinimide is the only product (no isocyanate is observed), some of succinimidyl radicals must spend some time in the open chain form before they abstract a hydrogen atom to form succinimide.

cis-3,4-Dideuteriosuccinimide was synthesized by reaction of maleimide with D_2 over a palladium catalyst[7]; this was converted into $[D_2]$-NCS and $[D_2]$-NBS. Reaction of the $[D_2]$-NBS with neopentane in the presence of Br_2 (CH_2Cl_2 solvent) resulted in formation of pure *cis* compound, identical (IR) with starting material. These are conditions for intermediacy of the π-succinimidyl[2]. On the other hand, reaction of $[D_2]$-NCS in the presence of alkene produced analytically pure dideuteriosuccinimide[8], which is 70% *cis* and 30% *trans* (IR). These are conditions for the intermediacy of σ-succinimidyl[2], and the experiment demonstrates the intermediacy of an open-chain species in the conversion of NCS into succinimide, an open-chain intermediate which is not trapped by NCS to produce an isocyanate, but instead, closes the ring and then abstracts hydrogen.

These new results add force to the earlier suggestion that thermal chain reactions involving succinimidyl radicals can involve either π or σ states of the radical.

[8] The 3,4-dideuteriosuccinimides were analyzed by mass spectra (parent ion, $m/e = 101$) and IR. The intensity of the CHD bands at 700 and 510 cm^{-1} decreases by 70% on reaction of $[D_2]$-NCS in the presence of alkenes while new bands appear at 730 and 525 cm^{-1}.

Methylenesulfur Tetrafluoride $H_2C{=}SF_4$[**]

By *Gert Kleemann* and *Konrad Seppelt*[*]

We have now synthesized the carbon analog of $HO{-}SF_5$[1] and $H_2N{-}SF_5$[2], namely $H_3C{-}SF_5$, in the following manner: Sulfur chloride pentafluoride reacts in the usual way[3] with ketene to give $SF_5CH_2{-}COCl$, which by hydrolysis is converted into the acid $SF_5CH_2{-}COOH$. Hunsdiecker degradation of the silver salt of this acid yields $SF_5{-}CH_2Br$, which in turn is reduced to the desired compound $H_3C{-}SF_5$.

$$SF_4 + Cl_2 + CsF \xrightarrow{250\,^{\circ}C} SF_5Cl + CsCl$$

$$SF_5Cl + CH_2{=}C{=}O \xrightarrow{CFCl_3,\ 20\,^{\circ}C} SF_5{-}CH_2{-}COCl$$
B.p. 48 °C/130 mbar

$$SF_5{-}CH_2{-}COCl \xrightarrow[-HCl]{H_2O} SF_5{-}CH_2{-}COOH$$
Subl. 40 °C/0.5 mbar, M.p. 64 °C

$$SF_5{-}CH_2{-}COOH \xrightarrow[-CO_2,\ -H_2O]{Ag_2CO_3} SF_5{-}CH_2{-}COO^{-}Ag^{+}$$

$$SF_5{-}CH_2{-}COO^{-}Ag^{+} + Br_2 \xrightarrow{CFCl_3} CO_2 + AgBr + SF_5{-}CH_2Br$$
B.p. 75 °C

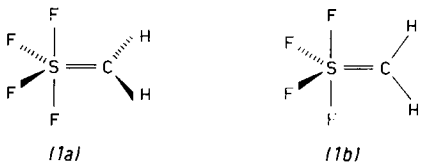
$$SF_5{-}CH_2Br \xrightarrow{Zn/HCl} H_3C{-}SF_5$$
B.p. 26 °C, M.p. −11.5 °C

Methylsulfur pentafluoride, which is colorless and stable towards hydrolysis, was characterized like all the precursors by elemental analysis and on the basis of mass, IR, and NMR spectral data. The ^{19}F-NMR spectrum of $H_3C{-}SF_5$ shows a typical AB_4 pattern, the B_4 resonances appear as a quartet ($J_{HF} = 9.8$ Hz), and the ^1H-NMR signal of the methyl group ($\delta_H = 3.4$) is split into a quintet.

[*] Priv.-Doz. Dr. K. Seppelt, Dipl.-Chem. G. Kleemann
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

In contrast to H_2NSF_5 and $HOSF_5$, H_3CSF_5 shows no tendency to eliminate HF at room temperature. The product of such an elimination is obtainable, however, by another method: the bromine-lithium exchange in SF_5—CH_2Br leads to spontaneous loss of LiF and formation of $H_2C{=}SF_4$.



$$SF_5{-}CH_2Br + n\text{-}C_4H_9Li \xrightarrow{-110\,^\circ C} SF_5{-}CH_2Li + n\text{-}C_4H_9Br$$

$$SF_5{-}CH_2Li \xrightarrow{-70\,^\circ C} LiF + H_2C{=}SF_4$$

B. p. −19 °C, m. p. −140 °C

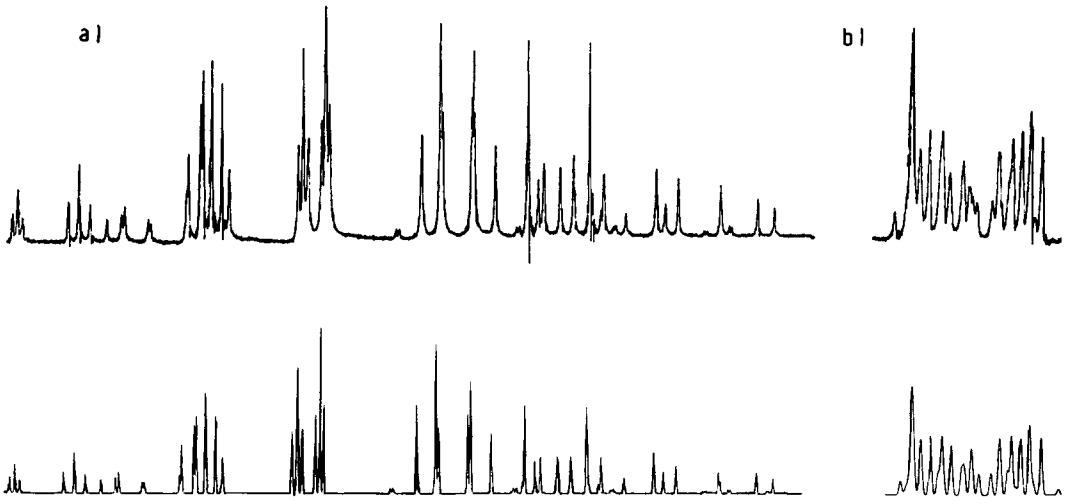
Methylenesulfur tetrafluoride is a colorless gas, stable up to at least 100 °C. Its composition was confirmed by its mass spectrum [70 eV: $m/e = 122$ ($CH_2SF_4^+$, 100%), 103 ($CH_2SF_3^+$, 21%), 102 ($CHSF_3^+$, 3%), 89 (SF_3^+, 65%), 84 ($CH_2SF_2^+$, 3%), and further fragments] and by Dumas vapor density determination [$M_{r,exp} = 121$].

$H_2C{=}SF_4$ is not an ylide. Its ^1H- and ^{13}C-NMR data ($\delta_c = 43.9$) differ markedly from those of typical ylides such as $H_2\overset{\ominus}{C}{-}\overset{\oplus}{P}R_3$[4]. The relatively low reactivity of this species is also consistent with the double bond formulation. The complex ^{19}F and ^1H nuclear magnetic resonances (Fig. 1) can be interpreted only in terms of a $A_2BB'XX'$ spectrum [−150 °C: $\delta_{F(A)} = -59.0$, $\delta_{F(B)} = -53.6$, $\delta_H = 2.6$; $J_{AB} = 154.4$, $J_{AX=AX'} = 10.5$, $J_{BX=B'X'} = 9.7$, $J_{BX'=B'X} = 58.1$ Hz].

(1a) (1b)

In the related pentacoordinated species such as PF_5, SOF_4, and $SeOF_4$ the fluorine atoms exchange geometrically nonequivalent sites even at −150 °C. The observed ^{31}P-^{19}F and ^{77}Se-^{19}F coupling constants provide proof of an intramolecular mechanism in PF_5[6] and $SeOF_4$[7], and the same can be assumed for SOF_4 (Berry or turnstile mechanism). Berry pseudorotation in $H_2C{=}SF_4$ leads to the structural transformation *(1a)* → *(1b)* with retention of nonequivalency of the fluorine atoms, unlike the situation in the case of $O{=}SF_4$. As in PF_5, SOF_4 and other molecules such a rearrangement can take place even at low temperatures. A striking change in the δ_F value with rising temperature is probably indicative of a rapid and reversible equilibrium of *(1a)* and *(1b)* in terms of a Berry mechanism.

The turnstile rotation would make all fluorine atoms magnetically equal, but this is not observed. Magnetic equality could theoretically also be achieved by a Berry mechanism of the fluorine atoms and a synchronous torsional motion of the



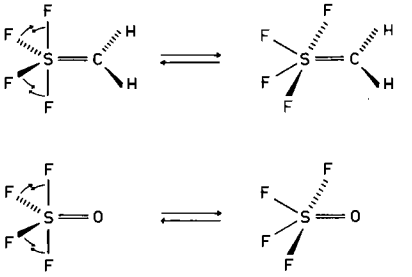


Fig. 1. a) ^{19}F- and b) ^1H-NMR spectrum of $H_2C{=}SF_4$ (56.4 and 60 MHz, respectively): above, experimental; below, simulated as $A_2BB'XX'$ spectrum.

This means that the methylene group is coplanar with a pair of fluorine atoms (BB'XX'); free rotation about the S=C axis is not observed. Since the spectra do not change in character up to +100 °C, the torsional barrier (double bonding contribution) is estimated to be over 25 kcal/mol. In the IR (gas) spectrum and in the Raman (liquid) spectrum a strong band is observed at 1170 cm^{-1} that is assigned to the S=C stretching vibration. This indicates a high bond order (1.9 according to *Siebert*[5], in contrast to 1.2 in the case of phosphorus ylides).

As yet it is uncertain whether the H atoms lie in a plane with the equatorial [*(1a)*] or the axial F atoms [*(1b)*]. For the double bond, a sulfur orbital of the type $3d_{xy}$ or $3d_{xz}$ (x = S=C axis) is conceivable. We hope to clarify this problem with the aid of theoretical calculations and, experimentally, on the basis of electron diffraction, microwave spectra, and crystal structures.

methylene group, but this is impossible because of the double bond.

The new methylene compound has been observed to undergo a number of reactions analogous to those of the carbenes, *e.g.*

$$CH_2{=}SF_4 \xrightarrow{h\nu} SF_4 + {}^1\!/_2\,CH_2{=}CH_2$$

$$CH_2{=}SF_4 \xrightarrow{Br_2} SF_4 + CH_2Br_2$$

8,13-Dichloro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene: Atropisomerism about a $C_{sp^3}{-}CH_2$ Bond[1]

By *Gaku Yamamoto* and *Michinori Ōki*[*]

Triptycene derivatives carrying a tertiary alkyl group at the bridgehead (C-9) are known to exist as stable rotational isomers, *i.e.* atropisomers, with barriers to rotation of more than 30 kcal/mol[2, 3]. The rotational barriers lower considerably when the bridgehead substituent is a primary or secondary alkyl group[4]. While 9-benzyltriptycenes carrying one *peri*-substituent exhibit barriers to rotation of *ca.* 13 kcal/mol, those carrying two *peri*-substituents show barriers of *ca.* 18 kcal/mol[4a]. It was reasonable therefore to expect that 9-benzyltriptycenes with three *peri*-substituents would have even higher barriers to rotation.

We have now found that introduction of three *peri*-substituents raises the barrier to such an extent that atropisomerism about the $C_9{-}CH_2$ bond is realized in 8,13-dichloro-1,4-dimethyl-9-(3,5-dimethylbenzyl)triptycene *(1)*.

sc-(1) is shown in the *Msc* form.

1,8-Dichloro-9-(3,5-dimethylbenzyl)anthracene *(2)* (m.p. 196—197 °C) was synthesized by addition of 3,5-dimethylbenzylmagnesium chloride to 1,8-dichloroanthrone[5] and subsequent dehydration with thionyl chloride/pyridine[6]. Reaction of *(2)* with 3,6-dimethylbenzyne generated *in situ* from 3,6-dimethylanthranilic acid and isoamyl nitrite in boiling dichloromethane afforded a mixture in which the ratio of *ap-(1)* to *sc-(1)* was about 9:1. Thus a pure sample of *ap-(1)*[7, 8] (m.p. > 300 °C) could be obtained by rough chromatography on alumina followed by recrystallization of the isomer mixture from chloroform/ethanol. Heating a solution of *ap-(1)* in benzene at 80 °C for 5 h gave an equilibrium mixture [*ap-(1)* : *sc-(1)* = 1 : 2], which was chromatographed on alumina (benzene/hexane 1:5), to give a pure sample of *sc-(1)*[7, 9] (m.p. > 300 °C). Assignment of the stereochemistry of each atropisomer followed from the ^{1}H-NMR spectral pattern of the methylene protons: the *ap* isomer shows a singlet, whereas the *sc* isomer shows an AB quartet.

The *ap*/*sc*-isomer ratio of 9 : 1 is consistent with our previous findings that the Diels-Alder reaction of 9-substituted anthracenes proceeds preferentially in a conformation where the bulkiest group at the α-carbon in position 9 occupies an anti-periplanar arrangement to the entering dienophile in the transition state and thus such an atropisomer predominates[3, 10]. The steric requirement is apparently the origin of the kinetic control of the products.

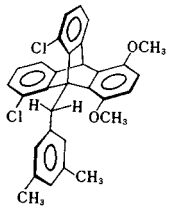

Table 1. Kinetic data for the isomerization of *(1)* in $CDCl_3$.

ap-(1) $\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}}$ (±)-*sc-(1)* $\quad K = k_1/k_{-1}$

T [°C]	$k_1 \times 10^5$ (s^{-1})	$\Delta G^{\neq}$ [kcal/mol]	K
69	111	24.7_4	2.0
61	42.4	24.7_8	2.0
54	17.1	24.8_4	2.0
48	8.35	24.8_3	2.0

$\Delta H^{\neq} = 27.0$ kcal/mol; $\Delta S^{\neq} \approx +6.6$ cal K^{-1} mol^{-1}.

Kinetic data for the *ap-(1)* ⇌ *sc-(1)* interconversion in $CDCl_3$ were obtained by following the change in relative signal intensities in ^{1}H-NMR spectra at 48—69 °C (Table 1). The equilibrium constant $K = 2.0$ was invariant throughout the temperature range examined.

(3)

The size of the *peri*-substituent seems important in determining the barrier. 8,13-Dichloro-1,4-dimethoxy-9-(3,5-dimethylbenzyl)triptycene *(3)*[7, 11] (m.p. 277—278 °C) showed the coalescence phenomenon of an AB quartet due to the benzyl methylene protons at 167 °C[12]. The free energy of activation for the interconversion of (+)-*sc-(3)* ⇌ (−)-*sc-(3)* at this temperature is calculated to be 22 kcal/mol.

[6] All the new compounds gave correct elemental analyses.
[7] The 3,5-dimethylbenzyl group in these compounds showed evidence for restricted rotation about the C_{ar}—CH_2 bond: both the methyl groups and the *o*-H atoms became nonequivalent at low temperatures. Coalescence temperatures were about 50°C and the barriers *ca.* 16 kcal/mol.
[8] ^{1}H-NMR ($CDCl_3$, −20°C): δ = 1.87 (3H, s, *m*-CH_3), 2.38 (3H, s, *m*-CH_3), 2.42 (3H, s, 4-CH_3), 2.85 (3H, s, 1-CH_3), 5.43 (2H, s, CH_2), 5.62 (1H, s, 10-H), and 6.1—7.5 (11H, m, aromatic).
[9] ^{1}H-NMR ($CDCl_3$, −20°C): δ = 1.84 (3H, s, *m*-CH_3), 2.18 (3H, s, 1-CH_3), 2.39 (3H, s, *m*-CH_3), 2.58 (3H, s, 4-CH_3), 5.21 and 5.65 (2H, AB-q, J = 18 Hz, CH_2), 5.59 (1H, s, 10-H), and 6.0—7.5 (11H, m, aromatic).
[10] G. Yamamoto, M. Ōki, Bull. Chem. Soc. Jpn. 48, 3686 (1975).
[11] ^{1}H-NMR ($CDCl_3$, −20°C): δ = 1.88 (3H, s, *m*-CH_3), 2.39 (3H, s, *m*-CH_3), 2.88 (3H, s, 1-OCH_3), 3.86 (3H, s, 4-OCH_3), 5.31 and 5.54 (2H, AB-q, J = 18 Hz, CH_2), 5.89 (1H, s, 10-H), and 6.2—7.5 (11H, m, aromatic).
[12] No sign of the existence of an *ap* form was found, probably due to the steric effect which makes the *ap* form unstable relative to *sc* forms. Thus the rate process observed by the NMR spectra is assumed to be a (+)-*sc* ⇌ (−)-*sc* interconversion.

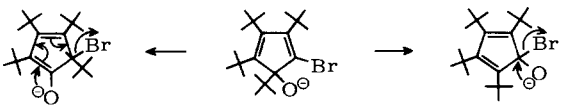
Tetra-*tert*-butylcyclopentadienone[1]

By *Günther Maier* and *Stephan Pfriem*[*]

While searching for precursors for the photochemical synthesis of tetra-*tert*-butyl-cyclobutadiene and/or -tetrahedrane[2] our choice fell upon tetra-*tert*-butylcyclopentadienone *(3)*. By systematic exploitation of the "antiaromatic"-type reactivity characteristic of the cyclopentadienone ring system, it proves possible to obtain this first example of a compound having four adjacent *tert*-butyl groups in an eclipsed arrangement.

Action of bromine on the tri-*tert*-butyl derivative *(1)*[3] led, in spite of steric hindrance, to a dibromide which readily eliminates hydrogen bromide on treatment with potassium hydroxide to form the bromo dienone *(2)*. Replacement of the halogen in *(2)* by the alkyl group of *tert*-butyllithium is possible only under "forbidden" conditions, *i.e.* in 1,2-dimethoxyethane at room temperature (−50°C should not

(1) *(2)* *(3)*



really be exceeded if reaction of the alkyllithium with solvent is to be avoided[4]).

The spectroscopic data of *(2)* and *(3)* are listed in Table 1. Bromination of *(1)* is observed to give first the 2,5-dibromo derivative *(4)* [^{1}H-NMR ($CDCl_3$): δ = 4.88 (ring H), 1.58, 1.50, 1.38; ^{13}C-NMR ([D_6]-benzene): ring C atoms at δ = 200.40, 159.22, 144.04, 84.34, 52.19; IR (CCl_4): 1750 cm^{-1}] which rearranges in solution to the α,β-unsaturated isomer *(5)* [^{1}H-NMR ($CDCl_3$): δ = 4.68 (ring H), 1.60, 1.47, 1.18; ^{13}C-NMR (C_6D_6): ring C atoms at δ = 197.80, 171.21, 149.10, 82.70, 61.90; IR (CCl_4): 1710 cm^{-1}]. Whether the bromine atoms in *(4)* and *(5)* are *cis* or *trans* has not been established.

(4) *(5)*

The unusual reaction conditions for the step *(2)* → *(3)* have their reason in the inability of the primary addition product *(7)* to eliminate a bromide ion. In a preceding step, it must undergo either a 1,5 shift of a *tert*-butyl group [*(7)* → *(6)*]—this is favored by enolate formation in *(6)*[5]—

(6) *(7)* *(8)*

or an oxygen migration [*(7)* → *(8)*]. However, such reactions require higher temperatures than are normally used in reactions with *tert*-butyllithium. Both *(6)* and *(8)* readily eliminate $Br^{\ominus}$ to give the product *(3)*.

Procedure

(2): To a solution of the dienone *(1)* (3.35 g, 13.5 mmol) in CCl_4 (125 ml) at room temperature is slowly added dropwise a mol. equiv. of a 1.55 M solution of Br_2 in CCl_4. The almost quantitative addition is accompanied by decoloration of the solution. 6 N aqueous potassium hydroxide (150 ml) is added, stirring is continued for 2d at room temperature, and the red CCl_4 phase is separated off, washed with water, and evaporated down after drying with $MgSO_4$. Recrystallization from light petroleum at −35°C affords *(2)* (3.55 g, 80%) as dark red crystals.

(3): To a solution of *(2)* (661 mg, 2.02 mmol) in anhydrous 1,2-dimethoxyethane (125 ml) under N_2 at −10°C is added within 5 min a solution of *tert*-butyllithium (3.07 mmol) in hexane. The mixture is maintained at this temperature for 15 min and stirring then continued at room temperature for 2d. Hydrolysis, extraction into light petroleum, evaporation

Table 1. Properties of *(2)* and *(3)*. The isolated compounds gave correct elemental analyses.

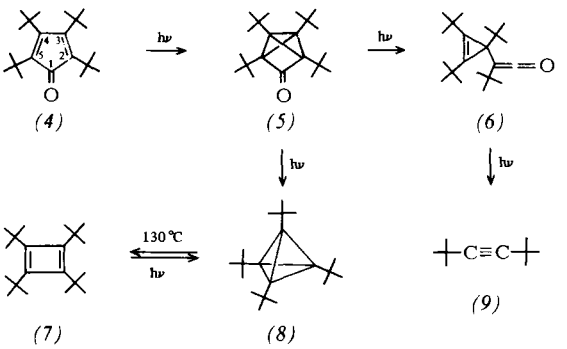
Tetra-*tert*-butyltetrahedrane[1]

By *Günther Maier, Stephan Pfriem, Ulrich Schäfer*, and *Rudolf Matusch*[*]

The synthesis of a tetrahedrane is one of the most attractive challenges yet to be accomplished in organic chemistry. Many setbacks[2] and discouraging theoretical predictions[3] have not deterred us from pursuing this goal.



Attempting the isolation of a tetrahedrane *(1)* raises a dilemma: valence-bond isomerization to cyclobutadiene *(3)* and fragmentation into two molecules of acetylene are orbital symmetry forbidden, thus imparting some degree of kinetic stability to *(1)* in spite of its high strain energy [540—574 kJ/mol (129—137 kcal/mol), *i.e.* 88—96 kJ/mol per skeletal bond[3g]]. Nevertheless, *(1)* can also undergo ring opening to the diradical *(2)*. The energy barrier of this reaction path decides whether a tetrahedrane can be obtained. In the tetra-

(1) *(2)* *(3)*

methyl series there are indications that the bicyclobutanediyl diradical does not undergo ring closure to give the tetrahedrane but instead suffers rupture of the backbone bond to give cyclobutadiene[4a]. Moreover, if it is also borne in mind that the *tert*-butyl groups will considerably lower the thermostability of a C—C bond[5], the prospect of preparing a $(CH_3)_3C$-substituted derivative of *(1)* appears very remote.

Our experimental results are therefore all the more astonishing: tetra-*tert*-butylcyclopentadienone *(4)*[1] exhibits entirely different photochemical behavior from the corresponding compound containing just one *tert*-butyl group less [*(4)*, H in place of *t*Bu at C-2]. While the latter cyclizes to housenone on irradiation with 405-nm light in argon at 10 K[4b], *(4)* does not undergo an analogous reaction (bridge formation between C-2 and C-5). However, if dienone *(4)* isolated in argon is excited by 254-nm light then the IR spectrum shows exclusive criss-cross addition to give the tricyclopentanone *(5)*—the carbonyl absorption of *(4)* diminishes and the double band corresponding to *(5)* appears. On prolonged irradiation, carbon monoxide is evolved (2135 cm^{-1}), and the typical band of ketene *(6)* appears, which is also photolabile and liberates further CO, albeit very slowly (a small amount of *(6)* is still present after 3 weeks).

(4) *(5)* *(6)* *(7)* *(8)* *(9)*

IR spectroscopy is insufficiently specific for identifying the hydrocarbons formed in this way. On GC/MS analysis of the photolytic product evaporated from the cold finger, only di-*tert*-butylacetylene *(9)* can be positively identified. The reaction sequence detected in argon can also be observed by IR spectroscopy in a Rigisolve matrix at −196 °C or in solution between −130 °C and room temperature; the final product contains only little acetylene *(9)* at low temperature but consists almost entirely of that compound under normal conditions.

Truly spectacular results were obtained from a long series of low-temperature ^1H-, and especially ^{13}C-NMR spectra. These measurements, which were indispensable for continuous checks of the irradiation experiments, served not only to optimize the reaction conditions, but also as a guideline in the isolation of the products. Thus the ^1H-NMR signals of *(5)*, *(6)*, and *(9)* appear on irradiation of *(4)* in solution at room temperature. However, if the reaction is carried out at −100 °C in $[D_{10}]$-diethyl ether, an additional signal appears at $\delta = 1.21$. This singlet belongs to a hydrocarbon which can be isolated by chromatography and gives three signals at $\delta = 32.26$, 28.33, and 10.20 in the ^{13}C-NMR spectrum. Such a spectrum is in complete agreement with that expected for tetra-*tert*-butyltetrahedrane *(8)*[6]. In view of the downfield shift due to a *tert*-butyl group ($\Delta\delta \approx 25$) which we have noted in numerous model substances, a value of $\delta = -15$ is calculated for the C atoms in the unsubstituted parent compound *(1)*[7].

The tetrahedrane *(8)* forms colorless crystals which are air-stable. The mass spectrum shows the correct molecular mass (field ionization, $M^+ : m/e = 276.1$), and high resolution confirms the composition $C_{20}H_{36}$ (calc. 276.2815; exp. 276.2814). The compound melts at 135 °C, a property which would make a tetrahedrane structure appear most unlikely if there were not the combined evidence of all the spectroscopic data listed in Table 1[8a]. Final confirmation is expected from an X-ray structure analysis[8b]. Almost equally informative is the thermal behavior of *(8)*[9]: heating of the tetrahedrane in cyclosilane[10] effects quantitative isomerization at 130 °C to give tetra-*tert*-butylcyclobutadiene *(7)*. The colorless solution of *(8)* becomes yellowish orange owing to an absorption maximum at 425 nm ($\varepsilon = 38$) in the spectrum of *(7)*. At the same

Table 1. Spectroscopic data of compounds *(5)*, *(6)*, and *(8)*.

	^{1}H-NMR ($CDCl_3$) (δ)	^{13}C-NMR ([D_{10}]-Et_2O) (δ, rel. to TMS) p = primary, q = quaternary	IR (Argon) [cm^{-1}]
(5)	1.37 (18H), 1.27 (18H)	188.71 (C=O), 60.58 (q), 33.42 (q), 33.11 (p), 30.99 (p), 30.24 (q), 29.32 (q)	1762, 1743 (C=O)
(6)	1.30 (18H), 1.15 (9H), 0.94 (9H)	206.15 (C=O), 129.16 (C=C), 44.92 (q), 40.77 (q), 39.32 (q), 32.72 (q), 32.03 (p), 31.72 (p), 31.11 (p), 30.60 (q)	2077 (C=C=O)
(8)	1.18 (36H)	32.26 (p), 28.33 (q), 10.20 (q, ring C)	2962 (vs), 2928 (w), 2900 (w), 2865 (w), 1475 (w), 1461 (m), 1451 (w), 1383 (w), 1351 (vs), 1216 (s)

time, the singlet of *(8)* ($\delta = 1.49$, relative to the methylene group of the solvent) disappears from the ^{1}H-NMR spectrum in favor of a new peak at $\delta = 1.50$. The likewise long-sought cyclobutadiene *(7)*[11] shows three signals at $\delta = 152.70$, 30.11 (q), and 28.77 (p) in the ^{13}C-NMR spectrum. Unlike the tetrahedrane *(8)*, compound *(7)* is extremely sensitive to oxygen. Di-*tert*-butylacetylene *(9)* is not formed on heating of *(8)*. Irradiation (> 300 nm) of the cyclobutadiene *(7)* in solution at room temperature or in argon at 10 K regenerates the tetrahedrane.

We interpret the stability of *(8)* in the following way: substitution, especially by alkyl groups, should labilize the tetrahedrane ring skeleton because they favor formation of diradicals of type *(2)*[3a]. However, if all the corners of the tetrahedrane unit are occupied by bulky groups then on lengthening one bond of the ring skeleton of *(8)*, two *tert*-butyl groups tending to increase their mutual separation will be forced back together by the other ones ("corset effect"); a tetrahedral structure permits the four substituents to adopt a regular spherical distribution and hence a maximum mutual separation[12].

Procedure

(8): Tetra-*tert*-butylcyclopentadienone *(4)*[1] (313 mg, 1.03 mmol) in a Rigisolve matrix (35 ml) is irradiated with 254-nm light[13] for 77 h at the temperature of liquid nitrogen in thin quartz tubes. After removal of the solvent and chromatography of the crude orange product on SiO_2 [−5 °C; 85 × 1 cm, pentane/ether (50:1)] the following fractions are successively eluted: tetrahedrane *(8)* (100 mg, 35%), ketene *(6)* (37 mg), and a mixture (65 mg) of starting dienone *(4)* and tricyclopentanone *(5)*. Tetra-*tert*-butyltetrahedrane crystallizes from methanol as colorless feathery needles and after sublimation (40 °C/0.02 bar) melts at 135 °C (dec.).

[5] *H.-D. Beckhaus, G. Hellmann, Ch. Rüchardt*, Chem. Ber. *111*, 72 (1978).

[6] Remarkably, the quaternary C atoms of the *tert*-butyl groups appear upfield from the primary C atoms only in *(5)*, *(8)*, and *(9)*. The same also applies to di-*tert*-butylketene ([D_{12}]cyclohexane): $\delta = 201.96$, 51.74, 32.56 (p), 31.51 (q)]. There might be some connection between this jump in chemical shift and the sp-type hybridization of the C atom carrying the *tert*-butyl group.

[7] This value differs significantly from those for the ring atoms in prismane [$\delta = 30.6$; *Th. J. Katz, N. Acton*, J. Am. Chem. Soc. *95*, 2738 (1973)] or cubane [$\delta = 47.3$; *E. W. Della, P. T. Hine, H. K. Patney*, J. Org. Chem. *42*, 2940 (1977)] but fits well into the scheme found for bicyclobutane derivatives [cf. *M. Christl, H.-J. Lüddeke, A. Nagyrevi-Noppel, G. Freitag*, Chem. Ber. *110*, 3745 (1977)].

[8] a) Only end absorption [240 (750), 220 (2750), 200 nm (4800)] is seen in the UV spectrum. The Raman spectrum shows characteristic bands at 2970 (m), 2932 (m), 1459 (m), 1441 (m), 1209 (vs), 919 (s), 828 (vs), 575 (s), and 273 (s) cm^{-1}. Detailed analysis of the vibrational spectra, for which we thank Prof. *K. Dehnicke*, supports the proposed tetrahedrane structure *(8)*.—b) In progress in Prof. *H. Irngartinger*'s laboratory, Heidelberg.

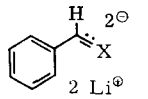
[9] Experiments by *K.-D. Malsch*.

[10] Cyclosilane (Merck): 1,1,3,3,5,5-hexakis(trideuteriomethyl)-1,3,5-trisilacyclohexane.

[11] Small amounts of *(7)* are also formed on irradiation of *(4)* (NMR analysis).

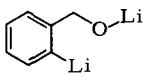
[12] This "all-or-none" principle, according to which only unsubstituted tetrahedrane or derivatives bearing bulky substituents at each corner have a chance of being isolated, is not only operative on formation of *(8)* from *(5)* or *(7)* but also on valence-bond isomerization of *(4)* to *(5)*.

[13] We used photoreactors or plain spiral lamps fitted with low pressure Hg lamps produced by the A. Gräntzel Company, Karlsruhe. Lines below 230 nm were filtered out with Vycor glass.



Lithium *ortho*-Lithiobenzyl Alkoxides

By *Norbert Meyer* and *Dieter Seebach*[*]



ortho-Lithiation reactions of arenes bearing substituents which contain hetero atoms are known from the early work of *Gilman* and *Wittig*[1]. They have recently been used in numerous directed electrophilic *ortho* substitutions[2].

While attempting to apply the α-deprotonation reaction observed to give *(1)*, X = S, from lithium benzyl thiolate[3], to lithium benzyl alkoxides we have now found that the *ortho*-lithiated derivative *(2)* can be produced in *ca.* 70% yield[4].

Other α-phenylalkanols react in the same way as benzyl alcohol. Thus we obtained the benzhydrols *(5a)*, *(5b)*, *(5c)* (mixture of diastereomers), and *(5d)* on treatment of the *ortho*-lithiated derivatives *(6a)*—*(6d)* (Table 1) of 1-phenylethanol, -1-propanol, -1-pentanol, and 2-phenyl-2-propanol, respectively, with benzaldehyde.

General procedure

A solution of *n*-butyllithium (20 mmol, *ca.* 1.5 M in hexane) is added in two portions, one half over a period of 10 min and the second all at once, to a vigorously stirred mixture of benzyl alcohol (10 mmol), light petroleum (b.p. 30—40 °C; 20 ml), and tetramethylethylenediamine (TMEDA) (20 mmol) at room temperature under an inert atmosphere. After heating under reflux for 11 h the mixture is cooled to −78 °C and the electrophile (7 mmol) is added. The temperature is allowed

Simple Method for the Esterification of Carboxylic Acids[1]

By *Bernhard Neises* and *Wolfgang Steglich*[*]

In spite of its successful use in the synthesis of some sugar and amino acid derivatives[3b] the dicyclohexylcarbodiimide (DCC)[2, 3a] method has not been generally adopted as a method for the preparation of carboxylates and thiolates,

[*] Prof. Dr. W. Steglich, B. Neises
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn (Germany)

chiefly because of the variable yields, which are satisfactory only in the case of phenols and thiophenols[4], and the tendency for undesirable *N*-acylureas to be formed. The favorable catalytic action of pyridine in such reactions[3] suggested that the 10^4-fold more effective acylation catalyst 4-dimethylaminopyridine (DMAP) might prove to be a useful agent in our present studies on the esterification of carboxylic acids[1, 5].

Indeed, we have found that addition of 3—10 mol % DMAP accelerates the DCC-activated esterification of carboxylic acids with alcohols or thiols to such an extent that formation of side products is suppressed and even sterically demanding esters *(1)* are formed in good yields at room temperature (see Table 1).

$$RCO_2H + R'XH \xrightarrow[DMAP]{C_6H_{11}N{=}C{=}NC_6H_{11}} RCOXR'$$

(1), X = O, S

Table 1. Esters and thioesters *(1)*.

	Compound	Yield [%] [a]
(1a)	Methyl 1-phenylcyclohexane-1-carboxylate	87
(1b)	Methyl cinnamate	98
(1c)	Methyl 4-methoxybenzoate	61
(1d)	Methyl 2,6-dihydroxybenzoate	96.5
(1e)	Methyl 2,4,6-trimethylbenzoate	74
(1f)	Methyl 1,6-dihydroxy-8-methoxy-3-methyl-anthraquinone-2-carboxylate (methyl dermoluteinate)	55
(1g)	Di-*tert*-butyl malonate	85.5, 29.5 [b]
(1h)	*tert*-Butyl hydrocinnamate	68
(1i)	*tert*-Butyl pentaacetyl-D-gluconate	82.5
(1j)	*tert*-Butyl 2,5-cyclohexadiene-1-carboxylate	84, 34 [b]
(1k)	*tert*-Butyl cinnamate	68
(1l)	*tert*-Butyl benzoate	40
(1m)	*tert*-Butyl 2,6-dihydroxybenzoate	54
(1n)	*tert*-Butyl 3,5-dinitrobenzoate	84
(1o)	Di-*tert*-butyl *rac*-4,4',6,6'-tetrachloro-diphenate	91.5
(1p)	Glycerol tristearate	87.5
(1q)	*S*-Ethyl propanethioate	85
(1r)	*S*-Ethyl 16-hydroxyhexadecanethioate	92
(1s)	*S*-Ethyl 2,5-cyclohexadiene-1-carbothioate	90
(1t)	*S*-*tert*-Butyl cyclohexanecarbothioate	91

[a] The yields refer to pure products and are not optimized. All esters gave correct elemental analyses and spectroscopic data consistent with their constitution. B.p. [and m.p.] of the new compounds: *(1i)* oil; *(1j)* 80 °C/0.5 torr (Kugelrohr); *(1m)* 135/0.5 (KR); *(1o)* [82—84 °C]; *(1r)* [57]; *(1s)* 60/0.2 (KR).
[b] Without DMAP addition.

Thus, the sensitive 2,5-cyclohexadiene-1-carboxylic acid is transformed into the *tert*-butyl ester *(1j)* and into the *S*-ethylthioester *(1s)* quite smoothly, while the method generally recommended for its esterification, namely the boron trifluoride-etherate method, can be used only for the preparation of esters of primary and secondary alcohols[6]. The *tert*-butyl esters of 3,5-dinitrobenzoic acid *(1n)* and glycerol tristearate *(1p)* can also be prepared by this method, in contrast to the non-catalyzed reaction in which *N*-acylureas are formed[7]. 2,4,6-Trimethylbenzoic acid, which can be regarded as inert under normal esterification conditions, reacts with methanol/DCC/DMAP to give the methyl ester *(1e)* in 74 % yield.

Also thioesters *(1)*[8] can be conveniently prepared by the DMAP-catalyzed DCC method, and the yields are considerably higher than those obtained in the non-catalyzed reaction[9]. As example it is shown that synthesis of the thioester *(1r)* of 16-hydroxyhexadecanoic acid is possible without protection of the hydroxy groups. In contrast to some of the other methods, the DCC/DMAP method has the advantage that the free thiols can be used.

The possibility of synthesizing *tert*-butyl esters reaches a limit with more bulky, *i.e.* sterically hindered carboxylic acids. Thus, in the case of adamantanecarboxylic acid, 1-phenylcyclohexane-1-carboxylic acid and 2,4,6-trimethylbenzoic acid the symmetrical anhydrides were isolated instead of the *tert*-butyl esters. The unreactive 4-methoxybenzoic acid also gives only the anhydride, together with some *N*-acylurea, whose formation has been established only in this reaction so far. In the esterification of *Z*-amino acids with *tert*-butyl alcohol or 2-methyl-2-propanethiol under standard conditions some racemization was observed, but this can be largely avoided at lower temperatures and with shorter reaction times.

Procedure

To a stirred solution of 10 mmol carboxylic acid in 10 ml anhydrous CH_2Cl_2 (in the case of sparingly soluble acids, in DMF) is added 30—110 mg DMAP and 20—40 mmol alcohol or thiol (10 mmol with alcohols or thiols which are not easily removable without significant loss; 3.4 mmol with glycerol). DCC is added to the reaction mixture at 0 °C, which is then stirred for 5 min at 0 °C and 3 h at 20 °C. Precipitated urea is then filtered off and the filtrate evaporated down *in vacuo*. The residue is taken up in CH_2Cl_2 and, if necessary, filtered free of any further precipitated urea. The CH_2Cl_2 solution is washed twice with 0.5 N HCl and with saturated $NaHCO_3$ solution, and then dried over $MgSO_4$. The solvent is removed by evaporation and the ester isolated by distillation or recrystallization. Crystalline products can be obtained in pure form by filtration on a short silica gel column (eluent CH_2Cl_2 or $CHCl_3$.

Photochemical Reductive *trans*-Elimination from *trans*-Diazidotetracyanoplatinate(IV)[**]

By *Arnd Vogler, Alfred Kern*, and *Jürgen Hüttermann*[*]

Oxidative additions and reductive eliminations number among the most important reactions of transition metal complexes and are of special utility in the chemistry of organometallic compounds. Reductive *cis*-eliminations have also been observed as light-induced processes[1]. Thus, irradiation of $[IrClH_2(PPh_3)_3]$ leads to *cis*-elimination of H_2 and formation of $[IrCl(PPh_3)_3]$ in a single step; the elimination of H_2 is concerted, no hydrogen atoms are formed in the photoprocess[1b]. Photochemical reductive *trans*-eliminations have so far not been reported. We have now been able to demonstrate such a reaction with $[Pt^{IV}(CN)_4(N_3)_2]^{2-}$, which on irradiation is quantitatively converted into $[Pt^{II}(CN)_4]^{2-}$.

Of particular interest to us was whether this two-electron reduction of Pt^{IV} proceeded *via* a Pt^{III} intermediate, since it is generally assumed that both thermal[2a] as well as photochemical[2b] conversions of Pt^{IV} into Pt^{II} complexes involve two successive one-electron reductions. Should a Pt^{III} intermediate not be formed, then there are two mechanistic possibilities: While the cleavage of the two ligands in *cis*-elimination obviously does not involve formation of ligand radicals in the initial reaction step[1b] this could be possible on steric grounds in the case of *trans*-eliminations.

We conclude from our investigations that two N_3 radicals are formed in the initial step of photochemical reductive *trans*-elimination from *trans*-$[Pt(CN)_4(N_3)_2]^{2-}$ by simultaneous two-electron reduction without formation of a Pt^{III} intermediate:

$$[Pt^{IV}(CN)_4(N_3)_2]^{2-} \rightarrow [Pt^{II}(CN)_4]^{2-} + 2N_3^{\cdot}$$

Reaction of $K_2[Pt(CN)_4Br_2]$[3] with a large excess of KN_3 in water (reaction time 2 d) afforded the compound $K_2[Pt(CN)_4(N_3)_2]$, which was isolated in analytically pure form after recrystallization from acetone. The *trans* structure (D_{4h}) of the anion follows from the appearance of an IR band[3] (2181 cm^{-1}) in the region of the CN stretching vibrations. The electron absorption spectrum shows only one intense maximum ($\lambda = 302$ nm, $\varepsilon = 18300$) in the longwave region which is assigned to a $(N_3 \rightarrow Pt)$CT transition.

Irradiation of the CT band of the salt dissolved in water led to rapid evolution of nitrogen according to

$$[Pt(CN)_4(N_3)_2]^{2-} \rightarrow [Pt(CN)_4]^{2-} + 3N_2$$

The spectral changes observed during the photolysis (Fig. 1) show that no other products are formed, since the final spectrum was identical with that of $[Pt(CN)_4]^{2-}$[4] after prolonged irradiation; nor was any free azide detectable[5]. On complete absorption of light by the starting complex, the photochemical formation of $[Pt(CN)_4]^{2-}$ followed a zero order reaction. At excitation wavelengths of 300, 333, and 366 nm the quantum yield for the formation of $[Pt(CN)_4]^{2-}$ in water was $\Phi = 0.34 \pm 0.02$; in acetonitrile and ethanol it increased to $\Phi = 0.58$ and 0.61 ± 0.02, respectively. Unlike in aqueous solution, photolysis in ethanol leads also to formation of N_3^- as well as evolution of N_2.

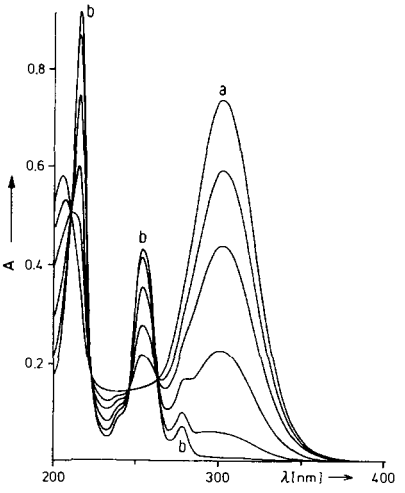

Fig. 1. Change in absorption spectrum during the photochemical transformation of *trans*-$[Pt(CN)_4(N_3)_2]^{2-}$, (a) in $Pt(CN)_4^{2-}$, (b) in aqueous solution (4×10^{-5} mol/l, 1 cm cuvette); excitation light: $\lambda = 300$ nm.

For identification of the primary products the photolysis of $[Pt(CN)_4(N_3)_2]^{2-}$ was carried out in ethanol glasses at 77 K and the irradiated samples investigated ESR spectroscopically. The observed signals could be assigned to N atoms[6] and CH_3CHOH radicals[7]. Pt^{III} signals[8] were not observed, even at 20 K.

N_3 radicals are extremely unstable. They dissociate very rapidly even at low temperatures into molecular nitrogen and N atoms[6b,c], which can be detected ESR spectroscopically. Finally, in the aqueous solution at room temperatures only N_2 is formed as stable end-product besides $[Pt(CN)_4]^{2-}$. In the presence of suitable reducing agents N_3 radicals can be reduced to azide[9]. The formation of CH_3CHOH radicals, which also were identified at low temperatures, and of free azide in the room temperature photolysis of $[Pt(CN)_4(N_3)_2]^{2-}$ in ethanol can be explained only in terms of a competing reaction of the N_3 radicals: besides dissociating, the N_3 radicals can obviously also be reduced by the solvent CH_3CH_2OH.

A Simple Synthesis of 2′-Deoxy-2′-fluorocytidine by Nucleophilic Substitution of 2,2′-Anhydrocytidine with Potassium Fluoride/Crown Ether[1]

By *Rudolf Mengel* and *Wilhelm Guschlbauer*[*]

Fluorine-substituted natural products are interesting both from the biochemical and the pharmacological point of view[2]. Thus, fluorosugar-nucleosides show cytostatic and virostatic activities[3a]; poly-2′-deoxy-2′-fluorouridylic acid selectively inhibits viral polymerases[3b]. 2′-Deoxy-2′-fluoropyrimidine nucleosides have been shown to adopt the 3′-*endo* conformation[4a] and the corresponding polynucleotides behave like polyribonucleotides[4b].

In order to study the pharmacology of poly-2′-deoxy-2′-fluorocytidylic acid we have searched for a simple and productive method for the synthesis of 2′-deoxy-2′-fluorocytidine *(2)*. So far *(2)* has been obtained from 2′-deoxy-2′-fluorouridine *via* the 4-thio analog, methylation and ammonolysis[4a, 5] or, in small amounts, by heating the 2,2′-anhydrocytidine hydrofluoride *(1)*[6]. Experiments analogous to the synthesis of 2′-deoxy-2′-fluorouridine to transform *(1)* into *(2)* by heating with HF in dioxane have been unsuccessful[6]. We have found that the transformation *(1)* → *(2)* can be performed by anion activation of fluoride with crown ethers[7] under total exclusion of moisture. Besides the increased nucleophilicity of the crown ether activated F^-, its increased basicity is very notable[8] and traces of moisture will lead to hydrolysis of *(1)* with formation of 1-β-D-arabinofuranosylcytosine (aracytidine) *(3)*[6]. Thus reactions of *(1)* with KF/crown ether in acetonitrile, DMF, dioxane or HMPT yielded mainly *(3)*. Only after complete elimination of traces of water by azeotropic distillation with benzene from the mixture DMF/KF/crown ether could the desired nucleophilic fluorine substitution be achieved.

Dr. W. Guschlbauer
Service de Biochimie, Département de Biologie, Centre d'Etudes Nucléaires de Saclay
B.P. No. 2, F-91190 Gif-sur-Yvette (France)

Procedure:

A mixture of 100 ml dimethyl formamide, 1 ml diperhydrobenzo[18]crown-6, 2.5 g (43.1 mmol) KF (dried over P_2O_5, 100°C/0.01 torr) and 100 ml benzene is heated at 135°C in an oil bath and the benzene slowly distilled off. On completion of distillation, 1 g (3.32 mmol) 2,2′-anhydrocytidine hydrochloride[9] is added under a nitrogen atmosphere. After four hours' heating at 120°C, the solvent is removed in a rotatory evaporator, and the residual oil absorbed on 5 g silica gel and transferred to a silica gel column (2.3 × 35 cm, $CHCl_3$). Elution is started with 250 ml chloroform, followed by a chloroform/methanol mixture (3:2). The first 450 ml of eluate are discarded, the following 350 ml contains 380 mg *(2)* (yield 40 %). The product can be recrystallized from methanol or water, m.p. 163—167°C. Spectroscopic data (UV, NMR) are identical with those for an authentical sample[4a].

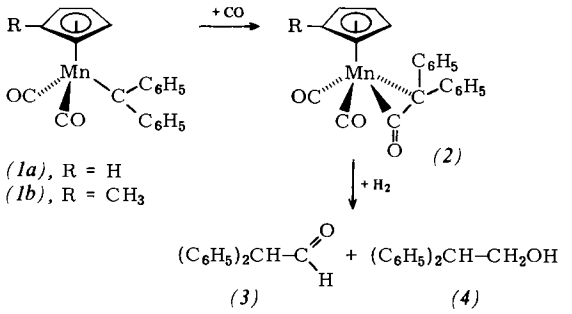
High-Pressure Carbonylation of Metal-Coordinated Carbenes and Hydrogenolysis of the Ketene Complexes[1]



By *Wolfgang A. Herrmann* and *Johann Plank*[*]

The reactions of transition metal carbene complexes with carbon monoxide[2a] and hydrogen[2b] currently attract considerable attention in connection with reawakened interest in the Fischer-Tropsch synthesis[3]. While the two substrates have hitherto only been observed to displace the carbene ligand from the metal[2] we have now accomplished the first carbonylation of metal-coordinated carbenes to give the corresponding ketene complexes and their hydrogenolytic degradation to aldehydes and alcohols.

Under the conditions of high-pressure carbonylation the diphenylcarbenemanganese complexes *(1)*[4] (CO addition, 30—45 % conversion) give the diphenylketene complexes *(2)*. Their physical and spectroscopic data are in agreement with those of the compounds obtained by ligand displacement from the tetrahydrofuran complexes $(\eta^5\text{-}C_5H_4R)Mn(CO)_2THF$

[*] Dr. W. A. Herrmann, J. Plank

Universitätsstrasse 31, D-8400 Regensburg 1 (Germany)

(R = H, CH_3) with diphenylketene[5]. Their identity was confirmed by X-ray structure analysis[5].

(1a), R = H
(1b), R = CH_3

(2) (3) (4)

This carbonylation reaction not only provides a new entry to the η^2-ketene complexes previously known only as isolated examples[6] but also constitutes preparative proof of the carbene→ketene conversion postulated by *Rüchardt* and *Schrauzer*[7] to occur in carbene-transition metal fragments. Moreover, our results substantiate the occurrence of free methoxy(phenyl)ketene deduced from the product spectrum of pressure carbonylation of pentacarbonyl(methoxyphenylcarbene)-chromium in the presence of vinylpyrrolidones[8].

The transformation of carbene complexes into ketene complexes is also of relevance as a model system for a step of the Fischer-Tropsch synthesis which probably proceeds *via* unstable metal-carbene intermediates[3] but is still largely unknown in its mechanistic details. We have now found that the carbonylation products *(2a)* and *(2b)* can be hydrogenolytically degraded under high pressure conditions to diphenylacetaldehyde *(3)* and 2,2-diphenylethanol *(4)* while *(1a)* and *(1b)* are not attacked by hydrogen below their decomposition temperatures. The carbonylation of carbenes can therefore successfully compete with reductive displacement of the carbene ligand from the metal. The reaction sequence carbene complex→ketene complex→aldehyde/alcohol provides a working hypothesis for the ultimate steps of the Fischer-Tropsch synthesis leading to "oxo products".

Procedure[9]

a) Carbene carbonylation: A solution of *(1a)* or *(1b)* (1 mmol) in tetrahydrofuran (30 ml) is treated in a 100-ml rotating autoclave with a glass insert with CO (650 bar initial pressure) at 50±5 or 35±5°C (jacket temperature) for 25 h. The brownish-yellow crude product obtained on evaporation with a water-aspirator is worked up by column chromatography on SiO_2 (activity II—III; 60×1.2 cm; +15°C), elution with benzene giving first a small amount of (η^5-C_5H_4R)$Mn(CO)_3$ as a fast-moving light yellow band which is followed by the bright yellow band of the ketene complex *(2a)* or *(2b)*. After recrystallization, the yellow compounds which are air-stable in the solid state are analytically pure (IR, MS, elemental analysis). Yield: *(2a)*, 122—167 mg (32—45%); *(2b)*, 116—161 mg (30—42%).

b) Ketene hydrogenation: *(2a)* or *(2b)* (2 mmol) is dissolved in tetrahydrofuran (30 ml) and reacted with H_2 (100-ml rotating autoclave with a glass insert, 20 h, 50±5°C jacket temperature, 750 bar initial pressure of H_2). High-vacuum distillation of the concentrated solution in a Kugelrohr apparatus (air-bath temperature 130—140°C) gives *ca.* 200 mg (51%) of a mixture of *(3)* (≈25%) and *(4)* (≈75%) as a yellowish oil (characterization by IR, MS, and ^{1}H-NMR).

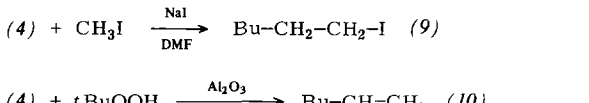
Reactivity of Phenyl Vinyl Selenide with Nucleophiles and Bases

By *Mireille Sevrin, Jean N. Denis*, and *Alain Krief*[*]

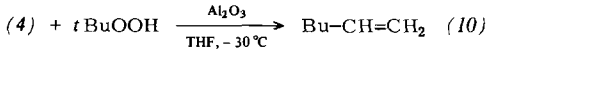
In continuation of our work on the reactivity of selenides with *n*-butyllithium[1] we have investigated the reaction of vinyl phenyl selenide *(1)* with various nucleophiles and bases

Scheme 1. Four possible modes of reaction of phenyl vinyl selenide *(1)* with nucleophiles. Route A: Se—C cleavage; route B: addition (in analogy to vinyl sulfides and silanes); route C: metalation (in analogy to vinyl sulfides and halides and ethyl vinyl ether); route D: elimination (in analogy to ethyl vinyl ether). Bu = *n*-butyl, Dec = *n*-decyl, Hex = *n*-hexyl, Ph = phenyl, *i*Pr = isopropyl.

[*] Dipl.-Chem. M. Sevrin, Dipl.-Chem. J. N. Denis, Prof. Dr. A. Krief
Département de Chimie, Facultés Universitaires de Namur
61 rue de Bruxelles, B-5000 Namur (Belgium)



and have found that, depending upon the nature of the reagents and conditions used (solvent, temperature), all the possible reaction routes A, B, C and/or D outlined in Scheme 1 can be observed. Some of these reactions are of synthetic value.



When phenyl vinyl selenide *(1)* is allowed to react with *n*-butyllithium in tetrahydrofuran (THF) for 1 h at −78 °C, and heptanal is then added, butyl vinyl selenide *(2)* (70%) and 1-phenyl-1-heptanol *(3)* (68%)[2] are formed *via* route A. Small amounts of hexyl phenyl selenide *(4)* (5%) and 2-phenylseleno-1-nonen-3-ol *(6)* (17%) are also formed, *via* addition (route B) and metalation (route C), respectively. When the reaction is performed at −30 to 0 °C the yield of addition product *(4)* increases (−10 °C: 28%) and that of the cleavage product decreases (−10 °C: 18%).

When THF is replaced by diethyl ether, route B largely predominates; if the reaction is conducted at 20 °C for 5 min before quenching with water, *(4)* is obtained in 65% yield[3]. With longer reaction times the yield of *(4)* drops considerably (30 min: 30%). The accompanying side-products were not identified[4, 5]. On addition of heptanal after 5 minutes reaction time at 20 °C, 40% of the corresponding 6-phenylseleno-7-tridecanol *(5)* is formed along with 10% of *(4)* (route B). *(2)* (13%) and *(3)* (20%) (*via* route A) as well as *(6)* (20%) (*via* route C) are also obtained.

Lithium diisopropylamide (LDA) is found to be the most effective reagent for metalation of the title compound: no C—Se cleavage was observed with this reagent[6]. However, depending on the nature of the solvent, elimination (route D) can occur as well as metalation (route C). For example, reaction of *(1)* and 1.5 equivalents LDA at −78 °C for one hour furnishes a carbanion, which can be trapped with D_2O in 80% yield as 1-deuteriovinyl phenyl selenide and with heptanal in 40% yield as 2-phenylseleno-1-nonen-3-ol *(6)*.

In hexamethylphosphoric triamide (HMPT)/THF (1:20, −78 °C, 1 h)[7] the alkylation is even more strongly favored. Addition of one equivalent of decyl bromide (−78 °C, 2 h) leads to 2-phenylseleno-1-dodecene *(7)* (70%) (route C) and decyl phenyl selenide *(8)* (23%) (route D). In HMPT/THF (1:3) the elimination reaction predominates; the selenide *(8)* is formed in 65% yield.

We have used the hexyl phenyl selenide *(4)* obtained *via* route B for the synthesis of hexyl iodide *(9)* and 1-hexene *(10)* (80% and 74% yield, resp.)[8]. 2-Phenylseleno-1-dodecene *(7)* can be readily hydrolyzed to 2-dodecanone (91% yield)[9].

[2] To a solution of *(1)* (1 mmol) in THF (2 ml) is added *n*-butyllithium (1 mmol) at −78 °C under argon and the mixture stirred for one hour. After slow addition of 1 mmol heptanal in THF (2 ml) the solution is allowed to stand for 2 h at −78 °C and 1 h at 25 °C, hydrolyzed, and worked up in the usual way.

[3] A solution of *(1)* (1 mmol) in ether (2 ml) is treated at 20 °C under argon with 1 mmol *n*-butyllithium and the mixture stirred for 1 h. After hydrolysis the mixture is extracted with ether and the extract dried. Distillation of the crude product affords pure *(4)*, b.p. 70 °C/0.1 torr, identical with an authentic sample.

[4] During the completion of our work a short communication appeared, dealing in part with the reaction of *(1)* with *n*-butyllithium: *Th. Kauffmann, H. Ahlers, H. J. Tilhard, A. Woltermann*, Angew. Chem. *89*, 760 (1977); Angew. Chem. Int. Ed. Engl. *16*, 710 (1977).

[5] If the reaction mixture is stirred for a longer time the initially formed α-selenocarbanion rearranges; as in the case of the analogous sulfur compounds, ring-metalated derivatives are formed. With CH_3I, a mixture of hexyl tolyl selenides is obtained; with heptanol, no β-selenoalcohol *(5)* is formed, but instead a mixture of 1-tolyl-1-hexanols is obtained.

[6] a) Synthesis of 1-lithio-1-methylseleno-1-octene (75%) from 1,1-bis(methylseleno)-1-octene by C—Se cleavage: *A. Krief*, lecture at Rouen (France), July 3, 1977; b) Synthesis of β-lithio-β-phenylselenostyrene by C—Se cleavage: *B. T. Gröbel, D. Seebach*, Chem. Ber. *110*, 867 (1977).

[7] A solution of LDA (3 mmol) in THF (3 ml) is treated with 2 mmol *(1)* in HMPT/THF (1:9) at −78 °C and the mixture stirred for 1 h. After addition of 2 mmol decyl bromide in THF (3 ml) the reaction mixture is stirred for 2 h, hydrolyzed, extracted with ether, and the extract dried. The crude product is purified by preparative thick layer chromatography (SiO_2, (Merck) 2 mm, pentane, $R_f = 0.62$).

Synthesis and Structure of the Tetradecker Complex Bis(tricarbonylmanganese-μ,η-thiadiborolene)iron[1]

By *Walter Siebert, Christian Böhle, Carl Krüger*, and *Yi-Hung Tsay*[*]

The possibility of constructing oligo-decker and poly-decker complexes (quadruple-decker[2a], multiple-decked stacked compounds[2b]) has already received consideration. We have extended our studies on Lewis acid ligands in sandwich and triple-decker complexes[3] to tetradecker complexes and now wish to report the first trinuclear complex *(4)* containing two bridging thiadiborolene and six terminal carbon monoxide ligands.

(1)

(4)

(2)

Simultaneous reaction of the thiadiborolene derivative *(1)*[4a] with $Mn_2(CO)_{10}$ and $[(C_5H_5)Fe(CO)_2]_2$ gives the green air-stable triple-decker complex *(2)*, m.p. 194 °C [^{1}H-NMR: $\delta = 3.85$ (s, 5), 3.0—2.1 (m, 4), 1.53 (s, 6), 1.36 (t, 6) in CS_2 rel. to TMS int.; ^{11}B-NMR: $\delta = 18.0$ in CS_2 rel. to $Et_2O \cdot BF_3$ ext.; IR: $\nu(CO) = 2031$ (s), 1946 (s), 1935 (s) cm^{-1} in C_2Cl_4; MS: M^+ (14), $\{M-3CO\}^+$ (100), $\{(C_5H_5)FeL\}^+$ (9), ...]. A first example of this triple-decker type of complex containing *different* terminal ligands, *viz.* $[(C_5H_5)Co(C_2B_3)Fe(CO)_3]$, has recently been described[5].

[*] Prof. Dr. W. Siebert, Dipl.-Chem. C. Böhle
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg 1 (Germany)
Dr. C. Krüger, Dr. Y.-H. Tsay
Max-Planck-Institut für Kohlenforschung
Lembkestrasse 5, D-4330 Mülheim-Ruhr 1 (Germany)

As in ferrocene, the C_5H_5 ligand of *(2)* can be replaced with $C_6H_6/AlCl_3$ to give the red-violet triple-decker salt *(3)* which is sensitive to hydrolysis. Its thermolysis at 140°C/0.1 torr affords a low yield of the orange-red tetradecker complex *(4)*, m.p.: dark coloration above 155°C, decomposition at 210°C:

$$2\ [(C_6H_6)Fe\cdot\textit{(1)}\cdot Mn(CO)_3]^{\oplus}AlCl_4^{\ominus} \xrightarrow{\Delta} \underset{(3)}{} \textit{(4)} + 2\ C_6H_6 + [FeCl_2,\ 2\ AlCl_3]$$

The IR spectrum of *(4)* contains three strong bands at 2033, 1955, and 1944 cm^{-1} (in C_2Cl_4) showing a significant shift relative to the CO stretching vibrations of the triple-decker $[(CO)_3Mn\cdot\textit{(1)}\cdot Mn(CO)_3]$ (2021, 1966, 1956 cm^{-1}, in C_2Cl_4)[4b]. The FD mass spectrum exhibits an isotopic pattern for the molecular ion $[(CO)_3MnL]_2Fe^+$ [L = *(1)*] ($I_{rel}=100$ based on $^{11}B_4$) which is due to the presence of four boron atoms. Apart from M^+ (12), the following principal fragments are observed at 70 eV: $\{M-3CO\}^+$ (50), $\{Mn_2L_2Fe\}^+$ (16), $\{MnLFe-28\}^+$ (8), MnL^+ (4), L^+ (12), $(C_2H_5)_2C_2BCH_3^+$ (100).

The structure of the complex *(4)* is confirmed by X-ray structure analysis[6]. Both of the independent molecules in the triclinic unit cell have a center of inversion (Fe); they differ in the conformation of the substituents on the planar ($\pm 0.01\times10^{-10}$ m) C_2B_2S rings. Owing to the center of inversion these rings have a mutual transoid arrangement whereas they are staggered (each rotated 90°) in the comparable triple-decker sandwich $(C_2B_2S)_3Co_2$[7]. The bond lengths of the bifacially coordinated ring atoms are lengthened in a typical manner relative to the corresponding distances in unifacially coordinated C_2B_2S rings[8] (average values: B—S 1.928(7), B—C 1.544(9), C—C (1.477(9)). The Fe—Mn distances are 3.408(1) and 3.391(1) 10^{-10} m.

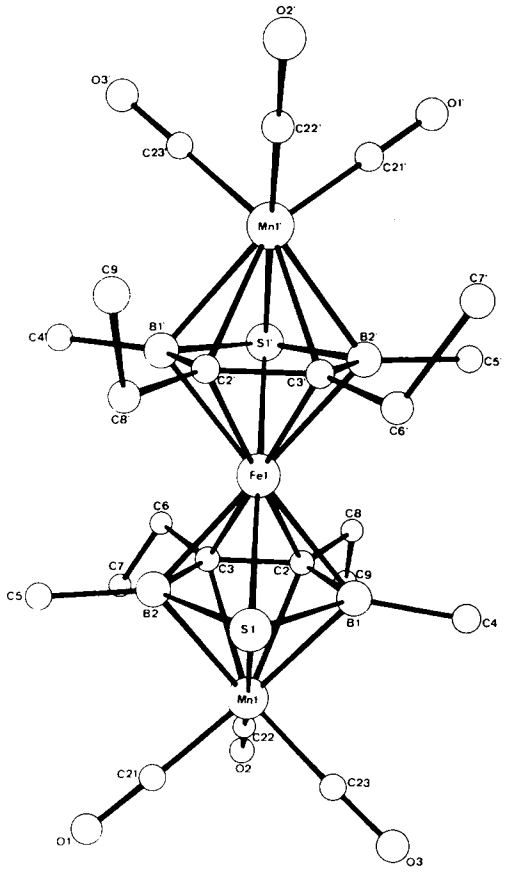

Fig. 1. Molecular structure of complex *(4)* in the crystalline state.

We attribute this first example of *trans* orientation of neighboring C_2B_2S rings to formation of two π^6-electron systems in the central $(C_2B_2S)_2Fe$ sandwich. Two equivalent approaches can be adopted in describing the bonding in *(4)*. According to the π^6/d^{6-8} viewpoint[9a] *(4)* is the first member of the tetradecker family with 42—48 valence electrons; four planes of ligands (two C_2B_2S rings as π^6-electron donors and two $(CO)_3$ groups as σ^6-electron donors) are held together by three d^6 metal ions. According to the *closo* approach[9b], *(4)* can be regarded as a double cluster of two pentagonal bipyramids with a common Fe apex; $2n+2=16$ skeletal electrons are necessary to hold the C_2B_2SMnFe clusters together; they are provided by C(2 × 3), B(2 × 2), S(4), Mn(1), and Fe(1).

Procedure

A mixture of *(1)* (0.85 g, 5.12 mmol), $Mn_2(CO)_{10}$ (1.49 g, 3.84 mmol) and $[C_5H_5Fe(CO)_2]_2$ (1.35 g, 3.84 mmol) in 20 ml mesitylene is heated under nitrogen for 0.5 h at 165°C. After removal of solvent the residue is taken up in hexane and chromatographed on dry silica gel (Woelm 100–200). The first band contains $Mn_2(CO)_{10}$ and some $[(CO)_3Mn\cdot\textit{(1)}\cdot Mn(CO)_3]$, the second band green *(2)* (0.82 g; best yield in analogous reactions 37 %).

A mixture of *(2)* (0.25 g, 0.58 mmol) and $AlCl_3$ (0.25 g, 1.87 mmol) in benzene (20 ml) is stirred under nitrogen for 0.5 h at 90°C. Reddish-violet *(3)* precipitates out. On heating *(3)* (0.2 g, 0.33 mol) to 140—160°C/0.1 torr a yellow-brown sublimate is obtained, which on recrystallization from CS_2 affords orange-red crystals; yield 3 mg (2.7 %).

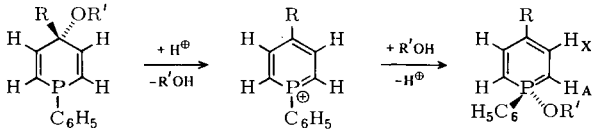
4-Alkoxy-1-phenylphosphacyclohexadiene → 1-Alkoxy-1-phenyl-λ⁵-phosphorin Rearrangement

By *Gottfried Märkl, Rainer Liebl*, and *Alois Hüttner*[*]

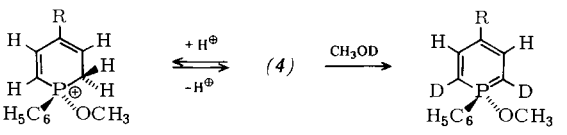


4-Alkyl- or 4-aryl substituted 1-aryl-4-methoxy-1-arsa-2,5-cyclohexadienes *(1)* undergo H^+-catalyzed rearrangement to 2-aryl-λ³-arsenins *(2)*[1].

[*] Prof. Dr. G. Märkl, Dipl.-Chem. R. Liebl, A. Hüttner
Chemisches Institut der Universität
Universitätsstrasse 31, D-8400 Regensburg 1 (Germany)

(1) (2)

The 4-alkyl- or 4-aryl-substituted 4-alkoxy-1-aryl-1-phospha-2,5-cyclohexadienes *(3)*[2], which are readily accessible by analogy to *(1)*, behave in a completely different manner. In the presence of catalytic amounts of *p*-toluenesulfonic acid in benzene (25 °C, 12 h) they give good yields of the corresponding 1-alkoxy-1-phenyl-λ^5-phosphorins *(4)*, the first *C*-monosubstituted λ^5-phosphorins (Table 1).



(3) (5) (4)

intramolecular rearrangement; the products of intermolecular rearrangement are formed in relative yields of below 10%.

3) If the rearrangement *(3)* → *(4)* is carried out in alcohols HOR″ instead of benzene, then HOR″ competes for *(5)* only to a limited extent with the alcohol HOR′ liberated by ether cleavage. Rearrangement of *(3c)* (R′ = CH_3) in ethanol, isopropyl alcohol, and *tert*-butyl alcohol gives the λ^5-phosphorins of the competing reaction in yields of 80, 40, and 15%, respectively. Thioalcohols and phenols cannot compete for *(5)*.

The pronounced upfield shift of the ring protons H^2, H^6 in *(4)* (see Table 1) support the assumption[7] that the λ^5-phosphorins *(4)* exist as cyclically conjugated alkylidenephosphoranes with a high π-electron density in positions 2, 4, and 6 due to ylidic resonance.

The λ^5-phosphorins *(4)* are protonated exclusively at C-2 by mineral acids to form *(6)*[8].

(6) (4) (7)

Table 1. Physical data of the 4-substituted 1-alkoxy-1-phenyl-λ^5-phosphorins *(4)*.

(4e)	$(CH_3)_3C$ C_2H_5	78	oil	$(CH_3)_3C$: 1.23 (s); CH_2CH_3: 1.10 (t), J_{HH} = 7 Hz; OCH_2: 3.37 (2q), J_{PH} = 10 Hz; H_A: 4.81 (2d), $J_{H_AH_X}$ = 12.0, J_{PH_A} = 9.6 Hz; H_X: 7.47 (2d), J_{PH_X} = 35 Hz		358 (4000) 335 (3400) (in $CHCl_3$)

[a] Recrystallization from light petroleum (50—70 °C). [b] 60 MHz, 100 MHz spectra, ^{31}P-broad band decoupling. The ring protons H_A, H_X appear as AA′XX′Y systems; H_A and H_X show characteristic fine structure. The values given for $J_{H_AH_X}$ are approximate values.

The ^{31}P-NMR chemical shifts ($CDCl_3$, H_3PO_4 ext., PH broad-band decoupling) of *(4a)*, *(4b)* and *(4c)* (δ = −40.4, −40.2 and −38.3, respectively) are in complete agreement with those of 1,1-dimethoxy- and 1-diethylamino-1-ethoxy-2,4,6-triphenyl-λ^5-phosphorin (δ = −65.2 and −45.0, respectively)[9].

The differing behavior of *(1)* and *(3)* is rationalized in terms of the greater energy of the P—C bond (65 kcal/mol)[3] compared with that of the As—C bond (≈ 50—55 kcal/mol)[4]; the greater stability of the λ^5-phosphorins relative to λ^5-arsenins also plays a role.

The following results suggest that the rearrangement *(3)* → *(4)* is predominantly intramolecular, proceeding *via* the planar[5] phosphorinium ions *(5)* (phosphorinium ions have already been proposed as intermediates in the formation of λ^5-phosphorins from triarylpyrylium salts and phenylphosphane[6]):

1) The mixtures of *cis-(3)* and *trans-(3)* obtained in the synthesis rearrange to *(4)* at the same rate as the pure isomers.

2) A crossover experiment with *(3a)* and *(3e)* gives almost exclusively the λ^5-phosphorins *(4a)* and *(4e)* resulting from

The nucleophilic character of positions 2 and 6 of *(4)* is apparent from the rapid uncatalyzed H/D exchange of H^2, H^6 in CH_3OD at room temperature; *(7a)*, R = *c*-C_6H_{11}, m.p. 71—72 °C; *(7c)*, R = C_6H_5, m.p. 74—75 °C.

Synthesis of *N*-Methyliminosulfur Tetrafluoride, $CH_3N{=}SF_4$, from the Cation $CH_3NSF_3^+$[**]

By *Rüdiger Mews*[*]

The addition of polar reagents RF to the formal triple bond of NSF_3 to give products of the type $R_2N{-}SF_5$ (*e.g.* R = H, Cl[1]) has been suggested to proceed *via* the following mechanism[2]:

$$N{\equiv}SF_3 + \overset{\delta+}{R}{-}\overset{\delta-}{F} \longrightarrow \{R{-}N{=}SF_3^+F^-\} \longrightarrow \{RN{=}SF_4\}$$
(1) *(2)* *(3)*

$$\xrightarrow{RF} \{RN{-}SF_5^-R^+\} \longrightarrow R_2N{-}SF_5$$
(4) *(5)*

The intermediates *(2)*, *(3)* and *(4)*, however, could previously never be isolated, since the cation in *(2)* is attacked by the nucleophilic F^-, and the pentacoordinated sulfur in *(3)* reacts, with increase in coordination number, to give the anion *(4)*, from which the compound *(5)* is then formed. We have now been able to carry out the first stepwise addition of "methyl fluoride" and to isolate the intermediates of type *(2)* and *(3)*.

$$(1) + CH_3Br + AgAsF_6 \xrightarrow[-AgBr]{SO_2} CH_3OSO^+AsF_6^- + (1)$$

$$(1) \xrightarrow{-SO_2} CH_3NSF_3^+AsF_6^-$$
(6)

As methylating reagent we used the cation CH_3OSO^+[3], also readily accessible *via* other routes. This reaction is generally applicable to alkyl halides RX (*e.g.* $R=CH_3$, C_2H_5; X = Br, I); the alkylation step can be regarded as nucleophilic exchange of SO_2 by the weak base *(1)*. $ROSO^+$ is an extremely good alkylating agent, enabling even the preparation of the cations $R_fRNSF_2^+$ and R_fRNSO^+ ($R_f=CF_3$, C_2F_5, *i*-C_3F_7; $R=CH_3$, C_2H_5) from the corresponding perfluorinated alkyliminosulfur difluorides and oxides[4].

In the ^{19}F- and ^{1}H-NMR spectra the colorless salt *(6)*, m.p. 190 °C, shows the expected quartet ($\delta_{SF}=48.2$; $\delta_{CH}=3.87$; $J_{HF}=8.7$ Hz; $\delta_{AsF}=-60.85$; $J_{AsF}\approx 900$ Hz). We assign the band observed at 1790 cm^{-1} in the IR spectrum to the SN stretching vibration; it thus lies about 100 wavenumbers higher than the previously reported highest ν_{SN} band of $F_3B{\cdot}NSF_3$[5]. On heating *(6)* with an excess of NaF *in vacuo* at 160 °C the covalent tetrafluoro derivative *(7)* is formed in 67 % yield.

$$(6) + NaF \xrightarrow{\Delta} CH_3N{=}SF_4 + NaAsF_6$$
(7)

Compound *(7)* is a colorless stable liquid, b.p. 21.8 °C/760 torr (extrapolated). At room temperature the ^{19}F-NMR spectrum shows a broad signal ($\delta_{SF}=71.3$), the ^{1}H-NMR spectrum the expected quintet ($\delta_{CH}=2.97$, $J_{HF}=3.65$ Hz)[6]. In the IR spectrum ν_{SN} appears at 1313/1307 cm^{-1}, the SF stretching vibrations lie in the region between 800 and 900 cm^{-1} (852, 815 cm^{-1}) characteristic for S^{VI} derivatives. The reaction behavior of *(7)* ought to resemble that of $O{=}SF_4$. As expected *(7)* is a weaker acceptor for F^-; a salt analogous to $Cs^+OSF_5^-$[7] is not stable at room temperature.

$$CsF + (7) \not\longrightarrow Cs^+CH_3NSF_5^-$$

$$BF_3 + (7) \longrightarrow CH_3NSF_3^+BF_4^-$$
(8)

Conversely the ability of *(7)* to act as donor of F^- is increased. Thus, the tetrafluoroborate *(8)* is extraordinarily stable and sublimes *in vacuo* only above room temperature.

Procedure

a) $CH_3NSF_3^+AsF_6^-$ *(6)*: A mixture of $AgAsF_6$ (8.50 g, 28.6 mmol), *(1)* (3.50 g, 34 mmol) and CH_3Br (3.10 g, 32.6 mmol) in 10 ml SO_2 is stirred for 20 h at room temperature. After filtration and removal of solvent by evaporation 8.35 g of crystalline crude product is obtained (yield 95 %). Reaction of *(7)* with AsF_5 in SO_2 affords analytically pure *(6)*.

b) CH_3NSF_4 *(7)*: *(6)* (8.06 g, 26.25 mmol) is heated with an excess of NaF for 20 h at 160 °C *in vacuo* and the volatile products are collected in a trap cooled with liquid N_2. Repeated fractional condensation (−80 °C, −110 °C, liquid air) at −110 °C affords 2.40 g *(7)* (yield 67 %).

c) $CH_3NSF_3^+BF^-$ *(8)*: A mixture of *(7)* (0.94 g, 6.9 mmol) and BF_3 (0.61 g, 9.0 mmol) is condensed with 5 ml SO_2 in a glass bomb and brought to room temperature. After removal of SO_2 the residue is dried by suction: 1.40 g colorless *(8)*, m.p. 116 °C (yield quantitative). NMR: $\delta_{SF}=47.90$, $\delta_{BF_4}=-145.7$; $\delta_{CH}=3.73$; $J_{HF}=8.6$ Hz.

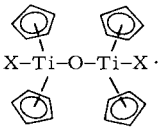
[6] The temperature dependence of the NMR spectrum shows that the interchange of equatorial and axial fluorine atoms in



is already slowed down at room temperature (the halfwidth of of the ^{19}F-signal is 200 Hz). Below 0 °C both the ^{19}F- as well as the ^{1}H-signal changes into a complex multiplet the peaks of which continually change, down to the lowest temperature of measurement. The complexity of the spectra is caused, on the one hand, by exchange processes at the sulfur atom and, on the other, by hindrance of inversion at the nitrogen (rotation about the C—N axis) [cf. also, discussion of the spectrum of CF_3NSF_4: *E. L. Muetterties, W. Mahler, K. J. Packer, R. Schmutzler*, Inorg. Chem. *3*, 1298 (1964)].

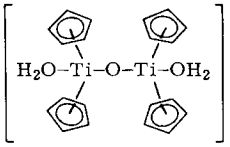
An Organometallic Complex with Coordinatively Bound Water: $[\{(\eta\text{-}C_5H_5)_2Ti(H_2O)\}_2O]S_2O_6$[**]



By *Ulf Thewalt* and *Gerhard Schleussner*[*]

Owing to its stability and the multiplicity of reactions which it undergoes with retention of the $(C_5H_5)_2Ti$ group, dichlorobis(η-cyclopentadienyl)titanium has proved to be one of the most important and preparatively useful complexes in organotitanium chemistry[1]. On reaction with NaX (X = Br, I, NO_3) in aqueous solution it affords dinuclear complexes, previously formulated as *(1)*[2].

(1a), X = Br
(1b), X = I
(1c), X = NO_3

However, when X is an oxoanion, as in *(1c)*, a structure of the type *(2)*, in which X and H_2O have exchanged their roles as ligands in the inner and outer spheres, is also plausible.

(2)

Organometallic compounds containing adjacent η-C_5H_5- and H_2O-ligands have—apart from postulated or incompletely characterized species—to our knowledge not been described in the literature.

We have now found by X-ray structure analysis of the salt *(2a)*, with 2X = dithionate and $n = 2$, that this complex can in fact be formulated as in *(2)*.

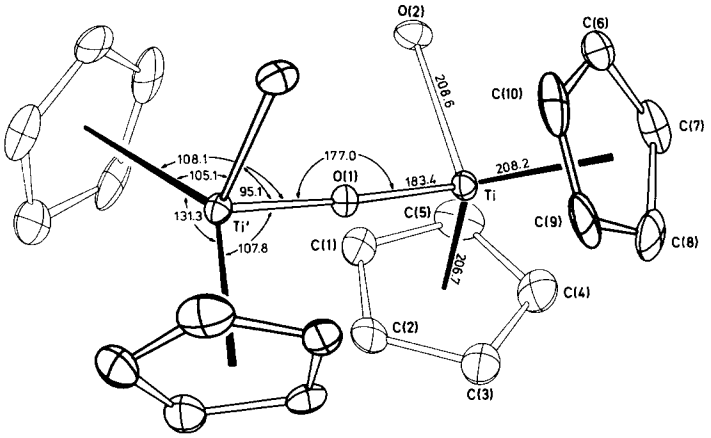


Fig. 1. The dinuclear cation of *(2a)*. The errors for the given bond lengths and angles are 0.5 pm and 0.3°, respectively. The figures quoted are with respect to the center points of the C_5H_5 rings. The angle Z(1)—Ti—O(2) is 103.3° [Z(1) = center of the ring containing C(1)].

The compound *(2a)* can readily be prepared by reaction of $(C_5H_5)_2TiCl_2$ and $Na_2S_2O_6 \cdot 2H_2O$ in water[3]. It forms hard, air-stable, orange-colored, short prismatic orthorhombic crystals[4]. As in $(C_5H_5)_2TiCl_2$[5] the Ti centers are surrounded by four ligands. One coordination position per Ti atom is occupied by a H_2O molecule. Both the $S_2O_6^{2-}$ anion as well as the complex cation occupy a special position in the unit cell: both exhibit exact C_2-2 symmetry, and their twofold symmetry axes coincide with the twofold symmetry axes determined by the space group. Figure 1 shows the cation with its essential bond lengths and angles. The Ti—O—Ti group is almost linear with a bond angle of 177°. The Ti—O—Ti angle in the corresponding compound $C_5H_5(Cl_2)TiOTi(Cl_2)C_5H_5$ is 180°[6]. The dihedral angle O(2)—Ti—Ti'—O(2) between the two halves of the complex is 74.1°. As in $(C_5H_5)_2TiCl_2$ the C_5H_5 groups are staggered.

(2a) and the complex with ClO_4^- as anion are the first organotitanium(IV) compounds displaying coordination of H_2O to a central Ti atom. This would suggest the complex formulated as in *(1c)* most likely has an analogous structure.

[**] Metal-π-complexes of Benzene Derivatives, Part 9. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 8: *Ch. Elschenbroich, R. Möckel*, Angew. Chem. *89*, 908 (1977); Angew. Chem. Int. Ed. Engl. *16*, 870 (1977).

to display a change from intramolecular π-π repulsion (free ligand) to bonding η-arene-metal interaction (complex).

We have now cocondensed [2.2]paracyclophane with chromium atoms and obtained bis(η^6-[2.2]paracyclophane)chromium(0) *(2)*, (η^{12}-[2.2]paracyclophane)chromium(0) *(3)*, and oligomeric products according to the reaction

$$(C_{16}H_{16})_g + (Cr)_g \xrightarrow[\text{Cocondensation}]{-196\,^\circ C} (2) + (3) + \cdots$$

The complex *(3)* can be separated together with free cyclophane by sublimation (10^{-3} torr, 120 °C) and subsequently isolated in pure form *via* the redox system *(3)*/*(3)*$^+$[2]. The lability of *(2)*$^+$ towards solvolytic attack precludes the use of this method for the isolation of pure complex *(2)* from the residue left on sublimation. The presence of *(2)* can however be demonstrated mass spectroscopically (FD-MS: $m/e = 468$, $C_{32}H_{32}Cr^+ = M^+$) and by the ESR spectrum of *(2)*$^+$ (Table 1). The given structure of *(3)* follows from the appearance of two sharp singlets in the ^{1}H-NMR spectrum ([D]$_6$-benzene: δ = 2.64 (s, $H_{methylene}$), 4.63 (s, H_{arene}); int. 1 : 1), which are shifted upfield by 0.19 and 1.70 ppm, respectively, relative to free [2.2]paracyclophane; it is also in accord with the mass spectrum [70 eV: $m/e = 260$ (21 %, $C_{16}H_{16}Cr^+ = M^+$), 208 (13, $C_{16}H_{16}^+$), 156 (33, $C_8H_8Cr^+$), 104 (100, $C_8H_8^+$), 78 (12, $C_6H_6^+$), 52 (96, Cr^+)].

A comparison of the X-ray structure data of [2.2]paracyclophane (inter-ring C—C distance 278—309 pm[3]) with those of bis(η^6-benzene)chromium(0) (Cr-ring plane distance 161 pm[4]) would suggest that *(3)* represents a compressed sandwich complex. This manifests itself quite clearly in the ESR data of *(3)*$^+$, which are listed together with the corresponding data for *(2)*$^+$ and *(4)*$^+$ in Table 1.

Table 1. ESR data of the radical cations of *(2)*, *(3)* and *(4)* [a].

	⟨*g*⟩	$a(^1H_{arene})$ [G]	$a(^1H_{methylene})$ [G]	$a(^{53}Cr)$ [G]
(3)$^+$	1.9905	4.0 ±0.05 (8 H)	0.25 ±0.01 (8 H)	16.5 ±0.2
(2)$^+$	1.9865	3.55 ±0.05 (8 H)	[b]	18.5 ±0.2
(4)$^+$	1.9865	3.7 ±0.05 (8 H)	0.57 ±0.05 (12 H)	17.8 ±0.2

[a] Produced by air oxidation of the neutral complex dissolved in methanol and subsequent degassing. Recorded at −55 °C.
[b] Coupling not resolved.

In the case of *(3)*$^+$ the hyperfine coupling constants for the ring protons are greater and for ^{53}Cr smaller than in *(2)*$^+$ and *(4)*$^+$. This finding reflects a slightly more extensive Cr($3d_{z^2}$)→arene (σa_{1g}) spin delocalization in *(3)*$^+$, which is probably caused by a shorter metal-ligand distance than in *(4)*$^+$[5]; the smaller deviation in the isotropic *g*-factor from 2.0023 is also consistent with a smaller spin population at the central metal in *(3)*$^+$. On the other hand, the ESR data for *(2)*$^+$ closely resemble those for *(4)*$^+$, since a normal Cr-arene distance is possible in this case. It is tempting to explain the small differences of a (^{1}H) and a (^{53}Cr) for *(2)*$^+$ and *(4)*$^+$ in terms of a smaller Cr($3d_{z^2}$)-arene (σ, a_{1g}) overlap in *(2)*$^+$ due to the non-planar benzene rings of [2.2]paracyclophane orienting their convex sides towards the central metal atom. This concept could also serve to explain the surprisingly different reactivities of *(2)*$^+$, *(3)*$^+$, and *(4)*$^+$ in solvolytic metal-ligand cleavage. Whereas *(4)*$^+$ takes up an intermediate position, being indefinitely stable in methanol but being destroyed immediately by conc. HCl, *(2)*$^+$, on the one hand, slowly releases its ligands if dissolved in methanol at room temperature ($t_{1/2} \approx 8$ h, ESR) and *(3)*$^+$, on the other hand, is unaffected by conc. HCl over a period of weeks. The high stability of *(3)*$^+$ is explained by the fact that in this case the concave sides of the non-planar benzene rings of [2.2]paracyclophane, functioning as a rigid chelate ligand, are oriented towards the central metal, thus shielding the latter from solvolytic attack. In the case of *(2)*$^+$, however, the cleavage can take place in two steps *via* the half-sandwich complex (η^6-[2.2]paracyclophane)chromium$^+$, whereby the initial attack is easier than in *(4)*$^+$, because coordination *via* the convex sides of the non-planar benzene rings leaves the central metal atom exposed to attack by the solvent.

Procedure

Chromium (0.48 g) is evaporated from a Mo-wire (φ 1 mm) spiral (12 V, 44 A) in a 1 l reaction vessel (−196 °C, 10^{-4} torr) at the same time as [2.2]paracyclophane (2.5 g) from a heatable reservoir (1 V, 1.5 A, wall temperature ≈100 °C). The co-condensate is dissolved in warm toluene (+60 °C). Filtration, removal of the solvent by evaporation, and subsequent sublimation of the residue affords an ivory-colored material, which is then treated with 200 ml of toluene and 100 ml of water. The yellow aqueous solution obtained after brief passage of air is washed with 5 × 100 ml of toluene. To the washed solution is added 30 ml of toluene and 20 g each of KOH and $Na_2S_2O_4$ and the mixture stirred for 2 h. The yellow toluene solution is dried over KOH, the solvent removed, and the residue sublimed at 100 °C/10^{-3} torr. Approximately 10 mg (5 % based on unrecoverable ligand) of lemon-yellow *(3)* is obtained.—Ligand recovery: The residue from the first sublimation, which contains *(2)* as well as oligomeric complexes, is decomposed in air with 20 % KOH and extracted with 3 × 100 ml of toluene. From the combined extracts 2.25 g (90 %) [2.2]paracyclophane can be isolated.

Higher-Order Derivative Spectrophotometry for the Fine Resolution of UV/VIS Spectra

By *Gerhard Talsky, Lothar Mayring*, and *Hans Kreuzer*[*]

Although various mechanical, optical and electrical methods have already been employed for some 25 years or more for

[*] Univ.-Doz. Dr. G. Talsky, Dipl.-Chem. L. Mayring, H. Kreuzer
Institut für Technische Chemie der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

recording derivative spectra (differentiation of signals)[1], derivative spectrophotometry itself is still in its infancy, but—thanks to the progress made in modern electronics—has now been in general use for more than 2 years. However, only first- and second-derivative spectra have so far been exploited. A closer study of these derivative spectra indicates that resolution of many hitherto unsolvable problems can only be realized by higher order differentiation of signals.

For this purpose we have developed an analog computer unit, with operational amplifiers, differentiators, separating modules and attenuators as well as active and passive filters, which enables the first analog on-line recording of low-noise, readily reproducible seventh order derivative spectra. The broad scope for variation of the differentiation time constants, attenuation, and critical frequencies, and the quality of the filters made it possible to adapt the apparatus to most problems presently at hand.

Investigations have shown that in most cases optimum resolution can be achieved with derivatives of the 4th order. As a rule all shoulders, terraces and inflection points of the unipolar signals are then transformed into bipolar signals and undesired background functions are eliminated. The signal-to-noise ratio can be kept low, thus enabling excellent reproducibility and quantitative evaluation.

We have tested this new method of higher-order derivative spectrophotometry (HODS method; $n > 2$) on a series of practical examples from various sectors of analytical chemistry and have obtained surprisingly good results. The areas of application which we have so far examined include: trace analysis (inorganic and organic), characterization of isomeric and homologous compounds, quality (purity) control, food analyses, drug analyses, clinical analyses, investigation of amino acids, peptides, proteins, nucleic acids, dyes and pigments, polymers *etc.*, measurements on turbid and deeply colored samples, on solids and gases, special applications in chromatography, reaction kinetics.

The efficiency of the HODS method becomes evident on examining the spectrum of Congo Red (Fig. 1). The absorption maximum of the azo dye lies in the visible spectrum region at 495 nm. Whereas very weak shoulders on the flanks of the absorption peak are barely recognizable in the fundamental spectrum, the superposed peaks become somewhat more discernable in the first and second derivative spectra, and very much more pronounced in the derivative spectra of third and fourth order. Derivatives of a still higher order do not provide any further important information in this particular example.

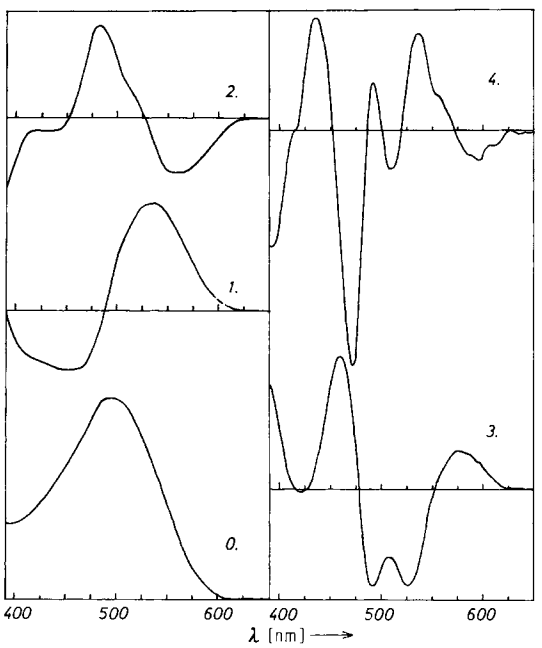

Fig. 1. Fundamental spectrum (below, left) and 1st to 4th derivative spectra of Congo Red; conc. 0.002% in water (water: scan 5 nm/s; range 2*E*).

More complex spectra show similar "fingerprints", as observed *e.g.* in IR spectroscopy. Trypsin and chymotryopsin, two proteases, which differ in the composition of their UV-active amino acids Phe, Tyr and Trp, both show a typical protein spectrum with a maximum at 280 nm and a minimum at 250 nm (Fig. 2a). The fundamental spectra differ very little from each other. However, the two proteins can be very easily characterized by their fourth derivative spectra. It can be seen from Figure 2b that the maxima and minima appear at almost the same λ values, but the amplitudes are different owing to the different proportions of Phe, Tyr and Trp. We are presently examining how far it is possible with this new method to determine various chromophores simultaneously and quantitatively.

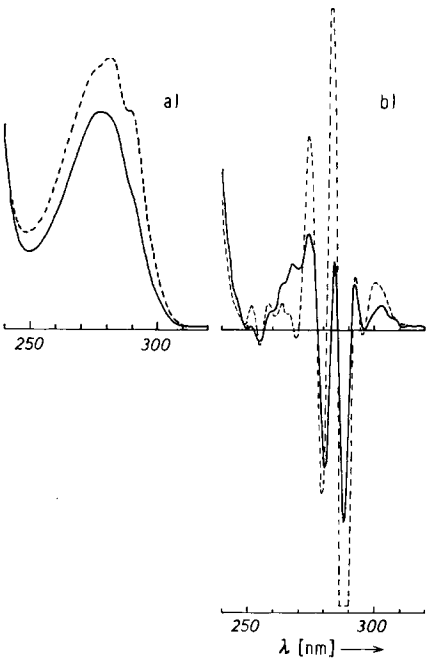

Fig. 2. a) Fundamental spectrum of bovine trypsin (——) and bovine chymotrypsin (– – –); conc. 0.05% in water (water; scan 2 nm/s; range 2*E*). b) 4th derivatives.

From the results so far it can be expected that the HODS method will greatly enhance the scope of UV-VIS spectrophotometry and provide new routes for the solution of analytical problems previously unresolvable by first- and second-derivative spectra[2].

Complex Stabilization by Bifurcated Hydrogen Bonds: Bis[2-(*o*-methoxyphenoxy)ethoxyethyl] Ether-Thiourea[***]

By *Il-Hwan Suh* and *Wolfram Saenger*[*]

Cyclic, chiral crown ethers are of considerable interest because they form inclusion complexes with suitable ionic or neutral guest molecules and therefore can be used to separate racemic mixtures[1]. X-ray diffraction analyses have shown that such complexes are stabilized by $-NH_3^{\oplus}\cdots O$ or $C-H\cdots O$ interactions between the guest molecules and the cyclic crown ether oxygen atoms[2]. The steric limitations of complex formation imposed by cyclic crown ethers have been considerably reduced by preparing linear polyethers[3]. Recently, we have determined the structures of some complexes of metal ions with linear polyethers and found that the cations are coordinated with all the hetero atoms[4]. In order to determine what kind of interactions are involved we have now examined the 1:1 adduct of thiourea and bis[2-(*o*-methoxyphenoxy)ethoxyethyl] ether *(1)*[5].

(1) was recrystallized from acetone to yield flaky, yellowish crystals, m.p. 97—98 °C, space group Cc, cell constants $a=9.507$ Å, $b=21.200$ Å, $c=12.817$ Å, $\beta=95.61°$. 1197 X-ray diffractometer data were collected in the $2\theta/\omega$ scan mode using graphite monochromated MoK_α radiation. The structure was solved by direct methods and refined by full matrix least squares techniques to $R=2.9\,\%$ (Fig. 1).

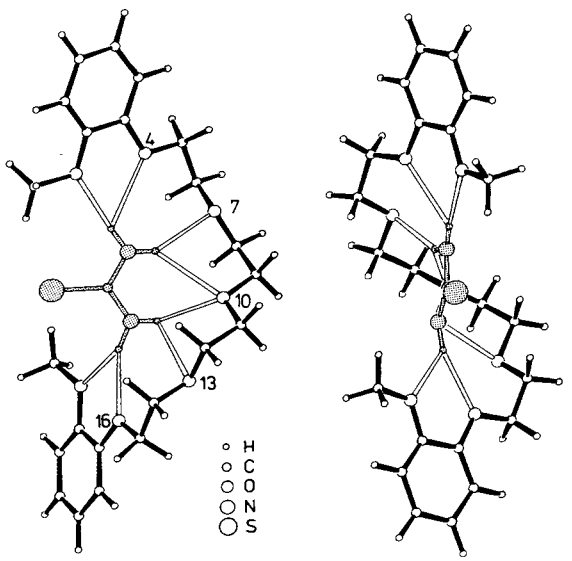

Fig. 1. Structure of complex *(1)*, viewed nearly perpendicular to the thiourea plane (left) and along the S···O(10) vector (right). Hydrogen bonds indicated by open lines, thiourea molecule shaded. H···O distances [Å] are, going from O(1) to O(19): 2.05, 2.64, [2.27, 2.41], 2.14, 2.71, [2.12, 2.39] (the numbers in brackets indicate bifurcated hydrogen bonds).

In complex *(1)* the thiourea molecule is hydrogen bonded through NH···O(ether) interactions with all seven oxygen atoms of the ligand, the central atom O(10) accepting two hydrogen bonds while the other six oxygen atoms accept one hydrogen bond each. The conformation of the polyether is such that it enables the thiourea molecule to utilize all the possible multidentate interactions offered by the partner. It does so without violating stereochemical restrictions, *i.e.* all torsion angles C—C—O—C and C—O—C—C along the polyether chain are *trans* while the angles O—C—C—O are *gauche*, as observed in a number of other linear polyether complexes with metal ions[6]. In these complexes, however, the ligands are wrapped more tightly around the small cation (radius ≈1 Å) in order to coordinate with all the donor atoms, while in case of the thiourea (radius ≈2 Å) the ligand has a more elongated configuration. In both types of complexes the host molecule recognizes the guest by means of a number of relatively weak interactions and fits itself to the geometry of the guest—a necessary and promising requirement for tailoring polyether ligands for certain specific purposes.

The hydrogen bonds formed in complex *(1)* are noteworthy because hydrogen bonds to ether oxygen atoms are only rarely observed, and here we even have bifurcated hydrogen bonds, which have previously been demonstrated with certainty only in very few cases[7]. These bonds, with N···O distances in the range between 3.059(5) Å and 3.258(5) Å, are longer than the hydrogen bonded N···O distances between amino (or imino) groups and keto oxygen atoms of *ca.* 2.90 Å, thus indicating the relative weakness of the hydrogen bond interactions involving ether oxygen atoms. The distances N(1)···O(10) [3.258(5)] and N(2)···O(10) [3.059(5) Å] differ in length, probably due to crowding in the "center" of the complex, while further out along the wings of the polyether chain the N···O distances are comparable for identically substituted oxygen atoms.

From X-ray studies hydrogen atoms cannot be located very accurately; therefore the NH-hydrogen atoms were fitted mathematically into "ideal" positions determined by a neutron diffraction study on thiourea[8]. Using the criteria outlined by *Donohue*[7], we find bifurcated hydrogen bonds with H···O distances shorter than the corresponding van der Waals distance, 2.60 Å, between N(1) and O(7), O(10) and between N(2) and O(16), O(19). Normal hydrogen bonds exist between N(1) and O(1), and between N(2) and O(10). No interactions (>2.6 Å) are evident between N(1), O(4) and between N(2), O(13) (cf. Fig. 1). This hydrogen bonding arrangement is valid only for the crystalline state. In solution, dynamic equilibrium will allow all the N—H hydrogen atoms to participate equally in bonding to the ether oxygen atoms.

Directed Synthesis of $[Mo_3S_{13}]^{2-}$, an Isolated Cluster Containing Sulfur Atoms in Three Different States of Bonding

By *Achim Müller, Sabyasachi Sarkar, Ram Gopal Bhattacharyya, Siegfried Pohl,* and *Mechtild Dartmann*[*]

The directed synthesis of cluster-compounds is a current problem in transition metal chemistry[1]. For the subgroup VI metals (Mo and W) with d^n configuration, cluster types are expected to be dumb-bell shaped (in the case where $n=1$), triangular ($n=2$), tetrahedral ($n=3$) and octahedral ($n=4$) (here n also indicates the number of metal-metal bonds originating from each metal atom). Recently, the first binary species with $n=1$, *viz* $[Mo_2(S_2)_6]^{2-}$, has been isolated in the form of its ammonium salt[2]. We now report the synthesis of the homologous cluster with $n=2$ from a solution containing Mo^{IV}. Hitherto, the transition metal sulfur clusters, as model compounds of bioinorganic interest, could only be obtained by unusual reactions from unusual reactants and often only in low yield[3].

The dark-red, crystalline compound $(NH_4)_2[Mo_3S(S_2)_6]\cdot 1/2H_2O$ *(1)* is formed in aqueous solutions of molybdenum(IV) ions by treatment with polysulfide ions, and has been characterized by elemental analysis, DTA-, TG- and magnetic measurements, as well as by ESCA-, VIS-, IR- and Raman spectra, and a single-crystal structure analysis[4]. The salt is diamagnetic and the main IR absorption bands of the anion occur at 545 (m), 511 [m; ν(SS)], 459 [w; ν(Mo_3S)], 386 (w), 362 (w), 342 (m), 330 cm^{-1} [s; ν(MoS)] (assignments[5] by the use of ^{92}Mo- and ^{100}Mo-isotopes). The compound is extraordinarily stable and is not even decomposed by hydrochloric acid. It is almost insoluble in water and is only moderately soluble in dimethylformamide.

Like $[Mo_2^V(S_2)_6]^{2-}$[2] the new cluster $[Mo_3^{IV}S_{13}]^{2-}$ also contains both terminal and bridging disulfide groups (Fig. 1), and the equivalent bonds in both the anions have roughly

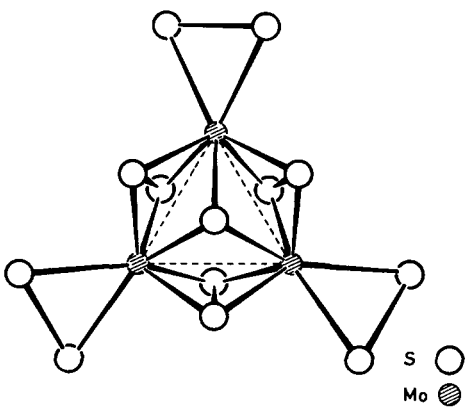

Fig. 1. Structure of the cluster $[Mo_3S_{13}]^{2-}$ in crystals of *(1)* [schematic].

the same length[2]. As expected, the Mo—Mo distances (2.67 Å) are somewhat shorter in *(1)* and the coordination number of molybdenum is again 9[4].

The S_2^{2-} ligands favor high coordination numbers and are suitable for stabilizing metal clusters, since an optimum shielding of the metal atoms is achieved through the high coordination numbers arising due to the small MS_2-angle. From the above mentioned scheme the existence of the homologous cluster $[Mo_4^{III}S_4(S_2)_4]^{4-}$ could be predicted[6]. Obviously the stability of these compounds is also connected with the occurrence of only tricoordinated sulfur in the central units $\{Mo(S_2)_2Mo\}$[2], $\{Mo_3S(S_2)_3\}$ (in *(1)*) and probably $\{Mo_4S_4\}$[6] (for the low reactivity cf. [3]).

Experimental

30 ml of saturated ammonium polysulfide is added to a reddish brown solution of 2.0 g of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ and 1.5 g of $NH_2OH\cdot HCl$ in 30 ml water. The resulting solution is warmed to 40—50 °C for 1 h, then cooled to room temperature, filtered, and the filtrate heated at *ca.* 90 °C for 3—4 h. Dark-red crystals of *(1)* then separate. The crystals are washed with $(NH_4)_2S_x$, H_2O, ethanol, CS_2 and ether; yield: 0.5 g. *(1)* can also be obtained directly by adding $MoCl_4(C_5H_5N)_2$ to a polysulfide solution (the high tendency of formation is comparable with that of $(NH_4)_2[Mo_2(S_2)_6]\cdot 2H_2O$).

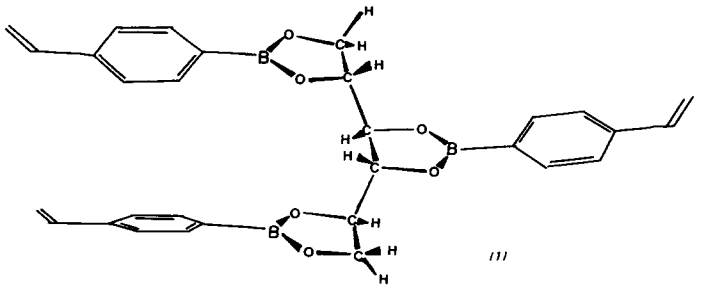
Optically Active Polyvinyl Compounds with Chirality in the Main Chain[**]

By *Günter Wulff, Karl Zabrocki,* and *Johann Hohn*[*]



We recently described a method for the preparation of synthetic polymers having cavities containing functional groups in a definite steric arrangement[1,2]. Functionally substituted polymerizable vinyl compounds were bound to a suitable chiral template molecule and then copolymerized under stringent crosslinking conditions. After removal of the template from the polymer the latter contains microcavities, whose shape is largely determined by the shape of the template, and within which the functional groups are in a fixed stereochemistry corresponding to the structure of the template. Such polymers can be used for the resolution of racemates[2].

In order to clarify whether the asymmetry of the microcavities is due only to an asymmetric crosslinking of the polymer, or also to chiral regions in the linear chains, we used for our investigations the previously described monomer *(1)*[1,3] with D-mannitol as template and copolymerized it by radical initiation together with methyl methacrylate (molar ratio 16:84) in benzene, but this time without the addition of a further crosslinking agent.

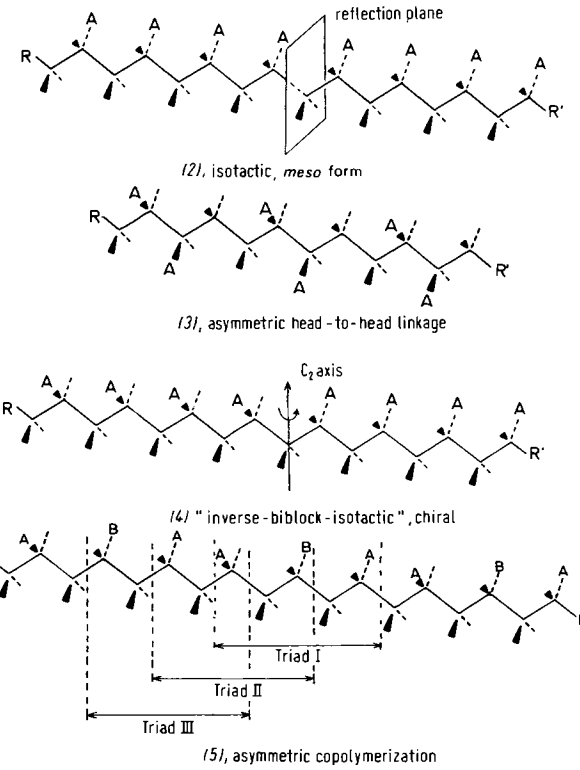
[**] Chirality of Polyvinyl Compounds, Part 1. This work was supported by the Fonds der Chemischen Industrie.

(1)

After removal of the crosslinking template D-mannitol, we now obtained a soluble copolymer of *p*-vinylphenylboronic acid and methyl methacrylate with a monomer ratio of 1:2 (average molecular weight $\bar{M}_n = 120000$, membrane osmometric). The copolymer had an optical activity of $[\alpha]_{365}^{20} = -29.4°$ ($\alpha = -0.123 \pm 0.002°$, acetone/water 9:1, $c = 0.42$) [monomer *(1)*: $[\alpha]_{365}^{20} = +270$ (chloroform)].

In order to prove that incorporation or incomplete removal of D-mannitol was not responsible for the observed optical activity, the experiment was repeated with ^{14}C-labeled D-mannitol. We found that only 0.2% of the total D-mannitol was still present in the polymer, thus ruling out the possibility of it having any notable influence on the optical rotation. Moreover, addition of D-mannitol to polymer solutions was found to lead to a change in the rotation to positive values until precipitation of the polymer due to progressive crosslinking by the mannitol.



From these findings we conclude that our copolymer of 1-substituted olefins possesses chirality localized in the main chain by asymmetric induced polymerization. Optically active polymers or copolymers of 1-substituted olefins were previously unknown—excepting those having chirality centers in the side-chains[4]. According to the literature[4, 5] optical activity is not expected to occur in polyvinyl compounds, since in each step of the polymerization of a 1-substituted olefin a chiral center is formed from a prochiral center but in atactic polymers, with irregularly, in syndiotactic with regularly alternating *R*- and *S*-configuration. Chains of this type could indeed be chiral, but the optical activity is intramolecularly compensated and therefore is not measurable. Isotactic polymers *(2)*[6] could begin with an *R*- or with an *S*-configuration with formation of two enantiomorphic chains. If, however, the difference in the end groups can be neglected ($R—CH_2- \cong —R'$), as is always permissible in the case of longer chain lengths, the molecule possesses a symmetry plane (*meso* form) and does not show any optical activity[4].

On the other hand, for polymers with 1,2-substituted segments, which are obtainable *e.g.* from cyclic olefins such as maleic anhydride, the occurrence of chirality in the main chain is to be expected[5a], and numerous optically active polymers have already thus been obtained by asymmetric induction[4].

We should like to discuss here how also optically active polyvinyl or polyvinylidene compounds with chirality in the main chain can occur, and thus offer an explanation for the optical activity observed by us.

One possibility would be by head-to-head polymerization of the monomers *(3)*, in which 1,2-disubstituted chiral segments can be formed, as in the case of 1,2-substituted monomers. However, in the case of the monomers used by us such a manner of polymerization can be ruled out.

Chirality in the main chain would also be possible if the substituents near the center of the chain in an isotactic polymer chain change to the other side of the main chain *(4)* with respect to the Fischer projection. Since each part of the chain

has in itself a strong isotactic structure, we propose for this type of arrangement the designation "inverse-biblock isotactic". It should be pointed out that in an "inverse-biblock isotactic" chain the configuration of all asymmetric C atoms remains the same, whereas in a strictly isotactic chain it changes in the middle from *R* to *S*. With identical chain ends *(4)* has only one twofold symmetry axis and is therefore chiral as a whole.

While the concept "inverse-biblock isotactic" applies for both uni- as well as co-polymers, there should also be a type of chirality of polymer chains which can occur only in copolymers. *(5)* represents an example of several possibilities. In this copolymer the three different triads I, II and III are asymmetric.

It must be decided whether in our case the optical activity is due to an "inverse-biblock isotactic" structure or to an asymmetric copolymerization. Moreover it must be remembered that optical activity can already occur if such structures are only partially realized in the chains.

In the case of "inverse-biblock isotactic" structures, a unipolymer must also be optically active, so we tried to synthesize optically active poly(*p*-vinylphenylboronic acid). *(1)* was polymerized and the mannitol subsequently removed; or *(1)* and *p*-vinylphenylboronic acid glycol ester were copolymerized

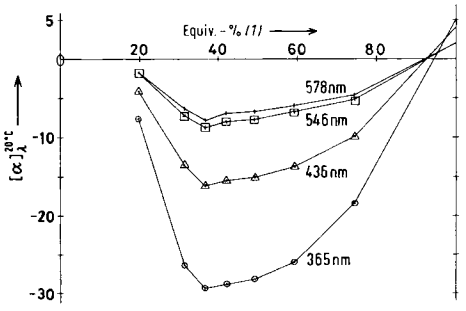


Fig. 1. Specific optical rotation of copolymers of methyl methacrylate and *(1)* after removal of D-mannitol. Equiv.% *(1)* (1 equiv. *(1)* = 1/3 mol *(1)*) in the polymerization mixture and rotation of various wavelengths are given.

and the mannitol and glycol removed. The polymers obtained, however, showed no significant optical activity. Further indications were given by the copolymerizations of methyl methacrylate with varying amounts of *(1)*. The specific rotation of these copolymers after removal of the mannitol is strongly dependent upon the molar ratio of the comonomers (cf. Fig. 1), the maximum negative rotation being reached at 16 mol-% *(1)* (36 equiv.% boronic acid groups). This means that a definite composition of the copolymerization mixture corresponds to the highest asymmetric induction. We also obtained copolymers with negative rotation after removal of D-mannitol on using styrene as comonomer of *(1)*.

These results suggest the likelihood of an asymmetric copolymerization which can be explained in terms of the spatial structure of *(1)*: A methyl methacrylate molecule could be introduced stereo- and enantiospecifically in the chain between each two *p*-vinylphenylboronate moieties in the 1,2- and 5,6-positions of the mannitol, with asymmetrical triads being formed as in Formula *(5)*, Triad I.

Directed Cooperativity and Site Separation of Mercapto Groups in Synthetic Polymers[1]

By *Günter Wulff* and *Ilona Schulze*[*]

With the aid of chiral template molecules it has been possible to prepare polymers having chiral cavities which contain functional groups in definite stereochemical arrangement[2]. The ability of such polymers to separate racemates might depend upon the asymmetric structure of the cavities[3] and the exactness of orientation of the functional groups. In order to acquire more detailed information about the influence of the stereochemistry of the functional groups on the specificity we sought a model system which is sensitive only to the distance between the functional groups.

For this purpose bis(*p*-vinylbenzyl) disulfide *(1)*[4] was copolymerized under various conditions with styrene and divinylbenzene. On polymerization the two vinyl groups of the disulfide *(1)* ought to be incorporated at various positions of a growing chain or in various chains ("discontinuate words" arrangement[2a]). If the disulfide bridges are reductively transformed into mercapto groups then they should remain in a definite related position to each other in a strongly cross-linked polymer (cf. Fig. 1).

Since mercapto groups can be selectively re-oxidized to disulfides[5], retention of this spatial relationship can be quantitatively determined on the basis of the re-oxidized portion (degree of re-oxidation).

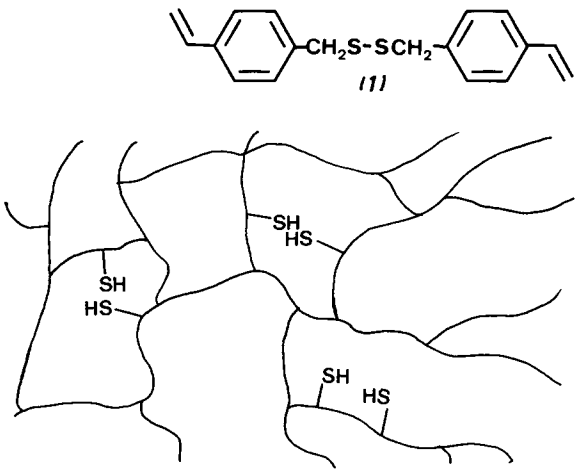

Fig. 1. SH-groups in definite stereochemical arrangement by polymerization of *(1)*.

For an exact assessment, however, comparison is necessary with a polymer which contains the mercapto groups in the same concentration but in a random distribution (Fig. 2). Polymers of this type were obtained from *p*-vinylbenzyl thioacetate *(2)*[6]. On complete site separation of the mercapto groups no reoxidation of these polymers should occur.

Table 1 lists the composition of the monomeric mixtures used for the preparation of the polymers. Using the two monomers a total of three series of polymers were prepared having as far as possible comparable polymeric properties and containing the same amounts of sulfur. A complete comparability is not to be expected owing to the different polymerization properties of a mono- and a difunctional monomer.

Table 1. Percentage composition of the monomer mixture used for preparation of the polymers [a].

Monomers	Polymers					
	A1	A2	B1	B2	C1	C2
(1) (mmol *(1)* per g)	24.2 (0.81)	—	20.2 (0.68)	—	2.3 (0.077)	—
(2) (mmol *(2)* per g)	—	24.7 (1.30)	—	26.7 (1.28)	—	2.9 (0.15)
Styrene	75.8	72.5	—	—	7.2	7.2
Divinylbenzene (techn.)	—	2.8	79.8	73.3	90.5	89.9

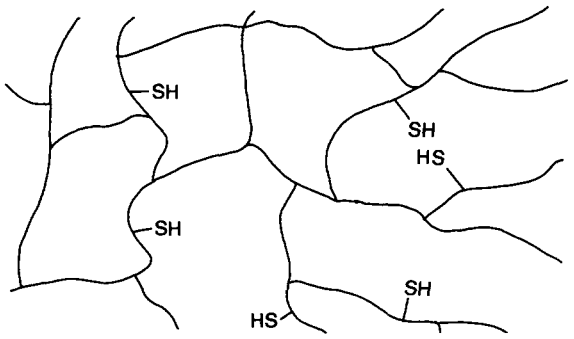

Fig. 2. SH-groups in random distribution by polymerization of *(2)*.

The polymers were prepared by free-radical copolymerization of the monomers *(1)* and *(2)* with varying amounts of styrene and divinylbenzene as crosslinking agent in acetonitrile/toluene (2:1). For both types of polymers the reductive generation of the SH-groups was carried out with diborane ($NaBH_4$ and $AlCl_3$)[7] in diglyme. In this way more than 90% of the total sulfur present in the polymer (except in the case of polymer B1) could be converted into SH-groups (see Table 2). This finding shows that chain-transfer reactions, possible in the case of disulfides and thioacetates, do not occur to any appreciable extent.

The reoxidation of the SH-groups was carried out with iodine in methanol[5] (Table 2). Polymers with less crosslinking exhibited higher degrees of reoxidation, being still 69% even in the case of polymer A2. Apparently the polymer chains retain considerable flexibility, making reactions possible also in the case of randomly distributed SH-groups over a particular distance. Remarkably, however, 33% reoxidation has been observed even in highly-crosslinked polymers from monomer *(2)* (polymer B2). But the reaction kinetics are noticeably different to those in the case of polymer B1. Whereas 98% oxidation was achieved within 1.5 h in the case of polymer B1 the ultimate degree of oxidation of polymer B2 was reached only after about 30 h. The incomplete site separation observed for the polymer B2 is in agreement with the experiments of other authors concerning site separation of functional groups in polymers. *Crowley* and *Rapoport*[8] recently correlated these findings and came to the conclusion that almost all previous attempts to achieve complete site separation were not very successful.

When the concentration of the SH-groups on the polymer in our experiments was reduced about tenfold, oxidation was no longer possible in the case of polymer C2 with randomly distributed SH-groups, *i.e.* complete site-separation could be achieved. Under the same conditions the analogously prepared polymer from monomer *(1)* then showed 95% oxidation. This comparison clearly indicates that practically all SH groups in the polymer C1 remain at a distance from a second SH-group allowing reoxidation to the disulfide. The degrees of oxidation are strongly dependent upon the swelling ability of the solvent used in the oxidation. Thus the degree of reoxidation of polymer B2 in the strongly swelling solvent toluene increased owing to the better mobility of the chains. In contrast, the degree of reoxidation of polymer B1 in the same solvent decreased, since apparently the separation between the two groups is considerably increased by the swelling. Thus the method described here permits investigation of the influence of several parameters on the stability of the functional groups in a "discontinuate words" arrangement[9]. Moreover, it is also possible to determine quantitatively the site-separation of functional groups on polymers. Especially interesting is the possibility of introducing functional groups (in our case two SH-groups) in a definite cooperativity in a polymer. Such polymers can be used as redox resins and serve as models for enzymes containing SH-groups.

A New High-Pressure Phase of Barium Disilicide[**]

By *Jürgen Evers, Gilbert Oehlinger*, and *Armin Weiss*[*]

The isolated Si_4 tetrahedra present in the orthorhombic normal-pressure(NP)-phase[1] of barium disilicide can be transformed into corrugated Si layers of the trigonal $EuGe_2$-type[2] by high-pressure/high-temperature treatment. Surprisingly the polymerization can also lead to a regular three-dimensional Si network. This new high-pressure(HP)-phase of $BaSi_2$ is metastable at normal pressure; it is obtained if the orthorhombic modification is heated to 600—800°C at 40 kbar in a belt apparatus[3] and then quenched to room temperature under pressure. The silvery to golden compound is stable in the absence of air and moisture. Complete retransformation into the phase with isolated Si_4 tetrahedra takes place, when it is heated to approximately 400°C at normal pressure.

The powder diagram of the new HP-phase can be indexed cubic showing the characteristic sequence of reflections for the $SrSi_2$-type structure[4]. The intensities are also consistent with this type of lattice. The best agreement between observed and calculated intensities (24 reflections, $Mo_{K\alpha}$ radiation) was obtained for the positional parameter $x_{Si}=0.419$ (reliability factor $R=0.087$). The crystallographic data of the cubic, trigonal and orthorhombic modifications of $BaSi_2$ are listed in Table 1.

Axes [pm]	$a=671.5\pm0.5$	$a=404.7\pm0.3$ $c=533.0\pm0.5$	$a=892\pm6$ $b=675\pm6$ $c=1157\pm6$
Cell volume [pm³]	302.8×10^6	75.6×10^6	$696.6\cdot10^6$
Density [g/cm³]			
obs.	4.2_7	4.2_6	3.54
calc.	4.246	4.251	3.68
Number of formula units	4	1	8
Atomic positions	4 Ba in 4a 8 Si in 8c	1 Ba in 1a 2 Si in 2d	4 Ba_I in 4c 4 Ba_{II} in 4c 4 Si_I in 4c 4 Si_{II} in 4c 8 Si_{III} in 8d

The $SrSi_2$-type structure has hitherto been reported for $SrSi_2$(NP) itself only. The cubic modification of $BaSi_2$(HP) is the second binary representative of this lattice type. Its Si sublattice is built up of very flat trigonal pyramids, rotated against each other, thus forming a three-dimensional array. The cavities within the skeleton contain the metal atoms. The characteristic feature of this lattice type is the three-dimensional network of only tridentate silicon. The ideal Si sublattice of this structure ($x_{Si}=0.375$) with three-bonded atoms is the analog to the diamond lattice with four-bonded atoms[5].

The number of nearest neighbors, their bond distances and the $Si^{Si}Si$ bond angles of the cubic and the trigonal HP modifications of $BaSi_2$ are compared in Table 2. The nearest distance between the three-bonded Si atoms is 245 pm; it is the same in both HP phases. The $Si^{Si}Si$ bond angle in the trigonal phase is larger than in the cubic phase.

Table 2. Nearest neighbors, bond distances, and $Si^{Si}Si$ bond angles of the two high-pressure modifications of barium disilicide.

	Cubic	Trigonal
Ba neighbors	6 Ba 411 pm	6 Ba 405 pm
		2 Ba 533 pm
	6 Si 337 pm	6 Si 328 pm
	2 Si 342 pm	6 Si 382 pm
Si neighbors	3 Si 245 pm	3 Si 245 pm
	3 Ba 337 pm	3 Ba 328 pm
	1 Ba 342 pm	3 Ba 382 pm
∢ SiSiSi	$118.2°$	$111.6°$

In a very formal interpretation of the structure as $Ba^{2+}(Si^{-})_2$ according to the Zintl-Klemm-Bussmann concept each Si atom would have five valence electrons. Of these, three would be required for bonding to the three Si neighbors. If the two remaining electrons were to act as a "lone pair", the $Si^{Si}Si$ bond angle would approach that of the tetrahedral angle. On the other hand, if they were to participate in the bond system, coplanar triangular groups would be expected. In the trigonal modification the Ba—Ba and the Ba—Si bond lengths (Table 2) are slightly smaller than in the cubic modification. The coordination in the cubic phase is 8:4 (Ba has 8 Si neighbors, Si has 4 Ba neighbors), in the trigonal phase 12:6. Surprisingly, the higher coordination in the trigonal phase is not reflected in its density (Table 1); both the cubic and the trigonal polymorph are 13% more densely packed than the orthorhombic phase.

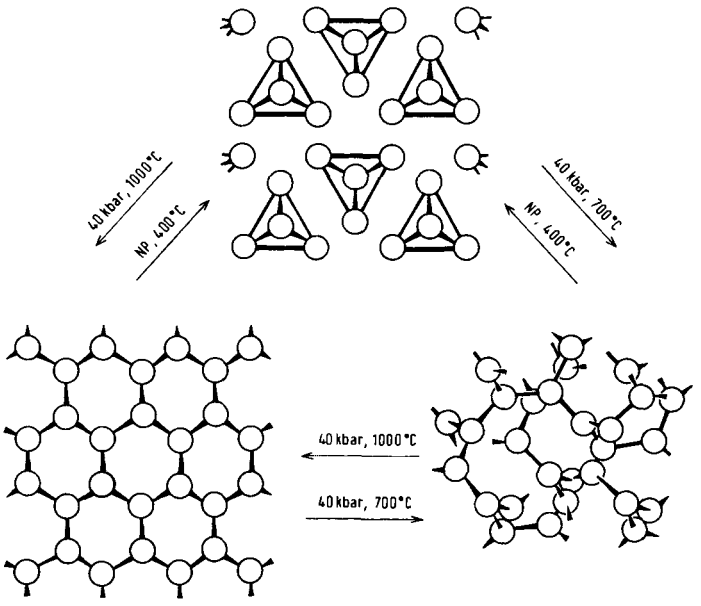

Fig. 1. Transition scheme between isolated Si tetrahedra, corrugated Si layers and three-bonded Si skeleton in barium disilicide.

The relations between isolated Si_4 tetrahedra, corrugated Si layers and the three-dimensional Si network are schematically shown in Figure 1.

The role of cerebroside sulfate as opiate receptor is discussed in an article by *H. H. Loh, P. Y. Law, T. Oswald, T. M. Cho*, and *E. L. Way*. Cerebroside sulfate possesses most of the properties required of an opiate receptor, namely high affinity and the ability to bind stereoselectively. Although these findings still do not allow proof of identity, it is most likely that some interrelationship exists. Cerebroside sulfate is a component of brain tissue, and a partially purified opiate receptor from mouse brain proved to be chemically the same as cerebroside sulfate. Further investigations showed that reduction in the availability of cerebroside sulfate was accompanied by a decrease in analgesic action of morphine and the number of binding sites. [Possible Involvement of Cerebroside Sulfate in Opiate Receptor Binding. Fed. Proc. *37*, 147—152 (1978); 36 references]

[Rd 25 IE]

In cyclophosphazene clathrates the guest molecules are located in a tunnel, the dimensions of which are dependent upon the substituents of the host molecule. *H. R. Allcock* surveys this field. The parent molecule *(1)*, which was discovered by chance to act as a host molecule, forms planar aggregates of three molecules at a time. The next layer is twisted in such a way that a tunnel of 4.5—5 Å diameter is formed which can accept, *e.g.*, benzene. *(1)* is suitable for separating mixtures of, say, heptane and cyclohexane as well as *m*-xylene, *p*-xylene, and ethylbenzene. The analog of *(1)* obtained from 2,3-naphthalenediol also forms clathrates; the tunnel has a diameter of 9—10 Å. As shown for compound *(2)* which does not form clathrates, it is the shape of the molecules of this series which is responsible for their properties. [Cyclophosphazene Clathrates—Exploring the Adjustable Tunnel. Acc. Chem. Res. *11*, 81—87 (1978); 33 references]

The identification and regulation of α- and β-adrenergic receptors form the subject of a review by *R. J. Lefkowitz*. Methods for the direct binding of radioactive ligands to α- and β-adrenergic receptors have been developed in the course of the last few years. Radioactively labeled adrenergic antagonists or agonists are used in order to identify receptors in the membrane fractions of catecholamine-sensitive tissues. In the case of β-adrenergic receptors the close relationship between binding and activation of adenylate cyclase simplifies identification. Such direct receptor-binding investigations provide further useful information about the molecular and regulatory properties of receptors. [Identification and Regulation of Alpha- and Beta-Adrenergic Receptors. Fed. Proc. *38*, 123—129 (1978); 87 references]

[Rd 23 IE]

Affinity-labeling of estrogen receptors is the subject of a report by *J. A. Katzenellenbogen*. As shown by competition experiments, estradiol and hexestrol derivatives bearing photoreactive diazocarbonyl or azide groups exhibit receptor-binding activity, and, after irradiation, inactivate the receptor. In unpurified uterus specimens other proteins besides the receptor are labeled. From previously purified specimens a photolabeled product can be isolated which shows all the properties of an estrogen receptor. [Photoaffinity Labeling of Estrogen Receptors. Fed. Proc. *37*, 174—178 (1978); 28 references]

BOOK REVIEWS

Elektrolytgleichgewichte und Elektrochemie (Electrolyte Equilibria and Electrochemistry). Fachstudium Chemie, Arbeitsbuch 5. By *E.-G. Jäger, K. Schöne* and *G. Werner*. Verlag Chemie GmbH, Weinheim—New York, 1977, 1st edit., 308 pp., 64 figs., numerous tables, paper, DM 34.00.

The present volume is part of a comprehensive work intended to provide chemistry students with the necessary fundamentals. Textbooks and workbooks serve as an aid to self-study, tutorials, and practicals.

The introductory text contains a number of basic questions following a short presentation of the problem. The aim is to check whether the student has understood the corresponding section in the textbook. This section is followed by instructions for practical experiments and calculation exercises, the solutions to which are given at the end of the book.

The present volume deals mainly with electro-analytical applications of electrochemical equilibria. Problems of kinetics are only briefly touched upon in the introductory chapter on the fundamentals, where the authors discuss the conductivity of electrolyte solutions, reversible cell potentials, and polarization when a current is flowing, together with experimental methods. The other chapters consider various equilibria (redox, acid-base, complex, precipitation, extraction, and ion-exchange), methods for the determination of equilibrium constants, and the corresponding analytical methods, such as redox titrations, complexometry, and gravimetry.

The book conveys sound basic knowledge. In a few cases the terminology is not quite appropriate: *e.g.* "depolarizer", or "resistance capacity" of a conductivity cell (instead of cell constant). Some definitions could be improved (*e.g.*, not every

cell through which no current flows is in equilibrium). In another place, the wrong impression is given that corrosion depends only on local cell action. It is particularly regrettable in a modern textbook that the IUPAC recommendations for definitions and nomenclature are often ignored. Apart from such minor shortcomings, however, this book should prove a valuable study aid that will find many friends, not least because it is reasonably priced and well presented.

K. E. Heusler [NB 431 IE]

Biophysik—ein Lehrbuch (Biophysics—A Textbook). Edited by *W. Hoppe, W. Lohmann, H. Markl,* and *H. Ziegler.* Springer-Verlag, Berlin—Heidelberg—New York 1977. 780 pp., 640 figs., bound, DM 98.—.

The title of this book, which contains contributions by fifty-two experts, inevitably poses the question: "What is biophysics?" Since animate and inanimate nature obey the same laws, biophysics cannot be understood as a science *sui generis.* However, living processes can be treated physically, just as there are genetic and chemical ways of consideration, and it is as such that biophysics surely wants to be known. Each of these modes of treatment has given birth to its own tools and techniques. Since more and more physicists are turning to biology, and physical methods are used increasingly to understand life processes, there is bound to be an interest in a textbook explaining the mode of thinking and the physical laws and techniques that have decisively contributed to the solution of biological problems and have introduced an eminently fruitful development, though admittedly this is credited to molecular biology rather than to biophysics. The present attempt at writing a textbook on biophysics has unfortunately been unsuccessful, because the basic biological concept is missing. There is no guiding principle that could tie together the many jewels that occur in this book in a clear and logical manner. Without such a thread of Ariadne the reader soon gets lost in a maze of problems that appear to lead an isolated life of their own. The editors must be given the credit of anticipating these difficulties and trying to overcome them. They therefore decided to incorporate "supplementary scientific material" taken from biology in concentrated form, though this was bound to remain a patching-up operation. The core of the book should have been made up of topical problems in biology, and some of these are indeed dealt with. Physics and physical chemistry should then have provided the requisites for describing these topical biological problems in physical and physicochemical terms, for analyzing them, and for making them comprehensible. Only thus would an unfortunate intermixing of physics, chemistry, and biology have been avoided.

The book begins by describing the cell, nucleic acids, and proteins. *Walter Hoppe, Brunner* and *Dransfeld et al.* then describe physical methods, namely X-ray and electron diffraction and light scattering in detail and searchingly—in fact uniquely in this form. It was these methods that elucidated the structure of biological molecules and made possible a study of biology on the molecular level. However, one misses the cornerstones of molecular biology, which are only offered later in Chapters 9 and 10 by *Huber* and *Zillig* as "supplementary scientific material". A possible criticism is the emphasis given to the discussion of various physical methods for the investigation of biological molecules (Chapter 3). For example, IR and more especially Mössbauer spectroscopy are described in greater detail by *Kalvius* and *Parak* than the methods of nuclear magnetic and electron spin resonance. I doubt whether the student will really understand how important these methods were for the elucidation of membrane structure or enzyme catalysis, for example, when reading about resonance spectroscopy. The fundamental Chapter 4 on intramolecular and intermolecular interactions *(Hofacker, Ladik)* reinforces my view that physical and physiochemical aspects are best described by physicists, physical chemists, and theoretical chemists, who would hardly describe themselves as biophysicists. A competent treatment suffices for the demands of the chemists and physicists just a much as it teaches the molecular biologists. I am here including the contributions by *Hans Kuhn* and *Friedrich Dörr* about energy-transfer mechanisms (Chapter 5) and thermodynamics (Chapter 8). These contributions, including the already discussed Chapters 3 and 4, could have been made into an excellent textbook of physics and physical methods for biologists and biochemists. For the reader interested in membrane structure and function Chapter 11 is a source of valuable but not easily digested information. Certain carefully selected examples from Chapter 12 (receptor transduction) and Chapter 13 (photophysics, photochemistry, and bioenergetics) might have merited consideration, but such a degree of heterogeneity is hardly justified. Bioenergetics could have been a central theme, but then the physical principles would have had to be coordinated better with the biological and biochemical phenomena. Photobiology could have been followed by a selective treatment of physical influences on life processes (cf. Chapters 15 and 16), because what hides under the term "biomechanics" (Chapter 14, pages 503—600) are system physiology and engineering applied especially to biological locomotion. Like routine methods (use of isotopes) and special fields such as radiation physics (Chapter 6) this should have been left to relevant handbooks. The up-to-date and readable treatment of the molecular biology of muscle contraction by *Mannherz* and *Holmes* is amiss in this chapter; it ought to have been coordinated with *Huber*'s contribution to reinforce the relationship to molecular biology. The last two chapters, on Cybernetics (Chapter 17 by *Marko, Creutzfeldt* and *Reichardt*) and Evolution (Chapter 18), are undoubtedly part of the central theme of present-day biology. They open up fascinating insights into complex biological systems (for example the flight orientation of flies by *Reichardt*) and the evolution of biological systems *(Hans Kuhn).* (The Eigen theory of evolution is presented by a well-known, already published, popular introduction by *Peter Schuster.*) There was a splendid opportunity here of awakening an understanding of where the boundaries of physical knowledge about nature lie if these contributions had been put at the center of the physical considerations and analysis together with ones about structure and function of biopolymers (proteins and nucleic acids) and membranes as main biological reference points. The whole would then have become better than its parts and not the parts better than the book as a whole.

The editors have made little effort to critically edit and coordinate the individual contributions, and they emphasize this themselves in the preface. Unfortunately, they cannot be praised for this laissez faire attitude. The biologist is going to find it difficult to recognize the relationships to physics, currently so topical, and the physicist and the chemist are going to miss the biological relationships which help them to understand the laws of the make-up and function of living systems, the "logique du vivant" as *François Jacob* puts it. What remains is a mixture of essays about physics, chemistry, and biology, some of which are so good that despite all reservations they can be recommended with good conscience. Sadly, the textbook as such cannot be recommended.

Ernst J. M. Helmreich [NB 420 IE]

Reaction Mechanisms in Organic Chemistry. By *F. Badea.* Abacus Press, Tunbridge Wells 1977. 1st Edit., 701 pp., numerous figs., bound, £ 18.85.

The author attempts to provide a comprehensive textbook on reaction mechanisms, intended mainly for advanced students and postgraduates working on their PhD, and thus to render valuable service in the field of reaction mechanisms.

Part 1 explains the significance of symmetry and different types of bonds (90 pages), Part 2 methods for the elucidation of reaction mechanisms and reactive intermediates (90 pages), and Part 3 (heterolytic reactions) discusses aliphatic nucleophilic and electrophilic substitutions, the analogous reactions of aromatic compounds, and finally elimination and addition reactions (350 pages). The final Part 4 deals with homolytic and pericyclic reactions (120 pages). A subject index closes the book; there is no author index. Problems are given at the end of each chapter, but unfortunately without any indication of their solution. The printing of the reviewer's copy was not of the highest standard.

In view of the rapid development of the field of reaction mechanisms, it is doubtful whether a textbook of this kind could be satisfactorily written by a single author, for it is almost impossible for any single person to give a balanced and competent judgment in all parts of the field. In this book there are very diverse judgments, which incidentally do not correspond to the trend found in the primary literature. For example, the description of 1,3-dipolar cycloaddition (3 pages) hardly gets beyond the definition of the possible 1,3-dipoles. In the reviewer's opinion, however, the greatest shortcoming of this book is that the very numerous literature citations (and thus the arguments in the text) hardly ever reach 1974 and almost never go beyond it. For a "revised up-dated English version" of the Romanian edition of 1974 a more intense rewriting and supplementation would have been desirable.

Jürgen Sauer [NB 411 IE]

Vibrational Spectra of Organometallic Compounds. By *E. Maslowsky, Jr.*, John Wiley & Sons, Ltd., New York—London 1977. 1st Edit., xii, 528 pp., numerous figs. and tables, bound, £ 18.75.

Enormous advances have been made in organometallic chemistry in the last 25 years, and accordingly the number of important textbooks, monographs, and research reports is already legion. It is therefore all the more surprising that up to now there has been no collection and clear description of the IR and Raman spectroscopy of organometallic compounds. This is also surprising because IR and Raman spectra often provide the decisive proof for the structure of these compounds. This book is an attempt to close that gap. It is assumed that the reader is already familiar with the theoretical principles of vibrations and with problems of practical measurement. The results of other physical methods, such as X-ray structure analysis, NMR spectroscopy, and electron diffraction are always reported briefly if they are important for the interpretation of the vibrational spectra.

According to the Foreword, all compounds with direct metal-carbon interaction are considered, and the concept of a metal is thereby stretched very widely: it ranges from boron and silicon through the subgroup elements up to phosphorus. Purposely excluded, however, are the metal carbonyls and metal cyanides, unless other metal-carbon bonds exist there apart from M—CO or M—CN bonds. This limitation seems reasonable, since several reviews have been devoted to these compounds in recent years. However, it is not easy to see why metal-carbene and metal-carbyne complexes should not have been included.

The book is divided into three sections. Alkylmetal compounds are treated in the first section and compounds with unsaturated acyclic groups in the second. The third section is devoted to the metal derivatives of unsaturated cyclic organic ligands.

The internal arrangement of the book and presentation of the theme are very clear and easy to understand. Compounds of complicated structure are clarified by structural formulas. It is most welcome that the IR and Raman spectra of important complexes are not only described but also illustrated. The very many tables scattered throughout the text and the more than 2000 references (literature considered up to April 1976), together with the index—brief but very clearly set out—make the book equally suitable as a reference work. In this respect it is rather regrettable that there is no author index.

By and large the text has been carefully composed. A number of printing errors are distracting but do no appreciable harm. The book should, however, in no way be regarded as a mere collection of spectroscopic data. The author prevents this by occasionally mentioning controversies over the interpretation of the results or describing gradual approaches to the "truth" often extending over many years. Now and then too the limitations of the method are indicated. Thus, in spite of the rather inflexible material a book has arisen that reads easily for long stretches, and which will be of much value to the organometallic specialist, but can also be recommended to the general inorganic or organic chemist.

Helmut Fischer [NB 413 IE]

Elektrokinetische Grenzflächenvorgänge (Electrochemical Interfacial Processes). By *J. Weigl.* Verlag Chemie GmbH, Weinheim—New York, 1977. 1st edit., 196 pp., 98 figs., 10 tables, Reprotext, paperback, DM 36.00.

The electrokinetic or zeta potential plays an important role in colloid-chemical phenomena such as the stability or flocculation of dispersions. Since there is definitely a need for a handy book giving the fundamentals, the experimental methods, and some examples of applications, it is unfortunate that *Weigl*'s book fails to satisfy this need. In the fundamentals, the DLVO theory—the basis of the modern concept of colloid stability—is given only a very perfunctory treatment; it may perhaps be taken as an indication that the name *Deryagin* appears differently every time (but never correctly). It is difficult to see why, in a book published in 1977, the equations for the determination of the zeta potential from the electrophoretic mobility do not conform to SI units. The effect of non-potential-determining ions on the observed zeta potentials is mentioned only incidentally, without examples, and corrections for retardation and relaxation are not even mentioned. The description of the measurement methods is also very brief. Sources of error are not discussed. The book is best at the description of applications (mainly from the paper industry where the author's experience lies), and one can find here a few interesting connections between the zeta potential and other characteristics. Unfortunately, however, the author never mentions essential parameters involved in the determination of the zeta potential, such as the nature and charge of the gegenions and the ionic strength.

The book gives the impression that it was written in a hurry to meet a deadline, which may explain the stylistic shortcomings and the omission of some figure legends. Certain passages extending over pages are taken word for word from

other authors' publications (however, the author forgets the statement on page 46 that the text refers to TiO_2 and gives a misquotation on p. 165). In the references, the authors' initials are sometimes missing; reference 134 is Lehrbuch der Allgem. Chemie without the name of the author or the publisher.

"Reprotext" is the direct photomechanical reproduction of a typescript, and there can be no objection to it if it makes the book inexpensive. However, it calls for a correct typescript. In the present case, the bottoms of the letters often have not come out; one is also put off by the variations in spacing, the irregularities of the left-hand margin, and the consequences of not sticking the text together neatly, so that sometimes the lines are not even horizontal Blanks very often occur within words. It should have been the publishers' duty to eliminate such avoidable blemishes before printing. The back of the book broke after a single reading.

It is impossible to recommend this book.

H.-P. Boehm [NB 426 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

Polymer Sequence Determination, Carbon-13 NMR Method. By *J. C. Randall.* Academic Press, London 1977. xi, 155 pp., bound, £ 11.70.—ISBN 0-12-578050-8

Akute Syndrome. Edited by *A. Anglhardt* and *H. Lommel.* Vol. 3 of the series "Methodische Fortschritte im medizinischen Laboratorium".—Verlag Chemie, Weinheim 1978. ix, 293 pp., bound, DM 62.—.—ISSN 0303-6278

A Coordination Chemist's View of Surface Science

By E. L. Muetterties[*]

Structure, a necessary element for an understanding of chemistry, has not been precisely defined, in molecular detail, for the surface species formed at a solid-gas interface. Dramatic advances in theory, instruments and experimental procedures have now provided the surface scientists with an impressive arsenal of structural and electronic probes. Chemistry in the form of the classic displacement reaction can also provide an insight to the structure of surface compounds. In fact, many of the experimental procedures and systematics of the coordination and organometallic chemist can be effectively utilized in a complementary fashion with surface physics techniques to gain a more definitive picture of chemisorption states and or reactions at a surface.

1. Introduction

A molecular understanding of chemical processes that occur at surfaces is essential to the advancement of science and technology in many diverse areas of surface science such as adhesion, corrosion, electrochemistry, catalysis and soil chemistry[1a]. Despite major theoretical and experimental advances during this century, especially in the last fifteen years[1b], the chemisorption process at a gas-solid interface remains a somewhat vaguely defined phenomenon in a structural context. Lack of a single definitive and general structural technique for the chemisorbed states has been and is still the major reason why a more precise molecular definition of chemisorption processes has not been realized. There are no precise analogs in the surface scientist's repertoire of physical techniques of the molecular chemist's three-dimensional X-ray analytical and nuclear magnetic resonance techniques, which so accurately and quickly limn the essential structural and stereochemical details of molecules. Advances in surface physics techniques have been especially impressive during the last decade notably in low energy electron diffraction[2] and angle resolved photoemission spectroscopy[3]. However, none of these techniques has the incisive and general applicability for full structural determination of the molecular chemists' three-dimensional X-ray analysis. Accordingly, surface scientists often must rely upon a complimentary set of data from many different physical measurements in order to infer the full molecular features of the chemisorbed state. Some of these techniques can be *relatively* simple in application and others presently require a dedicated experimental arrangement. Important among the former set are Auger spectroscopy[4], which can yield an elemental analysis of a surface, low energy electron diffraction[2] which can sense the ordering of metal atoms and of chemisorbed species at a surface, and mass spectrometry which samples the gas phase above the surface. An important new technique among the "dedicated" set is high resolution energy loss spectroscopy (HRELS)[5] which analyzes electrons inelastically scattered from a surface and which can provide vibrational information about chemisorbed species. A lexicon of common surface physics techniques is presented in Table 1.

Presently, a *structural interpretation at the molecular level* of data obtained from surface physics techniques is a nontrivial experimental and theoretical exercise. For example, low energy electron diffraction (LEED) data are difficult to interpret in precise and full structural detail at the molecular level. There are five distinct processes that must be considered in the

[*] Prof. Dr. E. L. Muetterties
Department of Chemistry, Cornell University
Ithaca, New York 14853 (USA)

Table 1. Lexicon of common surface physics techniques.

Technique	Principle	Application	Sensitivity (monolayer)	Penetration depth
Auger electron spectroscopy (AES)	Stimulated (typically electron stimulated) emission from valence or inner shell creates an excited ion. Auger electron is emitted in the deexcitation of the excited ion	Analysis of surface composition and electronic features	10^{-2}—10^{-3}	1—7 layers
Ion scattering spectroscopy (ISS)	Energy loss for rare gas ion scattering from a surface reveals the mass of the surface atom involved in the scattering process	Analysis of surface composition	$\approx 10^{-3}$—10^{-4}	1 layer
Secondary ion-mass spectroscopy (SIMS)	Ion (typically rare gas ion) stimulated secondary ion emission	Analysis of surface composition	$\approx 10^{-6}$	1 layer
Ion neutralization spectroscopy (INS)	Incident low-energy ions are neutralized by electron transfer from surface atoms which then stimulate an Auger electron emission	Analysis of surface composition and valence band structure	10^{-2}	1 or >1 layer
Electron spectroscopy for chemical analysis (ESCA)	X-ray stimulated electron emission from valence and inner shells of surface atoms	Analysis of surface composition and of surface atom oxidation states	$\approx 10^{-1}$—10^{-2}	1—7 layers
Ultraviolet photoelectron spectroscopy (UPS)	Ultraviolet radiation stimulated electron emission from valence shell of surface atoms	Electronic structure and orientation of chemisorbed molecules	10^{-1}—10^{-2}	1—3 layers ≈ 1 layer in synchroton radiation mode
Low energy electron diffraction (LEED)	Elastic scattering of low energy electrons from the surface and the near surface atoms	Symmetry features of surface atom environments, unit cell dimensions, and structural features of the surface	$\approx 10^{-1}$—10^{-2}	1—7 layers
High resolution electron loss spectroscopy (HRELS)	High resolution analysis of energy loss in inelastically scattered electrons from a surface	Analysis of vibrational states	10^{-2}	1—7 layers
Appearance potential spectroscopy (APS)	Programmed escalation of incident electron energy with scanning of the resultant X-rays from the surface	Analysis of surface composition and electronic features	10^{-2}—10^{-3}	1—7 layers

theoretical analysis[6] and a key consideration is the change in the potential function near the surface. Relatively definitive[7] structural interpretations of diffraction data have been achieved only for the case of chemisorbed atoms on a metal surface[8], and the only "molecular" chemisorptions to receive detailed analysis are those of acetylene on Pt(111)[9] and carbon monoxide on Ni(100)[10]. With recent experimental and theoretical advances[3], angle resolved photoemission spectroscopy can be employed to assess the orientation of chemisorbed molecules like CO, NO and CN on a "flat" metal crystal. Extensions to molecules of greater complexity are feasible but nevertheless more difficult. The low energy electron diffraction and angle resolved photoemission studies are complementary, with the former primarily sensitive when operated in the normal incidence mode[11] to distance parameters (distance between metal surface layer and the center of gravity of the chemisorbed molecule) and the latter very sensitive to the orientation of the chemisorbed molecule with respect to the metal surface plane. Both techniques have identified the same basic structures for sulfur atoms on Ni(100) (sulfur on four-fold sites within bonding interaction of four nickel atoms)[12, 13] and carbon monoxide on Ni(100) (carbon sitting atop individual nickel atoms)[10, 14]. Other techniques, now under study and development, should dramatically improve the arsenal of surface techniques, *e. g.* elipsometry for electronic and vibrational analysis, acoustical spectroscopy, surface sensitive (Auger-like electron) extended X-ray absorption fine structure, electron stimulated desorption, reflectance infrared and small angle neutron scattering.

Surface chemistry in its state of molecular development only ten or so years ago was rather analogous to the state of coordination chemistry at the turn of the century when no spectroscopic or diffraction techniques of structural significance were available. At that time, *Werner* in Germany[15] and *Chernyaev* in Russia[16], by utilizing chemistry that included displacement reactions, began to correctly infer stereochemical and structural features in coordination complexes. (This comparison is really invalid or at least unfair because the coordination complexes were susceptible to isolation and elemental analysis, and because resolution of enantiomers was feasible and was effectively utilized in the stereochemical studies.) There can be a similar utilization of the displacement reaction[17] in surface science, and, with the modern ultra-high vacuum chamber, the chemistry of individual single crystal metal faces can be explored. The displacement reaction, guided by analogy to established coordination chemistry, and of course supplemented with data derived from surface physics techniques could assist the advancement of the state of molecu-

lar structural knowledge of chemisorption processes. The potential of such a combined chemical and physical approach to surface science is described in this article. Analogy to coordination chemistry is utilized to structure the discussion and to incisively define critical regions where the analogy itself breaks down.

2. Terminology and Boundary Conditions

All the surface chemistry described below is referenced to a rather idealized world of surface science, a world far removed from the physical conditions that prevail under most practical surface science conditions. It is the world of ultra-high vacuum, $\approx 10^{-9}$ to 10^{-12} torr, the interface between a metal and a near vacuum. Experimentation in this area has been enabled by dramatic advances in vacuum technology[18]. There is a sound scientific basis for beginning with this idealized world. A pristine metal surface is a well defined starting state. The conditions which are essential to chemical studies of a clean metal surface can be realized only with the modern ultra-high vacuum chamber, and techniques, especially those based on electron diffraction and electron or photon spectroscopy, can be routinely applied to the chemisorbed state under these conditions. Although the extreme reactivity of a metal surface requires the clean ultra-high vacuum conditions, the chemistry of the surface can be explored under more conventional conditions. With a cell that may be lowered and raised so as to isolate the metal crystal from the vacuum chamber[19], it is feasible to effect chemical reactions, for example catalytic reactions, at the same metal surface under atmospheric or superatmospheric conditions and at virtually any temperature without major contamination of the main vacuum chamber and then later reexamine the metal crystal under high vacuum conditions by surface physics techniques[20]. The small area of the crystal face (about 0.5 cm^2) presents no problem today for the chemical studies because modern gas chromatographic and mass spectral techniques need only infinitesmally small amounts of material. The metal may be in virtually any physical form, a film, dispersed particles on a support, or a single crystal. Single crystals offer distinct advantages. A systematic investigation of the surface chemistry of the individual low Miller index faces as well as the high Miller index faces can identify the surface sites of low and high reactivity (see Fig. 1). It is also possible to selectively block different sites with foreign atoms as a further check of reactivity sites. The gap between ultra-high vacuum surface science and "real world" surface science can be and is being bridged today[21].

Chemisorption processes at metal surfaces typically are divided into two major groups: (i) associative processes in which there is no fragmentation of the molecule and (ii) dissociative processes in which bonds in the molecule are broken on chemisorption to give chemisorbed species that are molecular fragments. The paradigmatic dissociative process is that of chemisorption of hydrogen on transition metal surfaces to give hydrogen atoms which are bonded to metal atoms, *i.e.* to form metal-hydrogen bonds. The partitioning of chemisorption processes into associative and dissociative processes faithfully follows surface science terminology but the terms may convey to chemists a different and improper aspect of reaction mechanistic information. Unfortunately, the coordination chemist characteristically employs the terms dissociative and associative quite differently in a reaction mechanistic context[22].

For the individual classes of chemisorption, I shall employ as a partitioning scheme the types of reactions established in coordination and organometallic chemistry and will reference the discussion of surface chemistry to that of the coordination chemistry of zerovalent or low-valent transition metal chemistry.

3. The Surface Experiment

Since there will be extensive reference to the displacement reaction using metal single crystals in an ultra-high vacuum chamber, a brief description of equipment and procedure is presented here.

The single crystal of the desired orientation may be shaped[23] from a large crystal to the appropriate dimensions, *e.g.* a 5 mm diameter disk with a thickness[24] of about 1 mm and polished by a combination of mechanical, electrochemical and chemical procedures. The orientation is checked with the Laue X-ray diffraction pattern. If for example, the desired surface is a (111) face of a hexagonal close packed metal, the vast majority of the metal atoms will, in fact, reside in a pseudo-hexagonal environment after appropriate annealing of the crystal in the vacuum chamber. However, the surface is unquestionably heterogeneous. If viewed microscopically, the crystal will clearly display scratches and defects. Also there will be steps (see Fig. 1). The crystal will not be perfectly

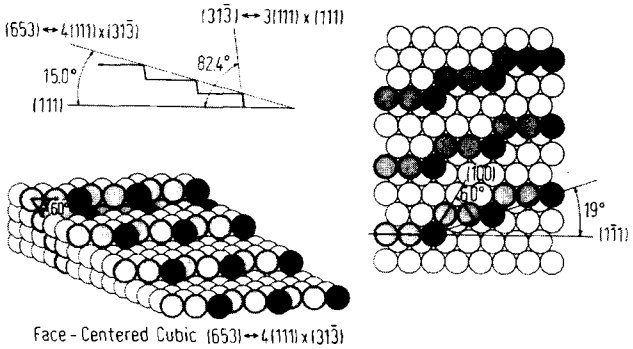

Fig. 1. A representation of a high Miller index plane for a face-centered cubic metal structure in which there are discrete areas described as: (i) "terraces", which are (111) sections with surface metal atoms (unshaded circles) that have a coordination number of nine, *i.e.* nine nearest neighbor metal atoms; (ii) "steps", where the metal atoms (light shading) have a coordination number of seven; and (iii) "kinks", where the atoms (dark shading) at the leading edge have a coordination number of six. (This drawing was prepared by Ms. *Carol E. Smith* at Berkeley.)

flat; a helium beam scattering experiment would show only 30—60 %[25] of the surface atoms to be in the same plane. However, these deviations from ideality do not appear to be severe limitations in the final analysis if there is a systematic chemical study of crystal faces. It is critical to underscore the point that many of the surface physics techniques that directly address the issue of structure focus primarily on the ordered structure and "ignore" the disordered structure—a point that surface scientists explicitly acknowledge but one that the casual reader of surface science literature may tend to either miss or forget.

After the orientation check by X-ray crystallography, the crystal is then welded either directly to metal support rods (the same or different metal) or to a metal (*e.g.* tantalum) backing to which is then welded tungsten wire and attached to insulated supporting rods[26]. The former arrangement provides a means of electrical resistance heating whereby all the current passes through the crystal and the latter an indirect heating arrangement with most of the electrical current passing through the metal backing[27]. Alternative mounting configurations have advantages in specific applications. A photograph of a mounted crystal is shown in Figure 2. The mounted crystal is then attached to the manipulator and inserted typically through the top port of the vacuum chamber (Fig. 3 and 4). The manipulator has rotational and translational degrees of freedom to allow for proper positioning of the crystal for individual experiments.

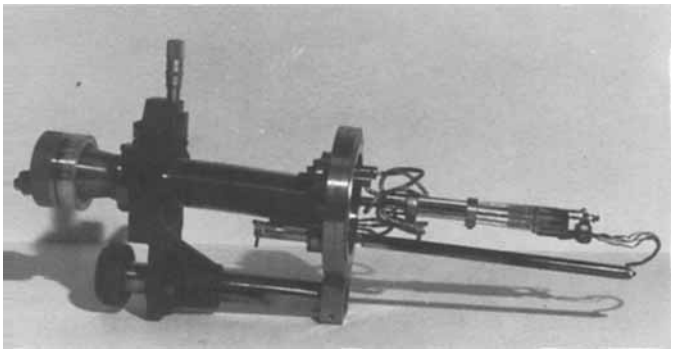

Fig. 2. Photograph of a metal single crystal mounted on a manipulator (from the laboratories of Prof. *Robert P. Merrill*). There are many possible variations in the mounting and peripheral features such as the heating element for the crystal. The arrangement illustrated here has a shielded cup that can be heated by an electron gun and thereby indirectly heat the crystal. Because the typical metal crystal has a very small volume, no significant thermal gradient across the crystal exists even at quite elevated temperatures. By modification, it is possible to cool the metal crystal to temperatures below 65 K. Temperature control and measurement can be quite precise. The depicted crystal manipulator effects controlled translational as well as meridianal and azimuthal rotational degrees of motion of the crystal. (This photograph was kindly provided by Mr. *Herbert Sawin*.)

After opening the chamber to emplace a crystal, an extended chamber reconditioning period is required. A bakeout at 500—550 K for a period of two days is typical. At this point, cleaning of the crystal can begin. The crystal is not only contaminated on the surface but also internally and these trace bulk impurities are potential surface contaminants. Very high initial bulk purities of six "nines" can lead to low surface purities if there is any tendency for segregation of impurities at the surface when the crystal is heated. The number of surface atoms in a metal crystal is about 10^{15} per cm^2 as compared to a bulk density of about 10^{22} atoms per cm^3. If there were 0.0001 % carbon impurity in the bulk and if there were a high degree of segregation at the surface, then the metal crystal could have a full monolayer of carbon on the surface after an annealing treatment. Thus, the metal crystal must be subjected to a stringent purification procedure.

Details of crystal cleaning procedures and the characterization of surface states often are not fully presented in the surface science literature[28]. Crystal cleaning procedures are recipes based on the crystal chemistry, the chemistry and the impurity segregation features peculiar to each metal. A

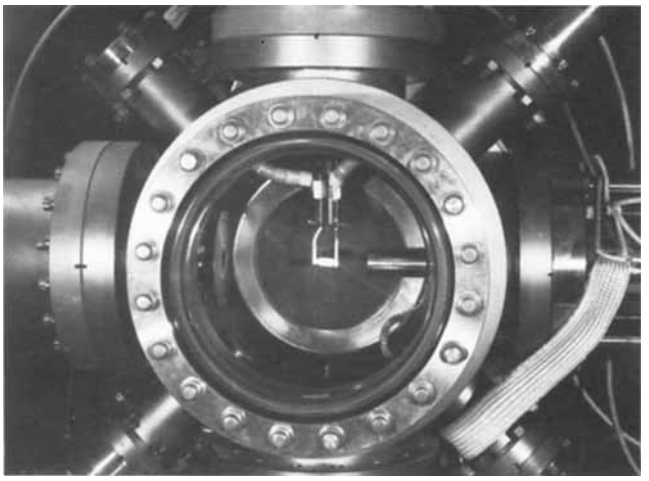

Fig. 3. A close-up photograph of an ultra-high vacuum chamber. In direct line of sight is the viewing port and within the chamber and in the center can be seen the metal crystal. Directly to the left of the crystal is the inlet to the mass spectrometer and to the right is an evaporating element for coating the metal surface by sublimation. To the 1:30 o'clock position is the glancing incidence Auger electron gun, the 4:30 position the leak valve connection and the 7:30 position the ion gun for ion sputtering experiments. To the rear is the low-energy electron diffraction screen and, hidden from view by the crystal, the electron diffraction gun which is at the center and to the rear of the screen. At the top and out of view is the crystal manipulator. (This photograph was kindly supplied by Prof. *G. A. Somorjai*.)

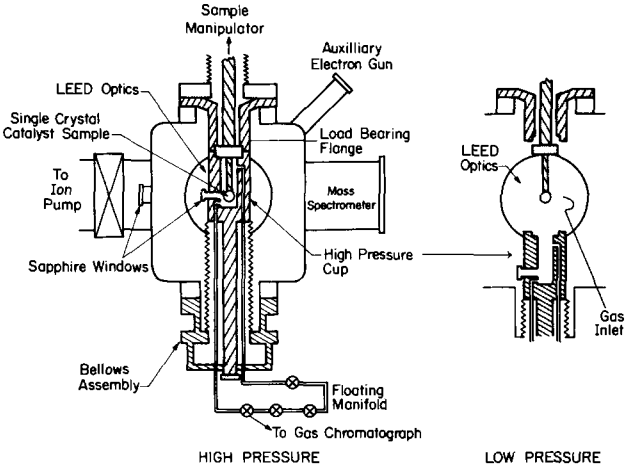

Fig. 4. A schematic drawing of a vacuum chamber, equipped with an isolation cell, and the peripheral equipment (courtesy of Prof. *G. A. Somorjai*). To the left is the schematic of the high pressure configuration and to the right the high vacuum configuration with the isolation cell lowered.

conventional cleaning procedure consists of ion (charged argon ion) sputtering of the surface at some temperature whose upper limit is set by phase transitions or the melting point of the metal and impurity segregation characteristics and whose lower limit is set by impurity atom mobility. For example, the major impurities in nickel are sulfur and carbon. Essentially all the sulfur and some of the carbon can be removed by argon ion bombardment at 1000 K. Because the carbon has a substantial bulk solubility at 1000 K, it is not quickly removed by sputtering at these temperatures. Surface segregation is however substantial at 680 K and this is the optimal temperature for carbon removal. Total cleaning time for nickel is about twelve to twenty-four hours and although minor traces of carbon may remain in the bulk, the surface will be essentially clean.

Surface purity is established by an Auger analysis[4] in which high energy electrons (1—5 keV) are directed at the metal crystal at grazing incidence angles or a normal incident angle (the conventional configuration of the low energy electron diffraction experiment)[29] (Fig. 5). The ejected electrons in this experiment have a relatively short mean escape depth, *ca.* 5—20 Å, so that the analysis is largely a surface elemental analysis. Figure 6 shows an Auger analysis of a carbon-doped nickel(111) surface. The Auger analysis for many elements can be very sensitive but is only semiquantitative (factor of two at best) as commonly applied[30].

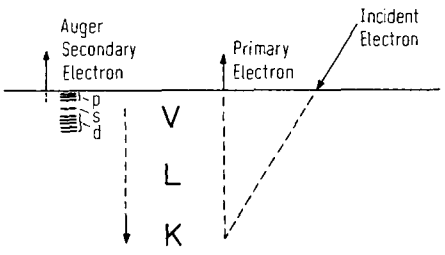

Fig. 5. A schematic representation of the Auger experiment. A beam of electrons or X-rays (1—5 keV) is directed at a surface. Electrons in the inner levels of an atom may be ejected if their binding energy is less than those of the incident beam. An electron vacancy created by this stimulation can be filled by a process in which an electron in a higher level drops into the vacancy. The energy released in this transition can be transferred to another electron (same or a different atom), which if its binding energy is less than the deexcitation energy transferred to it may be ejected into the vacuum. This secondary electron is the Auger electron and it has an energy characteristic that is a primary function of energy level separation in the ion. Thus an energy analysis of the emission electrons provides an elemental analysis of the surface. The emission escape depth of the Auger electron is a function of the energy and ranges from 1 to 7 atomic layers. The energy (energy shift) and the line shape (intensity *vs.* energy) can, in principle, provide electronic information about the environment of the atoms.

After a clean surface has been obtained and also defined by the Auger experiment, the surface must be annealed to correct surface irregularities that resulted from the crystal preparation and from ion bombardment[31] in the cleaning process. For nickel metal, an annealing at 1000 K for about one hour is usually sufficient as judged by the sharpness of the low energy electron diffraction spots and the lack of diffuse background in the diffraction pattern.

At this point, with a clean, oriented crystal face, the chemisorption experiment can begin; but before describing the chemisorption experiment a few comments about the vacuum and the critical pumping scheme would be in order. The vacuum chamber may be evacuated with a diffusion pump provided that efficient cold traps separate the pump and the chamber, otherwise hydrocarbon vapor would contaminate the vacuum system. A high-efficiency ion pump and a titanium sublimation pump are frequently employed, whereby vacuums in the 10^{-10} to 10^{-11} torr range can be attained. At 10^{-10} torr, the major gaseous species are usually H_2 and CO. Unfortunately, chemisorption of H_2 and CO are significant processes on metals like nickel at these pressures. Hence the metal surface will be "clean" at such fluxes for a period of about 60 minutes assuming a unitary sticking coefficient for the residual gaseous impurities. It is highly desirable to further reduce this background pressure because the lifetime of the "clean" surface would be raised and because the study of displacement reactions would be simplified. Reduction of H_2 and CO background to the nondetectable (mass spectrometric)

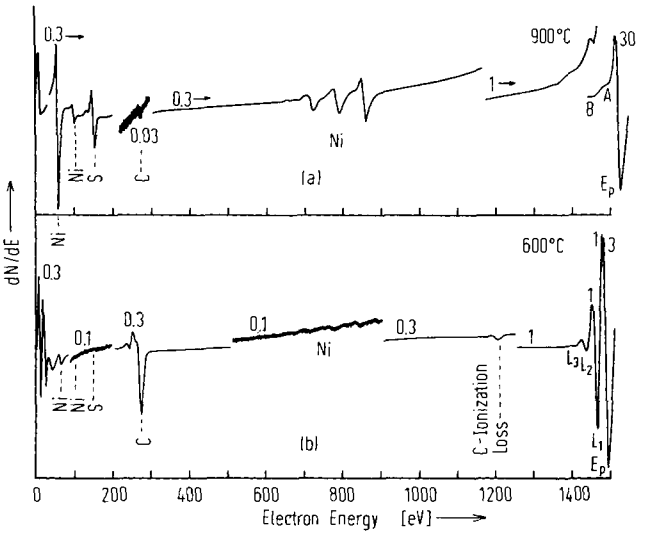

Fig. 6. Auger spectra from a nickel(111) surface, using a cylindrical mirror analyzer, which illustrates the phenomenon of impurity segregation in metals. The nickel specimen had been doped with carbon and there was a small sulfur impurity. a) This Auger spectrum is essentially that of a pure nickel surface at 900 °C, the carbon impurity atoms are largely in the bulk. b) At lower temperatures, 600 °C, there is a carbon segregation at the surface. The numbers 0.3, 0.03, *etc.* refer to sensitivity settings. The loss peaks L_1, L_2 and L_3 (plasma losses) are equally separated ($\approx$29 eV apart). (The spectra were kindly supplied by Prof. *J. Blakely* (cf. *H. R. Pati, J. M. Blakely*, J. Appl. Phys. *45*, 3806 (1974).)

level requires some type of cryogenic pump or a liquid nitrogen-cooled sublimation pump, which coupled in parallel with a turbomolecular pump is an excellent pumping arrangement in terms of speed and effective vacuum. A good turbomolecular pump can quickly reduce the pressure in a chamber to 10^{-9} torr, at which point the cryogenic pump can then preside to further reduce pressure to the 10^{-11} to 10^{-12} torr level. This pumping configuration although not common today may be so in several years.

In the chemisorption experiment, the reactant molecule is slowly introduced through a leak valve from a glass or metal manifold into the chamber through a hollow metal needle[32] directed at the crystal so as to minimize chamber contamination; alternatively an isolation cell may be employed to maximally limit chamber contamination. For less than a monolayer coverage of the metal crystal face, the exposure times required are a function of the flux of the molecule being introduced and the sticking coefficient for the molecule on the metal. With a near unity sticking coefficient, exposure times of 10—30 seconds are sufficient with quite low fluxes (10^{-9} to 10^{-10} torr pressure). This experiment is monitored with an ionization gauge and a mass spectrometer and optionally by the low energy electron diffraction pattern. The diffraction pattern has diagnostic value in that ordering of the chemisorbed layer usually will be evident immediately and, if not, the increase in background is a qualitative measure of the extent of coverage (Fig. 7). Care must be taken in electron scattering experiments to ascertain whether the electron beam itself may be affecting the structure of the chemisorbed species; the electron beam can damage the surface species. Auger electron spectroscopy provides the semiquantitative elemental analysis of the surface relative to the metal itself. At this point, a thermal desorption experiment, with the metal crystal face turned toward the inlet to the mass spectrometer, qualitatively measures the thermal reversibility

of the chemisorption process. In a reversible process, there is a regeneration of the clean metal surface and volatilization of the original molecule which can be so identified by its mass spectral pattern. If the thermal reactivity of the chemisorbed molecule is high relative to a molecular desorption process, the mass spectral analysis of gaseous desorption products will delineate the volatile decomposition products and an Auger analysis of the resultant surface will define the residual contaminant elements and their relative concentrations. The thermal desorption process[33-35] also can be assessed semiquantitatively so as to establish the heat of the desorption process and the order of the desorption process through a study of the desorption profile as a function of heating rate.

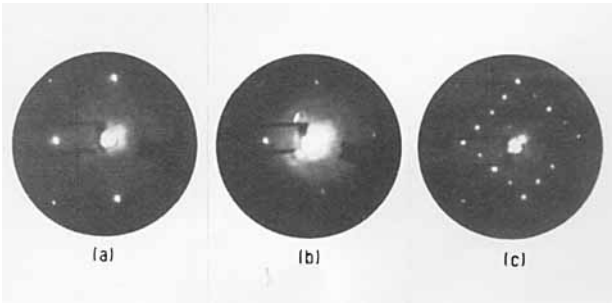

Fig. 7. a) A low energy electron diffraction pattern for a clean palladium(100) surface. The strong central spot is the zero level spot; three of the four first order spots can be clearly seen. b) Chemisorption of carbon monoxide at less than 0.5 monolayer yields a disordered chemisorption state on this palladium surface as shown by the much higher level of background in the pattern in the center; close inspection will reveal hazy higher order spots which demonstrate that there is some ordering of the carbon monoxide molecules under these conditions. c) Diffraction pattern for a half monolayer of CO on the Pd(100) surface. The pattern can be indexed as a centered (4×2) pattern rotated by 45°. This system was originally described by *J. C. Tracy* and *P. W. Palmberg*, J. Chem. Phys. *51*, 4852 (1969). (These photographs were kindly supplied by Dr. *S. D. Bader*, Argonne National Laboratory and Prof. *J. Blakely*, Cornell University.)

In a displacement reaction, the following is the ideal protocol: The molecule to be displaced and the displacing molecule should contain at least one element not common to the other so that the Auger analysis of the surface before and after attempted displacement has an incisive qualitative significance[36]. Ideally, the initial molecule should be chemisorbed on the metal surface with the metal crystal closed off from the major chamber by the isolation cell. With the metal crystal so isolated from the main chamber, the main chamber may be "lightly" preconditioned with the displacing molecule and then thoroughly evacuated. This procedure will maximize the possibility that the displaced molecule is generated from the metal crystal face rather than from the far reaches of the vacuum chamber. Then, the isolation cell may be removed and the introductory gas needle repositioned close to the metal surface. As the displacing gas is introduced through the needle, the system is monitored by mass spectrometry for detection of the original molecule if it is displaced. Finally, an Auger elemental analysis of the surface may be performed. In this manner, a semiquantitative analysis of the displacement reaction can be achieved. The displacement reaction may be effected at any temperature that is less than the temperature of molecular desorption or of some irreversible surface reaction. Because surface temperatures can be minimized in displacement reactions, this chemical probe should be a more general one than thermal desorption; the problem of thermal reactivity can also be minimized[36].

For the nonexpert, a measure of practical experimental time scales is noteworthy. The time required for a chemisorption experiment (after a clean surface has been achieved), the critically associated physical analyses (Auger and diffraction experiments) and a thermal desorption or chemical displacement reaction is about two hours. If, for example, a nickel(111) crystal is contaminated with carbon after these experiments, another 5—12 h of crystal purification procedure may be required. Practically speaking, the number of experiments per week per chamber is about three to seven for hydrocarbon-nickel(111) reactions. This number would be larger for iridium or tungsten which are easier to clean and substantially lower for iron which is extremely difficult to clean.

4. Classes of Chemisorption at a Metal Surface and a Chemical Approach to Characterization of these Classes

4.1. The Main Classes

Within the three main classes of chemisorption processes, associative, dissociative and polymerizative, there are many potential subclasses that are differentiated by reversibility, general structural features and molecular rearrangements[36]. All these classes and subclasses have their analogs in coordination chemistry[36]. I discuss first the three main classes of chemisorption reactions.

4.2. The Simple Associative Reaction Class

The conceptually simplest class of chemisorption processes is an associative and thermally reversible one in which the molecule is bound to one or several surface metal atoms with σ or σ-π bonds. For example, carbon monoxide chemisorbs on the (111) crystal face of platinum, and angle resolved photoemission data[37] for the platinum and nickel(111) cases are best interpreted in terms of a more or less perpendicular orientation of the CO molecule with respect to the surface with metal-carbon not metal-oxygen bonding—*i. e.* structural and stereochemical features that would be anticipated by analogy to coordination chemistry. It is not known whether the carbon atom is centered on a metal atom (terminal position) or between two or three metal atoms (bridging position); all three possible stereochemistries, the terminal and two bridging positions are known in molecular metal carbonyl clusters (see Fig. 8). Chemisorption of carbon monoxide on platinum or nickel is thermally reversible. On heating a nickel crystal (111 orientation) with chemisorbed CO, the desorption of CO has been detected by the sudden pressure increase, and confirmed by mass spectroscopic analysis, at *ca.* 440 K. The desorption process, a first order process, yields an *upper estimate* of the Ni—CO bonding energy of about 25—30 kcal/mol which is very close to the average Ni—CO bond energy in $Ni(CO)_4$[36].

To illustrate the potential of the chemical approach to surface science consider the specific example of acetonitrile chemisorption. Acetonitrile is a molecule characterized in transition metal coordination chemistry as a relatively weak ligand[38]; it is a weak σ donor and π acceptor. In contrast, CO, a weak σ donor but strong π acceptor ligand, is a relatively

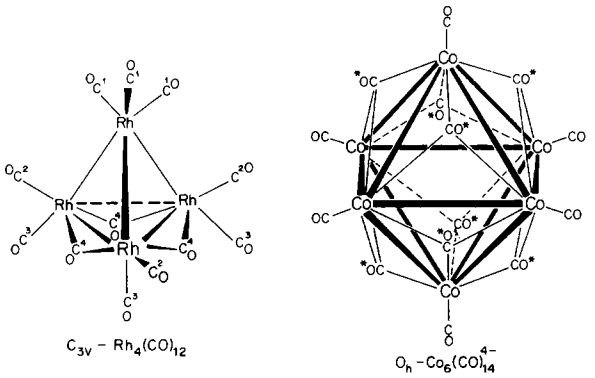

Fig. 8. Molecular geometry of the clusters $Rh_4(CO)_{12}$ and $Co_6(CO)_{14}^{4-}$, which, respectively, have idealized C_{3v} and O_h symmetry. In the former, there are four types of CO environments denoted by superscripts. One set comprises bridging carbonyl groups, superscript 4, which are C-bonded to two rhodium atoms. In $Co_6(CO)_{14}^{4-}$, there are six equivalent terminally bonded CO groups and eight triply bridging CO groups that are centered over the faces of the Co_6 octahedron. For crystallographic details see *C. H. Wei, G. R. Wilkes, L. F. Dahl*, J. Am. Chem. Soc. *89*, 4792 (1967); *V. G. Albano, P. L. Bellon, P. Chini, V. Scatturin*, J. Organomet. Chem. *16*, 461 (1969).

strong field ligand for zerovalent or low valent metal atoms. This characterization of CH_3CN and CO in coordination chemistry is nicely reflected in metal surface chemistry. For example, CH_3CN is weakly chemisorbed on the Ni(111) surface at 300 K and is reversibly desorbed at 360 K[36]. The estimated *upper* limit bond energy for the surface CH_3CN—Ni bond is 18—22 kcal/mol, a value substantially lower than that for carbon monoxide[36,39]. Most importantly, it has been shown that carbon monoxide easily displaces acetonitrile from the nickel surface, a process monitored by mass spectroscopy to show that the acetonitrile is actually displaced as the CH_3CN molecule. Auger analysis demonstrated that the resultant surface was free of nitrogen (CH_3CN) after the CO displacement reaction[36,39].

Another type of chemical experiment demonstrated that CH_3CN was not rearranged to CH_3NC in the chemisorbed state on nickel[39]. The isocyanide, CH_3NC, is a very strong field ligand in zerovalent or lower valent transition metal coordination chemistry and in molecular displacement chemistry; isocyanides generally displace CO readily from coordination complexes. As expected then by this analogy, CH_3NC was strongly chemisorbed on Ni(111) and could not be displaced by either CH_3CN or CO[39]. From this finding, it can be concluded that CH_3CN is not rearranged to CH_3NC, or *vice versa*, in these chemisorbed states. This chemical technique of utilizing structural isomers can be exceedingly valuable in establishing qualitative structural and stereochemical information about the chemisorbed state.

The structure of the chemisorbed state for CH_3CN on Ni(111) is not established. It is believed that the molecule is normal to the surface. Low energy electron diffraction studies show an ordered state; there is a (2×2) pattern which indicates that the unit cell of the ordered surface structure is twice that of the nickel surface structure and that in a rotational context the surface structure is aligned with the metal surface structure (Fig. 9)[37]. In principle, an analysis of the intensity

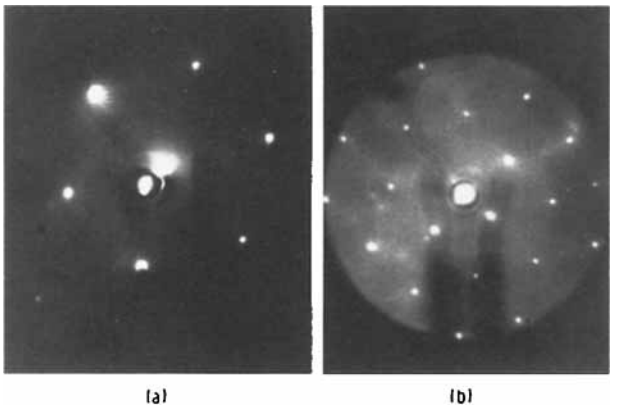

Fig. 9. a) Normal incidence low energy electron diffraction pattern for the face centered cubic nickel(111) crystal face. The large diffuse central spot is the zero order spot. In the ring of six spots, the real three-fold symmetry is qualitatively in evidence for these first order spots. b) (2×2) ordered pattern for CH_3CN on this nickel(111) surface taken at the same electron energy and a *nearly* identical perspective. All the first order nickel spots except two (to the right) can be seen and at half order positions are the additional spots that established the (2×2) pattern. The unit cell of the CH_3CN ordered structure is twice that of the nickel unit cell. The furrow patterns on the right are not fingerprints but are reproductions of the screen texture.

variation of the diffraction spots with change in incident electron energy could provide a structural characterization, but a definitive analysis would be very difficult. In point of fact, the size of the chemisorbed CH_3CN unit cell is a very important piece of information—it virtually requires that the molecule be normal to the surface; it cannot be linear and parallel to the surface. Considering the van der Waals' radii, it is not possible to place a perpendicularly oriented acetonitrile molecule above each nickel atom—but it is possible to place one molecule over every other nickel atom. This would then generate a (2×2) cell (also consistent with the diffraction data would be a displacement of the CH_3CN lattice so as to place the nitrile molecules in bridging positions; see Fig. 10).

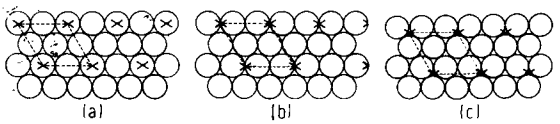

Fig. 10. Superimposed on the close-packed array of spheres representative of the (111) face of nickel are marks (X) that denote three of the symmetry limiting positions for CH_3CN molecules in the (2×2) chemisorbed state of CH_3CN (presumed to be normal to the surface). There is an infinite array of possible (2×2) structures because the only constraint here is a rotational correspondence between the lattices representative of the nickel atoms and of the chemisorbed acetonitrile molecules.

One might ask whether CH_3CN actually dissociatively chemisorbs—to give for example CH_3 and CN chemisorbed species. This specific possibility appears unlikely because it was demonstrated that the chemisorption of cyanogen $(CN)_2$ on nickel(111), where CN chemisorbed species are presumably

formed, is an irreversible process[39]. Cyanogen chemisorbed on a nickel(111) face is very strongly bound and thermally reacts above 770 K to evolve nitrogen gas[39].

An alternative and definitive chemical probe for detection of dissociative chemisorption processes is isotopic labeling. Thus, in the case of acetonitrile, chemisorption of a mixture of CD_3CN and $CH_3{}^{13}CN$ would not be expected to yield any $CD_3{}^{13}CN$ molecules on thermal desorption (a doubly labeled ^{13}CO—$C^{18}O$ experiment can be employed to detect reversible dissociative chemisorption of CO).

This limited and very simple study of CH_3CN and CO chemisorbed on nickel illustrates the potential of the displacement reaction for a characterization of the nondissociative, molecular class of chemisorption. A systematic study based on the displacement reaction should establish a ligand field strength series referenced to the various transition metals. It is anticipated that any nondissociatively or molecularly chemisorbed molecules should be subject to displacement by another molecule, if (i) their heats of chemisorption are not too disparate and (ii) the molecule is not rearranged or extensively rehybridized on chemisorption. In the first qualification, the constraints are not too severe because a thermodynamically unfavorable displacement reaction can be driven readily on a mass action basis in surface chemistry: the partial pressure of the displacing molecule can be varied over an enormous range, *e.g.* a pressure change by six orders of magnitude is a feasible change for an experiment. The second qualification relates to structural information and is nicely illustrated for the case of acetylenes and olefins.

Olefins or acetylenes bound to a single metal atom in a coordination complex are readily displaced by other molecules and the limited calorimetric data indicate that the metal-olefin bond energy is slightly less than the metal-carbon monoxide bond energy in a zerovalent transition metal complex[40]. Chemisorption of either acetylene or ethylene is not an especially exothermic process on copper and is probably endothermic on silver. The bonding of a molecule like ethylene on a copper surface may be a weak σ-π interaction analogous to the Dewar-Chatt-Duncanson model[41] (Fig. 11) of π bound

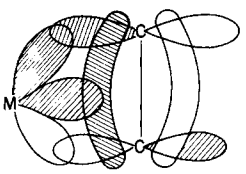

Fig. 11. Qualitative representation of the orbital interaction of the π and π* orbitals of an olefin with the acceptor and donor orbitals of a transition metal as originally presented by *Dewar* and by *Chatt* and *Duncanson* [41].

olefins in coordination complexes. The story for nickel metal is quite different. Acetylene, ethylene, propylene, and 2-butyne are all irreversibly chemisorbed on the nickel(111) face; attempted thermal desorption yielded only hydrogen desorption peaks at about 370 K[37]. Clearly these molecules are not simply bound in a σ-π fashion at single metal atoms at the surface of the metal. There remain two possibilities. These unsaturated molecules may be bound to two or more surface metal atoms by relatively strong σ metal-carbon bonds with an extensive rehybridization at the "unsaturated" carbon atoms of the acetylenic or olefinic molecule. Alternatively, these molecules may chemisorb with concomitant cleavage of C—H bonds to give molecular fragments that individually are no longer susceptible to a displacement reaction. Distinction between these two possibilities remains a major challenge in surface chemistry for it is directed to a very important general class of surface reactions.

It is desirable to effect displacement reactions at relatively low temperatures to avoid complicating side reactions derived from thermal reactivity of the chemisorbed molecule. Some displacements at a metal surface will proceed at room temperature and slightly below. Thus the activation energy for displacement can be as low as 15—20 kcal/mol. If the activation energy for chemisorbed molecules that contain C—H bonds were to exceed *ca.* 40 kcal/mol, the displacement reaction may not be effective because dehydrogenation, cleavage of carbon-hydrogen bonds, of the molecule will have an activation energy of this magnitude. These points raise interesting questions about the mechanistic details of the displacement reaction but there is no substantive information. For the time being, we may envisage a displacement reaction using a localized surface model. If a displacing molecule chemisorbs in a vacant site adjacent to the initially chemisorbed molecule there *may* be a weakening of the binding for the latter—chemisorption of another displacing molecule in another nearby site may then be sufficient for the displacement of the original molecule. For a flat metal crystal, associative[22] (bimolecular) displacement reactions at a single metal site are improbable simply because of geometric constraints.

4.3. The Simple Dissociative Reaction Class

Many diatomic molecules, X_2, chemisorb on transition metal surfaces with scission of the bond and the formation of M—X surface species. This dissociative type of chemisorption process is the invariant mode for hydrogen. Hydrogen chemisorption is reversible and the temperature required for the desorption of hydrogen as the hydrogen molecule is a function of the metal-hydrogen (surface) bond strength. For example, the desorption temperature (flash desorption maximum) is *ca.* 380 K for hydrogen on Ni(111)[39]. Hydrogen chemisorption is an oxidative addition reaction in that there is a small but net electron transfer from the metal to the hydrogen atom to form a "hydride-like"[42,43] ligand. A measure of the electron transfer in a chemisorption reaction can be obtained by a relatively simple electrical measurement in which the *change* in the work function is determined; this is the change in work function on chemisorption referenced to the clean surface. This experiment is an important adjunct to the other analyses of the chemisorption process although the derived information obtained in this fashion is qualitative in character.

Hydrogen chemisorption on a metal is analogous to the reversible oxidative addition of hydrogen to low valent transition metal complexes as in eq. (1), where there is a formal oxidation of rhodium from Rh(I) to Rh(III) with the formation of the two σ Rh—H bonds[44].

$$Rh^{I}Cl(PR_3)_3 + H_2 \rightleftharpoons H_2Rh^{III}Cl(PR_3)_2 \quad (1)$$

Analogous oxidative additions of halogens, oxygen, nitrogen and even carbon monoxide to some transition metal surfaces

are well established but generally these are irreversible, dissociative chemisorption processes. Among these diatomic molecules, an oxidative addition to a metal center in a coordination complex is known only for halogens [eq. (2)]. A dissociative

$$Ni^0(PR_3)_3 + Br_2 \rightarrow Ni^{II}(PR_3)_3Br_2 \quad (2)$$

addition of O_2, N_2, or CO probably would require a minimum of two metal atoms. Hence this type of process may be found only, if at all, for nitrogen and carbon monoxide in additions to dinuclear metal complexes or to metal clusters.

Cyanogen appears to behave like hydrogen; it oxidatively adds to the surfaces of nickel group metals, reversibly in the case of Pt(110) and irreversibly in the case of Ni(111) where N_2 is thermally desorbed at high temperatures leaving carbon on and in the nickel crystal. As a check of the parallel between this metal surface chemistry and coordination chemistry, we have found that thermal decomposition of $Ni(CN)_2$ yields N_2 and $(CN)_2$ whereas $Pt(CN)_2$ forms cyanogen[45]. Oxidative additions of cyanogen to metal centers in zerovalent and low-valent coordination complexes are well established [see *e.g.* eq. (3)[46]]. Thus, there is a qualitative parallel in the

$$(CN)_2 + Pt(PR_3)_3 \rightarrow (R_3P)_3Pt(CN)_2 \quad (3)$$

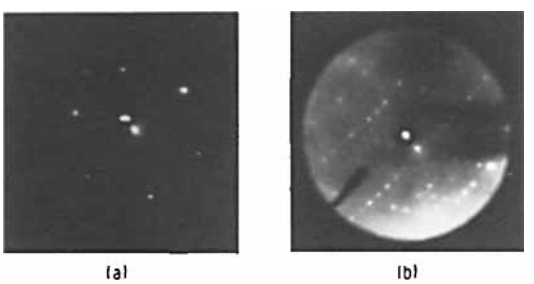
chemical behavior of these metal surfaces and their coordination complexes for this cyanogen chemistry. Nevertheless, a major differentiation between metal surfaces and zerovalent metal complexes is evident in their reactions with nitrogen, and, in some cases (some metal surfaces), with carbon monoxide. Complexation without fragmentation prevails in coordination chemistry and dissociative chemisorption in surface chemistry. It is this very differentiation that is the basis of the relatively facile hydrogenation of nitrogen or carbon monoxide by some metal surfaces, *e.g.* iron. Conceivably, a highly unsaturated metal cluster might be capable of dissociating nitrogen, but such a reaction is relatively improbable. The analogy between metal surfaces and coordination complexes or clusters will be invalid or inapplicable in some chemical areas; the area of CO and N_2 chemistry is one of these *for the more reactive metals like iron.*

Displacement of dissociatively chemisorbed molecules like hydrogen and halogens by another molecule requires a surface recombination of the "radicals". Displacement of hydrogen in surface M—H bonds or of halogen in surface M—Cl bonds into the gas phase as $H^{\bullet}$ or $Cl^{\bullet}$ or as H^- or Cl^- is clearly an improbable event. In a thermodynamic sense, the probability of displacement of dissociatively chemisorbed halogen or oxygen by some molecule is low for most metals but displacement of dissociatively chemisorbed hydrogen, as the hydrogen *molecule*, by another molecule is a different matter. Since the temperature required for thermal desorption of hydrogen is not very high for most transition metals—the maximum in the flash desorption of hydrogen from nickel(111) is *ca.* 380 K—, displacement of dissociatively chemisorbed hydrogen would seem to be a distinct possibility, and parenthetically an important finding, as will be discussed in Section 5.3. To date, our limited exploratory studies have been negative[39]. Exposure of a nickel crystal face(111), partially covered with hydrogen, to carbon monoxide did not seem to lead to desorption of hydrogen nor to a reduction in the flash desorption maximum for hydrogen. Perhaps the partially oxidized (through hydrogen oxidative addition) nickel surface so reduces the CO heat of chemisorption that a substantial weakening of the Ni—H bond is not feasible[39]. A stronger acceptor molecule then seems to be required. Donor molecules should increase the strength of the Ni—H bond *if* in this sector the analogy to coordination chemistry is reasonably valid. Alternatively, the displacing molecule could be selected among the diatomic molecules that strongly and dissociatively chemisorb. Cyanogen, a *quasi* diatomic or halogen-like molecule in that the C—C bond is weak and readily broken, could be an excellent molecule for hydrogen displacement from a surface. Iodine is a reasonable alternative to cyanogen but not a very practical one because of substantial contamination problems[47]. In some of these interactions, there may be a chemical reaction rather than a simple displacement so as to yield HX rather than H_2—in such a variation, the diagnostic value would be retained.

4.4. The Polymerizative Chemisorption Class

The antithesis of dissociative chemisorption is a molecular chemisorption whereby there is polymerization or oligomerization of many or several of the molecules. A possible example is the trimerization of acetylene to benzene. Because this type of chemisorption is not a first order process it is an unlikely event unless there is a high mobility of the molecules on the surface so that two or more molecules can approach and orient in such a fashion as to allow oligomerization to proceed. Polymerization initially at or on the surface and then out away from the surface (not totally on the surface) is however a well-established phenomenon in surface chemistry[48].

Chemisorption of cyanogen on nickel(111) at 300 K does not give an ordered chemisorbed layer[39]. However, warming to 400 K gives a very stable ordered (6×6) structure (see Fig. 12)[39]. Because the C—C bond energy in cyanogen, NC—CN, is low and because CN is a strong field ligand in metal coordination chemistry, initial dissociative chemisorption is a highly probable event. Now CN could be normal or parallel to the metal surface. In binary low-valent transition metal cyanides, the cyanide ion is bonded to two metal ions in



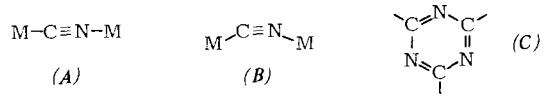


Fig. 12. a) Low energy electron diffraction pattern for a clean (111) face of nickel; b) (6×6) ordered pattern of cyanogen chemisorbed on this nickel face. The centered light spot with a dark halo is from the electron gun itself.

(A) (B) (C)

a linear array (*A*). This geometry is not feasible on a flat (111) metal face but a bent array (*B*) is feasible and plausible. If a parallel orientation prevails for CN on Ni(111), mobility of the CN species on the surface could allow for a polymerization of the CN species to give a bound triazine derivative with the skeletal array (*C*). Two of these units could neatly fit into a (6×6) unit cell or to give a net similar to the layer nets observed in nickel group cyanides, *e.g.* $Ni(CN)_2$.

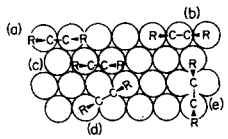
Polymerization of unsaturated organic molecules on coordination to a low-valent metal atom is established in coordination and organometallic chemistry. Trimerization of acetylenes to benzenes is a relatively common reaction and the trimerization of butadiene to 1,5,9-cyclododecatriene[49] is known for zerovalent mononuclear nickel complexes.

5. Subclasses of Chemisorption on a Metal Surface

5.1. Subclasses of Associative Chemisorption: Extensive Rehybridization within the Molecule

Chemisorption of molecules that contain multiple bonds may involve an extensive rehybridization at the multiply bonded atoms. This possible type of chemisorption is appropriately considered with respect to the coordination chemistry for an acetylene molecule, RC≡CR. The simplest form of an acetylene chemisorption would be a σ-donor interaction of a π acetylene orbital and π-acceptor interaction of a π* acetylene orbital with surface metal atom orbitals[50]. This would be fully analogous to the Dewar-Chatt-Duncanson[41] model of the ethylene-metal interaction (Fig. 11), and by analogy would yield a relatively weakly bound molecule which should be susceptible to facile displacement by other molecules such as carbon monoxide. However, acetylene compounds such as acetylene itself and 2-butyne, are very strongly bound on nickel(111)[39], as an example of one well studied metal surface, and are not displaceable from the nickel surface by other molecules[39].

There is an alternative binding of an acetylene if there are two or more adjacent metal atoms. Significant rehybridization of the acetylene carbon atoms may allow σ carbon-metal bonds, minimally two in number per acetylene carbon atom,



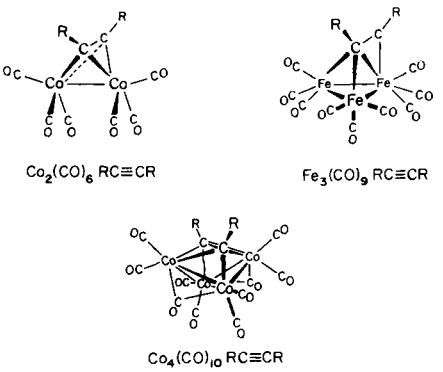


Fig. 13. Possible orientations (a—e) of a molecule RC≡CR on a close-packed metal surface ((111) face). All orientations other than the one centered on a single metal atom yield two or more metal-carbon bonds to the acetylenic carbon atoms.

to be formed (Fig. 13)[51]. This type of acetylene binding is well documented in coordination chemistry for metal dinuclear and cluster complexes (Fig. 14)[51,52]. Rather extensive studies of these polynuclear metal acetylene complexes have demonstrated a robust acetylene binding. Acetylene exchange reactions in these polynuclear complexes does not occur readily whereas such exchange reactions are facile in mononuclear metal acetylene complexes (Fig. 11)[52]. For example, diphenylacetylene exchange with di-*p*-tolylacetylene is extremely slow in the nickel-acetylene cluster complex, $Ni_4[CNC(CH_3)_3]_4(C_6H_5C{\equiv}CC_6H_5)_3$ at 300 K (reaction times of days). In the case of $[C_5H_5Mo(CO)_2]_2C_2H_2$ the exchange is detectable only at temperatures above 370 K[52].

$Co_2(CO)_6\,RC{\equiv}CR$ $Fe_3(CO)_9\,RC{\equiv}CR$

$Co_4(CO)_{10}\,RC{\equiv}CR$

Fig. 14. Molecular structure of three classes of polynuclear metal-acetylene complexes (see discussions in references [51] and [52]). The bond length $d_{C\equiv C}$ in $Co_2(CO)_6RC{\equiv}CR$ is 1.35 Å, in $Fe_3(CO)_9RC{\equiv}CR$ 1.41 Å, and in $Co_4(CO)_{10}RC{\equiv}CR$ 1.44 Å (mean values).

If the surface-coordination chemistry analogy is valid, an unsaturated molecule bound to a metal-surface through extensive σ-bonding of adjacent metal atoms to the (initially) unsaturated atoms, will not be subject to facile displacement by another molecule, at least at 300 K. The activation energy may be high for such displacements; in some cases, the activation energy may be greater than for alternative thermal reactions of the chemisorbed molecule. Possibly the displacement may be more readily effected with a molecule whose dissociative chemisorption raises the level of surface oxidation and decreases the binding energy of the initially bound molecule.

5.2. Subclasses of Associative Chemisorption: Molecular Rearrangement

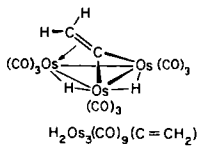
A molecule may chemisorb on a metal surface without fragmentation (dissociation), but through a rearrangement of bonds within the molecule it may yield a chemisorbed species topologically disjoint from the original molecule. For example, an allene $R_2C{=}C{=}CR_2$ molecule may on chemisorption yield an acetylenic bound species ($R_3CC{\equiv}CR$). This possibility can be accurately probed by examining the chemisorption process for the individual isomers. We have exploited this chemical probe so as to demonstrate that CH_3CN and CH_3NC chemisorb as chemically and physically distinguishable isomers on the (111) face of platinum and nickel[39].

All isomerization-based chemisorption processes are definable by a study of isomeric molecules and, if necessary, by isotopic labeling for an ultimate characterization by mass spectroscopic analysis of gaseous desorption products from a displacement reaction.

5.3. Subclass of Dissociative Chemisorption: Molecular Fragmentation in Hydrocarbons

The chemical feature that sharply distinguishes metal surface chemistry from known coordination chemistry, either that of mononuclear or polynuclear complexes, is the ease with which carbon-hydrogen bonds in organic molecules can be cleaved. Dehydrogenation of organic molecules is a thermodynamically and kinetically favorable process for clean metal surfaces, particularly under conditions whereby these reactions are effected in ultra-high vacuum chambers. This type of reaction is incisively documented for the chemisorption of ethylene on tungsten, where dehydrogenation occurs below 300 K to yield chemisorbed acetylene (or an isomer) and then C_2 (carbon) chemisorbed species are formed as the temperature is raised above 300 K[53].

This potentially complex pattern of hydrocarbon chemisorption on a metal surface is of fundamental significance, especially in heterogeneous catalysis. For example, ethylene might chemisorb at 25 °C to give (i) a molecular ethylene complex, (ii) vinyl ($CH{=}CH_2$) and hydride metal surface species, (iii) an acetylene and two hydride metal surface species, or (iv) a carbene or quasiallene species (CCH_2) and two metal hydride surface species. An example of the last possibility established in metal cluster chemistry is illustrated in Figure 15[54].



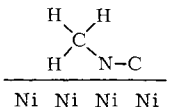


Fig. 15. Molecular structure of the cluster reaction product of ethylene and $H_2Os_3(CO)_{10}$ [54].

Actually, dissociative chemisorption of ethylene on metal surfaces is a relatively common surface phenomenon but the nature of the resultant chemisorbed hydrocarbon is not known.

Only one physical technique is available that will distinguish definitively between a molecular or an associative chemisorption and a dissociative chemisorption in which a molecular fragment or new molecule is generated by one or more carbon-hydrogen bond scissions per molecule. This technique, high resolution energy loss spectroscopy[5], can discern the energy loss in inelastically scattered electrons associated with metal hydrogen bond vibrational excitations. At present this is not a routine technique and cannot be used with facility in general chemical studies of the chemisorbed state. Nevertheless, the four to six instruments, extant or under construction, could answer a number of key scientific questions in metal surface-hydrocarbon chemistry.

If M—H surface species could be displaced as hydrogen gas by a second molecule, then surface science would have a facile diagnostic chemical technique of tremendous general import. One practical problem in accurately assessing hydrogen desorption through a displacement reaction is that when a molecule with any capacity to chemisorb on metals is introduced into the chamber there will be a momentary increase in the hydrogen background—typically, most of this is not associated with desorption from the single crystal of metal but rather from chamber walls or a bit of ion pump indigestion which literally throws hydrogen gas back into the chamber. An isolation cell and cryogenic pumping can minimize this problem; the elegant solution is a molecular beam displacement experiment. Development of such a diagnostic chemical probe is a major objective of our research.

Methyl isocyanide is strongly chemisorbed on the (111) face of nickel[39]. Initial chemisorption probably involves a bonding interaction of the carbon and nitrogen atoms of the isocyanide with several nickel atoms; there is a precedent for such a bonding interaction in a nickel isocyanide cluster molecule, $Ni_4[CNC(CH_3)_3]_7$[55]. In this case, the C—N axis would be above and more or less parallel to the nickel surface as in (*D*) and this then places the hydrogen atoms of the

(*D*)

methyl group proximal to the surface. In coordination chemistry, the close approach of a ligand hydrogen atom to a coordinately unsaturated metal atom can lead to an oxidative addition of the C—H bond[56, 57]. Hence, oxidative addition of a C—H bond to a proximal nickel atom in the methyl isocyanide case should be a relatively favorable process.

CH_3NC is irreversibly chemisorbed on nickel and is not susceptible to displacement by other molecules. With flash heating, hydrogen is desorbed at several temperatures, the lowest of which is 380 K, the characteristic desorption temperature for hydrogen[39]. If the crystal with chemisorbed CH_3NC is annealed at *ca.* 350 K before flash heating, no hydrogen is desorbed at 380 K, though hydrogen desorption does occur at elevated temperatures[39]. These thermal desorption experiments suggest that CH_3NC on chemisorption undergoes a further reaction, a dehydrogenation, either at 300 K or slightly above. Dehydrogenation reactions of ligands are not as common in coordination chemistry as on metal surfaces but they are well documented for low valent and coordinately unsaturated complexes in which a ligand hydrogen atom is in close proximity to the metal atom[56, 57]. Several examples are illustrated in Figure 16.

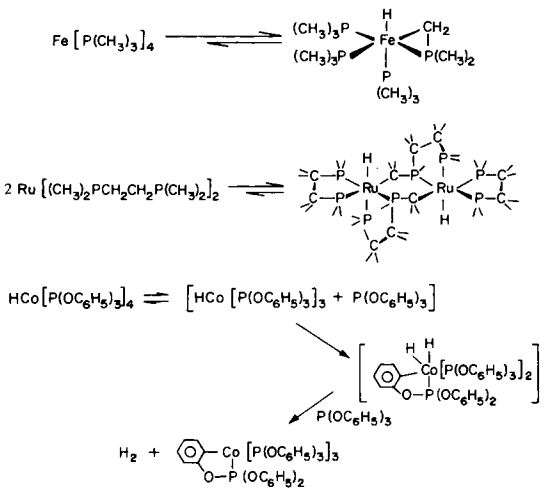

Fig. 16. Examples of molecular metal complexes in which an intramolecular C—H bond addition across the metal center has occurred to yield a metal-carbon and a metal-hydrogen bond. (For a more complete discussion, see the reviews by *Parshall* [56] and by *Webster* [57].)

Any chemisorption of an unsaturated hydrocarbon or hydrocarbon derivative that places carbon-hydrogen bonds close to surface metal atoms is apt to be accompanied by a cleavage of these carbon-hydrogen bonds. In the acetonitrile chemisorption on nickel, the perpendicular alignment of the nitrile places the carbon-hydrogen bonds of the methyl group sufficiently distant from the surface nickel atoms that C—H bond scission does not substantially occur on chemisorption at 300 K. On the other hand, olefins and acetylene should chemisorb initially with the unsaturated carbon-carbon bond more or less parallel to the metal surface thereby orienting substituent atoms near the metal surface. In these cases, carbon-hydrogen bond cleavage is a probable process near or slightly above room temperature at least for the more active metals. Aromatic hydrocarbons should exhibit a similar behavior. Low energy electron diffraction data for benzene chemisorbed on platinum are available but an intensity analysis has not been made[58]. The unit cell size is such that several models would appear to be possible. One possible model has a bound dehydrobenzene molecule formed by a dehydrogenation reaction. This dehydrobenzene species could be bound to the platinum surface through two σ Pt—C bonds and then, by tilting of the ring away from the normal, further bound through a π bond with additional surface metal orbitals. Interestingly, there is a model for this suggested chemisorbed state of benzene in molecular metal cluster chemistry. Benzene reacts with $Os_3(CO)_{12}$ at *ca.* 473 K to form a dehydrobenzene complex which presumably[59] has the structure shown in Figure 17.

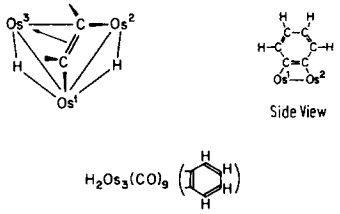

Fig. 17. Structure postulated for the reaction product from $Os_3(CO)_{12}$, or better $H_2Os_3(CO)_{10}$, and benzene [59]. An X-ray crystallographic study is required for confirmation of this postulate. A precise determination of C—C bond separations in the six-membered ring may provide a better indication of the nature of the bonding between the ring carbon atoms and the unique osmium atom.

One intriguing chemical possibility for modification of a dissociative (C—H bond scission) chemisorption of an olefin, an acetylene, or an aromatic hydrocarbon would be to presaturate the surface with hydrogen before chemisorption of the hydrocarbon—this might inhibit or even totally block carbon-hydrogen bond scission in the bound hydrocarbon.

6. A Model for Hydrogen Atom Mobility in Hydrocarbons

A general feature of surface chemistry is the hydrogen atom lability in hydrocarbon species chemisorbed on metal surfaces; H—D exchange is generally a facile process in C_xH_y—C_xD_y or C_xH_y—D_2 mixtures. Recently, *Shapley et al.*[60] showed that a methyl derivative of an osmium cluster is in a facile equilibrium with a methylene-hydride cluster derivative (Fig. 18). This discovery in metal cluster chemistry provides a possible model for the nearly pervasive phenomenon of hydrogen atom lability in chemisorbed hydrocarbon species.

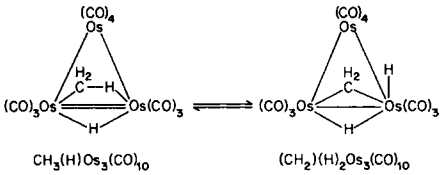

Fig. 18. The structures [60] of the equilibrium solution species of composition $Os_3(CO)_{10}CH_4$ [60]. The methylene structure has been defined by an X-ray crystallographic analysis of a single crystal of this isomer. Although the precise structure of the methyl derivative is yet to be defined for the crystalline state, the spectroscopic data suggest that the methyl group is in an unsymmetric bridging position.

7. Orientational Effects

The obvious critique of the high vacuum, single crystal surface technique is that a single crystal face hardly emulates a metal film or highly dispersed metal particles. The point is granted. However, a careful assay of the chemistry of a given metal requires a systematic investigation of the key crystal face chemistry for the metal in question. Crystal face chemistry can be demonstrably diverse. For example, the platinum (110) surface reversibly chemisorbs cyanogen in a relatively strong fashion yet the (111) face of platinum reversibly interacts with cyanogen to a very minor extent. Thus, the details of single crystal metal chemistry can delineate, in principle, the essential bonding or geometric details of the chemisorption process. *Somorjai et al.*[19] have demonstrated the difference in reactivity of surface metal atoms that lie in different environments, *e.g.* the atoms in the terraces, steps and kinks of high Miller index faces which come closer to real surfaces than do low index or "flat" crystal faces.

The metal-metal coordination number for individual surface metal atoms is markedly affected by the nature of the crystal face. In the terrace or flat section of a (111) face of a face-centered cubic metal, the coordination number is nine—if there is a break, a step, in this terrace, the metal atom at the top of the riser has a coordination number of seven—if the step is irregular so as to generate a kink, the leading atom of a kink has a coordination number of six (Fig. 1). Adatoms on a terrace have coordination numbers of three, four and five for a single, a pair and a triad of adatoms, respectively.

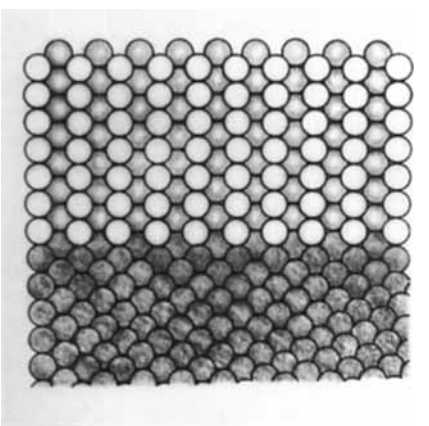

Fig. 19. A representation of the (110) face-centered cubic structure. The representation is generated from the (111) face (dark shaded lower region) and clearly shows the ordered step-like character of this low Miller index face, a face of relatively low thermodynamic stability which often undergoes reconstruction under the conditions of a chemisorption process.

A (110) face of a face-centered cubic metal is like a stepped surface (Fig. 19 and 20) and the "protruding" atoms have a coordination number of only seven. We would expect to a first approximation that site reactivity of surface metal atoms

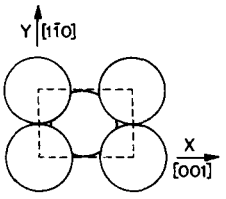

Fig. 20. The unit cell for the (110) face of a face-centered cubic crystal. Coordination number for the top four atoms is only seven whereas it increases to eleven for the partially covered central metal atom.

will rise sharply with the decrease in the metal-metal coordination chemistry as observed for molecular coordination compounds. The initial studies of *Somorjai* are consistent with this speculation; it will be of great importance to test this hypothesis in general systematic chemical studies of metal crystal face chemistry.

I wish to sincerely thank the Chemistry Faculty and the Hitchcock Foundation of the University of California at Berkeley for their hospitality and support during my stay in Berkeley in the spring of 1977. The research was generously supported by the Department of Energy. I am especially indebted to Professor Gabor Somorjai and Dr. John C. Hemminger for an introduction to surface science. Much of the preliminary research (cited in this article) based on a chemical approach to surface science resulted from collaborative research with Drs. Somorjai and Hemminger.

I also wish to acknowledge the detailed and constructive comments of my Cornell colleagues, particularly Professors John Blakely, Thor Rhodin and Robert Merrill and the support of my research in coordination chemistry by the National Science Foundation and the Cornell Materials Science Center.

[6] According to *Tong* [2] these are (i) energy dependent electron scattering cross sections from surface atoms, (ii) inter- and intraplanar multiple scattering of electrons from surface atoms, (iii) inelastic damping of the incident flux by surface plasmon and single particle excitations, (iv) electron-phonon scattering contributing to an effective Debye-Waller factor, and (v) diffraction of electrons at the potential discontinuity at the vacuum-solid interface.

[7] In the final analysis, there is a visual comparison of the experimental curve with the theoretical curves for postulated models. If carried out systematically, this analysis gives a complete picture for *atoms* chemisorbed on the surface. Comprehensive analysis of the chemisorption state of a *molecule* on a surface is at best difficult because a molecule may chemisorb, with the topological or graphical features of the molecule intact, with rearrangement, with polymerization, or with scission of one or more bonds. As was true in the early days of electron diffraction of gaseous molecules, chemical intuition is a most important element in the study of molecules chemisorbed on surfaces.

[8] A comprehensive enumeration of low energy electron diffraction studies has been presented by *Tong* [2]. The especially notable studies of atoms chemisorbed on a metal surface initiated by *T. N. Rhodin et al.* (Cornell University) and by *S. Andersson et al.* (Chalmers Institute of Technology) set the stage for the theoretical development of the analysis by *Duke, Pendry, Jepsen* and *Marcus*. See the application by *J. E. Demuth, D. W. Jepsen* and *P. M. Marcus*, Phys. Rev. Lett. *31*, 540 (1973) and *32*, 1182 (1974) for the overlayer structures of O, S, Se and Te atoms on Ni(100), Ni(111) and Ni(110).

[17] One of the earlier utilizations of this technique in surface science was by *K. H. Maxwell* and *M. Green* for germanium surfaces. J. Phys. Chem. Solids *14*, 94 (1960).

[18] Not too many years ago, attainment of 10^{-10} torr vacuum was the basis for doctoral physics dissertations but the realm of 10^{-10} to 10^{-12} torr vacuum is now routinely accessible.

[19] *G. A. Somorjai*, Acc. Chem. Res. *9*, 248 (1976).

[20] The alternative is a molecular beam reaction with differential pumping. Although this alternative can present high flux densities to the metal surface, momentum transfer conditions may complicate the interpretation of data.

[21] In some instances, there is no significant kinetic or thermodynamic differentiation between the high vacuum and the atmospheric or super atmospheric reactions, as in the $CO+O_2$ reaction (*D. R. Monroe*, Ph. D. Thesis, University of California, Berkeley 1972). For other reactions, the thermodynamic parameters change markedly with pressure. Most critically, a pure metal surface is often not representative of the so-called metal catalysts where oxide phases and carbon overlayers are often the dominant surface phases.

[22] In surface science, the terms associative or dissociative refer explicitly to chemisorption processes of molecules that occur, respectively, with no fragmentation or with fragmentation of the molecule. In coordination chemistry, the term dissociative or associative reaction has a reaction mechanistic connotation. A dissociative reaction follows a step sequence

$$ML_x \rightleftharpoons ML_{x-1} + L \quad \text{and} \quad L' + ML_{x-1} \rightleftharpoons ML_{x-1}L'$$

whereas associative follows the sequence

$$ML_x + L' \rightleftharpoons ML_xL' \quad \text{and} \quad ML_xL' \rightleftharpoons ML_{x-1}L' + L$$

(See *C. H. Langford, H. B. Gray:* Ligand Substitution Reactions. Benjamin, New York 1966, Chap. 1.) Since reactions of molecules with a metal surface will almost invariably be associative in a reaction mechanistic context, the less compact terminology of molecular associative and molecular dissociative chemisorption is now recommended to avoid any confusion by scientists from different disciplines. New chemisorption terminology such as fragmented and intact, although more concise, might be less readily accepted by the surface science community because the present terms are of long standing usage.

[23] The desired crystal may be cut from a larger crystal by an electric arc or a diamond saw or alternatively may be purchased to specification.

[24] Diameter and thickness will vary substantially in practice depending upon the nature of the physical and chemical studies.

[25] With care, this percentage figure can be raised to 80—90%.

[26] This is not a standard or preferred mounting procedure but merely an example.
[27] The metal sample may also be heated indirectly by electron bombardment of a shielded metal cup as shown in Figure 2.
[28] Full characterization details for surface states are critical elements in scientific publications. Cleaning procedures should also be presented for further insight into the research and for assistance to others not familiar with the particular metal in question.
[29] The grazing incidence experiment has the advantage of greater sensitivity. With the cylindrical mirror analyzer which is of the window filter type, a maximal signal-to-noise ratio can be realized. With a cylindrical mirror analyzer, the Auger analysis can be achieved in a very short time, 10^{-2} seconds, compared to times of about one minute for the retarding grid analyzer—thus, potential electron beam damage to the surface species can be minimized. This method of Auger electron analysis is the method of choice if line shape information is desired.
[30] A careful analysis of standards can raise the level of the Augur analysis to a substantial degree. In addition, the line shape of the Auger peaks can, in principle, provide details of the structural and electronic states of the chemisorbed states. Careful comparative studies of the isolated gas phase spectra of molecules with their spectra on chemisorption on surfaces may provide information about intimate features of the chemisorbed states; see *J. M. White, R. R. Rye, J. E. Houston*, Chem. Phys. Lett. *46*, 146 (1977).
[31] Ion bombardment actually results in some rare gas ion implantation in or near the metal surface. The implanted ions are removed on annealing the metal.
[32] The needle method of introduction or the alternative sintered glass channel plate present problems for uniform introduction of gas molecules to the metal surface. A more uniform flux presentation to the surface can be achieved with an effusive molecular beam.
[33] Thermal desorption studies, despite their conceptual simplicity, require experimental sophistication if quantitative details are to be derived [34, 35].

[42] The issue of the electronic character of the transition metal-hydrogen bond is still open to interpretation. It is a covalent—not an ionic bond. Polarity of the bond would appear to be best [43] represented as $M^{\delta+}—H^{\delta-}$. *P. W. Selwood*, J. Catal. *42*, 148 (1976) supports such a view of H on nickel surfaces.

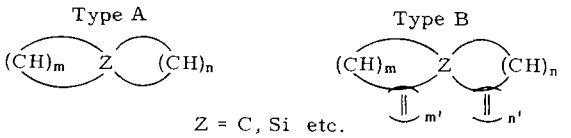
Spiroconjugation



By Heinz Dürr and Rolf Gleiter[*]

Dedicated to Professor Georg Wittig

Spiro compounds having mutually perpendicular π-electron systems ("spiro-polyenes") exhibit a new kind of homoconjugation, which is designated as spiroconjugation. Spiro-polyenes are readily accessible, *e.g.* by cycloaddition, by elimination of dinitrogen from 1,2-diazaspiro-polyenes, and by cyclization of carbenium ions or carbanions. The magnitude of the effect exerted by spiroconjugation is estimated by model calculations. It can be detected, for instance, by comparison of the electronic and photoelectron spectra of spiro-polyenes and analogous compounds which are unable to undergo such interaction.

1. Introduction

Linkage of two cyclic systems by a central atom Z (Z=C, Si, *etc.*) gives rise to spiro compounds. If both rings contain π-electron systems we call the compounds *spiro-polyenes* or *spirenes* in order to avoid the complex systematic nomenclature. In principle, spiro-polyenes can be divided into two large groups A and B. In spiro-polyenes of type A only endocyclic double bonds are present, while molecules of type B also possess exocyclic double bonds. The CH groups can be replaced by hetero atoms.

Aa: m, n = odd (3, 5, 7)
Ab: m, n = even (2, 4, 6)
Ac: m = even (2, 4, 6, 8), n = odd (3, 5, 7)

B: m = even, n = even, m' = even or odd, n' = even or odd
Ba: $m = n = 0$, $m', n' = 2, 3, 4$
Bb: $m, n = 2, 4, 6, 8$, $m', n' = 1, 2, 3$
Bc: $m = 0$, $n = 2, 4, 6$, $m' = 2, 3, 4$, $n' = 1, 2, 3, 4$

As a result of their mutually perpendicular π-electron systems, spiro-polyenes exhibit a new kind of homoconjugation which has been termed spiroconjugation[1-5].

Spiroconjugation should be detectable by known physical methods and also manifest itself in the reactions of these compounds. Compounds of type Ac are an exception since the effect can only be observed in ions and radicals.

Ba  *(4)*

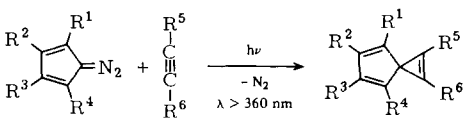
Bb  *(5)*

Bc  *(6)*

Apart from these theoretical aspects, spiro-polyenes are also of industrial interest. Hetero-spirenes of type A are photochromic systems which can undergo reversible photochemical (or also acid-catalyzed) ring opening. They have therefore been examined with regard to their utility in silver-free imaging systems and as memories in data display systems[6].

So far spiro-polyenes have only been found in partially hydrogenated form in nature; some of them are employed as drugs (*e.g.* griseofulvin)[7].

The present survey is concerned exclusively with fully conjugated spiro-polyenes of types A and B (for literature concerning partially saturated systems, see refs. [8, 9]).



2. Syntheses of Spiro-Polyenes

2.1. Cycloaddition

In principle, spiro compounds can be synthesized in a very simple manner. One general approach is the [1,2] cycloaddition of suitable precursors (cycloalkenylidenes) to alkynes or benzene derivatives. This method gives: spiro[2.5]heptatriene *(9)*, spiro[2.4]octatrienone *(11)*, spiro[4.6]undecapentaene *(16)*, spiro[4.8]tridecahexaene *(18)*, and the dibenzo-annelated species spiro[5.8]tetradecahexaenone *(20)*. Some hetero spiro-polyenes are also obtained by cycloaddition.

2.1.1. [1+2] Cycloadditions of Cycloalkenylidenes

Photolysis of diazocyclopolyenes *(7)* gives cycloalkenylidenes (cyclic carbenes) which can undergo intermolecular [1+2] cycloaddition, *e.g.* to alkynes *(8)*. Spiro[2.4]heptatrienes *(9)* are formed in good yields by this reaction[10-13].

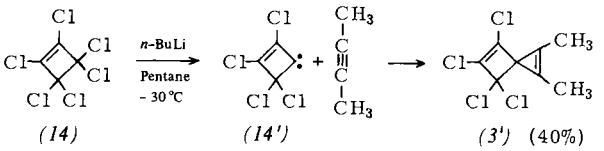
Institut für Organische Chemie der Technischen Hochschule
D-6100 Darmstadt (Germany)

Substituted diazocyclopentadienes *(7)* have to be irradiated with long-wavelength UV light ($\lambda > 360$ nm) since secondary photoreactions of the products *(9)* will otherwise occur[11–13].

A related hetero spiro-polyene, 2,3-diphenylspiro[cyclopropene-1,1'-phthalan]-3'-one, was obtained by photolysis of benzocyclobutenedione in tolan; in this case 3-oxophthalan-1-ylidene undergoes [1+2] cycloaddition[14].



The cyclic carbene generated from the *p*-quinone derivative *(10)* reacts with alkynes *(8)* in the same way to give spiro[2.5]-octatrien-6-ones *(11)*[15,16].

(10) *(8)* *(11a), (11b)*

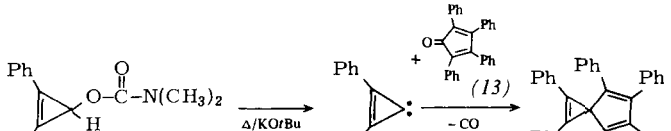
Heavy-metal catalyzed thermolysis of tetrachlorodiazocyclopentadiene *(7b)* in alkynes leads to the spiro[2.4]heptatrienes *(9)* in reasonable yields[17a]. No other examples of this reaction are known.

(14) *(14')* *(3')* (40%)

[1+2] Cycloaddition and valence-bond isomerization: Cycloalkenylidenes are capable of [1+2] cycloaddition with benzene or benzene derivatives—in a reaction resembling that with alkynes. A spiro-norcaradiene *(15)* is formed initially and subsequently yields spiro[4.6]undecapentaene *(16)* by thermal disrotatory ring cleavage[19]. The position of the equilibrium between *(15)* and *(16)* depends upon the substituents[19] (cf. [22,23]).



Extension of this synthesis to larger ring system by cycloaddition of cyclopentadienylidenes *(7')* to cyclooctatetraene does not lead to spiro[4.8]tridecahexaenes *(18)* but instead to the valence-bond isomers *(17)*. The NMR spectrum of the dibenzo derivative (42% yield) indicates an equilibrium between the valence-bond isomers *(17)* and *(18)* at higher temperatures.

(7) *(15)* *(16)*

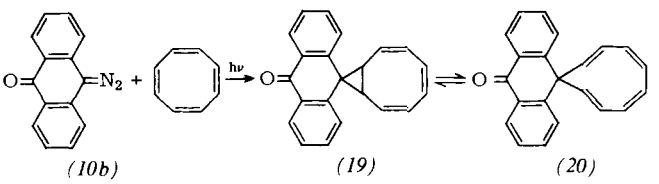
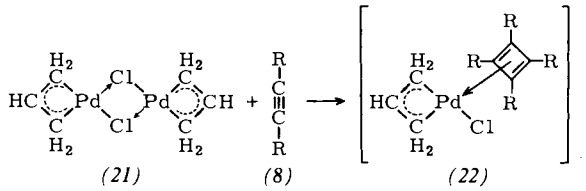
An interesting route *via* a cycloaddition of diphenylcyclopropenylidene *(12')* to tetracyclone *(13)* with concomitant C=O elimination also provides an entry to the spiro[2.4]heptatriene system *(9)*[17b].

(12) *(12')* *(9c)*



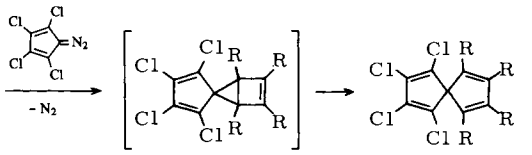
Attempted synthesis of the spiro[2.6]nonatetraene system *(33)* (see Section 2.2) by an analogous method was unsuccessful[18].

Cycloaddition of a carbenoid intermediate has been observed on treatment of hexachlorocyclobutene *(14)* with *n*-butyllithium. The intermediate tetrachlorocyclobutenylidene *(14')* undergoes [1+2] cycloaddition with 2-butyne to give 4,5,6,6-tetrachloro-1,2-dimethylspiro[2.3]hexa-1,4-diene[25].



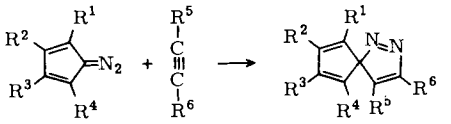
(7) *(17)* *(18)*

By analogy, the diazoanthrone *(10b)* reacts with cyclooctatetraene to give compound *(19)* which exists in equilibrium with the spiro[5.8]tetradecahexaene *(20)*[21,24].



(10b) *(19)* *(20)*

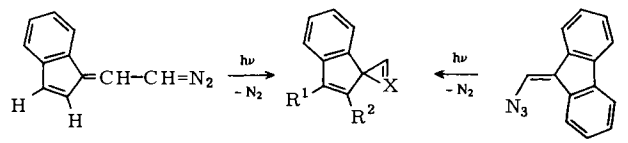
An addition reaction between thermally generated tetrachlorocyclopentadienylidene to the Pd complex *(22)* (prepared from alkyne and $PdCl_2$) to form spiro[4.4]nonatetraenes *(24)*[17] has not been entirely elucidated.



(21) (8) (22)

(23) (24a), R = CH_3, (16%) (24b), R = C_2H_5, 10%

be carried out at room temperature in aprotic solvents. Moreover, the 1 and ω positions of the diazocycloalkene should be substituted since 1,3-dipolar cycloadditions will otherwise be followed by [1,5] sigmatropic shifts even at room temperature.



8-Oxa- and 8-thia-1,2-diazaspiro[4.5]decatetraenes *(31)*[32] and 1,2-diazaspiro[4.5]decatetraenones *(32)*[33] can be synthesized in similar manner.

(7) (8) (29)

R^1	R^2	R^3	R^4	R^5	R^6	Yield [%]

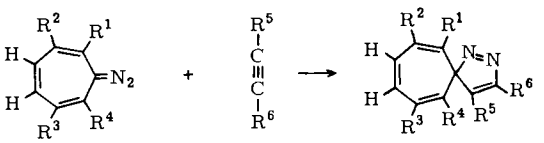
(27)→*(26)*: X = N; $R^1 = R^2$ = —CH=CH—CH=CH— : 74%[27]

2.1.2. 1,3-Dipolar Cycloaddition



1,3-Dipolar cycloaddition of diazocycloalkenes to alkynes *(8)* leads exclusively to heterospiro-polyenes, or more precisely to diazaspiro-polyenes. This reaction has been studied in great detail. The yields of 1,3-dipolar cycloaddition are usually good to very good; the basic reaction has been known for some time[28a].

The diazocycloalkene acts as 1,3-dipole and the alkyne as dipolarophile. Examples are the reactions of *(7)* to give *(29)*, of *(28)*, X = —CH=CH—, O, or S, to give *(30)* or *(31)*, X = —CH=CH—, O, or S, and of *(10)* to give *(32)*, X = CO.

(7), (10), (28) (8) (29)-(32)

At higher temperatures, irreversible [1,5] sigmatropic rearrangements may occur; hence the reactions should ideally

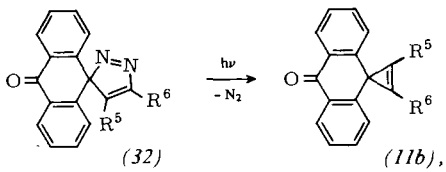
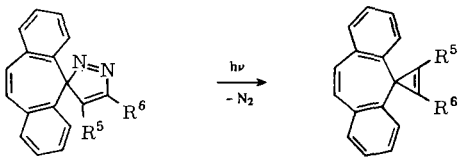
—CH=CH—CH=CH—					$-(CH_2)_6-$	64 [31]

2.2. Elimination of Dinitrogen from 1,2-Diazaspiro-Polyenes



Another simple entry to spiropolyenes is provided by elimination of dinitrogen from 1,2-diazaspiro-polyenes *(29)*—*(32)*. In special cases this elimination can be induced thermally; however, the photochemical procedure is milder.

Secondary reactions can be avoided by use of mono- or dibenzo derivatives of the diazaspiro-polyenes *(29)*—*(32)*. Photochemical elimination of N_2 then occurs practically quantitatively and spiro-polyenes are formed in high yields. The route permits synthesis of spiro[2.*n*]polyenes only. Three examples are cited.



(29) (9g)-(9i)

(30) $-R^5-R^6- = -(CH_2)_6-$ (33) (10%) [31]

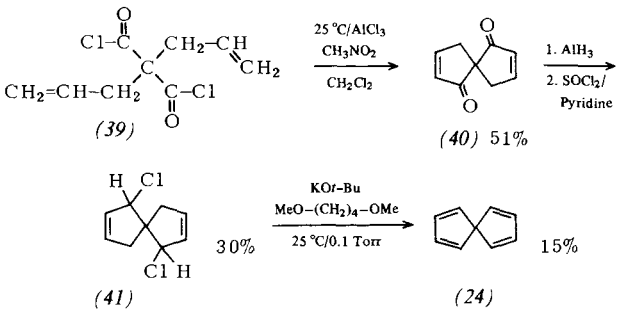
Derivatives of spiro[2.5]octatriene were obtained in the same way[32].

If the cyclopentadiene ring of (29) bears only phenyl substituents then an alternative reaction occurs to give benzocyclopropenes[35c].

Cycloaddition of the ketene (34) with azobenzene gives spiro[2.3]hexenes (35)[35d] having exocyclic double bonds as in type Bc.

(34) (35) (37) (36) (38)

1,3-Dipolar cycloadditions of the diazo compounds (36) lead to spiro[3.4]octenes (37) and (38) which likewise correspond to the Bc type.



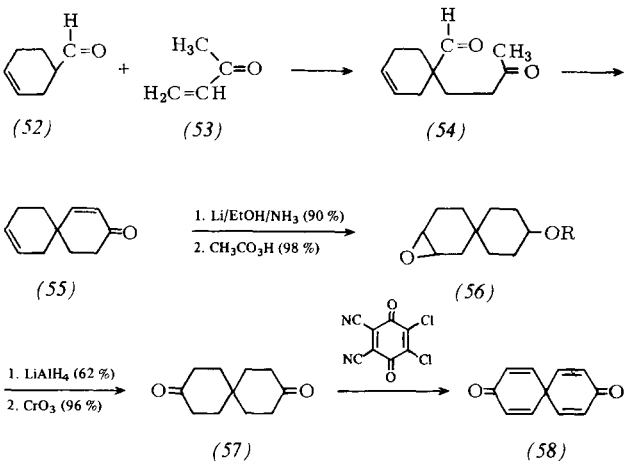
Hetero[2.5]-[35e] and hetero[4.5]spirenes[35f] were also obtained by cycloaddition.

2.3. Cyclization of Carbenium Ions or Carbanions

2.3.1. Cyclization of Carbenium Ions

A classical route to spiro-polyenes starts from cyclization of suitable carbenium ions. The cyclization product often has to be transformed into the spiro-polyene in a series of steps—usually elimination reactions. This synthetic approach is therefore less direct and generally gives lower yields than cycloaddition and cycloelimination.

The synthesis of the unsubstituted spiro[4.4]nonatetraene (24) is shown schematically as an example[36].

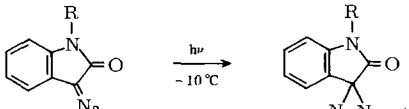


(39) (40) 51% (41) 30% (24) 15%

Analogous examples are compiled in Table 1. Other known spiro-polyenes include a dibenzo-annelated tetraazaspiro[4.4]nonadiene[39e] and a monobenzotetraoxa[5.5]spiropolyene[39f]; tetraoxa[6.6]spiro-polyenes are also known[39g].

In formation of the spiro compound on treatment of pentaerythritol tetrabromide with sodiomalonic ester an S_N reaction occurs as the crucial step[40]. Decarboxylation and subsequent elimination (Hofmann degradation or Cope elimination) gives spiro[3.3]heptadiene[41].

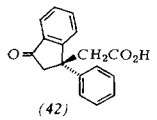
2.3.2. Cyclization of Carbanions

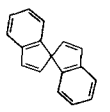


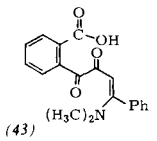
An intramolecular aldol reaction occurring as the decisive reaction step (54)→(55) in spiro-polyene formation plays an important role in the synthesis of spiro[5.5]undecatetraenedione (58)[42].

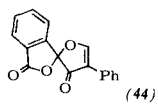
(52) (53) (54) (55) (56) (57) (58)

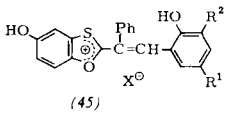
2.4. Other Synthetic Methods

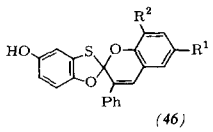


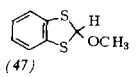


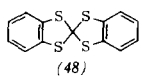


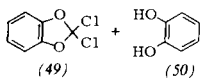


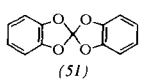






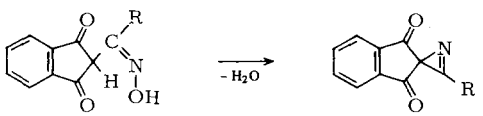






Spiro compounds can also be formed by valence-bond isomerization. A remarkable example is seen in the photochemical valence-bond isomerization of the diazo ketone (59) to the triazaspiro[2.4]heptadienone derivative (60)[43].

(59) (60)



R = H: 5%; R = CH_3: 11%

Dehydration can convert oximes into azaspiro[2.4]heptadienedione derivatives.

R = C_6H_5, CH_3

An extremely interesting route to spiro-polyenes is provided by the rearrangement of carbenium ions. Thermally induced rearrangement of the 1,2-diphenyl-3-(2,3-diphenyl-2-cyclopropenyl)cyclopropenylium ion in refluxing CH_2Cl_2 proceeds *via* ring expansion to give the spiro[2.3]hexadienylium ion *(3)*. This species can be trapped with water or methanol as a spiro[2.3]hexadiene derivative[44]. Further syntheses are enumerated in ref. [45].

(3'), R = H : 51%
R = CH_3 : 68%

3. Model Calculations

Let us consider the phenomenon of spiroconjugation in unsubstituted spiro[4.4]nonatetraene *(24)* (type Ab, $m = n = 4$) with the aid of a qualitative interaction diagram.

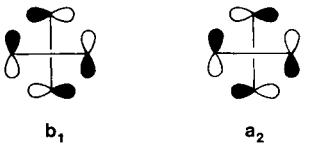
The four π orbitals of the butadiene fragment are shown on the left and right of Figure 1, and characterized

(24)

Fig. 1. Qualitative interaction diagram for two mutually perpendicular butadiene moieties (spiro[4.4]nonatetraene *(24)*). The symbols A and S denote antisymmetric and symmetric, respectively, with reference to the planes a and b.

with respect to the two planes a and b. The symbols A and S mean antisymmetric and symmetric, respectively, with respect to the planes of symmetry[*].

Symmetry considerations reveal that only those orbitals which are antisymmetric to both planes of symmetry (AA) can interact with each other. In the case of *(24)* the occupied and the unoccupied orbitals each give two linear combinations which belong to the irreducible representations b_1 and a_2 in the D_{2d} point group. These two linear combinations are shown as Newman projections in Figure 2.



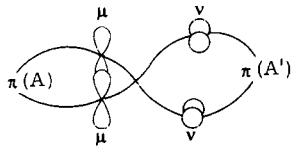


Fig. 2. Phase relationship of orbitals b_1 and a_2 of *(24)* (Newman projection).

The reason for the splitting of the AA level in the interaction diagram (Fig. 1) lies in the spatial interaction of the 2p atomic orbitals of centers C^1 and C^4 with those of C^6 and C^9[**].

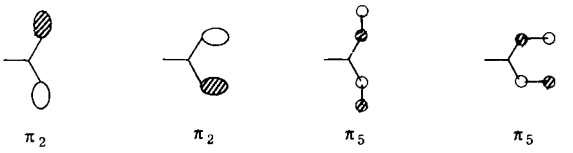
The splitting between the two highest occupied levels in *(24)* is found by Extended-Hückel and MINDO/3 calculations to be *ca.* 0.6 eV[46, 47].

Generalizing, only those orbitals of the π system will interact which possess an odd number of nodal planes. Referred to the planes a and b of Figure 1 this means that they must possess the symmetry designation AA.

With the aid of perturbation theory[48] it can be deduced that the spiro-interaction of two mutually perpendicular π systems (π(A) and π(A')) is all the greater, the greater the

interaction integral $\beta^{\mu\nu}_{spiro}$ and the smaller the energy difference between the basis orbital energies of the interacting orbitals.

$$\beta^{\mu\nu}_{spiro} = \langle \pi^{\mu}(A)/H/\pi^{\nu}(A') \rangle$$



The requirement that $\beta^{\mu\nu}_{spiro}$ should be as large as possible has its limitations in that the centers μ and ν cannot approach each other at will.

The second condition for maximum spiro-interaction, *i.e.* keeping the energy difference between the basis orbitals of the systems A and A' as small as possible, favors spiro systems with D_{2d} symmetry (π(A)=π(A')).

Figure 3 shows the π-orbital diagrams of *(1)*, *(4)*, *(9)*, and *(61)* to *(64)* before and after spiroconjugation. Comparison of the interaction diagrams in Figures 1 and 3 confirms the above statement: interaction is large only when the two subsystems are identical (π(A)=π(A'); D_{2d} symmetry). If π(A)≠π(A'), as in *(9)*, *(61)*, and *(62)*, spiroconjugation is only slight and may be masked by other effects, as shown by the example of the spiroheptatriene *(9)*[48].

Comparison of the MO diagrams of *(4)* and *(24)* shows that the greater splitting of the occupied AA orbitals is found in *(24)*, while the greater splitting of the unoccupied AA orbitals is found in *(4)*. These results can also be understood in terms of perturbation theory. While the energies of the basis orbitals of the butadiene subsystems in *(24)* and *(4)* are equal to a first approximation, the coefficients differ at the linkage sites in the corresponding wave functions.

In *(63)* and *(64)*, on the other hand, the coefficients at the coupling sites of the wavefunctions bearing the symmetry designation AA are of equal magnitude; identical interaction diagrams therefore result.

The systems of greatest interest to the chemist are those in which spiroconjugation leads to a stabilization of the ground state. In *(62)* the HOMO is stabilized by spiroconjugation (Fig. 3). Charge delocalization extending over the five-membered ring can thus take place.

Another system predicted to be stabilized is *(1)*[2] (cf. Fig. 3). This stabilization is particularly extensive[2] if the following relation is satisfied for a spiro compound of type Aa:

$$m = n = 4q + 3 \quad \text{for } q = 0, 1, \ldots$$

Only in these systems does the highest singly occupied orbital of the subsystems *m* and *n* possess AA symmetry. As a result of spiro conjugation, the B_1 linear combination of the two wave functions is stabilized and the A_2 linear combination destabilized. The interaction can be so large that the singlet state of the corresponding biradical is stabilized relative to the triplet state. Thus, model calculations on *(1)* by the PPP-CI method[2] have shown, for example, that the singlet state ($^1A_1$) is 0.64 eV more stable than the lowest-lying triplet state ($^3B_2$). MINDO/3 calculations with reduced CI, on the other hand, show an energy difference of 0.63 eV in favor of the $^3B_2$ state[47].

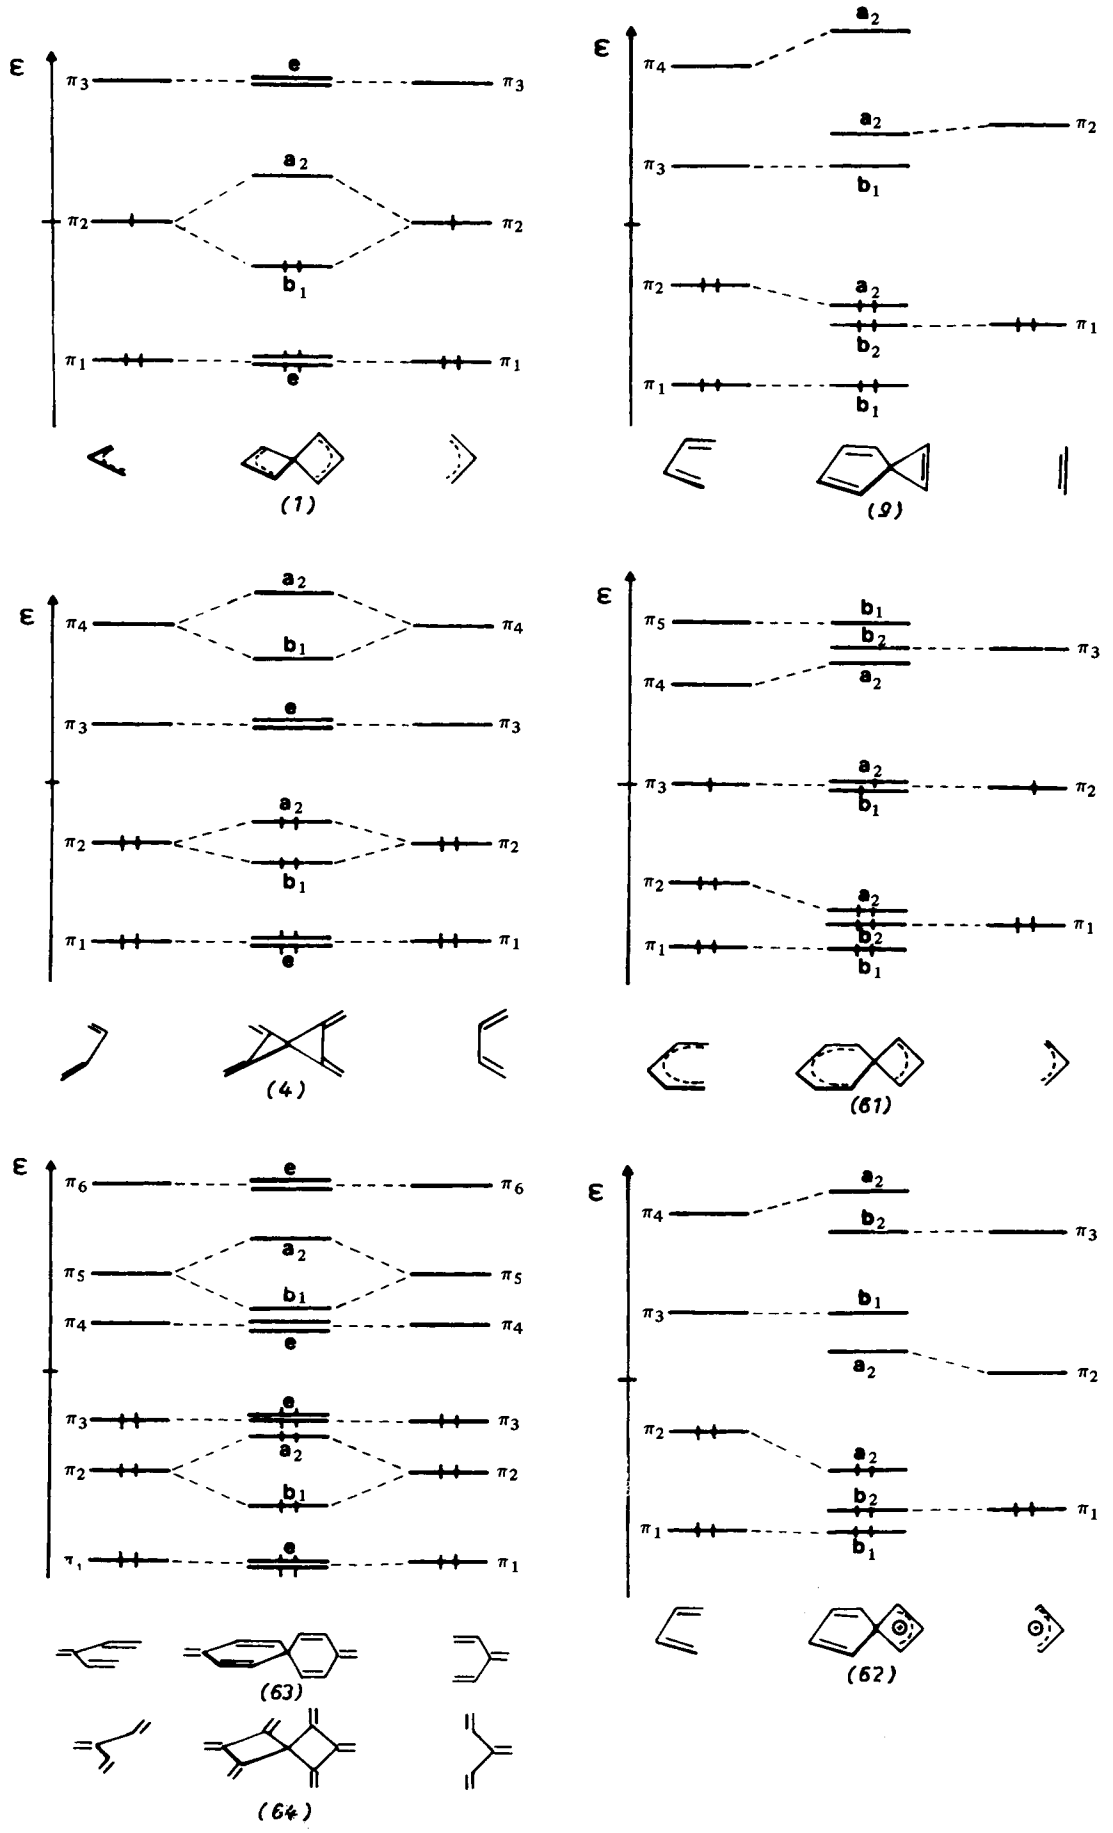
All valence electron methods confirmed the concepts[1, 2] derived from π approximations[3, 46, 47]; however, comparison of experimental and theoretical results[46] showed that the spiro-interaction is predicted as being too small. The geometries of spiro compounds[47, 49] predicted by the MINDO/3 method are in good agreement with experimental data. Model calculations performed in connection with spectroscopic studies will be considered in the following Sections.

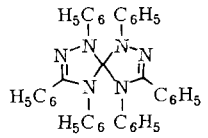
4. Spectroscopic Detection of Spiroconjugation

Proof of spiroconjugation by molecular spectroscopy generally consists in a comparison between the spectrum of the spiro compound and that of a reference substance without spiroconjugation.

[*] Construction of the interaction diagram of Fig. 1 requires that only orbitals of the same symmetry interact.

[**] The overlap integral is calculated to be 0.025 for the distances between C^1 and C^6 and C^4 and C^9 (2.51 Å). The relatively large interaction between the AA levels can be rationalized as arising four times.





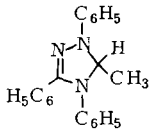


Fig. 3. Qualitative interaction diagrams for the spiro systems *(1)*, *(4)*, *(9)*, and *(61)* to *(64)*.

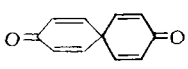
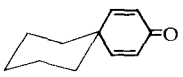
4.1. Electronic Absorption Spectroscopy

The spiroconjugation model proved of value in discussions of the electronic spectra of 3,3'-spirobis(triazoline) *(65)*[50]. The electronic spectrum of *(65)* exhibits a hypsochromic shift of the longest wavelength band by 2500 cm^{-1}[51] relative to the first band of the electronic spectrum of *(66)*.



(65)



(66)

The electronic spectra of some ketals derived from cyclopentadienones, cyclopropenones, and tropone revealed shifts of the longest wavelength bands to longer (cyclopentadienone derivatives) and to shorter wavelengths (cyclopropenone and tropone derivatives), respectively, on comparison with the corresponding dialkyl compounds[1]. These observations could also be readily explained in terms of the spiro model: the HOMO is destabilized by spiro-interaction in the cyclopentadienone ketals, and stabilized in the other two cases.

Further examples of spiroconjugation were discovered on comparison of the electronic spectra of spirobi(indene) *(24c)* and indan[37], of spiro[5.5]undeca-1,4,7,10-tetraene-3,9-dione *(58)* and spiro[5.5]undeca-1,4-dien-3-one *(67)*[52], of *(24)* and spiro[4.4]nona-1,3-diene *(68)*[36,53], and of spiro[2.4]-heptatriene *(9)* and spiro[2.4]heptadienes[11b,12].

(58)

(67)

On comparison of *(58)* and *(67)* a bathochromic shift of the second $\pi^* \leftarrow \pi$ band by 7400 cm^{-1} is observed. From this a value of $\beta' \approx -0.5$ eV may be calculated for the spiro resonance integral.

In contrast to these findings, the electronic spectra of fluorene, 9,9'-spirobi(fluorene) *(24d)*, and its doubly bridged derivative [6.6]vespirene can be interpreted without invoking spirointeraction in *(24d)*[54].

4.2. Photoelectron Spectroscopy

Provided that Koopmans' theorem $(-\varepsilon_J = I_{V,J})$[55] holds[*], photoelectron spectroscopy is the method of choice for demonstrating the presence of spiroconjugation. The examples studied so far are 3,3-divinyl-1,4-pentadiene ("tetravinylmethane")[56], tetravinylsilane[57], 9,9'-spirobi(fluorene) *(24d)*[58], 1,1'-spirobi(indene) *(24c)*[59], 1,4,6,9-tetrathiaspiro[4.4]nonane[60], as well as the unsubstituted compounds *(24)*[53] and *(9)*[49]. Interaction effects between 0.3 and 1.5 eV were recorded for systems having D_{2d} symmetry. As a result, the spiro resonance integral can be estimated as $\beta' \approx 0.2$—0.3 eV considering the coefficients of the wave function[52,59,60].

Of particular interest are studies on *(24)*. The experimental energy difference between the first two ionization potentials (1.23 eV) corresponds to the energy difference between the first two bands in the electronic absorption spectrum of this compound. Owing to the high symmetry (D_{2d}) of *(24)*, the Coulomb and the exchange integrals for the first two electron transitions ($8e \leftarrow 1a_2$ and $8e \leftarrow 1b_1$) can be neglected[53]. This means that $\Delta E = \Delta I$ in this case, *i.e.* the experimental energy difference (ΔE) between the first two bands in the electronic absorption spectrum is equal to the difference (ΔI) between the first two ionization potentials. This could be demonstrated by comparison of the electronic absorption and PE spectra of *(24)* with those of spiro[4.4]nona-1,3-diene *(68)* (Fig. 4): the electronic absorption spectrum (Fig. 4b) of *(68)* contains only *one* band between 30×10^3 and 55×10^3 cm^{-1}, namely that at 39.5×10^3 cm^{-1} corresponding to the $\pi_3 \leftarrow \pi_2$ transition. In contrast, the electronic absorption spectrum of *(24)* shows *two* bands at 37.0×10^3 cm^{-1} and 48.0×10^3 cm^{-1}. These two bands correspond to the $8e \leftarrow 1a_2$ and $8e \leftarrow 1b_1$ transitions, the energy difference being 1.23 eV.

A similar situation is found in the PE spectra of compounds *(24)* and *(68)* (Fig. 4c). The band at 8.38 eV in the PE spectrum of *(68)* is due to ionization from π_2. In the case of *(24)* there are two bands (7.99 and 9.22 eV) in the PE spectrum

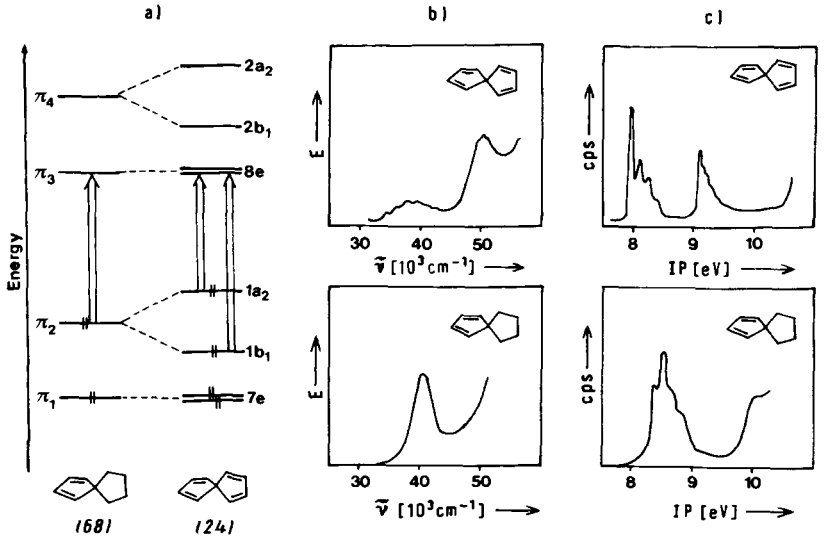


Fig. 4. a) HMO diagram of the highest occupied and lowest unoccupied π-MOs for *(68)* and *(24)*; b) electronic absorption and c) photoelectron spectra of *(24)* and *(68)*.

[*] This theorem assumes that the ground state of a molecule and the states of the corresponding radical cations can be described by the same molecular orbitals.

which are assigned to ionization processes starting from $1a_2$ and $1b_1$. The energy difference between the two bands is 1.23 eV.

4.3. NMR and ESR Spectroscopy

A change in net charge in the spiro compound as compared with the corresponding monocycle is predicted as a result of spiro-interaction[1, 47]. It is, however, impossible to establish a direct correlation between the measured ^{13}C chemical shift and the charge densities calculated by the MINDO/3 procedure in the case of *(24)*, *(68)*, *(9)*, *(16)*, and spiro[2.4]hepta-4,6-diene[61]. A schematic survey is presented in Figure 5.

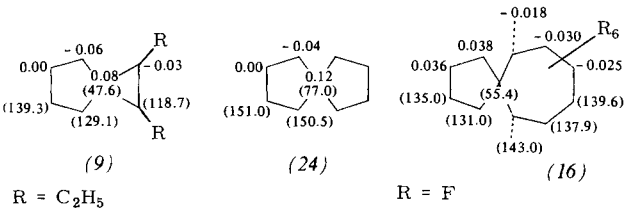

Fig. 5. Charge densities according to MINDO/3 and measured ^{13}C-NMR shifts of the spiropolyenes 1,2-diethyl(methyl)spiro[2.4]hepta-1,4,6-triene [type *(9)*], spiro[4.4]nona-1,3,6,8-tetraene *(24)* [36], and 6,7,8,9,10,11-hexafluorospiro[4.6]undeca-1,3,6,10-pentaene [type *(16)*]. The charge densities were calculated for the parent compounds [47]. $\delta(^{13}C)$ is given relative to TMS = 0.

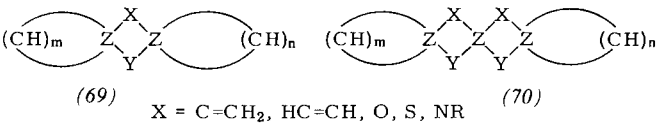
The radical anions of *(58)* and *(67)*[62] and of spirobi(fluorenes) *(24d)* can be studied by ESR spectroscopy[63]. In no case could spiroconjugation be detected, because the unpaired electron occupies an orbital which is unaffected by spiroconjugation.

5. Reactivity

A significant change in reactivity as compared with a reference system without spiroconjugation is expected in spiro systems of type Ab having $m=n$, *e.g. (24)*, only in those cases where the HOMO or the LUMO is influenced by spiroconjugation. For instance, the HOMO should be destabilized in *(24)* and the LUMO stabilized in spiro[2.2]pentadiene *(2)*.

However, spiroconjugation not only alters the energies of the interacting levels but actually modifies the corresponding wave functions. The AO coefficients in the wave functions of the spiro systems which are antisymmetric with reference to the planes a and b (AA) should be smaller than in the wave functions of the isolated subsystems.



The two kinds of changes, that of the energy levels and that of the wavefunctions, have opposing effects on reactivity. Destabilization (stabilization) of the HOMOs (LUMOs) would lead to greater reactivity towards electrophiles (nucleophiles) and *vice versa*. However, the decrease of the coefficients mentioned above should reduce the extent of interaction.

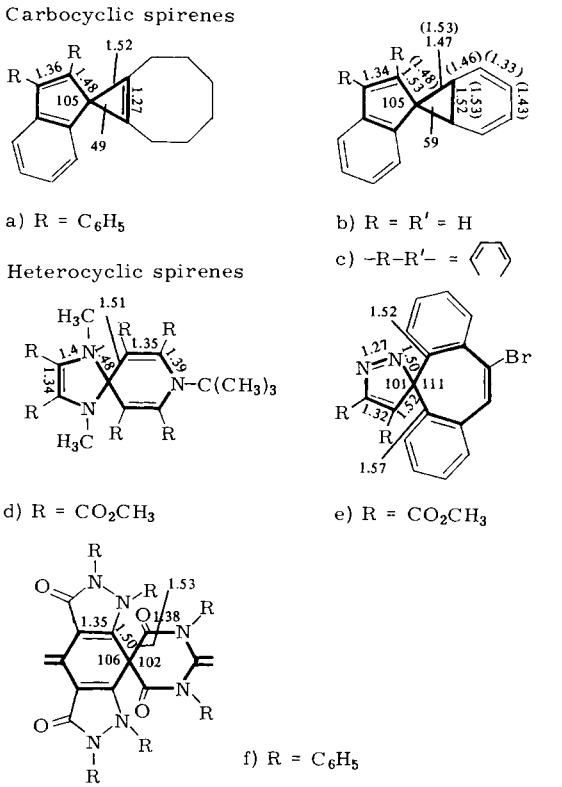
Only few studies on the reactivity of spiro compounds have been published so far. There is no indication of the expected greater reactivity of *(24)* towards dienophiles, but a pronounced tendency to undergo dimerization is observed[36]. A theoretical interpretation of these observations has recently been proposed on the basis of perturbation theory[46]. Apart from *(24)*, cycloadditions were also found in the case of *(9)*[11]. Interestingly, *(24)* undergoes thermal rearrangement to indene[64], and thermolysis of *(16)* affords phenylcyclopentadiene[65]. Diels-Alder reactions have not been observed with *(16)*[32].

6. Outlook

The results available so far show spiro compounds to be an interesting field of study for synthetic and physical chemists.

Since the spiro effect was postulated eleven years ago, mainly bicyclic spiro-systems have been synthesized to explore the limitations of this concept. Very recently, reports have appeared about the synthesis of polycyclic systems[66, 67] derived from *(69)* and *(70)*.

It is remarkable that only few structural investigations[43a, 45b, 67c, 68] have been published, in spite of numerous spectroscopic studies (see Fig. 6).



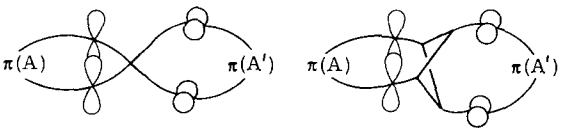


Fig. 6. Bond lengths [Å] and angles [°] in spiro-polyenes with and without hetero atoms. Values for c) are given in parentheses.

Proposals aiming to increase the interaction occurring in mutually perpendicular π systems are of interest. These include the incorporation of central atoms Z with low-lying d-orbitals[69] or replacement of spiro interaction by through-bond interaction[47, 70]. This brief survey shows that spiro compounds and spiro interactions are promising research topics.

Spiroconjugation Through bond

Financial support of our own research work cited in this article by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

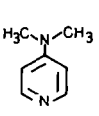
New synthetic methods (25)



4-Dialkylaminopyridines as Highly Active Acylation Catalysts[1, 2]

By Gerhard Höfle, Wolfgang Steglich, and Helmut Vorbrüggen[*]

The synthesis of 4-dialkylaminopyridines can be accomplished in two steps starting from pyridine. Compared to pyridine, these derivatives are approximately 10^4 times more active when used as acylation catalysts. Dialkylaminopyridines are being used with ever-increasing frequency for acylation reactions which proceed either incompletely or not at all in pyridine. This article reviews the various possible applications of 4-dialkylaminopyridines in terpene, steroid, carbohydrate and nucleoside chemistry as well as in the transformation of amino acids into α-acyl aminoketones and polymerization of isocyanates. In addition, *N*-substituted 4-dialkylaminopyridinium salts can be used for the transfer of sensitive groups to nucleophiles in aqueous medium. The exceptional catalytic effect of these derivatives, even in non-polar solvents, is due, in part, to the formation of high concentrations of *N*-acylpyridinium salts which are present in solution as loosely-bound, highly reactive ion pairs.

1. Introduction

The reaction of acetic anhydride/pyridine with hydroxy compounds is a mild, dependable and general method for the preparation of the corresponding acetates. This procedure was first developed in 1901 by *Verley* and *Bölsing*[3] for the quantitative determination of terpene alcohols in essential oils and the method was successfully extended by *Emil Fischer* and *Bergmann*[4] to carbohydrate chemistry. The esterification of hydroxy compounds with acid chlorides was also found to proceed better in the presence of pyridine[5].

DMAP

PPY

In 1967, *Litvinenko* and *Kirichenko*[6] found in the course of kinetic studies (which became known at a somewhat later date) that replacing pyridine by 4-dimethylaminopyridine (DMAP) resulted in a rate increase of *ca.* 10^4 for the benzoylation of *m*-chloroaniline. Independent of this group, *Steglich* and *Höfle*[7] described in 1969 the extremely strong catalytic effect of DMAP and 4-pyrrolidinopyridine (PPY) in prepara-

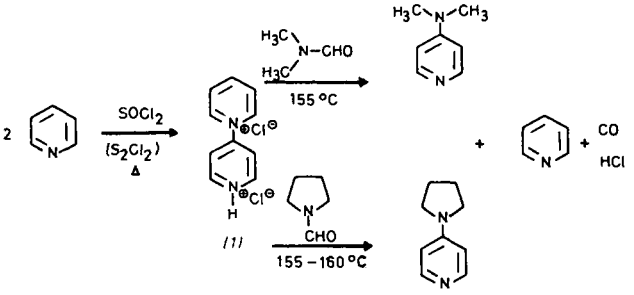
tive scale acylations, thereby providing the impetus for the broad-scale use of these acylation catalysts. The enormous increase in reaction rate is illustrated by the following comparison:



Equimolar quantities of anhydrous or 96% ethanol (29 ml, 0.5 mol) and acetic anhydride (47 ml, 0.5 mol) are mixed in two Erlenmeyer flasks with stirring and to the first flask is added pyridine (8 ml, 0.1 mol). Within 3–4 min the reaction mixture begins to boil. When a solution of DMAP (0.6 g, 0.005 mol) dissolved in a small amount of ethanol is added to the second flask, the solution begins to boil spontaneously under esterification.

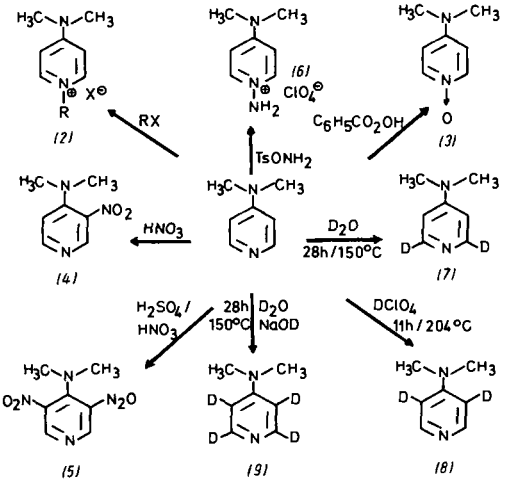
Since the development of a convenient and economic procedure for the preparation of 4-dialkylamino-substituted pyridines by *Vorbrüggen et al.*[2], these new catalysts, DMAP and PPY[8], have become available in any desired amount.

2. Preparation

Dimethylaminopyridine (DMAP) was first obtained by reaction of 4-chloropicolinic acid with dimethylamine followed by decarboxylation[9]. Almost all later syntheses started with pyridine substituted at the 4-position. Such methods, however, are not suitable for the preparation of DMAP on a technical scale[2].

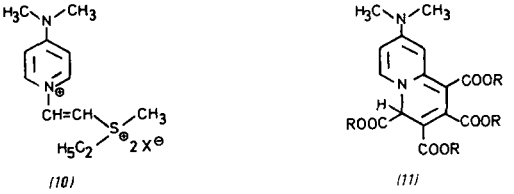
An economic technical synthesis of DMAP in ton quantities under normal pressure became possible as a result of the recently discovered transformation of 1-(4-pyridinio)pyridinium dichloride *(1)* (easily prepared[10–13] by reaction of thionyl chloride with pyridine) with *N,N*-dimethylformamide (DMF) at 140–160 °C. The yield of DMAP lies in the range of 65–70%, based on thionyl chloride[2]. The analogous reaction of *(1)* with *N*-formylpyrrolidine gives 4-pyrrolidinopyridine (PPY)[2,8,14] in similar yields.

DMAP (m.p. 112–113 °C) and PPY (m.p. 57—58 °C)[14] are colorless, crystalline substances which are very soluble in methanol, ethyl acetate, chloroform, methylene chloride, 1,2-dichloroethane, acetone, and acetic acid and less soluble in cold hexane, cyclohexane, and water. DMAP can be recrystallized from ethyl acetate and PPY from pentane or hexane.



The basicities of DMAP[15–24] and PPY[23] in water as well as the dipole moment of DMAP[25–27] in benzene and dioxane have been determined by several groups. Of especial interest are the thermodynamic investigations concerned with the protonation of DMAP in water[18] and calculations whereby the influence of substituents on the basicity has been determined[24,27,28].

pK_a (DMAP) = 9.70 (20 °C)[19]
(PPY) = 9.90 (20 °C)[23]
dipole moment: DMAP = 4.31 D (benzene, 25 °C)[26]



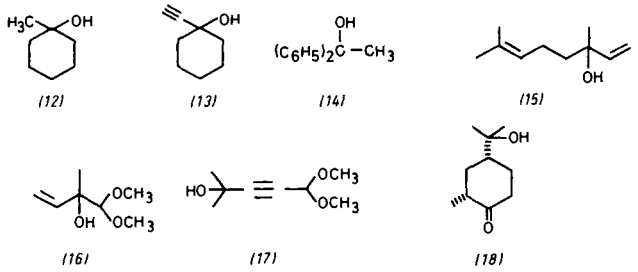
In addition, the UV[15–17,22,29–31] and NMR spectra[18,19,32–37] have been measured and analyzed. There is a characteristic bathochromic shift in water [λ_{max} = 259 nm ($\log\varepsilon$ = 4.26)] on protonation of the ring nitrogen [λ_{max} = 280 nm ($\log\varepsilon$ = 4.24)][16].

3. Chemical Reactions

DMAP reacts readily with electrophilic reagents. It is possible to quaternize DMAP in high yield with either methyl iodide or ethyl bromide to *(2)*, R = CH_3 or C_2H_5[38,39]. *(2)*, R = CH_3, decomposes quantitatively in the presence of aqueous alkali to *N*-methyl-4-pyridone[38].

On reaction with perbenzoic acid the strongly polar *N*-oxide *(3)*, m.p. 214—215 °C, is formed[15,40]. Nitration of DMAP with HNO_3/H_2SO_4 gives the 3-nitro derivative *(4)* in 81% yield and, under forcing conditions, the 3,5-dinitro compound *(5)* is obtained[37,41]. Reaction with *O*-(*p*-toluenesulfonyl)hydroxylamine affords the *N*-amino compound *(6)* in 67% yield which is isolated as the perchlorate[42]. By treatment with D_2O it is possible to selectively exchange the α-protons in DMAP to give *(7)*, with $DClO_4$ to exchange the β-protons to furnish *(8)*, and with D_2O/NaOD to replace all aromatic protons by deuterium to yield *(9)*[43].

Addition of DMAP to *S,S'*-diethyl-*S,S'*-dimethyl-*S,S'*-1,2-vinylenedisulfonium salts results in the smooth formation of the salt *(10)* with concomitant generation of ethyl methyl sulfide[44]. Reaction of DMAP with acetylenedicarboxylic acid leads spontaneously to the bis-adduct *(11)* in high yields[45].



4. Applications as Acylation Catalysts

4.1. Acylation of Alcohols

The high catalytic activity of DMAP and PPY can be used for acylating sterically-hindered secondary or tertiary alcohols

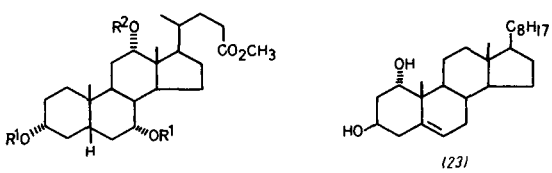
with carboxylic anhydrides or acyl halides when the pyridine method fails. In most cases, it is necessary to use only 0.05—0.2 mol of catalyst per mol of substance and the acid which is formed can be bound with an equivalent amount of triethylamine[1, 7] or pyridine[46]. Such solvents as hexane, toluene, benzene, methylene chloride, chloroform, ethyl acetate, tetrahydrofuran, triethylamine, pyridine, or acetic anhydride are suitable for use with these catalysts.

Among the tertiary alcohols which can be easily acylated with DMAP and PPY, mention should be made of 1-methyl-

(12) (13) (14) (15) (16) (17) (18)

cyclohexanol *(12)*, 1-ethynylcyclohexanol *(13)*, 1,1-diphenylethanol *(14)*, linalool *(15)*, 1,1-dimethoxy-2-methyl-3-buten-2-ol *(16)*, 5,5-dimethoxy-2-methyl-3-pentyn-2-ol *(17)*, and *cis*-4-(1-hydroxyisopropyl)-2-methylcyclohexanone *(18)* (Table 1). The mild reaction conditions allow the acetylation of *(16)* and *(17)* to be performed with preservation of the acid-labile acetal function. *Bohlmann et al.*[51] have utilized PPY in pyridine for the acetylation of sensitive terpene and polyacetylene alcohols.

Linalyl acetate:



A mixture of linalool *(15)* (7.7 g, 50 mmol), triethylamine (10 ml, 75 mmol), acetic anhydride (7.6 g, 75 mmol), and DMAP (0.5 g, 4 mmol) is allowed to stand for 14 h at 24 °C. The solution is partitioned between ether and 2 N HCl, the organic phase is washed with saturated $NaHCO_3$ solution, dried over $MgSO_4$ and evaporated *in vacuo*; yield: 7.9 g (80 %); b.p. 100 °C/10 torr.

Formylation with a mixture of formic acid and acetic anhydride can also be accelerated to an extraordinary extent by using DMAP and PPY as catalysts. Even tertiary alcohols such as *(13)* can be selectively formylated under basic conditions when the reaction temperature is kept below −30 °C to prevent decomposition of formic acid to carbon monoxide[23].

1-Ethynylcyclohexyl formate

1-Ethynylcyclohexanol (0.62 g, 5 mmol), formic acid (0.45 ml, 12 mmol), triethylamine (3.2 ml, 25 mmol), and DMAP (0.5 g, 4 mmol) are dissolved in 40 ml methylene chloride and the solution is cooled to −40 °C. Acetic anhydride is then added and the mixture is stirred at −35 °C for 30 min and thereafter allowed to slowly warm to room temperature over 1 h. The reaction solution is extracted with 2 N HCl followed by saturated $NaHCO_3$ solution, dried over $MgSO_4$ and distilled *in vacuo*; yield: 0.55 g (72 %), b.p. 90 °C (oven)/10 torr. The product contains less than 0.5 % of *(13)* and its corresponding acetate.

In the steroid series, there are numerous instances where DMAP and PPY have been used successfully as acylation catalysts. When methyl cholate *(19)* is reacted with acetic anhydride/pyridine, the hydroxy groups at the 3- and 7-position are preferentially acetylated to form the diacetate *(20)*[52]. When PPY is used, the axial 12α-OH group is also rapidly acetylated and, after 2 h reaction time at 24 °C, the triacetate *(21)*[1] is formed quantitatively. A mixture of formic acid and acetic anhydride yields the triformate *(22)*[53] under DMAP catalytic conditions. It is even possible to acetylate both hydroxyl groups of 1α-hydroxycholesterol *(23)* with acetic anhydride/DMAP at room temperature[54].

(19), $R^1 = R^2 = H$; (20), $R^1 = Ac$, $R^2 = H$
(21), $R^1 = R^2 = Ac$; (22), $R^1 = R^2 = CHO$

(23)

Methyl 3α,7α,12α-triformylcholate (22):

Methyl cholate *(19)* (1.7 g, 4 mmol), DMAP (0.5 g, 4.1 mmol), triethylamine (8 ml, 58 mmol), and formic acid (1 ml, 20 mmol) are dissolved in 100 ml dichloromethane and cooled to −15 °C. Acetic anhydride (6 ml, 63 mmol) is added dropwise with stirring to the reaction solution over 30 min and the mixture is then stirred for an additional 30 min at 0 °C. After addition of a few ml of methanol, the solution is evaporated *in vacuo* and the residue is dissolved in ethyl acetate. The resulting solution is washed with 1 N HCl followed by saturated $NaHCO_3$ solution; the organic layer is then dried over $MgSO_4$ and evaporated *in vacuo*. The residue consists of 2.0 g (97 %)

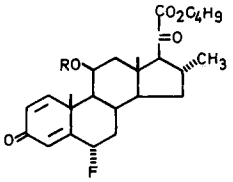


Table 1. DMAP- and PPY-catalyzed acylation of tertiary alcohols with carboxylic anhydrides.

Alcohol	Carboxylic anhydride	Catalyst/auxil. base	t [h]	T [°C]	Yield [%]	Ref.
(12)	$(Bz)_2O$	DMAP/NEt_3	13	80 [a]	87	[1]
(13)	$(C_2H_5CO)_2O$	DMAP/NEt_3	1	24 [a, b]	94	[1]

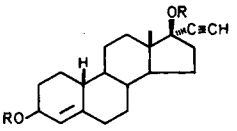
of (thin-layer chromatographically) pure *(22)* as an amorphous powder.

The axial 11β-OH group in *(24)* can be acylated with either acetic anhydride or butyric anhydride in pyridine in the presence of DMAP within 16 h at 27 °C to give *(25)* or *(26)*, respectively[55]. With formic acid/acetic anhydride/DMAP, the 11β-OH group in *(27)* can be formylated under basic conditions[53].

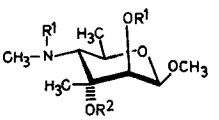
(24), R = H; *(25)*, R = Ac;
(26), R = *n*-C_3H_7CO



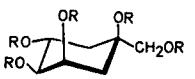
(27)

n-Butyl 11β-acetoxy-6α-fluoro-16α-methyl-3,20-dioxo-1,4-pregnadien-21-ate (25):

To a solution of the ester *(24)* (2.0 g, 0.45 mmol) in 30 ml pyridine and 5 ml acetic anhydride is added DMAP (0.1 g, 0.8 mmol) and the mixture is allowed to stand overnight at room temperature. The reaction product is precipitated with ice water and taken up in dichloromethane. The solution is washed several times with water, dried over $MgSO_4$, and the residue remaining after evaporation is chromatographed on silica gel [eluent: *n*-hexane with 17–21 % acetone]. Recrystallization from acetone/hexane yields 1.80 g (82 %) *(25)* m.p. 148.3 °C.



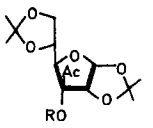
Of special interest is the esterification of tertiary 17β-OH groups in 17α-ethynyl steroids, since highly-active progestational agents are formed. The reaction, for example *(28)* → *(29)*, can be performed under mild conditions with acetic anhydride/DMAP/triethylamine (24 h, 24 °C)[56].



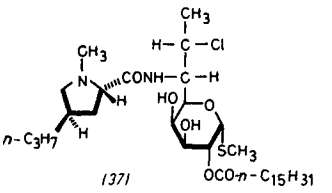
(28), R = H
(29), R = Ac

The DMAP-catalyzed acetylation of sterically-hindered hydroxyl groups has also been used to advantage in the total synthesis and acylation of natural products[46,49,57–59].

DMAP has also been employed as a catalyst for the acylation of sterically-hindered hydroxyl groups in carbohydrates. The reaction of methyl sibirosaminide *(30)* with acetic anhydride/pyridine yields only the *N*-acetyl acetate *(31)* whereas with acetic anhydride/DMAP/triethylamine the *N*-acetyl diacetate *(32)* is smoothly formed[60]. When treated with acetic anhydride/pyridine at room temperature (−)-*(33)* yields a mixture of products; however, after addition of DMAP the pentaacetate *(34)* is formed[61].



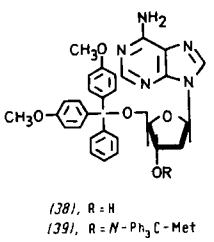
(30), $R^1 = R^2 = H$
(31), R^1 = Ac, R^2 = H
(32) $R^1 = R^2$ = Ac



(33), R = H
(34), R = Ac

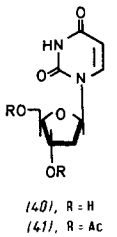
Paulsen et al.[62] were able to benzoylate the tertiary hydroxyl group in the furanose derivative *(35)* with benzoyl chloride, pyridine, and DMAP. The benzoyl moiety was then reductively removed from *(36)* with tri-*n*-butyltin hydride.

(35), R = H
(36), R = C_6H_5CO



(37)

3-C-Acetyl-3-O-benzoyl-1,2:5,6-di-O-isopropyliden-α-D-allofuranose (36):



The sugar derivative *(35)* (0.39 g, 1 mmol) in 5 ml anhydrous pyridine is treated with 2 ml benzoyl chloride and DMAP (100 mg, 0.8 mmol) at 0 °C. After allowing to stand for 2 days at 24 °C, the mixture is diluted with 10 ml acetone/water (1:1), and solid $NaHCO_3$ is added until saturation is obtained. After 1 h, the solution is evaporated *in vacuo*. The residue is taken up in chloroform and the resulting solution is washed twice with water, then with 1 N H_2SO_4 followed by saturated $NaHCO_3$ solution, and finally with water. The chloroform layers are dried over $MgSO_4$ and evaporated *in vacuo*. The oil thus obtained is dissolved in $CHCl_3$/*n*-hexane (1:1) and stirred for *ca.* 30 min with 1 g silica gel. After filtration, *(36)* is crystallized from *n*-hexane at −20 °C; yield: 0.34 g (85 %), m.p. 107 °C; $[\alpha]_D^{20} = +120°$ ($c = 1.0$ in $CHCl_3$).

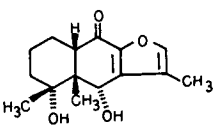
The enormous increase in acylation rates and the quantitative conversions obtained with DMAP or PPY as catalysts make their use attractive also for acylations of unhindered primary and secondary alcohols. *Connors* and *Albert*[63] recommend the use of the acetic anhydride/DMAP/pyridine reagent for the quantitative determination of hydroxyl groups in alcohols and phenols. The rate of acetylation of isopropanol at 54 °C is increased by a factor of 2×10^4 when pyridine is replaced by DMAP. Clindamycin palmitate *(37)* can be quantitatively acetylated with DMAP catalysis within 30 min at 24 °C whereas the same transformation in pyridine requires 3 h at 95 °C[64].

It is also possible with the aid of DMAP to fix Boc-amino acids on hydroxymethyl resins for the solid phase synthesis of peptides[65–67]. *Robins et al.*[68] have used catalytic quantities of DMAP to effect acylation of 2′-deoxyadenosine derivatives *(38)* with the symmetrical anhydride generated from *N*-trityl-L-methionine and dicyclohexylcarbodiimide *in situ*.

(38), R = H
(39), R = *N*-Ph_3C-Met

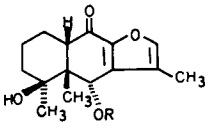
(40), R = H
(41), R = Ac

In pyridine alone, no trace of the product *(39)* could be detected. In the acylation of *(40)* to *(41)*, the use of DMAP as catalyst prevents the formation of colored side products and a diacetate of such purity (yield >90 %) is obtained that further purification by chromatography is no longer necessary[69].



Generally, the esterification of carboxylic acids with alcohols and thiols with the aid of dicyclohexylcarbodiimide in the presence of catalytic quantities of DMAP proceeds in high yields. Thus, methyl 2,4,6-trimethylbenzoate is obtained in 74% yield, di-*tert*-butyl malonate in 86% yield, and *S*-ethyl thiopropionate in 85% yield[70].

Dicarboxylic anhydrides react with alcohols in the presence of DMAP or PPY catalysis to form the half esters, which can be used, for example, for the resolution of racemates[1, 71].

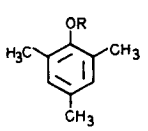


Mono-(−)-menthyl phthalate

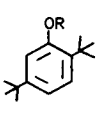
A solution of (−)-menthol (3.1 g, 20 mmol), phthalic acid anhydride (6.0 g, 34 mmol), triethylamine (4.1 ml, 30 mmol), and DMAP (0.5 g, 4.1 mmol) in 20 ml dioxane is allowed to stand for 6 h at 24 °C. After dilution with ether, the mixture is extracted with 2 N HCl and the organic layer is dried over $MgSO_4$. After evaporation of excess solvent, the oily residue is dissolved in CCl_4 and separated from the phthalic acid present by filtration. After evaporation and drying *in vacuo*, 5.6 g (92%) of the half ester, m.p. 90—93 °C, is obtained; after recrystallization from methanol/water, m.p. 111 °C, $[\alpha]_D^{20} = 89.2°$ ($c = 5$ in $CHCl_3$).

Whereas *tert*-butyl alcohol can be esterified with isobutyric anhydride in the presence of DMAP as catalyst, reaction of the same alcohol with pivalic anhydride does not take place[1]. The limits of this method also become evident on attempted esterification of the sterically-hindered sesquiterpene diols *(42)* and *(43)*: in the case of *(43)* it is possible

(42)

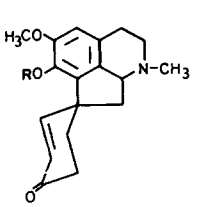


(43), R = H
(44), R = Ac



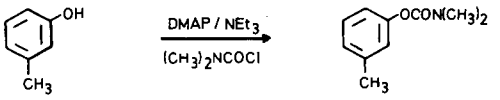
to acylate only the secondary hydroxyl group with acetic anhydride/DMAP, while *(42)* remains unchanged as a result of the strong hydrogen bond between the OH groups[72].

4.2. Acylation of Phenols



In the acylation of phenols, DMAP and PPY effect a similar increase in reaction rate as is found in the case of alcohols. Hence, the method is of interest for the acylation of sterically hindered phenols. For example, mesitol *(45)* can be smoothly acetylated with acetic anhydride/DMAP to *(46)*[1] and 2,5-di-*tert*-butylphenol *(47)* and analogous compounds can be transformed into acyl derivatives of the type *(48)* in high yields[73]. 11,12-Dihydroglaziovine *(49)* smoothly affords the acyl derivative *(50)*[74].

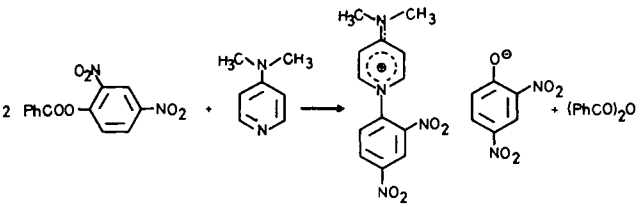
(45), R = H
(46), R = Ac



(47), R = H
(48), R = COCOCl

(49), R = H
(50), R = Ac

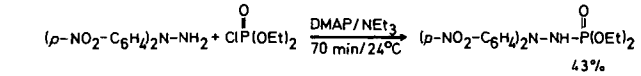
m-Cresol, dimethylcarbamoyl chloride, and triethylamine remain unchanged even after 2 hours' heating under reflux in tetrahydrofuran. Addition of 2 mmol DMAP to 100 mmol reaction mixture under the same conditions effects quantitative conversion into the dimethylcarbamate *(51)*[75].



(51)

As mentioned in Section 4.1, phenols can be analytically determined with the aid of acetic anhydride/DMAP/pyridine[63].

4.3. Acylation of Amines

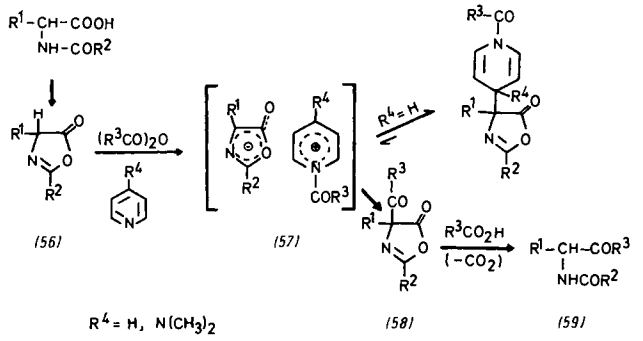


DMAP and PPY have been seldom used for the acylation of amines. The kinetic investigations of *Litvinenko* and *Kirichenko*[6] have shown that an enormous increase in reaction rate is observed when acylations are carried out in aprotic solvents. These authors have determined the following relative rate constants (in parentheses) for the amine-catalyzed acylation of *m*-chloroaniline with benzoyl chloride in benzene: *N*,*N*-dimethylaniline (0.1); triethylamine (0.072); 2,6-dimethylpyridine (0.03); pyridine (1.80); 4-methylpyridine (10.0); and DMAP (10600).

According to investigations by *Pietta* and *Brenna*[76], acetic anhydride/DMAP in dichloromethane could possibly be suitable for blocking unreacted amino groups on Merrifield resins. Attempts to increase the rate of reaction of *N*-(benzoyloxycarbonyl)valine *p*-nitrophenyl ester with valine methyl ester remained unsuccessful[77]. The more strongly activated 2,4-dinitrophenyl benzoate is attacked by DMAP (as a nucleophile) at the aromatic ring to form the pyridinium salt *(52)* and benzoic anhydride[78].

(52)

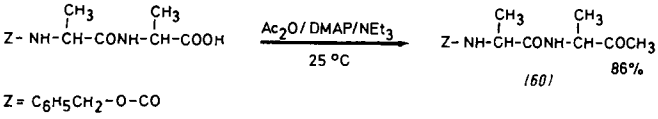
A catalytic effect of DMAP was observed in the phosphorylation of 1,1-bis(*p*-nitrophenyl)hydrazine *(53)*. When *(53)* is allowed to react with diethyl chlorophosphate *(54)* in the presence of DMAP, the desired hydrazine derivative *(55)* is formed. When pyridine or triethylamine is used, no reaction is observed[79].



(53) *(54)* *(55)* 43%

4.4. Acylation of Enolates

Acylations involving CH-acid compounds which can be performed with pyridine or triethylamine as catalyst are found to proceed at a much higher rate when DMAP or PPY is



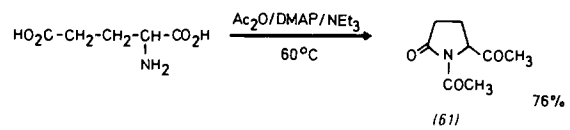
used. The Dakin-West reaction of *N*-acyl amino acids[80], in which a 2-oxazolin-5-one *(56)* is acetylated at C-4 with a carboxylic anhydride in pyridine with formation of a new C—C bond to give *(58)*, has been extensively investigated[81–83]. The combination products, consisting of the ambident oxazolin-5-one anions and *N*-acylpyridinium cations initially formed under kinetic control, are transformed *via* the ion pair *(57)* into the thermodynamically most stable product *(58)*[84,85]. Decarboxylative ring opening by the subsequently formed carboxylic acid yields the α-acyl amino ketone *(59)*[83,86,87].

(56) *(57)* *(58)* *(59)*

In the presence of DMAP or DMAP/NEt_3, this transformation can be carried out at room temperature or with gentle warming[7,88,89]. Normally, much higher temperatures and longer reaction times are required. It is therefore possible to avoid side reactions and to convert even sensitive amino acids such as tryptophan into α-acyl amino ketones in good yields.

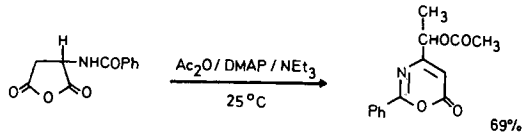
These mild reaction conditions permit the exchange of a carboxyl group for an acyl group in *N*-protected peptides; for example, as in *(60)*[89].

(60)



This method can obviously be used for the determination of C-terminal amino acids in peptides[90].

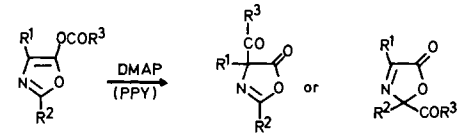
3-(N-Benzyloxycarbonylalanylamino)-2-butanone (60):



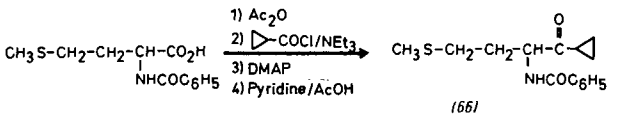
To *N*-benzyloxycarbonylalanylalanine (1.47 g, 5 mmol) in acetic anhydride (1.53 g, 15 mmol) and triethylamine (1.01 g, 10 mmol) is added DMAP (0.05 g, 0.4 mmol). After evolution of CO_2 has subsided, the mixture is treated with 20 ml methanol[*] and evaporated *in vacuo*. The residue is dissolved in ethyl acetate and the resulting solution is washed successively with 1 N HCl, aqueous $NaHCO_3$ solution, and water. After evaporation of excess solvent *in vacuo*, there remains 1.20 g (86%) *(60)*, m.p. 119 °C (recrystallized from ethyl acetate/petroleum ether).

In some cases the acyl amino ketones formed from the amino acids undergo further reactions. Thus, glutamic acid is found to yield 1,5-diacetyl-2-pyrrolidone *(61)*, and *N*-benzoylaspartic anhydride *(62)* the 1,3-oxazinone *(63)*[88].

[*] DMAP catalyzes the removal of excess acetic anhydride by ester formation. The addition of 1—2 equivalents of methanol is also advisable in the isolation of other acetylation reaction products. Compare also the preparation of *(22)*.



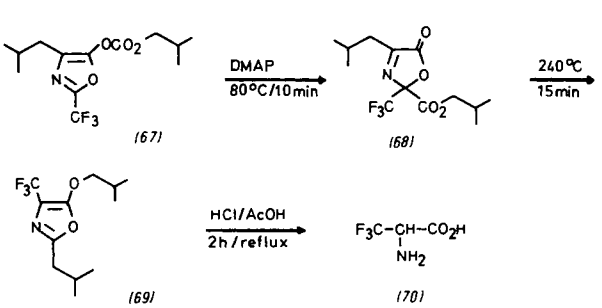
(61)



(62) *(63)*

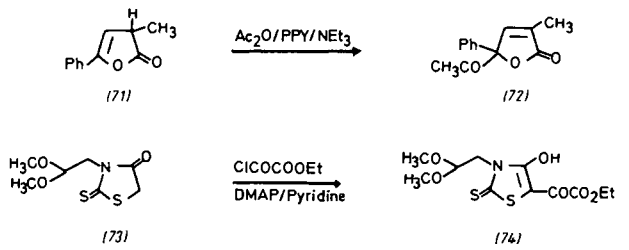
Of preparative interest is the DMAP-catalyzed rearrangement of 5-acyloxyoxazoles *(64)* to 4-acyl-2-oxazolin-5-ones *(58)* or 2-acyl-3-oxazolin *(65)*[8].

(64) *(58)* *(65)*



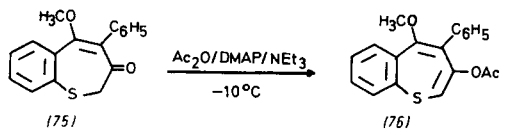
With pyridine, *(64)* (R^1 = *i*-Pr, R^2 = Ph, R^3 = Me) has to be heated for several hours at 100 °C to effect complete rearrangement, whereas addition of 5 mg DMAP is sufficient to complete the rearrangement of 100 mg of this oxazole within a few minutes (the reaction is very exothermic). When R^2 in *(64)* is an electron-withdrawing group, the acyl moiety is directed to the 2-position, allowing synthesis of compounds of the type *(65)*[8,92]. The rearrangement *(64)* → *(58)* can also be used to advantage when the Dakin-West reaction is performed with sensitive carboxylic acids. The *N*-acyl amino acid is transformed into the oxazolinone *(56)* which yields *(64)* upon treatment with R^3COCl/NEt_3[91]. After addition of a catalytic amount of DMAP or PPY, *(64)* rearranges to *(58)*, which on warming with oxalic or acetic acid in pyridine furnishes the α-acyl amino ketone *(59)*[91]. The intermediates do not have to be isolated. An example of this transformation is the synthesis of the α-acyl amino ketone *(66)* in 85% overall yield[93].

(66)



The DMAP-catalyzed rearrangement of the oxazole *(67)* to the 3-oxazolin-5-one *(68)* permits the effective synthesis of 3,3,3-trifluoroalanine *(70)*[92].

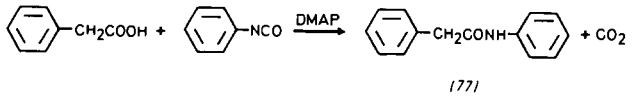
Further examples of *C*-acylation include the reaction of the furanone *(71)* with acetic anhydride/PPY/NEt_3 to give



(67) *(68)* *(69)* *(70)*

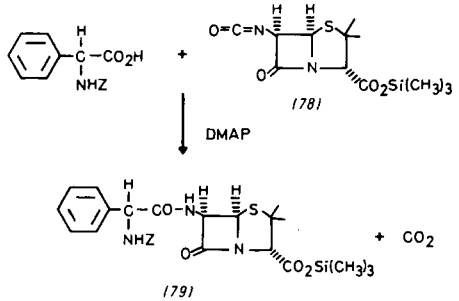
the 5-acetyl derivative *(72)*[94] and the transformation of the rhodanin *(73)* into the 5-ethoxalyl derivative *(74)* with ethoxalyl chloride/DMAP/pyridine[95].

(71) *(72)* *(73)* *(74)*



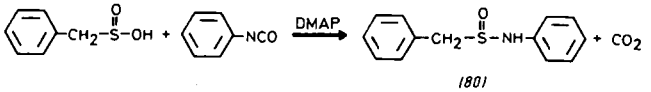
In some cases, the reaction of enolates with acetic anhydride/DMAP results in *O*-acylation. Thus, *Hofmann et al.*[96] were able to transform the bicyclic ketone *(75)* into the 1-benzothiepin derivative *(76)*.

(75) *(76)*



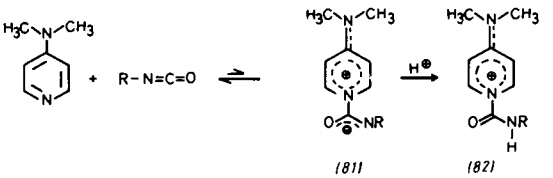
4.5. Reactions of Isocyanates

Pyridine-catalyzed reactions of isocyanates with carboxylic acids to form amides are found to be strongly accelerated on replacement of pyridine by DMAP. Phenylacetic acid is found to react with phenyl isocyanate in 1,2-dichloroethane at 24 °C to give the amide *(77)* in 66% yield in less than 5 min; whereas on using the same amount of pyridine only 53% *(77)* could be isolated after 2 h. With triethylamine, only very little *(77)* is formed besides diphenylurea[97, 98].



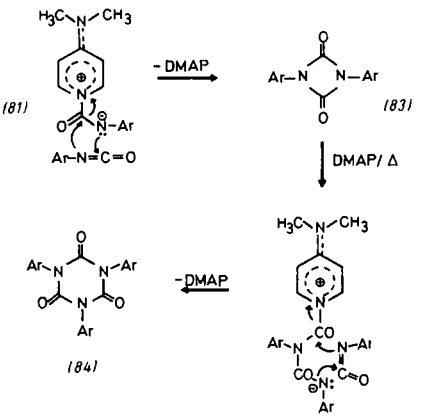
(77)

Similarly, reactions of trimethylsilyl 6-isocyanatopenicillanate *(78)* with, for example, D-*N*-benzoyloxycarbonyl-2-phenylglycine to give the ampicillin derivative *(79)*, are markedly accelerated by DMAP[97].



(78) *(79)*

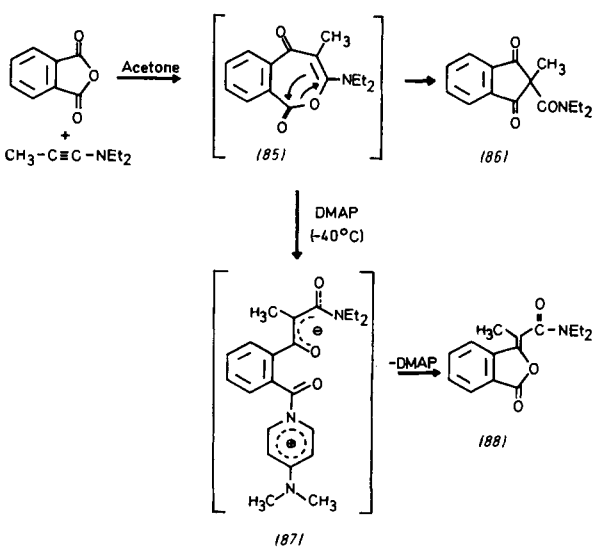
Reaction of phenyl isocyanate or trimethylsilyl 7-isocyanatocephalosporanate with sulfinic acids in the presence of DMAP affords the sulfinamides, *e.g. (80)*, in high yields[99].



(80)

Since pyridine and triethylamine are poor catalysts for this transformation, it is assumed that DMAP and the isocyanate are in equilibrium with the dipole *(81)* which is converted by protonation into the more reactive *N*-carbamoylpyridinium ion *(82)*. *(82)* reacts readily with carboxylates, phenolates, and alkoxides (with loss of CO_2) to yield amides or urethanes.

(81) *(82)*



When no other reactant is present, the dipole *(81)*, R = Ar, reacts further with free aryl isocyanate in ethyl acetate to form the dimeric isocyanate *(83)*[100]. On heating, these 1,3-diazetidinediones are transformed into the more stable isocyanurates *(84)*.

(81) *(83)* *(84)*

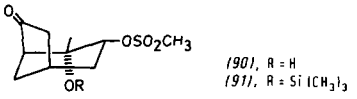
In such dimerization and trimerization reactions, DMAP effects no increase in the rate of reaction, and the yields of products are not improved compared to those obtained in transformations with the usual catalysts such as 4-morpholinopyridine, 4-ethoxypyridine, or pyridine[101].

An interesting directive effect is observed in the reaction of phthalic anhydride with *N*,*N*-diethyl-1-propynylamine. Dipolar intermediates similar to those described above are

(85) *(86)* *(87)* *(88)*

also involved in this transformation[102]. Normally, the indandione *(86)* is formed, *via* intermediate formation of the vinylogous anhydride *(85)*. When 0.1 equivalents of DMAP are added, ring-opening of *(85)* takes place with formation of the dipole *(87)*, which is stabilized by exclusive recyclization to the phthalide *(88)*. With 30 equivalents of pyridine, *(86)* and *(88)* are formed in the ratio of 9:1.

DMAP catalyzes also the polymerization of isocyanates such as *(89)*[103]. In a similar manner, polyesters of adipic acid, ethylene glycol, and glycerol (still containing free hydroxyl groups) with 2-methyl-1,4-phenylene diisocyanate as additive can be prepared with DMAP catalysis[104]. Polymeric

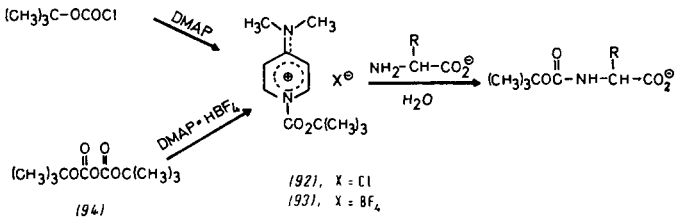


(89)

foams are obtained from phenols and polyisocyanates, especially 4-methyl- (or 2-methyl-)1,3-phenylene diisocyanates[105] and isophorone diisocyanate[106], with addition of DMAP.

4.6. Miscellaneous Applications

DMAP has been used in the hardening of epoxy resins with dicyanodiamine[107], in the transformation of nitriles into thioamides[108], and in the transfer of silyl groups to tertiary hydroxyl groups as shown by the conversion of *(90)* to *(91)*[109].

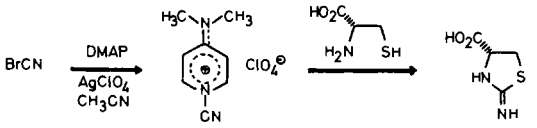


(90), R = H
(91), R = Si(CH$_3$)$_3$

5. Stable 4-Dimethylaminopyridinium Salts as Reagents for the Transfer of Functional Groups

In contrast to the behavior of *N*-acetyl-4-dimethylaminopyridinium ion in aprotic solvents, the hydrolysis of this salt in water proceeds approximately 2000 times slower than that of 1-acetylpyridinium ion[110] (see also Section 8.3). Dimethylaminopyridinium salts are therefore interesting reagents for the transfer of acyl and also cyano and phosphono groups in aqueous medium.

5.1. Transfer of Boc-groups

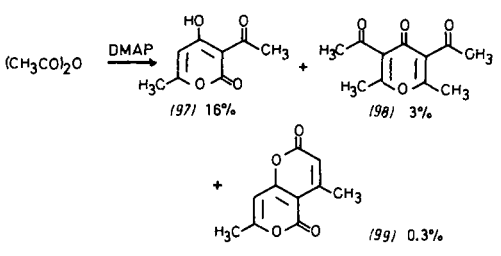


Wakselman and *Guibé-Jampel*[111] introduced 1-*tert*-butoxycarbonyl-4-dimethylaminopyridinium chloride *(92)* as a water-soluble reagent for the transfer of Boc-groups to amines and amino acids. *(92)* can be synthesized from DMAP and the labile butoxycarbonyl chloride in ether. The tetrafluoroborate *(93)* has proved to be more stable than *(92)* and can be prepared from the commercially-available di-*tert*-butyldicarbonate *(94)* and DMAP·HBF$_4$[112]. Both reagents lead to Boc-derivatives of amines and amino acids in aqueous solution.

(92), X = Cl
(93), X = BF$_4$
(94)

5.2. Transfer of Cyano Groups

The reaction of cyanogen bromide with DMAP and silver perchlorate yields the stable 1-cyano-4-dimethylaminopyridinium perchlorate *(95)*[113]. Further reaction of this salt with cysteine in aqueous solution gives the intermediate *S*-cyano compound which undergoes cyclization to the 2-iminothiazolidine-4-carboxylic acid *(96)* in quantitative yield. The salt *(95)* is also well suited for the transformation of SH groups in proteins.

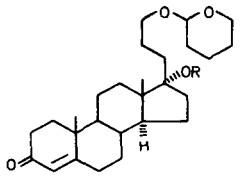


(95) *(96)*

5.3. Transfer of Phosphono Groups

Lawlor[114] and *Wakselman*[110] have prepared stable *N*-phosphono-4-dimethylaminopyridinium salts which, according to kinetic investigations[114], were capable of transferring the phosphono group to methylamine. A more detailed investigation would be worthwhile. (For the transfer of diethyl chlorophosphate *(54)* to amines in non-aqueous solution, see Section 4.3.)

6. Side Reactions



Acetic anhydride and DMAP in high concentrations can react to yield unwanted condensation products of acetic anhydride. Upon mixing equimolar quantities of DMAP and acetic anhydride the solution begins to boil spontaneously after a short induction period and becomes colored. Among the products formed are dehydracetic acid *(97)* as well as the condensation products *(98)* and *(99)*[115]. Self-acetylation of acetic anhydride has also been observed during the transformation of difficultly acylatable 17α-hydroxy steroids of type *(100)* with excess acetic anhydride and DMAP in pyridine[116].

(97) 16% *(98)* 3% *(99)* 0.3%

In addition to the expected acetate *(101)*, there are also formed the acetylacetate *(102)* and the (*E*)- and (*Z*)-enol acetates *(103)* derived therefrom[116].

Side reactions of this kind are undoubtedly exceptions which do not occur in dilute solutions. Reactions involving DMAP and PPY and acetic anhydride in high concentrations should therefore be avoided.

(100), R = H; *(101)*, R = Ac; *(102)*, R = $COCH_2COCH_3$
(103), R = $COCH=\underset{\displaystyle OAc}{\overset{\displaystyle |}{C}}-CH_3$

7. Toxicity of DMAP[117]

Table 2 shows the results of systemic tolerance studies of DMAP administered as a single dose in aqueous emulsion or solution.

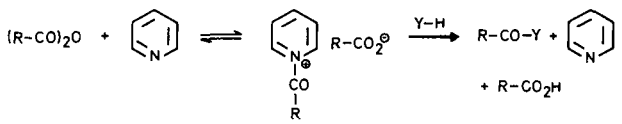
Table 2. Toxicity data of DMAP.

Application	Animal	LD_{50} [mg/kg]	Confidence limits
oral	rat (M+F)	230	192—278
oral	mouse (F)	119	102—130
oral	mouse (M)	127	121—134
dermal	rat (M+F)	*ca.* 500 [a] 50 [b]	

[a] 5% (w/v) aqueous solution. [b] 12.5% (w/v) aqueous emulsion.

DMAP solutions or emulsions are found to cause serious changes when applied to intact and scarred rabbit skin which can lead to necrosis. The mucous membranes of rabbit eyes become strongly inflamed and burns appear. Contact of DMAP with the skin should therefore be avoided because of the danger of local and systemic effects. With DMAP salts (such as citrate), the dermal toxicity is reduced to such an extent that even high concentrations (12 g/100 ml) of this substance produce only a local irritation. In case of contamination of the skin with DMAP, it is advisable to wash the affected areas with dilute acids.

8. Mechanism of Acylation Reactions with 4-Dialkylaminopyridines



8.1. Introductory Remarks

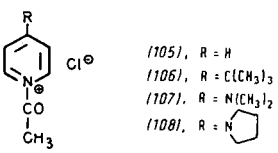
For a discussion of the exceptional catalytic activity of the 4-dialkylaminopyridines, the role of bases in acyl-transfer reactions has to be discussed in more detail. Bases can assume three functions in this process:

1) As Brønsted bases B, they can produce an anion Y^- from a substrate H—Y. This anion is a better nucleophile than H—Y and therefore reacts more rapidly with the electrophilic acylating reagent. The extent of general base catalysis depends upon the relative basicities of B and Y^-, *i.e.* upon the position of the acid-base equilibrium

$$Y{-}H + B \rightleftharpoons Y^- + H{-}B^+$$

2) It has been found that in addition to attacking the substrate, nucleophilic and sterically unhindered bases are especially prone to attack the acylation reagent with formation of salt-like intermediates. For example, carboxylic anhydrides and pyridine yield small amounts of the *N*-acylpyridinium carboxylates *(104)*[118,119] which, because of their charge, are more capable of transferring an acyl residue to a nucleophile than the anhydride itself. Even acyl halides react slower with nucleophiles than *(104)*.

(104)



The extent of this nucleophilic catalysis[120] depends on the reactivity and concentration of the acylium salts which is, in turn, determined by the position of the equilibrium.

3) The third function of the base lies in the neutralization of acid generated during the reaction. To maintain the catalytic effect until complete conversion into product has been attained, it is necessary to use one equivalent of base for this purpose.

On comparing the basicity of pyridine ($pK_a = 5.29$) with that of DMAP ($pK_a = 9.70$), it could be surmised that the increase in reactivity of DMAP is due to the 2.6×10^4-fold increase in basicity. That this is not the case is shown by triethylamine ($pK_a = 10.65$) which is about as active as pyridine. Hence, the only possible reason for the increase in activity is the increased nucleophilic catalysis.

8.2. Formation of *N*-Acylpyridinium Salts

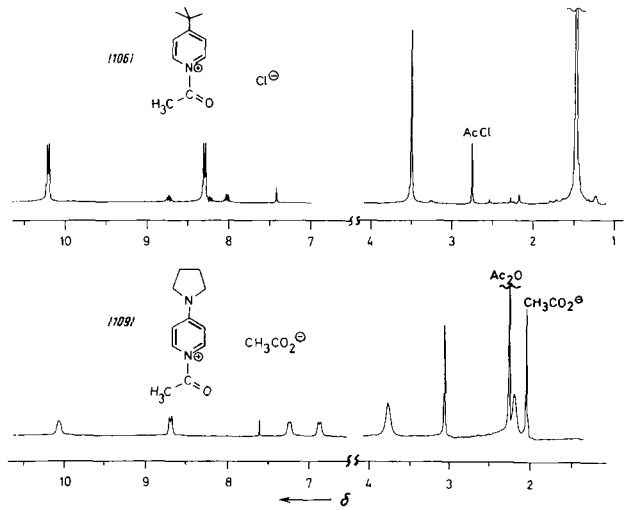
Reaction of pyridine with acyl chlorides usually furnishes the crystalline *N*-acylpyridinium halides[121] such as *(105)* in quantitative yields under mild conditions. These substances are also highly activated acid derivatives.

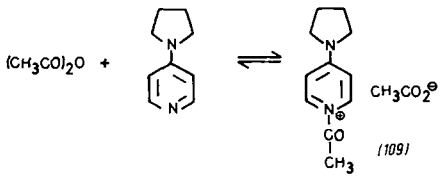
(105), R = H
(106), R = $C(CH_3)_3$
(107), R = $N(CH_3)_2$
(108), R = N⬠

These salts are of little use for preparative acylations, being insoluble in aprotic solvents[*]. However, a *tert*-butyl substituent on the pyridine ring increases the solubility to such an extent that the NMR spectrum of *(106)* can be investigated at −75 °C[23] (Fig. 1). As expected, acetyl chloride reacts with DMAP and PPY to form the salts *(107)*[110] and *(108)*[23], respectively, which are readily soluble in DMSO but less soluble in $CDCl_3$.

While examining the acetic anhydride/pyridine system several years ago, *Fersht* and *Jencks*[119] proved the existence of *N*-acetylpyridinium acetate *(104)*, R = CH_3, in aqueous solution by UV spectroscopy. However, in aprotic solvents, *i.e.* in those solutions in which acylation reactions are generally

[*] When pure *(105)* is suspended in $CDCl_3$, a *ca.* 0.5 mol/l solution is formed which is shown by its NMR spectrum to consist of a mixture of pyridine and acetyl chloride[23] ($\delta_{CH_3} = 2.68$).





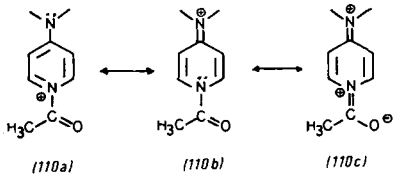


Fig. 1. ^{1}H-NMR spectra of 1-acetyl-4-*tert*-butylpyridinium chloride *(106)* (0.75 mol/l in $CDCl_3$) at −75 °C and 1-acetyl-4-pyrrolidinopyridinium acetate *(109)* (from 0.3 mol/l PPY and 0.45 mol/l acetic anhydride) in $CDCl_3/CD_2Cl_2$ (1:1) at −115 °C. Measurements made with Bruker WH-270 instrument at 270 MHz and −70 to −115 °C. The temperature dependence of the equilibrium concentration of *(109)* was determined in each instance with 0.1 M solutions of PPY and acetic anhydride in $CDCl_3$.

carried out, the existence of *N*-acetylpyridinium acetate could not yet be demonstrated[122] and its occurrence in these solvents has been seriously doubted[123]. In mixtures of acetic anhydride and DMAP or PPY appreciable quantities of *N*-acetyl-4-dialkylaminopyridinium acetate *(109)* can be detected, even in such solvents as $CDCl_3$ and CD_2Cl_2, provided that the exchange of acetyl with anhydride is sufficiently suppressed by lowering the temperature[23].

From the position of the equilibrium [50% *(109)* at −70 °C and 80% at −100 °C], it can be estimated that *(109)* is *ca.* 25 kJ/mol lower in energy than the starting materials and that 5—10% of *(109)* must be present at room temperature. PPY is converted completely into *(109)* with 1.5 equivalents of acetic anhydride at −115 °C[23] (Fig. 1). This extraordinary shift in equilibrium (when compared with pyridine) is caused by the gain in energy due to the mesomeric stabilization of the *N*-acyl-4-dialkylaminopyridinium ion *(110)*.

That the mesomeric form *(110c)* also contributes considerably to the stabilization of this anion has been shown by the NMR spectrum. Two sets of signals are observed for the α- and β-protons of the pyridine nucleus which arise from restricted rotation (at very low energy) around the acetyl-nitrogen bond (Fig. 1)[23].

An indication of the charge distribution can be obtained by the position of the acetyl-methyl signals. In compound *(106)*, where the positive charge is largely localized on the nitrogen, $\delta = 3.53$, whereas with 4-dialkylaminopyridinium salts *(109)* $\delta = 3.05$ and *(107)* $\delta = 3.04$ in $CDCl_3$[23]. Solvation with DMSO leads to a signal shift in compound *(107)* to $\delta = 2.82$[110]. The same tendency is found for the IR carbonyl frequencies which appear at 1800 cm^{-1} for compounds *(105)*[121] and *(106)*[23] and at 1755 cm^{-1} for *(107)*. The increase in the equilibrium concentration of acylpyridinium ions on introduction of a 4-dialkylamino group is accompanied by a pronounced reduction of the carbonyl activation.

8.3. Reactivity of *N*-Acylpyridinium Salts

Table 3 summarizes the results of acetylation of 1-ethynylcyclohexanol *(13)* with various acetylation reagents and catalysts in $CDCl_3$, a nonpolar solvent system[23].

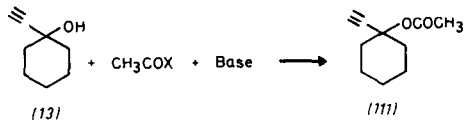

Table 3. Rate of acetylation of 1-ethynylcyclohexanol *(13)* (0.2 mol/l) with acetic anhydride or acetyl chloride (each in concentration of 0.4 mol/l) in the presence of various bases (catalysts) in $CDCl_3$ at 27 °C. The reactions were monitored by NMR spectroscopy (270 MHz, Bruker WH-270); the conversion was measured by integration of the signals of the acetylene protons in *(13)* ($\delta = 2.48$) and *(111)* ($\delta = 2.60$).

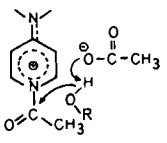
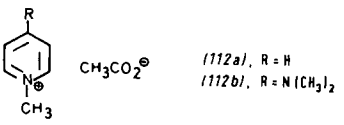


Run	Base	*c* [mol/l]	Acetylation reagent	$\tau_{1/2}$ [min] [a]
1	PPY	0.6	$(CH_3CO)_2O$	3
2	DMAP	0.6		7
3	Pyridine	0.6		1000
4	Pyridine	0.6		1000
	NEt_3	0.6		
5	DMAP	0.6	CH_3COCl	20 [b]
6	*tert*-Butylpyridine	0.6		60 [b]
7	*tert*-Butylpyridine	0.6		40 [b]
	NEt_3	0.4		

[a] The rate was determined as the time required for 50% conversion into *(111)* ($\tau_{1/2}$; error ±10%).
[b] Formation of side products.

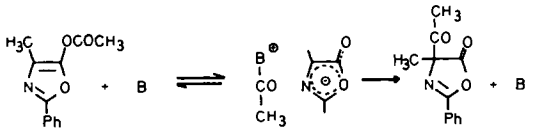


Runs 1—4 demonstrate once again the enormous catalytic activity of DMAP and PPY. PPY is, in this instance, *ca.* twice as active as DMAP (see [8,47]). Surprisingly, acylations with acetyl chloride (runs 5 and 6) are found to proceed much more slowly than those with acetic anhydride. The rate of acylation with acetyl chloride appears even more unfavorable when it is considered that only 5—10% of the acetylating species [for example *(109)*] is present at equilibrium in the case of acetic anhydride (see Section 8.2) when compared to 100% of *(107)* in the case of acetyl chloride. Varying amounts of free base have no significant effect on the reaction rate (run 7).

It can be deduced from Table 3 that in nonpolar solvents the rate of acyl transfer from *N*-acylpyridinium salts depends less upon the activation of the carbonyl group than upon the structure of the ion pair. According to our concept, an

increased mesomeric stabilization of the cation and anion leads to an increased expansion of the ion pair which, in turn facilitates attack of an external nucleophile. The *N*-acetylpyridinium chlorides *(105)* and *(106)* are very tightly bound ion pairs and therefore, in spite of the high degree of carbonyl activation, react very slowly. In *N*-acetyl-4-pyrrolidinopyridinium acetate *(109)*, the deactivation of the carbonyl group is more than compensated by the greater availability of the cation in the ion pair. At the same time, the acetate ion (which is always in the vicinity of the cation) can cause an increase in reaction rate by abstracting a proton from the nucleophile (general base catalysis)[124].

An indication of the greater ion mobility in pyridinium salts is provided by measurements of the specific conductivity. In 0.1 M solution in CH_2Cl_2 $\varkappa = 11.5 \times 10^{-3}$ for compound *(112a)*, and $56 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ for *(112b)*[*].



(112a), R = H
(112b), R = $N(CH_3)_2$

As expected, the degree of solvation has a strong effect on the reactivity of *N*-acylpyridinium salts. Experience has shown that acylation with DMAP or PPY proceeds best in non-polar solvents and this effect has been confirmed by comparing the acetylation of 1,1-diphenylethanol in various solvents: 75% acetylation occurred within 24 h in carbon tetrachloride or hexane, only 30% in methylene chloride or ether, and no reaction was observed in acetonitrile, nitromethane, or dimethylformamide[47].

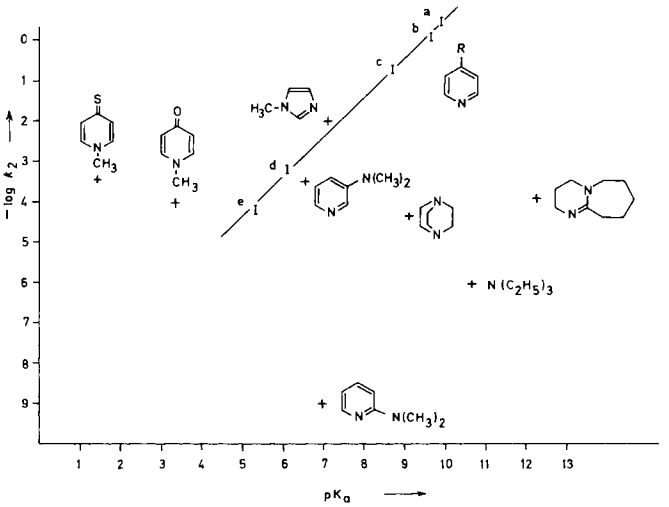
Acylation proceeds even more slowly in protic solvents such as ethanol and especially in water. *N*-Acetyl-4-dimethylaminopyridinium chloride *(107)* hydrolyzes *ca.* 2000 times slower than the pyridinium salt *(105)* in acetate buffer solution at pH = 5.5[110]. Similar differences were observed with the *N*-phosphonopyridinium salts derived from γ-picoline and DMAP[114].

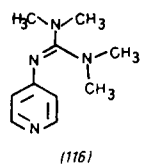
This reversal of reactivity in aqueous medium is understandable in view of the fact that the ion pairs do not react themselves but only the dissociated and solvated *N*-acylpyridinium ions. These then exhibit their "true" reactivity expected from their mesomeric stabilization and spectrochemical properties.

A comparison of the nucleophilic catalysis of several bases without interference from solvent effects and general base catalysis can be performed by studying the intramolecular acyl shift of 5-acyloxyoxazoles such as *(113)*. This transformation is catalyzed by many bases B to yield initially the ion pair *(114)* as intermediate which then rearranges to form the oxazolone *(115)*[8, 23, 91] [see *(64)* → *(58)* in Section 4.4].

(113) *(114)* *(115)*

In Figure 2, the reaction rates in benzene are plotted *versus* the pK_a value of the various bases. In the 4-substituted pyridine series, a linear free energy relationship is observed in which PPY exhibits the greatest activity. Because a further increase in the basicity of the pyridine system is hardly possible, it is unlikely that a better acyl transfer reagent than PPY will be found. 4-(Tetramethyl-2-guanidino)pyridine *(116)* is 90% as active as PPY for the acylation of alcohols[47].





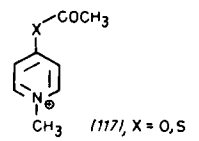


Fig. 2. Rate of the base-catalyzed rearrangement of *(113)* to *(115)* as a function of the dissociation constant of the base. The rearrangements were performed in benzene with 0.75 M solutions at 35°C with 1.5×10^{-3} to 0.35 mol/l of base and were monitored by NMR spectroscopy. The rate constants were first order and proportional to the concentration of the base. R in the 4-substituted pyridine-derivatives stands for: a, pyrrolidino (=PPY); b, $N(CH_3)_2$ (=DMAP); c, morpholino; d, CH_3; e, H.

N-Methylimidazole, a reagent which is also utilized[8] for this rearrangement, is *ca.* twice as active as a pyridine derivative with the same basicity. This is due to the smaller hindrance of the nucleophilic nitrogens by the α-protons. When the nucleophilic center is hindered by substitution, very small rearrangement rates are observed in spite of very high basicity,

(116)

(117), X = O, S

for example with 2-dimethylaminopyridine, triethylamine, and diazabicyclo[5.4.0]undecene (DBU). Diazabicyclo[2.2.0]octane, which has been recommended for use as an acylation catalyst[125], is as effective as pyridine because of the advantagous steric construction ("e" in Figure 2).

[*] *G. Höfle, B. Lange, H. Vorbrüggen*, unpublished; the conductivities were measured at 20°C in anhydrous CH_2Cl_2. Solutions of acetic anhydride (0.8 mol/l) and DMAP or pyridine (0.1 mol/l) exhibited specific conductivities of 1.4×10^{-3} and $1.6 \times 10^{-5}\ \Omega^{-1}\ cm^{-1}$. These results indicate that 2.5% of the DMAP is present as a salt *(112b)*. The poor conductivity of pyridine systems can be due to *(104)* as well as hydrolysis products.

Remarkably high rates of rearrangement are observed with relatively weak bases such as *N*-methyl-4-pyridone and *N*-methyl-4-thiopyridone, which form the activated 4-acyloxy- or 4-acylthiopyridinium salts *(117)* as intermediates. These bases are exceptions as the nucleophilic centers (oxygen and sulfur) are subject to negligible steric hindrance. They might conceivably be used for acylations in weakly acid solution.

In summary, two factors are responsible for the high activity of DMAP and PPY as acylation catalysts in aprotic, nonpolar solvents:

1) As a result of their pronounced nucleophilicities, these bases form high concentrations of *N*-acylpyridinium salts from acylation reagents even in nonpolar solvents. DMAP and PPY are far superior to pyridine and other amines in this respect.

2) Because of charge delocalization, the *N*-acyl-4-dialkylaminopyridinium salts are present as loosely-bound ion pairs, thus greatly facilitating attack of nucleophile on the activated acyl group with general base catalysis by the neighboring anion. This effect also explains why carboxylic anhydrides are better suited for these acylations than the corresponding acyl chlorides.

Financial support of our work by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Schering AG is gratefully acknowledged.

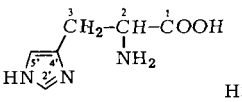
Histidine in Enzyme Active Centers

By Friedhelm Schneider[*]



Dedicated to Professor Peter Karlson on the occasion of his 60th birthday

The presence of histidine in the active center of an enzyme can be demonstrated by kinetic measurements, chemical modification, NMR spectroscopy or X-ray structure analysis. Histidine is the only naturally occurring amino acid to contain an imidazole residue as a side chain. The role of histidine in enzyme catalysis depends, *inter alia*, upon the special features of the imidazole residue: it thus tends to form hydrogen bonds, combines donor and acceptor properties and can take part in either nucleophilic or base catalysis. In some of these enzymes the position of each atom is known; however, the theories as to how the catalysis proceeds at a molecular level are controversial.

1. Introduction

The amino acid histidine was isolated simultaneously in 1896 by *Kossel*[1] from sturine (a sturgeon sperm protein) and by *Hedin*[2] from several protein hydrolyzates (including those of casein and ovalbumin). *Pauly*[3] succeeded in elucidating the structure of histidine which was then finally proved in 1904 by *Knoop* and *Windaus*[4]. *Best et al.*[5] found that histamine, which had already been synthesized in 1907 by *Windaus* and *Vogt*[6], was by far the most important metabolic product of histidine.

Scientists were then mainly concerned with the histidine contents of proteins, especially with regard to their nutritional

physiology. The function of histidine in proteins, particularly in enzymes, first became of major interest at the beginning of the nineteen fifties when the concept of enzyme active centers had been firmly established[7]. Model reactions[8,9] were of valuable assistance to enzymologists and protein chemists in their efforts to elucidate the role of histidine in enzyme catalysis. A prerequisite for this work was, primarily, the development of specific methods for the identification of histidine in the active center. Well-founded proposals for the possible functions of histidine in enzyme catalysis could, however, only be made after the exact chemical, physicochemical and catalytic properties of imidazole were known.

2. Properties of Imidazole

2.1. Chemical and Physicochemical Properties

Imidazole (Im) is a flat heterocyclic molecule with six π electrons[10]; it has a resonance energy of 15.4 kcal/mol[11]. It is structurally related to both pyridine and pyrrole (resonance energies 20.9 and 8.5 kcal/mol, respectively). The aromatic cations ImH^+ and ImM^+ are formed by acceptance of a proton or complex formation with a metal ion respectively. N-1 and N-3 are equivalent in the imidazolium ion ImH^+.

Im ImH^+ ImM^+

In aqueous solution a tautomeric equilibrium is established with the solvent by means of proton exchange. The predominant exchange reaction in acid solution is

$$ImH^+ \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Im + H^+$$

and in alkaline solution

$$Im + H_2O \underset{k_4}{\overset{k_3}{\rightleftharpoons}} ImH^+ + OH^-$$

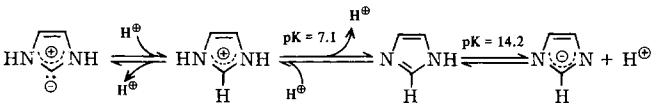
The back reactions are thermodynamically favored; they have rate constants which are typical of diffusion-controlled processes, namely $k_2 = 10^{10.2}$ and $k_4 = 10^{10.4}\,s^{-1}\,l\,mol^{-1}$[12]. Since the p$K$ value of imidazole is 7.0 and $k_1/k_2 = K_a = 10^{-7}$, k_1 can be calculated to be $10^{3.2}$ and k_3 to be $10^{3.4}\,s^{-1}$. The similarity between these two values is due to the fact that

$$K_a = 10^{-7} = \sqrt{K_w} = [H^+] = [OH^-]$$

Imidazole is thus an optimal catalyst and buffer in aqueous solutions close to the neutral point[12]. The slowest step in the exchange between the hydrogen bonded to the nitrogen atom and the solvent components in alkaline solution is the protonation of neutral imidazole by water (k_3).

The protonation can be accelerated by general acid catalysis. If the imidazolium ion acts as an acid, the reaction proceeds according to the equation

$$Im + ImH^+ \rightleftharpoons ImH^+ + Im$$



The rate constant for the forward and back reaction is approximately $10^{8.5}\,s^{-1}\,l\,mol^{-1}$.

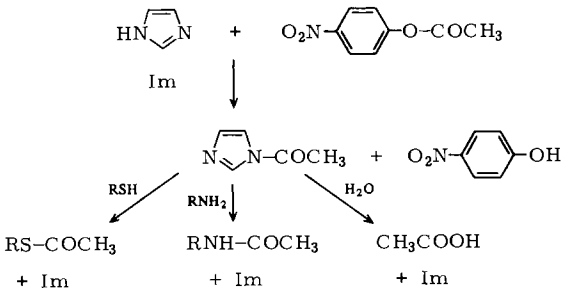
Imidazole can be protonated not only at N-3 to give a cation ImH^+ (imidazolium ion; p$K = 7.1$; 25 °C, ionic strength 0.2), but can also be deprotonated in strongly alkaline solution at N-1 to give an anion (imidazolide ion; p$K = 14.2$ to 14.6)[13]. This anion, which is also aromatic, possesses two equivalent coordination sites and is thus a potent bond-forming ligand.

The formation of the ylide $Im^{\pm}$ by deprotonation of the imidazolium ion at C-2 must be mentioned, although in aqueous solution this is quantitatively of minor importance in the equilibrium. Exchange of the C-2 proton in D_2O proceeds rapidly; the half time of this reaction at 65 °C and pD = 6.9 is 10.9 min[14].

The protonation equilibria of imidazole can be summarized as follows:

$Im^{\pm}$ ImH^+ Im

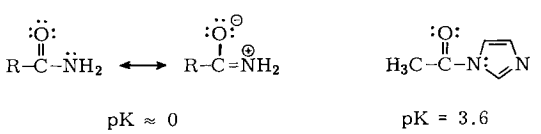
Finally, the complex forming properties of imidazole must be mentioned[15]. In neutral solution unprotonated imidazole forms complexes using the free electron pair of N-3 (bonding with a metal at N-1 is very unlikely). Complex-bound imidazole can no longer participate in nucleophilic reactions since its nucleophilic center is required for the coordination of the metal ion. The aromatic character of imidazole is preserved in the formation of imidazole-metal complexes. The structure of the metal complexes and derivatives of imidazole together with those of histidine and histidine peptides cannot be dealt with here in more detail (for a review see[15]). The similarity between the binding constants of proteins and those of imidazole derivatives and histidine peptides led to the assumption that imidazole residues were involved in the binding of metals to proteins; more recently this assumption has been directly confirmed by X-ray structure analysis.



The fact that imidazole tends to form hydrogen bonds is one of its physicochemical properties which could be of importance for its role in enzyme catalysis[16]. The pyrrole nitrogen atom (N-1) tends to lose its protons whereas the pyridine nitrogen atom (N-3) can accept a proton. Donor and acceptor properties are thus combined in imidazole at pH values close to the neutral point! These features make imidazole an ideal substance for forming hydrogen bonds in biological systems, particularly in enzymes.

2.2. Catalytic Properties

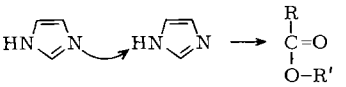
Intensive study of the catalytic properties of imidazole began after *Hartley* and *Massey*[17] had observed that benzoyl histidine methyl ester catalyzed the hydrolysis of *p*-nitrophenyl acetate. Imidazole was thus the first organic base to be recognized as a catalyst of an ester hydrolysis. It was shown



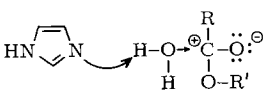
in numerous investigations that, depending on the structure of the ester, imidazole can take part in either nucleophilic or base catalysis.

Nucleophilic catalysis of ester hydrolysis was studied most thoroughly using the example of *p*-nitrophenyl acetate[18–22]; this is also an example for the catalysis of acyl transfer. Imidazole cannot displace strongly basic alcoholate ions from normal esters on account of its weak basic character; nucleophilic catalysis is therefore only observed during the hydrolysis of activated esters (anhydride character) which are derived from weakly basic alcoholates. Hydrolysis takes place with the intermediate formation of *N*-acetylimidazole, the decomposition of which is the slowest step in the entire reaction. In the presence of other nucleophilic agents such as SH compounds or amines, hydrolysis is replaced by acyl transfer—a reaction which is highly selective and which also takes place when there is a large excess of water[9, 19].

Imidazole has several properties which make it a particularly efficient nucleophilic catalyst[12]: it is a tertiary amine whose *N*-substituents are fixed in such a way that they are of only slight steric hindrance, this is because the nitrogen atom is a component of a five-membered, aromatic ring system. Imidazole's nucleophilic reactivity, which is higher than that of primary and secondary amines, can thus exert its full effect (in contrast to common tertiary amines). In addition imidazole, having a p*K* of 7, is the strongest base known at the neutral point (see Section 2.1).



The intermediate *N*-acetylimidazole is much more reactive towards nucleophiles than normal amides on account of its low resonance stabilization. The lone electron pair of the nitrogen atom which can react with carbonyl groups in normal amides, is integrated within the π electron system of the imidazole in *N*-acetylimidazole and is thus not available.



The basicity of acetylimidazole (p$K = 3.6$) is relatively high since a N atom other than the one which is acyl-substituted is protonated[23]. At the present time there is no convincing evidence that enzyme-bound imidazole acts as a nucleophilic catalyst in enzymatic acyl transfer reactions; in most biological acyl transfer reactions the substrates are not activated acyl compounds.

Some studies support the theory that imidazole can act as a nucleophilic catalyst in enzymes catalyzing the transfer of phosphate. *N*-Phosphonoimidazole has been identified as an intermediate in several enzymes (see Table 1). Using non-enzymatic model reactions, it was shown that imidazole is not a particularly good nucleophile towards monosubstituted phosphoric acid esters; under certain conditions, however, imidazole or phosphonoimidazole can catalyze the hydrolysis of phosphoric acid esters or phosphate transfer respectively[24–26]. Phosphonoimidazoles are approximately as reactive as other phosphoric acid amides.

As the basicity of the alcoholate in the ester increases, the nucleophilic catalysis of imidazole becomes less effective; ultimately, a second order dependence on the imidazole concentration is found in the rate equation which can be accounted for by a general base catalysis of the following type[27, 28]:

If the carbonyl carbon atom of the ester is positively polarized (as is the case, for example, with ethyl chloroacetate), imidazole acts as a general base catalyst in the hydrolysis of the ester; imidazole accepts a proton from a water molecule whose OH group then attacks the carbonyl carbon atom[29]:

Although an unequivocal model reaction utilizing imidazole as a general acid catalyst is not yet known, it is assumed that it can take part in general acid-base catalysis in enzymes.

General base catalysis of ester hydrolysis by imidazole requires the acceptance of a proton from a water molecule. Since the rate constant for proton transfer from a water molecule is $10^3\ s^{-1}$, the rate of this reaction should be the upper limit for hydrolytic, general base-catalyzed processes involving imidazole. Bases which are stronger than imidazole are protonated more rapidly but their conjugate acids are deprotonated more slowly than the imidazolium ion. In the case of a catalyst, protonation and deprotonation must follow one another; the rate of the catalyzed reaction is then determined by the slowest step. Imidazole is the most effective general base catalyst close to the neutral point for the reasons cited above. As the turnover numbers of hydrolytic enzymes are $10-15^5\ s^{-1}$ and the upper limit for catalysis involving imidazole is 10^3, it must be assumed that neighboring acidic or basic groups can enhance the rates of protonation and deprotonation. Turnover numbers in model experiments have been increased by factors of up to 100 by neighboring group effects[30]. Rate constants of up to $10^5\ s^{-1}$ are thus attained which correspond to those of the most efficient enzyme-catalyzed reactions. Rate constants of less than $10^3\ s^{-1}$ are found if other steps are rate limiting.

The importance of general acid-base catalysis for the action of enzymes is due to the fact that the same effect is obtained as that resulting from the intermediate formation of hydroxide or hydrogen ions. The base accepts a proton from the attacking water molecule and enhances the nucleophilic reactivity of the water without forming free hydroxide ions. In spite of this, general acid-base catalysis has only been demonstrated for a few enzymatic reactions (see Section 4).

3. Methods for the Identification of Histidine in Enzyme Active Centers

The question as to whether a certain amino acid is involved in the catalytic reaction of an enzyme or whether it is part of the active center can largely be investigated by the following methods:

1. kinetic measurements,
2. chemical modification and covalent labeling,
3. NMR spectroscopic measurements,
4. X-ray structure analysis.

3.1. Kinetic Measurements

Kinetic measurements of the pH dependence of enzyme activity can be used to determine the pK value of an amino acid essential for catalysis in favorable cases where the amino acid contains a dissociable group. Under certain conditions studies of the influence of pH on V_{max} and K_m also allow differentiation between groups which are directly involved in the catalysis and those which are primarily responsible for substrate binding[31]. In addition, the temperature dependence of the pH dependence can be utilized to obtain the dissociation energy of the functional group for which the pK has been determined. The pK value and dissociation energy can sometimes be assigned to a specific dissociable group essential for catalysis. It is obvious that kinetic measurements alone only permit identification of essential groups in favorable cases as, for example, the pK ranges of the functional groups of proteins overlap with one another to some extent and the information about their possible extreme values in enzymes is incomplete. Other factors give rise to apparent pK values which bear no relationship to those of the functional groups involved in the catalysis, this is particularly so with high and low pK values. The same considerations apply to the dissociation energies of functional groups within the protein.

pK values of between 5.6 and 7.0 are generally assumed for imidazole residues with dissociation energies of between 6.9 and 7.5 kcal/mol. The pK values of imidazole thus lie within a pH range in which protein denaturation scarcely ever occurs and where enzyme activity can usually be easily measured.

Nowadays it is not sufficient to assign the essential groups of an enzyme solely on the basis of kinetic measurements—a combination of several, independent experimental procedures has to be used.

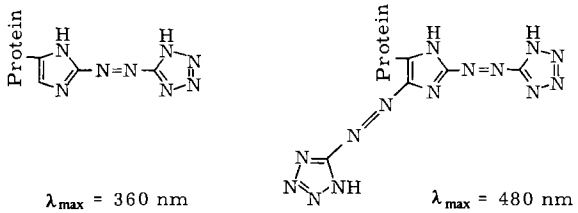
3.2. Chemical Modification

The catalytic activities of enzymes in which individual amino acids have been chemically modified are now being investigated in many laboratories[32]. The modifying reagents should

1. have a specificity for a given amino acid which is as high as possible, and
2. react with the amino acid under the mildest conditions possible.

Although histidine's imidazole residue is, in principle, capable of undergoing numerous reactions (*e.g.* acylation, alkylation and electrophilic substitution), the number of suitable reactions for specific modification under mild conditions is small. Consultation of the literature shows that only a few reactions have found extensive application; of these reactions photooxidation must be mentioned first of all.

3.2.1. Chemical Modification by Photooxidation



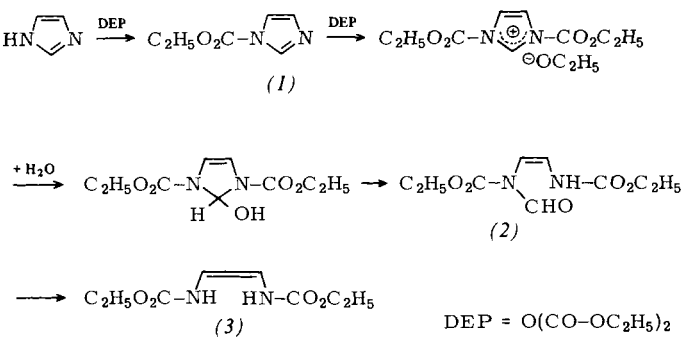
Photooxidation in the presence of methylene blue[33] or rose bengal[34] as sensitizers is used most frequently for the chemical modification of histidine residues in proteins. This procedure is gentle but still leaves something to be desired as far as specificity is concerned since tyrosine, tryptophan and cysteine can also be oxidized; the specificity depends to some extent on the pH of the reaction solution[35]. Histidine is thus especially sensitive to photooxidation in neutral solution in the presence of rose bengal. Its reaction products are aspartic acid and urea[36].

In order to obtain reliable information about the relationships between histidine oxidation and loss of enzyme activity, the pH dependence of the decrease in activity due to photooxidation should be included in the investigation and the tryptophan, tyrosine and methionine contents of the photooxidized protein should also be checked by amino acid analysis. Any methionine *S*-oxide formed can be reduced to methionine by SH compounds (*e.g.* thioglycollic acid, mercaptoethanol). After the reaction the dye is best removed by gel filtration, which, in the case of rose bengal, sometimes gives rise to difficulties. Complete removal of the dye by dialysis often takes a long time.

3.2.2. Chemical Modification by Azo Coupling

Pauly[3] had already observed in 1904 that histidine and tyrosine in proteins could couple with aromatic diazonium salts to give azo dyes. Since then this reaction has often been employed in immunology and enzymology to modify proteins; it takes place under mild conditions. The tetrazolediazonium ion introduced by *Horinishi* in 1964 is well suited[37,38]. It has the advantage that it does not form any colored side products which would increase the blank values in optical measurements. When histidine and tyrosine residues are coupled, mono- and bisazo compounds are produced, some of whose absorption maxima differ considerably and which under favorable conditions (not too much residue to be coupled, exclusive formation of the bisazo product) therefore permit the degree of modification to be determined spectroscopically; the absorption maxima of bis(tetrazolylazo)histidine and mono(tetrazolylazo)tyrosine are almost identical. It is thus highly desirable to check the degree of modification by amino acid analysis. The coupling rates of histidine and tyrosine residues with the tetrazolediazonium ion decrease drastically with decreasing pH.

Although valuable information about the essential histidine residues of enzymes can be gained from coupling experiments of this type, the fact that the specificity of this reaction is



low must not be overlooked. In addition to histidine and tyrosine which form colored coupling products, amino groups, tryptophan and arginine also react and do so with a greater reactivity than histidine and tyrosine[39,40]. Under certain conditions the tetrazolediazonium ion is therefore also well suited for the modification of tryptophan[39]; the degree of modification of the tryptophan residues must be determined by amino acid analysis[41]. It should not be forgotten that the tetrazolediazonium ion is explosive and can only be synthesized from the amine in small quantities.

3.2.3. Chemical Modification by Diethyl Dicarbonate

As was shown in 1967[42], diethyl dicarbonate ("diethyl pyrocarbonate") (DEP) can be used under mild conditions as a reagent for modifying proteins with a considerable specificity for histidine. In addition to histidine, it can also react with tyrosine, tryptophan and amino groups[43]. DEP reacts with histidine at pH 4—7 to give N^{Im}-ethoxycarbonylhistidine *(1)* which has an absorption maximum at 240 nm that can be utilized for spectrophotometric measurements. The reaction is reversible: N^{Im}-ethoxycarbonylhistidine can, for example, be cleaved under mild conditions with hydroxylamine.

After difficulties arose with some enzymes in calculating the degree of modification from the published extinction coefficients for *(1)*[44,45], *Loosemore* and *Pratt* demonstrated in 1976[46] that the imidazole ring can also be cleaved under mild conditions in a subsequent, undesired reaction (Bamberger reaction). This reaction invalidates the spectrophotometric results as the spectra of *(1)*, *(2)* and *(3)* overlap one another. Amino acid analysis of the modified protein must therefore be performed to obtain the number of histidine residues destroyed. The precise conditions which favor quantitative ring cleavage of *(1)* in the protein molecule or which completely inhibit it are not known.

(1) *(2)* *(3)*

Spectrophotometric evaluation of the degree of modification at 240 nm is not possible if *(2)* and *(3)* are formed in significant quantities.

3.2.4. Chemical Modification by α-Halo Acetates, Chloromethyl Ketone and Iodine

In this section a few reagents will be mentioned which, in special cases, have given valuable information concerning the function of histidine in enzymatic reactions. Normally, α-halogen acetates only react very slowly with imidazole residues in proteins. In some enzymes, however, certain histidine residues show an unusually high reactivity which surpasses that of the imidazole in histidine itself[47–49]. High affinity of the modifying reagents for the enzyme active center containing the histidine residue is responsible for this exceptional reactivity. This is also the principle on which K_s inhibitors are based. The high specificities of these inhibitors are due to binding in the active center which follows a covalent reaction with a functional group[50]. Chloromethyl ketones, such as tosyllysylchloromethyl ketone[51] and tosylphenylalanylchloromethyl ketone[52] are K_s inhibitors which have been employed for the covalent labeling of the imidazole residues in the active centers of trypsin and chymotrypsin.

When interpreting alkylation experiments with α-halogen acetates and chloromethyl ketones, the fact that 1- and/or 3-substituted imidazoles and eventually 1,3-disubstituted imidazoles can be produced has to be taken into consideration. In the case of carboxymethyl derivatives the positional isomers can be identified by conventional amino acid analysis as the derivatives withstand acid hydrolysis.

As yet there are scarcely any examples of iodination being utilized to identify essential histidine residues[53]. Iodination of histidine gives 5′-iodo- and then 2′,5′-diiodohistidine[54,55] which are both destroyed by acid hydrolysis with the result that iodination can only be indirectly measured by amino acid analysis.

Histidine is only slightly more slowly iodinated than tyrosine. The ratio between tyrosine iodination and histidine iodination depends very strongly on the protein and conditions used[56]; it seems that the number of reacting histidines is often lower the higher the tryptophan content of the protein. At pH values >9, iodination of histidine is favored with respect to that of tyrosine; a pH optimum of 8.5 has been cited for tyrosine iodination.

3.3. NMR Spectroscopic Measurements

As is shown in Table 1, NMR spectroscopic measurements have yielded valuable information about the function and state of histidine residues in a series of enzymes. Although NMR spectroscopy gives reliable information about the structure and dynamic properties of low molecular weight compounds, the application of this technique to macromolecules and the interpretation of the results is not always simple[57]. First of all there must be adequate quantities of the compound and it should have a sufficiently high solubility in D_2O. The signals must be clearly separated from one another and it should be possible to assign them to known chemical groups within the system; furthermore, it should be possible to interpret the data with regard to the structure and dynamics of the system.

The ^{1}H-NMR signal of histidine's C-2′ proton is shifted by 1 ppm to a lower field strength by protonation of its imidazole nitrogen atom[58]. The pK values of the imidazole can then be determined by using the pH dependence of this shift. The pK values are influenced by interactions between imidazole and its neighboring groups, ions, substrates, inhibitors or other effectors. Conclusions about the rate of exchange between two or more states of the C-2′ proton can also be drawn from the changes in signal width. NMR measurements thus allow statements to be made about the alterations in the states of protein imidazole residues which accompany changes in the pH value.

Table 1. List of enzymes containing essential histidine residues and the methods used to identify the histidine.

No. (EC)	Enzyme	Method of detection [a]	Ref.
1.1.1.1	Alcohol dehydrogenase	DEP	[81]
1.1.1.30	D-3-Hydroxybutyrate dehydrogenase	DEP	[82]
1.1.1.37	Malate dehydrogenase	DEP	[83]
1.1.1.40	"Malic enzyme"	DEP	[84]
1.1.1.41	Isocitrate dehydrogenase	DEP, photoox. (M), alk. (α-Hal.)	[85]
1.1.1.64	Estradiol dehydrogenase	alk.	[86]
1.1.3.9	Galactose oxidase	alk. (α-Hal.)	[87]
1.4.3.2	L-Amino acid oxidase	kin., thermodyn.	[88]
1.4.3.4	Monoamine oxidase	DEP, photoox. (R), azo	[89]
1.5.1.11	Octopine dehydrogenase	photoox. (R)	[90]
1.13.12.4	Lactate 2-monooxygenase	DEP	[91]
1.15.1.1	Superoxide dismutase	$Br^{\bullet}$ (pulse radiolysis)	[92]
2.1.3.2	Aspartate transcarbamylase	photoox. (P), alk.	[93, 94]
2.2.1.2	Transaldolase	photoox. (R), [b]	[95, 96]
2.4.1.1	Phosphorylase	photoox. (R)	[97]
2.4.2.1	Purine nucleoside phosphorylase	kin.	[98]
2.6.1.1	Aspartate aminotransferase	photoox. (M), alk., kin.	[99]
2.7.1.11	6-Phosphofructo kinase	photoox. (M)	[100]
2.7.1.37	c-AMP-dependent histone kinase	[^{32}P]-P-His	[78, 101]
2.7.1.40	Pyruvate kinase	DEP	[102]
2.7.3.2	Kreatine kinase	DEP	[103]
2.7.3.3	Arginine kinase	DEP	[104]
2.7.4.3	Adenylate kinase	NMR	[105]
2.7.4.6	Nucleoside diphosphate kinase	kin.	[106]
		P-His	[107]
2.7.9.1	Pyruvate phosphate dikinase	[^{32}P]-P-His	[108]
3.1.1.3	Lipase	photoox., kin.	[109]
		DEP	[110]
3.1.1.4	Phospholipase A_2	alk. (*p*-bromoph.)	[111]
3.1.1.7	Acetylcholinesterase	kin.	[112]
3.1.3.1	Alkaline phosphatase	photoox. (M, R)	[113]
3.1.3.2	Acid phosphatase	photoox. (R)	[114]
		P-His	[115]
3.1.3.9	Glucose-6-phosphatase	kin.	[116, 117]
		P-His	[76]
3.1.4.3	Phospholipase C	DEP	[118]
3.1.4.5	Desoxyribonuclease	alk. (iodoacetate)	[119]
3.1.4.22	Ribonuclease (pancreas)	photoox.	[120]
		alk. (α-Hal.)	[121]
		kin.	[122]
		NMR	[123, 124]
3.1.4.23	Ribonuclease T_1	photoox.	[125]
		alk. (iodoacetamide)	[126]
		NMR	[127, 128]
3.1.6.1	Arylsulfatase A	kin., DEP	[129]
		azo	[130]
	Arylsulfatase B	DEP, azo	[131]
3.2.1.1	α-Amylase	kin., thermodyn.	[132]
3.2.1.2	β-Amylase	photoox.	[133]
3.2.1.4	Cellulase	kin., azo	[134]
3.2.1.26	Invertase	kin.	[135, 136]
3.4.11.1	Leucine aminopeptidase	photoox., DEP	[137]
3.4.12.2	Carboxypeptidase A	X-ray	[72, 138, 139]
3.4.12.4	Carboxypeptidase Y	alk. (Z-Phe-CK)	[140]
3.4.21.1	Chymotrypsin	kin.	[141]
		alk. (TPCK)	[142]
		photoox.	[143]
		X-ray	[144]

[a] Abbreviations: alk. = alkylation with bromoacetylarginine methyl ester (BrAc-Arg-OMe), *p*-bromophenacyl bromide (*p*-Brph.), α-halo acetates (α-Hal.), tosyllysylchloromethyl ketone (TLCK). tosylphenylalanylchloromethyl ketone (TPCK), benzyloxycarbonyl-L-phenylalanylbromomethyl ketone (Z-L-PheX) and benzyloxycarbonyl-Phe-chloromethyl ketone (Z-Phe-CK); azo. = azo coupling; DEP = diethyl dicarbonate ("diethyl pyrocarbonate"); kin. = kinetic data; P-His = *N*-phosphonohistidine; photoox. = photooxidation with methylene blue (M), pyridoxal phosphate (P) and rose bengal (R); X-ray = X-ray structure analysis; thermodyn. = thermodynamic data.

4. Enzymes with Essential Histidine Residues

Enzymes which contain essential histidine residues in their active centers are listed in Table 1; the methods employed for identification are also given. In many cases there is no doubt that additional experiments are required to verify that the histidine residues are essential for catalysis. In other cases the evidence for the direct participation of histidine residues in catalysis is irrefutable; their specialized functions are, however, still under discussion (*e.g.* pancreatic ribonuclease or papain, see below). The position of each atom in these enzymes is known but the theories as to how the catalysis proceeds at a molecular level are controversial.

In some enzymes the role of histidine has been studied especially carefully and thoroughly; chymotrypsin, pancreatic ribonuclease, papain, carboanhydrase, carboxypeptidase and

Table 1. continuation.

[b] "Active site peptide" method.
[c] Cross linkage of the essential SH group with a histidine residue.
[d] Alkylation with chloromethyl ketone and subsequent oxidation with performic acid.
[e] Carboxymethylation.

aldolase belong to this group. The functions which can be ascribed to histidine in catalysis will now be briefly described using these examples.

In the case of the serine proteases[59] chymotrypsin, trypsin, thrombin elastase and subtilisin, it is assumed that histidine's imidazole residue takes part in a general acid-base catalysis; it facilitates the splitting off of a proton from an hydroxyl group of a serine residue or from water and thus enhances the nucleophilic reactivity of the remaining anion[60]. The interaction between imidazole and the carboxylate group of an aspartic acid residue can further increase the nucleophilicity of the serine oxygen atom *via* a "charge-relay" system and can also stabilize the tetrahedral intermediate of the catalysis (Fig. 1)[61].

General acid-base catalysis by imidazole is also assumed to occur in the cysteine proteases papain, ficin, bromelain

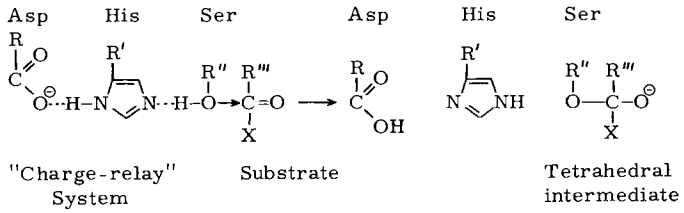

Fig. 1. Mode of action of serine proteases [59–61].

and streptococcal protease; the nature of the interaction between imidazole and the SH group is still not clear[62]. Some evidence supports a similarity with the mode of action of the serine proteases[63] (Fig. 2).

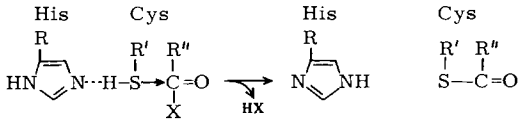

Fig. 2. Concepts of the modes of action of cysteine proteases [62, 63].

Although the exact structure of the active center of pancreatic ribonuclease is known, several reaction mechanisms are under discussion, some of which differ considerably[64]. Some authors assume that there is a general acid-base catalysis with participation of two histidine residues[65–67]; other consider that there is a hydrogen-bonded system composed of two imidazole residues which does not behave as an acid-base catalyst but only serves as part of the catalytic center to maintain the geometry of the active center and the necessary electrophilicity of a proton (Fig. 3)[68].

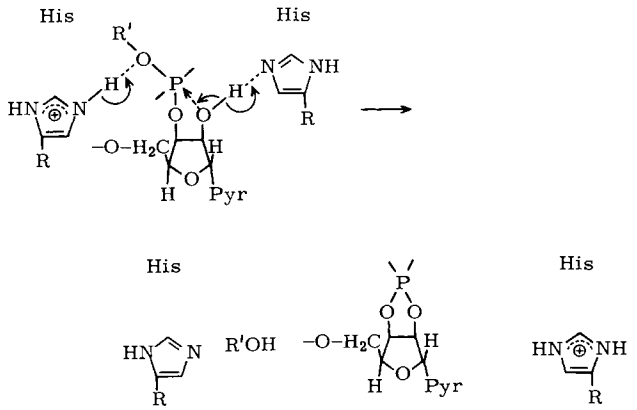

Fig. 3. Acid-base catalysis in ribonuclease [65]. Pyr = pyrimidine base.

Imidazole also acts as an agent for transferring protons to an intermediately formed carbanion in fructose-1,6-bisphosphate aldolase. This carbanion is produce from a fructose-1,6-bisphosphate by aldol cleavage and liberation of the first product, glyceraldehyde-3-phosphate (Fig. 4)[69].

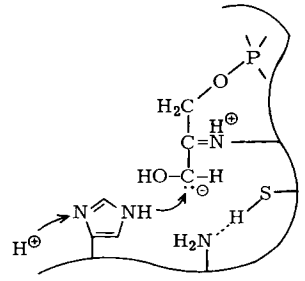

Fig. 4. Proton transfer by an imidazole residue in fructose-1,6-bisphosphate aldolase [69].

For some time the concept of concerted acid-base catalysis with involvement of imidazole residues has attracted special attention. *Jencks*[70] has, however, pointed out that concerted, general acid-base catalysis of complex reactions in aqueous solution is only possible if a marked change in the pK value occurs during the reaction and if the pK value of the catalyst lies between the initial and final pK values of the substrate. Since these criteria are often not satisfied, most reactions proceed in a stepwise and not a concerted fashion.

Carboanhydrase C from human erythrocytes is one of the enzymes which has been best investigated and in which histidine imidazole residues serve as ligands for the binding of zinc which is essential for activity. In this enzyme zinc is bound by three imidazole residues in a distorted tetrahedron whose fourth coordination site is occupied by a water molecule[71]. An imidazole residue is also involved in the binding of zinc in carboxypeptidase A[72].

As has already been mentioned in Section 2.2, *N*-phosphonohistidine has been identified as an intermediate in the enzymatic reactions of several phosphotransferases and hydrolases. Acid phosphatase[73, 74], succinate thiokinase[75], glucose-6-phosphatase[76], phosphoglycerate mutase[77], histone kinase[78] and pyruvate phosphate dikinase[79] are examples of these enzymes. Whereas in the case of acid phosphatase it must be assumed that a histidine imidazole residue participates in a nucleophilic reaction and that a phosphonohistidine is a direct intermediate in the reaction pathway from substrate to product, the significance of the phosphonohistidine demonstrated in phosphotransferases (kinases) is not totally clear. The phosphoenzyme (phosphonohistidine) seems, in at least some cases, to be a side product and not an intermediate of the enzymatic reaction[80].

Numerous enzymes containing essential histidine residues are listed in Table 1 together with the methods used to identify the histidine.

It is certain that other enzymes among the more than 1800 which have so far been classified and characterized by specific reactions will be found to contain essential histidine residues—experience shows that evolution utilizes tried and tested principles as often as possible.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their support of our own work cited in this article.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

$\mathscr{S}_f$ Parameters—A Measure of the Front Strain of Alkyl Groups[**]

By *Hans-Dieter Beckhaus*[*]

The influence of structural modifications on the reactivity of molecules is often interpreted qualitatively in terms of steric effects. However, quantitative descriptions, *e.g.* as linear free-energy relationships[1], seldom prove possible. One reason is that the known steric substituent parameters E_S, E_S^c, E_S^0, $E_S^{\prime}$[1] and ν[2] are defined in terms of the rates of reference reactions. Thus they are not free from additional factors affecting reactivity. Nor do they distinguish between steric effects of different kinds, such as enthalpic and entropic effects. Whenever substituent constants reflect complex effects they suffer a loss of utility and scope[3].

A new approach to the analysis of steric affects was introduced by the use of empirical force field calculations[4]. For a number of reactions a linear relationship was established between the change in free energy of activation and the change in strain energy between the ground state and the transition state[5, 8b]. However, this procedure will not be applicable to the majority of reactions in the forseeable future owing to the incomplete parametrization of the force fields. *DeTar*[6] expediently used alkanes as models for the ground state and transition state in calculations on the acid-catalyzed esterification of carboxylic acids (cf. [9]).

In deriving new substituent constants intended as a measure of the F strain[7] of the substituents we also employed hydrocarbons as models. The F strain, *i.e.* the steric repulsion of the attacking or leaving group of a reaction, is frequently regarded (*e.g.* in the formation and hydrolysis of carboxylic esters[1], the thermolysis of highly substituted ethanes[8], the chromic acid oxidation of secondary alcohols[9a], the reduction of ketones by tetrahydridoborate[9b], and in radical reactions such as termination (cf. [8a]) and halogen transfer[10]) as the principal factor determining reactivity. The steric interaction of a substituent (R) with the core of a molecule is determined by the distance, size, and shape of the latter acting as a steric counterpart. The methyl and *tert*-butyl groups were chosen as the two alkyl groups of highest symmetry to serve as molecular core for the new steric parameters $\mathscr{S}_f(R)$. The $\mathscr{S}_f$ values [eq. (a)] were defined as the difference between the heats of formation of the *tert*-butyl derivative of R, $\Delta H_f^0[R{-}C(CH_3)_3]$, and those of the methyl derivative, $\Delta H_f^0[R{-}CH_3]$. The additive term in eq. (a) appears on normalization to $\mathscr{S}_f(CH_3)=0$.

$$\mathscr{S}_f(R)=\Delta H_f^0[R{-}C(CH_3)_3]-\Delta H_f^0[R{-}CH_3]+8.87 \quad [10^4\ \mathrm{J/mol}] \qquad (a)$$

The heats of formation were all calculated with the aid of the Engler-Schleyer force field[4b, 11]. Table 1 lists the $\mathscr{S}_f$ values of a selection of simple and cyclic alkyl groups.

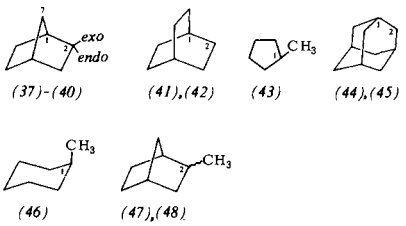

Table 1. Steric substituent constants $\mathscr{S}_f(R)$ [10^4 J/mol^{-1}] for acyclic and cyclic alkyl groups.

	R	$\mathscr{S}_f$		R	$\mathscr{S}_f$
(1)	CH_3	$\equiv 0$	(31)	*cyclo*-C_4H_7	−0.21
(2)	C_2H_5	0.86	(32)	C_8H_7 (Cubyl)	−0.04
(3)–(8)	$CH_2(CH_2)_nCH_3$ (n)	0.89(1),	(33)	*cyclo*-C_3H_5	1.33
		0.86(2),	(34)	*cyclo*-C_5H_9	1.81
		0.85(3–5),	(35)	*cyclo*-C_6H_{11}	2.29
		0.84(6)	(36)	*cyclo*-C_7H_{13}	2.94
(9)	$CH_2CH_2C(CH_3)_3$	0.85	(37)	2-*exo*-	1.83
(10)	CH_2-*cyclo*-C_6H_{11}	1.36	(38)	1-	2.57
(11)	$CH_2CH(CH_3)_2$	1.86	(39)	2-*endo*-	2.71
(12)	$CH_2C(CH_3)_3$	2.29	(40)	7-	3.11
(13)	$CH_2C(CH_3)_2C_4H_9$	3.24	(41)	2-	2.37
(14)	$CH(CH_3)_2$	2.29	(42)	1-	3.49
(15)	$CH(CH_3)C_2H_5$	2.51	(43)	1-	3.81
(16)	$CH(CH_3)CH_2C(CH_3)_3$	2.78	(44)	1-	4.08
(17)	$CH(CH_3)C_6H_{13}$	2.87	(45)	2-	4.45
(18)	$CH(C_2H_5)_2$	3.29	(46)	1-	4.92
(19)	$CH(CH_3)C(CH_3)_3$	4.93	(47)	2-*exo*-	4.98
(20)	$CH[CH(CH_3)_2]_2$	5.61	(48)	2-*endo*	6.20
(21)	$CH(C_2H_5)C(CH_3)_3$	7.26			
(22)	$CH(C(CH_3)_3)_2$	10.68			
(23)	CH(1-Adamantyl)$_2$	12.65			
(24)	$C(CH_3)_3$	3.82			
(25)	$C(CH_3)_2C_2H_5$	4.36			
(26)	$C(CH_3)_2CH_2C(CH_3)_3$	4.40			
(27)	$C(CH_3)_2C_8H_{17}$	4.85			
(28)	$C(CH_3)(C_2H_5)_2$	5.26			
(29)	$C(C_2H_5)_3$	6.28			
(30)	$C(CH_3)_2C(CH_3)_3$	7.51			

The $\mathscr{S}_f$ constants reflect only the steric repulsion of the groups R by a symmetrical counterpart and therefore contain no additional conformational effects such as "gear"[12a] or "cogwheel" effects[12b]. They are therefore ideally suited for the analysis of reactions in which no "gear" effects are operative alongside the F strain. Such a situation is expected in the exothermic reactions of radicals such as termination and halogen transfer[10b].

Moreover, $\mathscr{S}_f$ values should be useful in detecting "gear"-type interactions between substituents and the reaction center.

[**] This work was supported by the University Computer Center at Freiburg (Germany)

This will be demonstrated for the acid-catalyzed esterification of carboxylic acids.

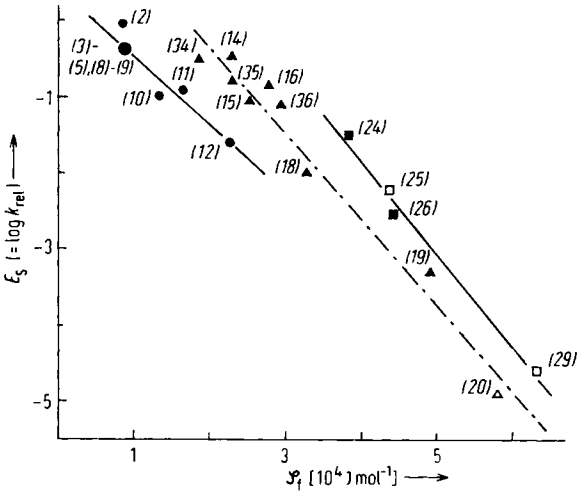

Fig. 1. Correlation of the E_S values (= $\log k_{rel}$) for acid-catalyzed esterification of carboxylic acids (R—COOH) with $\mathcal{S}_f$ values; values corresponding to the open symbols were taken from *P. J. Sniegoski*, J. Org. Chem. *41*, 2058 (1976), and the other from [1]. Correlation coefficients: R = *prim*-alkyl (●), $r = -0.962$ (9 values); R = *sec*-alkyl (▲), $r = -0.972$ (9 values); R = *tert*-alkyl (■), $r = -0.994$ (4 values). The differences in the intercepts are highly significant according to the Student's T test (confidence limits 99.9%).

This reaction is subject to steric hindrance by an increase in steric strain on transformation of the carbonyl C atom of the carboxylic acid into a four-coordinate C atom in the transition state[1, 6]. In the ground state the alkyl groups R can avoid the repulsion exerted by the flat carboxyl group to various degrees, depending upon the number of substituents present on the α-C atom of R, by rotation about the R—COOH bond. The α-substituent in primary R can always find a "conformational gap", the two α-substituents in secondary R can avoid interaction less easily, while the tertiary groups R experience the full effect of repulsion. These possible ways of evasion are limited in the transition state and should therefore appear as differences in reactivity. Correlation of the reaction rates ($\log k_{rel} = E_S$) with the $\mathcal{S}_f$ parameters gives linear plots for primary, secondary, and tertiary groups R with similar slopes but significantly different intercepts (Fig. 1). This is to be regarded as an indication that the E_S parameters include an additional effect depending upon the number of H atoms attached to the α-C atom of R. Most likely this effect is due mainly to the special conformational features of the carboxylic acids.

As may be seen from this and another example[10b], $\mathcal{S}_f$ values prove to be a useful tool for the analysis of F strain effects on reactivity. They are easily calculated even for very bulky groups, *e.g. (24)* and *(25)*, and numerous unsaturated[11b] hydrocarbon groups.

Front Strain of π and σ Radicals[**]

By *Bernd Giese* and *Hans-Dieter Beckhaus*[*]

Radicals are classified as planar π radicals (1) and nonplanar σ radicals *(2)*.

(1) *(2)*

It was deduced from the temperature dependence of the ^{13}C and ^1H coupling constants of ESR spectra[1] that the pyramidal conformation becomes energetically more favorable with increasing alkylation of the radical carbon atom[2]. While the methyl radical is planar (π radical), the *tert*-butyl radical should possess almost tetrahedral geometry (σ radical)[1, 2]. More recent studies have shown that the bending of the *tert*-butyl radical is caused by solvents at low temperature[3]. In the absence of this matrix effect the *tert*-butyl radical should have planar geometry, like the methyl radical[3].

Evidence for a common structure of alkyl radicals above 273 K in solvents of low polarity such as CCl_4 is also provided by our observation[4] that the reactions of methyl and of

prim-, *sec*-, and *tert*-alkyl radicals in the competition system $BrCCl_3/CCl_4$

$$RCl \xleftarrow[\Delta H^{\ddagger}_{Cl}]{CCl_4} \underset{(3)}{R\bullet} \xrightarrow[\Delta H^{\ddagger}_{Br}]{BrCCl_3} RBr \qquad (a)$$

can be described by a common isoselective relationship[4] which differs significantly from the isoselective relationship of σ radicals.

In order to gain a further insight into the preferred conformation of alkyl radials we have developed a method based on the various degrees of steric shielding of the radical carbon atoms. Thus, owing to their planar geometry π radicals *(1)* should have a greater F strain than similarly substituted σ radicals *(2)* because the latters' substituents will be bent away from the frontside. The F strain of the groups R can be calculated from the differences between the heats of formation of the hydrocarbons *(4)* and *(5)*[5]. A suitable radical reaction is halogen capture according to eq. (a) which is controlled by steric parameters of the radicals *(3)*[6].

$R-C(CH_3)_3$ *(4)* $\qquad$ $R-CH_3$ *(5)*

Plotting the experimentally determined activation energies $\Delta H^{\ddagger}_{Cl} - \Delta H^{\ddagger}_{Br}$ of the competing radical reaction (a) *versus* the values of the F strain $\mathcal{S}_f$ calculated from *(4)* and *(5)* gives two straight lines (Fig. 1).

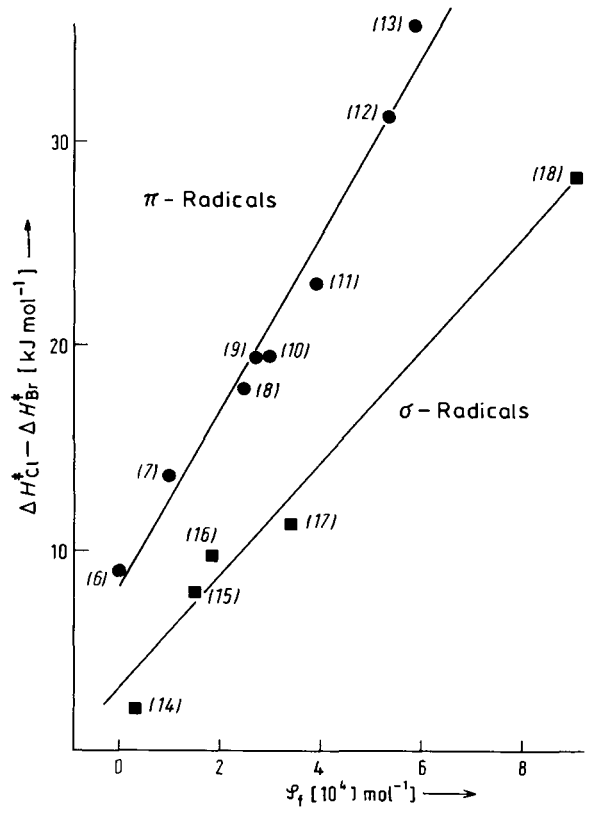

Fig. 1. Variation of the differences in activation energies $\Delta H^{\ddagger}_{Cl} - \Delta H^{\ddagger}_{Br}$ of halogen abstraction (a) with the values of F strain $\mathcal{S}_f$ calculated from the differences in heats of formation of *(4)* and *(5)*. *(6)*: CH_3, *(7)*: 1-$C_6H^{\bullet}_{13}$, *(8)*: *c*-$C_6H^{\bullet}_{11}$, *(9)*: 2-bicyclo[2.2.2]octyl, *(10)*: 2-$C_8H^{\bullet}_{17}$, *(11)*: $C_4H_9C(CH_3)_2\dot{C}H_2$, *(12)*: $C_8H_{17}\dot{C}(CH_3)_2$, *(13)*: $CH_3\dot{C}(C_2H_5)_2$, *(14)*: $CH_2{=}\dot{C}H$, *(15)*: *c*-$C_3H^{\bullet}_5$, *(16)*: $C_6H^{\bullet}_5$, *(17)*: 7-norbornyl, *(18)*: 2-*t*-$C_4H_9C_6H^{\bullet}_4$.

The lower, less steep line represents the σ radicals whose carbon atoms do not have a planar conformation either in the radical *(3)* or in the hydrocarbons *(4)* and *(5)*. The steeper slope of the upper line shows that the corresponding radicals have a larger F strain than is calculated for the nonplanar hydrocarbons *(4)* and *(5)*. In the transition state of halogen abstraction (a) the radicals *(6)*—*(13)* therefore exert a comparatively greater repulsion on the halogen transfer agent $XCCl_3$ (X = Cl, Br) than the σ radicals *(14)*—*(18)*. These differing steric effects indicate that there is only slight pyramidalization, if any, in the radicals *(6)*—*(13)*. Not only the methyl radical *(6)* but also the *prim*-, *sec*-, and *tert*-alkyl radicals *(7)*—*(13)* are therefore largely planar above 273 K. A transition from planar to tetrahedral conformation with increasing number of alkyl substituents[2] cannot be reconciled with our experimental results.

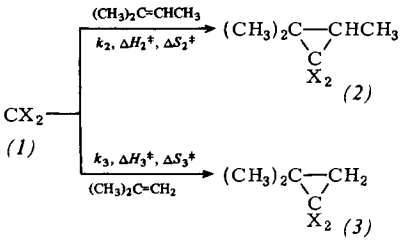
Temperature Dependence of Carbene Selectivities: A New Example of the Isoselective Relationship[**]

By *Bernd Giese* and *Jürgen Meister*[*]



Hardly any absolute rate constants have been published so far for carbene reactions[1]. Selectivity values (relative reactivities) therefore usually have to be employed in interpreting such reactions[2]. However, this can lead to serious errors if temperature effects are disregarded. For example, several series of reactions are known in which the selectivities of molecules become equal in a narrow temperature range, the

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

isoselective temperature T_{is}[3]. Above and below T_{is} the order of selectivities is reversed.

It was recently suspected that the isoselective temperature can lie within the range of experimental determination for carbenes too[3,4]. We have now studied the cycloadditions of difluorocarbene *(1a)*, dichlorocarbene *(1b)*, and dibromocarbene *(1c)* in the 2-methyl-2-butene/2-methylpropene competition system between 233 and 433 K.

(a), X = F; *(b)*, X = Cl; *(c)*, X = Br

The carbenes *(1a—c)* were generated in the temperature range 353 to 433 K from the corresponding trihalomethyl(phenyl)mercury derivatives by the method of *Seyferth*[5a]. Reaction of CHX_3 (X = Cl, Br) with bases such as $(CH_3)_3COK$ was found to be a better method for generating CX_2 (X = Cl, Br) below 353 K[5b]. The selectivity values of the difluorocarbenes generated from difluorodiazirine at 309 and 364 K were taken from the literature[6]. We employed an at least 10-fold excess of the 2-methyl-2-butene/2-methylpropene competition pair in formation and reaction of the carbenes in order that the selectivities ($\log k_2 - \log k_3$) could be determined over large temperature ranges from the ratio of cyclopropanes *(2)*/*(3)* (gas chromatography) according to eq. (A) (Fig. 1).

$$\frac{k_2}{k_3} = \frac{[(2)][(CH_3)_2C{=}CH_2]}{[(3)][(CH_3)_2C{=}CHCH_3]} \qquad (A)$$

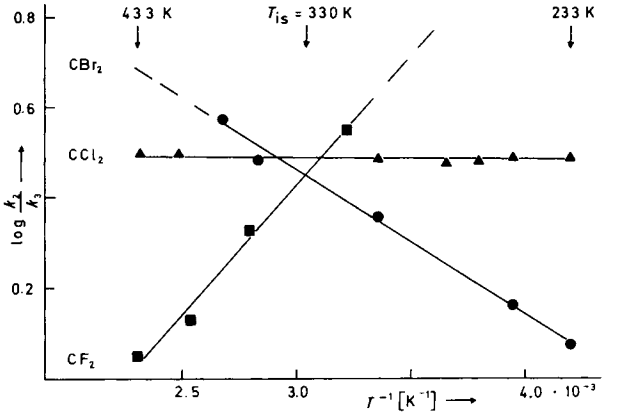

Fig. 1. Temperature dependence of the selectivities ($\log k_2/k_3$) of the carbenes CX_2 (X = F, Cl, Br) in 2-methyl-2-butene/2-methylpropene as competition system [7].

Whereas *(1a)* is the most selective of the carbenes studied below 330 K (order of selectivity: $CF_2 > CCl_2 > CBr_2$), the selectivities assume the same values in the temperature range 330 ± 15 K ($CF_2 = CCl_2 = CBr_2$). Above this temperature *(1c)* is the most selective species ($CF_2 < CCl_2 < CBr_2$). Conclusions concerning differences in reactivities or stabilities of the individual carbenes from experimentally available selectivities are possible only if this influence of temperature is observed. The temperature dependence of the selectivity sequence is due to changes in activation enthalpies, and entropies which are therefore more suitable experimental data for the interpretation of reaction mechanisms[3].

Table 1. Differences in enthalpies of activation $\Delta H_3^{\ddagger} - \Delta H_2^{\ddagger}$ [kJ mol^{-1}] and entropies of activation $\Delta S_3^{\ddagger} - \Delta S_2^{\ddagger}$ [J mol^{-1} K^{-1}] of the carbenes *(1a—c)* in the competition system 2-methyl-2-butene/2-methylpropene.

Carbene	$\Delta H_3^{\ddagger} - \Delta H_2^{\ddagger}$ [a]	$\Delta S_3^{\ddagger} - \Delta S_2^{\ddagger}$ [b]
CF_2	11	26
CCl_2	0.0	− 9.5
CBr_2	−6.1	−27

[a] Mean error ±7%.
[b] Mean error ±5 J mol^{-1} K^{-1}.

Thus the data compiled in Table 1 show that the activation enthalpy $\Delta H_2^{\ddagger}$ for reaction with the sterically more shielded 2-methyl-2-butene becomes less favorable relative to $\Delta H_3^{\ddagger}$ (reaction with 2-methylpropene) with increasing bulkiness of the carbenes ($CF_2 < CCl_2 < CBr_2$). The electrophilic character of CCl_2 and CBr_2, *i.e.* their greater reactivity towards the more nucleophilic 2-methyl-2-butene, is due to entropic effects[9]. In the case of CBr_2, the faster reaction even has the greater activation enthalpy (cf. Table 1).

metallic $Pd_2Mo_2(\eta^5\text{-}C_5H_5)_2(\mu_3\text{-}CO)_2(\mu_2\text{-}CO)_4(PEt_3)_2$ cluster *(1)* instead of a linear trimetallic complex. Complexes $\eta^5\text{-}C_5H_5(OC)_3Mo\text{—}Mo(CO)_2(PEt_3)\eta^5\text{-}C_5H_5$ *(2)* and *(1)* are the only products isolated[4]. The structure of *(1)* was elucidated by X-ray crystallography (Fig. 1)[5].

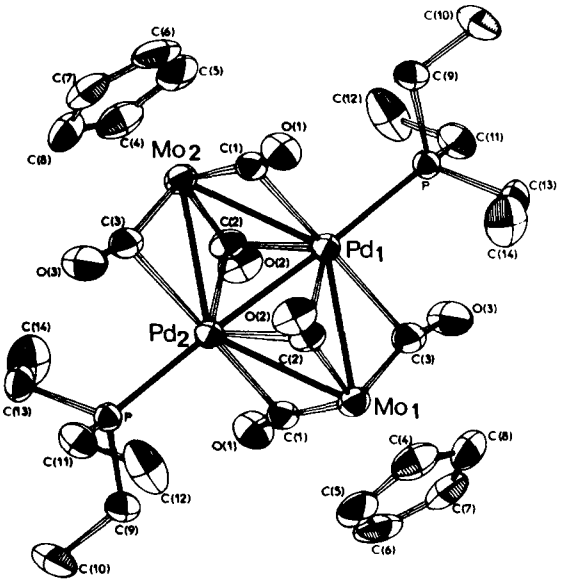

Fig. 1. Structure of the molecule *(1)*; metal-metal bond lengths in [pm]: Pd(1)—Mo(1), 282.7(1); Pd(1)—Mo(2), 286.5(1); Pd(1)—Pd(2), 258.2(1).

The four metal atoms in *(1)* form a planar, triangulated frame, with a center of symmetry in the middle of the Pd—Pd bond. There is one triply bridging μ_3-CO group on each Pd_2Mo triangle [ν(CO) (cm^{-1}) in KBr: 1772 cm^{-1} (vs)] and one bridging μ_2-CO group on each PdMo bond [ν(CO) (cm^{-1}) in KBr: 1842 (vs) and 1801 cm^{-1} (m)]. Each of the two $\eta^5\text{-}C_5H_5$ rings is bonded to a Mo atom and forms an angle of 74.7° with the plane of the metal atoms, whereas the PEt_3 ligands are bonded to the Pd atoms and are collinear with the Pd—Pd bond.

In the 68-electron cluster *(1)*, the presence of two 18 electron Pd and two 16 electron Mo atoms accounts for the five metal-metal bonds. This cluster and its structure appear very significant for the following reasons:

1) each Pd atom has the unusual coordination number eight;

2) it is the first example of an *hetero*polymetallic palladium cluster;

3) it permits the third determination of the metal-metal bond distance between palladium and another transition metal (Pd—Fe[6a], Pd—Co[6b]);

4) the only other reported example of a planar, triangulated cluster is the *homo*tetrametallic $[Re_4(CO)_{16}]^{2-}$ complex[7].

Experimental

All reactions and operations were carried out under nitrogen. Solvents were dried and distilled under nitrogen before use. A tetrahydrofuran solution (60 ml) of $Na[Mo(\eta\text{-}C_5H_5)(CO)_3]$, prepared from $[\eta\text{-}C_5H_5Mo(CO)_3]_2$[8] (2.15 g, 5 mmol), was filtered and added to a suspension of *trans*-$Pd(PEt_3)_2Cl_2$ (2.06 g, 5 mmol) in THF (50 ml) at room temperature. This mixture was stirred for 7.5 h. The residue obtained after filtration and evaporation under reduced pressure was chromatographed on a silica gel column (Kieselgel 60, Merck). Elution with toluene/pentane (1 : 10) gave a pale yellow compound which was not further investigated. Further elution with toluene/pentane (1 : 2) gives a red-mauve solution of *(2)*, which can be recrystallized from toluene/pentane. Yield 0.03 g (0.5 %). With toluene, a dark violet solution was collected which afforded *(1)* as dark-violet crystals from toluene/pentane or CH_2Cl_2/pentane, m.p. 193—196 °C (decomp.); yield 1.75 g (75 % based on Pd, 40 % based on Mo).

4-Dimethylamino-3-butyn-2-one as Activating Agent for Peptide Synthesis[**]

By *Hans-Joachim Gais*[*]

The chemoselective activation of carboxyl groups in polyfunctional molecules is very easily accomplished with 4-dimethylamino-3-butyn-2-one *(1)*[1]. The resulting activated enol esters *(4)* have proved to be excellent acyl transfer agents, *e.g.* in the synthesis of thiol and selenol esters[1].

(1)

(3) *(4)*

It appeared tempting, therefore, to test the utility of the acetylene derivative *(1)* as activating agent for peptide synthesis. We found that *(1)* readily reacts with *N*-acylamino acids *(2a—i)* or *N*-acylpeptides *(2j—m)* in anhydrous aprotic solvents at −60 to 0 °C to give the *N*-acylamino acid- *(4a—i)* or *N*-acylpeptide (*Z*)-1-methyl-2-dimethylcarbamoyl vinyl esters *(4j—m)* in almost quantitative yields (Table 1)[2]. In general, these esters are readily crystallizable, hydrolysis-stable, and, up to *(4e)*, air-stable compounds. The non-isolable primary adducts *(3)* cannot be detected NMR spectroscopically, even at −60 °C[1].

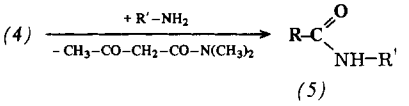
Petersenstrasse 22, D-6100 Darmstadt (Germany)



[**] Part of a lecture delivered at the Chemiedozententagung in Berlin, April 5, 1978.

Table 1. *N*-Acylamino acid- *(4a—i)* and *N*-acylpeptide (*Z*)-1-methyl-2-dimethylcarbamoylvinyl esters *(4j—m)*.

N-Acylamino acid or *N*-acylamino peptide		Enol ester	Yield [%] [a]
(2a)	Boc-L-Tyr	*(4a)*	97
(2b)	Boc-L-Ser	*(4b)*	96
(2c)	Z-L-Ser	*(4c)*	97
(2d)	Z-L-Hyp	*(4d)*	98
(2e)	Ac-L-Cys	*(4e)*	92 [b] [c]
(2f)	Z-L-Gln	*(4f)*	94
(2g)	Boc-L-Asn	*(4g)*	91
(2h)	Z-L-Phe	*(4h)*	98
(2i)	Bz-L-Leu	*(4i)*	99
(2j)	Z-Gly-L-Phe	*(4j)*	95
(2k)	Boc-Gly-L-Pro	*(4k)*	93
(2l)	Z-Gly-L-Met	*(4l)*	96
(2m)	Z-L-Leu-L-Val	*(4m)*	96

[a] The yields refer to isolated pure compounds.
[b] Rearranges at room temperature with loss of *N*,*N*-dimethylacetoacetamide.
[c] Determined NMR spectroscopically.

The chemoselective activation of the carboxyl group in Boc-tyrosine *(2a)*, Boc-serine *(2b)*, Z-hydroxyproline *(2d)*, Ac-cysteine *(2e)*, Z-glutamine *(2f)* and Boc-asparagine *(2g)* proceeds smoothly, and the unprotected side-chain functions are not attacked even by an excess of *(1)*. With less than equimolar amounts of *(1)*, no carboxylic anhydride is formed. The activated esters *(4)* react both with amino acid esters and with amino acid ester hydrochloride/triethylamine within a few hours at −10 to 0°C to give the *N*-acylpeptide esters *(5)*[3] in very high yields (Table 2)[2].

(5)

[a] The amide bond being formed is indicated by a vertical line.
[b] The yields refer to isolated pure compounds.

In most cases the crude products are crystalline and already analytically pure. The facile and clean synthesis of peptides *(5)* from the amino acids *(2)* with unprotected side-chain functions deserves special mention. The *N*,*N*-dimethylacetoacetamide formed along with *(5)* is readily soluble in water, carbon tetrachloride and ether and thus can be easily separated from hydrophobic and hydrophilic products. The synthesis of *(5)* from *(2)* can also be carried out as a one-pot reaction.

Of crucial importance is the racemization-free formation of the amide bond. On IR spectroscopic investigation of the synthesis of the enol ester from hippuric acid and *(1)* no azlactone formation was observed (Woodward test[4]), which is generally held responsible for the racemization[5]. In accord with this finding the very sensitive Young test[6], modified according to Anderson[7], shows that no racemization takes place in the synthesis of *(5i)* from *(4i)* and glycine ethyl ester-hydrochloride/triethylamine. According to the Anderson test[8] *(5j)* is also formed without racemization.

General Procedure

N-Benzyloxycarbonyl-L-serine (*Z*)-1-methyl-2-dimethylcarbamoylvinyl ester *(4c)*: A solution of *(2c)* (2.39 g, 10.0 mmol) in anhydrous THF (50 ml) is added dropwise with stirring at −30°C to a solution of *(1)* (1.12 g, 10.1 mmol) in anhydrous THF (30 ml) in the absence of moisture. After 30 minutes' stirring at −30°C the reaction solution is warmed to room temperature and the solvent removed by evaporation *in vacuo*. Recrystallization of the crystalline residue from ethyl acetate/*n*-hexane affords 3.39 g (97%) *(4c)*, colorless crystals, m.p. 109—110°C, $[\alpha]_D^{23} = -99.7°$ (2, $CHCl_3$), ^{1}H-NMR (60 MHz, [D_6]-DMSO, δ rel. TMS int). 1.94 (d, $J = 0.7$ Hz, 3H), 2.81 (s, 3H), 2.97 (s, 3H), 3.66 (m, 2H), 4.26 (m, 1H), 4.95 (t, $J = 7$ Hz, 1H), 5.10 (s, 2H), 6.00 (q, $J = 0.7$ Hz, 1H), 7.40 (s, 5H), 7.48 (m, 1H).

N-Benzoyl-L-leucyl-glycine ethyl ester *(5i)*: A solution of *(2i)* [m.p. 103.5—105°C, $[\alpha]_D^{23} = -7.0°$ (2.6, C_2H_5OH)] (2.35 g, 10.0 mmol) in anhydrous THF (50 ml) is added dropwise with stirring at −30°C to a solution of *(1)* (1.12 g, 10.1 mmol) in anhydrous THF (30 ml) in the absence of moisture. After 30 min at −30°C the reaction solution is warmed to 0°C, treated with 1.53 g (11.0 mmol) glycine ethyl ester-hydrochloride and 1.53 ml (11.0 mmol) anhydrous triethylamine, and stirring continued for 12 h at room temperature. After removal of solvent *in vacuo*, the residue is taken up in 100 ml ethyl acetate and the resulting solution washed with water, saturated $NaHCO_3$ solution, 1 N hydrochloric acid and brine, and finally dried over $MgSO_4$. Removal of solvent *in vacuo* affords 3.04 g (95%) *(5i)*, colorless crystals, m.p. 155.5—156.5°C, $[\alpha]_D^{23} = -33.7°$ (3, C_2H_5OH) (−33.5°[7]).

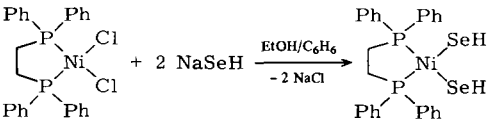
Ethylenebis(diphenylphosphane)dihydrogenselenidonickel(II)



By *Max Schmidt* and *Gerhard G. Hoffmann*[*]

Paramagnetic nickel(I) complexes containing SH-, SR-, or SeH-ligands have recently been described[1]. This has prompted us to report on the first results of studies aimed,

[*] Prof. Dr. M. Schmidt, Dipl.-Chem. G. G. Hoffmann
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

inter alia, at the synthesis and investigation of previously unknown "acidic transition metal selenides" of the type $L_xM(SeH)_y$.

Our attempts to convert dichloroethylenebis(diphenylphosphane)nickel(II) *(1)* into (diphos)Ni$(SH)_2$ with hydrogen sulfide have, in contrast to reactions of comparable palladium(II) and platinum(II) compounds[2], so far failed (mainly NiS formation). Surprisingly, however, we have been able to synthesize the homologous complex (diphos)Ni$(SeH)_2$ *(2)* by reaction of *(1)* with sodium hydrogen selenide in ethanol/benzene according to

(1) *(2)*

The new compound *(2)* is the first hydrogen chalcogenide of nickel(II). The reddish-brown, tetracoordinated d^8-complex is insoluble in unchlorinated hydrocarbons, alcohols, and water. In the solid state it is astonishingly air-stable, despite the two vicinal HSe groups; decomposition, with, *inter alia*, evolution of H_2Se, is only observed above *ca.* 100 °C (the DTA diagram shows a second maximum at 146 °C).

Solutions of *(2)* in CH_2Cl_2 or $CHCl_3$, on the other hand, decompose slowly in the presence of air (formation of a black precipitate). The clearly identifiable ^{1}H-NMR spectrum ($CDCl_3$, TMS int.) shows a singlet for the SeH protons at $\delta = 1.7$. In the IR spectrum (Nujol) the SeH stretching vibration appears at 2259 cm^{-1}; the bands at 249 and 209 cm^{-1} are assigned to the Ni—Se stretching vibrations.

Procedure

To a solution of 5.00 mmol sodium hydrogen selenide [prepared from 0.39 g (5.00 mmol) selenium and 0.2 g (5.30 mmol) sodium tetrahydridoborate] in 25 ml ethanol and 10 mol benzene is added 1.30 g (2.50 mmol) (diphos)$NiCl_2$ *(1)* under an atmosphere of N_2; the resulting suspension slowly turns rusty-brown in color. After stirring for 0.5 h it is filtered, washed with water, ethanol and *n*-hexane, and dried over P_4O_{10}. Yield 81.2 %. The elemental analysis (C, H, Ni, Se) of the product corresponds to the composition of *(2)*.

2,4-Bis(dimethylcarbamoyl)-1,1-dioxo-3-phenyl-1λ^6,2,4,3-thiadiazaboretidine: a BN_2S Ring by "Insertion" of Sulfonyl Diisocyanate[**]

By *Herbert W. Roesky* and *Sushil K. Mehrotra*[*]

Four-membered boron-nitrogen heterocycles have been well documented[1, 2]; however, no compounds having sulfur in the ring have so far been described[3]. In connection with our studies on sulfur-nitrogen compounds we were interested in the combination of electron-rich and electron-deficient elements, in order to obtain further information about the bonding in such systems. We have now been able to synthesize the thiadiazaboretidine *(3)* in quantitative yield by reaction of bis(dimethylamino)phenylborane *(1)* with sulfonyl diisocyanate *(2)*.

(3)

The amorphous, white solid product *(3)* is sensitive to hydrolysis and is soluble in benzene. The mass spectrum (70 eV) shows the molecular ion of *(3)* at $m/e = 324$ (31 % rel. int.) and $(CH_3)_2NCO^+$ as base peak at $m/e = 72$ (100 %). The ^{1}H-NMR spectrum shows the expected singlet at $\delta = 3.52$ for the methyl protons and a multiplet at $\delta = 7.84$ (TMS ext.) for the phenyl protons. The absorptions observed at 1620 and 1597 cm^{-1} in the IR spectrum are assigned to the C=O stretching vibrations. Both the IR and mass spectra as well as the high solubility of *(3)* in weakly polar solvents are inconsistent with the alternative structure of a dipolar addition product.

Procedure

A solution of *(2)* (2.81 g, 18 mmol) in CH_2Cl_2 (10 ml) is added to a solution of *(1)* (3.3 g, 18 mmol) at room temperature. Reaction is exothermic, and a colorless solution is obtained. After one hour's stirring the solvent is removed *in vacuo* without application of heat. The white residue is taken up in a little benzene and the solution filtered and finally concentrated by evaporation. *(3)* precipitates; yield 5.9 g (97 %), m.p. 197—200 °C. The composition of the compound is confirmed by elemental analysis (C, H, B, N and S).

An Unusually Versatile Solid-State Structure: Polyiodides of Type $Tl_6I_6M^{n+}_{2/n}(I_4)^{2-}$ (M = Ag, Au, Tl, Pb, Bi, Ln, Zr, Hf, Th)

By *Albrecht Rabenau* and *Wolfgang Stoeger*[*]

In the polyiodide $Tl_6I_6Pb^{2+}(I_4)^{2-}$ (Tl_6PbI_{10})[1] three channels are formed per unit cell of the skeletal structure parallel to the hexagonal *c*-axis (space group $P\bar{6}2c$). One of the channels consists of a column of face-sharing I_6 octahedra

[*] Prof. Dr. A. Rabenau, Dr. W. Stoeger [+]
Max-Planck-Institut für Festkörperforschung
Heisenbergstr. 1, D-7000 Stuttgart 80 (Germany)
[+] New address: Semicron GmbH, Sigmundstr. 200, D-8500 Nürnberg 15 (Germany).

in which the Pb^{2+} ions are arranged linearly. In the two other channels the linear array of iodine atoms of the polyiodide group are coordinated by thallium in a distorted octahedral arrangement (cf. Fig. 1).

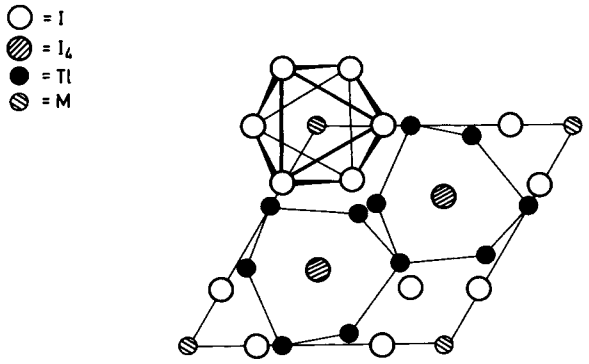

Fig. 1. Projection along [001]. The boundary of the unit cell and the atoms of the channel wall are joined by lines. I_6 octahedron outlined perspectively.

The similarity between this structure and that of the superposed structure of Tl_3I_4[2], in which thallium replaces lead, would immediately suggest that variation in the occupation of the octahedral columns is possible. We have in fact confirmed this concept in numerous examples, and observed that there is unusually large tolerance regarding the size, charge, and electronic configuration of the species M. According to single crystal structure analyses already carried out on some of the compounds the channels are extremely flexible regarding the accommodation of cations. While bismuth occupies the octahedral centers, in the case of lead[1b] and silver[3a] the atoms are displaced somewhat from the octahedral centers, leading in the latter case to pair formation. On the other hand, in the case of gold[3b] 5/6 of the atoms lie in triply-coordinated positions in the faces shared by adjacent octahedra.

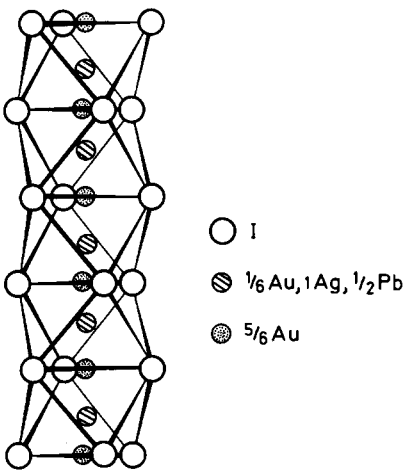

Fig. 2. Distribution of the metals M within the I_6 octahedral column with accommodation possibilities (idealized).

The polyiodide atoms accommodate to the type and occupation of the cationic sites. Whereas equidistant I_4^{2-} groups are present in the lead compound, in the silver compound the bond lengths are clearly different, corresponding to the situation in $Cu(NH_3)_4I_4$[2,4]. In the gold compound the combination I_3^-, I predominates over I_4^{2-}.

The results of further structural investigations should prove interesting, especially in the case of the lanthanoid (Ln) compounds and Zr^{4+} and Th^{4+}. A compilation of results available thus far is given in Table 1. The extraordinary versatility regarding the physical properties of this "model structure", in which a one-dimensional arrangement of very different ions is possible, is immediately recognizable. The preparative scope of such a structure can obviously be extended even further through solid solution formation. Obviously, the combination $M^{\geq 3+}$, Tl^+ contributes to the stability of this structure. Its belonging to a symmetry class without a symmetry center ($\bar{6}2m$) is also of interest in this connection.

[a] Superposing structure [1b].

Procedure

For the synthesis of compounds which show no indication of second phases from X-ray diffraction the carefully purified starting materials thallium iodide, an iodide of element M, and iodine were transferred in stoichiometric amounts to a quartz ampule, which was cooled with liquid nitrogen and then sealed under vacuum. An excess of iodine was necessary for compensation of the free volume. The mixture of reactants was heated until molten, the ampule shaken and then quenched in water. Finally the ampule was allowed to stand for two to three weeks at a temperature just below the melting or decomposition temperature. Thus far, single crystals of the Ag, Au, Pb, and Bi compounds have been obtained by hydrothermal synthesis in hydriodic acid[5] and by the Bridgman method[6].

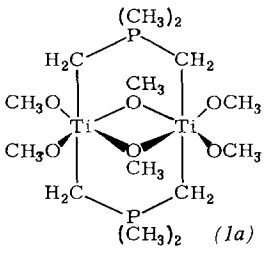
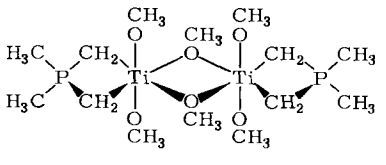
An Organotitanium Compound with Ylide Clamps between Two Octahedrally Coordinated Metal Atoms[**]

By *Wolfgang Scharf, Dietmar Neugebauer, Ulrich Schubert,* and *Hubert Schmidbaur*[*]



Organometallic compounds derived from phosphorus ylides are of topical interest owing to their novel structural and bonding features[1] and their potential use in homogeneous catalysis[2]. Derivatives of such compounds with titanium as the central metal atom, which are especially promising in this connection, are so far limited to only a few examples[2a, 3]. We report here on the synthesis and structural characterization of a binuclear titanium compound, for which there is no precedent in the coordination chemistry of ylides.

Reaction of methoxytitanium halides with (trimethylphosphonio)methylide in ether, even in non-stoichiometric amounts, leads with redistribution of the methoxy groups to a yellow crystalline product of the composition $(CH_3O)_6Ti_2[(CH_2)_2P(CH_3)_2]_2$ *(1)*. At the same time, tetramethylphosphonium halide is formed as a by-product of the transylidation according to the idealized equation:

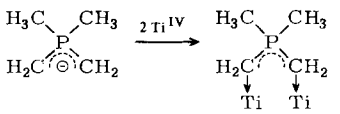


$$2(CH_3O)_3TiCl + 4(CH_3)_3P{=}CH_2 \rightarrow 2[(CH_3)_4P]Cl + (1)$$

$(CH_3O)_3TiCl$, $(CH_3O)_2TiCl_2$ *etc.* react very similarly, thus indicating an unusually high tendency for formation of *(1)*, m.p. 93–95 °C (dec.); the formula of the binuclear complex is confirmed by elemental analysis and the mass spectrum ($M^+ - OCH_3$, $m/e = 430$).

From the spectroscopic data two alternative highly symmetrical structures *(1a)* and *(1b)* are plausible. Two singlets (area ratio 2:1) are observed for the methoxy groups, both in the ^{1}H-NMR spectrum ($\delta CH_3O = 4.45$ and 4.28) and in the ^{13}C-NMR spectrum ($\delta CH_3O = 62.09$ and 59.18) as well as two doublets in each case for each of the alkyl groups on phosphorus [$\delta CH_3P = 1.03$, d, 6H, $^2J(PCH) = 12.0$ Hz; $\delta CH_2P = 0.45$, d, 4H, $^2J(PCH) = 13.5$ Hz and $\delta CH_3P = 20.72$, d, 2C, $^1J(PC) = 32$ Hz; $\delta CH_2P = 18.73$, d, 2C, $^1J(PC) = 39$ Hz, respectively]. The $^1H\{^{31}P\}$-experiment gives s(6H), s(3H), s(6H), s(4H) and the $^{31}P\{^1H\}$-spectrum shows a sharp singlet ($\delta P = 26.56$).

(1a)



(1b)

Only the X-ray structure analysis[4] shows unequivocally that the complex does not have the chelate structure *(1b)*, for which there are numerous examples in the case of other metals[1, 5], but the novel structure *(1a)* with ylide-bridging of the coordination octahedra.

Noteworthy are the remarkably long Ti—C σ-bonds (cf. Fig. 1 and *e.g.* [6]), while at the same time the P—CH_2 bond lengths are so short that the bridge ligand has, at least in part, preserved its ylidic nature.

Consistent with this finding is the high chemical reactivity of this sensitive compound.

The Ti—Ti distance (325 pm) infers that there are hardly any bonding interactions between the metal atoms. Bridge and terminal Ti—O distances are expectedly very different. The folding of the formal $P_2C_4Ti_2$ eight-membered ring is the same as that observed in the analogous copper[7] and gold complexes[8], in which, however, the metal atoms are not six-coordinated but only two-coordinated.

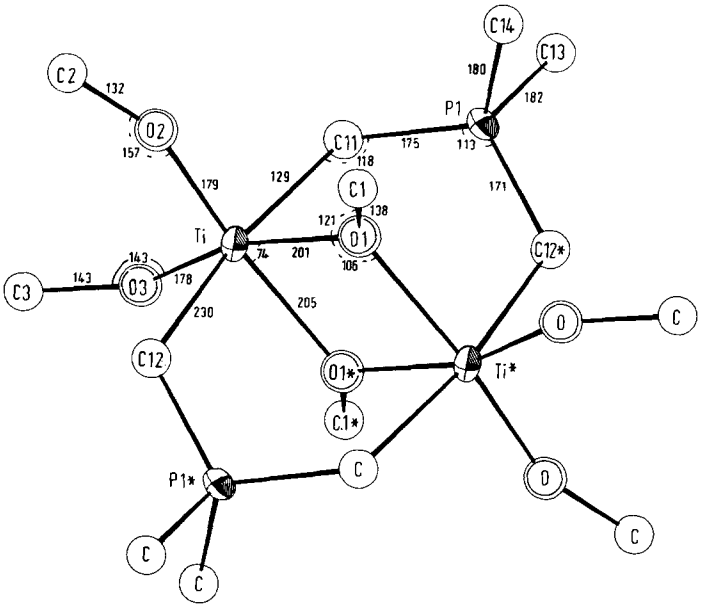


Fig. 1. Structure of complex *(1)* in the crystal, with bond lengths [pm], bond angles [°].

Procedure

To a solution of dichlorodimethoxo- or chlorotrimethoxotitanium in diethyl ether at room temperature is added an excess of (trimethylphosphino)methylide [molar ratio ≥ 1:2]. After one hours' stirring the reaction mixture is filtered and the filtrate evaporated down almost to complete dryness and allowed to crystallize at −20 °C. Recrystallization from toluene affords yellow crystals of *(1)* in 20—60 % yield.

Cycloadditions with [*n*]Cyclophanes[1]

By *Karl-Ludwig Noble, Henning Hopf, Maitland Jones, Jr.*, and *Seetha L. Kammula*[*]

Benzene and its simple derivatives generally do not tend to play the role of the diene component in Diels-Alder reactions[2]. However, this passive nature can occasionally be overcome by drastic experimental conditions, Lewis acid catalysis, or by the use of strong dienophiles such as dicyanoacetylene, perfluoro-2-butyne, or tetrafluorodehydrobenzene[3].

Another possibility of increasing reactivity consists in the use of sterically strained arenes. Thus, *e.g.* [2.2]paracyclophane (strain energy *ca.* 31 kcal/mol) reacts with dicyanoacetylene[3a] and with tetrafluorodehydrobenzene[3c] to give 1:1 and 1:2 adducts. No cycloaddition takes place with the less reactive dimethyl acetylenedicarboxylate; however, this dienophile does add to the more highly strained [2.2.2](1,2,4)cyclophane (170 °C, 1 h, 61 %)[4].

Since [*n*]cyclophanes with small numbers of bridging members have become readily accessible recently[5], the question of their behavior in [2+4] cycloadditions has attracted interest. We report here on the Diels-Alder reactions of [7]-*(1a)* and [8]paracyclophane *(1b)* and of [7]metacyclophane *(4)*.

The hydrocarbons *(1a)* and *(1b)* react with an excess of perfluorobutyne *(2)*, R = CF_3, on heating to 160 °C for 3 h to give 1:1 adducts (MS analysis) in 52 and 12.5 % yield, respectively, whose structures *(3a)* and *(3b)* follow from spectroscopic data. The ^{1}H-NMR spectra of these bridged barrelenes are highly informative[6]. In the more complex spectrum ($CDCl_3$) of the solid *(3b)* (m.p. 53 °C) the olefin protons H^a appear as a pseudo double-doublet at $\delta = 6.45$ (2H, $J_1 = 6.0$, $J_2 = 2.0$ Hz, coupling with H^c no longer resolved), the bridgehead protons H^b as a sharp double doublet at 4.59 (2H, $J_1 = 6.0$, $J_2 = 2.0$ Hz), the methylene protons H^c at 2.25 (4H, ps-t, $J = 6.5$ Hz) and the remaining bridge protons as an unstructured multiplet between 1.7 and 0.8 (12H). For the oily adduct *(3a)* the corresponding signals are observed at $\delta = 6.52$ (2H, ps-d, $J = 5.5$ Hz, H^a), 4.64 (2H, dd, $J_1 = 5.5$, $J_2 = 1.5$ Hz, H^b), 2.24 (4H, m, H^c) and 1.26 (10H, m, H^d). If the reaction time is prolonged to 24 h in the case of *(1b)*, the yield of *(3b)* increases to 76.5 %. The shorter-bridged phane thus proves to be more suitable for addition; this can be explained in terms of its higher strain energy in comparison to *(1b)*[7]. Under comparable conditions (*o*-dichlorobenzene, 170 °C, 24 h), dicyanoacetylene *(2)*, R = CN, does not react with *(1b)*; cycloaddition to the solid *(3c)* (m.p. 186 °C) [24.6 %; NMR[6] ($CDCl_3$): $\delta = 6.45$ (2H, ps-dd, $J_1 = 2.0$ Hz, H^a), 4.58 (2H, dd, $J_1 = 6.0$, $J_2 = 2.0$ Hz, H^b), 2.27 (4H, ps-t, $J = 7.0$ Hz, H^c), 0.8—1.7 (12H, m, H^d)] takes place only on addition of aluminum trichloride (*o*-dichlorobenzene, 120 °C, 24 h). Finally since dimethyl acetylenedicarboxylate *(2)*, R = $COOCH_3$, does not add to *(1b)*, even with this type of activation ($AlCl_3$/*o*-dichlorobenzene, 120 °C, 24 h) the dienophilicity of the triple bond dienophiles *(2)* towards the arenes *(1)* decreases along the series R = $CF_3 > CN \gg COOCH_3$.

If *(1a)* is treated with a mixture of fluorosulfonic acid and *p*-toluenesulfonic acid in benzene, it isomerizes to the [7]metacyclophane *(4)*. This hydrocarbon also reacts with perfluorobutyne at 150 °C to give an oily 1:1 adduct (50 %), which according to spectroscopic analysis is the isomer *(5)* of *(3a)* [NMR[6] ($CDCl_3$): $\delta = 6.28$ (2H, d, $J = 6.0$ Hz, H^a), 4.82 (2H, t, $J = 6.0$ Hz, H^b), 4.72 (2H, ps-s, H^c), 2.30 (4H, m, H^d), 1.37 (10H, m, H^e)]. As shown by all the above additions the passive nature of benzene rings towards dienophiles can also be overcome by bridging with a relatively short polymethylene chain. Furthermore, the adducts *(3a—c)* and *(5)* are of interest for photoisomerization studies, since their parent compound barrelene may be photorearranged to semibullvalene and cyclooctatetraene[8].

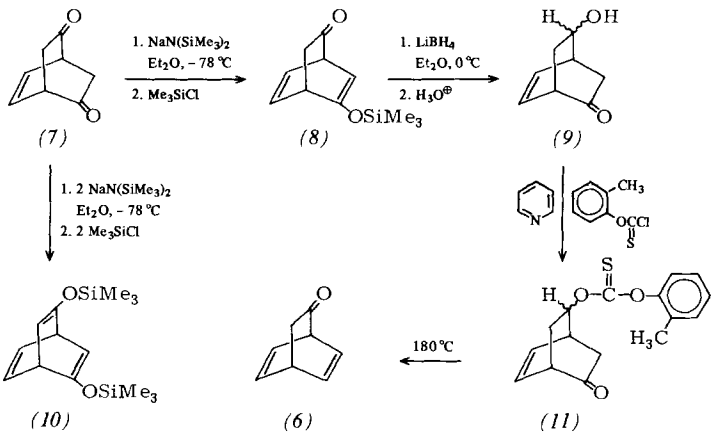
Bicyclo[2.2.2]octa-5,7-dien-2-one ("Barrelenone")[**]

By *Rudolf Gompper* and *Karl-Heinz Etzbach*[*]

Polar substituents influence the reactive behavior of ambifunctional anions and cations by inducing an alteration in charge distribution (allopolarization principle[1]). The aromaticity of a ring system can also alter the polarity and reactivity of an ambifunctional system. The same would appear to apply for bicycloaromaticity: reaction of the anion of bicyclo[4.2.2]-decatrienone with dimethyl sulfate[2] gives a remarkably high yield of enol ether (*O*-methylation).

In continuation of our investigations on the alkylation of the dibenzobarrelenone anion (predominantly *C*-methylation, cf. [1]), we have therefore synthesized bicyclo[2.2.2]octa-5,7-dien-2-one *(6)* in order to study the alkylation of its anion bicyclo[2.2.2]octa-2,5,7-trien-2-olate.

On heating dihydrophthalic anhydride *(1)* (prepared from dihydrophthalic acid and acetic anhydride) with the acrylonitriles *(2a)* and *(2b)* (for the use of *(2)* as ketone equivalent cf. [3]), 7-acetoxy-7-cyanobicyclo[2.2.2]octa-5-ene-2,3-dicarboxylic anhydride *(3a)* (45%, yellow, amorphous powder) and the 7-chloro analog *(3b)* (50%, colorless powder, m.p. 159—161 °C (from chloroform) are obtained, respectively.



(a), R = OAc; *(b)*, R = Cl

Electrolysis of *(3a)* and of *(3b)* (pyridine/triethylamine/water, 90 V, 0.6—0.4 A, room temperature 7 h; cf.[4]) leads to 7-acetoxy-7-cyanobicyclo[2.2.2]octa-2,5-diene *(4a)* (*ca.* 20%; colorless oil, b.p. 100 °C/0.01 mbar (bulb-to-bulb dist.) and the 7-chloro analog *(4b)* (25—30%; colorless needles (from ether) m.p. 62—64 °C), respectively.

Alkaline hydrolysis of *(3a)* yields the dicarboxylic acid *(5)* (70%, colorless, amorphous powder). Both electrolysis of *(5)* (22% yield) as well as alkaline hydrolysis of *(4a)* (70% yield) then afford the barrelenone *(6)* (colorless oil, b.p. 90 °C/17 mbar (bulb-to-bulb dist.); ^{1}H-NMR ($CDCl_3$): $\delta = 1.86$ (d, $J = 3$ Hz; 2H, CH_2), 3.76—4.32 (m; 2H, CH), 6.60 (mc; 4H, —CH=); IR (film): 3065, 2990, 2923, 1725, 1615, 1580 cm^{-1}; 2,4-dinitrophenylhydrazone: red needles m.p. 183—184 °C (from ethanol)).

A second route to *(6)* starts from bicyclo[2.2.2]oct-7-ene-2,5-dione *(7)*[5]. Reaction of *(7)* with Na-bis(trimethylsilyl)-amide in ether at −78 °C affords the Na-salt, which reacts

with trimethylchlorosilane to give the barrelenone derivative 5-trimethylsiloxybicyclo[2.2.2]octa-5,7-dien-2-one *(8)* (75—80%; colorless oil, b.p. 119 °C/17 mbar). Reaction of the disodium salt of *(7)* with trimethylchlorosilane yields 2,5-bis-(trimethylsiloxy)bicyclo[2.2.2]triene *(10)*, a new barrelene derivative (70%, colorless oil). Reaction of *(8)* with $LiBH_4$ and acid hydrolysis of the reaction mixture affords 8-hydroxybicyclo[2.2.2]oct-5-en-2-one *(9)* (68%, colorless needles (from ether/hexane), m.p. 150—155 °C). *(9)* can be converted by known methods[5] into the thiocarbonate *(11)* (99%; yellow-red oil) whose subsequent thermolysis (180 °C/17 mbar) likewise affords barrelenone *(6)* in 70% yield.

Table 1. Methylation of the Na-salts [a] of bicyclic ketones with methyl fluorosulfate in the presence of [18]-crown-6 at 78 °C in ether.

Ketone	$P_{O/C} = l_O/l_C$ [b]	Q_O/Q_C [c]
Barrelenone *(6)*	1.63	0.05
Benzobarrelenone *(12)*	2.02	0.10
Dibenzobarrelenone *(13)*	2.33	0.35
Dihydrobarrelenone *(14)*	2.06	0.53
Dihydrobenzobarrelenone *(15)*	2.39	0.87
Tetrahydrobarrelenone *(16)*	2.78 [d]	1.90

[a] Prepared with $NaN[Si(CH_3)_3]_2$ in Et_2O at −78 °C.
[b] l = HMO charge, calculated with $h_O = 1.0$, $k_{CC} = k_{CO} = 1.0$, homoconjugation $k_{CC} = \pm 0.5$.
[c] Yield ratio % *O*-methylation to % *C*-methylation.
[d] Calculated for the anion of 2-butanone.

The course of methylation of Na-salt of *(6)* and other bicyclic ketones proceeds according to predictions based on the allopolarization principle: As can be seen from Table 1 the tendency towards *O*-methylation also increases with increasing polarity index $P_{O/C}$ in the series[6]

Synthesis and Properties of Tris(trimethylgermyl)aluminum[**]

By *Lutz Rösch* and *Wolfgang Erb*[*]

Organoaluminum compounds are well known and are of considerable preparative interest. In contrast, very few analogs with germanium replacing carbon have so far been described. $R_3Ge—AlR_2$ has been postulated as an intermediate in the reaction of germanium halides with alkylaluminum derivatives[1], and *Calas* and co-workers recently isolated the salt $Li^+[(C_6H_5)_3GeAlH_3]^-$ [2] in the reaction of hexaphenyldigermane with lithium aluminum hydride.

We have now synthesized the first alkylgermylaluminum compound by reaction of bis(trimethylgermyl)mercury with aluminum:

$$3\,Hg[Ge(CH_3)_3]_2 + 2\,Al \xrightarrow{THF/Pentane} 2\,Al[Ge(CH_3)_3]_3 \cdot THF + 3\,Hg$$

The colorless, crystalline tetrahydrofuran adduct *(1)* ignites spontaneously in air; its decomposition in water or D_2O leads to formation of trimethylgermane or trimethyldeuteriogermane, respectively.

The new compound *(1)* is readily soluble in organic solvents such as ether, benzene, or pentane. The ^{1}H-NMR spectrum (benzene) shows only one additional sharp signal in the TMS region besides the coordinated tetrahydrofuran, as well as the ^{13}C-NMR spectrum which shows only one signal for the trimethylgermyl group at $\delta = 1.18$. The structure of *(1)* is confirmed by elemental analysis and the mass spectrum (molecular ion with expected isotopic satellites). *(1)* has an astonishingly high thermal stability; it melts without decomposition at 81 °C, but at 10^{-5} torr it loses part of the coordinated solvent at this temperature. The ^{1}H-NMR spectrum of the residue shows a broad signal in the TMS region. Hydrolysis affords trimethylgermane together with methane, which can be detected by IR spectroscopy. This would indicate decomposition with formation of dimethylgermanediyl, corresponding to the mode of decomposition already observed in the case of the homologous silicon compound[3].

$$Al[Ge(CH_3)_3]_3 \cdot THF \xrightarrow{81\,°C/10^{-5}\,torr} \{Al[Ge(CH_3)_3]_3\} + THF$$
$$\downarrow$$
$$CH_3Al[Ge(CH_3)_3]_2 + \{Ge(CH_3)_2\}$$

Isolation of the intermediary solvent-free tris(trimethylgermyl)aluminum is not possible under these conditions.

Attempts to prepare the likewise unknown tin compound *(2)* in an analogous way showed that *(2)* already decomposes below room temperature.

$$Al[Sn(CH_3)_3 \cdot THF \quad (2)$$

On reaction of bis(trimethylstannyl)mercury with aluminum the solution instantaneously decolorizes. During workup a colorless solid is obtained which contains tin as well as aluminum, but no mercury, and which ignites spontaneously in air. Hydrolysis leads to formation of trimethylstannane and methane. The ^{1}H-NMR spectrum shows a broad multiply split signal in the TMS region, thus indicating spontaneous decomposition of the initially formed tris(trimethylstannyl)aluminum with loss of dimethylstannanediyl under such reaction conditions. This instability in comparison to the germanium compound is consistent with the properties of the corresponding mercury compounds. Bis(trimethylgermyl)mercury is stable up to 120 °C[4], bis(trimethylstannyl)mercury decomposes at −10 °C[5].

Procedure

5 g $(Me_3Ge)_2Hg$ is dissolved in 50 ml pentane and 2 ml THF and stirred together with 8 g aluminum powder under argon until disappearance of the green color (*ca.* 24 h). The solution is filtered through a glass frit and the readily volatile components removed in an oil-pump vacuum at room temperature. The residue is recrystallized twice from a little pentane at −78 °C. 3.86 g (80 %) $Al[Ge(CH_3)_3]_3 \cdot THF$ is obtained as a white crystalline powder.

Evidence for a Dialkoxyalkene Radical Cation in Aqueous Solution

By *Günter Behrens, Eberhard Bothe, Johann Eibenberger, Günther Koltzenburg*, and *Dietrich Schulte-Frohlinde*[*]

In connection with our investigations on the radiation damage of DNA[1] we were interested in the elimination of phosphoric acid from β-phosphatoalkyl radicals[2]. As model species for our studies we used the 1-methoxy-2-phosphatoethyl radical, which rapidly loses phosphate in aqueous solution ($k = 3 \times 10^6\,s^{-1}$) and is converted into $CH_3O—\dot{C}H—CH_2OH$ and $CH_3O—CH(OH)—\dot{C}H_2$[2]. An analogous reaction in which chloride instead of phosphate is eliminated

[*] Prof. Dr. D. Schulte-Frohlinde, Dr. G. Behrens, Dr. E. Bothe, J. Eibenberger, Dr. G. Koltzenburg
Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung
Stiftstrasse 34–36, D-4330 Mülheim-Ruhr 1 (Germany)

has been reported by *Norman et al.*[3], but no experimental evidence for formation of the postulated intermediary radical cation $CH_3\overset{\oplus}{O}{=}CH{-}\dot{C}H_2$ was given. We have now been able to demonstrate such an elimination reaction for the first time: $Cl^{\ominus}$-cleavage from the radical $(CH_3O)_2\dot{C}{-}CH_2Cl$ *(1)* leads directly to the 1,1-dimethoxyethylene radical cation *(3)*.

$\dot{O}H(SO_4^{\ominus})$ radicals, generated by irradiation of aqueous solutions of H_2O_2 (or $Na_2S_2O_8$), react with 2,2-dimethoxyethyl chloride to give the radicals *(1)* and *(2)* in approximately equal yields. Owing to its short lifetime (pulse conductivity measurements $<5\,\mu s$) *(1)* cannot be observed; it decomposes into $Cl^{\ominus}$ and the radical cation *(3)*, which does not react with water during the observation period of a few milliseconds. *(3)* is represented by only one canonical form in the formula scheme. The radical character and structure of *(3)* were determined ESR spectroscopically, and the charge by pulse conductivity measurements.

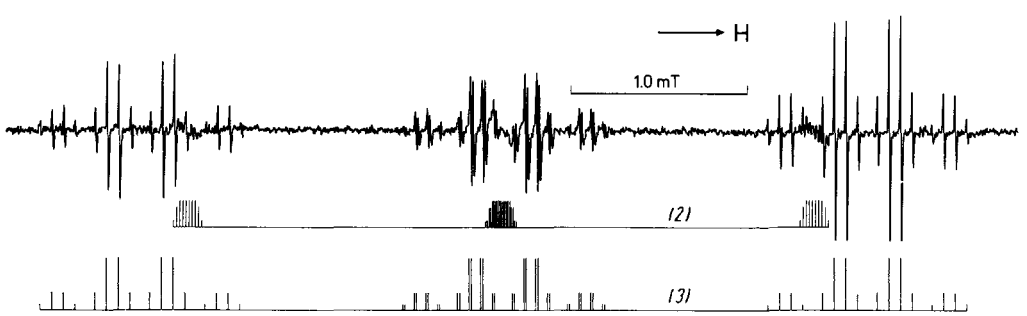

Fig. 1. ESR spectra of the radical cation *(3)* and the radical *(2)* at 276 K, measured during the UV irradiation of an aqueous solution (pH = 3.6) of 0.3 M acetone, 0.2 M 2,2-dimethoxyethyl chloride and 1.0×10^{-2} M peroxodisulfate. The spectrum of *(3)* consists of a triplet of two different quartets. The small doublet splitting of the central group (12.6 μT) arises from second-order effects. The lines of the central group appear somewhat broadened. This points to a small barrier to rotation about the C—C bond, resembling that in the case of ester radicals of the type $\dot{C}H_2{-}C(O)OCH_3$.

As also determined by time-dependent conductivity measurements, the radical cation *(3)* disappears bimolecularly ($2k = 2.5\times10^9$ l/mol·s) with subsequent addition of water and loss of a proton. The ESR spectrum [$a^{CH_{2(2)}} = 2.055$, $a_1^{OCH_{3(3)}} = 0.310$, $a_2^{OCH_{3(3)}} = 0.066$ mT; $g = 2.00306$] indicates the absence of chlorine and a high density of the positive charge on the oxygen atoms. The non-equivalence of the two methoxy groups indicates a difference in solvation and charge. An unsymmetrical spin- and charge-distribution has already been observed by *Symons et al.*[4] with *m*-dinitrobenzene radical anions and ascribed to a difference in solvation of the two nitro groups. According to thermochemical estimations an oxiranium structure for the radical cation *(3)* is less likely. The isomeric 1,2-dimethoxyethylene radical cation, prepared by reaction of $SO_4^{\ominus}$ with 1,2-dimethoxyethylene, is not observable ESR spectroscopically in water. On the other hand, radical cations of methoxybenzenes have already been observed in aqueous solution[5].

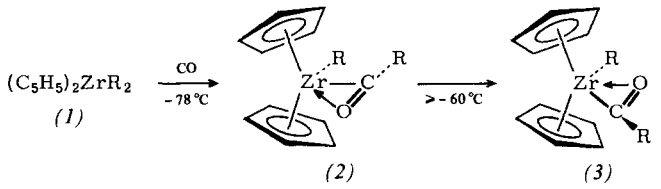
The Formation of Stereoisomeric (η^2-Aroyl)arylbis(η^5-cyclopentadienyl)zirconium(IV) Compounds[**]



By *Gerhard Erker* and *Frank Rosenfeldt*[*]

The problem of the mechanism of "insertion" of carbon monoxide into transition metal-carbon σ-bonds has stimulated extensive investigations owing to the key role of this reaction step in important catalytic processes[1]. The assumption of intermediary η^2-acyl complexes in the reactions is implied by the independent synthesis and isolation of such acyl complexes. Their description as η^2-acyl complexes follows from the structural determination or from the IR spectra [$\nu_{C=O}(acyl) < 1600\,cm^{-1}$][2]. We have now obtained new results on the stereochemistry of η^2-acyl complexes in the carbonylation of diarylbis(η^5-cyclopentadienyl)zirconium(IV) compounds *(1)*.

The stereoisomeric η^2-acyl compounds *(2)* and *(3)* ought to be obtainable by carbonylation of the compounds *(1)*[3]. However, according to *Floriani* the carbonylation of *(1)* at room temperature leads to a uniform product, which can be assigned the structure *(3)*[4].

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Dr. *W. Dietrich* for recording the ^{13}C-NMR spectra.

(a), R = C_6H_5; *(b)*, R = *p*-CH_3—C_6H_4

On reaction of *(1)* with CO at −78 °C we obtained a carbonylation product that was different from *(3)*. With bromine at −78 °C this afforded the same degradation products as *(3)*: aryl bromide, aroyl bromide, and Cp_2ZrBr_2. A comparison of the spectral properties (Table 1) indicates a stereoisomer of *(3)*. The unusual position of the CO stretching vibration band in the IR spectrum and the absorption of the acyl carbon in the ^{13}C-NMR spectrum at remarkably low field[5] indicate the presence of a η^2-aroyl ligand in this complex. On the basis of these data and the isomerization to *(3)* we ascribe the structure *(2)* to the product.

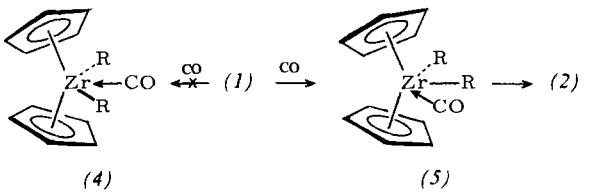

Table 1. Comparison of spectroscopic data of the stereoisomeric bis(η^5-cyclopentadienyl)*p*-toluoyl(*p*-tolyl)zirconium(IV) complexes *(2b)* and *(3b)*.

	(2b)	*(3b)*		
^{1}H-NMR (60 MHz, [D_8]-toluene, rel. to TMS), δ values, −68 °C)	5.57	5.28	(10H)s	$2C_5H_5$
	1.90	2.01	(3H)s	*p*-CH_3—C_6H_4
	6.8 (ν_A), 7.7 (ν_B)	6.8 (ν_A), 7.8 (ν_B)	(4H)AA'BB'	
	2.45	2.48	(3H)s	*p*-CH_3—C_6H_4—CO
	7.2 (ν_A), 8.2 (ν_B)	7.3 (ν_A), 8.3 (ν_B)	(4H)AA'BB'	
^{13}C-NMR (CD_2Cl_2/$CDCl_3$ 3:2, rel. to TMS, δ-values, −75 °C)	300	301	acyl carbon	
IR (CH_2Cl_2, −78 °C)	1480 cm^{-1} [a]	1505 cm^{-1}	$\nu_{C=O}$ (acyl)	

[a] Bands expected for a bent metallocene were also observed; *H. P. Fritz*, Adv. Organomet. Chem. *1*, 262 (1964).

When the solution of *(2)* obtained at −78 °C is allowed to warm to −60 °C, formation of *(3)* is observed (^{1}H-, ^{13}C-NMR, IR). This rearrangement proceeds intramolecularly. Crossover experiments with addition of *(1a)* to a solution of *(2b)* provide no indication of CO transfer; an exchange of aryl groups does not take place. The rearrangement is not reversible. The rates of rearrangement of *(2a)* to *(3a)* and of *(2b)* to *(3b)* were determined ^{1}H-NMR spectroscopically at −59 °C. The reactions can be described in terms of a first-order rate law with Gibbs activation energies of $\Delta G^{\neq}_{59\,°C} = 63.5 \pm 4.7$ [kJ/mol] and 65.2 ± 3.9 [kJ/mol], respectively[6].

It follows from these results that in the investigation of the stereochemistry of CO-insertion reactions the possibility of isomerization—and thus the loss or inversion of stereochemical information—at the stage of a η^2-acyl intermediate must not be ignored. The kinetically controlled, stereospecific

(4) *(5)*

formation of *(2)* in the reaction of *(1)* with CO would suggest that the CO coordination formulated as the initial step does not, as has repeatedly been postulated[4a, 4c, 7], take place at the central position between the two σ-bonded ligands to give *(4)*[8] but, in accordance with calculations by *Hoffmann*[9a] and spectroscopic investigations by *Dahl*[9b], *via* a further route to the product *(5)*.

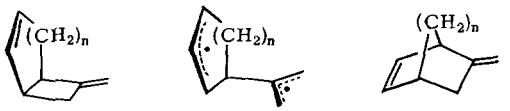
5-Methylenebicyclo[2.2.0]hex-2-ene, a Bicyclic Isomer of Toluene: Synthesis and Thermal Behavior[**]



By *Dieter Hasselmann* and *Klaus Loosen*[*]

At temperatures around 200 °C the bicyclic methylenecycloalkenes *(1b)*[1a] and *(1c)*[1b] undergo both degenerate methylenecyclobutane rearrangement and structural isomerization to the methylenebicyclo[2.2.*n*]alkenes *(2b)* and *(2c)*, respectively. The energy parameters of these rearrangements

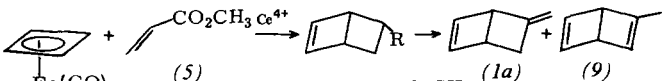
[**] Non-equilibrating Diradicals, Part 3. Presented in part at the Chemiedozenten-Tagung, Marburg, March 1977. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 2: [2].

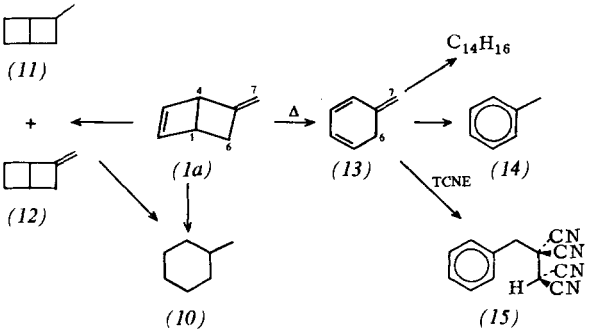


and the results of stereochemical investigations on *(1b)*[2] suggest participation of non-equilibrating diradicals *(3b)* and *(3c)*, respectively. The ratio of degenerate to structural isomerization in *(1b)* and *(1c)*, however, is strongly influenced by conformational effects[1].

(1) *(3)* *(2)*

(a), n = 0; *(b)*, n = 1; *(c)*, n = 2

Such effects should be minimal in the bisallyl diradical *(3a)* with C_s symmetry. As the first stage in our studies on *(3a)* we report here on the synthesis and behavior of 5-methylenebicyclo[2.2.0]hex-2-ene *(1a)* [≡*(2a)*]. This compound is of topical interest, not only as a bicyclic isomer of toluene, but also as a precursor of 5-methylene-1,3-cyclohexadiene *(13)*[3].



(4) *(5)* *(6)*, R = CO_2CH_3 *(1a)* *(9)*

(7), R = CH_2OH

(8), R = CH_2OTs

For the synthesis of *(1a)* we used as starting compound the ester *(6)*, which was obtained in 57% yield (*endo/exo* = 94/6) by oxidation of *(4)* with ammonium cerium(IV) nitrate in the presence of an excess of *(5)*[4]. Reduction with $LiAlH_4$ afforded the alcohol *(7)* as a viscous oil, which was esterified with *p*-toluenesulfonyl chloride in pyridine to the tosylate *(8)* (m.p. 39—40°C, 93%). Elimination with potassium *tert*-butoxide in DMSO (room temperature, 10^{-3} torr) led to two hydrocarbons (48%, 9:1) which were identified as *(1a)* and *(9)*[5]. Attempts to prepare *(1a)* directly by addition of allene to cyclobutadiene, generated from *(4)*, met without success. However, in the analogous reaction of *(4)* in the presence of propyne, *ca.* 15% *(9)* was formed.

The structure of *(1a)*, isolated in pure form by PGC, followed from its spectral data[6], its hydrogenation (Pd/C) exclusively to methylcyclohexane *(10)*, its reduction with diimine with retention of the bicyclo[2.2.0]hexane structure to *(11)* and *(12)* (which are likewise hydrogenated (Pd/C) to *(10)*), its reaction with dimethyl-1,2,4,5-tetrazine-3,6-dicarboxylate with evolution of nitrogen to give the cyclobutene monoadduct[7], and its thermal behavior.

The thermolysis of *(1a)*, both under flow conditions in the gas phase up to 200°C as well as in solution, initially leads exclusively to *(13)*[3,8]. In the gas phase *(13)* isomerizes partially to toluene *(14)*, in solution it reacts—apparently in the sense of a formal ene reaction—with *(1a)* still present to give the (as yet only mass spectroscopically identified) dimers $C_{14}H_{16}$. In the presence of an excess of tetracyanoethylene (TCNE) these secondary reactions can be suppressed quantitatively in favor of the 3-phenyl-1,1,2,2-propanetetracarbonitrile *(15)*[5,9]. *(1a)* itself does not react with TCNE.

We have monitored the kinetics[10] of thermal ring opening of *(1a)* in the presence of TCNE in [D_8]-THF and in CD_3CN. The rate of disappearance of *(1a)* and formation of *(15)* in 2 to 7 M excess of TCNE is independent of concentration and is almost uninfluenced by the difference in solvent polarity ($k_{CD_3CN}/k_{[D_8]\text{-THF}} = 1.1$—$1.2$). The opening of the C^1C^4 bond in *(1a)* to give *(13)* is thus rate-determining: it is strictly a first-order reaction. The activation energy for the orbital symmetry-forbidden cyclodissociation of *(1a)* determined in each case at six temperatures between 35.0 and 60.0°C (Table 1) is reduced by the exocyclic methylene substituent by about 7—8 kcal/mol compared to that of the unsubstituted system *(16)*[11a-11c] and thus is only slightly higher than that of Dewar-benzene *(17)*[11d].

Table 1. Activation parameters of compounds *(1a)*, *(16)* and *(17)*.

(1a) *(16)* *(17)*

Cpd.		E_a [kcal/mol] [a]	log *A* [s^{-1}]	Ref.
(1a)	[D_8]-THF	25.11 ± 0.16 [b]	12.76 ± 0.11	
	CD_3CN	24.71 ± 0.22	12.56 ± 0.15	
(16)	Gas phase	31.9 ± 0.2	13.28	[11a]
	Gas phase	32.95 ± 0.09	13.87 ± 0.04	[11b]
	Solution	31.7	13.6	[11c]
(17)	C_2Cl_4	23.0 ($\Delta H^{\neq}$)	−5.0 ($\Delta S^{\neq}$)	[11d]

[a] 1 cal = 4.1868 J. [b] Standard deviation by method of least squares.

In contrast to *(1b)* and *(1c)*, in *(1a)* no competitive opening of the peripheral C^1C^6 bond with rupture of the central bond can be detected by deuterium labeling in the exocyclic methylene position [*via* reduction of *(6)* with $LiAlD_4$] even after 91% conversion to *(13)*, either in the reisolated starting material or in the end product *(15)*. As expected the generation of an allylcyclobutenyl diradical *(3a)* requires other precursors than the bicyclic toluene isomer *(1a)*.

Intramolecular Electron Transfer of Coordinated Pyrazinecarboxylato Radicals to Cobalt(III): A Pulse Radiolytic Study[**]

By *Karl Wieghardt, Haim Cohen*, and *Dan Meyerstein*[*]

A possible "inner-sphere" mechanism for electron transfer (ET) between two redox-active metal centers through an organic bridging ligand proceeds *via* radical intermediates: an electron reduces the bridging ligand[1]. It is very difficult to obtain direct evidence for the occurrence of such radical species[2]. We have now been able to carry out the pulse radiolytic synthesis and characterization of the free radicals *(4)* and *(5)* for the first time, which have previously only been postulated as short-lived intermediates in the reduction of complexes *(1)* and *(2)* by Cr^{II}[2]. This is therefore regarded as direct demonstration of a "radical ion mechanism"[1] for electron transfer between metal ions.

(1) *(2)* *(3)*

(4) *(5)*

Upon irradiation with electrons (pulse intensity 800—3000 rad, 0.25—1 μs) of aqueous, 1 M isopropanol solutions saturated with N_2O (or Ar)[3], and containing the complexes *(1)* or *(2)* (1—10×10^{-5} mol/l), the formation of strongly absorbing species is observed. The absorption spectra are shown in Fig. 1. Under these conditions the isopropanol radical $(CH_3)_2\dot{C}$—OH reacts as electron transferring agent[3] with the complexes *(1)* and *(2)*, yielding acetone and the radicals *(4)* and *(5)* which are monoprotonated at the heterocyclic ring at pH > 3 (the actual site of protonation at the pyrazine ring is unknown):

$$(1) \text{ or } (2) + (CH_3)_2\dot{C}\text{—OH} \xrightarrow{k(4) \text{ or } k(5)} (4) \text{ or } (5) + (CH_3)_2C{=}O$$

The rate of formation of *(4)* and *(5)* is independent of pH (0—5) and pulse intensity, but dependent on the concentration of the complex[4].

The radicals *(4)* and *(5)* decompose intramolecularly according to a *first order* process with formation of one Co^{II} ion per radical cation; the decomposition is independent of the concentration of complex and the pulse intensity, but dependent on the pH (0—4) [Fig. 2]. The ratio of the $(CH_3)_2\dot{C}$—OH radicals produced by pulses to Co^{II} product is always 1:1; in contrast, the *p*-nitrobenzoato radical coordinated to Co^{III} disproportionates at high H^+ concentrations without formation of Co^{II}[3,6]. The doubly and singly protonated forms of *(4)* and *(5)* decompose at different rates[5]; the former have the longer lifetimes, they are formed at high

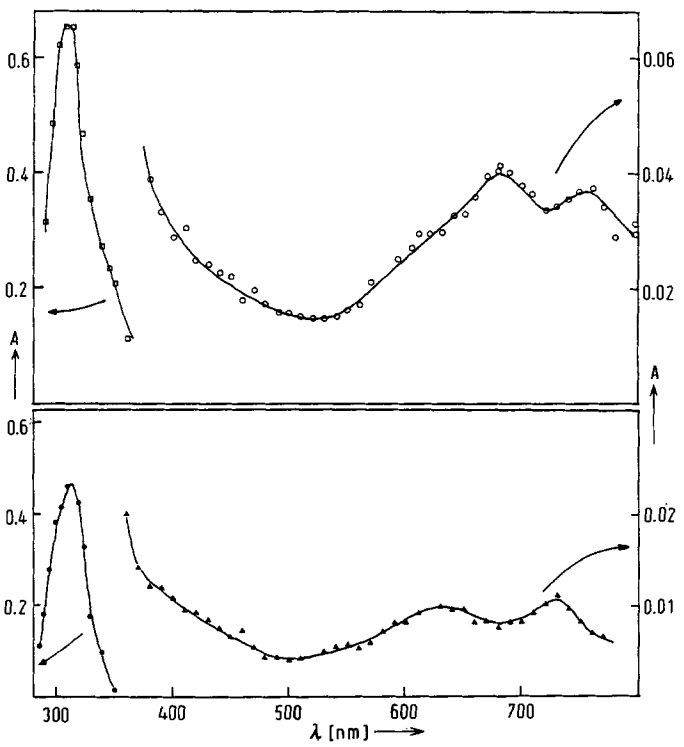

Fig. 1. Absorption spectra of fully protonated radical intermediates *(5)* (upper spectrum) and *(4)* (lower spectrum) at 22 °C. The spectra were recorded on solutions (Ar-saturated, 1 mol/l isopropanol, pH = 1) of the perchlorate salts of the complexes *(1)* and *(2)*.
□ $[(2)] = 2 \times 10^{-5}$ mol/l, pulse intensity 80 rad; ○ $[(2)] = 3 \times 10^{-4}$ mol/l, pulse intensity 860 rad; ● $[(1)] = 2 \times 10^{-5}$ mol/l, pulse intensity 80 rad; ▲ $[(1)] = 1 \times 10^{-4}$ mol/l, pulse intensity 800 rad.

H^+ concentrations (pH < 2.7). The pK_a values could be determined "kinetically" from Figure 2 (2.7 for *(4)* and 2.6 for *(5)*); they are in good agreement with spectrophotometrically determined values.

$$Co^{III}—\dot{L}H_2 \overset{K_a}{\rightleftharpoons} Co^{III}—\dot{L}H + H^+$$

$$Co^{III}—\dot{L}H_2 \xrightarrow{k_d} Co^{II} + LH_2$$

$$Co^{III}—\dot{L}H \xrightarrow{k_p} Co^{II} + LH$$

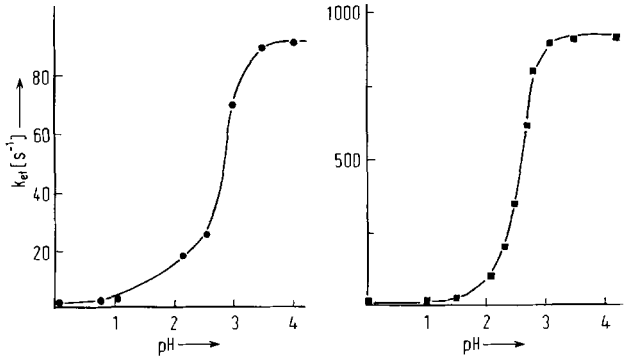

Fig. 2. Intramolecular ET rate constants, k_{et} [s^{-1}], of radicals *(4)* (left) and *(5)* (right) as a function of pH (22 °C).

(3) likewise reacts with $(CH_3)_2\dot{C}—OH$ with *direct* reduction of Co^{III} ($k = (9+2) \times 10^8$ l/mol·s, 22 °C, pH = 5) and *without* formation of a detectable radical intermediate. This indicates that the spin density of the radicals *(4)* and *(5)* is greatest at the N atoms of the aziridine ring. If one of these N atoms is coordinated to a Co^{III} center, electron transfer can take place far more rapidly than in *(4)* or *(5)*.

A General and Facile Synthesis of Aryl- and Heteroarylacetylenes[**]

By *Curt Wentrup* and *Hans-Wilhelm Winter*[*]

Flash pyrolysis is a useful experimental technique for the preparation of kinetically unstable, but thermodynamically stable compounds[1]. In a previous paper[2] we described the preparation of some simple arylacetylenes by flash pyrolysis of 4-arylmethylene-5(4*H*)-isoxazolones. We now report that this reaction permits the synthesis of several acetylenes whose preparation by classical methods is difficult or impossible.

Compounds *(3)* are generally obtained by condensation at room temperature of the corresponding aldehydes *(2)* with 3-methyl-5(4*H*)-isoxazolone *(1)* or its morpholine salt[3] in $CHCl_3$, ethanol, or mixtures of these solvents, or, in the case of *(3f)* and *(3h)* by refluxing in toluene/dimethylformamide[4] (Table 1).

(1) *(2)* *(3)* *(4)* *(5)*

via the carbenes *(4)* (Table 1[4]). The pyrolysis temperatures reported are those giving the highest yields while avoiding the formation of tarry by-products. The acetylenes all tend to polymerize, but are easily purified by distillation or sublimation *in vacuo*. A case in point is 2-ethynylpyrrole *(5a)*, which rapidly polymerizes at room temperature, so that its preparation in solution by conventional methods would be highly problematical. Indeed, previous attempts to isolate this compound failed[5]. Nevertheless, *(5a)* is a thermodynamically very stable compound, surviving gas-phase pyrolysis at temperatures up to 1000°C, and isolable in near-quantitative yield on the pyrolysis of *(3a)* (Table 1).

The preparation of 3-ethynylindole *(5f)* in 20% yield by classical methods was recently described[8]. The yield obtained by the present method (79%) is superior.

The feasibility of flash pyrolysis as a preparative method depends, of course, on the volatility of the starting material. The isoxazolones *(3a)*—*(3h)* all sublime without difficulty at 120—180°C. However, in other cases, *e.g.* the preparation of *p*-nitrophenylacetylene from the corresponding isoxazolone derivative, only low yields were obtained due to extensive decomposition prior to volatilization of the starting material. In such cases we have found that good yields can be obtained by allowing the solid starting material to drop into a vertical pyrolysis tube.

Experimental

Synthesis of *(3a)*: A mixture of *(1)* (2.48 g, 0.025 mol) and pyrrole-2-carbaldehyde *(2a)* (2.38 g, 0.025 mol) in $CHCl_3$-EtOH (1:3) (80 ml) was stirred under N_2 at 22°C for 16 h. After concentrating to half volume, the brown-yellow crystals were filtered and recrystallized several times from $CHCl_3$-hexane, yielding 4.20 g (95%) of *(3a)* as yellow crystals of m.p. 187—188°C.

Synthesis of *(3h)*: To a solution of the morpholine salt[3] (0.93 g, 0.005 mol) of *(1)* in EtOH (20 ml) was added azulene-1-carbaldehyde *(2h)*[9] (0.78 g, 0.005 mol) in EtOH (20 ml), and the mixture was stirred at 22°C under N_2 for 24 h. Work-up as above and recrystallization from $CHCl_3$ (200 ml) furnished *(3h)* (0.83 g, 70%) as dark-red crystals of m.p. 218—219°C.

Synthesis of *(5a)*: A pyrolysis apparatus similar to that previously described[10] was used. At a pressure of *ca.* 10^{-3} torr and an oven temperature of 800°C, *(3a)* (0.4 g, 2.27 mmol) was sublimed from a flask maintained at 120°C in the course of 5 h. The products were collected on a cold-finger at −196°C. Acetonitrile and CO_2 were removed *in vacuo* by allowing the temperature to rise to *ca.* 20°C. *(5a)* (0.20 g; 97%) was isolated by vacuum transfer at 40°C (*ca.* 10^{-2} torr) into a receiver cooled in liq. N_2. ^{1}H-NMR (CCl_4): $\delta = 3.07$ (s, 1H), 6.07 (m, 1H), 6.41 (m, 1H), 6.62 (m, 1H), 8.2 (br., NH).

Synthesis of *(5h)*: In a manner similar to *(5a)*, *(5h)* was prepared in 93% yield as blue crystals of m.p. 35°C by pyrolysis of *(3h)* at 700°C, followed by sublimation of the product at 20°C/10^{-3} torr. ^{1}H-NMR (CCl_4): $\delta = 3.42$ (s, C≡C—H), 7.06—7.70 (m, 4H), 7.96 (d, H^2, $J_{23} = 4$ Hz), 8.26 (d, H^8, $J_{78} = 10$ Hz), 8.57 (d, H^4, $J_{45} = 10$ Hz).

Molecular Sieve Properties of Polymeric Schiff Base-Metal Complexes

By *Manfred Riederer* and *Wolfgang Sawodny*[*]

Materials exhibiting specific absorption features due to pore openings of molecular dimensions, and thus capable of physically separating molecules or atoms according to their size and shape, are called molecular sieves. Examples of such materials already well documented include the zeolites, activated charcoals, porous polymers, and porous glasses.

We recently reported the synthesis of novel polymeric Schiff-base complexes and their ability to form addition compounds with neutral molecules[1]. In the meantime we have also been able to demonstrate their selective adsorption capacity as a function of the critical diameter of the guest component. Data for the most effective of the compounds known so far, *i.e. (1)*, are listed in Table 1.

(1), R =

Table 1. Comparison of the adsorption capacities of compound *(1)*, zeolite and active charcoal molecular sieves in wt.-% (20°C, *ca.* 760 torr).

Adsorbate	Critical diameter [Å]	Adsorbant *(1)*	Zeolite [a]	Active charcoal [a]
Pyridine	5.24	65.75		
CCl_4	6.88	56.72		
Benzene	5.24	50.64	18.80	37.13
CH_3OH	3.00	34.03	10.90	
CH_2Cl_2	4.48	32.01		
Cumene	5.34	29.92		
Cyclohexane	5.37	26.92	19.60	21.00
n-Pentane	4.89	17.38	12.40	
H_2O	2.60	10.75	33.00	28.00
1,3,5-Triethylbenzene	9.00	0.00		

[a] Highest value from the literature.

With exception of the results for water, *(1)* shows a greater adsorption capacity than molecular sieves of the zeolite or active-charcoal type.

We have also investigated the behavior of the polymeric compound *(1)* when used as stationary phase in molecular

[*] Prof. Dr. W. Sawodny, Dr. M. Riederer
Abteilung für Anorganische Chemie der Universität
Oberer Eselsberg, Postfach 4066, D-7900 Ulm (Germany)

sieve gas chromatography[2]. As an example of the efficiency of *(1)* as a molecular sieve, the complete separation of a mixture of noble gases (He, Ne, Ar, K, and Xe) except for He and Ne at room temperature is reproduced in Figure 1. Many other gases, such as Ar and O_2, can also be separated from each other in a similar way at room temperature.

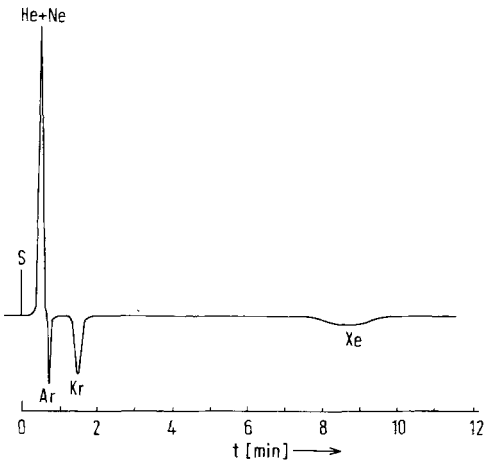

Fig. 1. GC separation of a noble gas mixture on *(1)* at 28 °C (column 200 × 0.2 cm, flow rate 30 ml/min, N_2).

Both the selective adsorption capacity of the polymeric Schiff-base complex *(1)* as well as its efficiency at separating gases in gas-chromatography are similar to that observed for zeolites of the type 13X having pore diameters of 8Å[3]. This lends support to the following molecular model (Fig. 2), based on the bond lengths and angles observed in the structure of Cu(salen)[4].

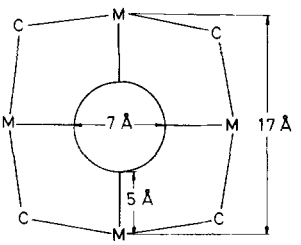

Fig. 2. Cavity in a possible helix structure of compound *(1)* (schematic).

Only the metal ion displaced from the ligand plane and the tetrahedral methylene carbon of the ligand bridge were considered, and were arranged assuming a helical structure. Such a polymeric molecule contains an internal cavity (diameter ≈ 7 Å), which is consistent with its selective adsorption capacity. Thus tetrachloromethane, with a diameter 6.88 Å, is quite readily adsorbed, whereas 1,3,5-triethylbenzene, with a diameter of 9 Å is not.

Ring Contraction by Peracid Oxidation: Preparation of *cyclo*-Heptasulfur Dioxide, S_7O_2, from S_8[1]

By *Ralf Steudel* and *Torsten Sandow*[*]

Sulfur rings S_n (n = 6—8) are oxidized by trifluoroperacetic acid to the monoxides S_nO, which are isolable in pure form[2]. Only on reaction of the sulfanes R_2S_n (R = organyl, n = 3, 4) with an excess of peroxy acid have disulfoxides been obtained. However, they very readily decompose to sulfones, particularly if the sulfoxide groups are separated by only one sulfur atom[3].

In an attempt to oxidize S_8 with excess peroxy acid to S_8O_2, we found that S_7O_2 was formed and could be isolated in pure form in 5—10 % yield:

$$S_8 + 4CF_3CO_3H \rightarrow S_7O_2 + SO_2 + 4CF_3CO_2H$$

Even on extensive variation of the molecular ratio of the reactants there was no indication of a higher oxide of S_8; on the other hand, the reaction product sometimes contained traces of S_7O, which could be identified along with S_7O_2 by Raman spectroscopy. S_7O_2 could also be obtained from S_8O, S_7, and S_7O, but the yields were lower or at best the same.

The formation of S_7O_2 from S_8 most likely proceeds *via* the following steps:

$$S_8 \xrightarrow{+O} S_8O \xrightarrow{+O} [S_8O_2] \xrightarrow{+O} [S_8O_3] \xrightarrow{-SO_2} S_7O \xrightarrow{+O} S_7O_2$$

We assume that the hypothetical S_8O_2 is oxidized very much more rapidly than S_8O, so fast that it cannot be isolated, and that S_8O_3 immediately decomposes into S_7O and SO_2, since it must contain two SO groups which at most can be separated by only one sulfur atom. Decomposition of S_8O_2 into SO_2 and S_7 can be ruled out since S_7 has never been observed as an intermediate.

S_7O_2 forms dark-orange crystals, which are more intensely colored and much less stable than S_7O. At 60—62 °C spontaneous decomposition occurs with vigorous evolution of SO_2 and formation of polymeric sulfur. At 25 °C decomposition begins within a few minutes and is complete after 2 h in the dark. Heating in a vacuum (50—60 °C) leads to the characteristic decomposition product of polysulfur oxides, namely S_2O, which is also observed in the mass spectrum[4] besides SO^+ and S_n^+ (n = 1—8). The composition of S_7O_2 was determined by elemental analysis and osmometric determination of the relative molecular mass in CS_2.

S_7O_2 is far less soluble in CS_2 (*ca.* 1 g/l CS_2 at 0 °C) than S_7O; the solution decomposes within 1 h to S_6, S_7, S_8, and SO_2. The IR spectrum of a freshly prepared solution shows two strong absorptions at 1138 and 1127 cm^{-1}, which can be assigned to the two SO stretching vibrations.

The Raman spectrum[4] shows the typical lines of the S_7 ring in the region 150—280 cm^{-1}, as well as the SO— stretching and SSO deformation vibrations characteristic for the —S—SO—S— groups (Table 1). Assignment of the signals is based on a comparison with the spectra of S_7[5] and S_7O[6]. There is a distinct connection between the wave numbers of the SS stretching vibrations of sulfur rings and the lengths of the corresponding bonds[7] from which the values for the

[*] Prof. Dr. R. Steudel, Dipl.-Chem. T. Sandow
Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

SS bond distances in S_7O_2 can be derived using the wave numbers given in Table 1. On the basis of these values, and observations made in structural studies on S_8O[8a] and S_7O[8b], we suggest the following structure for S_7O_2 (bond lengths in pm):

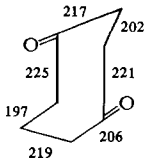

Table 1. Normal modes of solid S_7O_2 (cm^{-1}; Raman intensities in parentheses).

	Assignment		Assignment
1117(4)	ν_{SO}	333(100)	ν_{SS}
1103(16)		300(55)	
1083(23)		277(70)	δ_{ring}
559(10)	ν_{SS}	262(5)	
505(31)		240(36)	
461(14)		230(47)	
407(38)	δ_{SSO}	186(52)

378(41)		151(50)	
356(63)	ν_{SS}		
344(26)			

In this isomer the SO groups, generally observed in an axial array, are at the maximum possible distance.

Procedure

To a solution of S_8 (2.8 g) in analytically pure CH_2Cl_2 (800 ml) is added dropwise 139 ml CF_3CO_3H solution[2] (0.39 mmol CF_3CO_3H/ml; molar ratio S_8: $CF_3CO_3H = 1:5$) at −20 °C. After 2 hours' stirring the reaction mixture is cooled to −78 °C and the colorless CF_3CO_2H that crystallizes out is separated off on a coolable glass frit (−30 °C). The filtrate is treated with 500 ml *n*-hexane at −20 °C, and then allowed to stand for 14 days at −50 °C. The orange-red, crystalline crude product (1.2—1.6 g) is filtered off at −30 °C, dissolved in 1 l anhydrous CS_2 at 0 °C, filtered, and cooled to −78 °C. 100—300 mg S_7O_2 (4—11 %) crystallizes out.

Complete Enantiomer Separation by Chromatography on Potato Starch

By *Heinrich Hess, Günther Burger*, and *Hans Musso*[*]

The enantiomers of numerous chiral biphenyl compounds[1,2] and amino acid derivatives[3] can be enriched in the front and end fractions by chromatography on potato starch. In some cases they have even been isolated optically pure in small amounts.

It has now been found that, in many cases, by proper choice of buffer salt, its concentration and pH value, and temperature, complete separation of enantiomers can be achieved on 130 cm columns which, as shown for example by *(1)* and *(4a)*, can frequently be of preparative use. The UV spectroscopically and polarimetrically measured elution diagrams shown in Figures 1—3 illustrate some of these separations. Figure 1 indicates how the efficiency of separation

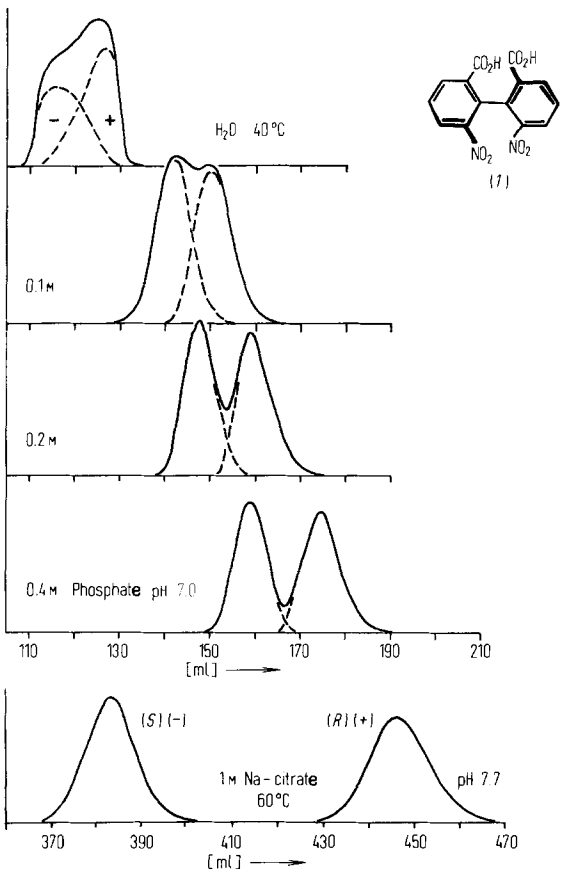

Fig. 1. Elution diagram for 2 mg each of (+)- and (−)-6,6'-dinitrodiphenic acid *(1)* on a 1.6 cm × 135 cm column.

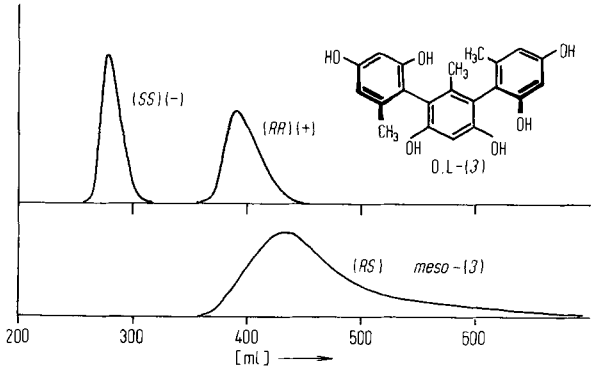
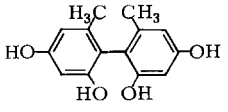
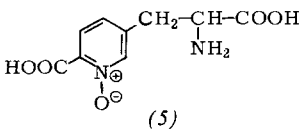
increases with increasing buffer concentration in the case of 6,6'-dinitrodiphenic acid *(1)*. In the case of the *m*-linked trimers of orcinol *(3)* there is a DL form and a *meso* form. Chromatographic separation on potato starch enabled assignment of the two different structures (Fig. 2)[1c]. All three diastereomeric racemates *(4a)*—*(4c)* of the homologous tetramer *(4)*[1] can be cleanly separated (Fig. 3)[4]. Preparative separation of *(4a)* is especially simple: the (−)-enantiomer is washed through a relatively short column with water; the (+)-form is almost completely retained on the column and can be

[*] Dipl.-Chem. H. Hess, G. Burger, Prof. Dr. H. Musso
Institut für Organische Chemie der Universität
Richard-Willstätter-Allee 2, D-7500 Karlsruhe (Germany)

eluted with increasing concentration of methanol. As a rule, increasing temperature reduces tailing and improves the separation. In the case of 2,4,2',4'-tetrahydroxy-6,6'-dimethylbiphenyl *(2)*, a reversal of selectivity is observed with incomplete separation: at 20 °C the (*R*)-(+)-enantiomer is first eluted[1b], at 59 °C the (*S*)-(−)-enantiomer[5].







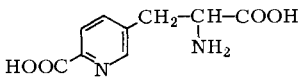


Fig. 2. Elution diagram for 50 mg each of *rac*- and *meso*-trimeric *(3)* on a 2 cm × 130 cm column; 0.2 M phosphate buffer, pH = 7. Rotation values and yields of the pure enantiomers, see [1c].

(2)

(5)

(6)

The precursors required for a biogenic-like synthesis of muscaflavin[6], the *rac.* carboxypyridylalanine derivatives *(5)* and *(6)*[7], have been analytically resolved on the first run on the starch column; the preparative separation meets with difficulties owing to the low column capacity and the large amounts of buffer salt.

Two preparative procedures for the isolation of optically pure enantiomers of *(1)* and *(4a)* demonstrate that it is worthwhile searching for the right conditions for complete separation of enantiomers on cheap natural products such as potato starch.

Procedures

Separation of enantiomers of 6,6'-dinitrodiphenic acid *(1)*: A warm solution of 500 mg of *(1)* and 120 mg of sodium hydroxide in 5 ml of 1.5 M sodium citrate buffer (pH = 7.9) was transferred to a 5.2 cm × 136 cm column and eluted at 80 °C with the same buffer (70 ml/h). The fractions from 5.60—6.61 l contained the pure (*S*)-(−) enantiomer, that from 6.74—7.85 l the pure (*R*)-(+) enantiomer. The intermediate fractions contained 1.2 % of the starting materials. The (*S*)-(−) and (*R*)-(+) fractions were each acidified with 150 g phosphoric acid/l eluate to pH = 4 and extracted with ethyl acetate. Recrystallization from water afforded: 190 mg (*S*)-(−)-*(1)*, m.p. 230—233 °C, $[\alpha]_D^{20} = -137.6°$; 190 mg (*R*)-(+)-*(1)*, m.p. 230—233 °C, $[\alpha]_D^{20} = +138°$ (*c* = 1, ethanol)[8, 9].

Separation of (*S*,*S*,*S*)-(−)- and (*R*,*R*,*R*)-(+)-2,4,2',4',2'',4'',2''',4'''-octahydroxy-6,6',6'',6'''-tetramethyl-*m*,*m*-quaterphenyl *(4a)*: A solution of 200 mg *(4a)* in 40 ml hot water was transferred to a 5.5 cm × 34 cm column and eluted at room temperature with water (3 fractions at 13 ml/h). The fractions 630—1080 ml contained the pure (−)-enantiomer. From 900 ml onwards the eluant solvent was continuously mixed with methanol in the 600 ml supply flask. The fractions 1700—2200 ml (70 % CH_3OH) contained the (+)-enantiomer. The residues obtained from both fractions by evaporation had to be purified on SiO_2 thin-layer plates with ethyl acetate/chloroform (7:3) for separation from dissolved starch. The recovered zones were eluted with acetone and the residues

Conformationally Induced Stereospecificity in the Multiple Epoxidation of *syn*-9-Chloro-*cis*-bicyclo-[6.1.0]nona-2,4,6-triene[**]

By *A. G. Anastassiou* and *R. L. Mahaffey*[*]

In work associated with our quest for novel nonbenzenoid aromatics[1] and specifically directed at the synthesis and study of monohetero and polyhetero annulenyl ions, we prepared a number of multicyclic progenitors *via* selective epoxidation of one or more of the π units of *syn*-9-chloro-*cis*-bicyclo[6.1.0]nona-2,4,6-triene *(1)*, *i.e.* a molecule whose "bridge" substituent is potentially capable of anionically or cationically assisted extrusion. Our specific choice of the sterically constrained extended *syn* epimer over the more flexible *anti* variant stemmed from an attempt to minimize the formation of undesirable stereoisomeric mixtures in the various steps.

Scheme 1.

Prolonged (5 days) exposure of *(1)* to an equivalent quantity of *m*-chloroperbenzoic acid (MCPBA) in CH_2Cl_2 at *ca.* 0 °C led, in 84 % yield (78 % conversion), to a four-component mixture consisting[2] of two symmetrical (^{1}H-NMR) monoepoxides, *(2)* (50 %) (m.p. 71—72 °C)[3] and *(3)* (20 %) (m.p. 92.5—93.5 °C)[3], one unsymmetrical monoepoxide *(4)* (8 %) (liquid)[3] and one unsymmetrical diepoxide *(5)* (22 %) (m.p. 87.5—88.5 °C)[3]. The specific stereochemical assignments depicted in *(2)* and *(3)* were made on the basis of ^{1}H-NMR shift studies (Fig. 1). Chemically, these assignments were secure-

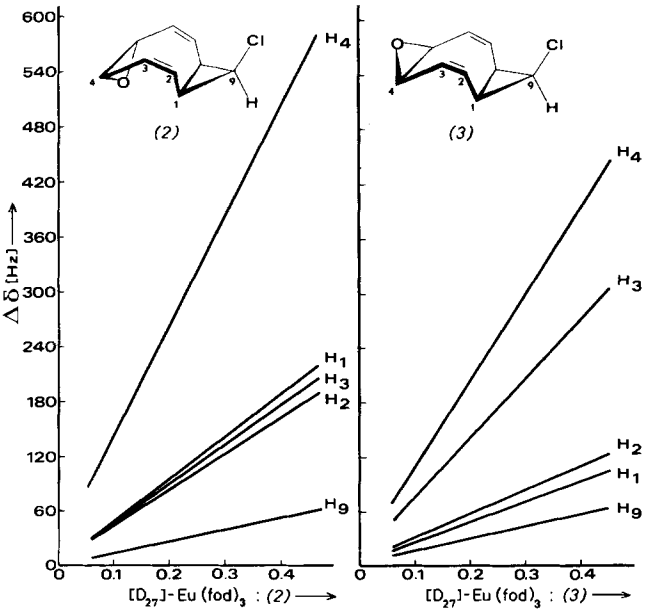

Fig. 1. Plot of *downfield* ^{1}H-NMR chemical shift Δδ *vs.* molar ratio of $[D_{27}]$Eu(fod)$_3$:*trans*-monoepoxide *(2)* (left) and $[D_{27}]$Eu(fod)$_3$:*cis*-monoepoxide *(3)* (right).

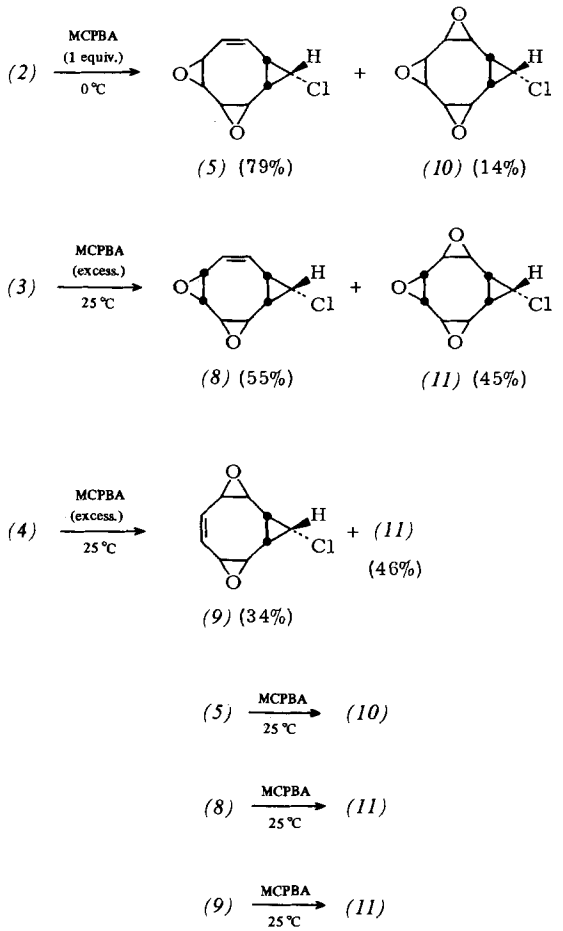

ly validated through the ability of the *trans* isomer *(2)* to undergo ready, clean, rearrangement to *(6)* upon heating at 100 °C ($\Delta G^{\ddagger} = 28.5$ kcal/mol)[4] and the complete resistance of the *cis* counterpart *(3)* to undergo any type of bond relocation on prolonged heating at 140 °C. The rationale behind this "chemical" distinction between *(2)* and *(3)* is, of course, that of the two substances only the former *(trans)* may, and in fact must for steric reasons, incorporate an oxirane function which is "folded" with respect to the eight-membered nucleus and thus properly directed to undergo "Cope" rearrangement[5] to *(7)* (unobserved)[6] which must obviously act as intermediate in the formation of *(6)*[7] (Scheme 1).

Additional exposure of *(2)*, *(3)*, and *(4)* to MCPBA at ambient temperature led to the formation of the various di- and trioxiranes depicted in Scheme 2. The structures of these substances, which obviously are properly constituted for potentially direct conversion to the desired dioxa- and trioxa-annulenyl ions, were established through fully consistent spectroscopic data.

With regard to mechanism it is perhaps interesting to note that the formation of dioxiranes *(5)*, *(8)*, and *(9)* from their respective monofunctional variants *(2)*, *(3)*, and *(4)* invariably occurs stereospecifically, *via exo* delivery of the oxygen function. Further, brief inspection of trioxiranes *(10)* and *(11)* reveals that their formation from the corresponding dioxiranes is similarly controlled. One significant point to

Scheme 2.

note in this connection is, of course, that *exo* addition *per se* does not fulfill the requirement for stereospecific generation of product and that it is only expected to do so when applied to a reactant which is rigidly held in a specific nonplanar arrangement such as the "extended" form adopted by *(1)*. Basically then, what one has here is a situation where product stereospecificity is realized strictly under the influence of conformational control[8].

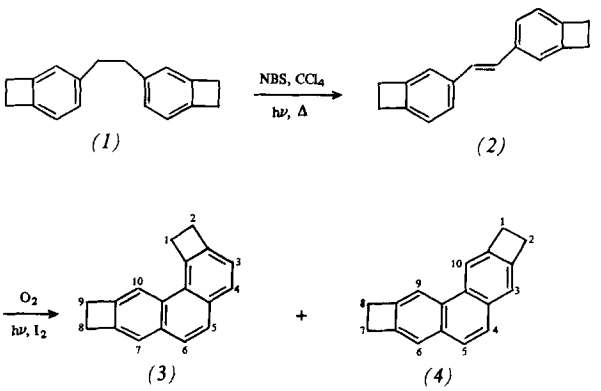
[2] The mixture was separated into its individual components by column chromatography (Al_2O_3) at *ca.* −15 °C. Subsequent purification entailed distillation for the liquids and recrystallization for the solids.

[3] Confirmed by ^{1}H-NMR, UV, IR, and MS.

[4] Calculated from the rate of consumption of *(2)* as monitored by ^{1}H-NMR spectroscopy.

[5] The requirement for a "folded" geometry in the "Cope" rearrangement of a *cis*-bicyclo[6.1.0]nona-2,4,6-triene was recognized several years ago; *A. G. Anastassiou, R. C. Griffith*, J. Am. Chem. Soc. *93*, 3083 (1971).

[6] For a related case where the dioxa analog of *(2)* thermolyzes to a tricyclic molecule analogous to *(7)* see: *A. G. Anastassiou, E. Reichmanis*, J. Org. Chem., in press.



[7] It is pertinent to note in this context that the *syn* disposition of the chlorine atom in *(7)* renders it readily amenable to cyclopropane-assisted 1,2-migration. For a detailed description of this phenomenon see: *R. B. Woodward, R. Hoffmann:* The Conservation of Orbital Symmetry. Verlag Chemie, Weinheim/Academic Press, New York 1970, Ch. 5, pp. 46—48.

[8] It is noteworthy that *exo* epoxidation of the hypothetical conformers of the various mono- and diepoxides described here, *i. e.*, those incorporating a folded cyclopropane appendage should produce stereoisomers of the di- and triepoxides observed in this work.

1,2,8,9-Tetrahydrodicyclobuta[*b*,*g*]phenanthrene and 1,2,7,8-Tetrahydrodicyclobuta[*b*,*h*]phenanthrene, Potentially Carcinogenic Activated Hydrocarbons[**]

By *P. Perkins* and *K. P. C. Vollhardt*[*]

Polycyclic aromatic hydrocarbons have become the subject of renewed vigorous research activity in connection with carcinogenesis by environmental pollutants[1] and the mechanism of hydrogenation of coal[2]. We have embarked on a program aimed at studying the effect of multiple strained ring activation[3] on the physical and chemical properties of polycyclic benzenoids. We now report the synthesis of the title compounds *(3)* and *(4)*, the first isomeric and doubly activated members in the series. Moreover, compound *(3)* is the first example of mutagenicity due to strained ring activation of a benzenoid hydrocarbon.

Cobalt-catalyzed trimerization[4] of 1,5-hexadiyne (*n*-octane, 126 °C, high dilution) gave *(1)*[5] in 55% yield. Photolytic NBS-bromination (boiling CCl_4) furnished the *trans*-stilbene *(2)* as colorless, slightly air-sensitive crystals[6, 7]. Iodine-catalyzed oxidative photocyclization[8] of *(2)* resulted in the desired activated phenanthrenes *(3)* and *(4)* (ratio 2:1) which could be separated by gas chromatography (0.7 × 168 cm Al column, 5% SE-30 on 60/80 Chrom-W-Aw, 220 °C) as colorless air- and heat-sensitive crystals[6, 7]. The electronic spectra of *(3)* and *(4)* in comparison with the parent phenanthrene system reveal the consequences of strained ring fusion in progressively bathochromic shifts and increased extinction coefficients (Fig. 1). The "bay-region" isomer *(3)* shows a particularly pronounced effect. This compound also exhibits an unusually shielded ($\delta = 7.88$) "bay-region" proton H^{10} in the ^{1}H-NMR spectrum[7] compared with H^4 in phenanthrene ($\delta = 8.62$), or the calculated value for H^4 in 2,3,5,6-tetramethyl-

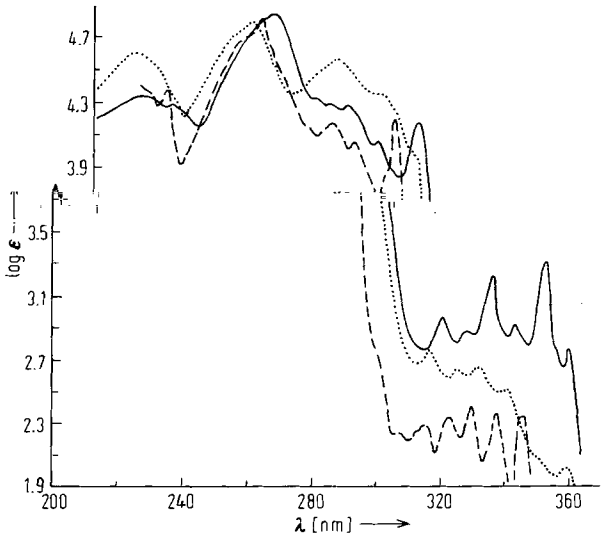
[**] This work was supported by the donors of the Petroleum Research Fund, administered by the American Chemical Society, the National Institute of Health (CA-20713), the National Science Foundation, the Chevron Research Company, the A. P. Sloan Foundation, and the Pressure Chemical Corporation. We are indebted to Ms. L. M. Donahue for performing the mutagenicity studies.

phenanthrene ($\delta = 8.47$)[9]. This probably reflects removal of the deshielding steric effect of the opposite bay proton (in phenanthrene) and tying of the methylene substituent back into the small ring. The difference between the calculated and observed value ($\Delta\delta = 0.59$ ppm) could be a measure of the true bay region steric effect in phenanthrene[10].



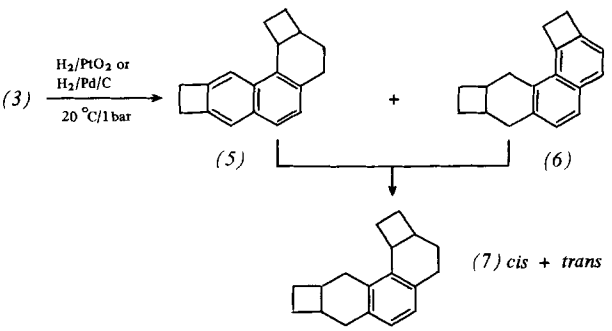


Fig. 1. Electronic spectra of *(3)* (——), *(4)* (···) and phenanthrene (– – –) in cyclohexane.

The consequences of strained ring activation are manifested in the chemical behavior of *(3)* and *(4)*. Thus, for example, rapid hydrogenation of *(3)* occurs under mild conditions exclusively at the outside rings and in a stepwise manner *via* the tetrahydro derivatives *(5)* and *(6)* (separable from *(3)* and *(7)* by charge transfer chromatography[11]) to eventually give *(7)* as an almost equal mixture of isomers[6]. This contrasts with the behavior of phenanthrene itself which is hydrogenated only under pressure and then only in the K region[12]. Interestingly, in competitive hydrogenations, we have also found *(3)* to be twice as reactive as *(4)*, as might be expected on the basis of bond-fixation arguments. The precursor *(1)* is hydrogenated only very slowly over PtO_2 or Pd/C (RT, 1 bar).

We have completed carefully standardized mutagenicity tests on the "bay region" isomer *(3)* (*Salmonella typhimurium*, "Ames test") and conclude that it has to be regarded as a weak mutagen. On the other hand *(4)* appeared inactive in this test. Phenanthrene was *inactive* and benzo[*a*]pyrene strongly active, as previously reported[13]. This constitutes the first indication that strained ring fusion at certain positions may transform a noncarcinogenic polycyclic hydrocarbon nucleus into a potential carcinogen. Caution should be exercised when working with activated compounds of this type.

IR Spectroscopic Detection of Molecular SiO_2[**]

By *Hansgeorg Schnöckel*[*]

In recent years the matrix isolation technique has permitted the spectroscopic investigation of many compounds in monomeric form, which under normal conditions have highly cross-linked structures[1]. Particles evaporating from a Knudsen cell are quenched with a large excess of an inert gas on a cold surface. If evaporation of the monomer from a solid compound is not possible owing to decomposition reactions, attempts are made to synthesize them on the cold surface by cocondensation of reactive components. Thus, *Bos* and *Ogden*[2] have obtained monomeric GeO_2 and SnO_2 by cocondensation of the respective metal vapor and O_2 in a matrix and characterized them by vibrational spectroscopy. The matrix isolation of SiO_2, however, has to our knowledge not been reported so far.

Since a comparison of the molecules SiO_2 and CO_2 is of special interest we have attempted the matrix isolation of monomeric SiO_2 *via* a novel route. SiO evaporated from a Knudsen cell was cocondensed in argon as matrix substance with atomic oxygen generated by microwave excitation[3]. Parallel experiments were also carried out with ^{18}O- enriched SiO and O_2.

The IR matrix spectra show strong signals of O_3 and unreacted SiO together with moderately strong bands in the region of 1400 cm^{-1}, which are assigned to the ν_3-vibration of the SiO_2 molecule (see Fig. 1). In addition weaker satellite bands are observed at about 26 and 53 cm^{-1} lower wavelengths, which are ascribed to association of SiO_2 particles with O_2 molecules. Such effects have been established on a number of occasions in the matrix spectra of reactive particles in the presence of O_2 or N_2[4]. After correction for anharmonicity the measured $^{16}O/^{18}O$ shift of ν_3 is 37.1 cm^{-1}[5]; it agrees within the limits of accuracy with the shift of 37.2 cm^{-1} calculated for a linear SiO_2 molecule[6].

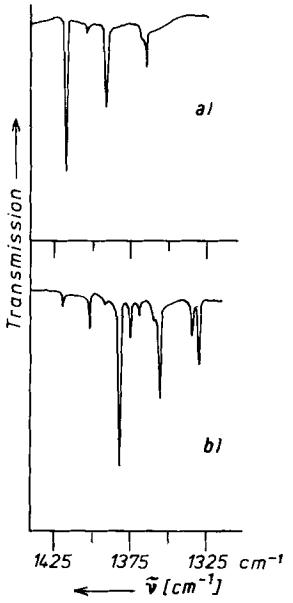

Fig. 1. Section of a IR-argon matrix spectrum after cocondensation of (a) $Si^{16}O + {}^{16}O$; (b) $Si^{18}O + {}^{18}O$.

From the observed value ν_3 one can immediately calculate the symmetry force constants $f_r - f_{rr} = 8.82 \times 10^2$ Nm^{-1} for monomeric SiO_2. The exact calculation of the valence force constant f_r is not possible without knowledge of ν_1. The determination of f_{rr} by additional evaluation of the isotopic shift $\Delta\nu_3$ in the case of $Si^{16}O^{18}O$ did not yield a meaningful result due to a limited accuracy of ± 0.15 cm^{-1} arising from anharmonicity and matrix effects. Hence, on the basis of data for comparison compounds (some siloxanes[7] and the isoelectronic AlFO investigated by us[8]) we estimate an expected value of 0.04 for the ratio f_{rr} to f_r in SiO_2. The valence force constant f_r of SiO_2 obtained using this value is given in Table 1 together with other valence force constants for CO and SiO bonds.

Table 1. Valence force constants f_r [10^2 Nm^{-1}] calculated from observed frequencies.

	Siebert rule [a]					
	>C—O—	>Si—O—	CO_2 [a]	SiO_2	CO [b]	SiO [b]
f_r	5.4	3.8	15.6	9.2	18.6	9.1

[a] *H. Siebert*: Anwendungen der Schwingungsspektroskopie in der anorganischen Chemie. Springer-Verlag, Berlin 1966.
[b] Cf. Ref. [5b].

The decrease $f(CO) \rightarrow f(SiO)$ in comparable compounds is not surprising, since as a rule the valence force constants for bonds between elements of the 1st period are considerably greater than for those in combinations of elements of the 2nd or of the 1st ad 2nd periods [$f(N_2) = 22.4$, $f(P_2) = 5.5 \times 10^2$ Nm^{-1}][5b].

According to the Siebert rule the bond order of the CO_2 molecule is 2.9, and that of the SiO_2 molecule is 2.5. This would indicate a considerable strengthening of the bonding in comparison with a double bond, which so far has not been satisfactorily explained even in the case of CO_2. In a similar way, bond orders of 2.0 and 1.9, respectively, have been calculated for the higher homologs GeO_2 and SnO_2[2]. A comparison of the force constants of SiO and SiO_2 shows that silicon itself can only link to oxygen *via* a double bond in the SiO molecule, whereas carbon in the CO molecule is coupled to the oxygen *via* a triple bond.

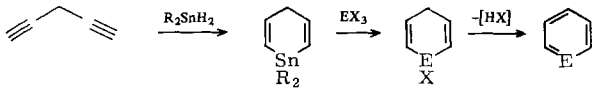
ABSTRACTS

This column contains abstracts of selected progress reports and review articles. Readers wishing to obtain the complete text of articles abstracted in this section are requested to approach a local library. A key to abbreviated source lists is provided in the Bibliographic Guide for Editors and Authors, published by Chemical Abstracts Service, Columbus, Ohio 43210, U.S.A.

The possibilities of reducing the freezing temperature in biological systems are considered by *Yin Yeh* and *R. E. Feeney*. Antarctic fish species were found to contain a group of very similar glycoproteins (AFGP) as natural antifreeze agents, while an Arctic fish contained just one major antifreeze protein of molecular weight ≈ 10000. Owing to the presence of AFGP and dialyzable salts, the serum of the Antarctic fishes freezes at -2.0°C whereas the freezing point of the seawater at the same location is -1.9°C. Experimental results obtained to date suggest that the antifreeze action is due primarily to

AFGP
n = 17-50



interactions with the surfaces of very small ice crystals, preventing further growth. [Anomalous Depression of the Freezing Temperature in a Biological System. Acc. Chem. Res. *11*, 129—135 (1978); 46 references]

[Rd 28 IE]

Solid electrolytes based on silver iodide are considered by *S. Geller*. The electrolytic conductivity in a true solid electrolyte is an inherent property of the crystal and is directly related to the crystal structure. Such a structure characteristically has (i) a large number of sites available to the mobile cations (or in some cases anions), (ii) a system of passageways resulting from the face-sharing of anion polyhedra (in some cases anion and cation polyhedra). The solid electrolyte with the highest conductivity is $RbAg_4I_5$; other remarkable compounds of this kind are $(C_5H_5NH)Ag_5I_6$, $(C_5H_5NH)_5Ag_{18}I_{23}$, and $Ag_{26}I_{28}W_4O_{16}$. [Silver Iodide Based Solid Electrolytes. Acc. Chem. Res. *11*, 87—94 (1978); 42 references]

[Rd 22 IE]

λ^3-Heterobenzenes containing Group V elements are the topic of a review by *A. J. Ashe, III*. In this context, particular interest attaches to the question whether the resemblance between the parent compound benzene *(1a)* and the first member of the hetero series pyridine *(1b)* extends to the other members of the series. *(1c)* through *(1f)* were synthesized from 1,4-pentadiyne. *(1c)* and *(1d)* are somewhat air-sensitive but distillable; *(1e)* can be isolated but polymerizes at room temperature; and *(1f)* can only be detected spectroscopically and *via* chemical trapping. The λ^3-heterobenzenes

(1)

(c), E = P; *(d)*, E = As; *(e)*, E = Sb; *(f)*, E = Bi

are shown by their spectra to be strongly aromatic. *(1c)* through *(1f)* were also found to resemble benzene in the cycloaddition of hexafluoro-2-butyne. [The Group 5 Heterobenzenes. Acc. Chem. Res. *11*, 153—157 (1978); 54 references]

[Rd 29 IE]

Affinity chromatography on columns containing nucleic acids is described in an article by *H. Potuzak* and *P. D. Degn*. The coupling of nucleic acids to a matrix, *e.g.* cellulose, can be achieved even by simple adsorption, but affinity adsorbents with higher capacity and stronger bonding between nucleic acid and matrix have to be prepared by chemical coupling. Chemical binding can be accomplished by UV-irradiation, by activation of the matrix with cyanogen bromide, or by reaction of matrix with ligand under the influence of carbodiimides or bisoxiranes. Affinity adsorbents containing nucleic acids are suitable for hybridizations with free nucleic acids, and for the selective adsorption of nucleic acid-binding proteins, some DNA- and RNA-polymerases, or of nucleases. [Affinity Chromatography on Columns Containing Nucleic Acids. FEBS Lett. *88*, 161—166 (1978); 68 references]

BOOK REVIEWS

Catalysis. Vol. 1. Senior Reporter: *C. Kemball*. Specialist Periodical Reports. The Chemical Society, London, 1977. xiv, 425 pp., numerous figs., bound, DM 137.70.

This book starts a new series on "Catalysis" under the general heading of Specialist Periodical Reports. The volume contains the following contributions: Catalysis on well-defined metal surfaces and non-metallic substrates (by *S. J. Thomson*); Reaction of hydrocarbons on alloys and bimetallic catalysis (by *R. L. Moss*); Catalysis on faujasitic zeolites (by *R. Rudham* and *A. Stockwell*); Catalytic properties of aluminas for reactions of hydrocarbons and alcohols (by *C. S. John* and *M. S. Scurrell*); Selective oxidation of hydrocarbons over mixed oxide catalysts (by *R. Higgins* and *P. Hayden*); Reactions on sulphide catalysts (by *P. C. H. Mitchell*); Ziegler polymeriza-

tion (by *A. D. Gaunt*); Olefin metathesis (by *J. J. Rooney* and *A. Stewart*); The homogeneous catalytic activation of C—H bonds (by *G. W. Parshall*); and Homogeneous catalysis involving carbon monoxide (by *P. J. Davidson, R. R. Hignett* and *D. T. Thomson*). The literature is covered up to the middle of 1976. The book gives a very good description of the subject and the research results in the fields specified, so that it is highly suitable both for experts and for chemists wishing to gain an insight into the subject. It deserves a wide readership among chemists, in higher education, and in industry. We can therefore look forward to the sequels with confidence. However, it is necessary to disperse some doubt about the need for this publication side by side with series having a similar orientation.

The book is well presented and is good value.

Perfluoro Compounds as Blood Substitutes

By Jean G. Riess and Maurice Le Blanc[*]

Inconceivable as it is, it has been proved that animals can survive after having had their blood massively or even totally replaced by emulsions of perfluorinated compounds in salines. "Bloodless" rats charged with an emulsion of perfluorotri-*n*-butylamine survived a five hour period in an atmosphere containing 50% oxygen and 50% carbon monoxide, *i.e.* in conditions where the transport of oxygen by the red cells is entirely blocked. This review discusses: 1) the experiments which have demonstrated the capability of blood substitutes based on perfluorinated compounds to sustain life; 2) the characteristics and preparation of the relevant perfluoro compounds and the production and handling of their emulsions; 3) their "physiology", *i.e.* toxicity, life-span in the blood-stream, effect on the organs and their functions, and excretion properties. Obstacles remaining to be overcome in order to provide a safe blood substitute for medical practice include the availability of numerous series of well-defined pure and inert perfluorinated chemicals, the production of stable emulsions, the optimization of fluid balance, and the attainment of reasonable excretion rates. The accent is placed upon the role of the chemist in the progress of this research.

1. Introduction

Blood transfusion has become an everyday, life-saving measure, and there is a chronic shortage of blood, plasma, albumin, and other blood products to meet annually increasing demands[1]. Thus there is no doubt that there is a need for blood, but one may ask the question whether there is a need for *artificial* blood, and we must face the fact that if the answer is Yes, it is in large part because of the insufficient social concern of the public with respect to blood donation.

A satisfactory artificial blood would have some properties enabling it to supplant natural blood. For one thing, it would be universal—there would be no problems of hemocompatibility, and therefore no need for typing and crossmatching. Artificial blood could be conserved for unlimited periods; it would be available at will; the risk of transmission of diseases such as hepatitis, which is becoming seriously high, would be eliminated; the delicate and costly collecting, packaging, handling, storing, and distribution of natural blood, which is a highly perishable material, would be eliminated; furthermore it would make life-saving by transfusion possible in countries which are not yet equipped for the handling and distribution of natural blood. Moreover, many other applications have been suggested[2], both in therapy and in biomedical experimentation, which cannot be performed with natural blood. The principal potential uses of perfluorinated compound-based blood substitutes will be briefly summarized in Section 5.1.

This article is intended to survey research on blood substitutes using perfluoro compounds[*] as oxygen carriers, a startling and unforeseen application of these compounds. Several brief reviews or accounts on this topic[3–7] as well as the

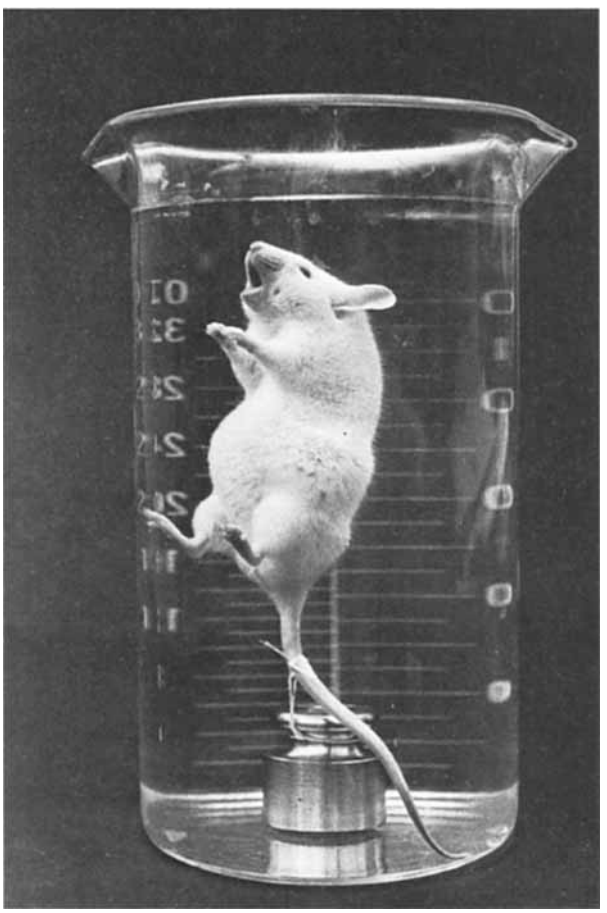
[*] The perfluorinated compounds used in this research field have often been rather loosely designated fluorocarbons, even when they contained some oxygen, nitrogen, or hydrogen atoms. We will in general call them perfluorinated or perfluoro compounds, and following the ACS recommendation [16] use the prefix "*F*" to indicate that a given compound is perfluorinated. For example, perfluorodecalin will be written "*F*-decalin". Any hydrogen atoms present will be indicated by the prefix "hydro".

proceedings of three state-of-the-art symposia[8] are already available. Since progress in the field is highly dependent on the availability of the relevant perfluoro compounds, the chemist's role in this research will be particularly emphasized in the present review. Its scope will be essentially limited to the preparation and uses of emulsions of perfluoro compounds as blood substitutes. Other solutions to the problem of blood replacement, such as the use of stroma-free hemoglobin[9], cross-linked hemoglobin[10], or synthetic oxygen-binding chelates[11], and other biomedical applications of perfluoro compounds, especially in liquid respiration[12] and lung lavage[13], in extracorporeal blood oxygenation[14] or as radiopaque[15], will not be considered here.

2. The Capability of Perfluoro Compound-Based Blood Substitutes of Sustaining Life

It may all have started in 1962 with *Kylstra*'s communication "Of Mice as Fish", when he showed that mice could be kept alive when immersed in hyperbaric solutions of oxygen in aqueous saline solutions[17]. Then, in 1966, *Gollan* and *Clark* found that the same result could be obtained under normal atmospheric pressure by using perfluoro compounds instead of water[18]. *Howlett et al.* had used these compounds as blood oxygenators in 1965[19]. Figure 1 shows a mouse in a breaker filled with perfluoro compounds saturated with oxygen. It is actually breathing the liquid.



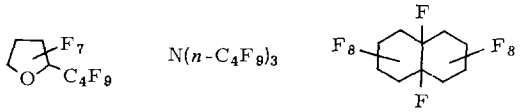


Fig. 1. Mouse breathing a liquid perfluoro compound saturated with oxygen (by courtesy of Prof. *L. C. Clark, Jr.*, Department of Pediatrics, University of Cincinnati).

Gollan and *Clark* were also the first to attempt to use perfluorochemicals instead of blood to supply an organ with oxygen, when they showed that the isolated heart of a rat would continue to contract vigorously when perfused with a perfluoro compound saturated with oxygen[20]. However, the perfusion had to be alternated every hour with that of oxygenated diluted blood in order to assure the supply of mineral salts, which are insoluble in the perfluoro compounds.

Very shortly afterwards, in 1967, considerable progress was made when *Sloviter et al.* replaced the pure perfluoro compound by an emulsion of this compound in a plasma[21]. In this way they solved the problem of the transport of mineral salts and metabolites. The preparations they used were rather crude emulsions (2—3 μm in diameter) containing 20% of FX-80, a perfluoro compound mixture marketed by the 3M Company, whose main constituent is *F*-2-butyltetrahydrofuran *(1)* emulsified in a plasma constituted by a Krebs-Ringer bicarbonate buffer solution with bovine serum albumin as

(1) *(2)* *(3)*

a surfactant. The ability of these emulsions to deliver oxygen to the tissues was tested on isolated rat brain, and compared with that of a suspension of erythrocytes in the same plasma, and with that of the plasma alone. The spontaneous electric activity of the brain (more than 5 μV) persisted for more than 2 hours with the plasma loaded with red cells and with the emulsion of perfluoro compound, compared to less than 5 minutes with the plasma alone (Fig. 2).

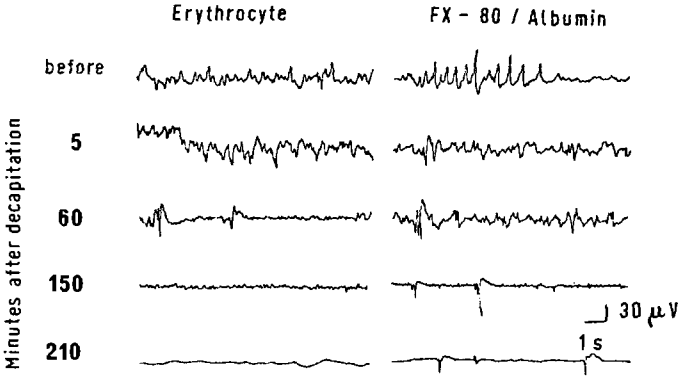

Fig. 2. Comparison of the spontaneous EEG activity of isolated rat brains perfused with an erythrocyte suspension and with an emulsion of the perfluorochemical FX-80 (from ref. [21]).

Considering how vulnerable the brain is to a shortage of oxygen—electric activity ceases if the perfusion is interrupted for just 30 seconds—it can be concluded that in these experiments the emulsion of perfluoro compound assured the oxygen supply just as well as a suspension of red cells. The curves for glucose consumption and lactate production were almost the same for both types of perfusion fluids, which indicates that the emulsion also maintained the metabolic activity of the brain.

In 1968, *Geyer* reported the first *complete* replacement of the blood of rats by an emulsion of FC-47, another 3M product whose main constituent is *F*-tri-*n*-butylamine *(2)*

with Pluronic F-68, a polyethylene oxide-polypropylene oxide block polymer, as surfactant. However, survival of the animals was limited to a few hours[22–25].

Another significant experiment by *Sloviter*'s team showed that mice whose blood contained 10 to 20% of emulsified FX-80 could survive for considerably longer times than controls in an atmosphere containing 4% carbon monoxide, *i.e.* in conditions in which the transport of oxygen by the red cells is almost completely inhibited by carbon monoxide[26].

By 1969 the aptitude of emulsified perfluorochemicals to supply oxygen to tissues, organs, and whole animals, including rats, mice, guinea pigs, frogs, rabbits, chickens, cats and dogs, had been established. However, the animals generally did not survive longer than a few hours. Then, from 1970 onwards, experiments started to be reported in which series of animals survived massive but still partial exchange perfusion with such emulsions[24, 25] and thereafter continued to live, grow, and develop, apparently normally. *Clark et al.* mention, for example, dogs that were perfectly healthy three years after having received a 25% emulsion of FC-47 in a posology of 50 ml/kg of body weight[27, 28]. Similar experiments, in which dogs survived the substitution of 80 to 85% of their blood, were reported by *Fujita et al.* in Japan[29].

The ability of perfluoro compounds to function as blood substitutes to sustain life was conclusively demonstrated when *Geyer*, in 1973, described experiments in which the blood of rats was progressively but *totally* replaced by emulsions containing 12% of FC-47, with subsequent survival of the animals[30, 31]. His experiments are shown schematically in Figure 3. The first stage is a perfusion during which the

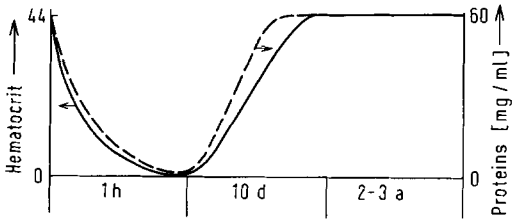

Fig. 3. Schematic view of the successive phases of *Geyer*'s total blood substitution experiments (from ref. [30]): exchange perfusion (1 h); regeneration phase (10 d); normal life-span (2—3 years).

hematocrit (the red cell content of blood) is brought down to less than 1 vol.%. In order to achieve this, *Geyer* perfused the animals under anesthesia with up to 30 times their normal blood volume (for a human being weighing 70 kg this would require about 160 l of emulsion). On awakening after perfusion, "bloodless rats" apparently behaved in a normal manner, and immediately resumed eating, drinking, urinating, defecating, building nests, and so on. After about 7 to 10 days, the plasma protein and hematocrit levels were back to the normal range. The animals continued to grow and develop without apparent abnormality throughout their usual life-span.

Unfortunately, however, it was found that *F*-tri-*n*-butylamine was retained for long periods, maybe the entire lifetime, in the body of the animals, mainly in the liver. Therefore the independent discovery by *Clark et al.*[32] and by *Naito et al.*[33] that some perfluorocompounds such as *F*-decalin *(3)* are excreted from the body much more rapidly than others was an important step forwards.

Recently, experimentation has begun on monkeys. A conscious rhesus monkey appeared to be completely unaware of the fact that about one third of his blood volume was being replaced by an *F*-decalin/Pluronic F-68 emulsion[34]. His pulse did not change appreciably, and according to the authors he apparently suffered no measurable physiological, chemical, or psychological perturbations. He was still alive over a year later. Eight out of a series of ten rhesus monkeys survived removal and dilution of about half their blood, followed by infusion with a 10% *F*-decalin emulsion, and appeared to be in good health (the two others died from surgical accidents). There were no significant changes in about 20 blood components analyzed[35]. Considerable variability between monkeys was noted in the amount of perfluoro compound they sequestered in their liver and spleen, and in the rate at which it left them; the half-life of *F*-decalin in the liver is probably around two weeks. Morphological studies showed no damage or residual effects of its temporary occupation of the liver.

Although all the above experiments were devised with the ultimate aim of achieving artificial blood substitutes, their significance is widely different, and must be critically evaluated. Some, such as the isolated brain perfusion experiments or the protection of mice against poisoning by carbon monoxide, show that the emulsions can assure oxygen transport and replace the erythrocytes in this one function. Those which led to survival after massive but still partial blood substitution in animals show that massive doses of the alien perfluorochemicals can be tolerated by the organism, but they do not really demonstrate that the oxygen supply is assured by the perfluorocompounds, since it is known that 10 to 20% of the erythrocytes suffice to sustain life provided the blood volume, osmotic and oncotic[*] pressure, and flow characteristics of blood are maintained. Thus only those experiments which led to survival of animals after complete blood substitution, so that there was no opportunity of relying on residual normal blood constituents, really demonstrated that the emulsions can function as blood substitutes.

In this respect one of the most significant experiments recently performed by *Geyer* was to assure the survival of his "bloodless rats" after they had been breathing an atmosphere containing 10% of carbon monoxide for 20 hours[4] (Fig. 4),

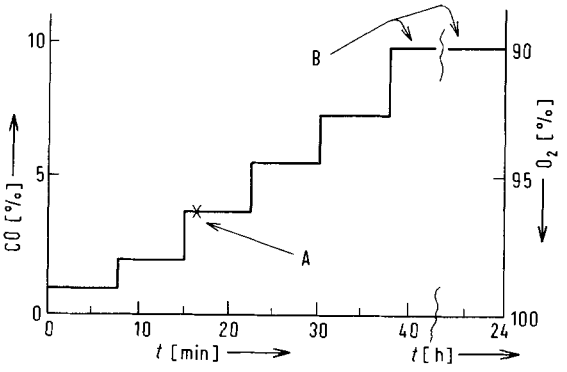

Fig. 4. Comparison of the survival of "bloodless" and normal rats in an atmosphere consisting of 10% CO/90% O_2 (from ref. [4]). A, controls dead; B, "bloodless" rats still alive and active.

[*] The oncotic pressure is the osmotic pressure due to the proteins.

or even an atmosphere containing 50% carbon monoxide for 5 hours[36]. The animals were subsequently returned to a nitrogen/oxygen atmosphere, and survived. These are conditions in which not only any residual red cells, but also the new cells which are continuously produced by the animal, are immediately blocked by carbon monoxide. This definitely proves that the emulsified perfluorochemical had assured the oxygen supply entirely for at least 24 hours. The survival of the animals afterwards moreover seems to mean that carbon monoxide does not act as a poison for tissues and organs.

3. Synthesis of the Relevant Perfluoro Compounds and Processing of Blood Substitutes

3.1. Requirements of an Artificial Blood Substitute

An artificial blood substitute must meet the following requirements:

1) It must maintain blood volume, osmotic and oncotic pressures, and flow characteristics close to those of normal blood; it must also assure proper pH control. These are in fact the requirements to be met by any effective *plasma* substitute.
2) It must assure proper O_2 and CO_2 transport and exchange.
3) It must be chemically inert, not react with O_2 or CO_2, and not develop toxic impurities during its functioning.
4) It may not interfere with any component of natural blood, not cause any irreversible damage no tissues and organs, nor perturb their normal functioning.
5) It must allow regeneration of red cells, proteins, and the other blood constituents at a reasonable rate.
6) It must allow for normal survival, growth, and development after complete blood substitution.
7) It must eventually be excreted from the body.

A substitute which fulfils these conditions is much more than a plasma, since it transports oxygen, *i.e.* replaces the erythrocytes in this function; but this of course constitutes only a part of the multiple and complex operations of transport, regulation, clotting, and defense performed by natural blood. In this respect use of the term "artificial blood" for a medium which satisfies only these requirements is certainly an overstatement.

3.2. Solubility and Availability of Oxygen in Perfluoro Compounds

Perfluoro compounds were chosen as gas carriers because they dissolve large amounts of gases[37–42], they are chemically inert, and they are generally atoxic[41,43]. However, it should be remembered that the requirements listed in Section 3.1 must be met, not by the perfluoro compound as such, but by its emulsions. The amount of oxygen dissolved can be measured by VPC[37b] or by the conversion of Fe^{2+} into Fe^{3+} followed by titration using $TiCl_3$[44].

Table 1 compares the solubility of O_2 and CO_2 in plasma, blood, several commonly-used perfluoro compounds, and two emulsions which are now commercialized for biomedical experimentation (Fluosols)[41]. One sees that the plasma alone dissolves 2 vol-% of O_2, the pure perfluorocompounds 40 to 50%, and the commercially available emulsions 7 to 9%. These emulsions thus dissolve roughly four times as much oxygen as a plasma. The direct comparison of these figures where blood and perfluoro compounds are concerned has in fact little meaning, since the mechanisms by which the oxygen is fixed, and therefore the *availability* of this oxygen, are entirely different.

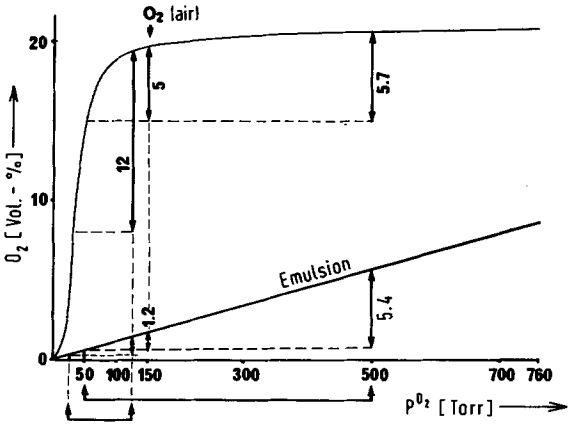

Fig. 5. Comparison of oxygen content and availability in blood and in a 30% emulsion of *F*-tri-*n*-butylamine (FC-43)/Pluronic F-68.

Figure 5 illustrates this point: in this figure the dissolved or fixed oxygen volume is plotted against oxygen partial pressure: in blood, oxygen is coordinated to the hemoglobin iron atom, and the oxygen uptake curve has an S-shape that rapidly levels off to a plateau, while the volume of oxygen dissolved in the emulsions of perfluoro compound increases linearly to a first approximation according to Henry's law.

Under biological conditions, the O_2 content of the arterial blood is about 20 vol-%; it drops to about 15 vol-% for venous blood after uptake of the oxygen by the tissues. It may be seen from Figure 5 that natural blood can easily release these 5 vol-% of O_2 when the animal breathes air. This corresponds on the curve to a drop in pO_2 from 150

Table 1. Gas solubilities (vol-% under 1 bar).

	O_2		CO_2		O_2 from air		Ref.
	25°C	37°C	25°C	37°C	25°C	37°C

[a] Emulsified with Pluronic F-68 in water [40].

torr—the partial pressure of oxygen in air—to 50 torr. When the same variation in pressure is applied to the emulsion it releases only about 1.2 vol-% of O_2, that is 4 times less. In order to be as effective as blood, the emulsion has to operate at a pressure drop of *ca.* 400 torr. The difference in behavior of the two systems is even more vital in the case of a shortage of oxygen: in a rarefied atmosphere, blood can still supply the oxygen demand, for example, about 12 vol-% of O_2 are released during the same pressure drop but from 125 to 25 torr, while the emulsion still releases only 1.2 vol-% of O_2. All this means that blood substitution experiments using perfluoro compounds have to be made with animals breathing oxygen-rich atmospheres.

Furthermore, a recent report shows that the emulsions of perfluoro compounds depress the O_2 uptake of isolated tissues, but that this depression can be overcome by the use of O_2 levels approaching saturation. This also suggests that high levels of inspired O_2 will have to be maintained when using perfluoro compound-based blood substitutes[50b].

3.3. Problems Relating to the Availability and Purity of the Relevant Perfluoro Compounds

An early and still serious drawback in this research concerns the availability of the relevant fluorochemicals. Those whose use in emulsion form as blood substitutes has been reported

Table 2. Perfluoro compounds tested as blood substitutes.

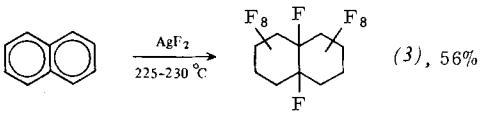
are listed in Table 2. A few other compounds have occasionally been mentioned, especially in the patent literature but no precise results on them have been made available. As can be seen, most of those Table 2 have been tested for acute toxicity only (generally by intravenous injection of small amounts), and the number of compounds that have been tested in any depth is still very limited. Moreover, their structures are disparate, and there were generally no homogeneous series available. First a branched cyclic ether was used, then a tertiary amine, some ethers, then saturated bicyclic fluorocarbons, and so on. This poses a problem, since such essential properties as their stability in emulsions, the physiological response of the organism to injection, and the rapidity of their excretion have been found to differ profoundly from one compound to another. Thus it is primordial that diverse sorts of homogeneous series should be made available if one is to establish which are the most favorable structural and physicochemical characteristics for this use.

This situation is primarily due to the relatively large quantities of compounds required for experimentation. Thus one was forced to use compounds that had already become industrially accessible.

This brings us to another serious difficulty, which arises from the insufficient purity, chemical definition, and reproducibility of these materials, which until recently were manufactured for completely different purposes, for which the standards of purity have nothing in common with those required for biomedical experimentation. This is particularly so with electrochemically produced materials, which are generally complex mixtures, whose composition is not even reproducible from one batch to the next. It is necessary to stress here the ambiguity that has therefore long hung over the exact composition of the substances used in the biomedical experiments, and to insist on the need to devise more specific, unequivocal routes allowing the synthesis of purer, better-defined compounds.

3.4. Synthesis of the Perfluoro Compounds Used in Blood Substitution

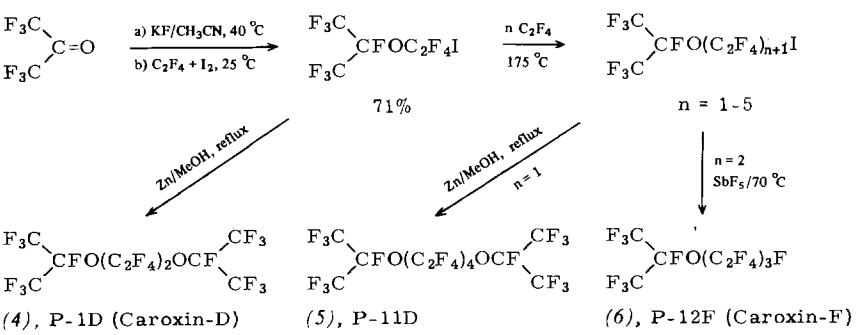


The principal routes that are employed for the preparation of the basic materials used so far in the preparation of blood substitutes will be briefly recalled. The most important one is electrochemical fluorination in anhydrous hydrogen fluoride. It was used in the preparation of the first perfluoro compounds tested in blood substitution (FX-80[97] and FC-47[98]). However, this method, which replaces a C—H bond (*ca.* 90 kcal/mol) by a C—F bond (100—120 kcal/mol), and therefore releases considerable amounts of energy, is very brutal and is generally accompanied by heavy degradation. For example, electrolysis of octanoyl fluoride with hydrogen fluoride gives the product FX-80 which, according to the patent, may consist largely of the following components:

(1)

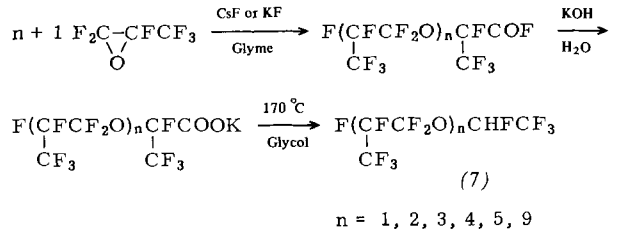
Light fluorocarbons, lower cyclic homologs having shorter side chains, and telomerization products are also present. Some of the samples used in the early experiments showed up to 16 constituents detectable by VPC[99].

The preparation of *F*-decalin *(3)* exemplifies another general route to perfluoro compounds, which uses metal fluorides as fluorinating agents. Thus *F*-decalin was first obtained by treating naphthalene with silver fluoride[100].



(3), 56%

The commercial product, PP5 manufactured by the Smelting Company, is probably obtained with cobalt trifluoride as a fluorinating agent. This is again a very drastic method which results in complex mixtures: the crude commercial products have boiling points ranging from 53 to over 93 °C, and the lighter fractions were shown to be definitely toxic[27]. Even the *F*-decalin purified by spinning band distillation, and commercialized by the Green Cross Corporation for medical purposes, still contains several impurities besides *cis*- and *trans*-*F*-decalin[41].



More recently, new techniques have been devised which allow a better control of the direct fluorination of organic compounds by elemental fluorine[101]. For example, adamantane was converted into 1-hydro-*F*-adamantane in 44 % yield using helium-diluted fluorine at −78 °C, and 2,2,4,4-tetramethylpentane was converted into 3-hydro-*F*-tetramethylpentane in *ca.* 60 % yield[102]. This certainly opens up interesting prospects for the synthesis of better defined perfluoro compounds.

The perfluoroisopropyl ethers *(4)*, *(5)*, and *(6)* are on the other hand examples of perfluoro compounds obtained by specific chemical routes. They are produced in 99% purity by Allied Chemical Corp.[103].

(4), P-1D (Caroxin-D) *(5)*, P-11D *(6)*, P-12F (Caroxin-F)

Du Pont's Freons E *(7)*, which have also been tested for blood substitution, are also produced by chemical routes[104].

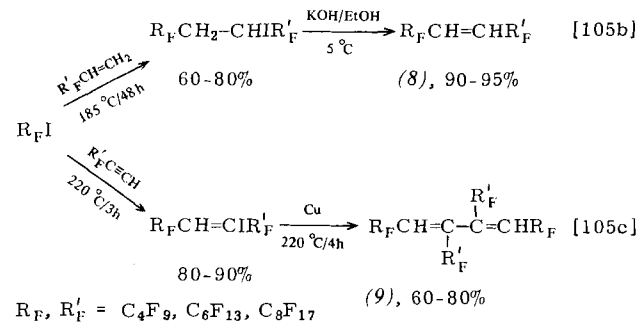
$$n + 1\ F_2C\!-\!CFCF_3 \xrightarrow[\text{Glyme}]{\text{CsF or KF}} F(CFCF_2O)_nCFCOF \xrightarrow[H_2O]{\text{KOH}}$$

$$F(CFCF_2O)_nCFCOOK \xrightarrow[\text{Glycol}]{170\,^\circ C} F(CFCF_2O)_nCHFCF_3$$

(7)

n = 1, 2, 3, 4, 5, 9

At present, various efforts are being made to produce compounds that are specifically fitted to serve as gas carriers for blood substitutes. These efforts are directed either towards assuring better control of electrochemical fluorination or of direct fluorination by elemental fluorine, or towards the use of selective chemical routes, starting from simpler but already perfluorinated starting materials.



Our own approach to the design of such tailor-made compounds belongs to the latter category, and is based on the following guidelines[105]:

1) The starting materials are industrially available perfluorinated building blocks such as the perfluoroalkyl iodides $C_nF_{2n+1}I$ ($n = 4, 6, 8$), which are produced in satisfactory purity by Produits Chimiques Ugine Kuhlmann by telomerization of tetrafluoroethylene with perfluoroethyl iodide.

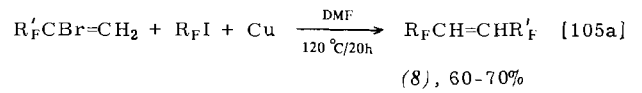
2) Several perfluoroalkyl groups are linked together into bundles by specific chemical routes.

3) Heteroatoms, such as oxygen and nitrogen, which were thought to be responsible for the retention of the compounds in the liver[89], are avoided.

4) Homologous series of compounds are prepared, in order to permit the stepwise optimization of such crucial parameters as vapor pressure or viscosity. Examples of such series are the bis-*F*-alkylethanes *(8)* and the tetrakis-*F*-alkylbutadienes *(9)* which were obtained by the following routes:

$$R_FCH_2\!-\!CHIR'_F \xrightarrow[5\,^\circ C]{KOH/EtOH} R_FCH{=}CHR'_F \quad [105b]$$

R_FI + $R'_FCH{=}CH_2$ (185 °C/48 h): 60–80%

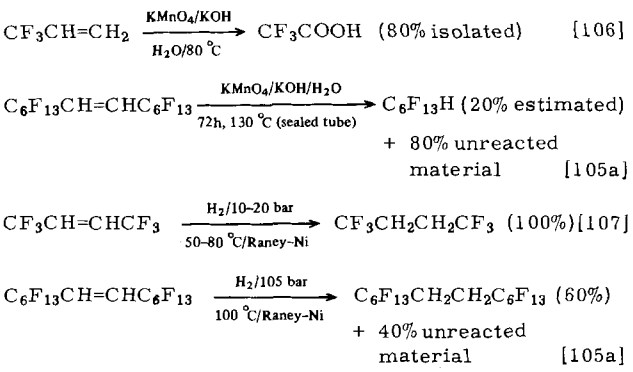


R_FI + $R'_FC{\equiv}CH$ (220 °C/3 h): *(8)*, 90–95%

$$R_FCH{=}CIR'_F \xrightarrow[220\,^\circ C/4h]{Cu} R_FCH{=}C(R'_F){-}C{=}CHR_F \quad [105c]$$

80–90% *(9)*, 60–80%

R_F, R'_F = C_4F_9, C_6F_{13}, C_8F_{17}

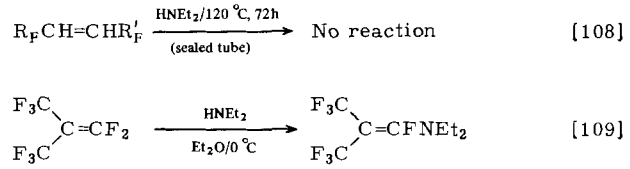


It is noteworthy that the bis-*F*-alkylethenes *(8)* can also be obtained by allowing the 1-iodo-*F*-alkanes to react with 1-*F*-alkyl-1-bromoethene in the presence of copper powder.

$$R'_FCBr{=}CH_2 + R_FI + Cu \xrightarrow[120\,^\circ C/20h]{DMF} R_FCH{=}CHR'_F \quad [105a]$$

(8), 60–70%

The chemical inertness of these bis-*F*-alkylethenes is illustrated by the experimental conditions required for their oxidation or reduction, which are much more drastic than those required when R_F is CF_3.



$$CF_3CH{=}CH_2 \xrightarrow[H_2O/80\,^\circ C]{KMnO_4/KOH} CF_3COOH \text{ (80\% isolated)} \quad [106]$$

$$C_6F_{13}CH{=}CHC_6F_{13} \xrightarrow[72h,\ 130\,^\circ C\ \text{(sealed tube)}]{KMnO_4/KOH/H_2O} C_6F_{13}H \text{ (20\% estimated)} + \text{80\% unreacted material} \quad [105a]$$

$$CF_3CH{=}CHCF_3 \xrightarrow[50\text{–}80\,^\circ C/\text{Raney-Ni}]{H_2/10\text{–}20\ bar} CF_3CH_2CH_2CF_3 \text{ (100\%)} \quad [107]$$

$$C_6F_{13}CH{=}CHC_6F_{13} \xrightarrow[100\,^\circ C/\text{Raney-Ni}]{H_2/105\ bar} C_6F_{13}CH_2CH_2C_6F_{13} \text{ (60\%)} + \text{40\% unreacted material} \quad [105a]$$

Their lack of reactivity towards primary or secondary amines contrasts with the behavior of the completely fluorinated alkenes, which easily add amines with subsequent elimination of hydrogen fluoride below room temperature.

$$R_FCH{=}CHR'_F \xrightarrow[\text{(sealed tube)}]{HNEt_2/120\,^\circ C,\ 72h} \text{No reaction} \quad [108]$$

$$(F_3C)_2C{=}CF_2 \xrightarrow[Et_2O/0\,^\circ C]{HNEt_2} (F_3C)_2C{=}CFNEt_2 \quad [109]$$

3.5. Crucial Characteristics of the Perfluorochemical Emulsions

All the perfluoro compounds tested so far are liquids, and have to be used in an emulsified form because: 1) pure compounds would cause immediate embolism[110]; 2) this solves the problem of the simultaneous transport of oxygen, mineral salts, and metabolites; 3) provided they are not too fine, the rheological properties of emulsions are closer to those of the continuous phase, and thus closer to those of the plasma.

The preparation and characteristics of the emulsions soon turned out to be a crucial problem. Without apparent reason some emulsions were good and others were toxic, and this often led different research groups to reach contradictory conclusions[53, 65].

An emulsion is a complex multi-parameter system[111], whose properties depend not only on its components (perfluoro compound, saline aqueous phase, surfactants) and their proportions, but also on the particle size and size distribution. The size of the liquid particles is an all-important factor, not only because it influences the stability of the emulsion, the surface area available for gaseous exchange, and, as regards the finer ones, their viscosity, but also because in the body it largely determines their toxicity, the time the perfluoro compounds will spend in the blood stream, and perhaps the extent to which they are phagocytized and stored in certain organs.

There is a correlation between particle size and the toxicity of the emulsions: acute toxicity was found to increase rapidly with the proportion of particles larger than 0.4 μm[66]. An average particle size of less than 0.1 μm with no particle larger than 0.6 μm is now recommended[40]. Such particles are much smaller than erythrocytes (7—8 μm), but they are far more numerous, and the commonly used emulsions thus offer 150—300 times as much surface area for gaseous exchange. Emulsions having such small particle sizes are almost optically clear, *i. e.* transparent, but become milky-white with increasing particle size.

It is, of course, essential that the emulsions be stable, and that their particle size should not increase while they are in the bloodstream. The stability depends on the nature of the perfluoro compound. Thus, the *F*-decalin/pluronic emulsions are much less stable than the emulsions of *F*-tributylamine, *F*-dimethyladamantane, or Freon E3 with the same surfactant[28,40,57,62]. The stability of the *F*-decalin emulsions can be improved by addition of egg yolk phospholipids, D-sorbitol[57], and traces of a fatty acid salt[67] as surfactant[40,49]. However, the intravascular stability of this emulsion is limited[56], probably as a consequence of the faster elimination of the yolk phospholipids leading to insufficient coverage of the particles by the surfactant. On the other hand, it has been reported that some emulsions were more stable *in vivo* than *in vitro*[26]; this seems surprising and the true explanation probably lies in the rapid removal of coarser particles from the bloodstream *in vivo*.

The surface charge of the particles may be important and influence the rate at which they will be phagocytized. In addition the blood platelets which are negatively charged will tend to clump together on positively charged sites and may promote formation of thrombi[41,49,51,73,112].

3.6. Problems Relating to Emulsification

The preparation of the emulsions involves several difficulties. Firstly, one has to select a surfactant in the absence of valid guidelines for such a choice. Of the dozen surfactants mentioned in blood substitution experiments, only two have come to the fore, *viz.* the polyethylene oxide-polypropylene oxide block polymer Pluronic F-68[113] and phospholipids from egg yolk[67,68]. Pluronic F-68, which is most widely used, is also one of the first to have been tested. This appears to have been a stroke of luck, since no better one has been found since. Not only is it atoxic, inert, and excretable, but it does not cause hemolysis (in contrast to most surfactants), it acts as a mild anticoagulant[45], and it has the seemingly unique property among the surfactants of also behaving as an oncotic agent[30,111c]. A few other surfactants, such as amine *N*-oxides[47,114,70] have occasionally been mentioned, as well as some perfluoroalkylated surfactants[55,70,71,115].

The emulsification procedures can be roughly divided into two kinds: those which subject the sample to large amounts of energy and those which do not. To the first class belongs the most commonly used sonication procedure using ultrasonic vibration (*e.g.* 20 kHz, 1000 W)[3,64]. However, it has been found that sonication promotes the release of fluoride ions[28], implying that some molecules have been degraded to form new molecular and ionic constituents; this adds to the complexity of the mixtures and to the uncertainty surrounding their composition. Some sonication devices were even observed to release titanium particles into the emulsion[45].

Although the toxicity of these emulsions can subsequently be reduced (see Section 3.7) and the fluoride ions removed (note that much larger doses of fluoride can be injected into the blood stream and appear to be well tolerated)[48], it nevertheless seems essential to search for methods of emulsification that do not modify the chemical constitution of the compounds being tested.

A rather puzzling discovery is that the generation of fluoride ions can be almost completely repressed if the sonication is performed in a carbon dioxide atmosphere[64].

Another procedure for the production of almost colloidal emulsions in large quantities uses the Manton-Gaulin high pressure homogenizer. This method exploits shearing forces, and also subjects the materials to high doses of energy.

More recently attention has been focused on milder emulsification methods. The use of self-emulsifying systems has been proposed in which two different emulsifiers are present. One emulsifier is more hydrophilic while the other is more lipophilic; together they form fine emulsions that are stable in a chosen temperature range. Mixtures of perfluoroalkylated surfactants of type $R_F(C_2H_4O)_nH$, with an average $n \approx 3$ for the "fluorophilic" surfactant and $n \approx 12$ for the hydrophilic one, were used for this purpose[71]. However, the emulsions produced so far have proved to be rather toxic[48].

Another novel method which is claimed to give stable microemulsions under gentle conditions involves dissolution of the perfluoro compounds in a volatile propellant such as freon 113 ($CF_2Cl-CCl_2F$) and subsequent addition to the aqueous phase containing the surfactants (one of which is fluorinated). Upon gentle stirring, a micro-emulsion spontaneously develops and the mixture becomes transparent. The light solvent is then removed by evaporation[70].

Table 3. Composition of artificial blood substitute for total exchange perfusion (*Geyer*, 1973) [30].

Perfluorotributylamine FC-47	11.0–13.0 ml
Pluronic F-68 [a]	2.3–2.7 g
Hydroxyethyl starch	2.5–3.2 g
Glucose (when present)	0.1 g
NaCl	54 mg
KCl	32 mg
$MgCl_2$	7 mg
$CaCl_2$	10 mg
NaH_2PO_4	9.6 mg
Na_2CO_3	to pH 7.44
H_2O	to 100 ml
Penicillin, streptomycin, phenol red	

[a] Polyethylene oxide-polypropylene oxide block polymer.

Table 3 represents the composition of a typical blood substitute, as used by *Geyer* in his total blood substitution experiments[4,64]. Other compositions for substitutes and detailed experimental procedures may be found for example in references[40,41,57,61].

3.7. Emulsion Control and Standardization

The paramount importance of having properly defined emulsions, and hence the need for standardized and reproducible preparation procedures, is now fully recognized. Indeed, it is surprising that this point could have been overlooked for so long.

It has meanwhile been established that only some of the constituents of the early "toxic" emulsions are actually toxic. This follows from the fact that the toxicity of such emulsions could be reduced by a simple filtration[67], passage over an ion-exchanger[3,28], or dialysis[3,45]. The same applies to the Pluronics, which are essentially atoxic in the pure state but lead to various complications such as pulmonary edema and

hemorrhages when used without preliminary purification by passage through a Millipore filter[45, 52].

The perfluoro compounds are now carefully washed and distilled; the emulsification is sometimes optically monitored and the emulsions characterized by optical density curves; sonication, for example, is applied until a plateau in the optical density is observed[28], thus providing reproducible emulsification procedures for a given fluoro compound/surfactant combination. The stability of an emulsion can also be judged from the rate at which optical density increases with time. The particle size is determined by electron microscopy, or more conveniently by ultracentrifugal sedimentation[40, 59, 66]. The effect of the increase in viscosity at very small particle sizes on the flow characteristics can be counterbalanced by the addition of hydroxyethyl starch[30, 31]. The oncotic pressure is adjusted and controlled by osmometry[93]. The importance of the atmosphere has been recognized; a CO_2 atmosphere facilitates emulsification, suppresses foaming, and prevents fluoride ion formation[64]. The preparations are sterilized by heat[27, 40, 67, 68] (pasteurized in the case of the less stable emulsions) or by filtration through Millipore filters[64], and may be frozen for storage[57]. Two standardized commercial emulsions are now available from the Green Cross Corporation (Japan)[41][*].

More effort will have to be devoted to achieving a better control of the emulsions, to making more standard emulsions available to biomedical teams, and to the definition of standard protocols for biological experimentation, if one is to arrive at meaningful comparisons and establish structure/properties correlations.

4. "Physiology" of the New Blood Substitutes

Blood substitution in a live animal can be envisioned as being, at the same time, an artificial organ transplant and a multi-organ perfusion. It is therefore essential to investigate the tolerability of the emulsions, their interactions with the animal's natural blood components, and more generally their cytotoxicity and effect on the organs and principal functions of the organism. Various but generally unrelated studies have been undertaken in this connection. Unfortunately, they often suffer from poor choice of the perfluoro compound or emulsifying conditions and from a lack of precise definition of the perfusing media. Moreover, no two investigators used the same procedures for the preparation, administration, and testing of the emulsions, which frequently led them to contradictory interpretations, and this often makes it illusory to draw definite conclusions at the present time. The amount of perfluoro compounds present in the organs and body fluids is most efficiently determined by gas chromatography[46, 116, 117] or pycnometry[91].

[*] Failures, leading to the death of the animals transfused, have been observed with these emulsions, and have been traced to hemoconcentration due to an extravasation (or escape) of water from the vascular system which causes the concentration of the perfluorochemicals to rise from 20 to 60%, with subsequent increase in viscosity [85]. *Geyer* also pointed out that some adjustments to the electrolyte composition had to be made to permit their successful use [93]. This again illustrates the importance of achieving adequate fluid balance.

4.1. Acute Toxicity

It now seems clearly established that, when the ingredients are meticulously purified, any direct toxicity of their emulsions arises not from chemical poisoning, but from a failure to comply with certain limits pertaining to their physical characteristics. For example, the particle size may be too coarse or the vapor pressure too high, leading to gaseous embolism (as is the case for FX-80)[110] and lung edema, or inadequate osmotic pressure.

4.2. Residence Time in the Bloodstream

It is not enough for the emulsion to be non-toxic; the perfluoro compounds should not be withdrawn too rapidly from the bloodstream. It is basically a question of baffling the reticuloendothelial system whose role it is to eliminate foreign particles from the bloodstream, but as yet very little is known about the possible reactions of this system to intruders as unnatural as perfluoro compounds. Their chance of survival may in fact be enhanced by their totally artificial nature: they do not resemble anything recognizable by the organism which therefore puts up only a weak defense.

The length of time the fluoro compounds remain in the bloodstream has been found to depend largely on the size of the particles[24, 40, 47, 52], as illustrated in Figure 6 which

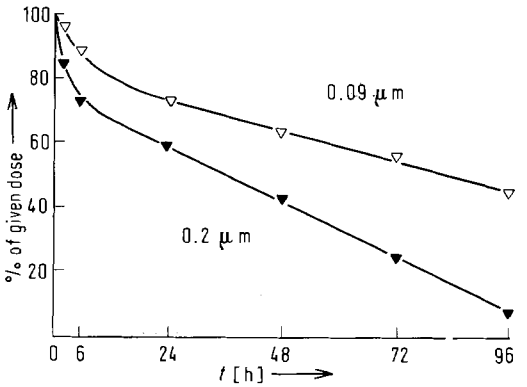


Fig. 6. Comparison of intravascular persistence of FC-43 between fine (average diameter 0.09 µm) and coarse (average diameter 0.2 µm) FC-43 emulsions in rabbits (from ref. [40]).

also shows that half-lives of several days may be obtained with a particle size of less than 0.1 µm. The intravascular persistence of the fluorochemicals was also found to be drastically influenced by the nature of the surfactant[45, 47], but it is not clear whether this is due to some direct action of the surfactant, to its faster elimination, or to differences in particle size.

Small particles appear to have little or no influence on the phagocytic activity of the reticuloendothelial system. Yet, according to some reports, blood appears to have some capacity for modifying the stability of the *F*-decalin and yolk phospholipid emulsions and the size of their particles[56]. This would suggest that the organism possesses some means of agglomerating foreign particles of almost colloidal size until they become phagocytable. On the other hand, particles larger than 1 µm are rapidly eliminated from the bloodstream, and tend to be deposited in the liver. Coarse emulsions may even cause a blockage of the reticuloendothelial system, which

then becomes unable to clear the blood of injected carbon particles[40].

4.3. Retention in the Organs and Excretion

A major physiological problem is raised by the fate of the perfluoro compounds when they have fulfilled their mission. After a period of residence in the bloodstream, whose length closely depends on the size of the particles and on the nature of the surfactant, the perfluoro compounds are removed from the circulation and are in part excreted and in part accumulated in the body. The principal collectors of the perfluoro compounds in the body were found to be the various sorts of mononuclear phagocytes located in the liver and spleen, but also in the bone marrow, lymph nodes, lymphoid tissues, thymus, and so on[27, 28, 43, 47, 72, 73]. To our knowledge there has never been any evidence reported of the perfluoro compounds' being catabolized. The search for fluoride ions in the blood[27], plasma, liver, and femoral bone, using a specific fluoride electrode[43], and for catabolites in the exhalation gases, liver, and spleen by VPC/mass spectrometry[43] gave negative results. When the perfluoro compounds are excreted it is in the original form by exhalation and through the skin[27, 32a], their rate of exhalation being highly dependent on their vapor pressure[40, 49, 55] (Fig. 7). Only trace amounts of perfluoro compounds were occasionally detected in feces, and none in the urine[27, 55].

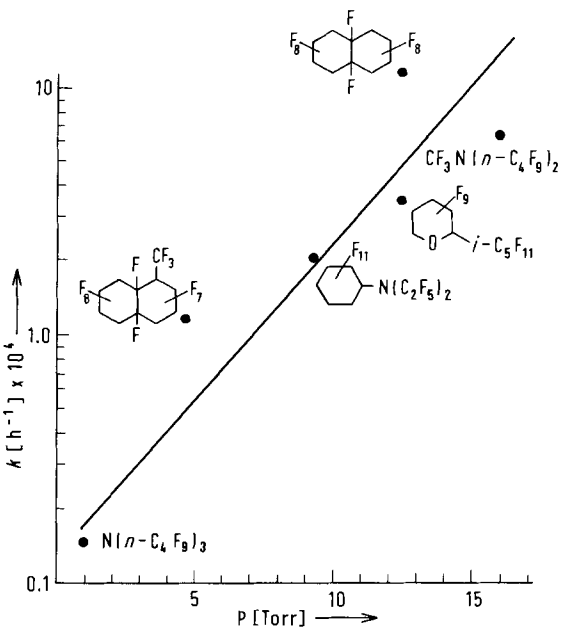

Fig. 7. Relationship between vapor pressure P of perfluoro compounds at 37°C and expiratory excretion rate constant k (from ref. [49]).

The retention time in the organs depends largely on which perfluoro compound is utilized. Some appear to stay there almost indefinitely; this is the case with *F*-tri-*n*-butylamine, while *F*-decalin (which unfortunately gives less stable emulsions) is eliminated in the space of a few weeks[32, 33, 40]. Figure 8 shows that, for the same dose, about 60% goes to the liver for *F*-tributylamine (FC-43), as compared with about 30% for *F*-decalin (FDC), but more important is the fact that after two weeks less than 1% of the *F*-decalin remains present in the liver, while the amount of *F*-tri-*n*-butylamine shows little or no decrease. There is a report according to which the excretion rate of *cis*-*F*-decalin is somewhat greater than that of the *trans* isomer[58]. What causes this retention is not yet clear. An early suggestion according to which the persistence of the compounds in the liver and spleen is linked to the presence of heteroatoms such as oxygen and nitrogen seems to be refuted by the long-term retention observed for *F*-methyldecalin[51], while on the other hand *F*-*N*-methyldibutylamine is eliminated rapidly[55].

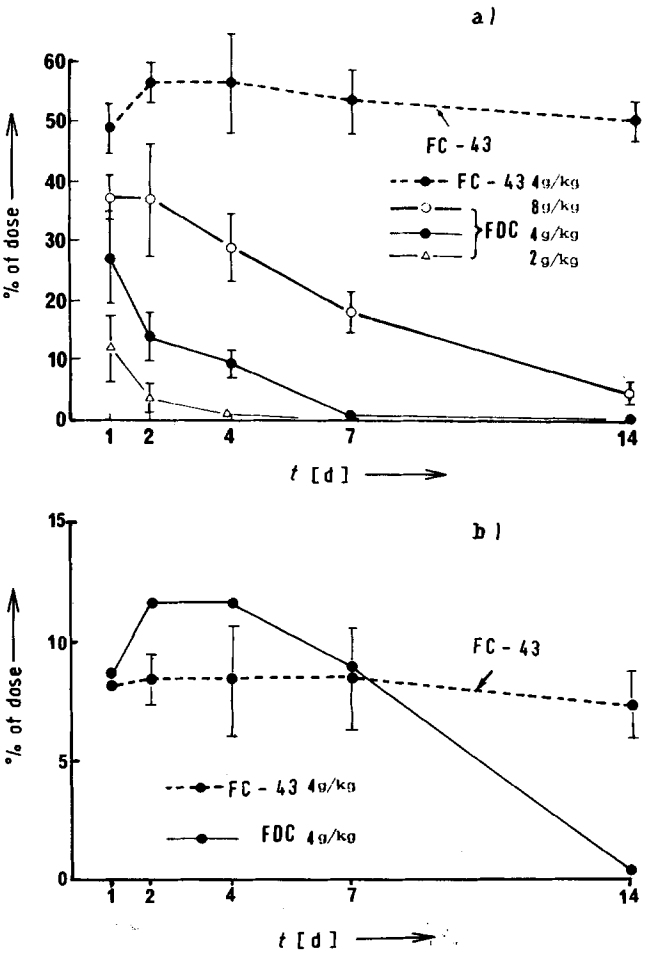

Fig. 8. Comparison of the elimination of *F*-decalin (FDC) and *F*-tri-*n*-butylamine (FC-43) from a) liver and b) spleen (from ref. [40]).

The morphological changes induced by *F*-tri-*n*-butylamine and *F*-decalin in the liver of mice, dogs, and cats were closely monitored microscopically. Only minor alterations, and no tissue toxicity, were observed in the liver, and the parenchyma, endothelium, and phagocytes regained their normal appearance upon elimination of the fluoro compounds[28, 72]. More recent experiments, however, performed with *F*-tri-*n*-butylamine on mice, evidenced some changes in reticulo-histiocytic and hemopoietic cells[73]. During other studies performed on dogs massively infused with *F*-decalin and yolk phospholipid emulsion, no irreversible damage appeared to have been caused to the tissues of the liver, spleen, kidney, lung, bone marrow, testes, endocrine organs, or hemopoietic cells[61].

4.4. Effect of the Emulsions on the Functioning of the Organs

The first organ to be considered is blood itself. It has been shown *in vitro* that a *F*-decalin emulsion and blood

do not influence each other's oxygen dissolution curves[44, 118]. *In vivo* an interaction of the fluoro compound-based substitutes resulting in platelet aggregation has been observed by some authors[51], and was considered responsible for pulmonary failure and death through blockage of the capillaries, while no aggregation or drop in platelet numbers was found by others[4], who see in this a dramatic illustration of how strongly the physiological and biochemical response to an artificial substitute depends upon its preparation. A prior hemodilution has been recommended as a way of circumventing this possible pitfall[61]. Some preparations also caused marked changes in blood clotting patterns[84], while others had no effect on the sedimentation rate of the red cells nor on hemagglutination related to blood grouping[49]. Distentions of blood vessels and of the right ventricle are believed to be a possible result of hemoconcentration[85]. On the other hand, the hemocompatibility of some preparations is clearly indicated by the survival of animals after total blood substitution, by the absence of significant changes in about 20 blood components analysed in a massive blood substitution experiment on monkeys[35], and by the successful use of perfluoro compounds in extracorporeal blood oxygenation[14, 119].

Cerebral micro-circulation has been studied in intact, partially transfused mice (hematocrit reduced from *ca.* 45 to 10—15 vol-%)[63], and it was concluded that the perfluoro compound-charged blood could support cerebral microcirculation and deliver enough oxygen to the brain to sustain electrical activity and to retain some capacity to respond to—and to recover from—brief periods of anoxia, as shown by increases in brain NADH levels during these periods, and the restoration of normal NADH and oxygen levels afterwards. Unfortunately, these studies were performed with "toxic" FX-80 emulsions again, and the author himself considers that it would be advisable to repeat them with a better suited material.

Rat liver, because it has manifold metabolic functions and because it displays an acute sensitivity to oxygen supply, has been extensively used for testing the gas-carrying capacity of perfluoro compound emulsions. The studies performed on live animals were mainly directed at localizing the perfluoro compounds in the organ[27, 28, 50, 72, 73] and the lesions their presence may have caused, while those performed on isolated livers were essentially devoted to the establishment of long-term perfusion systems for isolated organs[65, 74–77].

In a typical study[74] it was shown that a constant hepatic function could be maintained for at least 20 hours with a FC-43/Pluronic F-68 emulsion. Several representative liver functions, including bile production, maintenance of the metabolite steady state, linear release of various enzymes, galactose elimination from the perfusate, induction of tyrosine aminotransferase by dexamethasone, were monitored for a 10—20 hour period, and the results compared with those obtained with a commonly used red-cell-containing medium; and it was concluded that the fluorocarbon emulsion provided at least the same, or an even better hepatic function than the latter medium, with which functional impairment was generally observed after 5—6 hours, probably as a consequence of the aggregation of erythrocytes damaged by the mechanical action of the perfusion apparatus.

Other authors also found that perfusion of the isolated rat liver with FC-43 or FC-80 emulsions maintained the liver in good functional condition for at least 6 hours, as demonstrated by the synthesis of albumin and other proteins, incorporation of ^{14}C-labeled lysine into circulating proteins, secretion of bile, level of alanine aminotransferase, urea, and glucose in the perfusate, vitamin B_{12} binding capacity, fluid pressure in the portal vein, and so on[62, 65, 75–78]. These authors concluded that the perfluoro compounds could supply the organ with oxygen, and that they did not interfere with its functioning provided an optimal flow rate and a high oxygen partial pressure were employed. Indeed, it was found that the effectiveness of the FC-80 emulsion relative to that of other perfusion media depends on the flow rate[62, 75–77, 79]. This may explain some earlier conflicting reports[53, 65, 79].

Some interference with the liver cell metabolism has been recorded in the case of *F-n*-hexane: the fluorocarbon interacts with cytochrome P-450, to the same extent as hexane or cyclohexane, which triggers off NADPH oxidation; but, in contrast to the hydrocarbon substrates, its C—F bonds resist attack by the active oxygen. It therefore behaves as a dead-end inhibitor, which uncouples electron transport from mono-oxygenation[120]. The significance of such an uncoupling process for microsomal monoxygenases is however difficult to assess, since partial uncoupling seems to occur frequently, and was even found for *n*-hexane[120b].

Several attempts at kidney preservation either with pure perfluorochemicals[121] or with their emulsions[80, 81, 122, 123] have been made. Renal functions appeared to be dramatically improved when plasma was replaced by an FX-80 emulsion in the perfusion of the isolated organs[80]. However, despite these good perfusion characteristics, their transplantation after a 24 h period back into the donor animal—which then underwent a contralateral nephrectomy—was less successful than with kidneys perfused with plasma alone. Better results than with plasma alone—better creatinin clearance, and survival of all the five dogs which underwent transplantation[81]—were obtained with FC-43 emulsions.

Perfusion of isolated human ovaries by an FC-47/Pluronic F-68 emulsion was performed in order to evaluate the usefulness of experiments using an artificial medium which allows the experimental parameters to be controlled more closely[82]. It showed that glucose was utilized and lactate produced at a fairly constant rate for as long as 20 hours of perfusion, giving evidence of considerable metabolic activity in the perfused organs. ^{14}C-Progesterone and ^{14}C-17α-hydroxyprogesterone were synthesized from ^{14}C-acetate; estradiol was also secreted, and the production of these steroids appeared to be responsive to gonadotropins.

Hormonal regulation of tyrosine transaminase synthesis was investigated using isolated rat liver perfused with an emulsion containing perfluoro compounds[83]. It revealed remarkable differences from the effects observed when natural perfusion media were used. This exemplifies a new approach to the study of the regulation of organ function.

5. Outlook

5.1. Potential Uses of the New Blood Substitutes[2]

One should consider the artificial blood substitutes, not as a replacement of natural blood, but as a complement,

which permits a wider range of applications both in practice and for research purposes.

As a substitute for whole blood, with functions related to gas transport and maintaining of blood volume and oncotic and osmotic pressure, their use will complement that of natural blood in cases of blood losses accompanying hemorrhage, surgical interventions, and organ perfusion. Since no typing is required, these blood substitutes will be utilizable without delay in case of emergency or disaster. Substantial saving in natural blood will be possible during surgical interventions, and especially when extracorporeal techniques, which require large quantities of blood, are used (in the case of pulmonary failure, for example). They will be particularly suited to organ preservation and the consequent development of organ banks, which at present are severely limited by the brief *in vitro* life of red cells and plasma proteins, due to their vulnerability to the mechanical effects of pumps, oxygenators, and filters, and to the formation of debris which may gradually block the microcirculation of the organs. They will also make "blood transfusion" possible in animal surgery and veterinary medicine, for which no blood banks exist. Among the most serious limitations in these uses of the artificial blood substitutes at present existing, one should however mention the absence of bloodclotting factors and antibody defenses.

Where only the oxygen transport function is considered, the artificial blood substitutes might be useful in the treatment of certain diseases, such as various forms of anemia (aplastic anemia, sickle-cell anemia, cancer-associated anemia), and anaerobic infections, such as tetranus, which respond to the increase of p_{O_2}. In cases of partial blood vessel occlusions, the small size of the perfluoro compound particles should provide a way of circumventing the blood clots, and thus of carrying oxygen to the anoxic sites and at the same time transporting clot-digesting agents to the occluded areas. Total body washout for the removal of viruses, toxins (as in cases of hepatic viral coma), or drug overdoses should find a wide range of applications.

Another domain which will be opened concerns all the uses and experiments in which the presence of the natural blood constituents may mask or modify the action of the materials to be tested. In chemotherapy it could permit the administration of drugs—tumor antibodies for example—that otherwise would react with blood constituents or be attacked by enzymes normally found in the circulation, and therefore fail to reach the target cells.

Bloodless animals will constitute a powerful new tool in biomedical research, since it will become possible to remove and monitor the presence of the various blood constituents. hormones, enzymes, and so on. Thus, for example, investigations into hematopoesis and plasma protein metabolism, hormone production and transport, and detection of as yet unrecognized factors will be possible under precisely controlled conditions. Similarly the effects of various factors on hormone regulation of isolated organs could be studied one by one in clear-cut conditions. The absence of the osmolarity-sensitive red cells could permit action on the blood-brain barrier. The circulatory physiology and hemodynamics could be studied under entirely new conditions, since the viscosity, oncotic and osmotic pressures, and flow characteristics of the circulating fluid could be varied within wide limits, and the effect of the various kinds of blood cells on circulation could be studied separately.

5.2. Obstacles Remaining to be Overcome; Where the Chemist Comes in

Although this research has progressed rapidly, several obstacles remain to be overcome, most of them simultaneously, in order to bring a safe blood substitute into medical practice; and the chemist certainly has a decisive role to play in this connection:

1) It is clear, first, that this research is highly dependent on the availability of the appropriate perfluoro compounds. The chemist has to devise specific routes to numerous (cheap), well-defined, pure, inert perfluoro compounds, perhaps including labeled compounds. These compounds have to form homologous series, in order to permit the step-by-step adjustment of the most crucial parameters and the determination of which compounds and surfactants are best suited for this use. At present only about two dozen compounds have been tested to any extent (Table 2), and the only repeated achievement of *total* blood substitution with subsequent survival so far seems to have been that with *F*-tri-*n*-butylamine. On the other hand, massive substitutions have been successfully performed with *F*-decalin. The hitherto extensively used FX-80 has to be eliminated from the race as being too volatile and therefore definitely toxic. None of the other commercially available perfluorinated ethers (P-1D, P-11D, Freon E) has found acceptance. Encouraging preliminary results have been obtained with bis-*F*-alkylethenes; these substances give more stable emulsions than *F*-decalin, permit survival of rats after total blood substitution, and exhibit higher excretion rates than *F*-tri-*n*-butylamine[124].

2) The *in vivo* stability of the emulsions is a requirement of paramount importance. Thus it may be that *F*-decalin will have to be abandoned, in spite of its remarkable excretion properties, if one does not find a surfactant which confers upon its emulsions a better *in vivo* stability and a longer persistence in the bloodstream than the presently-used yolk phospholipids. The necessity of having precise standard reproducible preparation procedures for the emulsions is now recognized, and many efforts will have to be devoted to making more numerous standardized emulsions available for biomedical experimentation. The chemist may contribute to the engineering, analysis, and characterization of these emulsions, to the preparation and testing of new or modified surfactants, and to the matching of perfluoro compound and surfactant to obtain maximum emulsion stability.

3) Another crucial aspect concerns the optimization of fluid balance and the control of osmolarity. The osmotic and oncotic pressures must be kept very close to normal range, and many research groups appear to stumble at this point. The effects of certain adjuvants on these parameters, as well as on the stability and flow characteristics of the emulsions, certainly require further attention.

4) The long-term retention of some otherwise very attractive fluorochemicals such as *F*-tributylamine is probably the most serious impediment to their use in fluorochemical-based blood substitutes for humans. The origin, extent, and possible long-term effects of this retention clearly deserve further extensive investigation. For all these physiological aspects of blood

substitution, it is essential for the chemist to keep in close contact with the medical corps.

5) The chemists' efforts would have further utility in their contribution to the search for properties *vs.* structure relationships. In this respect, almost everything still remains to be done, and the few hypotheses that have been formulated (increased toxicity when hydrogen atoms are present in the perfluoro compound, increased stability of its emulsions, but also prolonged retention in organs, when it contains nitrogen or oxygen atoms) have not been borne out by further observations.

6) Besides these scientific and medical problems, the introduction of an artificial blood substitute into medical practice will encounter a wide range of further obstacles, including compliance with regulations and acceptance by the physicians and public, as well as various economic, social, and political issues.

In spite of these remaining drawbacks, the perfluoro compound-based blood substitutes seem to be the closest solution to the problem of blood replacement, including the oxygen-carrying function normally performed by the erythrocytes, within reach in the near future.

Thanks are due to our co-workers for their contribution to the synthesis of new perfluoro compounds: Dr. A Cambon, F. Jeanneaux, J. Gallucci, and Dr. G. Santini. We also wish to express our appreciation for the stimulating discussions we had with our industrial colleagues Dr. R. Lichtenberger and Dr. L. Foulletier, and for the financial support of Produits Chimiques Ugine Kuhlmann.

Phytoalexins, Chemical Defense Substances of Higher Plants?

By Hans Grisebach and Jürgen Ebel[*]

Phytoalexins are defense substances with antimicrobial properties which are produced by plants after infection. They include various groups of natural substances (*e.g.* isoflavonoids, terpenoids, polyacetylenes and dihydrophenanthrenes). Induction of phytoalexin formation can be caused not only by living microorganisms but also by products of microbial origin (elicitors) or by stress treatment (cold, UV light). The elicitor from the mycelial walls of the fungus *Phytophthora megasperma* var. *sojae* (Pms) is a β-1,3-glucan with branches at C-6. In some cases the basic features of the biosynthesis of the phytoalexins are known. The activity of the enzymes involved in phytoalexin biosynthesis is increased by the action of the elicitor on plant tissues. The ability of some microorganisms to chemically modify the phytoalexins may be related to their pathogenicity. The role of phytoalexins as defense substances is not yet fully clear.

1. Introduction

As is the case with humans and animals, plants are also exposed to numerous microorganisms. The phytopathogenic fungi and viruses are especially important pathogenic agents. Since plants do not possess an immune system, the question is raised as to how they can protect themselves against these pathogenic agents. One possibility, which depends on the induced production of chemical defense substances, will be dealt with in this article.

At the end of the 19th century, it had already been assumed that plants could have an acquired resistance and could react against infection by means of biochemical defense mechanisms[42]; it was, however, the studies of *Müller* and *Börger* on the Phytophthora resistance[**] of potatoes[43] which first led to decisive experimental progress in the elucidation of such defense mechanisms. The essential results of these investigations were: 1. Death of the parasite on the tubers of the resistant varieties was not due to a substance which already existed before infection "but is the result of *a change in the state* of the host cells which have come into contact with the fungus". 2. The plants defend themselves against the parasite by sacrificing the tissue layers infected by the fungus. During this reaction which is termed "defense necrosis", a defense substance is formed which was called "phytoalexin" (phyton = plant, alexin = to defend). Phytoalexins can thus be defined as defense substances with antimicrobial properties which are produced post-infectionally[***] by the host[44, 171].

Further investigations led to the important finding that the intensity of the defense reaction depended primarily on the genetic constitution of the host plant and the parasite[95, 170].

In 1960 a compound with fungitoxic properties was isolated by the drop-diffusate technique[*] from seed pods of peas *(Pisum sativum)* which were infected with spores of the fungus *Sclerotinia fructicola*[46]. The compound was called pisatin; its pterocarpan constitution [Table 1 *(17)*] was elucidated in 1962 by *Perrin* and *Bottomley*[45].

In the past few years the field of the phytoalexins has been intensively studied. Only the more recent of the numerous reviews are cited here[2a, 2b, 23, 24, 47].

The present article deals mainly with the biochemical aspects of the phytoalexins, their induction mechanism and biosynthesis being the principal topics. The role of the phytoalexins as defense compounds against infectious agents is also discussed.

2. Structure and Distribution of Phytoalexins

Phytoalexins are not a uniform class of substances but include various groups of natural products. The phytoalexins so far known are compiled in Table 1. The only compounds considered were those which satisfied the criteria of the phytoalexin concept, (*i.e.* substances which only appear in high concentrations after infection and which inhibit the growth of microorganisms). As can be seen from Table 1, the phytoalexins include isoflavonoids, sesquiterpenes, furanoterpenoids, polyacetylenes, dihydrophenanthrenes and other substances. A comprehensive survey of the nature and distribution of postinfectional defense substances in plants does not yet exist but there is a relationship between the chemical nature of the phytoalexins and the plant families[10]. The legumes generally produce isoflavonoids, the solanaceae diterpenes, the compositae polyacetylenes, and the orchidaceae dihydrophenanthrenes. Exceptions such as the formation of the furanoacetylene, wyeronic acid *(33)*, in broad beans *(Vicia faba)* are rare. In some cases phytoalexins can thus be used as taxonomic markers.

[*] Prof. Dr. H. Grisebach, Dr. J. Ebel
Lehrstuhl für Biochemie der Pflanzen,
Biologisches Institut II der Universität
Schänzelstrasse 1, D-7800 Freiburg (Germany)

[**] The fungus *Phytophthora infestans* (Phytiaciae) causes potato rot ("late blight"). It was the reason for the destruction of the Irish potato crop in 1845 and the years following, and resulted in extensive famine.

[***] There are also preinfectional defense substances. This group includes fungitoxic compounds which are already present in sufficient concentrations in non-infected plants to prevent infection [2b]. It is difficult to classify some compounds unequivocally as pre- or postinfectional defense substances.

[*] In the drop-diffusate technique a spore suspension of the fungus is introduced as a drop to the tissue in question (here the endocarp (nutrient tissue) of the seed pods). After the defense reaction has been triggered, some of the phytoalexin formed diffuses into the drop and can be extracted from the combined drops with organic solvents.

It is usually difficult to obtain large quantities of phytoalexins from infected plant tissue. In many cases, however, large quantities (30–100 mg) of these substances can be obtained in a relatively simple way by the method of *Keen*[77]. The seeds are cut and incubated for 3 to 5 days in the presence of the microflora found in the untreated seeds. The phytoalexins which are produced can be extracted with organic solvents and then be isolated by common purification procedures (*e.g.* preparative layer chromatography).

3. Induction of Phytoalexin Formation

A large number of studies on host-parasite interactions have shown that the ability to form phytoalexins is widespread in plants. Tissues from all parts of plants can produce phytoalexins in response to infection by pathogenic and non-pathogenic microorganisms. Fungi are exceptionally effective organisms in this respect. As a result of infection of soybeans *(Glycine max)* with *Phytophthora megasperma* var. *sojae*, glyceolin *(20)* can accumulate within 24–48 h from a concentration which is below the detection limit to quantities which account for more than 10% of the dry weight of the infected tissue[187]. Most plants seem to produce several, often structurally related phytoalexins as is clearly the case with green beans *(Phaseolus vulgaris)* and potatoes *(Solanum tuberosum)* (Table 1).

Phytoalexin formation is also found to be induced by infection of plant tissues with bacteria[89,90a–c,146,188,189], viruses[83,91,92,138,139] and nematodes[15,93]. The production of phytoalexins is induced ("elicited") not only by living microorganisms but also by cell-free culture filtrates or extracts[94–102]. Compounds of microbial origin which stimulate phytoalexin synthesis in plants have been named elicitors[103]. The possible biological significance of the elicitors of phytoalexin synthesis in the defense reactions of plants against microorganisms is discussed in Section 5.

Phytoalexins have repeatedly been described as "stress compounds" (*e.g.* [90a]) as their synthesis can, like numerous other primary and secondary metabolites, also be stimulated by different types of treatment which damage or poison plant tissues. Exposure to cold[104] or UV light[105,106] can trigger phytoalexin synthesis. Substances as chemically different as heavy metal salts[94,100,107,108], polyamines[109], ethylene[110], antibiotics and metabolic inhibitors[108,111–115], fungicides[116,117] and ribonuclease[96] are also inducers. These substances probably act in different ways; in every case, however, the result is a profound change in the metabolism of the challenged plant. Phytoalexins have acquired special importance among the compounds produced under stress conditions because, on account of their postinfectional formation and antimicrobial properties, they are associated with the defense reactions of plants against potential pests (see Section 5). If plants produce several phytoalexins, the composition of the phytoalexin mixture may depend on the inducing agent. Examples of this have been mentioned by *VanEtten* and *Pueppke* ([2a], Table IV) for combinations of *P. vulgaris* with four pathogenic microorganisms. *Keen*[177] has proposed a hypothesis based on a similar behavior of *Glycine max*[177], *Phaseolus lunatus*[15] and *Glycine wightii*[78] which states that, as a response to infection with a microorganism, plants preferentially accumulate those phytoalexins which exhibit the strongest inhibitory action against this organism. The response to an abiotic elicitor such as $CuCl_2$ is, on the other hand, less selective.

It is an attractive hypothesis that plants recognize products of microbial origin and that this then brings about induction of phytoalexin synthesis[118]. The first reports concerning elicitors synthesized by microorganisms were based on studies with preparations of unknown composition[94–102]. *Cruickshank* and *Perrin*[119] isolated and characterized an elicitor from *Monilinia fructicola*, a fruit parasite. This elicitor, monilicolin A, is a peptide with a molecular weight of approximately 8000 which, when applied in low concentrations (*ca.* 10^{-9} mol/l) stimulates the synthesis of the phytoalexins phaseolin *(18)* and phaseolidin *(19)* in beans *(Phaseolus vulgaris)*[119]. Beans, however, are not a host plant for this fungus. Monilicolin A does not stimulate phytoalexin synthesis in other non-hosts of this fungus such as the broad bean *(Vicia faba)* or pea *(Pisum sativum)*[119]. The physiological significance of monilicolin A in disease resistance is still not clear since a host of *M. fructicola* which reacts towards this elicitor has not yet been described.

Albersheim et al.[118,120–123] isolated an elicitor from *Phytophthora megasperma* var. *sojae* (abbreviated as Pms), the cause of stem and root rot in soybeans *(Glycine max)*. The Pms elicitor induced the synthesis of glyceolin *(20)* in cotyledons[120], hypocotyls[120] and cell suspension cultures[123] of soybean[*]. The various tissues of soybean react very sensitively to small quantities of the Pms elicitor. Concentrations of approximately 1 μg/ml are sufficient to stimulate glyceolin accumulation. No distinction was made between *(20)* and the structurally isomeric compounds *(21)* and *(22)* which were isolated by *Lyne et al.*[14] from infected soybeans and which had antimicrobial properties similar to those of glyceolin; this is because these compounds were not determined separately under the conditions used for the biological assay of the Pms elicitor.

The Pms elicitor is a structural polysaccharide of the mycelial walls of Pms. It can be partially solubilized from the walls with water on heating. The elicitor can also be isolated from cell-free culture filtrates of Pms and is presumably released into it by autolysis of the fungal mycelia. The stability of the Pms elicitor to heat for several hours, its insensitivity towards pH extremes, its resistance to pronase and the heterogeneity of its molecular weight indicated that it was a polysaccharide[118].

A more detailed characterization showed that the elicitor-active molecules were β-1,3-glucans which can have additional sugar residues at C-6 of some of their glucosyl residues. The average molecular weight of the elicitor extracted from the mycelial walls is 100000. Exo-β-1,3-glucanase from *Euglena gracilis* hydrolyzes approximately 90% of the glucan to give highly branched fragments with an average molecular weight of approximately 10000. These fragments contain most of the elicitor activity of the high molecular weight material. In order to characterize the elicitor-active glucan components even more accurately, the Pms mycelial walls were partially hydrolyzed with acid. Oligosaccharides containing approxi-

[*] The cotyledons (seed leaves) and the hypocotyl (section of the shoot between the origin of the root and the cotyledons) are parts of the seedling.

Table 1. (cont'd)

	Structure	Trivial name	Source
Miscellaneous			
	*(39)*	Vignafuran [d] [16]	Cowpea *(Vigna unguiculata)*
	*(40)*	[17]	Carrots *(Daucus carota)*
	*(41)*	Xanthotoxin [18]	Parsnip *(Pastinaca sativa)*
	*cis-* and *trans-(42)*, R = H	Resveratrol [86]	African ground nut *(Arachis hypogea)*
	cis- and *trans-(43)*, R = Dimethylallyl	[87]	American ground nut
	*(44)*	ε-Viniferin [e] [88]	Grape *(Vitis vinifera)*

[a] Since pisatin *(17)* as opposed to most natural pterocarpanes is dextrorotatory, it is assumed to have a (6a*S*,11a*S*)-configuration.
[b] Coumestrol *(23)* is accumulated after infection with the nematode *Pratylenchus scribneri*. It inhibits the mobility of this nematode but does not have a fungitoxic action.
[c] The fungitoxicity of *(27)* seems to be lower than that cited by *Katsui et al.* [39, 90a].
[d] Vignafuran *(39)* could be formed from a pterocarpene [cf. *(12)*].
[e] Resveratrol *(42)* which is also found in the grapevine may be the precursor of ε-viniferin *(44)*. *(44)* is significantly more fungitoxic than *(42)* [88].

mately eight glucosyl residues were isolated from the hydrolysate and were the smallest elicitor-active compounds[118].

Periodate oxidation of the elicitor preparation results in almost complete loss of activity in its biological assay[122]. A considerable part of the elicitor activity is, however, regained on reduction with $NaBH_4$ and subsequent acid hydrolysis under mild conditions. This finding suggests that periodate destroys the elicitor activity by modifying terminal glycosyl residues. Partial acid hydrolysis leads to liberation of new terminal glycosyl residues and thus to reactivation[118].

Elicitors with similar biological activities have been isolated from three races of Pms which differ in their pathogenicity towards soybean[121, 122]. Figure 1 shows the rate and extent of glyceolin accumulation in hypocotyls of soybean which were incubated with living mycelium of either a virulent Pms race, of an avirulent race, or elicitors isolated from these races[121]. In all three cases the glyceolin content of the hypocotyls starts to increase considerably 6—9 hours after the beginning of the incubation. Between 9 and 15 hours the increase continues in the same way in all three cases. The finding that the purified Pms elicitor induces glyceolin synthesis to the same extent as the Pms mycelium suggests that the elicitor is the component of the mycelium which is recognized by the plant[118]. The Pms elicitor should thus be an excellent agent in a model system for studying phytoalexin synthesis in soybean.

The biosynthesis of glyceolin *(20)* probably proceeds *via* the central intermediate of flavonoid biosynthesis, the flavanone (cf. Fig. 2 and Section 4). Induction experiments with elicitors in cell cultures[123] and cotyledons[64a, 64b] of the soybean demonstrated that glyceolin production was accompanied by a large increase in the activities of the enzymes of general phenylpropanoid metabolism (phenylalanine ammonia-lyase (PAL), cinnamic acid-4-hydroxylase, 4-coumarate: CoA ligase)

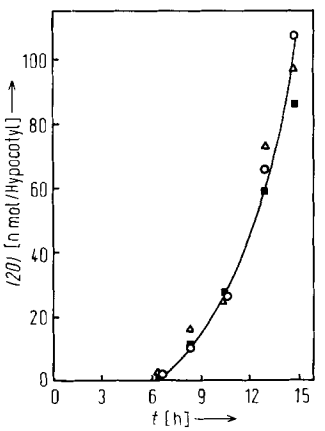

Fig. 1. Accumulation of glyceolin *(20)* after treatment of soybean hypocotyls with the Pms elicitor or with living Pms mycelium. ■, Pms elicitor; ○, mycelium of an avirulent Pms race; △, mycelium of a virulent Pms race (can kill the plant within 24 h).

and flavanone synthase (FS) (Fig. 2). An increase in PAL activity was also observed in other host-parasite interactions[59, 69, 124–129] as well as in mechanically damaged plant tissues in which the synthesis of phenylpropanoid compounds and the activity of the enzymes involved in general phenylpropanoid metabolism are stimulated[124, 130–133]. These observations leave doubt as to whether the increases in PAL activity measured in the host-parasite systems were not entirely or partially due to mechanical damage of the plant tissue[190].

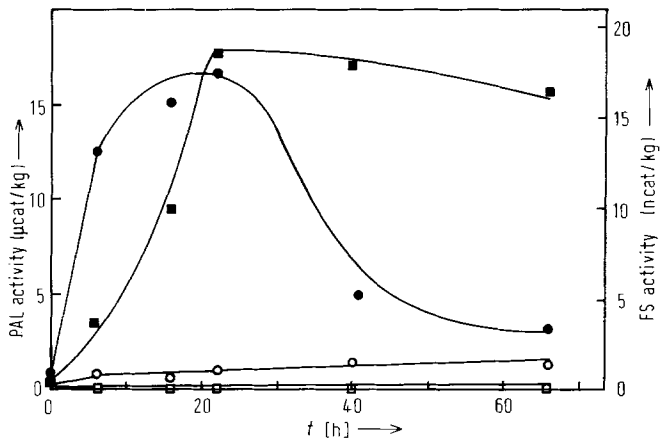

Fig. 2. Time dependence of the elicitor-induced changes in the activities of phenylalanine ammonia-lyase (PAL, ●) and flavanone synthase (FS, ■) in wounded soybean cotyledons. (Open symbols: control experiment with wounded cotyledons without elicitor.)

Induction experiments with mechanically damaged soybean cotyledons showed, however, that the activity of PAL and FS only drastically increased in the damaged cotyledons which were also treated with the Pms elicitor (Fig. 2). Induction experiments with soybean cell cultures in which the elicitor was added to the culture medium, also demonstrated increases in PAL activity and glyceolin accumulation which were independent of mechanical damage[123].

One important question concerning control of phytoalexin production is whether the elicitor-induced synthesis of glyceolin in soybean cotyledons is connected with the measured increase in enzyme activities. Incubation of soybean cotyledons with the elicitor and a competitive inhibitor of PAL (a derivative of α-aminooxy-β-phenylpropionic acid[184]) reduces glyceolin accumulation by approximately 60% whereas the *in vitro* activities of the enzymes involved in general phenylpropanoid metabolism correspond with those of the samples without the inhibitor[64b]. This suggests that elicitor-stimulated glyceolin synthesis is at least partially controlled by the enhanced activities of the enzymes of general phenylpropanoid metabolism.

Polysaccharide elicitors and their effects on phytoalexin synthesis are not restricted to the Pms/soybean system. Glucans similar to those from Pms are found in the walls of a large number of fungi[185]. Glucans from yeast (*Saccharomyces cerevisiae*)[118], the mycelial walls of *Colletotrichum lindemuthianum*[134] and *Phytophthora* spp.[135] stimulate phytoalexin synthesis in soybean, bean and potato. The molecular processes responsible for the effects of the Pms elicitor and the increased activities of the enzymes involved in phenylpropanoid metabolism are still unknown. It is remarkable that the Pms elicitor also enhances PAL activity in cell cultures of sycamore (*Acer pseudoplatanus*) and parsley (*Petroselinum hortense*)[123].

After virus infection, tobacco (*Nicotiana* spp.) produces a series of substituted cinnamic acids and benzoic acids together with their esters and also coumarins[136, 137] and sesquiterpenes[138, 139]. More detailed information about the antimicrobial properties of the cinnamic acid derivatives and coumarins and their significance as phytoaalexins in this host-parasite system is lacking. In spite of this, some more recent studies on the increase in phenylpropanoid metabolism observed after virus infection will be mentioned. A large increase in the activities of PAL, cinnamic acid-4-hydroxylase and *O*-methyltransferase was observed in virus-infected leaves which formed local necrotic lesions[140–142]. In this case the increased enzyme activity of PAL is due to an enhancement of the rate of enzyme synthesis caused by virus infection[125]. *Tanaka* and *Uritani*[132] came to a similar conclusion when accounting for the increase in PAL activity observed after mechanical damage to roots of the sweet potato (*Ipomoea batatas*).

4. Biosynthesis and Metabolism of Phytoalexins

4.1. Isoflavonoids

The majority of the phytoalexins so far known are isoflavonoids. These compounds are in turn a subgroup of the flavonoids whose biosynthesis is dealt with in recent comprehensive reviews[48, 49].

In order to understand the following account, the metabolic pathway leading to the flavonoids will first be briefly described. The coenzyme A esters of 4-hydroxycinnamic acid (4-coumaric acid) and malonic acid are required for the biosynthesis of the flavonoid skeleton. Cinnamic acid itself is produced by elimination of ammonia from L-phenylalanine which is catalyzed by PAL. After hydroxylation to 4-hydroxycinnamic acid it can be activated by a ligase in the presence of ATP and coenzyme A to its CoA ester. The enzyme flavanone synthase (FS)[50] then catalyzes the condensation reaction of 4-coumaroyl CoA with 3 molecules of malonyl CoA to give the flavanone naringenin (*45*) which occupies a central position in flavonoid metabolism (Fig. 3).

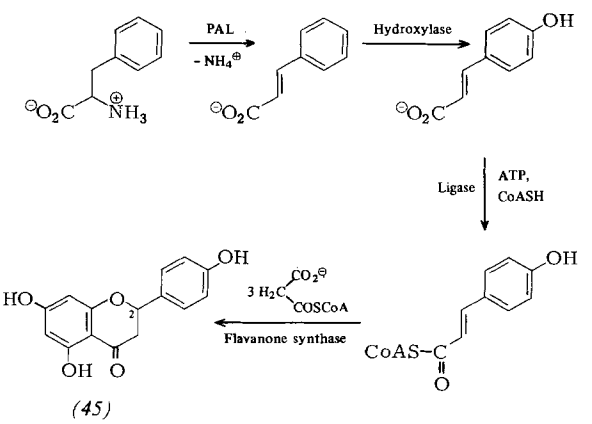

Fig. 3. Biosynthetic pathway from L-phenylalanine to the flavanone naringenin (*45*). PAL = phenylalanine ammonia-lyase.

Isotopically labeled naringenin has been utilized to show that isoflavones, *e.g.* (*46*), with the same type of substitution

as this flavanone[51], are formed by 1,2-aryl rearrangement of (−)-(2*S*)-naringenin. The precursor for the biosynthesis of 5-deoxyisoflavones *e.g. (47)* is 4′,7-dihydroxyflavanone[52] (Fig. 4). As yet, no enzymes are known which can synthesize the dihydroxyflavanone and rearrange flavanones to isoflavones.

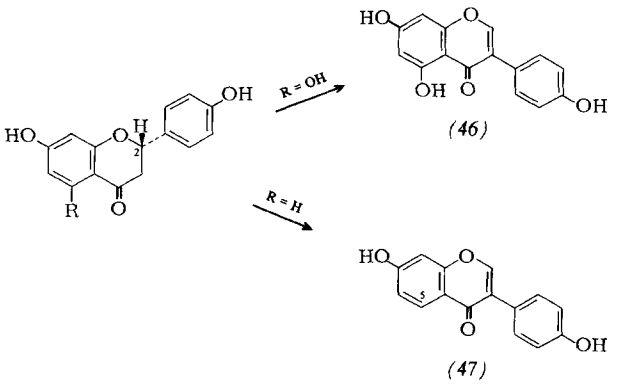

Fig. 4. Biosynthesis of the isoflavone genistein *(46)* and the 5-deoxyisoflavone daidzein *(47)* from the appropriately substituted flavanones.

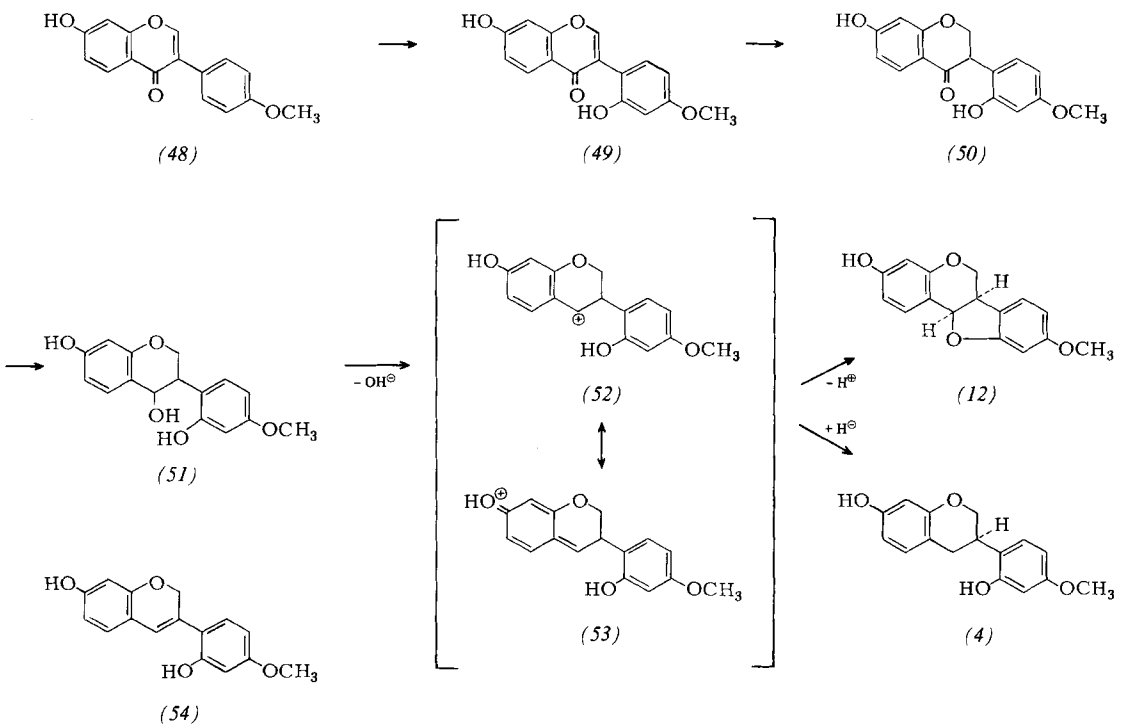
Details concerning the biosynthesis of the pterocarpan phytoalexins in red clover *(Trifolium pratense)* are known. After fungal infection[53] or in the presence of heavy metal ions (*e.g.* Cu^{2+})[54], synthesis of medicarpin *(12)* and maackiain *(16)* is induced in the seedlings. Incorporation experiments with ^{14}C-labeled precursors showed that 7-hydroxy-4′-methoxyisoflavone (formononetin) *(48)* and the isoflavanones *(49)* and *(50)* were very good precursors for *(12)* but not for vestitol *(4)*. Compounds *(49)* and *(50)* showed higher ^{14}C incorporation than *(48)*[56]. On the basis of these findings the biosynthetic pathway for medicarpin *(12)* shown in Figure 5 has been postulated. According to this, formononetin *(48)* is first hydroxylated to *(49)*. (The 2′-hydroxylation of isoflavanones has been demonstrated in investigations on the biosynthesis of coumestrol *(23)* in *Phaseolus aureus*[55].) The isoflavone *(49)* could be reduced to the isoflavone *(50)* which would, on further reduction, give the isoflavanol *(51)*. Loss of OH^- leads to the carbenium ion *(52)* mesomeric with *(53)* which would be converted into medicarpin *(12)* by cyclization and release of a proton. Vestitol *(4)* could be produced by addition of a hydride ion to the carbenium ion. The existence of the intermediate carbenium ion *(52)* is strongly supported by the mutual interconversion of *(12)* and *(4)* in lucerne *(Medicago sativa)*[57] which apparently takes place *via* a common intermediate. The isoflavene *(54)* could be an alternative to the carbenium ion *(52)*.

The stereochemistry of the reduction sequence from *(49)* to *(12)* was studied with seedlings of *Trigonella foenum-graecum*[*] which accumulate large quantities of medicarpin *(12)* after treatment with $CuCl_2$ or UV irradiation[58]. The medicarpin *(12a)* (Fig. 6) isolated from the seedlings after application of the isoflavone *(49a)* labeled with deuterium at C-2 gave only one signal in its ^2H-nuclear magnetic resonance spectrum at $\delta = 3.92$ which can be attributed to the deuterium in the 6-pro-*R* position. The biosynthesis of *(12)* from *(49)* thus proceeds formally by *trans* addition of hydrogen to the double bond.

The biosynthetic pathway proposed for medicarpin is similar to that for coumestrol *(23)* in seedlings[55] or cell cultures[62] of mung bean *(Phaseolus aureus)*. The pterocarpene *(55)* was postulated to be a direct precursor of *(23)* (Fig. 7) as it can be easily oxidized to coumestrol[63]. In mung bean, however, coumestrol is not a phytoalexin in the strict sense



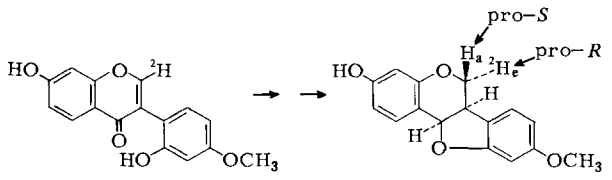


Fig. 5. Postulated biosynthetic pathway from the isoflavone formononetin *(48)* to medicarpin *(12)* and vestitol *(4)*.

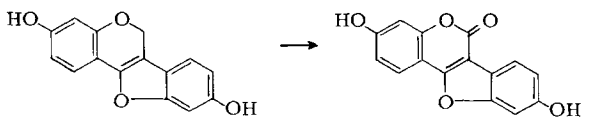

[*] *Trigonella* is the main ingredient of the artificial curry sauce which can be obtained in Germany. It has scarcely anything in common with the asiatic curry mixture.

of the word as it is already present in higher concentrations in healthy tissues.

(49a) (12a)

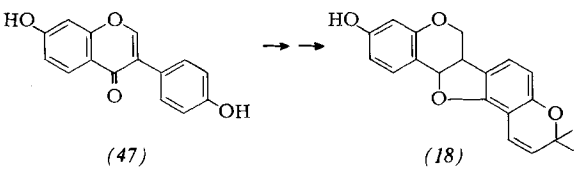

Fig. 6. Stereochemistry of the reduction of 2-deuterioisoflavone (49a) to deuterated medicarpin (12a).

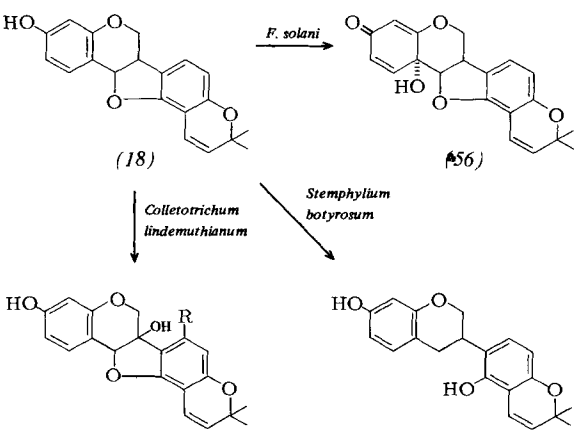
(55) (23)

Fig. 7. Postulated biosynthesis of coumestrol (23) by oxidation of the pterocarpene (55).



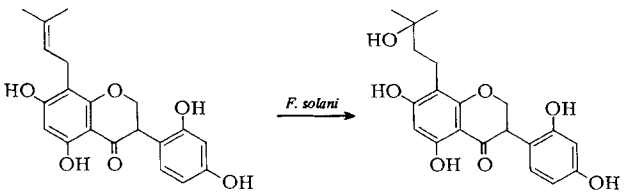
The incorporation of [^{3}H]-daidzein (47) into phaseolin (18) which takes place in bean pods[59] is also similar to the biosynthetic pathway for medicarpin (Fig. 8).

(47) (18)

Fig. 8. Conversion of daidzein (47) into phaseolin (18) (demonstrated by ^{3}H-labeling).

In accordance with the phytoalexin theory, it could be shown in experiments with beans that the precursors of phaseolin (18) only originate from the host plants and not from the parasites. Series of experiments were performed with ^{14}C-labeled spores ([^{14}C]-glucose) of *Sclerotinia fructicola* and with [^{14}C]-glucose-labeled host tissue[60]. The relationship between phytoalexin induction and the increase in the activity of the enzymes which are probably involved in their synthesis has already been discussed in Section 3.

(18) (56)

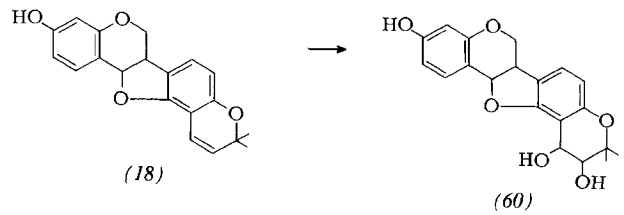


(57), R = H
(58), R = OH (9)

Fig. 9. Conversion of phaseolin (18) by fungi into (9) and (56)—(58).

Phytoalexins can be modified and probably also be catabolized by fungi. These reactions may be a defense reaction of the fungi against the phytoalexins; some of these metabolic products have a lower fungitoxicity (cf. also Section 5). Phaseolin (18) is oxidized to the more weakly fungitoxic hydroxyphaseolin (56) by the fungus *Fusarium solani* which is pathogenic for bean[65, 66] (Fig. 9).

Hydroxylation of (18) to the products (57) and (58)[61] and the reductive opening of the benzyl phenyl ether bond to give phaseolin isoflavane (9) (Fig. 9) are other reactions which are carried out by phytopathogenic fungi (for literature concerning these reactions see [2a] and [2b]). The modified products shown in Figure 9 can very probably be catabolized by the fungi to simple substances; the details of these processes, however, still have to be elucidated.



More metabolic products of the pterocarpanes are known[2a, b]. It has recently been demonstrated that kievitone (10) is converted into the product (59) by *Fusarium solani* which formally corresponds to addition of water (Fig. 10)[67].

(10) (59)

Fig. 10. Hydroxylation of kievitone (10) to (59) by *Fusarium solani*.

The metabolism of phytoalexins is not limited to the phytopathogenic fungi. *Septoria nodorum* and other fungi which are not pathogenic towards bean plants can convert phaseolin (18) into the much less toxic *cis*- and *trans*-12,13-dihydrodihydroxyphaseolin (60) (Fig. 11)[68]. Accordingly, the distinction between pathogenic and non-pathogenic fungi, in these cases at least, is not connected with their ability to catabolize phytoalexins.

(18) (60)

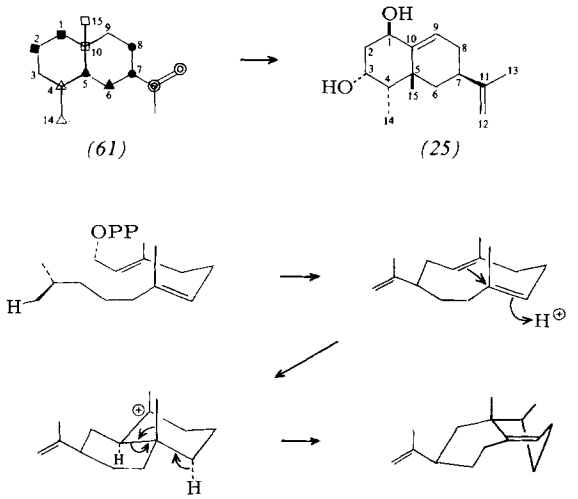


Fig. 11. Hydroxylation of phaseolin (18) to (60) by *Fusarium solani*.

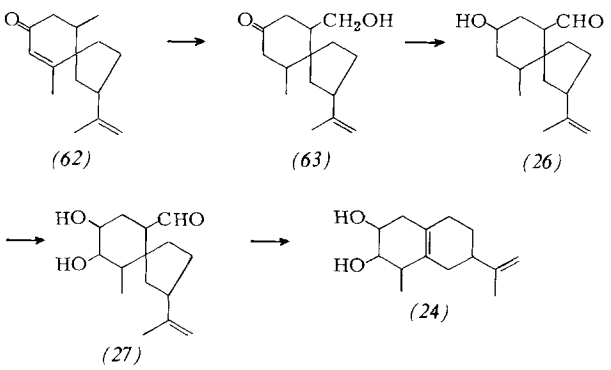
4.2. Sesquiterpenes, Furanoterpenoids

In this section only those experiments will be discussed in which the special features of the biosynthesis of these compounds are recorded, the evidence concerning their origin in general isoprenoid metabolism will not be dealt with[20, 23].

The biosynthesis of capsidiol (25) has been studied by injecting labeled precursors into peppers (*Capiscum annuum*) which had been treated with spore suspensions of *Monilinia fructicola*[70]. After addition of [1,2-$^{13}C_2$]-acetate, ^{13}C-^{13}C coupling between C-1/C-2; C-4/C-14; C-5/C-6; C-7/C-8 and C-11/C-12 could be observed in the ^{13}C-NMR spectrum of (25). In contrast, there was no coupling between C-5 and



C-15 which proved that these two C atoms do not originate from the same C_2 unit. This finding is in agreement with the hypothesis that the eremophilane skeleton of *(25)* is formed from the eudesmane skeleton *(61)* by migration of a methyl group from C-10 to C-5 (Fig. 12). The reaction pathway postulated for the conversion of farnesyl pyrophosphate into eremophilenes is shown in the lower part of Figure 12.

(61) *(25)*

Fig. 12. Biosynthesis of capsidiol *(25)* from the eudesmane skeleton *(61)* by methyl migration from C-10 to C-5. Lower part: postulated course of the reaction.

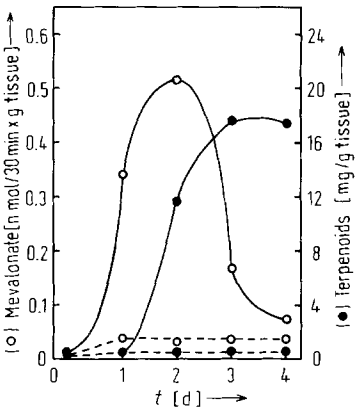
Several reports on the biosynthesis of rishitin *(24)* in potatoes have appeared[2b, 23, 71–73]; the biosynthetic pathway shown in Figure 13 was postulated on the basis of these results. The vetispira compounds isolubimin, lubimin *(26)* and 4-hydroxylubimin *(27)* have been proposed as intermediates and are also found to occur as phytoalexins in infected potatoes (Table 1).

(62) *(63)* *(26)* *(27)* *(24)*

Fig. 13. Postulated biosynthesis of rishitin *(24)* from the spirovetivadienone *(62)*. On conversion of 4-hydroxylubimin *(27)* into *(24)*, C-15 (—CHO) is lost [72].

On comparison of the incorporation of ^{14}C-labeled acetate and mevalonate into rishitin *(24)* an up to 5.9-fold higher incorporation was found in resistant potato varieties than in susceptible varieties[73].

The changes in the activities of enzymes which are involved in the biosynthesis of isopentenyl pyrophosphate were investigated after infection of root tissue of sweet potato *(Ipomoea batatas)* by spores of the fungus *Ceratocystis fimbriata*. Figure 14 shows the increase in activity of 3-hydroxy-3-methylglutaryl-coenzyme-A reductase (HMG-CoA reductase) after infection. This increase is followed by an increase in furanoterpenoids such as ipomeamarone *(30)*[74]. In tissue which is only damaged but not infected, however, neither the enzyme activity nor the furanoterpenoid content increases. The conditions are thus very similar to those during induction of glyceolin formation in soybean cotyledons (see Fig. 2).



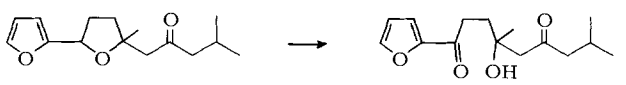


Fig. 14. Changes in the activity of HMG-CoA reductase (○—○) and terpene content (●—●) after infection of the root tissue of sweet potato by spores of the fungus *Ceratocystis fimbriata*. (Dashed curves: control experiment with wounded non-infected tissue).

It is not known whether HMG-CoA reductase is the rate-determining enzyme in furanoterpenoid synthesis as is the case in the biosynthesis of cholesterol in rat liver[75]. Increases in the activity of other enzymes of the pathway from mevalonate to isopentenylpyrophosphate (*e.g.* pyrophosphomevalonate decarboxylase) have been observed after infection of sweet potato[76].

(30) *(64)*

Fig. 15. Oxidation of ipomearmarone *(30)* to 4-hydroxymyoparone *(64)* by sweet potatoes.

Ipomeamarone *(30)* is oxidized to 4-hydroxymyoparone *(64)* by sweet potato slices treated with $HgCl_2$ (Fig. 15)[79]. *(64)* can be converted into lung-toxic metabolites by the fungus *Fusarium solani* which is pathogenic for sweet potato[80].

5. Role of Phytoalexins as Defense Substances

Numerous recent reports have been concerned with the significance of phytoalexins in the resistance of plants against diseases[2a, 23, 24, 47, 90a, 143, 144]. In this article only a few important observations and hypotheses will be dealt with.

Phytoalexins, often several compounds with similar structures, are not only produced as a response of a plant to infection but also, for example, on exposure of the plant to cold or UV radiation; they are also not specific toxins. Specificity is based on the way in which the plants react (susceptibility or resistance) in certain host-parasite combinations[*].

[*] The combination or interaction between the host plant and the pathogenic organism is termed as "compatible" if the host is susceptible and the pathogenic organism is virulent. The combination in which the host is resistant and the pathogenic organism is avirulent is accordingly described as "incompatible" [95].

Before the role of phytoalexins as defense substances can be evaluated, the following questions must be answered:

a) Are phytoalexins produced in sufficient quantities and at the appropiate time to account for the observed cessation of parasite growth?

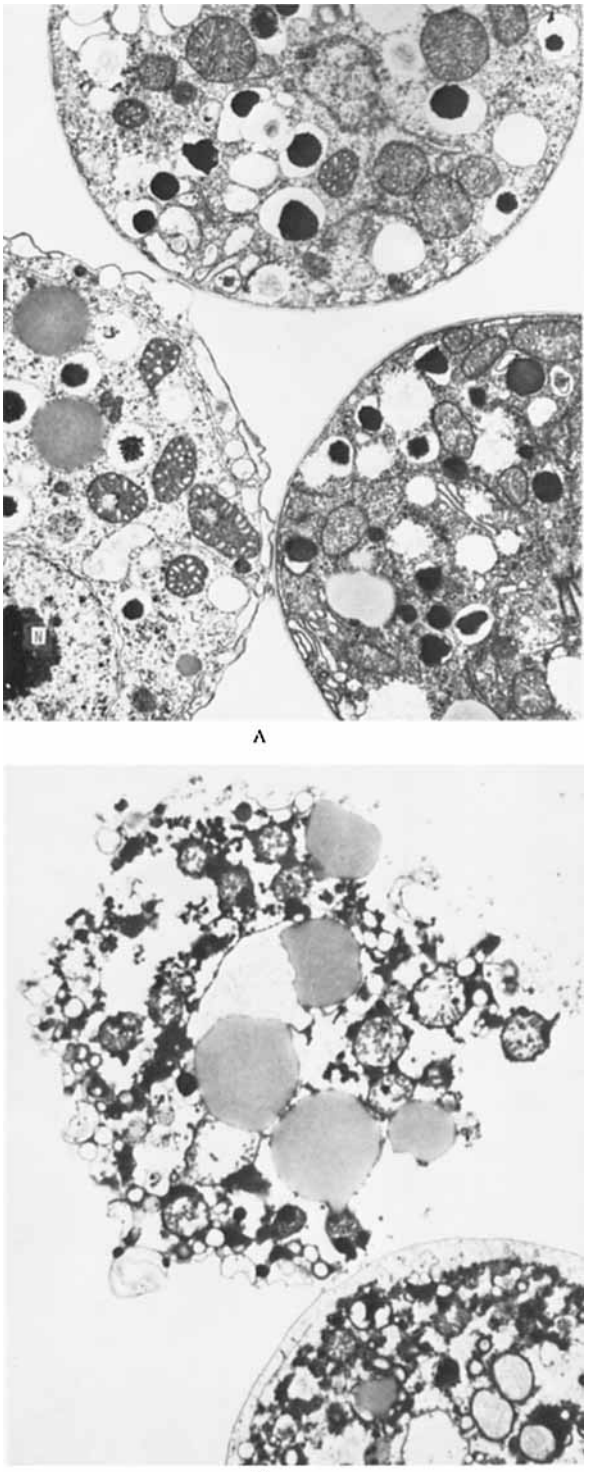

Fig. 16. Action of phaseolin *(18)* on zoospores of the soil fungus *Aphanomyces euteiches*, the cause of root rot in the pea. A) Two encysted zoospores and a non-encysted zoospore. The cell nucleus (N) and some organelles (control) can be recognized. B) Encysted and non-encysted zoospores 5 min after treatment with approximately 10^{-4} mol/l phaseolin. In both cases marked degenerative changes in the fine structure and disintegration of the ordered cell compartmentation are observed. The form of the encysted zoospores remains as the spore wall is not destroyed (magnification: ×25000. *H. C. Hoch, H. D. VanEtten* and *P. S. Matthews*, unpublished).

b) Do the phytoalexins appear at the sites within the plant where they could come into contact with the microorganism?

c) Are there any signs of an interaction between the phytoalexin and the microorganism?

d) Do other mechanisms play a role in the interaction between the host and the parasite and could this influence the growth of the parasite before the phytoalexins act?

The biological activity spectrum of the phytoalexins has been very extensively studied. The usual common bioassays make use of the phytoalexins fungitoxic action on spore germination, germ tube growth, radial mycelial growth on a solid nutrient medium or the accumulation of fungal mycelium in liquid culture. Isoflavonoid, terpenoid and polyacetylene phytoalexins inhibit a large number of pathogenic and non-pathogenic fungi in the above mentioned assays in concentrations of 10^{-5} to 5×10^{-4} mol/l[91,145–149,188]. The phytoalexins have been found to have fungistatic, fungicidic and in some cases also antibacterial properties[118,154,189]. *Hoch, VanEtten* and *Matthews*[191] examined cytological changes in zoospores of *Aphanomyces euteiches* which had been exposed to a phaseolin *(18)* solution. Figure 16 gives an impression of the action of this phytoalexin on the zoospores.

The fungitoxic properties measured *in vitro* can, however, vary greatly depending on the assay conditions[150–153, 188] and it is very difficult to evaluate the *in vivo* activity of the phytoalexins from these data. In many cases pathogenic fungi are insensitive to the phytoalexins of their hosts whereas non-pathogenic fungi are sensitive to the same phytoalexins[12,145,152,155,156,188]. Exceptions to this relationship between the pathogenicity of a fungus and its phytoalexin sensitivity have, however, also been described[91,107,156–159]. The tolerance of a fungus towards one or more phytoalexins of a certain plant as measured *in vitro* is thus not a prerequisite for the pathogenicity of the fungus towards this plant. The *in vitro* tolerance of fungi towards phytoalexins could be connected with the ability of the fungi to convert the phytoalexins into non-toxic compounds (see Section 4).

The *in vivo* situation in a host-parasite system is influenced by numerous factors. Of special interest are systems consisting of several varieties (cultivars) of a host plant and several differently pathogenic races of a microorganism in which some varieties of the host plant are susceptible and some are resistant (varietal specific resistance). The resistance reaction in such systems is often accompanied by the hypersensitive reaction in which some cells at the site of the infected plant tissue rapidly die, defense necroses are formed and phytoalexins accumulate. Examples of such host-parasite combinations are systems composed of several races of the fungus *Colletotrichum lindemuthianum* and varieties of bean *(Phaseolus vulgaris)*, of the fungus *Phytophthora megasperma* var. *sojae* (Pms) and soybean *(Glycine max)* as well as of the fungus *Phytophthora infestans* and potato *(Solanum tuberosum)*[23,150,158,160–163,169]. Although several races of the pathogenic agents are almost equally sensitive to the phytoalexins of their hosts[150,158,160] and the host varieties produce the same phytoalexins[23,150,169], some varieties of the host plant are susceptible and others are resistant. This varying behavior could be due to the fact that phytoalexin synthesis commences after different lag periods, proceeds at different rates and leads to different concentrations. Some observations showed that higher concentrations of phytoalexins were more rapidly

formed in incompatible combinations of host varieties and parasite races (*i.e.* with resistance) than in compatible combinations[150, 158, 160, 164, 169]. After the hypersensitive reaction had commenced in incompatible combinations with *C. lindemuthianum*, phaseolin *(18)* and related compounds accumulated in bean hypocotyls in concentrations which by far exceeded those required for *in vitro* inhibition of germ tube growth[150, 160, 164]. The accumulation of phaseolin and the appearance of necrotic cells were connected with restriction of fungal growth in the hypocotyls[165]. On the basis of these findings it is thought that the phytoalexins probably inhibit fungal growth in necrotic cells of bean hypocotyls but it also has to be remembered that phytoalexins could never come into contact with the germ tubes of *C. lindemuthianum*, or if so they would be too late to restrict their growth[24]. If the fungal metabolites of the phytoalexins which have been characterized *in vitro* can also be demonstrated *in vivo*, this will support the hypothesis that fungi invading the plants come into contact with their phytoalexins[2a].

Careful studies at the cellular level on the site of phytoalexin accumulation and distribution as compared with the distribution of the penetrating microorganism could help to solve this problem. Shortly after the germ tubes of *Botrytis cinerea* have entered the leaf cells of broad bean *(Vicia faba)*, the invaded cells and those in their immediate neighborhood become necrotic with the result that necrotic spots appear on the leaves within one day after innoculation. The distribution of *B. cinerea* is normally restricted to these first local lesions[166]. Fluorescence microspectroscopy showed that the vacuole content of the living cells in the vicinity of the necrotic cells had spectral properties similar to those of the isolated phytoalexins wyerone *(34)* and wyeronic acid *(33)*; these compounds accumulated in high concentrations in tissues infected with *B. cinerea* within two days[149, 167].

Comparative investigations using thin tissue sections were performed on the growth of the hyphae of *P. megasperma* var. *sojae* (Pms) and the local accumulation of glyceolin *(20)* in the area surrounding the spreading hyphae. These studies showed that the phytoalexin concentration in resistant soybean hypocotyls already exceeded the value required for the *in vitro* inhibition of fungal growth when the fungal growth had stopped in the soybean hypocotyls[178]. Similar findings were obtained from peppers *(Capiscum frutescens)* by measuring their capsidiol *(25)* content and by performing cell structural studies. According to these results the rate and extent of capsidiol formation in incompatible host-parasite combinations are more than sufficient to limit the infection[179–182]. Pepper, however, may be a special case; in ultrastructural studies a compatible interaction could be distinguished from an incompatible one only 4 h after innoculation with *Phytophthora capsici;* the fungus had not penetrated the cell wall and had not come into contact with the cytoplasm of the host cell[179, 183]. It seems possible that phytoalexin production in pepper is a secondary effect and that the specificity in this system is linked with the early stage of hypersensitivity or an as yet unknown factor[90a].

The experiments with the elicitors of phytoalexin synthesis demonstrate that they cannot determine varietal specificity in the Pms-soybean system. The elicitors isolated from virulent and avirulent Pms races and also living mycelium of these races are capable in all assays used, to induce glyceolin synthesis in soybean hypocotyls and cotyledons to a similar extent (Fig. 1)[121]. These results show that differences in the rates of glyceolin accumulation probably cannot account for resistance or susceptibility of the various soybean varieties towards different races of Pms.

Other findings, however, demonstrate that the elicitors are of importance for resistance. Soybean plants can be protected from a virulent Pms race if the elicitor is applied to the hypocotyl 6 h before innoculation with the mycelium of the virulent race. The elicitor cannot, however, protect the soybean plant if it is applied at the same time as the virulent Pms race. It is not known how the virulent race overcomes the inhibitory action of glyceolin. The widespread distribution of elicitors in nature[23, 118, 135] and their biological properties indicate that the elicitor concept is of general validity[118].

The ability to synthesize phytoalexins seems to be a widespread, effective means for plants to defend themselves against non-pathogenic microorganisms. As the examples of varietal-specific resistance (or susceptibility) show, phytoalexin formation does not, however, seem to be sufficient to protect plants against virulent races of microorganisms and against pathogenic microorganisms in general. It is not yet known which factors are responsible for the specificity of parasitism in plants. Earlier reports which state that the Pms elicitors of phytoalexin synthesis are the determinants of race specificity[168] contradict the findings discussed here[118].

In the following it will be indicated how it could be possible for pathogenic organisms to overcome the toxic effects of the phytoalexins. Conversion of phytoalexins by microorganisms to less toxic products has already been discussed in Section 4. Another possibility is that insensitivity towards the phytoalexins plays a role in the pathogenicity of some microorganisms. In neither case is it known whether the pathogenicity of the parasite is maintained on loss of its ability to metabolize the phytoalexins of the host plant or on loss of its insensitivity respectively. Finally, the phytoalexins could remain ineffective because the pathogenic agent does not come into contact with them during its development in the plant.

The pathogenic organism could also prevent the plant from synthesizing phytoalexins. It should be established whether the phytotoxins produced by pathogenic microorganisms[172–174] can be considered as effectors for such mechanisms. Other possible mechanisms would be inhibition of elicitor action by competitive factors[122] or inactivation of the elicitors before they reach their site of action in the plant cells. Terms such as "induction of susceptibility"[175] or "suppression of hypersensitive response and phytoalexin accumulation"[176] which have entered into the literature require a more detailed analysis of their significance at a molecular level.

6. Outlook

Phytoalexins have a wide spectrum of action against a large number of fungi and also against some bacteria and viruses. As yet there is no generally accepted opinion as to their importance in disease resistance of plants. The ability to synthesize phytoalexins seems to be an effective way in which plants can limit the growth of non-pathogenic microorganisms. In contrast, the contribution of phytoalexins in systems with varietal-specific resistance is still not clear; in these

systems the interactions between the host and the parasite are precisely controlled by genetic components[95].

The inducibility of phytoalexin synthesis is an interesting subject for studying the regulatory mechanisms of plant metabolism. Defined elicitors should be used in order to assess the possible involvement of inducer-receptor interactions and the reactions which they trigger in the redirection of metabolism. The questions which are raised concerning the processes at a molecular level which are connected with the stimulation of secondary plant metabolism are of fundamental importance for the understanding of gene expression in eukaryotic cells[186]. In the future, elicitors could also find practical application for the "induced protection" of plants against disease. The phytoalexins, which include different groups of natural substances, may finally provide a stimulus for conceiving novel, non-polluting pesticides.

Our work was supported by the Deutsche Forschungsgemeinschaft (SFB 46) and the Fonds der Chemischen Industrie. We thank Prof. G. Drews for his critical reading of the manuscript. We also thank Prof. H. D. VanEtten for the two electronmicrographs.

Protein Biosynthesis: The Codon-Specific Activation of Amino Acids

By Eggehard Holler[*]

Dedicated to Professor Hermann Hartmann

At the start of protein biosynthesis the amino acids are chemically activated by esterification with transfer ribonucleic acids bearing the appropriate anticodons. The esterification is catalyzed with an exceptionally high specificity by aminoacyl-tRNA synthetases. Current knowledge of the structural properties of the reactants, the course of the reaction, and the reasons for its specificity are summarized.

1. Introduction

The function of transfer ribonucleic acids (tRNA) in protein biosynthesis is to convey amino acids to the ribosomal synthetic apparatus in an order which is dictated by messenger ribonucleic acid (mRNA) (see Fig. 1). The esterification of the amino acids by tRNA activates their carboxy groups; the tRNA anticodon characteristic for each amino acid is responsible for the translation of the nucleic acid code into an amino acid sequence of the growing peptide. This translation is extremely accurate. The chance incorporation of L-valine instead of L-isoleucine into a mammalian hemoglobin chain shows that the resulting amino acid sequence corresponds with the genetic "template" in at least 99.97% of the cases[1].

Ester formation between the amino acids and the tRNA is catalyzed by aminoacyl-tRNA synthetases. They are the central topic of the present article. For earlier reviews see ref. [2].

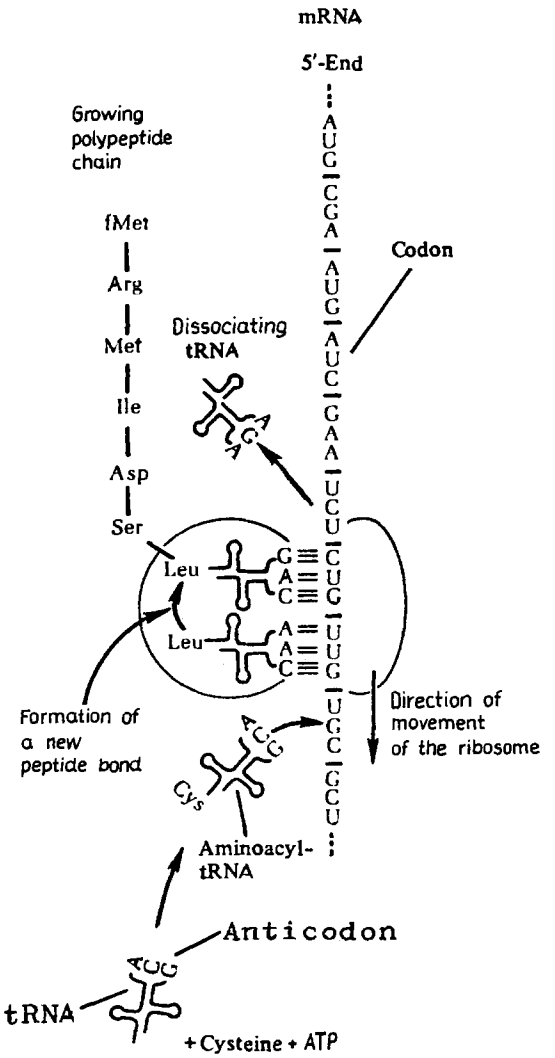

Fig. 1. The important steps of protein synthesis.

2. Aminoacyl-tRNA Synthetases

2.1. Occurrence

In bacterial cells, an individual aminoacyl-tRNA synthetase is assigned to each amino acid. In plant and animal cells, the enzymes of the cytoplasm and the organelles (mitochondria and chloroplasts) are not identical. They preferentially aminoacylate only the tRNA of the same compartment. Cytoplasmic synthetases form larger, apparently membrane-bound complexes with molecular weights approaching 10^6[3].

The intracellular concentrations of aminoacyl-tRNA synthetases and of tRNA in bacterial cells are of the order of 10^{-6} mol/liter. No estimates can be made for plant and animal cells because of compartmentation. It can be deduced from the values of the concentrations and dissociation constants that a considerable portion of the synthetases is complexed with the tRNA. However, recent findings seem to indicate that most of the tRNA is aminoacylated and complexed with the ribosomal elongation factor EFTu.

2.2. Structure

Synthetases consist of a single peptide chain (α type), of two identical (α_2 type), or of two non-identical chains ($\alpha\beta$ type), and of pairs of non-identical chains ($\alpha_2\beta_2$ type). Single- or double-chain synthetases have molecular weights in the region of 46000 to 140000; the molecular weights of the tetrameric synthetases are of the order of 220000 to 290000. The synthetases have a predominantly dimeric structure if the tetrameric enzyme is considered as $(\alpha\beta)_2$. The tertiary

[*] Dr. E. Holler
Institut für Biophysik und physikalische Biochemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (Germany)

structures of the monomeric synthetases consist of globular folded subregions (domains). Some regions have repeating amino acid sequences[4]. The homologous sequences most probably originate from the duplication and fusion of single, ancestral genes.

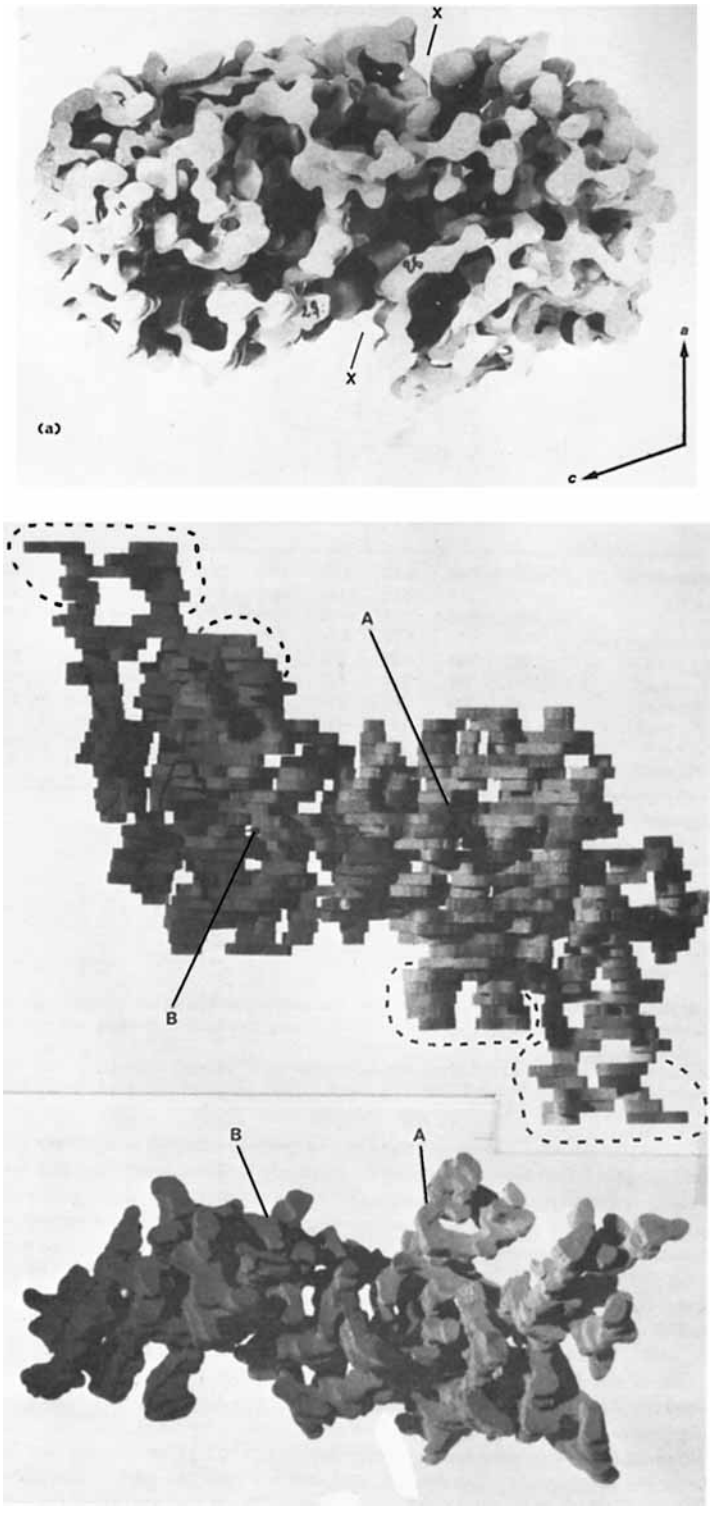

Fig. 2. Structural models of two aminoacyl-tRNA synthetases based on X-ray crystallographic studies. (a) Proteolytic fragment of methionyl-tRNA synthetase from *E. coli* at a resolution of 4 Å [6]. The fragment is an enzymatically active monomer and has a molecular weight of 64000. Native methionyl-tRNA synthetase is a dimer and has a molecular weight of 172000. The fragment is composed of two domains which are covalently linked at their contact surfaces (X—X). (b) Two orthogonal views of a structural model for tyrosyl-tRNA synthetase at a resolution of 3.5 Å [5]. The enzyme is a dimer and has a molecular weight of 90000. The components encircled by dashed lines are mobile and their positions cannot be determined precisely. The two active centers are located at A and B.

X-Ray structure analysis has been performed on the tyrosyl-tRNA synthetase from *Bacillus stearothermophilus* with a resolution of 2.7 Å, and on the tryptic (enzymatically active) fragment of the methionyl-tRNA synthetase from *Escherichia coli* with a resolution of 4 Å[5, 6] (Fig. 2). In the case of the latter enzyme, the X-ray small-angle scattering has also been measured[7]. The common result of these studies is that the synthetases have a less compact structure than do other enzymes. The monomer of the tyrosyl-tRNA synthetase (MW 45000) occupies a volume of 60×40 Å^3 and the dimer has a maximum extension of 130 Å.

As is the case with other enzymes made up of identical subunits, aminoacyl-tRNA synthetases exhibit negative cooperativity[*] for substrate binding and half-of-the-sites reactivity[**][8–10]. In the $\alpha_2\beta_2$ type proteins, the problem arises as to how the substrate binding sites or active centers should be assigned to the different subunits. Results obtained with the phenylalanine-specific system of *E. coli* support the notion that complex formation with the amino acid and with the tRNA occurs at different subunits[11]. In the glycine-specific system of *Bacillus brevis* the smaller subunit (α) only catalyzes amino acid-dependent ATP-[^{32}P]pyrophosphate exchange (see Section 4.2), whereas the complete enzyme ($\alpha_2\beta_2$) is needed for aminoacylation of tRNA[12].

With the exception of the lysine-specific system of *E. coli*, the aminoacyl-tRNA synthetases are reversibly inhibited by substances which react with sulfhydryl groups [mercury(II) or disulfide compounds] and are irreversibly inhibited by alkylating agents. At the same time unfolding of the protein is frequently observed which, in the case of enzymes with quaternary structures, is paralleled by a dissociation into the subunits[13]. Sulfhydryl groups are not considered to be essential for the catalysis.

Histidine-specific reagents such as diethyl pyrocarbonate and rose bengal (photochemical oxidation) were found to inhibit the catalytic function of the phenylalanine-tRNA synthetase from *E. coli*[14]. Prolonged incubation also led to a dissociation into subunits. Lysine side chains have been found to be involved in the anchorage of ATP[68].

Metal ions can stabilize the protein structure and activate the enzyme[9, 15]. The effective concentration range of Mg^{2+} for phenylalanyl-tRNA synthetase is found to be between 10^{-4} and 10^{-2} M.

The enzymatic activity of aminoacyl-tRNA synthetases in mammalian tissues is regulated by a hormone-controlled phosphorylation/dephosphorylation[16].

2.3. Catalysis

The reactions catalyzed by aminoacyl-tRNA synthetases consist of amino acid activation [equation (a)] and amino acid transfer [equation (b)].

[*] Negative cooperativity is observed in enzymes which are composed of identical or similar protein chains. These have identical or similar binding sites for the same substrate. The tendency for forming an enzyme-substrate complex is the same at each binding site as long as one of the sites is not already occupied by a substrate molecule. As more substrate binds to the enzyme the affinity to bind at the other sites that are still free decreases.

[**] Half-of-the-sites reactivity occurs if only half of the number of the active sites of an enzyme are catalytically active.

$$MgATP + AA + E^{AA} \rightleftharpoons E^{AA}\cdot AA \sim AMP + MgP_2O_7^{2-} \quad (a)$$
$$E^{AA}\cdot AA \sim AMP + tRNA^{AA} \rightleftharpoons E^{AA} + AA - tRNA^{AA} + AMP \quad (b)$$

AA signifies the amino acid, E^{AA} the specific synthetase, and $tRNA^{AA}$ the codon-specific tRNA. Adenosine 5'-triphosphate only acts as a substrate when combined with Mg^{2+} (*i.e.* MgATP). The products of the two reactions are magnesium pyrophosphate ($MgP_2O_7^{2-}$), adenosine 5'-monophosphate (AMP), and the aminoacyl-tRNA (AA-$tRNA^{AA}$).

During amino acid activation [equation (a)], the amino acid (AA) and MgATP associate with the active center of the synthetase (E^{AA}) in a sequence which is probably kinetically but not obligatorily ordered. The primary association step is followed by a possibly multistep rearrangement of the complex in which the amino acid carboxylate group approaches the triphosphate residue of the ATP after overcoming the electrostatic repulsion. At the same time the anhydride bond P_α—O—P_β of the ATP is polarized in the direction of the pyrophosphate cleavage; the production of the aminoacyl adenylate (AA ~ AMP) is thus finally facilitated. The free energy that is required to enforce the juxtaposition of the negatively charged groups (7 to 10 kcal/mol depending on the kind of synthetase) is obtained during the formation of the secondary bonds (electrostatic and hydrophobic interactions, as well as hydrogen bonds) between the enzyme and the substrates during the rearrangement of the enzyme·substrate complex. As a result, the synthesis of the synthetase·aminoacyl adenylate-$MgP_2O_7^{2-}$ complex as given in equation (c) is favored over reaction (d) by several kcal/mol[17–19].

$$E^{AA}\cdot AA\cdot MgATP \rightleftharpoons E^{AA}\cdot AA \sim AMP\cdot MgP_2O_7^{2-} \quad (c)$$
$$AA + MgATP \rightleftharpoons AA \sim AMP + MgP_2O_7^{2-} \quad (d)$$

The aminoacyl adenylate (AA ~ AMP), which is highly labile in its free form, remains associated with the synthetase (binding constant 10^9 liter/mol) on account of its tendency to form complexes. $MgP_2O_7^{2-}$ is liberated and hydrolyzed by another enzyme to orthophosphate. This causes the equilibrium to shift in the direction of adenylate formation.

The synthesis of the intermediate is followed by transfer of the amino acid residue to the 2'- or 3'-hydroxy group of the 3'-terminal ribose residue of the tRNA depending on the kind of synthetase[20]. It is not known whether a covalent aminoacyl synthetase is formed as intermediate[21]. The transfer is followed by a rapid 2',3'-isomerization (half-time of 0.3 s for leucyl-tRNA)[22]. It is an open question whether the isomerization takes place in the complex or after dissociation of the aminoacyl-tRNA from the enzyme. The primary acylation site was identified by the use of transfer ribonucleic acids with 2'- or 3'-deoxyribose in the terminal position.

The final step in the catalysis is the dissociation of the aminoacyl-tRNA from the enzyme. The dissociation constants for the tRNA (substrate) and the aminoacyl-tRNA (product) are of similar magnitudes (10^{-7} to 10^{-6} mol/liter). The enzyme kinetics show product inhibition.

What are the rates with which the elementary steps described above follow one another? Table 1 gives a summary. Rapid formation of the complex between the synthetase and the substrates is followed by a more time-consuming synthesis of the aminoacyl adenylate intermediate and then by the considerably slower transfer of the aminoacyl residue to the tRNA. This step is limiting in most systems under steady state kinetic conditions. The phenylalanine-specific system of *E. coli* is an exception, since here a rearrangement of the synthetase·phenylalanyl-tRNA complex appears to be the rate-limiting step[23].

2.4. The Problem of Product Inhibition

In an enzymatic synthesis, the problem of competitive inhibition[*] by a product X—Y arises if this product consists of fragments of the substrates X and Y and if the substrates associate with the synthetase *via* the same fragments (Fig. 3). The dissociation constant for the complex between the enzyme and the reaction product is then approximated by

$$K_{X-Y} = (1/55)\cdot K_X \cdot K_Y$$

where K_X and K_Y are the dissociation constants for the complexes between the enzyme and the substrates X and Y. The factor $^1/_{55}$ results from the choice of the thermodynamic standard condition (1 M aqueous solution).

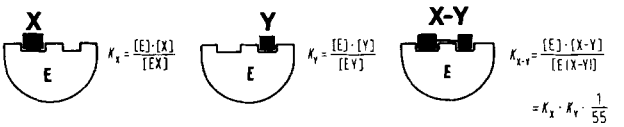

Fig. 3. Calculation of the dissociation constant K_{X-Y} for a complex between an enzyme and the ligand X—Y using the dissociation constants K_X and K_Y of the complexes with the fragments X and Y. The example given is simplified: the complexes EX and EY are held together by the same secondary bonds as the complex E(X—Y). The factor $^1/_{55}$ results from reference to standard thermodynamic conditions (1 M aqueous solution) [43].

Aminoacyl-tRNA synthetases form tight complexes with their substrates (amino acids and tRNA). According to the equation for K_{X-Y}, they should form an even tighter complex with the product (aminoacyl-tRNA) and thus be competitively inhibited at very low product concentrations (10^{-10} to 10^{-12}

[*] Competitive inhibition occurs when the inhibitor (in the present case the product) competes with the substrate for the binding site on the enzyme.

Table 1. Rate constants for the elementary steps of amino acid activation and transfer. Measurements were performed at 25°C, pH = 7 to 8, with an ionic strength of 0.05 to 0.2 mol/liter and a magnesium concentration of 0.001 to 0.01 mol/liter.

Direction	Complex formation of synthetase with			Adenylate formation [equation (c)]	Aminoacyl transfer [equation (b)]	Overall reaction under steady-state conditions
	AA	MgATP	$tRNA^{AA}$ or AA-$tRNA^{AA}$			[equations (a) + (b)]
→	[liter/(mol·s)] 10^6	[liter/(mol·s)] 10^6	[liter/(mol·s)] $(1-3)\times 10^8$	20—350	2—28	2—6
←	[s^{-1}] 15—25	[s^{-1}] 400 [17]	[s^{-1}] 5—120	30—1000	10 [23]	10 [23]

mol/liter depending on the kind of synthetase). However, the aminoacyl-tRNA has been found to have the same tendency to form a complex with the enzyme as has the (free) tRNA. The aminoacyl residue thus does not seem to contribute to the stability of the enzyme·aminoacyl-tRNA complex. The amino acid and tRNA fragments in the aminoacyl-tRNA complex cannot associate simultaneously with the amino acid and tRNA binding sites for steric and/or energetic reasons (Fig. 4). After transfer of the amino acid residue to the tRNA, the unstable complex *(2)* is only formed as an intermediate. Interaction between the synthetase and the amino acid residue is eliminated by the subsequent rearrangement *(2)→(3)*. It is interesting that this rearrangement is rate-limiting for phenylalanyl-tRNA synthetase from *E. coli*[23].

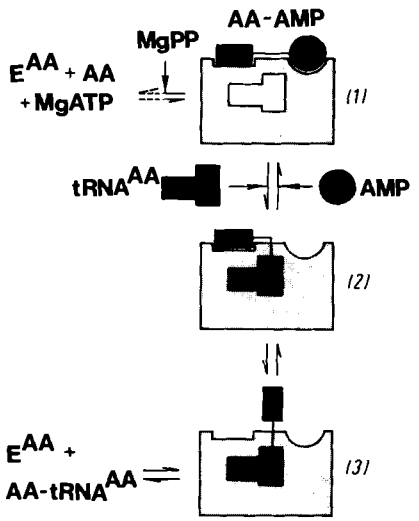

Fig. 4. Reaction scheme for the transfer of an amino acid residue from AMP to tRNA and the dissociation of the aminoacylated tRNA. The enzyme is shaded in gray. The substrates and their components are black (amino acid: rectangle, AMP: circle, $tRNA^{AA}$: T-shaped symbol). The transfer of the amino acid residue to the tRNA takes place in step *(1)→(2)*. The complex *(2)* is unstable because the amino acid and the tRNA fragments cannot complex with the synthetase at the same time for steric and/or energetic reasons. It rearranges to complex *(3)* with the dissociation of the amino acid residue from the amino acid binding site.

The energetics leading to the elimination of the interaction between the enzyme and the amino acid residue are shown in Figure 5; the free energy is schematically represented as a function of the reaction coordinate. The synthetase·amino acid·MgATP complex is utilizing free energy to establish the special geometry of the enzyme·substrate complex. This energy becomes available when the aminoacyl adenylate is synthesized because the electrostatic and/or steric arrangement is reorganized. This energy is not released but is picked up for the synthesis of the aminoacyl adenylate[9, 17, 24].

The group transfer potential[*] of the aminoacyl-AMP is 14 kcal/mol[25] and that of the aminoacyl-tRNA 7 kcal/mol[26]. On transfer of the aminoacyl residue from AMP to the tRNA 7 kcal/mol are thus liberated. This amount of free energy causes the observed destabilization of the synthetase·aminoacyl-tRNA complex by expelling the aminoacyl residue from the enzyme binding site.

[*] The group transfer potential of a compound A—B is identical with the value of the standard free energy measured on hydrolytic cleavage of A—B to A—H and B—OH under standard conditions (pH = 7.0, 25°C, ionic strength 0.1 mol/liter).

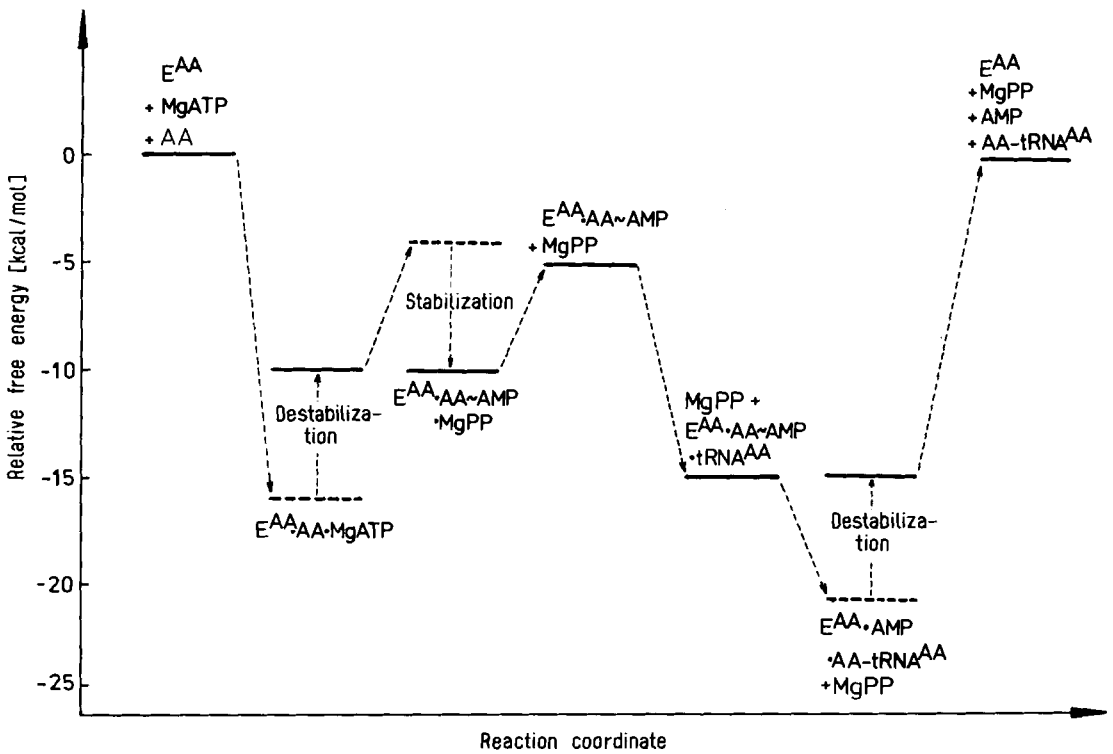

Fig. 5. Free energy of the catalytic pathway as a function of the reaction coordinate of tRNA aminoacylation. The formation of the synthetase·substrate, synthetase·intermediate and synthetase·product complexes is shown. Activated transitional complexes have been omitted. The levels denoted by dashed lines represent the hypothetical case where the secondary bonds between the synthetase, amino acid and MgATP or aminoacyl-tRNA are not used as a supply for the energy consuming orientation of the ligands in the complex. The complex between the synthetase and the substrate fragments was taken as a basis for calculating the values. The numerical values refer to the phenylalanine-specific system of *Escherichia coli* [9].

3. Transfer Ribonucleic Acids

3.1. Occurrence and Function

Transfer ribonucleic acids are components of the cytoplasm and of the cell organelles (mitochondria and chloroplasts). Like the aminoacyl-tRNA synthetases they exhibit a compartment-specific differentiation. They are the codon-specific "suppliers" of activated amino acids in ribosomal protein biosynthesis. Some species of tRNA serve as amino acid "suppliers" in the non-ribosomal synthesis of bacterial cell walls[27] and the maturation of proteins and phosphatides[28]. Transfer ribonucleic acids are involved in the regulation of the synthesis of certain enzymes[29]. A tryptophan-specific tRNA is used as a primer[*] of DNA synthesis in the presence of RNA-dependent DNA-polymerase[30]. A tRNA-like structure which can be aminoacylated is found at the 3'-end of plant virus RNA[31].

3.2. The Clover Leaf Structure

Transfer ribonucleic acids have an average molecular weight of 25000 and are composed of 73 to 93 ribonucleosides some of which are modified in the mature[**] tRNA. The nucleotide sequences of more than sixty tRNAs are known. All transfer ribonucleic acids have the same secondary structure which is called the "clover leaf" structure on account of its appearance (Fig. 6).

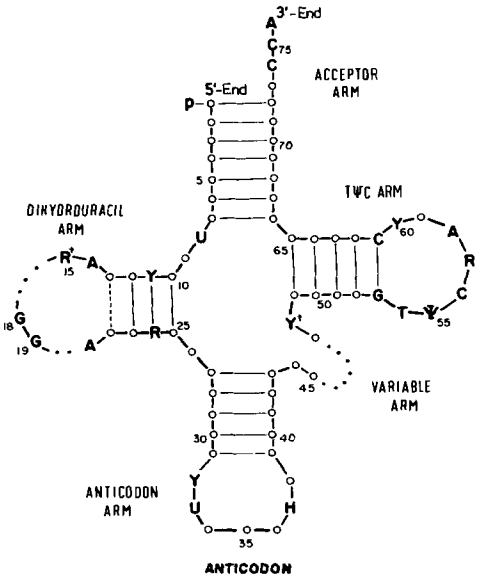

Fig. 6. Secondary structure (clover leaf structure) of transfer ribonucleic acids (not including initiator-tRNA). The bases are numbered with reference to the structure of yeast $tRNA^{Phe}$. Y signifies pyrimidine, R purine, and H hypermodified purine. The sequences denoted by dots are of variable length. The figure is taken from a review article [32].

Beginning at the 5'-terminus, all transfer ribonucleic acids have an "amino acid acceptor stem" that consists of 7 base pairs. This region is followed by the "dihydrouracil" stem with 3 or 4 base pairs, the anticodon stem with 5 base pairs, and the TΨC stem with 5 base pairs. The base pairs are held together by Watson-Crick-type hydrogen bonds[*]. There are always two nucleotides between the amino acid acceptor stem and the dihydrouracil stem and a single nucleotide between the dihydrouracil and anticodon stems. The nucleic acid forms loops at the ends of the stems. The loops can be imagined to form the leaflets of the clover leaf. The anticodon and TΨC loops are each composed of 7 nucleotides and the dihydrouracil loop of 7 to 10 nucleotides. Each stem plus loop constitutes an "arm". The variable (or extra) arm has 4 to 21 nucleotides.

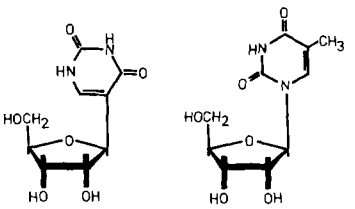

Fig. 7. The modified nucleotides pseudouridine and ribothymidine are components of all transfer ribonucleic acids with the exception of mammalian initiator-tRNA.

The modified nucleosides ribothymidine (T) and pseudouridine (Ψ) (Fig. 7) are components of all transfer ribonucleic acids apart from the initiator tRNA of mammals. The sequence G—T—Ψ—C is believed to associate with the 5S ribosomal RNA of bacterial ribosomes during the elongation phase of protein synthesis.

The anticodon consists of three variable nucleotides located in the middle of the anticodon loop. On complex formation with the ribosome it associates with the appropriate codon of the messenger RNA.

The single-stranded amino acceptor terminus has an identical nucleotide sequence, —CCA, in all transfer ribonucleic acids.

3.3. Tertiary Structure

The three-dimensional structure (tertiary structure) of the phenylalanine-specific tRNA ($tRNA^{Phe}$) of yeast is shown in Fig. 8. The diagram is the result of X-ray diffraction (2.5, 3, and 4 Å resolutions) and X-ray small-angle scattering analysis as described in review articles[32,33].

The tertiary structure has the following characteristics: 1) $tRNA^{Phe}$ is L-shaped; 2) The stems are composed of double helices; 3) The amino acid acceptor stem and the TΨC stem are stacked upon each other making them appear to form a single double helix. The same is found for the dihydrouracil stem/anticodon stem; 4) The CCA terminus and the anticodon are at the ends of the "L"; 5) The dehydrouracil and TΨC loops form the corner of the "L".

The tertiary structure is mainly the result of interactions between the dihydrouracil arm, the TΨC arm, and the variable arm (*i.e.* those arms in the corner of the "L"). The interactions

[*] A primer is a short nucleic acid strand which is associated with the longer template strand. The synthesis of the daughter strand complementary to the template joins on at the 3'-end of the primer.

[**] tRNA is formed by "maturation" of precursors which are synthesized by gene transcription. During maturation, the precursors are cut to the sizes of tRNA by nucleases and are chemically modified at some of the bases by specific enzymes.

[*] Watson-Crick hydrogen bonds are those between the bases guanine/cytosine and adenine/thymine in the double helix of DNA and between the bases guanine/cytosine and adenine/uracil in the double helix of RNA.

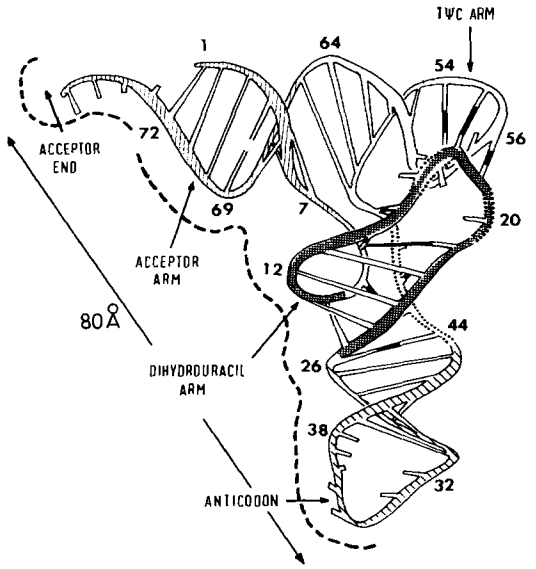

Fig. 8. Schematic representation of the three-dimensional structure (tertiary structure) of yeast $tRNA^{Phe}$. The ribose-phosphate strand is shown by a continuous band. The hydrogen bonds are represented by bars. The arms of the tRNA are denoted by different hatchings. The sequences marked by dotted lines differ in length depending on the type of tRNA. The dashed line shows the surface of the molecule that is in contact with the aminoacyl-tRNA synthetase. The figure is taken from a review article [50].

include: 1) Hydrogen bonds between bases, between bases and ribose residues and between different ribose residues; 2) Electrostatic repulsion between phosphate groups; 3) Coordination with Mg^{2+}. The electrostatic repulsion destabilizes the tertiary structure. Electrolytes such as NaCl improve the stability by shielding of the negative charges[34,35]. Under physiological conditions the tertiary structure is probably modulated on formation of the complexes with the reaction partners (aminoacyl-tRNA synthetase, ribosomal elongation factor EFTu or the ribosome).

Studies on other transfer ribonucleic acids indicate that they also possess the properties described above. Findings for the aqueous solution agree with those for the crystal structure.

4. The Codon-Specific Recognition of Amino Acids and Transfer Ribonucleic Acids by the Aminoacyl-tRNA Synthetases

During the aminoacylation of tRNA, every aminoacyl-tRNA synthetase must select the only amino acid from the twenty kinds present in the cell that matches the cognate tRNA. High precision is necessary as the ligation between the amino acid and the tRNA is not checked again during the later stages of protein synthesis. A mistake made during amino acid activation may thus result in a defective protein molecule.

Whether the amino acid and the tRNA that have been selected by the synthetase are the correct ones is checked and verified several times during the synthesis of the aminoacyl-tRNA (see Fig. 9), namely on formation of the enzyme·amino acid complex, at the level of the enzyme·aminoacyl adenylate complex, and by hydrolytic "proofreading" after formation of the enzyme·aminoacyl-tRNA complex.

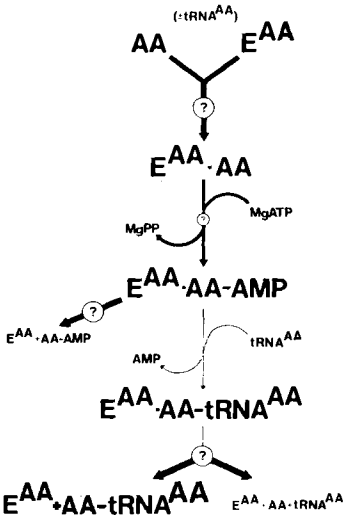

Fig. 9. Verification of matching anticodon and amino acid. The steps which represent a barrier for the codon-mismatching amino acids are indicated by question marks and their importance is represented by the width of the arrows. The discriminatory reaction steps are, from top to bottom: formation of the enzyme·amino acid complex, synthesis of the aminoacyl-adenylate, stability of the synthetase·aminoacyl adenylate complex and corrective hydrolysis of the misacylated tRNA.

4.1. Recognition of the Amino Acid

The most efficient step in "sieving" for the cognate amino acid is the formation of the synthetase·amino acid complex. According to the structural elements of an amino acid, the aminoacyl-tRNA synthetases have binding regions for the primary ammonium group, for the carboxylate group, and for the side chain[19,36]. Apart from a few exceptions[37], recognition is stereospecific with respect to the configurations at C-2 and C-3.

The interaction between the zwitterionic region of the amino acid and the synthetase is electrostatic[19]. Complex formation with the side chain of the amino acid is, depending on the nature of the side chain, a result of polar or hydrophobic interactions. Hydrophobic mechanisms are employed particularly for the recognition of aliphatic amino acids[17,38,39]. In the case of the isoleucine-specific system it has been shown that the "correct" amino acid has the highest association entropy[40].

Discrimination between related amino acids such as L-tyrosine and L-phenylalanine or L-isoleucine and L-valine depends on the interaction between the aminoacyl-tRNA synthetases and the characteristic components of the side chains such as the OH group in L-tyrosine and the additional CH_3 group in L-isoleucine. The degree of discrimination is extremely high; L-tyrosine is preferred over L-phenylalanine by a factor of 2000 and L-isoleucine over L-valine by a factor of 100. Such differences in affinity cannot be accounted for by simple models involving solely hydrogen bond formation or interactions between hydrophobic moieties[17,18]. As in the isoleucine-specific system[17], conformational changes in the enzyme structure that could lead to a solvation of newly exposed residues might be of importance.

Binding studies with substrate fragments have shown that the triphosphate moiety of MgATP and the zwitterionic region of the amino acid interact with one another in the ternary

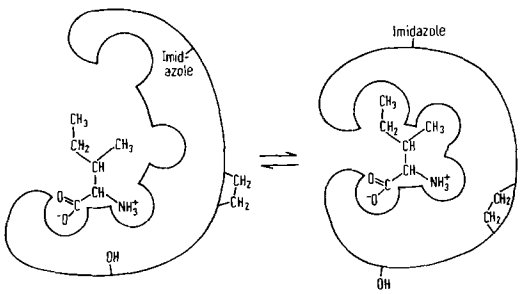

Fig. 10. Schematic representation of a structural change that could increase the tendency for forming the enzyme·amino acid complex. The binding of the substrate L-isoleucine to the synthetase is coupled with a conformational change. This causes an alteration in the hydration of the synthetase, which is here arbitrarily represented by exposure of an imidazole residue and of a hydroxy group, together with the transfer of an ethylene group into the interior of the enzyme structure.

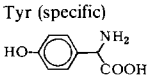
enzyme·substrate complex[19,24]. The electrostatic attraction between the α-ammonium group and the triphosphate residue stabilizes the complex and the electrostatic repulsion between the carboxylate group and the triphosphate residue destabilizes it. The sizes of these opposing interactions are such that they cancel each other out and both the amino acid and the MgATP apparently associate with the synthetase independently of one another[19][*].



4.2. Thermodynamic Control of Formation of the Enzyme·Aminoacyl Adenylate Complex

Table 2 shows that the dissociation constant

$$K_{Diss} = \frac{[E^{AA}][AA]}{[E^{AA} \cdot AA]}$$

for the enzyme-substrate complex formed in the first step of the amino acid activation is, in the case of the amino acid pair isoleucine/valine, two orders of magnitude smaller for the codon-specific amino acid (isoleucine) than for the nonspecific amino acid. The Michaelis-Menten constants for the ATP-[^{32}P]pyrophosphate exchange[**] of other pairs are compared in Table 2; under the experimental conditions used[41], the values are the same as those of the Michaelis-Menten constants K_m^{AA} for amino acid activation and approximately the same as the dissociation constants K_{Diss}. In the case of the amino acid pairs tyrosine/phenylalanine and valine/threonine it can be seen that the synthetase·amino acid complex of the codon-specific amino acid is thermodynamically favored by several orders of magnitude.

Table 2. Dissociation constants, Michaelis-Menten constants, and relative rate constants for the amino acid activation of pairs of structurally similar amino acids.

Amino acid	K_{Diss} [μmol/liter]	ATP-[^{32}P]pyrophosphate exchange K_m [μmol/liter]	k (relative)
Ile (specific)	4.5 [64]	4—6 [41, 42, 66]	1.0
	5.8 [17]	42, 66] 5 [67]	
Val	570 [64]	800 [67]	0.77 [67]
			
Tyr (specific)	10 [65]	1.8 [65]	1.0
		25 [37]	
Phe		50000 [65]	0.4 [65]
			
Val (specific)	66 [66]	140 [39]	1.0
		30 [38]	
Thr		17000 [39] 7000 [38]	0.38 [39] 0.42 [38]
			

This situation is further improved by the amino acid concentrations which exist in the cell: if the specific amino acid competes with a nonspecific amino acid for the synthetase then the operational dissociation constant $K^u_{Diss(app)}$ of the complex with the nonspecific amino acid is given by

$$K^u_{Diss(app)} = K^u_{Diss}\left\{1 + \frac{[AA]}{K^{AA}_{Diss}}\right\}$$

i.e. the chance of the nonspecific acid forming the "wrong" synthetase·amino acid complex is lower the higher the concentration [AA] of the "correct" amino acid.

The specificity is further improved by the fact that, during the catalytic aminoacylation of the tRNA, the "correct" amino acid binds very tightly with the synthetase in the form of its aminoacyl adenylate complex and thus again reduces the chance of an association between the enzyme and a "wrong" amino acid. Any enzyme·aminoacyl adenylate complex containing a "wrong" amino acid is removed by hydrolysis[44] or by esterification with the tRNA and subsequent hydrolytic "proofreading"[38] (see Section 4.4).

4.3. Recognition of the Transfer Ribonucleic Acid

The interactions between the enzyme and the tRNA are mainly a result of the formation of hydrogen bonds between the amino acid side chains of the synthetase (Asn, Gln, and Arg) and the purine bases of the tRNA[45]. "Stacking" interactions between the bases and the aromatic side chains of the amino acids are less important. It is not clear whether Mg^{2+} ions stabilize the enzyme·tRNA complex by interacting between the surfaces of the synthetase and the tRNA which

[*] The electrostatic repulsion between the triphosphate group and the carboxylate group, and the strain-inducing interaction between the triphosphate moiety and the MgATP binding site are the reason for the synthetase·amino acid·MgATP complex having a relatively high energy content (see Fig. 5). The "internal strain" of the ternary complex is released by the reaction producing the enzyme·aminoacyl adenylate complex.

[**] By following the ATP-[^{32}P]pyrophosphate exchange, the reverse of amino acid activation [equation (a)] (*i.e.* reaction of the synthetase·aminoacyl adenylate complex with [^{32}P]pyrophosphate) is measured. The system is in chemical equilibrium. At sufficiently high pyrophosphate concentrations, the rate of synthesis of the aminoacyl adenylate also determines the rate of [^{32}P]-labeling of the ATP. The ATP-[^{32}P]pyrophosphate exchange is thus an indirect measurement of the formation of the synthetase·aminoacyl adenylate complex.

come into contact with one another[46-48] or whether Mg^{2+} selectively stabilizes the tertiary structures of the enzyme and tRNA which form particularly strong complexes with one another[9,15,49].

The synthetase and transfer ribonucleic acid in the enzyme·tRNA complex come into contact along the angled side of the L-shaped tRNA molecule (Fig. 8)[50], probably along a cleft on the protein surface. The binding region of the tRNA is formed by components of the acceptor stem and the dihydrouracil stem and in some cases by the anticodon. The TΨC arm and the variable arm do not touch the synthetase. Most of the variable bases are found in the regions of the contact sites.

The acceptor end —CCA is thought to play a key role in recognition of the tRNA by the synthetase, the mechanism of which is unknown[51]. This region probably changes its conformation on aminoacylation[52].

The formation of the synthetase·tRNA complex in some systems is coupled with the formation of the enzyme·amino acid and/or enzyme·MgATP complex. Depending on the nature of the synthetase, the coupling exhibits positive[53] or negative cooperativity[9,10,54]. In some cases when the enzyme has a dimeric structure, coupling appears only if both of the active centers are occupied by the substrates.

The association resulting in the synthetase·tRNA complex proceeds in two stages[49,55]. Initially, a relatively unspecific diffusion-controlled complex is formed which, on developing probably specific secondary bonds, rearranges to give the stable enzyme·substrate complex. In the glutamine- and phenylalanine-specific systems, formation of the enzyme·tRNA complex is accompanied by a rearrangement of the tRNA molecule[56].

Discrimination between the "correct" and the "wrong" transfer ribonucleic acids depends much more on kinetic control than on the thermodynamic properties of the enzyme·tRNA complex[57]; the "correct" amino acid is 10^3 to 10^4 times more rapidly aminoacylated than the "wrong" one.

4.4. Hydrolysis of Misacylated tRNA

In spite of the "precautions" described above, transfer ribonucleic acids are occasionally acylated with a "wrong" amino acid. This misacylation is more frequent the greater the similarity between the amino acids.

A wrongly loaded aminoacyl-tRNA is, however, hydrolyzed by the tRNA-specific synthetase. Examples of this are Val-$tRNA^{Ile}$[38,58,59], Thr-$tRNA^{Val}$[38,60], and Ile-$tRNA^{Phe}$[61]. Correction takes place after formation of the enzyme·aminoacyl-tRNA complex and proceeds rapidly as compared with the esterification between the "correct" amino acid and the tRNA[59,60]. A "wrong" newly synthesized ester is presumably cleaved prior to dissociation of the enzyme·aminoacyl·tRNA complex.

The efficiency of proofreading parallels the frequency of mistakes a synthetase makes during the activation of the amino acids. The "correctly" aminoacylated tRNA is also hydrolyzed but much more slowly than the misacylated tRNA. It is not known how the aminoacyl-tRNA synthetase recognizes the amino acid residue of the aminoacyl-tRNA; the amino acid binding site of the synthetase is probably not involved. Misactivated amino acids always have a smaller side chain than the "correct" ones. It is possible that the smaller side chain fits into a hydrolytically active site whereas this is not possible in the case of the "correct" amino acid[44].

The enzymatic hydrolysis of aminoacyl-tRNA is activated by Mg^{2+}. Its dependence does not correspond to the Mg^{2+} dependence of aminoacylation[62]. Sulfhydryl reagents inhibit the hydrolysis in a manner that is different from the inhibition of tRNA aminoacylation[62]. The synthetase probably has a second active center for hydrolysis. The non-esterified hydroxy group in the 2'- or 3'-position of the adenosine residue at the acceptor end of the tRNA appears to be catalytically essential[59,63].

5. Summary and Conclusions

Aminoacyl-tRNA synthetases catalyze the codon-specific esterification of amino acids and transfer ribonucleic acids. The corresponding reactants find each other by normal enzymatic mechanisms, namely as a result of the tightness of the enzyme·substrate complex and of a maximal reaction rate. A feature which is unusual is a correction step catalyzed by the synthetase in which the "wrongly" formed esters are hydrolyzed. This mechanism comes into play if the usual methods for distinguishing between the structurally similar amino acids are not adequate.

The specificity is further improved by the fact that, under physiological conditions, the "correct" amino acid occupies the synthetase in the form of its aminoacyl adenylate and thus minimizes the chance of an association between the enzyme and a "wrong" amino acid. Furthermore, the intracellular concentrations are such as to saturate the synthetases with the "correct" amino acids and tRNAs.

The codon-specific amino acids and transfer ribonucleic acids have high affinities for "their" enzymes. This would, however, result in a catalytically unsuitable saturation of the synthetases with aminoacyl-tRNA if the product did not easily dissociate from the complex. The driving force for the destabilization of the complex is provided at the beginning of the reaction as a result of the fact that the amino acid and ATP occupy energy-rich positions. On transfer of the amino acid residue to the tRNA, the excess energy causes the liberation of the amino acid residue from the active center and thus facilitates dissociation of the synthetase·aminoacyl-tRNA complex.

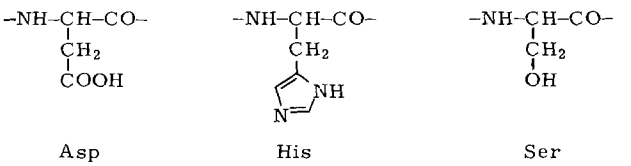
Polymeric Catalysts

By Georg Manecke and Winfried Storck[*]

The present-day position in the field of polymeric catalysts is outlined. The following selected groups of polymeric catalysts are discussed: synthetic hydrolases, immobilized enzymes, phase-transfer catalysts, nucleophilically active bases, polymers with conjugated π-systems, photosensitizers, polymers as carriers for catalytically active metals or ions, and immobilized homogeneous catalysts. Polymeric catalysts have the following valuable properties: insoluble polymeric catalysts are readily separable from reaction solutions and can often be re-used without loss of activity; a hydrophobic matrix protects the organometallic active center from deactivation by oxygen and water; by fixation of finely divided metals on an ion exchanger, multistage reactions may be effected successively in one reactor. Polymeric carriers may influence the catalytic properties; for example, in the case of immobilized enzymes on polyionic carriers the pH of the activity maximum may be shifted.

1. Introduction

Attempts have long been made to use polymers as catalysts for chemical reactions, following the prototype of enzymes, the natural polymeric catalysts. Enzymes are characterized by high specificity and high catalytic activity, properties that have also been the goal with synthetic polymeric catalysts. The first advances in this direction were made above all with hydrolytically active polymers: it was observed very early that polymeric acids and polymeric bases, such as occur in ion-exchange resins, can catalyze hydrolytic reactions.



Since then both soluble and insoluble polymeric catalysts have been prepared. The insoluble types have certain practical advantages: they can be separated readily from the substrate and product solutions, they can be used in continuous processes, and they can be simply regenerated and re-used. Valuable metals contained in their active centers can also be easily recovered.

This rapidly expanding field of research has been described in many reviews, often specialized in certain directions. Only a few of these can be cited here[1a–13c], and these without attempting their evaluation.

2. Hydrolytically Active Catalysts

For the sake of a better understanding of the field of synthetic polymeric catalysts we shall first briefly discuss chymotrypsin, probably one of the best investigated enzymes. In proteins and peptides it catalyzes especially the hydrolysis of amide bonds R—CO—NH—R′ whose carbonyl group is derived from an aromatic L-amino acid. X-Ray structure analysis shows that the α-chymotrypsin molecule is ellipsoidal ($51 \times 40 \times 40$ Å^3) and that the active center forms a hydrophobic concavity [(10...12) × (5.5...6.3) × (3.5...4.5) Å^3[14]]. The enzyme-substrate complex appears to be stabilized mainly by an interaction between this hydrophobic reactive grouping and the hydrophobic substrate.

According to *Blow et al.*[15], the functional groups in the side chains of aspartic acid, histidine, and serine in the reactive grouping of α-chymotrypsin are linked by a series of hydrogen bonds.

This association of functional groups is called a "charge relay system". Figure 1 shows the proposed course of amide hydrolysis by chymotrypsin. By means of the "charge relay system" the electrons of the aspartic acid residue ionized at pH 8, lying in the interior of the enzyme, are transferred by way of hydrogen bonds to the serine residue situated on the surface, the nucleophilicity of the latter residue being thus greatly enhanced (Fig. 1a). The hydrolysis itself consists of two partial processes:

In the acylation step the ionized hydroxyl group of the serine attacks the amide-carbonyl group nucleophilically. The enzyme is then acylated and at the same time the amide-nitrogen is protonated. The resulting amine is liberated and the "charge relay system" is broken (Fig. 1b).

In the deacylation step the hydrogen bond system is re-established by the introduction of a water molecule. Under the influence of the ionized aspartic acid the enzyme is deacylated, the carbonyl group is hydroxylated, and the acid is liberated (Fig. 1c).

Since amides and esters were known to be hydrolyzed in the presence of mineral acids, the question whether proteins can be hydrolyzed by ion-exchange resins was already investigated as long ago as in the 1950's. Such reactions were indeed successful[16], and in fact the strongly acidic ion exchangers containing sulfonic acid groups proved to be more active than HCl[17–20]: dipeptides are hydrolyzed about 100 times faster by ion exchangers than by HCl. This can be attributed to bonding of the protonated amino group to the polyanion and to the high proton concentration in the exchanger particles.

A further increase of the catalytic efficiency in ester hydrolysis by cross-linked acids can be achieved by replacing some

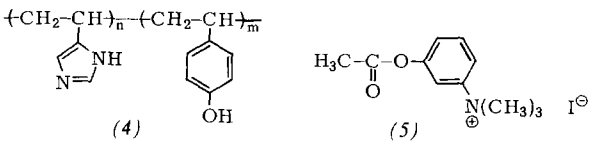
of the protons of the ion-exchanger by cetyltrimethylammonium ions. A more favorable distribution of the hydrophobic substrate follows from the increased hydrophobicity of the polymer[21]. On partial loading with Ag^+ ions the rate of the hydrolysis of allyl acetate can be increased over that of propyl acetate. Apparently the Ag^+ ions form complexes with the allyl group of the ester and thus increase the latter's concentration in the exchanger[22].

The many investigations in this field show that polyacids or polyanions catalyze the hydrolysis of esters, amides, and ethers[23], and indeed often more strongly than mineral acids. The catalytic activity is favored by the higher concentration of protons in the exchanger than in the solution, though this effect is slight. Nevertheless, if the substrate concentration in the polymeric anions is increased by electrostatic and hydrophobic forces of attraction, the catalytic efficiency also increases. Similar results have been reported for hydrolysis by polycations[24–27].

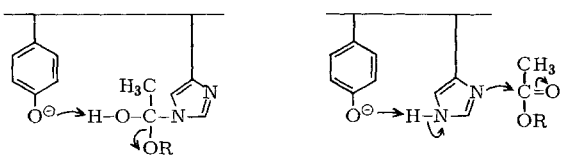
As shown above, the histidine residue in particular is concerned in the catalytic action of hydrolases. Imidazole and its derivatives have therefore been especially studied as catalysts for the hydrolysis of esters. Since the weakly basic imidazole group is unable to remove the much more basic alkoxide ion in a simple ester, most of the investigations were concerned with the catalytic hydrolysis of activated esters such as *p*-nitrophenyl acetate *(1)*.

Overberger[28] was the pioneer in the field of catalytic activity of vinyl polymers containing imidazole groups. His research group synthesized polymers of 4(5)-vinylimidazole and 5(6)-vinylbenzimidazole.



(1) *(2)* PVIm *(3)* PVBIm

The catalytic action of poly[4(5)-vinylimidazole] (PVIm) *(2)* on *(1)* is pH-dependent. Depending on the pH of the medium, the imidazole group may be present in cationic, neutral, or anionic form. In imidazole-catalyzed solvolysis the rate constant k_{Im} depends linearly on the proportion of neutral imidazole. However, the polymer-bound imidazole

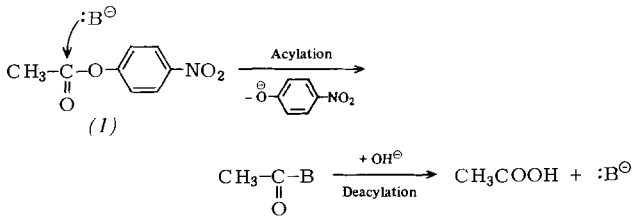


shows an exponential increase in activity with increasing proportion of neutral imidazole, a result explained as due to the cooperative action of two imidazole units[29]. The increased catalytic activity of polymers can also be attributed to attraction of the substrate by secondary forces of attraction. A marked increase in the reaction rate was observed on using long-chain substrates, and this was attributed to increased hydrophobic interaction[30].

The catalytic activity of the imidazole polymers can be considerably influenced by copolymerization. The copolymer *(4)* of 4(5)-imidazole and 4-vinylphenol can be adduced here as example[31]. At high pH a high catalytic activity is found for *(1)*, as also for (3-acetoxyphenyl)trimethylammonium iodide *(5)*. At pH 9.1 the solvolysis of *(5)* in the presence of the polymer *(4)* is 63 times as fast as in the presence of imidazole.

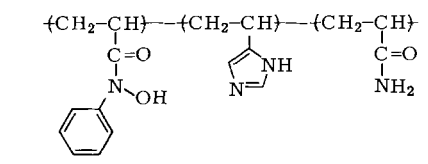
(4) *(5)*

Here there may occur an electrostatic attraction between the cationic substrate *(5)* and the catalyst *(4)*, but the increase in the reaction rate may also be due to a bifunctional attack by the imidazole and the phenolate ion. Imidazole can attack the substrate nucleophilically, while the phenolate ion acts as base on the intermediate (a). The other possibility is a support of the nucleophilic attack by neutral imidazole through the phenolate ion (b).



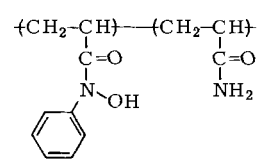
(a) (b)

It could be shown that electrostatic and hydrophobic interactions with the catalytically active grouping caused an

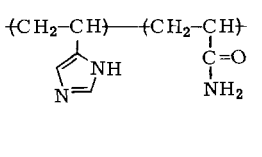


increase in the activity. The chemical structure and the conformation of the polymeric catalyst determine the nature and structure of the catalytic center.

Vinyl polymers with nucleophilic groups other than imidazole can also catalyze hydrolytic reactions; examples are the polymeric hydroxamic acids[32].

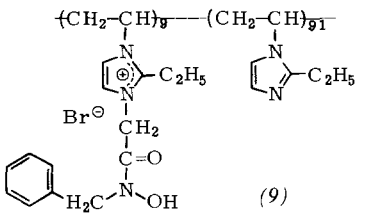


Particular interest attaches to the catalysts prepared by *Kunitake* and *Okahata*[33–35], which contain two nucleophilic groups, for example a hydroxamic acid and imidazole. In the hydrolysis of a *p*-nitrophenyl ester with nucleophilic catalysis by a base an acylated intermediate product is formed, which is deacylated in a second step.



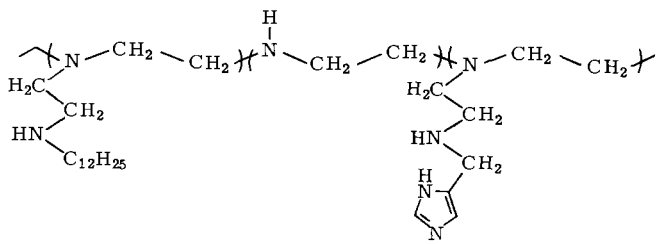
The catalysis is efficient if both the acylation and the deacylation steps occur rapidly. This is difficult to realize if the catalyst contains only one kind of functional group, because a good nucleophile does not usually release the electrophilic partner so easily. An efficient catalyst can be made by combining two functional groups with complementary action: a good nucleophilic group and a second functional group that aids deacylation of the intermediate product. The hydroxamate ion has a high nucleophilicity; deacylation of the acylhydroxamate is a very slow process. To accelerate it, *Kunitake et al.* introduced the imidazole group into the polymer containing the hydroxamic acid. Acrylamide was polymerized in as a hydrophilic component. The polymers *(6)*, *(7)*, and *(8)* were investigated (Table 1).

(6) Poly(PHS-VIm-AAm)



(7) Poly(PHS-AAm)

(8) Poly(VIm-AAm)



The catalytic activity ($k_{turnover}$) of the bifunctional polymer *(6)* is much greater than that of the monofunctional polymers *(7)* and *(8)*, which contain only the hydroxamic or only the imidazole group. The high catalytic activity of poly(PHA-VIm-AAm) *(6)* is due to the favorable combination of the rate constants k_a and k_d for acylation and deacylation, respectively. k_a is very large for the monofunctional catalyst Poly(PHA-AAm) *(7)*, whereas $k_{turnover}$ is small because of the extremely low k_d. The deacylation rate is increased by a factor of 10^3 by the additional introduction of the imidazole group. The imidazole group can facilitate deacylation in two ways: in general base catalysis it assists attack by water on the intermediate acylhydroxamate; in nucleophilic catalysis transfer of the acyl group of the hydroxamate to the imidazole group results, this reaction being followed by hydrolysis of the acylated imidazole group. The base catalysis appears to predominate.

The nucleophilicity of the hydroxamate ion can be increased by a hydrophobic environment, as has been shown by investigations with cationic polysoaps[37]. Also, hydroxamates that are bound to a cationic poly(vinylimidazole) possess an excellent catalytic activity[38]. An example is the polymer *(9)*.

(9)

As further polymers that catalyze hydrolysis, mention may be made of the poly(ethylenimine) derivatives. Distinct catalytic activity is found in poly(ethylenimine), which is produced by ring-opening polymerization of ethylenimine (aziridine)

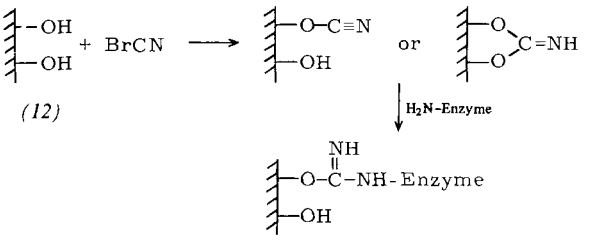
and has a strongly branched structure with primary amino groups[39]. *Klotz et al.*[40–42] were able to demonstrate that solvolysis of *p*-nitrophenyl esters is considerably accelerated in the presence of lauroyl-substituted poly(ethylenimines). According to *Klotz*, a very high catalytic activity is shown by a poly(ethylenimine) of type *(10)*, whose primary amino groups are completely alkylated by (chloromethyl)imidazole and dodecyl iodide[43–44b]. This polymer has a catalytic activity toward 2-hydroxy-5-nitrophenyl sulfate (4-nitrocatechol sulfate) *(11)* that is 100 times that of type IIA arylsulfatase.

Klotz called this very highly active polymeric catalyst "synzyme" (synthetic enzyme) and explained the high catalytic efficiency as due to the highly branched, compact structure.

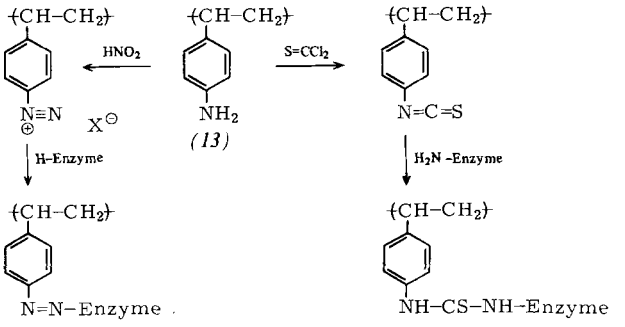
Investigations by *Kabanov* and his colleagues[45a,45b] showed that alkyl-substituted poly(ethylenimines) have maximal activity toward *p*-nitrophenyl esters when the catalyst and the substrate contain long alkyl groups.

Since the fully synthetic polymeric catalysts in most cases fail to attain the specificity and the activity of naturally occurring catalysts, *i.e.* enzymes, attempts were made at an early date to prepare semisynthetic catalysts—immobilized enzymes—by combination of an enzyme with a polymeric carrier.



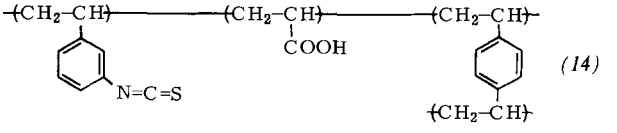
3. Immobilized Enzymes

By treating reactive, insoluble, polymeric carriers with enzymes it proved possible to prepare covalently bonded, insoluble, and immobilized enzymes that retained their biological activity[3,4,46,47]. These immobilized enzymes could be used in studies of metabolic processes. However, they also provide new and interesting possibilities for preparative reactions and for industrial processes. Their especial advantages are their ready separability from the reaction solutions—without this the products are impure—and the possibility of including them in continuous processes. Since they can be re-used, many enzymatic reactions that were previously much too expensive have now become of economic interest.



The enzymes can also be immobilized by inclusion in cross-linked gels and by microencapsulation, but immobilization by covalent bonding is for our purposes the most important method[5].

For this purpose insoluble polymers that can swell to a limited extent in water and whose reactive groups can react with the reactive groups of the enzyme are treated with the enzymes under mild reaction conditions. If the bonding does not occur at the biologically active center of the enzyme, the latter's catalytic activity is retained, although usually to a reduced extent.



The reactive carriers can be prepared by two methods. The first is the introduction of reactive groups into already known natural or synthetic polymers. For example, cellulose or Sephadex *(12)* is activated by the cyanogen bromide method and then treated with enzymes.

Poly(aminostyrene) *(13)* can be converted into a reactive polymer by diazotization or treatment with thiophosgene. The two fully synthetic polymers also make it possible to immobilize enzymes with retention of their biological activity.

The other principal method of preparing reactive carriers is copolymerization of vinylated compounds that already carry reactive groups, generally with a hydrophilic comonomer and a cross-linking agent. The copolymer *(14)* is presented below as an example.

Many other reactive carrier polymers have been developed. It is now known that it is impossible to prepare a single, generally useful, polymeric reactive carrier. The carrier and the immobilization conditions must be optimized for each enzyme and for each application. Factors other than just the composition of the carrier and the nature of the reactive groups are also responsible for the immobilization reaction and for the properties of the immobilized enzyme. The size of the carrier particles and their specific surface area influence the amount of enzyme bound; in this connection spongy polymers have proved particularly useful. The swelling power of the carrier is also important for the immobilization reaction and for the properties of the immobilized enzyme. The number of reactive groups on the carrier influences the amount of immobilized enzyme. However, there is a limit to the bonding of the enzyme molecules; it is reached when a monomolecular layer has been formed on the accessible inner and outer surfaces of the carrier. If the carrier contains many reactive groups, then the multiple bonding of the enzyme markedly reduces

its catalytic activity. In polyionic carriers the ability to swell is pH-dependent; this also causes the bonding of the enzyme to be pH-dependent. Immobilized enzymes on polyionic carriers generally show a pH shift of their activity maxima; enrichment in the product also often leads to these pH shifts.

In the case of hindered diffusion of the substrate or product in the immobilized enzyme, apparent Michaelis-Menten constants $K_{m(app)}$ are found that are higher than the K_m values of the native enzyme in solution. If, however, the substrate concentration in the immobilized enzyme exceeds that in the external solution, *e.g.* for a polyanionic carrier and a cationic substrate, then $K_{m(app)}$ may be reduced[3].

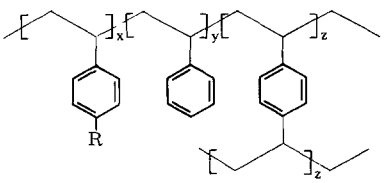
In some cases immobilized enzymes are more stable to heat than are the native enzymes[48,49]. In the proteases immobilization prevents autodigestion. The activity of some immobilized enzymes does not decrease even on prolonged storage and repeated use[50,51].

Immobilized enzymes offer interesting possibilities for industrial application and for preparative work. Isomerization of glucose to fructose is nowadays probably the most successful industrial process that is effected by immobilized enzymes. It is said that two million tons of isomerized glucose are prepared annually in the United States alone[52,53].

Immobilized lactase is used to cleave lactose to glucose and galactose, and the hydrolyzed lactose finds use as a sweetener for milk products[54].

The hydrolysis of proteins is of special interest to the food industry, as it often improves the taste, solubility, and digestibility of albuminous substances. Thus, casein or soya can be hydrolyzed into free amino acids or into soluble proteins, respectively[55,56]. Fruit juices and wine can be clarified by immobilized pectinase[57]. Large quantities of synthetic DL-amino acids are manufactured; since biological systems utilize only the L-form, it is necessary to separate the racemates. Japanese scientists were the first to separate DL-amino acid mixtures by means of immobilized L-amino acid acylases in a continuous process[58].

As a preliminary step toward semisynthetic penicillin, 6-aminopenicillanic acid is prepared industrially by means of immobilized penicillin amidase[59].



It has further been possible to immobilize complete cells or bacteria that contain suitable enzymes; these retain their activity even on immobilization by inclusion in polymer gels. This process is appreciably cheaper than use of isolated enzymes[60,61]. Thus, fumaric acid has been converted into L-aspartic acid by immobilized cells of *Escherichia coli*. Moreover, several cooperating enzymes may be immobilized in the same matrix[62]. Such immobilized multienzyme systems have much greater overall reaction rates than the corresponding enzymes in a mixture in solution[47], owing to an enrichment of the product of the first enzyme reaction, this being effected in the immediate vicinity of the second immobilized enzyme.

Attempts have also been made to make use of immobilized enzymes in medicine. Encapsulated urease has been used to reduce the blood urea level[63], and L-asparaginase to suppress the growth of L-asparagine-dependent tumors[63]. Immobilized enzymes are also used for analytical purposes[64,65].

Research in the field of immobilized enzymes is in a period of rapid growth, and only a fraction of the results can be mentioned here. Nevertheless, the industrial technology of immobilized enzymes is still in its infancy; polymer chemists have an important part to play in this development, because for each specialized application a tailor-made carrier and an optimized immobilization method are required.

4. Polymeric Phase-transfer Catalysts and Nucleophilically Active Polymers

Systems with onium groups attached to long aliphatic chains can catalyze phase-transfer reactions (catalysis in micelles [66a,66b]). As a result of the action of these catalysts, anions previously added in a high concentration to an aqueous phase are transferred into the organic phase, were they then undergo a nucleophilic exchange reaction with the organic substrate. Loss of the difficultly recoverable, surface-active catalysts can be avoided by anchoring them to polymers. *Brown* and *Jenkins*[67] have prepared polystyrene derivatives of types *(15)* and *(16)*. For nucleophilic displacement of bromide in *n*-octyl bromide by cyanide, the resins *(15)* and *(16)* have the same efficiency as the conventional phase-transfer catalyst tetra-

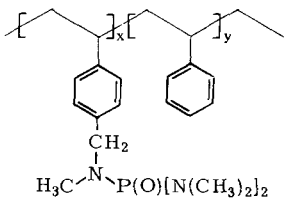
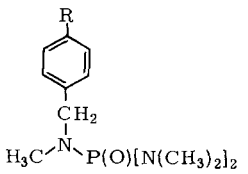
butylammonium bromide. According to *Regen*[68,69a], the length of the alkyl chains does not have any great influence on the reaction rate, whereas the latter is drastically affected by the extent of substitution by groups R: if more than 20% of the phenyl groups are substituted, the rate falls to 1/200th of the value found for 10% substitution. *Regen* ascribes this to the fact that slightly substituted polymers swell more strongly in organic solvents, whereas the more heavily substituted polymers have a considerable affinity for water and thus transfer the anions less well into the organic phase. The technique of phase-transfer catalysis with polymeric onium compounds has also been successfully applied to halogen exchange between activated and non-activated halides, to addition of dichlorocarbene to double bonds with the formation of substituted cyclopropanes[69b] and to *C*-alkylation of nitriles[69c]. Optically active polymeric ammonium compounds lead to chiral products when they are used as catalysts in carbene addition reactions[70a,70b].

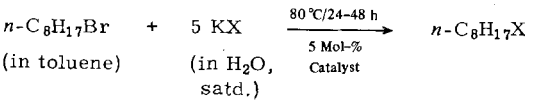


Particular interest attaches to the observation, made by *Brown et al.*[67], that the polymers *(15)* and *(16)* selectively

catalyze *O*-benzylation rather than *C*-alkylation of sodium 2-naphtholate *(17)*: a selectivity of 90% was observed when a molar ratio >0.6:1 of polymer-bound trimethylammonium groups to naphtholate is used.

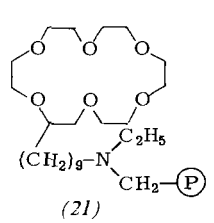


(17)

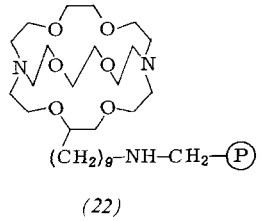


Replacement of the ammonium by a phosphonium group leads to catalysts distinguished by higher thermal and chemical stability[71]. Recently a Japanese group of chemists[72] described the use of polymers of type *(18)* with phosphoramide groups as phase-transfer catalysts for the nucleophilic displacement of bromide by iodide or by acetate. The non-crosslinked polymer was more active than the model compounds of low molecular weight *(19)* and *(20)*; this was ascribed to a cooperative effect of neighboring groups in the polymer during cation formation.

(18), x = 9,5...44
x + y = 100



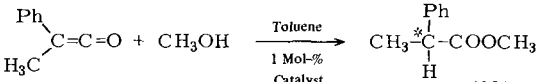
(19), R = H
(20), R = CH=CH2



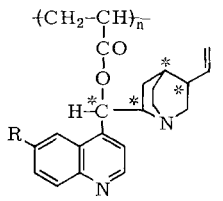
X = I, CH_3COO

Polymer-bound crown ethers, cryptates, and channel compounds can also be counted among the polymeric phase-transfer catalysts. They catalyze certain reactions on the basis of selective complex formation. *Montanari et al.*[71] studied the nucleophilic replacement of bromine in *n*-octyl bromide by iodide or cyanide in the presence of the oxygen heterocycle [18]-crown-6 *(21)* or the cryptand[222] *(22)*, in each case

(21)



(22)



anchored to polystyrene cross-linked with 2% of divinylbenzene. With substitution of ≥2.5 mol-% and the use of 1 mol-% of catalyst, the yields amounted to 95%; these are better than the yields obtained with polymeric onium compounds. The catalytic activity is due to complexing of the cations and the resulting increased nucleophilicity of the anions. The inclusion of a substrate in a channel enables orientation and thus a selective attack: an *O*-alkylated polymer prepared under basic conditions from epichlorohydrin and α-cyclodextrin takes up anisole into its channel; with aqueous hypochlorous acid the anisole can then be converted into *p*-chloroanisole with a specificity of >99%[73]. Poly(acryloyl-β-cyclodextrin) catalyzes the hydrolysis of *p*-nitrophenyl esters more strongly than does free β-cyclodextrin[74].

Addition reactions of H-acidic compounds HX at C=C double bonds in aprotic solvents are catalyzed by tertiary amines. Thus, *Inoue et al.*[75-77] were able to add dodecanethiol to prochiral C=C bonds with optically active poly(*N*-isoalkyl-ethylenimine) as the catalyst, whereby one antipode was formed in slight excess, *i.e.* the reaction product was optically active. The same type of reaction was used by *Yamashita et al.*[78a] when they added methanol to methyl phenyl ketone in the presence of optically active polymeric tertiary amines: the most favorable result was obtained at −78°C in the presence of 1 mol-% of poly(quinine acrylate); a 17% optical yield of the levorotatory methyl (*R*)-2-phenylpropionate *(23)* was obtained, whereas under the same conditions but with poly(cinchonine acrylate) the (*S*)-isomer was formed in an optical yield of 35%[78b].

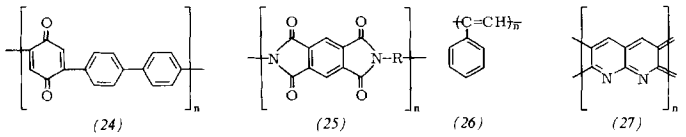
5. Polymeric Catalysts with Conjugated π-Systems



A very different type of chemical structure is involved in those polymers that contain a more or less extensive system of conjugated π-bonds. These polymers catalyze hydrogen-transfer reactions, redox reactions, and—owing to their often considerable concentration of paramagnetic centers—also symmetry-forbidden reactions.

A subsidiary role has hitherto been played in the field of catalysis by oxidation-reduction polymers (redox resins), *i.e.* by polymers that contain isolated (not conjugated) redox systems (mainly quinones) within the polymer chain or as substituent. Sulfide[79] and sulfite[80] solutions can be caused to react with oxygen in the presence of such redox resins containing quinone groups; this reaction has attracted interest in connection with the purification of waste waters.

However, particularly in the sixties, very intensive research was carried out on the properties of polymers that contain an extensive system of conjugated π-bonds. In Table 2 are collected some examples of these polymers and the reactions catalyzed by them. According to *Manassen*[9], it is in most cases possible to understand the mechanism of the catalysis

by recalling the reaction schemes obtained for low-molecular models.

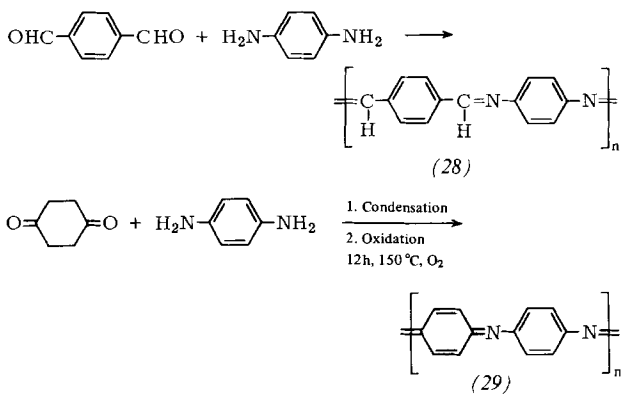


Table 2. Polymers containing extended systems of π-bonds and reactions catalyzed by them.

Summarizing the available extensive experimental material, it appears that dehydrogenations are catalyzed by polymers only if they contain a quinonoid structure. *Manassen*[96a] demonstrated this strikingly for the two linear and polyconjugated condensation products *(28)* and *(29)*. Only the product *(29)*, having a quinonoid structure, catalyzed the dehydrogenation of cyclohexane to benzene, while compound *(28)* was totally inactive. Further investigations of Schiff bases of type *(29)* have been carried out by *Uehara*[96b]. A similar high selectivity was found by *Iwasawa et al.*[99a] with poly(naphthoquinone): ethylbenzene was dehydrogenated exclusively to styrene, and cyclohexanol yielded 98% of cyclohexanone and 2% of cyclohexane; hydrogen sulfide was dehydrogenated to sulfur[99b]. However, pyropolymers also exert a dehydrogenating effect: since, however, these have been subjected without exception to often drastic thermal treatment in the presence of oxygen, the formation of acidic functions must be taken into account. This can be recognized in the ability to dehydrate alcohols and to catalyze isomerizations; as an example only pyrolyzed poly(acrylonitrile) *(27)* will be mentioned here (cf. Table 2).

(28) (29)

The extended π-systems in the polymers considered here influence their physicochemical properties. Thus, the high concentration of delocalized electrons along the conjugated chain that also often contains hetero atoms and in many cases is cross-linked two- or three-dimensionally leads to the following three phenomena: 1. a high content of free spin; 2. a decrease in the internal energy of the system; 3. a lowering of the triplet excitation energy. These give rise to the paramagnetic behavior, the good thermal stability, and the semiconductor properties of the polymers.

Although it had often been assumed that there is a direct relation between the catalytic activity and electrical conductivity, this could be confirmed directly only for series of polymers of the same type and very similar chemical structure[100]. Since, however, a high proportion of the polymers examined have semiconductor properties, it follows that conductivity is a necessary but not sufficient prerequisite for catalytic activity. An appreciably more precise relationship has been found between the concentration of free spin and some decomposition and rearrangement reactions that are themselves symmetry-forbidden. In particular, *Gallard*'s school[83, 85, 86a–c] succeeded in establishing relationships between the magnetic properties of organic polymers and the symmetry-forbidden

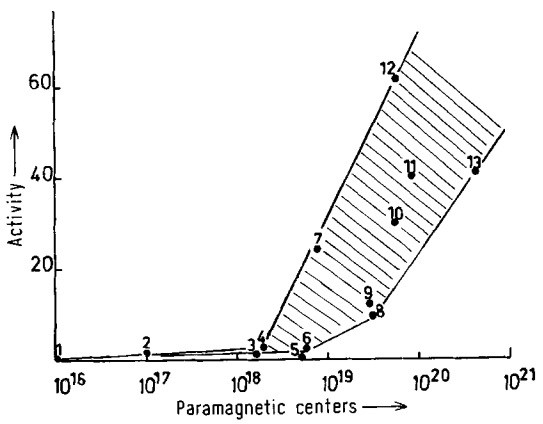

Fig. 2. Correlation between the catalytic activity for the decomposition of dinitrogen oxide

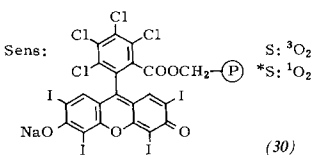
$N_2O \rightarrow N_2 + {}^1/_2 O_2$

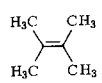
and the logarithm of the concentration of paramagnetic centers in the catalyst [83]. 1) Melon; 2) terephthalaldehyde-benzidine polycondensate; 3) tetrachloro-*p*-benzoquinone-benzidine polycondensate; 4) poly(quinoxaline) 1; 5) poly(diphenyldiacetylene); 6) poly(quinoxaline) 2; 7) poly(acrylonitrile), pyrolyzed at 250 °C; 8) Aniline Black; 9) Paramine Brown; 10) poly(benzimidazole); 11) poly(isoprene), treated with tetrachloro-*p*-benzoquinone; 12) poly(acrylonitrile), pyrolyzed at 350 °C; 13) poly(isoprene), treated with *p*-benzoquinone. The activity is measured in arbitrary units with respect to 1 m^2 of surface area of the catalyst [86a–c].

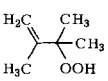
decomposition of dinitrogen oxide catalyzed by them. As an example reference can be made to the very extensive investigations into the correlation of catalytic activity and concentration of free spin (Fig. 2)[83]. Below a concentration of $10^{18.5}$ spins/g none of the thirteen polymers studied had a marked catalytic activity, whereas at higher spin concentrations the active polymers, which have widely differing structures, occupy a relatively narrow field in Figure 2. The relationship thus presumed between the effective length of the unbroken system of conjugated π-bonds in the polymer chain and the catalytic activity of the paramagnetic centers has been confirmed by measurements on a series of structurally different poly(pyromellitimides) and poly(indoloimidazoles)[83].



6. Polymer-bound Photosensitizers

A different kind of catalysis is involved in the excitation of molecules into the excited state: a sensitizer (Sens), generally a dyestuff, is excited by light energy *hv* to the singlet state, passes without emitting radiation into a longer-lived triplet state, and can then activate a substrate molecule (S), itself returning to the ground state:





$$\text{Sens} \rightarrow {}^*\text{Sens} \rightarrow {}^3\text{Sens}$$
$${}^3\text{Sens} + \text{S} \rightarrow {}^*\text{S} + \text{Sens}$$

Neckers et al.[101a] bonded the sensitizer Rose Bengal in ester fashion to cross-linked poly(styrene) and used this for the production of singlet oxygen; the latter at once reacted with oxidation with suitable acceptors. Table 3 shows that

Table 3. Oxidation with photochemically produced singlet oxygen $^1O_2$ [101a]. Sensitizer: Rose Bengal *(30)*, bound to poly(styrene) Ⓟ cross-linked with divinylbenzene.

(30)

$^1O_2$ acceptor	Product	Yield [%]
		95
		69
		82

the reactions proceed in high yield; the sensitizer can be simply filtered off from the solution and re-used.

For potential use in solar energy storage the conversion of norbornadiene to quadricyclene by sun light in the presence of various polymeric sensitizers is under study[101b].

7. Polymeric Organic Catalysts Containing Metals

In this section we shall consider polymeric organic catalysts containing metals. These will be divided into two groups: in the first group the catalytic centers contain free metal, in the second the metal is bound to the polymer in the form of an ion, a complex, or a chelate. Coordination polymers are not considered in this connection.

7.1. Catalysts Containing Free Metal

At first sight the group of polymers containing free metal appears to correspond to the heterogeneous catalysts on inorganic carriers—a group used widely in industry—but with the difference that the carrier is a polymer. Here already the analogy breaks down, because organic polymers can assume varied chemical or physical forms and be suited to a specific purpose. For example, metal particles with a mean diameter of about 15 nm can be produced in a polymer gel: a metal salt solution is equilibrated with a neutral, slightly cross-linked gel of poly(2-hydroxyethyl methacrylate) and then reduced with sodium tetrahydridoborate. Since the swelling capacity of the gel varies according to the solvent, the selectivity can be controlled by diffusion for these nonpyrophoric, readily separable, and re-usable catalysts. This has been demonstrated, among other cases, for the hydrogenation of cinnamaldehyde, mainly to hydrocinnamaldehyde, in the presence of a Pd-containing gel; the selectivity is higher than with a conventional Pd/C catalyst[102]. On the other hand, PtO_2, Ni, or Rh particles can also be microencapsulated by cross-linking interfacial polycondensation; if ferromagnetic material is added to the batch, then after hydrogenation the capsules can be easily separated from the batch by a magnetic field[103]. As a third possibility, the catalyst particles may be dispersed in solid polymers that can then be processed into some form, *e.g.* film, that is advantageous for a technical process[104].

It has long been known for inorganic heterogeneous catalysts that the carrier influences the catalytically active material dispersed on it. A similar effect was therefore suspected for polymeric carriers. *Rase et al.*[105] confirmed this in their study of the catalytic activity of Pt deposited on chemically different polyamides for the hydrogenation of benzene to cyclohexane. Only considerably later were the differences found to be due to Pt complexes formed in the preparation, which contained the N atoms of two amide groups[106a, 106b]. *Beamer et al.*[107] precipitated Pd on optically active poly(amino acids) and used the product as a hydrogenation catalyst for prochiral C=C bonds. A close relationship was found between the tertiary structure of the support and the observed direction of optical activation.

An elegant method of depositing finely divided metals on or within polymers consists of the use of ion exchangers and ion-exchanging polymers. In this one can rely either on the mechanical and geometric properties—in the micro or macro region—of these well investigated polymers, or on the fact that the separately bound ion-exchange groups lead to an extremely homogeneous distribution of the metal ions or metal complexes. In a subsequent reducing process, *e.g.* with hydrazine or by a process not involving additional reagents, the metal is deposited in the form of extremely small particles with a diameter of ≤ 2 nm and high catalytic activity. Some examples are presented in Table 4. Special reference should be made to a series of papers by *Germain et al.*[114–118], whose results can be summarized as follows: the metal is precipitated in a highly disperse form in the exchanger, vari-

Table 4. Metal-charged ion exchangers as catalysts.

[a] C = cation exchanger; A = anion exchanger; m = macroporous; s = strong; w = weak; a = acid; b = basic.

ously active or selective zones being formed; the activity, calculated on the weight of the metal, is considerably higher than in conventional active-charcoal carriers; the selectivity for partial hydrogenation of triple bonds with Pd catalysts is good, and a certain selectivity for space-filling substituted substrates can be demonstrated. Particular attention should be paid to the possibility of catalyzing several reactions with the ion-exchanger/metal system, as shown in the following sequence[110]:

$$CH_3OH + CH_3COCH_3 \longrightarrow \left[\begin{array}{l} HO \quad OCH_3 \\ CH_3\text{–}C\text{–}CH_3 \end{array}\right] \xrightarrow[-H_2O]{}$$

$$\begin{array}{l} OCH_3 \\ CH_2{=}C{-}CH_3 \end{array} \xrightarrow{H_2} \begin{array}{l} OCH_3 \\ CH_3{-}CH{-}CH_3 \end{array}$$

The catalyst used for this sequence was a macroporous, strongly acidic cation exchanger charged with the complex $Pt(1,5\text{-cyclooctadiene})_2Cl_2$.

7.2. Catalysts Containing the Metal in the Form of a Compound, Ion, or Complex

Polymers in general, but particularly ion exchangers and polymers with ligands that form complexes or chelates, are also well suited as carriers for catalytically active metal compounds. Some examples have been collected in Table 5. The advantages of these catalysts are again that they can be easily separated and re-used. Additionally, for an immobilized complex in a rigid system there is no saturation concentration

$$CH_2{=}CH{-}CH_2Cl + CO \xrightarrow[68.9\ bar]{100\ ^\circ C} CH_2{=}CH{-}CH_2COCl \rightleftharpoons CH_3{-}CH{=}CH{-}COCl$$

and no inactivation by dimerization or polymer formation. *Haag* and *Whitehurst*[132] investigated the carbonylation of allyl chloride in the presence of Pd complexes (Fig. 3). While an initially completely soluble, low-molecular (homogeneous) catalyst with increasing concentration reaches saturation and thus an activity independent of the amount present, for a high-molecular catalyst—a strongly acid cation exchanger charged with $Pd(NH_3)_4^{2+}$—a linear relationship is found between its activity and its amount over a wide region. Saturation phenomena are thus avoided and in such cases an increased rate of conversion is attained.

This example shows very clearly the advantages that can be gained by immobilization—also called heterogenation—of catalysts that alone are highly active only in the homogeneous phase. If we recall that at present about 20 industrial processes are carried out with homogeneous catalysts[133], *e.g.* the hydrogenation of olefins, hydroformylation of olefins to aldehydes, carbonylation of alcohols to acids, oxidation of olefins to aldehydes, ketones, and vinyl esters, in addition to many polymerizations, we can recognize the importance afforded by such an advance in industrial practice. Since the end of the 1960's intensive efforts have therefore been devoted to the immobilization of homogeneous catalysts.

Homogeneous catalysts are clearly defined substances that can be prepared with a high degree of reproducibility. Since the steric and electronic environment of the catalytic centers in homogeneous catalysts can be varied within wide limits, the selectivity and the reaction rate can be controlled. This in no way applies to heterogeneous catalysts, which are therefore difficult to develop further. In addition, in the latter only a small proportion of the active centers are accessible and hence effective, whereas in the homogeneous phase in principle all active molecules take part in the course of the reaction. Furthermore, homogeneously catalyzed reactions can often be carried out under milder conditions and have better mass and temperature characteristics. Alongside these clear advantages of homogeneous catalysts, however, some problems that arise in industrial application must also be mentioned. In the first place, some of these noble-metal complexes have a corrosive action on the reactors, leading to deposition of metal on the reactor walls; this results in a loss of catalyst and in formation of new active centers with undesirable properties. Apart from the difficulty in realizing a continuous mode of the reaction, however, the main disadvantage is the difficulty of the catalyst's recovery. According to the nature of the catalyst and the product, this often necessitates a repetition of expensive separations. Moreover, in many cases the active catalyst cannot be recovered as such, but only a portion of the noble metal.

Many processes have been proposed for separation and recovery. *Manassen*[134] attempted to solve the problem by means of a homogeneous catalyst that was only slightly altered chemically by reaction in two immiscible liquid phases: one phase contained the catalyst, the other the substrate and the product. The first experiments have been encouraging, but in principle the possible applications are severely limited. *Bayer* and *Schurig*[135] also worked with a homogeneous phase; these authors bound homogeneous catalysts by ligand exchange to soluble poly(styrene) functionalized with phosphane groups; the polymeric catalyst isolated by membrane filtration was re-used successfully and repeatedly.

Industrial and academic activity is now concentrated on chemical fixation of known active homogeneous catalysts onto organic cross-linked polymers and, very recently, also onto inorganic carriers[136a–136c].

At present the great majority of polymers suitable for immobilization of homogeneous catalysts use arylphosphane groups, and are prepared almost exclusively by polymer-analogous reactions. The steps outlined in Figure 4 have proved useful for poly(styrene)[137].

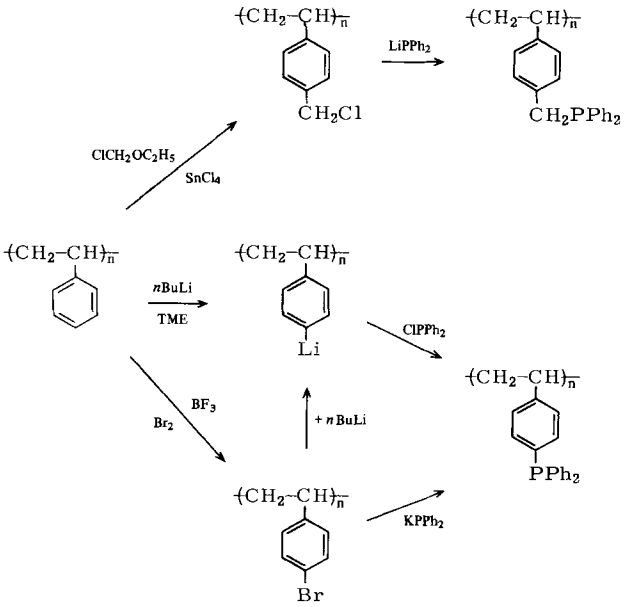

Fig. 4. Polymer-analogous reactions with poly(styrene) (homopolymerizate or bead polymerizate cross-linked with divinylbenzene) for the introduction of phosphane groups [137]. TME = tetramethylethylenediamine.

The catalyst itself is obtained in a further step by ligand exchange with a homogeneous catalyst; this is illustrated for the Wilkinson catalyst *(31)*.

$$\text{Ⓟ—PPh}_2 + \text{ClRh(PPh}_3)_3 \longrightarrow \left[\text{Ⓟ—PPh}_2\right]_x \text{RhCl(PPh}_3)_{3-x}$$

(31), $x \geq 1$

Special treatment is often necessary to endow the bound metal complex with catalytic activity. A prerequisite for catalytic activity is the presence of a free coordination site on the metal[138].

The test reaction generally used is hydrogenation, but hydrosilylations[139a, 139b], hydroformylations[140–142b], carbonylation of methanol[143a, 143b], isomerizations[144], oligomerizations, and cyclooligomerizations[145a, 146b] have so far also been studied with these new catalysts. In this work considerable differences in the product distribution have sometimes been observed in comparisons with the results for pure homogeneous catalysts.

In spite of their apparent simplicity, immobilized homogeneous catalysts present a very complicated picture. In many cases even the structure of the bound complex is unclear. While the properties of active metal complexes fixed on soluble polymers in the homogeneous phase are only slightly altered by the immobilization process, such alterations are considerable for catalysts bound to cross-linked polymers swelling only to a limited extent. The customary comparison with a homogeneous catalyst on the basis of the reaction rates

and the product distribution rarely indicates more than that a difference exists; hitherto it has not been possible to establish the reaction kinetics on a theoretical, quantitative basis.

For example, the catalytic process is influenced by the following factors: particle size of the polymer, distribution of the catalyst in the particles, percentage porosity, pore size, and pore structure under the reaction conditions, number of ligands on the polymer (multiple coordination), rigidity of the polymer (extent of cross-linking), and the influence exerted on the swelling behavior of the catalyst by the substrate, product, and solvent. It is difficult to establish how on the one hand the chemical structure of the catalytic centers and on the other the rates of diffusion of the substrate and product are influenced by these factors. It is therefore not surprising that the observed effects have many causes. For example, it is frequently found that the reaction rate is retarded by the size and branching of the substrate, as shown in Table 6 for hydrogenation with an immobilized Wilkinson catalyst[147]. The high selectivity observed here is certainly due to a combination of several parameters determining diffusion.

Table 6. Relative rates of hydrogenation of olefins in the presence of rhodium catalysts [147]. Hydrogenation conditions: 1 M olefin solution in benzene, 25°C, 1013 mbar. Catalyst I: [Ⓟ PPh_2]$_x$RhCl$(PPh_3)_{3-x}$:Ⓟ: chloromethylated styrene bead polymerizate cross-linked with 1.8% of divinylbenzene, ϕ 15—35 μm; 0.13 mmol Rh/g dry polymer. Catalyst II: $ClRh(PPh_3)_3$, 2.5 mmol.

Olefin	Cat. I	Cat. II
1-Hexene	2.55	1.4
Cyclohexene	1.00	1.00
Octadecene (isomer mixture)	1/2.06	1/1.4
Cyclooctene	1/2.54	1.0
Cyclodecene (*cis* and *trans*)	1/4.45	1/1.15
2-Cholestene	1/32	1/1.4

The absolute rate of hydrogenation with the heterogeneous catalyst is 1/6 of that for the homogeneous catalyst; in contrast, the rate was observed to be increased by a factor of 25 with immobilized titanocene[148,149] (Table 7). The presumed explanation was that deactivation by dimerization and polymerization was hindered by fixation of the titanium complex on the very rigid matrix.

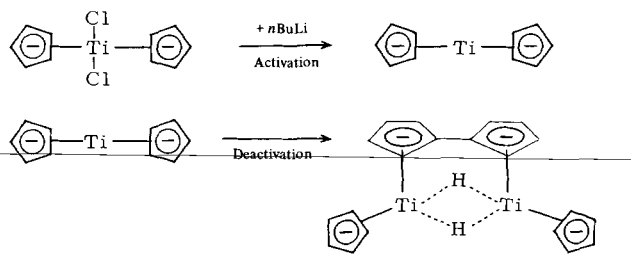

Table 7. Hydrogenation of cyclohexene with titanocene catalysts. Hydrogenation conditions: 1.16 M cyclohexene solution in *n*-hexane, 20°C, 1013 mbar [148].

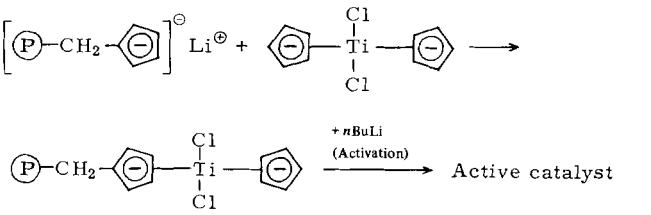
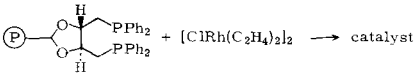
	v [ml H_2/(min·meq·Ti)]	$\frac{v_{heterogen.}}{v_{homogen.}}$
Homogeneous catalyst	28.0	—
Immobilized catalyst [a]	88.7	3.2
Immobilized catalyst, milled	714	25.5

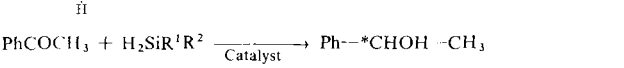


[a] Titanocene bound on macroporous styrene bead polymerizate cross-linked with 20% of divinylbenzene; 0.28 meq·Ti/g.

A very far-reaching influence of the matrix was observed by *Kagan et al.*[150] on using a chiral ligand (Table 8). When poly(styrene) cross-linked with 2% of divinylbenzene was used as the carrier for the rhodium complex, hydrogenation was possible only in benzene and the optical yields were only

Monomeric titanocene catalyst





Polymeric titanocene catalyst

$^1/_{10}$th of the yields found with the low-molecular homogeneous catalyst. The catalyst is unsuitable for reactions in polar solvents: *e.g.* it shrank very strongly in ethanol with loss of activity. When a dihydrosilane was used as the source of

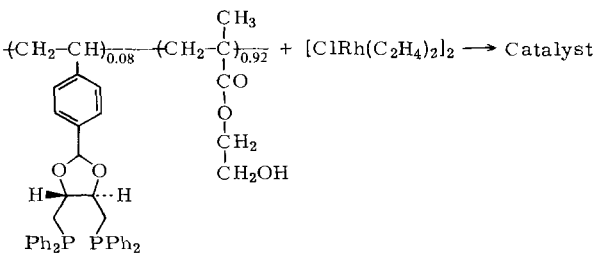


Table 8. Reduction of acetophenone by dihydrosilane in the presence of a polymeric chiral rhodium catalyst. Ⓟ = poly(styrene) cross-linked with 2% of divinylbenzene [150].

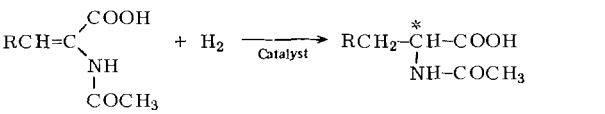

R^1	R^2	Opt. yield [%]

Ph	Ph	29
Ph	1-Naphthyl	52

hydrogen, acetophenone could be reduced to 1-phenylethanol in high chemical and optical yields. The optical yield was then just as large as with the low-molecular model and in both cases increased with increasing rigidity of the silane substituents. For the use of this effective chiral catalyst in polar solvents the polymeric carrier was changed by *Stille et al.*[151a,151b]: the copolymer from 2-*p*-styryl-4,5-bis(tosyloxymethyl)-1,3-dioxolane, 2-hydroxyethyl methacrylate

(32), R = Ph
(33), R = H

(34), 86% opt. yield
(35), 52-60% opt. yield

and a small amount of ethylene dimethacrylate gave, after phosphonation with sodium diphenylphosphide, a matrix that could swell well in polar solvents. α-Acetamidocinnamic acid *(32)* and α-acetamidoacrylic acid *(33)* were hydrogenated in ethanol with the resulting polar, chiral, heterogeneous rhodium catalyst. The optical yields of *(34)* and *(35)* were similar to those obtained in experiments with the low-molecular homogeneous catalyst. The heterogeneous catalyst could be re-used, but it was more sensitive to oxygen than the analogous catalyst based on poly(styrene).

Summarizing, it can be stated that there are very many gaps in our knowledge of immobilized homogeneous catalysts and that no more than a start has been made with a systematic investigation of their properties. The work to date has shown, however, that these new catalysts have valuable properties: they are easily separated and can be re-used without loss of activity; an alteration of their porosity leads to an altered selectivity[152]; the hydrophobic matrix that is often favored protects the active centers from deactivation by oxygen and water[119, 153]; by fixation of two or more catalysts on one carrier multistage reactions can be carried out successively in one reactor[143b, 154], on occasions indeed in conjunction with one another; fixation of the active centers on a rigid matrix prevents their deactivating reaction with one another[148, 149]; and the use of chiral ligands makes it possible to synthesize optically active compounds[150–151b]. This list of favorable properties will certainly be extended in the future.

The Responsibility of the Scientist[**]

By Hans Mohr[*]

The tradition of mutual trust between science and the public appears to have been broken in recent years. It is necessary to define the boundaries of science and to reflect upon the responsibility of the scientist.

The goal of science is knowledge.

Just a few years ago most scientists were full of confidence, and science was an unquestionable component of our culture. Any increase of knowledge was considered almost synonymous with moral progress, with more humanitarianism, more freedom, more happiness. The scientist expected the public to respect his work and to trust him. In most cases, this trust was granted *blindly*.

All that has now changed. Science as an institution and the scientist as a person have been drawn into the general crisis of confidence which has pervaded society. Science and the technology to which it gave birth are now largely regarded as *enemies* of mankind. The critics maintain that science has disappointed, and in particular that it has failed *morally*.

Has science really failed?

At first glance it would not appear to be the case. On the contrary: modern science was, and still is, remarkably effective. Advances in knowledge continue, in some disciplines at an unprecedented rate. We all live from the fruits of science; and we live better, far better, than mankind has ever lived before. Anybody who denies this does not know (or does not want to know) how our ancestors lived and suffered. Of course, the point of no return has long been passed. There are simply 3 or 4 billion people too many for any return to the *simple* way of life, even if it were desirable. If we wish to continue to live we must therefore overcompensate the decay phenomena of our culture by scientific and technological progress. If distrust of *Homo faber* were to lead man to turn his back on science, this would be his farewell to civilization.

Nor would science appear to have failed *morally*. The ethos of science, that particular moral law which provides the basis for objective knowledge, has stood the test better than any other set of norms and values in the history of man. There is not the slightest indication that science has lost any of its rigor in the classical disciplines. On the contrary, the severity of sanctions imposed upon those deviating from this ethos has increased.

How, then, did the accusation arise that science has failed? I think it is because mankind expects more from science than it can afford according to its goal and structure. Serious scientists, experts in their respective fields, were also guilty in the 1960's of cultivating the illusion that any problem is solvable if we really desire its solution; they promised not only knowledge and explanation, but also salvation. Science is now criticized as an institution because these promises cannot be fulfilled. It was partly the fantastic successes of those years, such as the first moon landing or the breaking of the genetic code, which deluded scientists into making such promises. The principal reason, however, lay (and still lies) in the inability of many scientists to distinguish between those problems which are *directly* accessible to a scientific or technological solution and those whose solution requires a change in the prevailing propensity structure or in the *system of values* of society. The latter problems cause the real difficulties because there are narrow limits set to the changes in values and the structure of natural tendencies.

It was a lack of insight into the nature and structure of problems which led to the overoptimistic view that a global attack by the elite of science could also solve the world's greatest problems: overpopulation, need and poverty, exhaustion of reserves, destruction of the environment, chauvinism, collective envy, economic extortion, ideological fanaticism.

Given clearly defined and simple aims and constant scales of values in society, the capability of science is almost without limit. If the aim is vague and attainable only after modification of the prevailing scale of values or the prevailing propensity structure of human society, then science proves inadequate or, far worse, partial scientific solutions (such as the "green revolution" in the fight against hunger) only *exacerbate* the overall problem.

At this juncture I must delineate the term *science* to avoid any future misunderstanding. The aim of science is knowledge;

[*] Prof. Dr. H. Mohr
Biologisches Institut II der Universität
Schänzlestrasse 1, D-7800 Freiburg (Germany)

[**] Based on an address delivered on the occasion of the Centenniel of the Technische Hochschule Darmstadt on October 20, 1977.

knowledge of the kind which provides a reliable basis for dealing with the real world (including people) and for dealing with ideas. Knowledge is expressed in the form of propositions. General propositions are called laws, while singular propositions are termed facts. The distinguishing feature of science, as compared with all other activities of the mind, is the existence of strict methods to examine whether a proposition is true or false.

The "scientific ethos" is a coherent and surprisingly consistent code of rules and regulations embracing the following requirements: primacy of knowledge (knowledge is better than ignorance in all circumstances), intellectual honesty, mutual respect, objectivity, freedom of thought (and hence renunciation of any rejection of information), symmetrical argumentation, clarity of expression. It is of particular importance that scientific statements should be testable without restriction at all times. A statement is permissible only if its correctness can be checked by anybody who is mentally and technically equipped to do so.

This code is strictly applied by the scientific community. Anybody who employs inadequately defined concepts, who reports false data, who makes careless statements, who operates with theories that cannot be subjected to empirical scrutiny, or who purposely tries to discredit others will lose his trustworthiness and the respect of his colleagues, and will sooner or later leave the sphere of science.

Of course, *unintentionally* false measurement, reasoning, and argumentation represent an unavoidable and ever-present danger threatening the advancement of knowledge. It is therefore all the more important that we do not have to consider *intentionally* false measurement, reasoning, and argumentation.

The scientific ethos is shown by its success to be an extremely powerful principle. However, and this limitation is of crucial importance, it is a *partial* ethos which imposes ethical standards on us solely with regard to a given end. This end is knowledge. As long as a person's actions have the aim of furthering scientific knowledge, he subjects himself to the scientific ethos. In the fields of human relationships, economics, or politics no binding maxims are forthcoming from the scientific ethos. It is a partial ethos which, moreover, only partially rules the life of the scientist. In their *personal* lives, and sometimes in their personal dealings with one another, scientists are neither particularly "noble", nor particularly "helpful", nor particularly "good". Why should they be? Their qualification and their status as *scientists* are independent thereof.

On the other hand, the international unity of science stabilized by the scientific ethos is a truly impressive phenomenon. Scientists from different cultures and social systems can readily engage in scientific communication. As long as they remain within the framework of science there will be no fundamental obstacles to mutual understanding.

The scientist can, of course, step out of this forum by expressing a *political* opinion or by talking *about* science but he must clearly reveal when he wishes to *persuade* (politically) and when he can offer *proof* (scientifically).

We thus face the question of how scientific knowledge influences social decision-making processes. The answer is not difficult to find. The contribution of science to the mastery of problems relating to human existence is always expressible in the form of "if-then" statements: given the constellation of factors x, then the consequences y will result; or, in order to achieve the consequences y then the constellation x must be brought about; or, if the consequences y are to be avoided then the constellation x must be avoided. Whether it is desirable or justifiable to achieve or avoid y is not implied by these propositions. Such a value judgment cannot be reached scientifically. Any *application* of scientific knowledge is therefore necessarily ambivalent. This is obvious from any piece of technology, whether a kitchen knife or penicillin, whether a herbicide or an atomic reactor. The moral responsibility of the scientist in his capacity as a scientist concerns only the reliability of the "if-then" propositions. However, this responsibility can hardly be overestimated because errors can cause immeasurable damage. *Reliable knowledge is a prerequisite for a right course of action.* Whether and in what situations a person applies "if-then" propositions to the solution of his problems nevertheless depends upon decisions lying outside the realm of science. Such decisions involve more than the addition of scientific "if-then" propositions. They also include the propensities, conventions, norms, motivations, and priorities which mold the actions of a state or society.

At this point we must consider that much-discussed question whether a scientist can contribute towards a more humane world by *withholding* knowledge. There have always been demands for a scientist's oath comparable with the Hippocratic Oath of medicine. Proposals for such an oath to be taken by the scientist are all based on the idea of committing oneself to work only on projects whose declared aim is compatible with particular value concepts—more humane value concepts. *Descartes* already had such an oath in view when he wrote, at the close of his "Discours": "I could not work on projects that are useful to some only by being harmful to others."

A contemporary proposal is due to *Dullart:* "Being admitted to the practice of the natural sciences I pledge to put my knowledge completely at the service of mankind. I shall prosecute my profession conscientiously and with dignity. I shall never collaborate in research aimed at the unjustified extermination of living organisms or the disturbance of the biological equilibrium which is harmful to mankind, neither shall I support such research in any way. Guide of my scientific work will be the promotion of the common welfare of mankind and in this context I shall not kill organisms nor shall I allow the killing of organisms for inferior, short-sighted, opportunistic reasons. I accept responsibility for unforeseen, harmful results directly originating from my work; I shall undo these results as far as lies in my power. This I vow voluntarily and on my word of honor."

The obstacles standing in the way of the introduction and implementation of such a commitment are obvious. How can a consensus be reached, and who will decide whether a given scientific project can be regarded as of service to mankind? Who would consider himself competent to make such a judgment? Take the Hippocratic Oath! The commitment to preserve human life under all circumstances and by all means has contributed essentially to the present situation in which the population explosion in many areas of the world represents a lethal threat to mankind, and the richness of genetic evolution, the variety and beauty of creation, have fallen victim to the exponential growth of man.

Any demand that the scientist should predict the possible consequences of his work and assume moral responsibility

for them *in advance* is unrealistic. Of course, *personal refusal* is a course open to everyone in a free society. Apart from very prominent heroic exceptions, however, it is ineffective because hardly anybody is indispensible in science.

As a variant of the Hippocratic Oath it is also argued that the expert scientist bears a *particular responsibility* for the common good. For example, one of the articles of the German Physical Society reads: "The Society commits itself and its members to take up the cause of freedom, veracity, and dignity in science, and to be conscious of the fact that those engaged in science bear a particularly high degree of responsibility for the shaping of the whole of human life". I consider the second part of this article to be an ill-considered empty phrase. *Particular* responsibility without *particular* legislative or executive power is, in a democracy, an unrealistic and morally dangerous postulate. A particular responsibility of the scientist would be feasible only if the scientist were to be assigned a *privileged* place in the legislative and executive. This is something I would oppose. Any swing towards technocracy and expertocracy affects the foundations of democracy and also overtaxes the scientist. Experience clearly refutes the idea that scientists are exceptionally qualified to formulate goals and to justify them ethically in areas lying *outside* their discipline. It is a flattering but false conclusion that scientific competence implies a high degree of normative reason. Most scientists have to learn sociopolitical thinking and action the hard way. It is certainly depressing to have to see how opportunism and shortsightedness gain ground among politicians. It is unnerving to see how the important decisions of our age overtax most people, and how the fear of progress and fear of risk also affects those who are not prepared to renounce progress. However, the alternative of wresting real power from the people, of a despotism bearing the trappings of moral respectability and appearing in the guise of a technocracy or expertocracy, is not acceptable. Science cannot provide an individual or a collective with a moral code, goals, or criteria which have the character and the validity of scientific propositions. Science has nothing to say about "the meaning of the world", about the "meaning of existence", or about the "aims of society". This is where the boundaries of science lie. We ought to respect them.

How can science overcome the crisis of confidence in which it is presently involved? I believe that there is only one answer. We must tell our fellow citizens in clear terms just what we can do and what we cannot. But first of all the scientist himself must clearly appreciate where scientific competence ends and presumptiousness starts. May I present an example.

Early in 1977, 650 scientists—physicists, chemists, biologists, physicians, engineers—from universities and research institutes all over West Germany declared the utilization of nuclear power to be both necessary and justifiable in an open letter addressed to the members of the German parliament. This source of energy represents the only short-to-medium-term way of adequately and inexpensively satisfying energy requirements even if all possible methods of saving energy are fully implemented and full use is made of domestic coal supplies. The 650 scientists were of the opinion "that the dangers of nuclear power are sufficiently under control and that this will also apply in the case of further expansion of nuclear power generation in view of the intense research work being performed on questions of safety". "The remaining residual risks" continues the letter "are taken seriously by us. However, they appear justifiable when set against the overall risk to civilization, and smaller than some other risks accepted as the price to pay for slighter advantages." Shortly afterwards, numerous other scientists—as they were called—signed a declaration demanding a drastic reduction and slow-down of existing nuclear power plant planning. The reasons given were, *inter alia*, that the safety problems accompanying the large-scale exploitation of nuclear power can by no means be regarded as solved. The consequences of plutonium production were cited. Police-state methods would be required to prevent the theft and misuse of plutonium. Moreover, the export of nuclear power plants by the Federal Republic of Germany creates further possibilities of misuse. Most of the signatories of this declaration were not scientists or technologists competent in the issues at stake, but sociologists, theologians, and publicists. And yet reports about the declaration appeared in the press and on television under the headline "one thousand scientists issue warning". Parliamentarians at Bonn faced two opposing declarations, both claiming to speak in the name of science. Since the mass media in the Federal Republic gave wide coverage with accompanying commentary only to the "Declaration of the sixteen-hundred", the public, already uneasy about nuclear energy, gained the impression that *science* almost entirely rejects the expansion of nuclear power generation capacity.

We cannot go on in this way. For the sake of science we must counter the hubris that scientists are the moral watchdogs of society and arbitrators in matters of political conscience. In making this claim of "critical science" the university has overstepped its limits. Science cannot tell people what is "good" and what is "beautiful", or where human life and the human race are going. Questions about "sense" and "purpose" cannot be definitively answered in the framework of science. Knowledge is a prerequisite, but is not a sufficient reason, for right action or for the right conduct of our lives.

Has science failed?—No, with regard to its effectiveness and its ethos. Yes, inasmuch as it has failed and continues to fail to give account of its limitations.

German version: Angew. Chem. 90, 651 (1978)

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Mild Oxidative Removal of the *p*-Methoxybenzyl Ether Protecting Group by Homogeneous Electron Transfer[1]

By *Werner Schmidt* and *Eberhard Steckhan*[*]

The benzyl ether function is one of the most common protecting groups for alcohols. It is usually removed by catalytic hydrogenation or less often by sodium in liquid ammonia[2]. If, however, the substrate contains additional reducible functions, this procedure is unsatisfactory.

We now report a simple and mild method for the removal of the *p*-methoxybenzyl ether protecting group by homogeneous electron transfer under *oxidative* conditions. The stable cation radical of tris(*p*-bromophenyl)amine is employed as electron transfer agent (mediator). Bond cleavage takes place in moist acetonitrile according to the following reaction scheme:

$$\underset{(1)}{(Br\text{-}C_6H_4)_3N^{\bullet\oplus}} + \underset{(3)}{RO\text{-}CH_2\text{-}R'} \rightleftharpoons \underset{(2)}{(Br\text{-}C_6H_4)_3N} + \underset{(4)}{[RO\text{-}CH_2\text{-}R']^{\bullet\oplus}} \quad (a)$$

$$\underset{(4)}{} + H_2O \rightleftharpoons RO\text{-}\dot{C}H\text{-}R' + H_3O^{\oplus} \quad (b)$$
$$(5)$$

$$\underset{(1)}{} + \underset{(5)}{} \rightleftharpoons RO\text{-}\overset{\oplus}{C}H\text{-}R' + \underset{(2)}{} \quad (c)$$
$$(6)$$

$$\underset{(6)}{} + H_2O \rightarrow ROH + R'CHO + H^{\oplus} \quad (d)$$

$R' = -C_6H_4-OCH_3$

The reversible potential of the redox couple *(1)*/*(2)* ($E^0 = +1.05$ V *vs.* SCE) is about 550 mV more negative than the irreversible oxidation potentials of the ethers *(3)*[3]. The driving force of the reaction is the deprotonation step (b). By addition of 2,6-dimethylpyridine the bond cleavage can be substantially accelerated[4].

The cation radical *(1)* can either be used in stoichiometric amounts as its readily obtainable[5] stable hexachloroantimonate (method 1), or it can be electrochemically generated and regenerated from the amine during the course of the reaction (method 2). In the latter case only catalytic amounts of the electron transfer agent are necessary.

Both methods usually give good to excellent yields and the alcohol is obtained in high purity. In contrast to the reductive deprotection procedures, double bonds are not attacked. Numerous oxidation-labile functions should tolerate the new procedure because the redox potential of the mediator is very low. Direct anodic deprotection, however, needs an anode potential of at least +1.6 V *vs.* SCE and fouling of the electrode is often encountered[6].

Table 1. Oxidative cleavage of the *p*-methoxybenzyl ether protecting group by homogeneous electron transfer.

$RO\text{—}CH_2\text{—}C_6H_4OCH_3$ *(3)* R	Yield of R—OH [%] [a] Method 1	Method 2
1-Octyl	86	95
1-Methylheptyl	81	87
E-4-Hepten-1-yl	75	83

[a] Material yield.

General procedure

Method 1: To a solution of 2 mmol of the respective *p*-methoxybenzyl ether *(3)* (2 mmol) and 2,6-dimethylpyridine (0.212 g, 2 mmol) in CH_3CN[7]/CH_2Cl_2 (5:1) a solution of tris(*p*-bromophenyl)ammoniumyl hexachloroantimonate (4.08 g, 5 mmol) in CH_3CN/CH_2Cl_2 (5:1) is added dropwise until the blue colour of the cation radical *(1)* persists. For product workup, water is added to the reaction solution which is subsequently reduced, saturated with KCl, and extracted with ether. After extraction with $NaHSO_3$ solution the ether phase is dried over $MgSO_4$. The alcohols are identified by gas chromatography and mass spectrometry on comparison with authentic samples and isolated by bulb-to-bulb distillation.

Method 2: In a divided beaker-type glass cell (20 °C, Pt anode, Pt cathode) a solution of tris(*p*-bromophenyl)amine (0.964 g, 2 mmol) in CH_3CN/CH_2Cl_2 (5:1; 0.2 M $LiClO_4$) is used as anolyte. The catholyte consists of CH_3CN/1.0 M $LiClO_4$. After application of an anode potential of +1.2 V (*vs.* Ag/AgCl) the blue color of *(1)* appears. When the respective *p*-methoxybenzyl ether *(3)* (5 mmol) and 2,6-dimethylpyridine (0.535 g, 5 mmol) are added the solution is decolorized. After reappearance of the blue color of the electron transfer agent (consumption of about 0.013 F) the electrolysis is stopped. The workup procedure is the same as in method 1.

Influence of Cyclopropyl Substituents on the Relative Rate of Dichlorocarbene Addition to Olefins[**]

By *Eckehard V. Dehmlow* and *Axel Eulenberger*[*]

Enormous rate enhancements caused by cyclopropyl rings adjacent to developing positive charges are well known. However, the influence of cyclopropane on additions to double bonds is less clear: In hydratation and bromination, cyclopropane accelerates relative to *n*-butyl by about 10^4[1], and in cycloadditions with tetracyanoethylene and arylsulfonyl isocyanates accelerations of 10^3 are found[2]. Only small differences are observed, however, when arylsulfenyl chlorides are added[1]. In the ene-reaction with singlet oxygen, the electronic effect of cyclopropane is comparable with that of methyl[3].

We subjected a number of cyclopropylalkenes to reaction with dichlorocarbene generated by phase-transfer catalysis[4] and characterized the products. The same olefins were subsequently employed in competition experiments with less than equivalent amounts of dichlorocarbene. Analysis was performed by gas chromatography after calibration for each of the products determined in the preliminary experiments. Table 1 shows the reactivities (±5%) relative to 3,3-dimethyl-1-butene *(14)*. Steric and electronic effects seem to counteract each other. A cyclopropyl ring exerts a powerful accelerating effect compared to its open-chain analog [*(10)/(12)*, *(11)/(14)*, *(5)/(13)*] but—depending on the steric situation—this effect is somewhat more [*(2)/(4)*] or somewhat less pronounced [*(3)/(1)*, *(5)/(4)*] than that of methyl. Furthermore, the effect of a double bond is roughly comparable to that of a three-membered ring. 1-Methylcyclopropyl compounds [*(6)/(11)*] are less reactive than the unsubstituted compounds [*(2)/(10)*] for steric reasons.

Table 1. Relative reactivities of various alkenes towards dichlorocarbene.

Dimethylsilanediyliron Complexes[1]

By *Hideki Sakurai, Yoshiyasu Kamiyama*, and *Yasuhiro Nakadaira*[*]

Schmid et al.[2] recently reported the preparation of *base-stabilized* silanediyliron complexes. We now wish to communicate our observations on the first *stable* mononuclear dimethylsilanediyliron complexes.

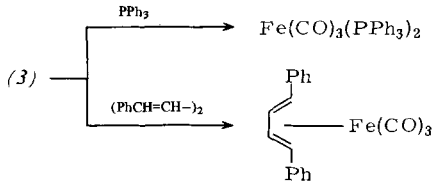
When a yellow-orange suspension of $Fe_2(CO)_9$ (1.00 g, 2.75 mmol) and pentamethyldisilane *(1)* (498 mg, 3.77 mmol) in benzene (10 ml) was stirred at room temperature for 15 h under argon, a yellow-brown homogeneous solution was obtained, from which a yellow-orange complex tricarbonylhydrido(dimethylsilanediyl)trimethylsilyliron *(3)* (523 mg, 1.92 mmol) was isolated in 70% yield as an oil, b.p. 30 °C/0.005 torr.

$$Fe_2(CO)_9 + H\text{–}SiMe_2\text{–}SiMe_2R \longrightarrow Me_2Si{=}Fe(H)(CO)_3 + \ldots \quad (SiMe_2R)$$

(1), R = Me; *(2)*, R = H

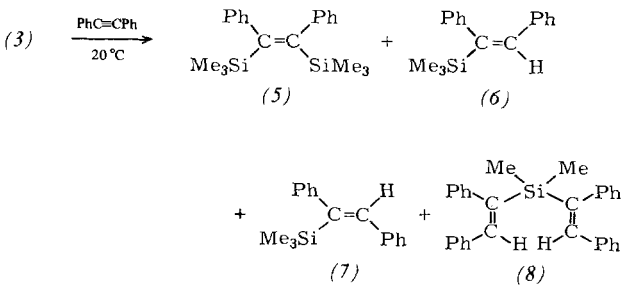
(3), R = Me; *(4)*, R = H

The complex *(3)* is extremely air-sensitive and decomposes instantaneously on exposure to air, but correct elemental analyses are obtained on careful handling. The ^{1}H-NMR (CS_2) spectrum of *(3)* shows, in addition to the FeH signal at



[*] Prof. Dr. H. Sakurai, Dr. Y. Kamiyama, Dr. Y. Nakadaira
Department of Chemistry, Faculty of Science, Tohoku University
Sendai 980 (Japan)

$\delta = -9.41$, two Si—CH_3 signals at $\delta = 0.36$ and 0.71 with a relative intensity of 3 : 2. The signal at $\delta = 0.71$ can be assigned to the terminally bonded Me_2Si group, since all the $SiCH_3$ signals of bridging Me_2Si groups in dinuclear complexes appear at lower field[3].



The mass spectrum of *(3)* (25 eV) shows the molecular ion at *m/e* 272 (5.0 %) and ions corresponding to the successive loss of CO leading to Me_2SiFe^+ (*m/e* = 114, 23.8 %) and Me_3Si^+ (*m/e* = 73, 100 %). In the νCO region of *(3)* there appear four bands at 2080 (s), 2030 (s, sh), 2000 (vs), and 1930 (s, sh) cm^{-1}.

Similar reaction of $Fe_2(CO)_9$ and 1,1,2,2-tetramethyldisilane *(2)* gave the corresponding yellow-orange complex *(4)*; b.p. 23 °C/5 × 10^{-3} torr. IR (neat): 2080 (s), 2030 (s, sh), 2000 (vs), 1930 (s, sh) cm^{-1}; MS (25 eV): *m/e* 258 (M^+, 11.4 %), 114 (100 %); ^{1}H-NMR (CS_2): $\delta = -9.4$ (1 H, s, Fe—*H*), 0.30 (6 H, d, *J* = 4.0 Hz, SiH—CH_3), 0.7 (6 H, s, Si—CH_3), 4.0 (1 H, sept., *J* = 4.0 Hz, Si—*H*).

The complex *(3)* reacts with triphenylphosphane and 1,4-diphenylbuta-1,3-diene to give the respective substitution compounds:

The reaction of *(3)* with diphenylacetylene results in the formation of several interesting compounds as shown in the following scheme:

+ $Fe(CO)_3(PhC{\equiv}CPh)_2$ + $Fe_2(CO)_7(PhC{\equiv}CPh)_2$
(9) *(10)*

(5) (6 %), *(6)* (20 %), *(7)* (2 %), *(8)* (5 %), *(9)* (7 %), and *(10)* (8 %) were isolated by TLC on silica gel.

Bis(thioacyl) Sulfides from Acyl Thioacyl Sulfides

By *Shinzi Kato, Katsumi Sugino, Masateru Mizuta*, and *Tomonori Katada*[*]

Bis(thioacyl) sulfides *(3)* are accessible by reaction of dithiocarboxylic acids and dicyclohexylcarbodiimide[1]. In the course of a study on the synthetic utility of acyl thioacyl sulfides *(1)*, it was found that compounds *(3)* are obtained in fair yield by treatment of *(1)* with lithium alkoxides or alkyl sulfides *(2)*. Preliminary experiments revealed that the yields of *(3)* are highly dependent upon the group R′ and upon the species *(2)*. The highest yield was obtained on reaction of *(1a)* with lithium ethyl sulfide. The reaction proceeds even on use of 1/3 mol of lithium salt per mol of *(1a)* to give over 60 % of *(3a)* (Table 1). This reaction also gives bis(acyl) sulfide *(4)*, which was detected IR spectroscopically.

R = Alkyl, Aryl
R′ = Alkyl
X = O, S

Table 1. Reaction of acyl(thioacyl) sulfides with lithium alkoxides or alkyl sulfides.

	R	R′	R″X	*(1)* : *(2)*		M.p. [°C]	Yield [%]
(1a)	4-CH_3—C_6H_4	CH_3	C_2H_5S	1 : 1	*(3a)*	74	76
(1a)	4-CH_3—C_6H_4	CH_3	C_2H_5S	1 : 0.3	*(3a)*		>60
(1b)	4-CH_3—C_6H_4	C_2H_5	C_2H_5S	1 : 1	*(3a)*		22
(1a)	4-CH_3—C_6H_4	CH_3	C_2H_5O	1 : 1	*(3a)*		48
(1a)	4-CH_3—C_6H_4	CH_3	C_6H_5S	1 : 1	*(3a)*		33

This is the first example of a base-catalyzed disproportionation reaction of acyl thioacyl sulfides.

Experimental

To a solution of *(1a)*[2] (0.42 g, 2 mmol) in *n*-hexane (30 ml) was added lithium ethyl sulfide (0.14 g, 2 mmol) and the mixture was stirred for 30 min at 0 °C under argon. The sky-blue solution becomes dark blue within 5 min, and formation of small amounts of green crystals is observed. Insoluble EtSLi is filtered off, and the filtrate is concentrated to *ca.* 15 ml *in vacuo*. Cooling to −50 °C gave a green precipitate of *(3a)* which was isolated by filtration [yield 0.25 g (76 %); m.p. 74 °C (74–75 °C[1a])] (76 %) and identified by comparison with an authentic sample[1a] (IR, UV, ^{1}H-NMR).

Facile Synthesis of 2-Aryl- and 2-Heteroarylpyrroles from *N*-Allylcarboxamides

By *Norbert Engel* and *Wolfgang Steglich*[*]

2-Aryl- and 2-heteroarylpyrroles are of interest as precursors for the synthesis of chemotherapeutics[1]. The syntheses hitherto described in the literature, however, are laborious and afford only moderate yields[2]. We have found that the pyrroles *(5)*, R^1 = aryl, heteroaryl, *tert*-alkyl, can be prepared in high yields from the imidoyl chlorides *(2)*[3]—readily available from *N*-allylcarboxamides *(1)*—by cyclization with potassium *tert*-butoxide in an inert solvent (Table 1)[4].

Special purification of *(2)* is not essential. Hence, this method provides convenient access to 2-(2-furyl)pyrrole *(5b)* and 2-(2-thienyl)pyrrole *(5c)*[5].

The cyclization to the pyrrole ring can be interpreted in terms of a 1,5 dipolar ring closure of the nitrile ylide *(3)*[6] formed by elimination of HCl from *(2)*, the primary product *(4)* subsequently isomerizing to *(5)*[7]. In the case of *N*-allylimidochlorides of the aliphatic acids bases promote elimination of HCl to give the ketenimines, which subsequently rearrange into γ,δ-unsaturated nitriles[8]. This novel method for the synthesis of pyrroles is therefore limited to allylamides of carboxylic acids which do not contain an H atom in the α-position.

[a] *(1a)*, *(1e)*, *(1f)*, *(5a)*, *(5d)*, *(5e)*, *(5f)* are well documented in the literature. The remaining compounds gave correct elemental analyses and spectroscopic data consistent with the given structures.
[b] Prepared from amine and acyl chloride in aqueous hydrogen carbonate at 0—5°C.
[c] A: referred to *(1)*; B referred to distilled imidoyl chloride: *(2a)*, yield 91%, b.p. 71°C/0.05 torr; *(2b)*, 84%, b.p. 68°C (bath temperature)/0.05 torr; *(2d)*, 74%, b.p. 53°C/17 torr.

General procedure

Synthesis of *(2)*: A mixture of *(1)* (10 mmol), a 20% solution of phosgene in toluene (20 ml), and 2 drops of dimethylformamide is stirred for *ca.* 15 h at room temperature. The solution is then heated to 40—50°C and the toluene removed *in vacuo* simultaneously. The residue is distilled *in vacuo* and stored, or used directly for further syntheses.

Synthesis of (5): A solution of *(2)* (10 mmol) in tetrahydrofuran (10 ml) is added dropwise at 5—10°C under N_2 to a solution of potassium *tert*-butoxide (30 mmol) in dimethylformamide (15 ml) [in the case of *(2f)* dimethyl sulfoxide and 90°C]. 10 minutes after completion of addition the violet to black reaction solution is poured into a 20-fold amount of ice-water and then extracted with ether. After removal of solvent the extract is purified by steam distillation and/or recrystallization.

cyclo-Triarsenic as μ,η-Ligand in Transition-Metal Complexes

By *Massimo Di Vaira, Stefano Midollini, Luigi Sacconi*, and *Fabrizio Zanobini*[*]

On reaction of white phosphorus P_4 with hydrated cobalt(II) and nickel(II) salts in the presence of 1,1,1-tris(diphenylphosphinomethyl)ethane, $CH_3C(CH_2PPh_2)_3$ (triphos), we recently obtained the first metal complexes containing *cyclo*-triphosphorus (δ-P_3) as a ligand[1]. This finding prompted us to

try to synthesize the corresponding complexes of *cyclo*-triarsenic (δ-As_3) by an analogous procedure using yellow arsenic (As_4). Elementary As_4 is extremely unstable and readily converts into the gray form, particularly on exposure to light. To overcome this difficulty we have employed a THF solution of yellow arsenic prepared by an improved method based on that described by *Erdmann et al.*[2].

This As_4 solution reacts smoothly with Co^{II} or Ni^{II} aquo-ions and the trisphosphane in THF/ethanol/acetone solution to give the As_3 complexes of general composition [(triphos)M-μ-(η-As_3)M(triphos)]X_2 (M = Co, Ni; X = BF_4, BPh_4). The new compounds have a triple-decker sandwich structure containing the bridging *cyclo*-triarsenic entity as an internal layer. The salts behave as 1 : 2 electrolytes and are exceptionally air stable, both in the solid state and in solution (acetone, nitroethane, *etc.*). The magnetic moments of both the cobalt and the nickel dinuclear units correspond to the existence of one unpaired electron for each unit.

An X-ray structural investigation has been undertaken on the compound [(triphos)Co-μ-(η-As_3)Co-(triphos)]$(BPh_4)_2$, which crystallizes with two molecules of acetone[3]. The complex cation possesses a triple-decker sandwhich structure in which the *cyclo*-triarsenic unit forms the internal slice

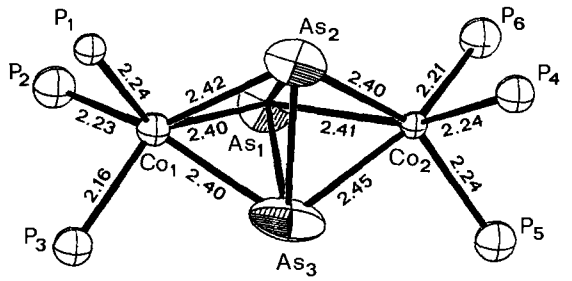

Fig. 1. Structure of the $[(triphos)Co(As_3)Co(triphos)]^{2+}$ dication with bond lengths [Å]. Bond angles: P—Co—P = 90—93°, As—Co—As = 60—61°.

(Figure 1). Each cobalt atom is six-coordinated by the three phosphorus atoms of one triphos ligand and by the three arsenic atoms of the bridging *cyclo*-triarsenic group.

The magnetic moments of these cobalt and nickel complexes, both correspond to a doublet ground state; in a qualitative MO model[4], the highest-occupied orbital (e, C_3-symmetry) contains one and 3 electrons, respectively. The two compounds are classified as 31 and 33-electron triple-decker complexes, 12 electrons being supplied by the donor atoms of the two triphos ligands, 3 by the *cyclo*-triarsenic ligand, the other electrons in the valence shell being provided by the two metal atoms. A mononuclear cobalt complex containing the As_3 ring as ligand, $As_3Co(CO)_3$, had already been synthesized by *Dahl et al.*[5] by reaction of $Co_2(CO)_8$ with $(AsCH_3)_5$.

Procedure

7 g of gray arsenic is heated for *ca.* 90 min at 560—580 °C (cf. [2]). The vapor of yellow arsenic is absorbed at *ca.* 0 °C in 250 ml of THF, the solution filtered and then concentrated to 150 ml in the dark, in a nitrogen stream, at room temperature. To this solution is added 0.680 g (2 mmol) of $Co(BF_4)_2 \cdot 6H_2O$ in 20 ml of ethanol and 1.25 g (2 mmol) of "triphos" in 30 ml of acetone. The resulting mixture is heated in the dark on a water-bath under a stream of nitrogen for 20 min, then concentrated in the light to *ca.* 30 ml by passage of nitrogen. The dark-green crystals which separate are filtered off and then dissolved in 50 ml acetone. To this solution is added 0.680 g (2 mmol) of $NaBPh_4$ in 20 ml ethanol. On concentration of the solution, black-green crystals precipitate. These are filtered off, washed with THF and ethanol, and dried in *vacuo*. Yield 75 %.

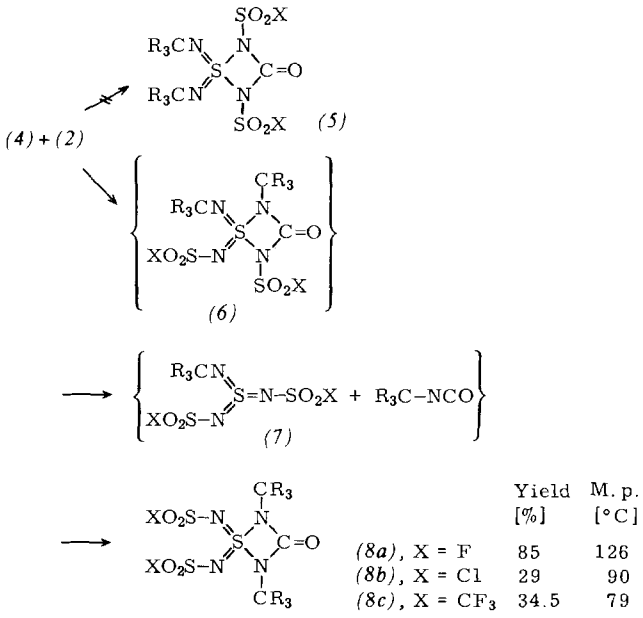
Synthesis of 1λ⁶,2,4-Thiadiazetidin-3-ones from Tris(imido)sulfur(VI) Derivatives and Sulfonyl Isocyanates[**]

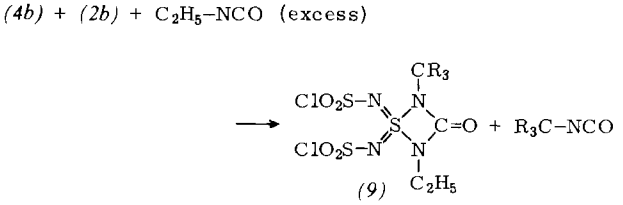
By *Frank-Michael Tesky, Rüdiger Mews, Bernt Krebs*, and *M. Ramakrishna Udupa*[*]

Characteristic reactions of sulfur compounds belonging to the "Y-triene" type $(RN{=})_3S$[1] involve an increase in the coordination number of the central S^{VI} atom[2]. We expected the reaction of the *tert*-butyl derivative *(1)*, R = CH_3, with sulfonyl isocyanates *(2)* to yield the cycloaddition products *(3)*.



However, thiadiazetidinones *(3)* bearing a strongly electronegative substituent on the ring nitrogen are unstable; like their S^{IV} analogs[3] they decompose with elimination of alkyl isocyanate. On reaction of *(1)* with an only slight excess of *(2)*, X = F, Cl, the corresponding monosulfonylimidosulfur(VI) compounds *(4)* can be isolated in good yields. The colorless solids *(4a)*, m.p. 55 °C, and *(4b)*, m.p. 91 °C, are stable for a long time at 0 °C. Thus the possible syntheses of "Y-trienes" $(RN{=})_3S$ are not restricted to derivatives with bulky groups R.

An excess of *(2)* reacts further with *(4)* to give the symmetrical thiadiazetidinones *(8)*.



The formation of *(6)* rather than *(5)* as the next addition product follows from the structure of the final product *(8)*.

Formation of *(9)* in the presence of a large excess of ethyl isocyanate is regarded as evidence for the intermediacy of *(7)*:

Compounds *(8)* were characterized by elemental analysis, as well as mass, IR, and NMR spectra. The ^{1}H- and ^{19}F-NMR spectra contain only singlets [*(8a)*: $\delta_{SF} = +60.7$, $\delta_{CH} = +1.646$; *(8b)*: $\delta_{CH} = +1.646$; *(8c)*: $\delta_{CF} = -78.1$, $\delta_{CH} = +1.625$]; as in other four-membered ring ketones[4], the CO stretching vibrations appear at high wavenumbers [ν_{CO}: *(8a)* 1840, *(8b)* 1842, *(8c)* 1840 cm^{-1}]. The spectroscopic data hardly permit any distinction between *(8)* and *(5)*; it took an X-ray structure analysis performed on *(8a)* to rule out the alternative *(5)*.

(8a) forms orthorhombic crystals [Pnma, $a = 16.075(4)$, $b = 12.990(3)$, $c = 8.071(2)$ Å; at -120 °C: $P2_12_12_1$, $a = 15.936(4)$, $b = 12.794(3)$, $c = 7.934(2)$ Å, $Z = 4$]. The structure was solved from low-temperature diffractometer data by direct methods and refined to $R = 2.8$ %. Figure 1 depicts the molecule with averaged bond parameters. The mutually perpendicular fragments SN=S=NS and C–N<C,S>N–C are almost planar (angles in ring: NSN 79.5(1), SNC 92.0(2), NCN 96.5(2)°).

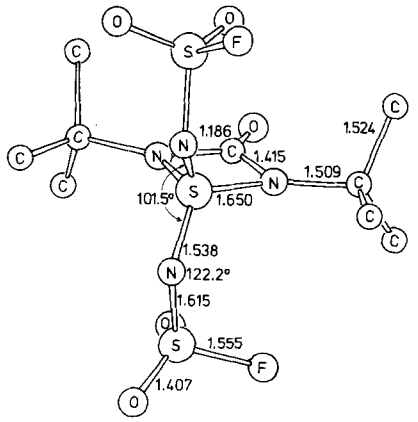

Fig. 1. Molecular structure of crystalline thiadiazetidinone *(8a)* with bond lengths and angles (standard deviation 0.002 to 0.004 Å and 0.2°, respectively).

Procedure

a) Bis(tert-butylimido)halosulfonylimidosulfur(VI) (4): A solution of halosulfonyl isocyanate *(2)* (8.4 mmol) in pentane (60 ml) is added dropwise at +10 °C to *(1)* (2.0 g, 8.16 mmol) in pentane (120 ml). After stirring for 16 h, the resulting colorless solution is decanted from the polymer adhering to the vessel wall and cooled to −100 °C. The precipitated product is filtered off at this temperature under nitrogen. Yield 58 % *(4a)* [NMR: $\delta_{SF} = +54.0$ (s), $\delta_{(CH_3)_3C} = +1.46$ (s); MS: $m/e =$ 271 (2.3 %) M^+] and 63 % *(4b)* [NMR: $\delta_{(CH_3)_3C} = +1.49$ (s); MS: $m/e = 287$ (1.5 %) M^+].

b) 1λ^6,2,4-Thiadiazetidin-3-ones (8): Analogous reaction of *(1)*, but with 24.8 mmol of sulfonyl isocyanate. *(8a)* is purified by sublimation (oil pump vacuum, 50–55 °C); *(8b)* and *(8c)* by crystallization from pentane [MS: M^+ at $m/e = 396$ (2.3 %), 428 (2.0 %), and 496 (1.8 %), respectively].

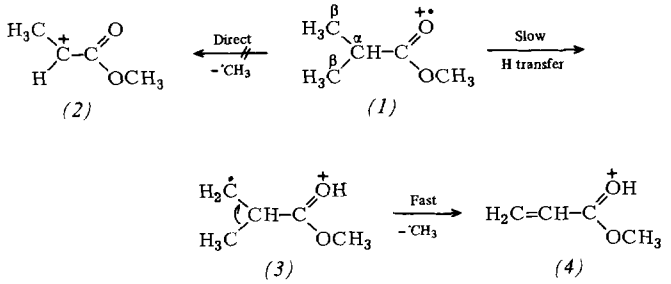
Elimination of CH_3 from the Radical Cation of Methyl Isobutyrate: Fast C—C Cleavage after Rate-Determining H-Migration[**]

By *Chrysostomos Wesdemiotis* and *Helmut Schwarz*[*]



Electron impact induced dissociations, which are actually the result of special neighboring group effects (*e.g.* anchimeric participations[1a] or *ortho*-effects[1b]), have already been reported in the literature on several occasions[1c]. We report here on the first example of a system in which the rupture of a C—C bond cannot be described in terms of a simple homolysis, but rather in terms of an intramolecular, rate-determining H-migration[2].

On electron impact ionization (70 eV) of methyl isobutyrate *(1)* the mass spectrum shows an intense signal for the methyl elimination from $M^{+\bullet}$ (13 % total ion current (TI)). In the case of unimolecular dissociation of *metastable* molecular ions of *(1)* the intensity increases to 77 %. In accord with theoretical predictions[3] this would indicate that the CH_3 elimination must be particularly favorable energetically and *cannot* proceed *via* a simple α-cleavage with formation of an energy-rich α-ketocarbenium ion *(2)*. Experiments with ^{13}C- or ^{2}H-labeled methyl isobutyrates *(1a)*—*(1d)* confirm (i) that the

[*] Prof. Dr. H. Schwarz, Dipl.-Chem. C. Wesdemiotis

[**] This work was supported by the Fonds der Chemischen Industrie and the Gesellschaft von Freunden der Technischen Universität Berlin.

carbon atom of the eliminated methyl radical stems *specifically* from a β-C atom and (ii) that the hydrogen of the neutral moiety derives almost exclusively from the β-methyl group. Slight contributions from the ester function can be attributed to incomplete H/D exchange in $M^{+\bullet}$. The fact that formation of $^{\bullet}CD_3$ predominates (66 % together with 9 % $^{\bullet}CD_2H$) over that of $^{\bullet}CH_3$ (25 %) in the unimolecular decomposition of *(1d)* cannot be explained in terms of a *secondary* inverse kinetic isotope effect, since this would be at least an order of magnitude smaller[4].

(2) *(1)* *(3)* *(4)*

Assumption that the elimination of a methyl group from *(1)* proceeds in *two steps* would provide a plausible explanation for all the experimental findings. In the *rate-determining* step a hydrogen atom is transferred from a β-methyl group to the ionized carbonyl group, thus generating the reactive intermediate *(3)*. This is followed by *fast* radical-induced homolysis *(3)* → *(4)*; the protonated methyl acrylate *(4)* is relatively stable in comparison with *(2)*. If, however, the H-transfer *(1)* → *(3)* is rate-determining for the overall reaction then in the case of *(1d)* the reactive intermediate *(3)* ought to be generated preferably by H-transfer over D-transfer—with the consequence that *mainly* $^{\bullet}CD_3$ will be eliminated (after H-transfer) and *to a lesser extent* $^{\bullet}CH_3$ (after D-transfer). Precisely this is observed (Table 1).

Table 1. Unimolecular methyl-elimination from methyl isobutyrate, with and without isotopic labeling [a].

		$^{12}CH_3$	$^{12}CD_3$	$^{12}CD_2H$	$^{12}CDH_2$	$^{13}C^{1}H_3$
$(CH_3)_2CHCOOCH_3$	*(1)*	100	—	—	—	—
$(^{13}CH_3)_2CHCOOCH_3$	*(1a)*	—	—	—	—	100
$(^{13}CH_3{}^{12}CH_3)CHCOOCH_3$	*(1b)*	52	—	—	—	48
$(CH_3)_2CHCOOCD_3$	*(1c)*	97	—	—	3	—
$(CD_3CH_3)CHCOOCH_3$	*(1d)*	25	66	9	—	—

[a] The data quoted in % (average value of 5 measurements) are based on total methyl-elimination (= 100 %); the measurements were carried out using the MIKES-technique [8] (mass spectrometer: Varian MAT 311 A).

A further experimental indication that the cleavage of methyl from *(1)* proceeds in two steps is afforded by a peak-shape analysis of the kinetic energy release (T_{kin}) in the unimolecular dissociation of metastable ions. Theoretically[3, 5], for a multistep reaction in which the actual decomposition is preceded by a rate-determining isomerization, T_{kin} ought to be greater than for analogous reactions which proceed in one step or in which the isomerization is not rate-determining. The measured T_{kin} value of 0.9 kcal·mol^{-1} is at least an order of magnitude too large for a simple C—C cleavage[3b, 6]; however, it lies in the range that would appear to be typical for dissociation processes in which either extremely stable product ions are generated[6] or the actual bond rupture is initiated by H-transfer[1b, 7].

Definite proof that the $[M-CH_3]^+$ ion of *(1)* (*m/e* = 87) has the structure *(4)* is provided by collision activation spectroscopy (CA spectroscopy[9]): the CA spectrum of the ion of *(1)* with *m/e* = 87 is identical with that of an independently generated ion of structure *(4)* (fingerprint criterion) and shows the structure-specific fragments for *(4)*, *e.g.* $H_2C{=}\overset{+}{C}H$.

Reactions of Nucleosides with the Triphenylphosphane/Diethyl Azodicarboxylate System[**]

By *Rudolf Mengel* and *Michael Bartke*[*]

Oxidation-reduction condensations with the triphenylphosphane/diethyl azodicarboxylate (TPA) system have recently found wide application[1-4], *inter alia*, in the esterification of alcohols. It is assumed that alkoxyphosphonium ions are formed as intermediates which react as strong alkylating agents with nucleophiles[2].

[*] Priv.-Doz. Dr. R. Mengel, M. Bartke

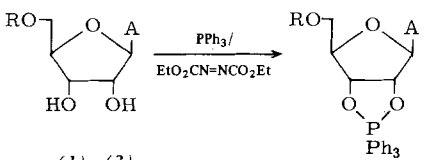
[**] Nucleoside Transformations, Part 8. Lecture at the Chemiedozententagung in Berlin, April 1978. – Part 7: *R. Mengel, W. Guschlbauer*, Angew. Chem. *90*, 557 (1978); Angew. Chem. Int. Ed. Engl. *17*, 525 (1978).

We have now investigated the reaction of TPA with compounds containing several hydroxyl groups in various configurations and of differing functionality; for example, the 9-(β-D-furanosyl)adenine derivatives *(1)*, *(3)*, *(5)*, and *(7)*.

According to *Mitsunobu*, reaction of adenosine *(1)* with TPA affords a 3′,5′-phosphorane[4e]. This structure is consistent with molecular models, and reactions with benzoic acid and thiobenzoic acid, which lead to the 5′-*O*-acyl derivatives.

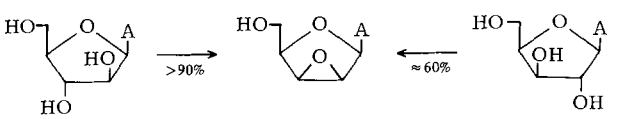


We have repeated the reaction of *(1)* with TPA and confirmed the previously quoted melting point of the product[5]. However, the NMR spectroscopic data favor the 2′,3′-phosphorane structure *(2)*:

a) The ^{1}H-NMR spectrum ([D$_6$]DMSO) shows a triplet at $\delta = 5.2$, which merges to a broad singlet on irradiation of the mean H$^{5'a}$, H$^{5'b}$ frequency and disappears on addition of D_2O.

b) In the ^{31}P-NMR spectrum ([D$_6$]DMSO) a signal is observed at $\delta = +26.6$ (standard: 85 % phosphoric acid), which lies in the region characteristic for triphenylphosphoranes.

c) Decoupling experiments reveal P—H coupling with H$^{2'}$ and H$^{3'}$, but not with H$^{5'a}$ or H$^{5'b}$.



d) The phosphorane *(2)* can be acylated with benzoyl chloride/pyridine to 5′-*O*-benzoyladenosine *(3)*, which reacts with TPA to give the phosphorane *(4)* (^{31}P-NMR: $\delta = +26.5$).

(1), *(3)* *(2)*, *(4)*

(1), *(2)*: R = H; *(3)*, *(4)*: R = PhCO; A = Adenyl

The question now was how do the furanosyl derivatives of adenine containing *trans* hydroxyl groups react? Reaction of 9-(β-D-arabinofuranosyl)adenine *(5)* with TPA for 40 min at 70 °C affords the epoxide *(6)* in almost quantitative yield[5]. This constitutes the simplest route to this epoxide[6a], whose ring-opening affords biochemically interesting derivatives[6b] and whose previous syntheses involved several steps. On the other hand, reaction of 9-(β-D-xylofuranosyl)adenine *(7)* with TPA also yields *(6)*; however, a much longer reaction time (6 hours) is required.

(5) *(6)* *(7)*

The above results have been confirmed in the case of *cis*- and *trans*-cyclohexanediols. On reaction with TPA, the *trans* isomer affords cyclohexane epoxide; the ^{31}P-NMR spectrum gave no indication of the presence of an intermediate. *Mitsunobu* likewise obtained the epoxide, though in this case the reaction was carried out in the presence of benzoic acid (2 h, room temperature)[4a]. *Zbiral* and *Loibner* carried out the reaction in the presence of *p*-nitrobenzoic acid and isolated *trans*-2-hydroxycyclohexyl-*p*-nitrobenzoate[3a]. This finding is also reconcilable with an epoxide as intermediate which undergoes ring-opening under the reaction conditions (14 h, reflux).

In the reaction of *cis*-cyclohexanediol with TPA we could demonstrate by means of the ^{31}P-NMR spectrum that the phosphorane postulated by *Mitsunobu* is in fact formed: $\delta = +39$ ppm (standard: 85 % phosphoric acid).

Procedure

Reaction of *(1)*, *(3)*, *(5)*, and *(7)* with TPA: A mixture of the nucleoside and 1.5 equivalents of triphenylphosphane in anhydrous dioxane is stirred for 10 min at 70 °C under N_2. Diethyl azodicarboxylate (1.5 equivalents) diluted with dioxane is then added dropwise and the mixture stirred for a further 40 min at 70 °C.

Workup of *(2)*: After cooling, the reaction product is separated on a glass frit under N_2, washed with a few milliliters of dioxane, and finally recrystallized from dioxane under N_2 (yield: 78 %).

Synthesis of *(3)*: *(2)* (0.53 g, 1 mmol) is dissolved in anhydrous pyridine (30 ml) under N_2. The solution is treated dropwise with 0.135 ml (1.15 mmol) benzoyl chloride, stirred for 60 min at room temperature, and then poured over 300 g ice. The resulting ice-cold solution is extracted with ethyl acetate (3 × 50 ml) and the combined organic phases dried over Na_2SO_4 and finally evaporated down. The residue is then purified by preparative thin-layer chromatography (silica gel plates 20 × 40 × 0.2 cm, eluent chloroform/methanol 4:1). Yield of *(3)*: 0.27 g (72 %).

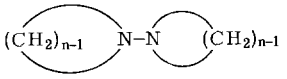
Synthesis and Conformation of 1,1′-Biazetidinyl

By *Karl Kirste, Wolfgang Lüttke*, and *Paul Rademacher*[*]



Hydrazine *(1)* and acyclic organic hydrazines have been shown to exist in the *gauche* form. This also applies for the unstrained 1,1′-bipiperidyl *(3d)*, whose conformation[1] corresponds to that of the tetramethylhydrazine *(2)*. For gaseous 1,1′-bipyrrolidinyl *(3c)* a mixture of *s-trans/gauche* conformers has been detected[1]. In contrast 1,1′-biaziridinyl *(3a)* assumes the *s-trans* conformation in all three aggregate states[2].

In order to examine how the conformation of the hydrazines *(3)* depends upon their ring size we synthesized the previously unknown 1,1-biazetidinyl *(3b)* and subjected it to a conformational analysis.

(1), R = H
(2), R = CH_3

(3a), n = 3; *(3b)*, n = 4
(3c), n = 5; *(3d)*, n = 6

All attempts to synthesize *(3b)* in an analogous way to *(3a)* and *(3c)* or *(3d)* met without success, but we were able to prepare it by photolysis of bis(trimethylene)tetrazene *(4)* in a steady state system in the gas phase[3]. *(4)* itself was prepared by gentle oxidation of 1-aminoazetidine *(5)*. Thus, an aminoazetidine was oxidatively dimerized for the first time, avoiding the nitrogen cleavage[4] otherwise observed. Pyrolysis of *(4)* in a dynamic gas-phase system at 300 °C did not lead to *(3b)*, but in 39 % yield to (1-azetidinyl)acetonitrile *(6)*, whose structure could be confirmed by an independent synthesis from azetidine *(7)* and chloroacetonitrile.

To determine the conformation of *(3b)* we recorded an IR spectrum of the liquid phase and Raman spectra of the liquid and solid (−100 °C) phases. For the centrosymmetric *s-trans* conformation with C_{2h} symmetry, 27 Raman and 27 IR lines without frequency-coincidence are to be expected; for all *gauche* forms with C_2 symmetry, 54 IR and 54 Raman lines with frequency-coincidence are to be expected.

The Raman spectrum of crystalline *(3b)* shows the requisite 27 lines for the *s-trans* form. Comparison of the IR and Raman spectra of liquid *(3b)* also demonstrates the validity of the exclusion rule for this conformation. This finding was supported by assignment of the vibrational spectra of *(3b)*, which correlated with those of *(4)* and *(7)*[3].

The Raman spectrum of liquid *(3b)* contains 17 additional lines, all of which coincide with IR bands of the liquid. It thus follows that a further conformer is present in the liquid phase in addition to the *s-trans* conformer. From the intensities of the lines it can be estimated that the *s-trans* form predominates.

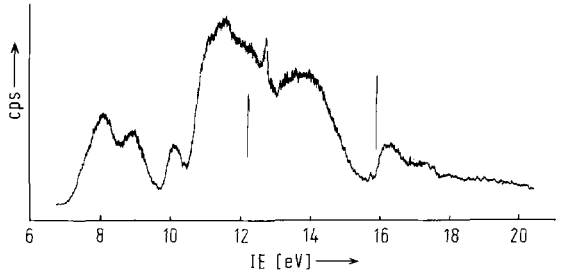

Fig. 1. PE spectrum of *(3b)*. The spectrum was recorded with a high-resolution photoelectron spectrometer (Model PS 16, Perkin-Elmer Ltd., Beaconsfield England; radiation source: He-I lamp, 21.22 eV).

We have been able to infer the conformation of gaseous *(3b)* from its PE spectrum (Fig. 1). In the region below 11 eV there appear three bands and a shoulder which can be ascribed to the ionization of electrons from the orbitals of the lone pair. The number of bands proves that two conformers are present[5], and their splitting patterns indicate, with the aid of a well-substantiated relationship between ionization potentials and dihedral angles of hydrazines[6], that they are the *s-trans*- ($\varphi = 180°$) and *gauche* conformers ($\varphi = 64°$). The splitting of 2.35 eV found for the *s-trans* form is only slightly smaller than that in *(3a)*.

Not only is twisting about the central N—N bond possible in *(3b)*, but also folding of the four-membered rings, leading to three inversion isomers analogously as in the isoelectronic hydrocarbon biscyclobutyl[7]. As yet we can only rule out the non-centrosymmetric *s-trans* inversion isomer in the solid phase.

In the case of *(3b)* all the hydrazines of type *(3)* with $n = 3$ to 6 have so far been demonstrated. Investigations have shown that the transition from the *s-trans* to the *gauche* form continuously takes place in the series *(3a)*, *(3b)*, *(3c)*, *(3d)*. Even highly strained compounds such as *(3b)* have a strong tendency to assume the *gauche* form.

Procedure

1-Aminoazetidine *(5)*: A solution of hydroxylamine *O*-sulfonic acid (22.6 g, 0.2 mol) in water (100 ml) is added dropwise at 0 °C to a stirred solution of *(7)* (57 g, 1 mol) and NaOH (40 g) in 400 ml water. After 1 h, three further portions of NaOH (each of 40 g) are added to the mixture. The organic phase is separated off and treated with powdered KOH until no water can be detected NMR spectroscopically. Fractional distillation (25 °C/22 torr) yields 6.9 g (26 %) *(5)*.

Bis(trimethylene)tetrazene *(4)*: To an ice-cooled solution of 0.66 ml conc. HCl and 0.5 g starch in 400 ml water under nitrogen is added 0.5 g (7 mmol) *(5)* and then 0.12 mol $Mg(OH)_2$. The mixture is titrated with a solution of 1.94 g (15.3 mmol) iodine and 5 g KI in 150 ml water. As soon as the end point is reached the solution is rendered alkaline with a solution of 8 g NaOH and 0.2 g $Na_2S_2O_3$ in 40 ml water, extracted three times with 80 ml pentane, and the combined extracts distilled after drying over $MgSO_4$. A single redistillation affords 0.15 g (31 %) *(4)*.

1,1'-Biazetidinyl *(3b)*: 100 mg (0.7 mmol) *(4)* is transferred to a 250 ml round-bottom flask and heated in an air-bath to 95 °C. After two hours' irradiation with a high-pressure mercury-vapor lamp (Hanovia 679A36) the contents of the flask are carefully redistilled. Subsequent gas-chromatographic separation (OV-210 column temperature 150 °C) furnishes 17 mg (21 %) pure *(3b)*.
