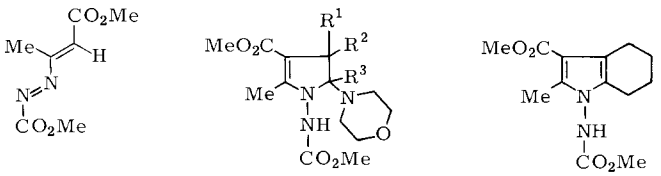
Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] Reactions with Azo Compounds, Part 6.—Part 5: [2].

The pyridazine structure *(7)*, which cannot be disregarded *a priori*, is ruled out on the grounds of the ^{13}C-NMR spectrum: it shows only two signals for the four pyrrole C-atoms

[δ(C-4a, C-4b) = 112.8, δ(C-8a, C-9a) = 126.4, [D$_6$]-DMSO/TMS].



Reaction of *(1c)*[3] with *(2b)* leads to the *N*-amino-2-pyrroline *(8a)* [95%, m.p. 123—124 °C, IR (KBr): ν(NH) = 3220 cm^{-1}]. It is plausible to assume that compounds of type *(8)*

(1c) *(8a)* *(4d)*

are formed as intermediates in the conversion of *(3)* into *(4)*. Like *(3)*, on heating above the melting point *(8a)* forms an *N*-aminopyrrole *(4d)* (Table 1).

On the basis of these results the enamine adducts of *(1d)* obtained previously, which were described as pyridazine derivatives[2], should be regarded as *N*-amino-2-pyrrole derivatives *(8b)* [86%, m.p. 127 °C] and *(8c)* [70%, m.p. 140 °C] and as the *N*-aminopyrrole derivative *(4e)* [32% referred to *N*-morpholino-1-cyclohexene *(2d)* for *(1d)*:*(2d)* in the ratio 1:2, m.p. 125 °C].

(1d) *(8b)*, R^1 = H, R^2–R^3 = –(CH$_2$)$_3$– *(4e)*
(8c), R^1 = R^2 = Me, R^3 = H

The compounds *(3)*, *(4)*, *(6)* and *(8)* gave correct CHN analyses, and IR, ^{1}H-NMR, ^{13}C-NMR and mass spectra in accord with the given structures[7].

[4+2]-Cycloadditions of Azoalkenes to Azodicarbonyl Compounds. A Novel Facile Route to the 1,2,3,4-Tetrazine System[**]

By *Sven Sommer* and *Ulrich Schubert*[*]

Aromatic 1,2,3,4-tetrazines have so far not been synthesized. This also applies in the case of nine of the total of ten possible partially or completely hydrogenated forms[1]. All previously known routes to this system lead exclusively to derivatives of 1,4,5,6-tetrahydro-1,2,3,4-tetrazine[1c,2]. Only in a few cases have yields of up to 50% been reported.

The ability of azoalkenes (1,2-diaza-1,3-butadienes) *(1)* to form [4+2]-cycloadducts with electron-deficient double bond systems[3] now opens up a novel simple entry to the 1,2,3,4-tetrazine system. Azoalkenes *(1)* react with the azodicarbonyl compounds *(2)*[4] (1:1 in benzene or tetrahydrofuran at room temperature) to give derivatives of the 1,2,3,6-tetrahydro-1,2,3,4-tetrazine *(3)* in good yields (Tables 1 and 2). The duration of reaction lies between *ca.* three hours and four days; acceptor substituents on *(1)* decrease the rate of reaction.

(1) *(2)* *(3)*

Table 1. 1,2,3,6-Tetrahydro-1,2,3,4-tetrazines *(3)* from azoalkenes *(1)* [a] and azodicarbonyl compounds *(2)* [a]. The yields refer to pure isolated compounds.

	R^1	R^2	R^3	R^4	Yield [%]	M.p. [°C]
(a)	Ph	(CH$_2$)$_4$		OMe	77	132 [b]
(b)	4-Br C$_6$H$_4$	(CH$_2$)$_4$		OMe	79	162—163 [c]
(c)	Ph	(CH$_2$)$_4$		OPh	90	161—162 [d, h]
(d)	Me	(CH$_2$)$_4$		OCH$_2$CCl$_3$	81	95—96 [e]
(e)	Me	Me	H	OCH$_2$CCl$_3$	80	68—69 [e]
(f)	Me	Me	PhNHCO	OMe	79	131—133 [f, h]
(g)	Me	Me	PhNHCO	OC(CH$_3$)$_2$CCl$_3$	72	176—177 [g, h]
(h)	Me	Me	H	Ph	34	133—134 [e]

[a] With the exception of *(1f)*, all the azoalkenes used have been described in the literature. Synthesis of *(1f)* [m.p. 131—133 °C (dec.), yield 44%]: *S. Sommer et al.*, unpublished.—With the exception of *(2g)*, all compounds *(2)* have been described in the literature. *(2g)* m.p. 173—174 °C (petroleum ether 60—90 °C), yield 85% was prepared from the corresponding *N,N'*-hydrazine dicarboxylate [m.p. 145—146 °C (ethanol/H$_2$O), yield 96%] by oxidation with HOCl following the method of *N. Rabjohn* (Org. Synth. Coll. Vol. III, 1955, 375). *(2g)*: ^{1}H-NMR (CDCl$_3$) 2.13 (s, C(CH$_3$)$_2$CCl$_3$); IR (KBr): ν(C=O) = 1784 cm^{-1}. [b] Ethyl acetate/petroleum ether 40—80 °C. [c] CHCl$_3$/petroleum ether 40—80 °C. [d] Benzene/petroleum ether 40—80 °C. [e] CH$_3$OH. [f] Tetrahydrofuran (THF). [g] THF/ether. [h] Decomposition.

Proof of the structure of adducts *(3)* is based on correct CHN analyses (within 0.3%), spectral data and an X-ray structure analysis. Except in the case of *(3f)* and *(3g)* (CO NHPh), no NH bands appear in the IR spectra. The weak C N band is comparable with the C N band of 1,4,5,6-tetrahydropyridazines[5]. The ^{13}C-NMR signal observed between δ = 147 and 157—in the region of the ^{13}C N

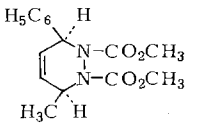
Table 2. Some spectroscopic data of compounds *(3)*. ^{1}H- and ^{13}C-NMR spectra in $CDCl_3$ with TMS as internal standard, δ values, coupling constants [Hz]. IR spectra in KBr, ν [cm^{-1}].

(3a), ^{1}H-NMR: 3.72 (s, OCH_3), 3.79 (s, OCH_3), 4.35 (br. dd, $J \approx 5$ and 11, CHN); ^{13}C-NMR: 53.4, 54.5 (2 OCH_3), 54.9 (CHN), 153.8, 154.6, 156.1 (2 C=O, C=N); IR: 1630 (C=N), 1725, 1755 (C=O)

(3b), ^{1}H-NMR: 3.79 (s, OCH_3), 3.85 (s, OCH_3), 4.4 (br. dd, $J = 5.0$ and 11.0, CHN); ^{13}C-NMR: 53.6, 54.8 (2 OCH_3), 54.8 (CHN), 154.1, 154.6, 155.9 (2 C=O, C=N); IR: 1630 (C=N), 1742, 1760 (C=O)

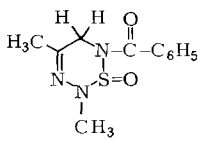
(3c), ^{1}H-NMR: 4.53 (br. dd, $J = 5.0$ and 11.5, CHN); ^{13}C-NMR: 55.2 (CHN), 152.5, 153.7 (2 C=O, C=N); IR: 1630 (C=N), 1750 (C=O)

(3d), ^{1}H-NMR: 3.01 (s, NCH_3), 4.41 (m, CHN), 4.58, 5.09 (AB spectrum, $J_{AB} = 12.0$, CH_2CCl_3), 4.75, 4.98 (AB spectrum, $J_{AB} = 12.0$, CH_2CCl_3); ^{13}C-NMR: 43.6 (NCH_3), 54.1 (CHN), 75.4, 75.8 (2 CH_2CCl_3), 94.8 (2 CCl_3), 152.3, 156.8 (2 C=O, C=N); IR: 1628 (C=N), 1720, 1750 (C=O)



(3e), ^{1}H-NMR: 1.99 (s, CH_3C=N), 3.07 (s, NCH_3), 3.99, 4.40 (AB spectrum, $J_{AB} = 18.5$, CH_2N), 4.65, 5.05 (AB spectrum br., $J_{AB} = 12.0$, CH_2CCl_3), 4.73, 5.02 (AB spectrum, $J_{AB} = 12.0$, CH_2CCl_3); ^{13}C-NMR: 21.3 (CH_3C=N), 43.2 (CH_2N), 44.5 (NCH_3), 75.5, 75.9 (2 CH_2CCl_3), 94.6 (2 CCl_3), 148.6, 152.5, 153.2 (2 C=O, C=N); IR: 1635 (C=N), 1740 (C=O)

(3f), ^{1}H-NMR: 2.29 (s, CH_3C=N); 3.03 (s, NCH_3), 3.88 (s, 2 OCH_3); 5.22 (s, CHN), 9.82 (s, NH); ^{13}C-NMR: 23.1 (CH_3C=N); 44.1 (NCH_3), 54.7, 54.9 (2 OCH_3), 59.2 (CHN), 147.0, 155.2 (2 C=O, C=N), 163.3 (CONH); IR: 1620 (C=N); 1689 (O–C–NHPh), 1719, 1735 (sh) (C=O)? 3320 (NH)



(3g), ^{1}H-NMR: 1.91 (s, 1 CH_3, ester), 2.02 (s, 3 CH_3, ester), 2.32 (s, CH_3C=N), 3.11 (s, NCH_3), 5.25 (s, CHN), 9.83 (s, NH); ^{13}C-NMR: 21.3 (1 CH_3, ester), 21.6 (3 CH_3, ester), 23.3 (CH_3C=N), 44.7 (NCH_3), 58.5 (CHN), 91.4 (2 $C(CH_3)_2CCl_3$), 105.3 (2 CCl_3), 144.7, 151.8 (2 C=O, C=N), 163.0 (CONH); IR: 1620 (C=N), 1690 (O–C–NHPh), 1722, 1740 (sh) (C=O), 3340 (NH)

(3h), ^{1}H-NMR: 1.90 (s, CH_3C=N), 2.79 (s, NCH_3), 4.20, 4.80 (AB spectrum, $J_{AB} = 18.5$, CH_2N); ^{13}C-NMR: 22.0 (CH_3C=N), 42.0 (CH_2N), 43.9 (NCH_3), 152.9 (C=N); 172.1, 173.6 (2 C=O); IR: 1637 (C=N), 1665, 1685 (C=O)

signals of hydrazones[6]—together with the signals of the two CO groups confirms the presence of a C=N group. Since the C=O signals appear further downfield in the spectrum of *(3h)* the assignment of δ(^{13}C=N) is unequivocal in this case.

(4)

(5)

The positions of these signals also rule out [3+2]-cycloadducts[7]. The strong IR bands between $\nu = 1720$ and 1760 cm^{-1} for the ester CO-groups of *(3a–g)* lie in the C=O absorption region of cyclic *N,N'*-hydrazinedicarboxylates [ν(CO) = 1710–1760 cm^{-1}][8a]; an example is *(4)* [ν(KBr) = 1718 and 1739 cm^{-1}]. The positions of the ^{1}H-NMR signals of the methoxycarbonyl protons of *(3a, b, f)* ($\delta = 3.7$–3.9) are also in good agreement with the corresponding δ-values of dimethyl esters[8b] such as *(4)*. Essential evidence for the six-membered ring and 1,2,3,4-tetrazine structure is provided by the fact that the geminal coupling constants of the ring protons in *(3h)* and *(5)* are of the same magnitude[3c].

For final proof of the structure, an X-ray structural analysis was carried out on *(3a)* (Fig. 1). This confirmed the proposed structure and showed that the 1,2,3,4-tetrazine ring in the crystal assumes a slightly distorted half chair conformation: N(3) lies 41 pm below, and N(4) 17 pm above the C(2) C(1)–N(1)–N(2) plane. 1,4-Dimethyl-1,4,5,6-tetrahydro-1,2,3,4-tetrazine 2-oxide[2f], on the other hand, has a distorted pyramidal conformation. While N(2) and N(3) are pyramidally configurated, N(4) is coplanar with the atoms to which it is bound, thus indicating conjugation of N(4) with the methoxycarbonyl group. This is confirmed by the significantly shorter N(4)–C(9) bond as compared with the N(3)–C(7) bond, as well as by the finding that the plane of the atoms around C(9) is rotated through an angle of only 9.4° from the plane of the atoms around N(4) (at N(3): 33.9°). The NN bond lengths are of the usual order, if one takes into consideration the nature of the substituents and the state of hybridization of the nitrogen atoms[9].

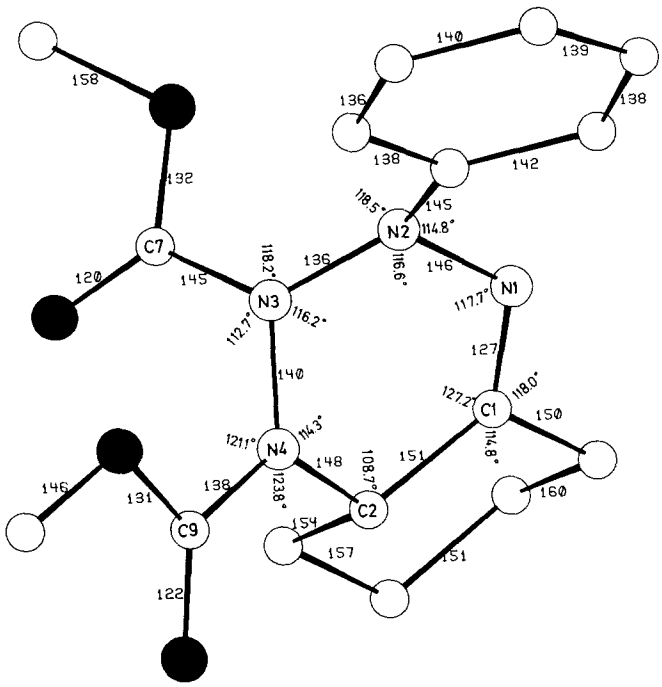


Fig. 1. Molecular structure of *(3a)*. The standard deviations are 1 pm for the bond lengths and 0.7° for the angles. 1487 structure factors ($F_o \geq 5.0\sigma(F_o)$). Syntex $P2_1/XTL$, $Mo_{K\alpha}$ radiation ($\lambda = 71.069$ pm), $2° \leq 2\theta \leq 40°$; $R = 0.109$. Triclinic, space group $P\bar{1}$, $a = 837(1)$, $b = 1092(1)$, $c = 1234(1)$, $\alpha = 100.29(8)$, $\beta = 91.04(7)$, $\gamma = 80.43(8)$, $Z = 2$, $V = 1095 \times 10^6$ pm^3, ρ(calc.) = 1.37 g/cm^3. The unit cell contains two molecules of $CDCl_3$ (not shown), which are strongly disordered.—A list of the atomic coordinates and structural factors are obtainable on request *(U. Sch.)*.

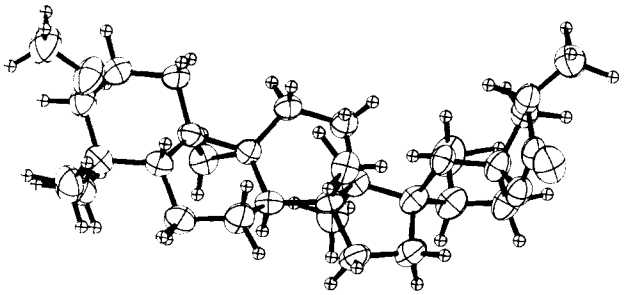
Abietospiran, the Triterpene from the Bark of the White Fir *(Abies alba)*

By *Wolfgang Steglich, Manfred Klaar, Lothar Zechlin,* and *Hans Jürgen Hecht*[*]

Dedicated to Professor Alfred Treibs on the occasion of his 80th birthday

On work-up of fruiting bodies of the fungus *Hymenochaete mougeotii* we recently isolated a triterpene, $C_{31}H_{48}O_4$, characterized by an IR band (KBr) at 1785 cm^{-1}[1]. A re-investigation showed that the compound arises from adhering particles of bark of the white fir (*Abies alba* Mill.) on which it forms a crystalline coating responsible for the silver-gray color of the bark.



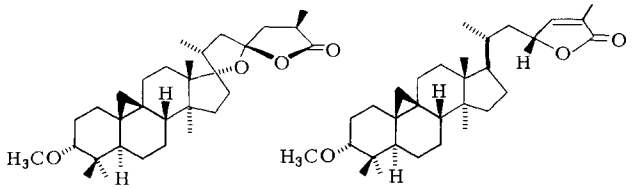


Fig. 1. Molecular structure of abietospiran (for the sake of clarity the enantiomer of formula *(1)* is shown).

The triterpene *(1)*, which we call abietospiran, can be readily obtained in a pure state by extraction of the topmost layer of the bark with light petroleum and recrystallization from ethyl acetate (*ca.* 0.14 g/g of bark). Its structure was determined by single-crystal X-ray structure analysis[2] (Fig. 1).

(1) *(2)*

(1) is closely related to cyclograndisolide *(2)* from the bark of *Abies grandis*[3]; hence we assign *(1)* the same absolute configuration. A 9(11)-dehydrolanostane derivative was recently isolated from needles of the white fir[4].

Isolation procedure

On Soxhlet extraction with light petroleum (40—60 °C, 2 d), a sample of the topmost layer of bark of *Abies alba*[5] (34.4 g) afforded 6.3 g of a crude substance, which yielded 4.9 g of *(1)* on recrystallization from ethyl acetate; m. p. 219—221 °C, $[\alpha]_{589}^{22}$ −16.8° (*c* = 0.68 in $CHCl_3$); IR (KBr): 1785 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ = 0.34, 0.47 (AB system, *J* = 4 Hz, cyclopropyl H), 0.86, 0.92, 1.03, 1.17 (each s, C—CH_3), 1.01, 1.24 (each d, *J* = 7 Hz, CH—CH_3), 2.84 (br. s, half-width 5 Hz, 3-H), 3.33 (s, OCH_3).

Crystal Structure of Na_3NO_4[**]

By *Martin Jansen*[*]

The Raman spectra of Na_3NO_4 and K_3NO_4 were interpreted assuming the presence of NO_4^{3-} groups[1]; in contrast to Na_3NO_3[2], therefore, those compounds can be regarded as "ortho salts". This is the first deviation from the pronounced tendency of oxoanions of first-row nonmetals to achieve low coordination numbers by forming multiple bonds, in contrast to their higher homologs. It thus appeared appropriate to confirm the results of vibrational spectroscopy by X-ray structure analysis, especially since no precise information was available about the dimensions of the NO_4^{3-} ion.

Growth of crystals was made difficult by the high reactivity and the thermal sensitivity of Na_3NO_4: addition of fluxes or solvents effected decomposition; temperatures above 500 °C led to attack of the crucible material owing to the basic and oxidizing properties of the orthonitrates. Long-term experiments at a maximum temperature of 415 °C finally proved successful. Several silver crucibles were filled with microcrystalline Na_3NO_4[1], closed with stoppers, and individually sealed into glass ampoules under argon. They were placed together in a crucible furnace and heated to 415 °C (heat-up rate 10 °C/h). The changes in degree of crystallization of the samples were examined by removal of one crucible at a time at intervals of 60 d. After 240 d, a size adaquate for single-crystal studies has been reached (diam. ≈ 0.1 mm); the slowly cooled samples (2.5 °C/h) contained crystals that appear free from defects on examination by optical and X-ray methods.

Structural analysis[3] proves the existence of tetrahedral orthoanions in solid Na_3NO_4. In view of the site symmetry 1,

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the dimensions of the NO_4^{3-} group are remarkably regular: T_d symmetry is present within the limits of error (cf. Table 1). The coefficients of the anisotropic temperature factors can be reasonably interpreted assuming librational motion of rigid NO_4^{3-} ions[4]; correspondingly corrected distances are also listed in Table 1.

The N—O distances are unexpectedly small; they lead to the shortest known contacts (226 pm) between oxygen particles not directly linked together. Considering the coordination number of N, a length of *ca.* 150 pm would be estimated for the N—O single bond. A value calculated approximately for the equilibrium distance by the EHMO method is of the same order of magnitude (151 pm)[5]. The only possible reason for the significant shortening to 139 pm lies in polar interactions superimposed on the single bond. This result emphatically demonstrates that pd-π bonding contributions[6] need not be invoked in explaining the bond lengths in oxoanions such as PO_4^{3-}, SO_4^{2-}, or ClO_4^-!

Molecular Structure and Spectroscopic Properties of Kekulene[1]

By *Claus Krieger, Francois Diederich, Dieter Schweitzer,* and *Heinz A. Staab*[*]

Kekulene *(1)*, the synthesis of which was recently reported[2], is the first example of a new class of aromatic compounds in which the annellation of six-membered rings leads to a cyclic system enclosing a cavity lined with hydrogen atoms. Compound *(1)*, for which 200 Kekulé structures with different arrangements of double and single bonds can be formulated[3], was of interest with regard to π-electron delocalization and the related problem of the diatropicity in the macrocyclic system for which, as long ago as 1951, different theoretical approaches were shown to lead to contradictory predictions in the specific case of *(1)*[4]. Experimentally, the ^{1}H-NMR absorption of the internal hydrogens did not show any evidence for a diatropicity in the macrocyclic system[2], in qualitative agreement with MO calculations of chemical shifts[4, 5]. In this context, and in connection with some spectroscopic properties of *(1)*, the determination of the molecular structure of kekulene by X-ray analysis was of special interest.

(1)

(1) crystallized from pyrene (purified by zone-melting) in a tube sealed under high-vacuum on slow cooling from 450 to 350 °C. Removal of pyrene by high-vacuum sublimation and washing the crystals with chloroform yielded yellow monoclinic needles suitable for a structure analysis [crystal size $0.05\times0.08\times0.4$ mm; space group C2/c; $a=2799(3)$, $b=458.7(5)$, $c=2271(2)$ pm, $\beta=109.6(1)°$, $Z=4$, $\rho_{calc.}=1.45$ g·cm^{-3}; $Mo_{K\alpha}$ radiation, 1596 observed reflections, $R=0.056$].

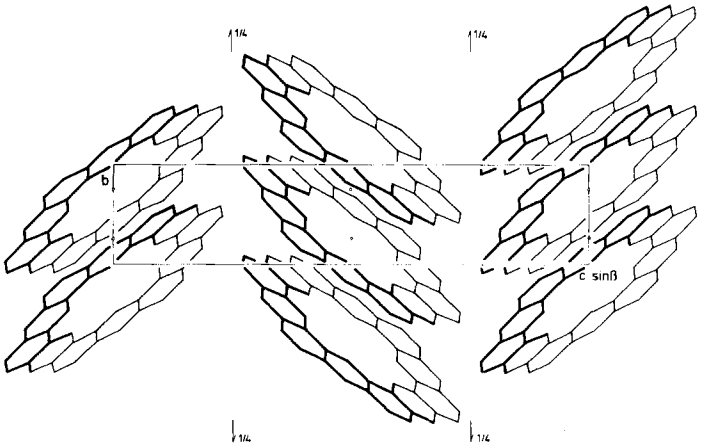

Fig. 1. Lattice structure of *(1)* as projected along the *a* axis (the rear half of the unit cell is not drawn).

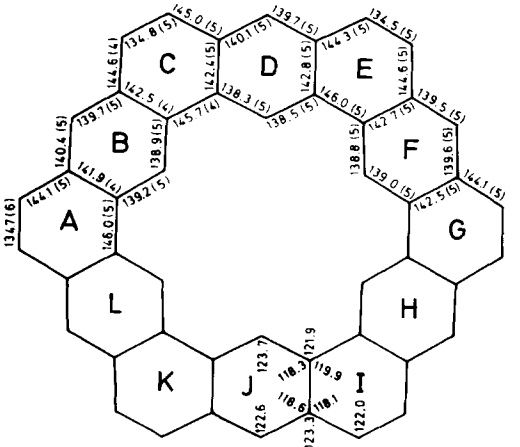
In the crystal lattice of *(1)* the molecules are stacked along the *b* axis with the stacking axis forming an angle of 42.9° with the molecular planes. Neighboring molecules in such a stack have an interplanar distance of 336 pm and are parallel-shifted by 312 pm. The molecular planes of adjacent stacks are inclined by 86° to each other, resulting in the "herringbone pattern" shown in Figure 1 as a side view along the *a* axis.

With a mean deviation of carbon atoms from the mean plane through the 48 carbon atoms of only 3 pm and a maximum deviation of 7 pm, *(1)* has an almost perfectly planar structure. This includes, with deviations of 5 and 10 pm, respectively, even the six internal hydrogens, although the non-bonding distances of 196(2) pm between adjacent hydrogen atoms are unusually short.



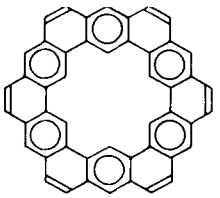


Fig. 2. Bond lengths of *(1)* in pm (standard deviations in units of the last figure given in brackets) and valence angles (as mean values of equivalent angles).

Figure 2 shows clearly that there is a remarkable difference between the bond lengths in the two groups of six-membered rings A, C, E, G, I, K and B, D, F, H, J, L. Only in the last-mentioned group, with mean values of 138.8 pm for the bonds of the internal *(1)*-perimeter and of 139.8 pm for the bonds of the external perimeter, are "normal" arene bond lengths observed; even here, all six radial bonds, having a mean value of 142.3 pm, are significantly stretched. Drastic deviations from the bond lengths of these "aromatic rings" (B, D,...), however, are found for the second group of six equivalent six-membered rings (A, C,...): The six peripheral CH—CH bonds of these rings have a mean value of 134.6 pm, *i.e.* almost the length of a normal C=C double bond; correspondingly, a mean length of 144.5 pm for the bonds between these "double bonds" and the "aromatic rings" (B, D,...) indicates a relatively high single bond character. An even stronger extension is found for the bonds (about 146 pm) which link the "aromatic rings" in the inner perimeter; they accordingly approach single bonds of the type found in polyphenyl systems.

Considering the number of 200 possible Kekulé structures of *(1)*, the considerable bond localization evident from the bond lengths might seem surprising. The observed variation in bond lengths was, however, predicted in its qualitative trend—though not in the extent actually found—by MO-SCF calculations[6]. Excellent agreement with the experimental bond lengths was found on evaluation of the Kekulé structures with regard to Pauling bond orders of the individual bonds in *(1)*[7]. On the basis of the structure analysis, a formulation employing *Clar*'s sextet notation *(1a)* is undoubtedly the best representation of the actual bonding situation in kekulene.

(1a)

Some spectroscopic properties of kekulene also agree well with the sextet formulation *(1a)*: The electronic spectrum of *(1)* shows an absorption at remarkably short wavelength as is generally observed, according to *Clar*[8], for arenes of the "condensed polyaryl type", such as hexabenzocoronene (Fig. 3).

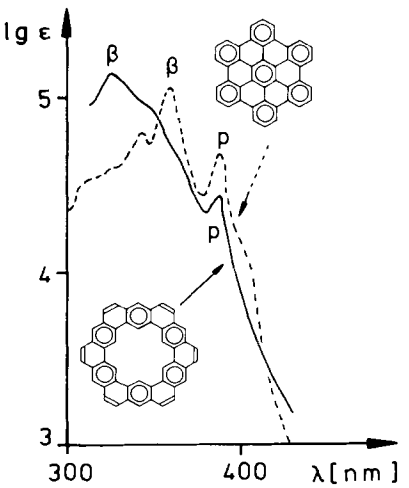

Fig. 3. Absorption spectra of *(1)* and hexabenzocoronene (in 1,2,4-trichlorobenzene).

3). The symmetry-forbidden α-band of *(1)* is obviously hidden under the long-wavelength part of the p-band; however, the strongly vibrationally structured fluorescence band at 453 nm evidently has to be assigned to this α-transition (Fig. 4a).

Just as hexabenzocoronene shows a strong phosphorescence at 575 nm (in 1,2,4-trichlorobenzene) at low temperatures[8], compound *(1)* in a [D_2]-1,2,4,5-tetrachlorobenzene matrix at 1.3 K exhibits a strong phosphorescence emission in the range 585—595 nm with several narrowly spaced "site"-dependent maxima and a vibrational structure resulting from combination with molecular vibrations in the range 1280—1630 cm^{-1} (Fig. 4b).

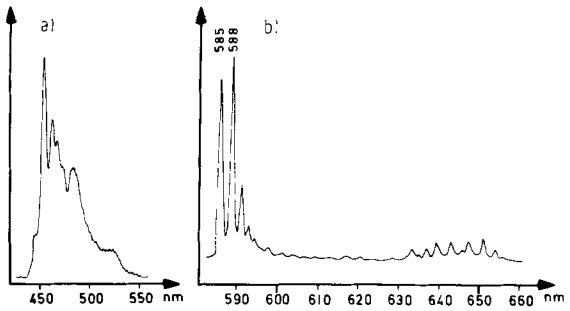

Fig. 4. a) Fluorescence spectrum of *(1)* (in 1,2,4-trichlorobenzene, 298 K, excitation 326 nm); b) phosphorescence spectrum of *(1)* (in [D_2]-1,2,4,5-tetrachlorobenzene, 1.3 K, excitation 365 nm); intensities in arbitrary units.

The strong phosphorescence of *(1)* permits application of the ODMR method for the determination of zero field splitting parameters |E| and |D| of the excited triplet state[9]. For *(1)* in a [D_2]-1,2,4,5-tetrachlorobenzene matrix, an |E| value of 0.001935 cm^{-1} was obtained which, as expected from the D_{6h} symmetry of *(1)*, is very low (benzene: $|E| = 0.0064$ cm^{-1}). However, the |D| value—which measures the dipolar coupling of the triplet electrons and, therefore, is inversely proportional to the third power of the average distance between these electrons—found for kekulene [$|D| = 0.10622$ cm^{-1}] is only slightly lower than for benzene and even greater than |D| for naphthalene and anthracene (cf. benzene 0.1581, naphthalene 0.0994, anthracene 0.0694 cm^{-1}). This unexpectedly small reduction of |D| in *(1)*[10] is very striking at first sight, considering the wide spatial extension of the π-electron system in kekulene. We seek to explain this result qualitatively as an effect of the partial compartmentization of the π-electron system in *(1)* as suggested by the X-ray structure analysis[11].

Cyclic Cleavage of Water into H_2 and O_2 by Visible Light with Coupled Redox Catalysts[**]

By *Kuppuswamy Kalyanasundaram* and *Michael Grätzel*[*]

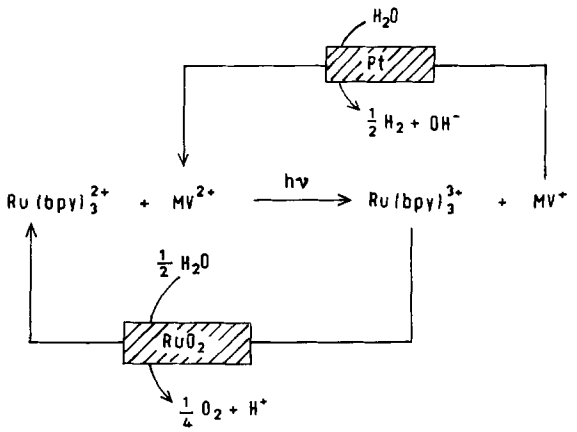
Hydrogen evolution from water can be catalyzed by suitable noble metal (oxide) dispersions[1]. Recently, we succeeded in developing redox catalysts which are capable of mediating oxygen production from water[2]. RuO_2 proved to be a judicious choice of material since it has an extremely low overpotential for O_2 evolution[3]. This paper reports on a system of two coupled redox catalysts permitting cyclic cleavage of water by light.

The water contained $Ru(bpy)_3^{2+}$ as a sensitizer, which after light excitation reduces an electron acceptor (A). Initially we added only RuO_2 to the solution and chose the acceptor such that it undergoes rapid subsequent reaction once it has been reduced. Such a system is suitable for separate investigation of the light-induced evolution of oxygen from water (Scheme 1).

Scheme 1

Table 1. Light induced evolution of O_2 from water with $Ru(bpy)_3^{2+}$ as sensitizer and RuO_2 as catalyst. t = irradiation time. Variant A: 50 ml of solution with 20 mg of RuO_2 powder or 0.3 mg of RuO_2 colloid. Variant B: 150 ml of solution with 50 mg of RuO_2 powder or 1.0 mg of RuO_2 colloid.

Acceptor Formula	c [mol/l]	pH	RuO_2 form	Variant	t [h]	O_2 [ml]
$TlCl_3$	8×10^{-3}	1.6	Powder	A	0.5	0.3
			Colloid	A	0.33	0.4
$[Co(NH_3)_5Cl]^{2+}$	10^{-2}	4.8 [a]	Powder	A	1.5	1.2
			Colloid	B	3	12
$[Co(NH_3)_5Br]^{2+}$	10^{-2}	4.8	Powder	B	9	3
			Colloid	B	9	3.2
$Co(C_2O_4)_3$	10^{-2}	4.8	Powder	A	1.5	0.3
			Colloid	A	1.5	0.4



[a] The pH value of the solutions with cobalt complexes increases during irradiation, leading to formation of a brown precipitate. Precipitation can be avoided by buffering with acetate; cf. also [9].

Results are shown in Table 1. Oxygen is obtained with all the acceptors employed. The pathway of decomposition of the cobalt(III) complexes[4] and the irreversible photooxidation of $Ru(bpy)_3^{2+}$ by Tl^{3+} have been described in the literature[5]. An advantage of the Tl^{3+} system is the high quantum yield of $Ru(bpy)_3^{2+}$ oxidation ($\phi = 2$); however, the pH of the solution has to be kept below 1.7 to avoid precipitation of hydroxide complexes. Higher O_2 yields are obtained at pH between 4 and 5. It is noteworthy that even after long irradiation periods there is practically no depletion in sensitizer, indicating that the reverse reaction of $Ru(bpy)_3^{3+}$ to $Ru(bpy)_3^{2+}$ (Scheme 2) occurs faster than thermal decomposition[6]. (The turnover number of the sensitizer must be at least 100.) Table 1 also shows that colloidal RuO_2 is much more effective in mediating O_2 evolution than the powdered compound, since almost the same yields are obtained at 50–100 times smaller concentrations. The colloidal dispersion also has the advantage of being completely transparent.

The experiments for the simultaneous light-induced production of H_2 and O_2 were performed with dimethylviologen (*N,N'*-dimethylbipyridine dication, MV^{2+}) as an acceptor. MV^{2+} is reduced by photo-excited $Ru(bpy)_3^{2+}$ in a diffusion-controlled process[1e,7]. The reaction products, *i.e.* $Ru(bpy)_3^{3+}$ and MV^+, have the thermodynamic ability to produce oxygen and hydrogen from water. However, to mediate these processes, very active redox catalysts have to be employed since the back reaction can occur with a rate constant of $k = 2.4\times10^9$ l mol^{-1} s^{-1}[1c]. We recently found that a finely dispersed, centrifuged Pt sol (10^{-3} mol/l) reoxidizes MV^+ within microseconds[8]. This is therefore used to catalyze H_2 formation: RuO_2, on the other hand, can mediate efficiently the O_2 evolution step. When illuminating a solution containing 10^{-4} mol/l of $Ru(bpy)_3^{2+}$ and 2×10^{-3} mol/l of MV^{2+} at a pH of 4.7 in the presence of RuO_2 powder (50 mg/150 ml) or colloidal RuO_2 (1 mg/150 ml) *and* colloidal Pt (4.5 mg/150 ml), *simultaneous evolution of H_2 and O_2* is indeed observed. Typically, we obtained 0.3 ml of O_2 and 0.6 ml of H_2 after 3 hours' illumination of 150 ml of solution with a 250-W projector lamp. Blank experiments showed that the presence of both redox catalysts is mandatory for production of both gases. The depletion of $Ru(bpy)_3^{2+}$ during 3 hours' irradiation is less than 5%, illustrating the cyclic nature of this cleavage of water. The two catalysts seem to be sufficiently specific to avoid short-circuiting of the back reaction. Also, it appears that charge transfer from MV^+ to Pt can compete efficiently with O_2 reduction according to

$$MV^+ + O_2 \rightarrow O_2^- + MV^{2+}$$

From these findings we deduce the following reaction sequence shown in Scheme 2.

Scheme 2

According to these findings, the cleavage of water by visible light is undoubtedly possible in a four-quantum process.

[**] Acknowledgment is made to the Swiss National Foundation for supporting this work under grant No. 4.061.076.04, and to Ciba-Geigy Ltd., Basel, Switzerland.

In the development of such systems we see a possibility of achieving solar energy conversion by use of homogeneous or microheterogeneous aqueous solutions.

Experimental

The RuO_2 catalysts used were $RuO_2 \cdot H_2O$, (Alfa Inorganics) and a colloidal suspension stabilized by a copolymer of styrene and maleic anhydride[10]. The colloid was prepared by treating a neutral solution of RuO_4 in water (50 mg) with a 0.5% aqueous solution (25 ml) of the copolymer. The pH is adjusted to 8 and the solution stirred for one hour. A RuO_2 sol is formed spontaneously with a mean particle radius of 300 Å.

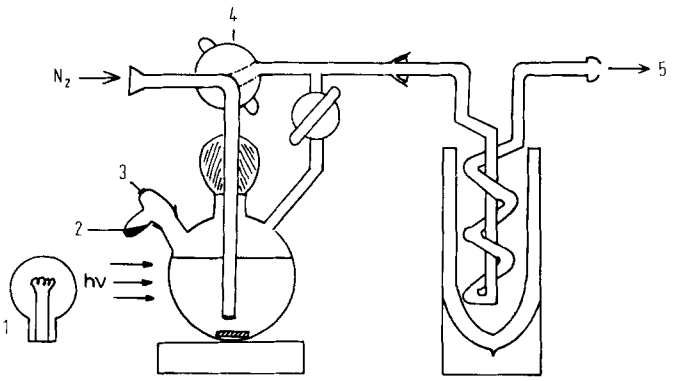

Fig. 1. Schematic illustration of the instrumental set-up used for light-induced cleavage of water. 1, 250-W lamp; 2, catalyst; 3, septum; 4, three-way stopcock; 5, to oxygen measuring instrument.

The solution is placed in a flask containing the solid catalyst in a side arm. This is also fitted with a septum allowing for injection of colloidal catalyst and removal of gas samples. The flask is connected to a trap and an End-O-Mess oxygen meter (Friedrichsfeld GmbH, Mannheim, Germany) (Fig. 1).

Prior to illumination, the whole system is carefully deaerated by flushing with nitrogen. The two stopcocks are then closed and the flask illuminated by a 250-W slide projector lamp. After irradiation the gas evolved in the solution is flushed out and transferred to the oxygen meter by a stream of nitrogen. In order to check hydrogen production a sample of gas is taken through the septum by an air-tight syringe and subjected to gas chromatography.

A test run was first made with a 8×10^{-3} M Ce^{4+} solution in 1 N H_2SO_4 which, on contact with the hydrated RuO_2 powder, gave oxygen in the dark[2] under simultaneous reduction of Ce^{4+} to Ce^{3+}. This reaction produces O_2 with a >80% efficiency. Unhydrated RuO_2 failed to give oxygen.

BOOK REVIEWS

Hummel/Scholl: Atlas of Polymer and Plastics Analysis. 2nd, revised edition. Vol. 1. Polymers: Structures and Spectra. By *D. O. Hummel.* Verlag Chemie, Weinheim/Carl Hanser Verlag, München 1978. xxxii, 671 pp., 1903 IR spectra, DM 475.00.

IR spectroscopists working with polymers will welcome publication of this new edition of "Hummel"—ten years after the appearance of the first edition. Subdivision and aim of the compilation of spectra have changed: Volume 1 now bears the title "Structures and Spectra", and the subsequent Volumes 2 (Plastics, Fibres, Rubbers, Resins) and 3 (Additives and Processing Acid) are subtitled "Spectra and Methods of Identification". The textual volume has been dropped. New features include the use of an improved decimal classification system, adoption of names recommended by IUPAC, and consistent use of a linear wave number scale.

The 1903 spectra depict a cross-section through the polymer chemistry of the past decade, ranging from materials of construction to polymers newly developed, *e.g.*, as ion exchangers, semiconductors, or carriers for enzymes. Most of the polymers have been described in the literature; the respective samples reached the author from laboratories throughout the world.

A problem attending such a work is always that of the purity of the substances concerned. Thus, a glance at page 2 of the book already shows absorption bands of ubiquitous silicone oil (spectrum no. 4) or gives an indication of oxidative degradation (spectra nos. 5 and 6). Whenever recognized, any impurities are mentioned in the accompanying text.

Searches are greatly facilitated by a list of contents, decimal classification, subject index, molecular formula index, and author index.

The spectra cover the range of 4000 to 400 cm^{-1}. The scale of the two formats adopted agree in the region between 2000 and 400 cm^{-1}. Comparison and reading off of wave numbers is often made difficult by the failure to emphasize the round hundreds on the wave number grid. There is no wavelength scale for those still accustomed thereto. (Perhaps a transparent foil bearing a wave number and wavelength grid could be supplied with futures volumes.)

In spite of its high price, the book can be recommended as a valuable tool to all concerned with the IR spectroscopy of polymers.

Hans H. Suhr [NB 474 IE]

Correlation Analysis in Chemistry. Recent Advances. Edited by *N. B. Chapman* and *J. Shorter*. Plenum Press, New York 1978. xiii, 546 pp., bound, $ 59.40.

Six years after the publication of "Advances in Linear Free Energy Relationships", *N. B. Chapman* and *J. Shorter* have produced a sequel, "Correlation Analysis in Chemistry". Specific aspects of linear free energy relationships are presented in great detail in ten chapters authored by specialists in the fields concerned.

Two contributions (*S. Wold* and *M. Sjöström; M. Godfrey*) are concerned with the fundamental question of the conditions under which linear correlations are to be expected between the characteristic properties of an ensemble of processes and systems (molecules). Since not only free energies (thermal and kinetic quantities) are correlated with one another, a somewhat less specific title was chosen for the book. It was then also possible to report about attempted correlations in biochemistry *(C. Hansch)*.

The topic of four surveys is the best known linear free energy relationship, the Hammett equation. *J. Shorter* reviews Hammett relationships which require more than a single σ parameter. *D. F. Ewring* summarizes correlations between σ values and NMR data. Linear correlations in polycyclic and heterocyclic aromatic compounds are described by *M. Charton*, and *O. Exner* provides a critical survey of the σ values of over 500 substituents.

Two further contributions consider the effects of substituents on alkenes *(G. P. Ford, A. R. Katritzky, R. D. Topsom)* and on nucleophiles *(C. Duboc)*. In conclusion, *R. P. Bell* retraces the first 50 years of the oldest known linear free energy relationship, *viz.* the Brønstedt equation.

The individual sections are broad in their coverage and each contains up to 400 literature references. The main emphasis is not placed on presentation of the very latest results; instead, an attempt is made to give a general description of the field covered.

This book is intended for chemists engaged in research and/or teaching in the area of reaction mechanisms. Apart from the value of the other contributions, the enormous collection of σ values by *Exner*, which renders further searching unnecessary, recommends the purchase of this book by chemical libraries.

Bernd Giese [NB 476 IE]

The Gamma Rays of the Radionuclides. By *G. Erdtmann* and *W. Soyka*. Verlag Chemie, Weinheim 1979. xv, 862 pp., bound, DM 240.00.

Gamma ray spectrometry is by far the most important method for the identification and activity determination of radionuclides. It has become an indispensable tool for work in pure nuclear physics, in nuclear and radio-chemistry, and for applications such as nuclear technology, activation analysis, and the monitoring of environmental radioactivity. A sound knowledge of data pertaining to the emitted gamma rays and the availability of corresponding tabulated values are essential requirements for practical gamma ray spectrometry.

The first edition of the catalog "Die γ-Linien der Radionuclide", published in 1973 as a special report of the Nuclear Research Establishment at Jülich was the sole complete compilation of the γ-lines of all the radionuclides then known. In view of the advances made in this field, it is hardly surprising that the authors have now provided a revised and greatly expanded edition of that work.

The book contains two tables listing all the radionuclides known in 1977 (2055). In the first table, they are arranged in order of increasing atomic and mass numbers, and the X-rays and γ-rays emitted on their disintegration are arranged according to their energy. Absolute intensities are given as percentages in most cases. Only in those cases where the authors were unable to obtain reliable absolute values are relative intensities given on the basis of the intensity of the most frequent γ-transition. Intensity data have been omitted only for a few of the radionuclides which are far removed from the stability line, and therefore difficult to produce and of very little practical importance. The evaluation and interpretation of complex gamma ray spectra is greatly facilitated by inclusion of escape lines which are generated by interaction of high-energy gamma rays ($E_\gamma > 1.022$ MeV) with detector material (by pair production processes) but appear in the guise of photopeaks of true gamma lines in the spectrum.

Since high-resolution Si(Li), Ge(Li), and very pure germanium detectors have become available, X-ray spectrometry has joined the γ-ray method as an important measuring technique, especially in activation analysis. Therefore the enormous efforts of the authors to arrive at the absolute intensities of X-ray lines deserve special praise, for these intensities have been measured for only few radionuclides. The $K_{\alpha 2}, K_{\alpha 1}, K'_{\beta 1}$, and $K'_{\beta 2}$ lines are normally given separately, being considered together only when the energy difference is less than 100 eV. In this way the tabulated data are very well adapted to the present situation, with today's detectors having an energy resolution around 140 eV.

The first table also contains data of radionuclides which do not emit γ-rays, *i.e.* pure β- or X-ray emitters; this ensures an optimum degree of completeness. Supplementary data characterizing radionuclides, such as half-lives and generation reactions, as well as parent and daughter nuclides can often be extremely useful.

The second table is intended for assisting in the evaluation of unknown spectra; it contains X-ray and γ-ray lines in the order of increasing energy, together with the corresponding radionuclide, its half-life, up to five further X-ray or γ-ray lines, and details concerning the generation of the radionuclide.

Credit must also go to the authors for the critical approach adopted in determining the values for the γ-lines; they were obtained either by searching for the "most reliable" value or by weighting the individual results. All the more pity, then, that limitations of space precluded the inclusion of information about the accuracy of energy and intensity values.

Considering the completeness, the quality, and the presentation of the data as assessment criteria, this tabular work is a masterpiece. As the most important catalog of X-ray and γ-ray lines presently available it should have a place in the library of every laboratory in which such spectrometric techniques are used. It should be mentioned, however, that one can justifiably expect a very valuable work for this handsome price which will unfortunately prevent most people from purchasing their personal copy.

Viliam Krivan [NB 478 IE]

pH-Wert-Berechnungen. By *C. Bliefert*. Verlag Chemie, Weinheim 1978. xvi, 255 pp., bound, DM 48.00.

In keeping with its title, this book provides a survey of acid-base theories and an introduction to the calculation of pH values. Starting from relatively simple problems, such as pH calculations for monoprotic acids and bases, the book progresses to a detailed treatment of more complicated systems (acid- and base mixtures, ampholytes), and the calculation of titration curves, pH diagrams, degrees of protolysis, *etc.* is explained. In this way it becomes possible to deal quan-

titatively with a large number of acid-base equilibria using simple mathematical tools. Not only exact calculations are considered, but approximation methods are also treated wherever they are of value. It appears particularly valuable that exact and approximate calculations are compared, giving numerical data concerning the effect of neglecting certain quantities for various concentration ranges and pK_a values in the approximate methods. This enables the user to select the method suitable or adequate for his purpose without having to always use the involved formula required for exact calculation. Many graphic representations aptly illustrate the calculations. Numerous questions at the end of each chapter not only introduce the reader to the problems involved but provide him with an opportunity to test his ability, and also furnish yet more information. The solutions—and in most cases the method of solution—are given for all questions. An appendix contains flow charts for some selected calculations which can be translated into computer language.

The book is written fluently and clearly. Its aim of showing the beginner and advanced student, as well as the practical chemist, how to calculate (approximately or exactly) the pH values of aqueous systems is undoubtedly fulfilled. It can therefore be wholeheartedly recommended to all interested persons, and particularly to teachers at all levels. The reviewer has just one wish for a second edition: It would be convenient if a further section could be included comparing calculated and measured pH values in somewhat more detail, *i.e.* if the influence of factors such as concentration, ionic strength, *etc.* on the activity were to be viewed more closely. The fact that measured pH values often deviate considerably from the calculated values, which often confuses the beginner, would then be easier to understand. In spite of this wish: the book truly enriches the available chemical literature.

Hans Rudolf Christen [NB 479 IE]

Kirk-Othmer: Encyclopedia of Chemical Technology. Editorial board: *H. F. Mark, D. F. Othmer, C. G. Overberger,* and *G. T. Seaborg.* John Wiley & Sons, New York 1978, 3rd Edit. Vol. 4: Blood, Coagulants and Anticoagulants to Cardiovascular Agents. xxv, 930 pp., bound, $ 95.00.

The fourth volume of Kirk-Othmer[*] contains entries on some 30 keywords, the longest ones being: carbon (*ca.* 150 pages); boron compounds (*ca.* 130 pages); carbides (*ca.* 60 pages); cardiovascular agents (*ca.* 60 pages); carboxylic acids (*ca.* 60 pages); blood fractionation (*ca.* 40 pages). The reader notes that not only chemical technology but also biotechnological aspects are treated at considerable length.

The subdivision of the material is very balanced, as in the first volumes. In addition to production and workup, space is always given to the physical and chemical properties of products, their uses, and the principal economic data of the processes. Presentation is generally terse, and yet highly informative. Omissions in the material are very rare. Production figures could be a little more up-to-date in some cases: those given for borate do not extend beyond 1973/1975. There is no mention, in the article about carbon dioxide, of the use of supercritical CO_2 for extraction of heat-sensitive natural products (such as coffee and tobacco) although plants utilizing this technology have already come on stream. Moreover, some sections consider only English-language literature.

Nevertheless, such minor points do not detract from the excellence of this work, specifically the present Volume 4.

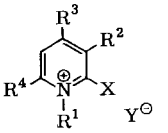
New Synthetic Reactions Based on the Onium Salts of Aza-Arenes

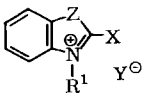
New synthetic methods (29)

By Teruaki Mukaiyama[*]



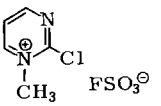
Effective syntheses employing 2-halogenated pyridinium, benzoxazolium, benzothiazolium, and pyridinium salts have been accomplished in the absence of strong acids and bases. Activation of carboxylic acids or alcohols with these onium salts leads to 2-acyloxy and 2-alkoxy intermediates which can be transformed into esters, amides, thiol esters, (macrocyclic) lactones, acid fluorides, olefins, allenes, carbodiimides, isocyanates, isothiocyanates, nitriles, and isocyanates. The possibility of performing stereospecific syntheses (involving configurational inversion) with onium salts deserves attention.

1. Introduction



Remarkable progress has been achieved in the field of synthetic organic reactions by the use of readily available strong bases such as alkyllithium and also of acidic reagents such as $TiCl_4$[1]. However, in the synthesis of complex molecules, such as biologically active substances having base- or acid-labile functionalities, it is highly desirable to be able to work under neutral or neutralization conditions. One approach is to utilize characteristic properties of trivalent phosphorus compounds and organosulfur compounds in "oxidation-reduction condensation"[2]. For example, this method affords carboxylic thiol esters from carboxylic acids and thiols without any assistance from an acid or a base[3]:

$$R^1CO_2H + R^2SSR^2 + (C_6H_5)_3P \rightarrow R^1C(O)SR^2 + R^2SH + (C_6H_5)_3P{=}O$$



In reactions of this type, the utilization of the onium salts seems to be promising, since ionic character in the intermediate should result in the close proximity of reacting species around the onium salts, thus promoting smooth reaction under mild conditions. On the basis of this consideration, we have investigated the use of onium salts of aza-arenes, and it has become clear that the onium salts are effective for the activation of carboxyl and hydroxyl components in the presence of such weak bases as trialkylamines under neutralization condition. Table 1 lists some of the onium salts used and various abbreviations.

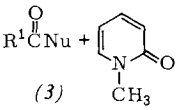
This review describes recent synthetic advances using 2-halopyridinium, 2-fluorobenzothiazolium, and 2-chlorobenzoxazolium salts with specific accounts of intermolecular and intramolecular dehydration, and syntheses of optically active substances.

2. Intermolecular Dehydration

2.1. Activation of Carboxylic Acids



2.1.1. Synthesis of Carboxylic Esters, Amides, and Thiol Esters

The study of these reactions was prompted by the following observations: 2-Acyloxy-1-methylpyridinium iodide *(2)*, an active acylating intermediate, should be produced easily and rapidly by a nucleophilic attack of a carboxylate ion on 2-chloro- *(1a)* or 2-bromo-1-methylpyridinium iodide *(1b)*, since the 2-halogen atom of these onium salts is easily replaced by nucleophiles. The intermediate *(2)* should in turn be converted into stable neutral molecules, *i.e.* the acylated product *(3)*, 1-methyl-2-pyridone, and the ammonium salt, by the attack of a nucleophile in the presence of a tertiary amine as hydrogen iodide captor. Since all the reacting species are in close proximity to the central pyridinium ion, the condensation reaction should be entropically advantageous.

(1a), X = Cl
(1b), X = Br

(2)

(3)

On the basis of these assumptions, the formation of carboxylic esters from equimolar amounts of carboxylic acids and alcohols was investigated[4]. In the first place, effective hydrogen halide captors were examined for the condensation of equimolar amounts of phenylacetic acid and benzyl alcohol using *(1a)*. Triethylamine, tributylamine, and 2,6-lutidine gave good results (98, 99, and 97% yield, respectively); the yield of benzyl phenylacetate decreased as the basicity of the amine decreased.

Table 2. Synthesis of esters from equimolar amounts of carboxylic acid and alcohol with 2-chloro- *(1a)* or 2-bromo-1-methylpyridinium iodide *(1b)* and tri-*n*-butylamine (3 h, reflux).

$R^1CO_2H + R^2OH \rightarrow R^1CO_2R^2$

Onium salt	R^1	R^2	Yield [%] in CH_2Cl_2	in toluene
(1b)	C_6H_5	$C_6H_5CH_2$	80	
	$C_6H_5CH_2$	C_2H_5	92	
	$C_6H_5CH_2$	$C_6H_5CH_2$	97	
	$C_6H_5CH_2$	$(CH_3)_3C$	70	82
	CH_3	$C_6H_5CH_2$	80

	CH_3	$C_6H_5CH_2CH_2$	74	
	$(CH_3)_3C$	$C_6H_5CH_2$	31	62

No significant solvent effect was observed in the reaction, benzyl phenylacetate being obtained in almost quantitative yield in diethyl ether (97%), dichloromethane (99%), acetonitrile (98%), pyridine (98%), toluene (99%), *etc.*—Examples of esterification are shown in Table 2.

The effect of changing the counterion and the halogen atom of the pyridinium salt on the yield of carboxylic esters urged us to look for more effective pyridinium salts. Thus ester formation from 3-phenylpropionic acid and benzyl alcohol (tri-*n*-butylamine, 1 h, reflux in dichloromethane) using the 2-halopyridinium salts *(1a)*—*(1d)* gave yields of 69, 61, 73, and 82%, respectively (Table 1).

Table 3. Synthesis of esters from equimolar amounts of carboxylic acid and alcohol with 2-bromo-1-ethylpyridinium tetrafluoroborate *(1d)* and tri-*n*-butylamine in CH_2Cl_2.

[a] Values in parentheses refer to the reaction with 2-chloro-1-methylpyridinium iodide *(1a)*.

Then the reaction of several carboxylic acids, including functionalized ones, with strictly equimolar amounts of alcohols was carried out with 2-bromo-1-ethylpyridinium tetrafluoroborate *(1d)* and tri-*n*-butylamine as coupling reagents; favorable results were obtained especially at room temperature (Table 3). Particular mention should be made of the esterification of pivalic acid, trichloroacetic acid, and benzoylacetic acid, also with various sterically hindered alcohols, such as *tert*-butyl alcohol.

When alcohols were replaced by primary or secondary amines as nucleophiles, carboxamides were obtained in high yields (Table 4)[5]. The preparation of carboxamides using 2-

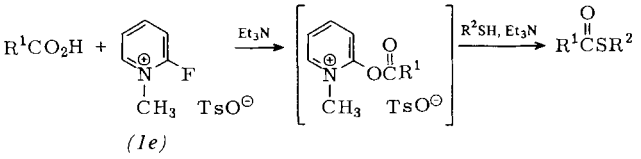
iodopyridinium salt as a coupling agent had been previously studied in detail by *Sutherland et al.*[6]. However, only modest yields were obtained. These results again indicate the significant effect of the halogen atom attached to position 2; only chlorine and bromine derivatives give favorable results.

3-Acylthiazolidine-2-thione *(5)*, obtained in high yield from a carboxylic acid and thiazolidine-2-thione *(4)* on use of a 2-chloro-1-methylpyridinium iodide *(1a)*, proved to be an interesting intermediate. When *(5)* was treated with aluminum hydride reagents, the corresponding aldehyde was produced selectively, free from alcohol. Thus the overall transformation provides a new and efficient method for the partial reduction of carboxylic acids to aldehydes[7].

In the above syntheses of carboxylic esters or amides, the use of two moles of tertiary amine per mole of acid is necessary to scavenge hydrogen halide formed during the reaction. Although at the end of the reaction, tertiary amine is completely converted into the ammonium salt, the reaction medium is initially weakly basic. Development of a less basic acid captor to replace the tertiary amine therefore appeared desirable. It was thought that dihydropyridopyrimidones *(6)* would be most promising captors since a betaine structure *(7)* can be written and, on treatment with an acid, they are converted into the onium salt *(8)*. The pyrimidone derivatives *(6a)* and *(6b)* are easily prepared from ethyl acrylate and 2-aminopyridine or 2-aminopicoline[8]. The use of *(6)* in place of a tertiary amine also gave favorable results in the preparation of carboxylic esters or amides from equimolar amounts of carboxylic acids and alcohols or amines[9].



(6a), R = H
(6b), R = CH_3

(7)

(8)

The basicity of pyrimidone *(6)* is low ($pK_b = -6.5$), and the pyrimidinium salt *(8)* formed by reaction with a hydrogen halide is insoluble in almost all organic solvents and precipitates from the reaction mixture. Consequently, condensation can be performed under almost completely neutral conditions. The reaction requires 2 moles of *(6)* per mole of acid; the yields of esters and amides are 70—97 and 80—*ca.* 100%, respectively.

A similar procedure proved unsuccessful for the preparation of thiol esters from carboxylic acids and thiols, since competitive attack of thiols on the 2-chloropyridinium salts caused the reaction to become rather complex. However, this difficulty was overcome by use of a stepwise procedure and employment of a 2-fluoropyridinium salt such as *(1e)*. When a carboxylic acid is treated with a 2-fluoropyridinium salt and triethylamine in dichloromethane at low temperature, a 2-acyloxypyridinium salt is formed immediately, and subsequent addition of thiol affords the corresponding thiol ester in high yield (Table 5)[10]. Since the yield of thiol ester from the reaction of acid fluoride and thiol under similar conditions is generally low, this result affords indirect support for the intervention of 2-acyloxypyridinium salts as an intermediate. The usefulness of 2-fluoropyridinium salts will be demonstrated in Section 2.1.3.

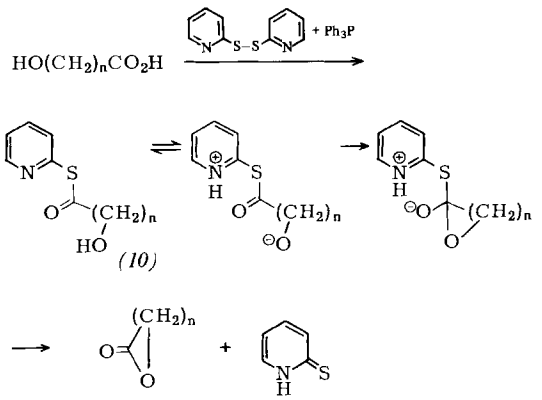
[a] Synthesis of hexanebis(*S*-phenyl thioate) from adipic acid and thiophenol in a molar ratio of 1:2. [b] With tri-*n*-butylamine as base.

Alternative methods for the direct preparation of thiol esters from free carboxylic acids include a method utilizing triphenylphosphane and diphenyldisulfane (or 2,2′-dipyridyldisulfane) which has been reported from our laboratory[2,3]. *Yamada et al.* used diethyl phosphorocyanidate or diphenyl phosphorazidate[11]. However, the present reaction provides a convenient method for the preparation of thiol esters with respect to (i) direct synthesis from equimolar amounts of free carboxylic acid and thiol and (ii) the mildness of the reaction conditions.

Furthermore, preparation of the thiol ester *(9)* derived from a hydroxy acid (12-hydroxyoctadecanoic acid) and thiophenol was successfully accomplished without protecting the hydroxyl group by adding the 2-fluoropyridinium salt *(1e)* to the carboxylic acid and triethylamine at room temperature, and treating the resulting mixture with thiophenol and triethylamine[10].

(9)



2.1.2. Synthesis of Macrocyclic Lactones[*]

The discovery of numerous macrolide antibiotics has generated a recent surge of interest in new solutions to the problem of macrocyclic lactone synthesis[12]. Since most of the

[*] Lactone synthesis will be considered in connection with intermolecular dehydration because the most favorable procedure occurs in two steps.

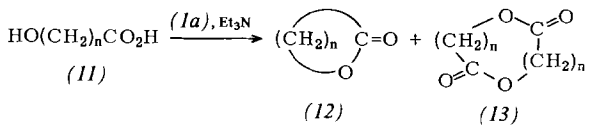
macrolide antibiotics have many acid- and/or base-labile functional groups in the molecule with many chiral carbons, the construction of the carbon skeleton of the hydroxy carboxylic acid, the precursor of the macrolide, is a most difficult problem which, however, can be overcome by a strategy involving properly selected reaction conditions and stereochemical control. However, the intramolecular lactonization reaction of hydroxy carboxylic acids has also remained an unsolved problem. In particular, two problems should be pointed out: i) How can macrolide formation be carried out selectively without accompanying undesirable intermolecular lactide formation?, and ii) how can the lactonization reaction be performed under neutral or neutralization conditions?

Corey et al.[13] and *Gerlach et al.*[14] found one of the effective routes for lactonizing hydroxy carboxylic acids *via* 2-pyridinethiol *(10)* or 2-imidazolethiol esters, prepared by employing the above-mentioned oxidation-reduction condensation[2].

In the above carboxylic ester synthesis utilizing 2-halopyridinium salt, the pyridinium salt participates in all reaction steps and the condensation reaction should be favored in terms of entropy. The intramolecular lactonization reaction was therefore investigated with the expectation that the reaction would proceed smoothly and effectively.

A preliminary investigation was undertaken to determine the efficacy of various bases as hydrogen halide acceptors; triethylamine was found to be the most suitable base. Further, it became clear that the lactonization could be successfully carried out in a variety of solvents; the optimum yield was obtained in refluxing acetonitrile. In this way various ω-hydroxy carboxylic acids *(11)* were lactonized to give the medium and large ring lactones *(12)* in better yields[15] than those obtained by previous methods (Table 6)[13a].

Subsequently we developed an efficient two-step method for cyclization of long chain hydroxy acids to macrocyclic lactones *via* 6-phenyl-2-pyridyl esters *(14)*[16]. This method was successfully applied to the syntheses of recifeiolide *(15)* and ricinelaidic acid lactone *(17)*[17]; however, it was feared that the cyclization of 6-phenyl-2-pyridyl ester with *p*-toluenesulfonic acid in the second step would limit its application to more complex molecules. In order to develop a more promising method for lactonization of complex molecules, the previous method[15] using 2-chloro-1-methylpyridinium salts such as *(1a)* was re-examined. The treatment of hydroxy acids with these salts and triethylamine afforded macrocyclic



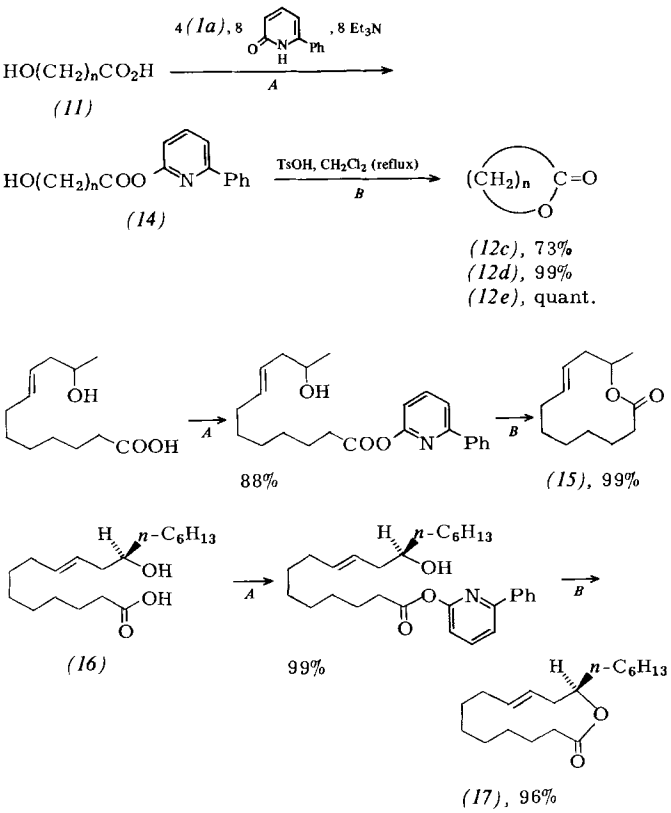


Table 6. Formation of lactones *(12)* and (undesired) lactides *(13)* from ω-hydroxy carboxylic acids *(11)* with 2-chloro-1-methylpyridinium iodide *(1a)* in boiling acetonitrile.

		Yield [%]	
	n	*(12)*	*(13)*

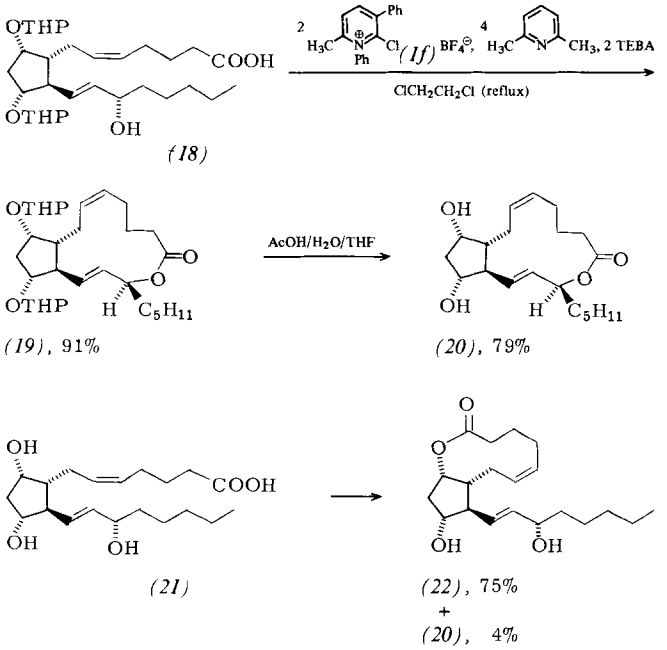
b	7	13	34
c	10	61	24
d	11	69	14
e	14	84	3

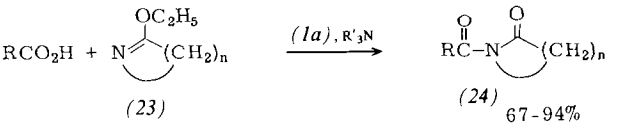
lactones in reasonable but not entirely satisfactory yields. This result was mainly due to the decomposition of the pyridinium salts under the cyclization conditions by the attack of triethylamine on the 1-methyl group or position 2 of the pyridinium ring to form 2-chloropyridine or 2-ammoniopyridinium salts.



In view of the above facts, a stable pyridinium salt, 2-chloro-6-methyl-1,3-diphenylpyridinium tetrafluoroborate *(1f)*, was prepared according to the procedure developed in our laboratory[18] and tested as a reagent for the lactonization reaction[19]. When 15-hydroxypentadecanoic acid *(11e)* was treated with *(1f)* and 2,4,6-triphenylpyridine in refluxing dichloroethane by the dilution method, no pentadecanolide *(12e)* could be obtained and the hydroxy acid *(11e)* was recovered. On the other hand, the transformation of *(11e)* into *(12e)* could be achieved by addition of benzyltriethylammonium chloride (TEBA). For example, a dichloroethane (50 ml) solution of *(11e)* (0.25 mmol) and 2,4,6-triphenylpyr-

idine (1.0 mmol) was added during 7 h to a refluxing dichloroethane (30 ml) solution of *(1f)* (0.5 mmol) and TEBA (0.5 mmol) under argon. The reaction mixture was refluxed for an additional 1 h and pentadecanolide *(12e)* was isolated in 99% yield. Similarly, 12-hydroxydodecanoic acid *(11d)* was lactonized to dodecanolide *(12d)* in 85% yield.

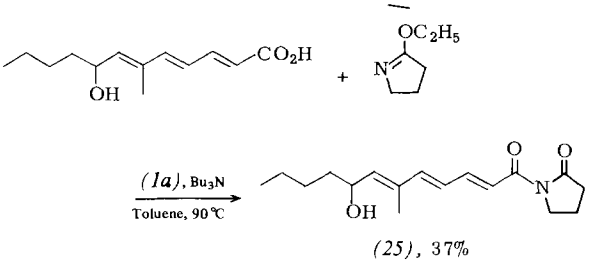
The use of the 2-chloropyridinium salt *(1f)* for lactonization of optically active hydroxy acids is illustrated by the lactonization of (*R*)-(+)-ricinelaidic acid. (*R*)-(+)-Lactone *(17)* was obtained in 91% yield without racemization upon treatment of the hydroxy acid *(16)* with *(1f)*, 2,4,6-triphenylpyridine, and TEBA in refluxing dichloroethane. On use of 2,6-dimethylpyridine the yield was 86%.



To demonstrate the applicability of this macrolactonization process to more complex hydroxy acids, the cyclization of prostaglandin $F_{2\alpha}$-9,11-bis(tetrahydropyranyl) derivative *(18)* was attempted[19]; the protected 1,15-lactone *(19)* was isolated in 91% yield. Removal of the protecting group gave prostaglandin $F_{2\alpha}$-1,15-lactone *(20)* (79%).

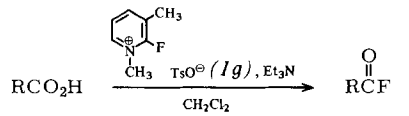
The lactonization of prostaglandin $F_{2\alpha}$ *(21)* under the same conditions as for *(18)*→*(19)* gave the 1,9-lactone *(22)* in 75% yield along with a small amount (4%) of the 1,15-lactone *(20)*. The successful synthesis of lactones *(16)*, *(20)*, and *(22)* described above demonstrates the utility of the present macrolactonization process.

2.1.3. Miscellaneous Acylation Reactions



Lactim ethers *(23)* can also act as nucleophiles toward the active key intermediates, 2-acyloxypyridinium salts; *N*-acyl lactams *(24)* are obtained in good yield[20]. *N*-Acyl lactams have been most widely prepared by reaction of acyl halide with lactim ether or *N*-trimethylsilyl lactam[21]. However, little work has been reported on the preparation of *N*-acyl lactams directly from free carboxylic acids and lactim ethers. On utilization of the 2-chloropyridinium salt *(1a)*, *N*-acyl lactams *(24)* can be produced in good yields from equimolar amounts of free carboxylic acids and lactim ethers (five- or six-membered ring system).

R = *n*-C_7H_{15}, *n*-$C_8H_{17}CH{=}CH(CH_2)_6$, $CH_3O_2CCH_2CH_2$, $CH_3COCH_2CH_2$

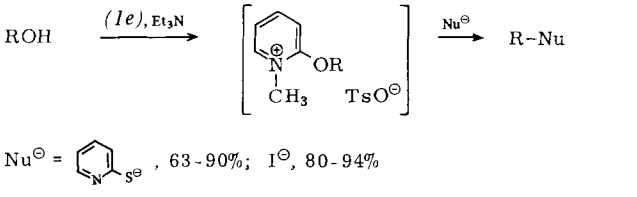


n = 2, 3

Using this method, DL-variotin *(25)*, an antifungal antibiotic, could be synthesized in simplified manner, *i.e.* without protection of the hydroxyl group[22].

In the reactions discussed so far, carboxylic acids are transformed, by treatment with a 2-chloropyridinium salt, into the active intermediate, the 2-acyloxypyridinium salt, which then reacts with various nucleophiles to produce the corresponding condensation product. In the absence of a nucleophile, competitive nucleophilic attack of chloride ion and carboxylate ion takes place, and a mixture of carboxylic anhydride and acid chloride is formed.

2-Fluoro-1,3-dimethylpyridinium tosylate *(1g)* is more reactive than 2-chloropyridinium salts such as *(1a)*. Carboxylate ion reacts with 2-fluoropyridinium salt much faster than with 2-acyloxypyridinium salt, and 2-acyloxypyridinium salt is formed exclusively. Thus it follows that, in the absence of the other nucleophiles, fluoride ion attacks the 2-acyloxypyridinium salt; this is the basis of a convenient synthesis of acid fluorides[23].



R = *n*-$C_{11}H_{23}$, quant.; $C_6H_5CH_2CH_2$, 88%; $C_6H_5CH_2$, 80%; C_6H_5, 93%; $C_6H_5CH(C_2H_5)$, 87%; $CH_3CH{=}CH$, 64%; $HO_2C(CH_2)_5$, 93%

2.2. Activation of Hydroxylic Compounds

2.2.1. Formation of 2-Alkyloxypyridinium Salts

In this section, alkylation reactions involving 2-alkyloxypyridinium salt or other onium salts of 2-alkyloxyazaarenes are discussed. At first, an unsuccessful attempt was made to produce the 2-alkyloxypyridinium salt by the reaction of 2-chloropyridinium salt and alcohol. As mentioned in Section 2.1.3, the 2-fluoropyridinium salt is more active than the 2-chloro salt; the desired 2-alkyloxypyridinium salt was readily obtained from the 2-fluoropyridinium salt *(1e)*, alcohol, and tertiary amine. Treatment of the 2-alkyloxypyridinium salt prepared *in situ* with thiolate ion or iodide ion gave the corresponding sulfide[24] or iodide[25] in good yield. In this method, 1-methyl-2-pyridone and unchanged pyridinium salts are easily removed by washing with water.

2.2.2. Olefin and Allene Synthesis by Selective Alkylation of Allylic and Acetylenic Alcohol

A Grignard reagent can also be employed as nucleophile in this reaction, and forms a carbon-carbon bond directly with the alcohol. Addition of 2-allyloxypyridinium salt to a tetrahydrofuran solution of Grignard reagent affords the corresponding coupling product in good yield. Primary and secondary alkylmagnesium bromides coupled with allyloxypyridinium salt exclusively at C-3 (S_N2' reaction). The situation is completely different in the case of phenylmagnesium bromide which attacks only C-1 (S_N2 reaction) (Table 7)[26].

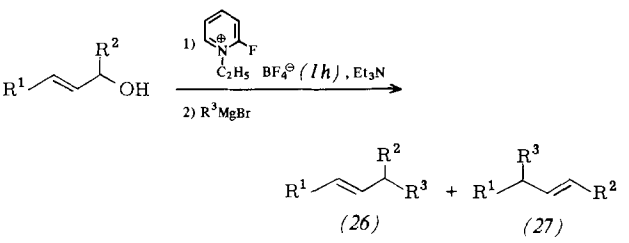


Table 7. Synthesis of olefins from allyl alcohols and Grignard compounds with 1-ethyl-2-fluoropyridinium tetrafluoroborate *(1h)*.

CH_3	$C_6H_5CH_2CH_2$	C_6H_5	92 [a]	

[a] Yield of *(26)* + *(27)*.

The 2-propargyloxypyridinium salt can be also attacked at the γ-position by Grignard reagents in the presence of a catalytic amount of cuprous iodide, and the corresponding allene *(28)* was obtained in high yield (Table 8)[28].

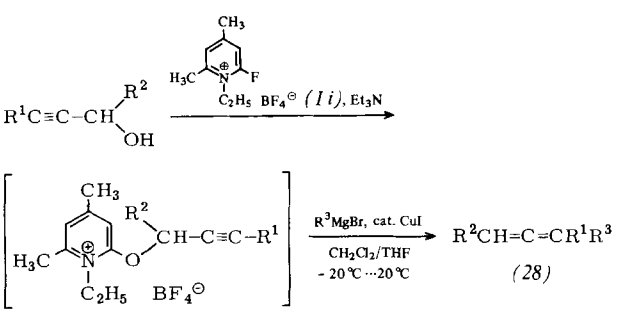

Table 8. Synthesis of allenes *(28)* from propargyl alcohols and Grignard compounds with 1-ethyl-2-fluoro-4,6-dimethylpyridinium tetrafluoroborate *(1i)*.

R^1	R^2	Yield [%] R^3 = n-C_4H_9	R^3 = c-C_6H_{11}	R^3 = t-C_4H_9

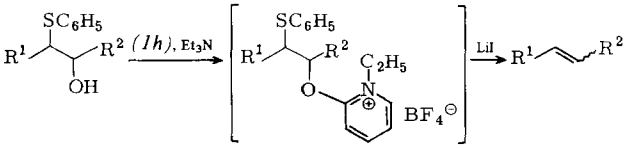
H	$C_6H_5CH_2$	83	89	
H	$C_6H_5CH_2CH_2$	92	99	91
H	n-C_8H_{17}	95	97	
n-C_4H_9	$C_6H_5CH_2CH_2$	77	78	94

2.2.3. Olefin Formation by Reductive β-Elimination

The reductive β-elimination of β-hydroxysulfides is also possible on use of a 2-fluoropyridinium salt. Treatment of an alkyloxypyridinium salt *(29)* derived from a β-hydroxysulfide with lithium iodide in refluxing acetone furnishes the olefin in good yield (Table 9)[29].



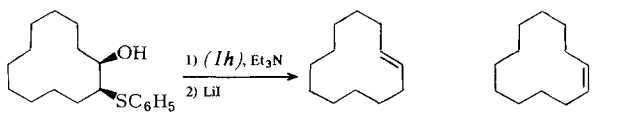


Table 9. Synthesis of olefins by reductive β-elimination from β-hydroxysulfides with 1-ethyl-2-fluoropyridinium tetrafluoroborate *(1h)* in boiling acetone.

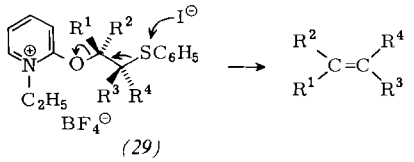
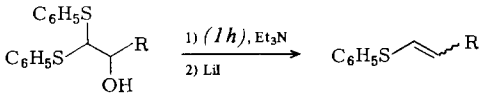


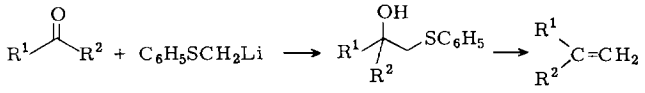
R^1	R^2	Yield [%]
C_6H_5	C_6H_5	81
C_6H_5	$C_6H_5CH_2CH_2$	91
C_6H_5	p-$(CH_3)_2NC_6H_4$	69

There are two potential pathways for attack on 2-pyridiniooxyethyl sulfides *(29)* by iodide ion: (i) attack at the sulfur atom to afford olefins with synchronous elimination of sulfenyl iodide and 1-ethyl-2-pyridone, and (ii) attack at the β-carbon to afford S_N2 displacement products. Since exclusive formation of olefins is observed (Table 9) the former reaction must be much faster than the latter. The sulfenyl iodide thus formed readily disproportionates into diphenyldisulfane and iodine. The stereospecificity of this reaction is demonstrated in the exclusive reduction of *erythro*-2-phenylthiocyclododecanol *(30)* and its *threo* isomer to *trans*- and *cis*-cyclododecene *(31)*, respectively.



erythro-*(30)* *trans*-*(31)*, 85% *cis*-*(31)*, 76%

These results indicate that the reductive elimination proceeds with perfect stereospecificity. Thus, a *trans* elimination mechanism involving direct attack of iodide ion at sulfur atom is suggested for 2-pyridiniooxyethyl sulfides *(29)*.



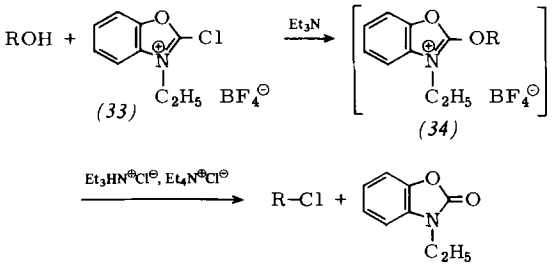
When 2-hydroxythioacetals *(32)* are used instead of β-hydroxysulfide, the corresponding vinyl sulfides are obtained in moderate yields[29].

(32) R = $C_6H_5CH_2CH_2$, 70%; n-C_7H_{15}, 71%

Since β-hydroxysulfides can be prepared from ketones or aldehydes, the reductive elimination of β-hydroxysulfides provides a useful method for the preparation of olefins starting from carbonyl compounds.—Alternative reductive elimination procedures[30] require rather drastic conditions (strong base or basic media) except when low valent titanium compounds are used as reducing agents[31].

2.2.4. Preparation of Alkyl Chlorides

2-Chlorobenzoxazolium salt *(33)* reacts with alcohols in the presence of triethylamine to afford the corresponding alkyl chlorides in good yields. Addition of tetraethylammonium chloride improves the yield[32].



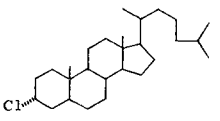


Table 10. Synthesis of alkyl chlorides from alcohols and 2-chloro-3-ethylbenzoxazolium tetrafluoroborate *(33)*.

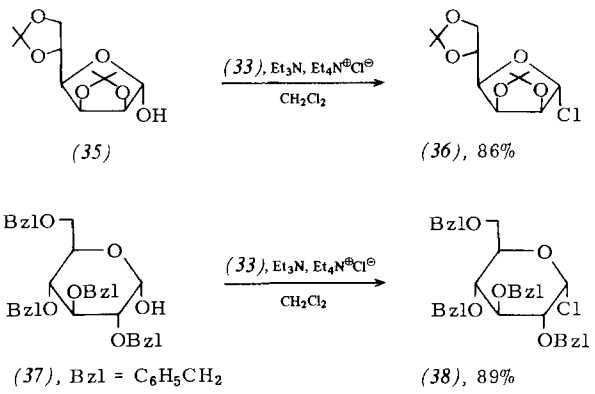
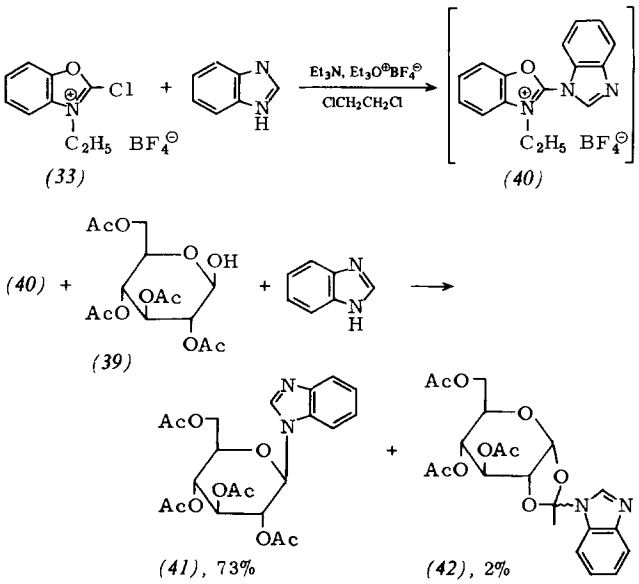


T [°C]	t [h]	Alkyl chloride	Yield [%]
20	2	$C_6H_5(CH_2)_3Cl$	97
20	2	n-$C_{18}H_{37}$	96
0	4	 [a]	76
0	4	 [b]	85

[a] Obtained from (*R*)-(−)-2-octanol with inversion of configuration. [b] Obtained from 3β-cholestanol with inversion of configuration.

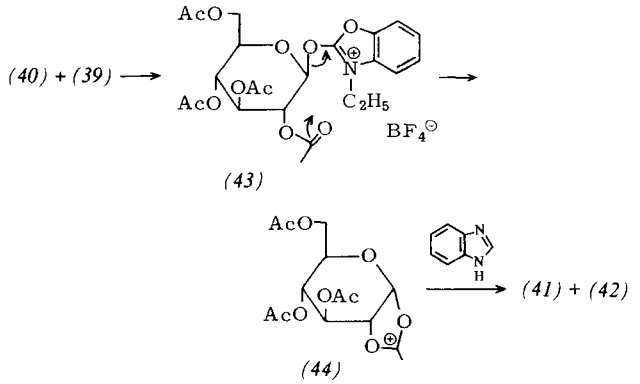
As shown in Table 10, an alicyclic alcohol (3β-cholestanol) as well as acyclic alcohols (primary and secondary) are converted into the chlorides in high yields. 3β-Cholestanol and (*R*)-(−)-2-octanol react with inversion of configuration.

The reaction may be explained by assuming initial formation of the 2-alkyloxybenzoxazolium salt *(34)*, which in turn reacts with chloride ion to afford alkyl chloride and 3-ethyl-2-benzoxazolinone. The high stereospecificity in the reactions of cholestanol and 2-octanol strongly indicates that *(34)* reacts with chloride ion in an S_N2 type process.



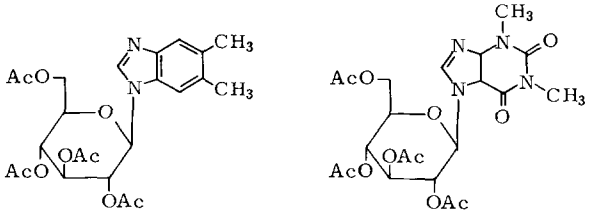
In order to examine the utility of the method, we employed two carbohydrates as substrates. When 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose *(35)* or 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose *(37)* is treated with *(33)* and tetraethylammonium chloride, one isomer [*(36)* or *(38)*], having the same configuration with the starting material, is obtained exclusively in excellent yield[32].

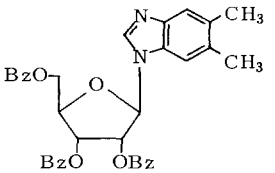
It is noted that the present method is suitable for the transformation of a wide variety of alcohols including alicyclic alcohols such as steroidal alcohols and carbohydrates. Thus, the benzoxazolium salt *(33)* is a promising reagent for the preparation of various optically active chlorides (see Section 4).



2.2.5. Nucleoside Synthesis

Nucleosides have also been prepared[33] from 1-hydroxy sugars and heterocycles utilizing the benzoxazolium salt *(33)*. The following procedure was adopted: To a stirred suspension of *(33)* and benzimidazole in 1,2-dichloroethane was added triethylamine in the same solvent at −23 °C, and the resulting mixture was heated for 5 h at 60 °C. The cooled reaction mixture was treated with triethyloxonium tetrafluoroborate in order to remove the resulting chloride ion as ethyl chloride. To this mixture was added a 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose *(39)* and benzimidazole in 1,2-dichloroethane and 1,2-dimethoxyethane, and the resulting mixture was heated for 10 h at 60 °C. Thus the desired 2,3,4,6-tetra-

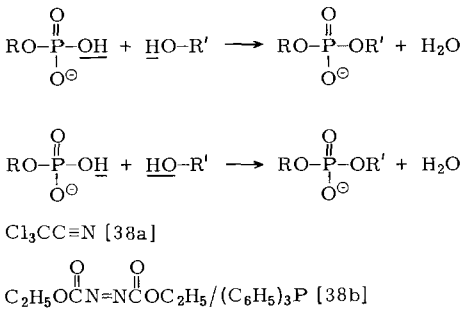




O-acetyl-β-D-glucopyranosylbenzimidazole *(41)* was obtained in 73% yield along with a trace of substituted glucopyranose *(42)*.

In the first stage of this reaction, a considerable amount of glucopyranose *(42)* was formed along with the desired nucleoside *(41)* (*ca.* 2:1). This may be explained as follows; the transient 2-(1-benzimidazolyl)benzoxazolium tetrafluoroborate *(40)* reacts with acetyl glucose *(39)* to give the intermediate *(43)*. With the assistance of the 2-acetoxy group of the sugar moiety, the elimination of 3-ethyl-2-benzoxazolinone from *(43)* takes place easily to give the acetoxonium ion *(44)*. This ion is then converted into the glucopyranose *(42)* or the *trans* nucleoside *(41)* by the nucleophilic attack of benzimidazole either on the electrophilic C atom or on the glycosidic center.

On heating *(42)* is converted into the thermodynamically more stable *(41)*. This transformation is assumed to proceed in a similar manner to the rearrangement of orthoesters of sugars to *trans* glycosides[34]. In a similar manner, the *trans* nucleosides *(41a–c)* were prepared in high yields.



There are two general methods for the preparation of nucleosides: (i) the reaction of heavy metal salts of heterocycles and glycosyl chlorides[35], and (ii) the fusion of heterocycles with acylated sugars in the presence of acidic catalysts[36]. The striking feature of our onium salt method is that *trans* nucleosides are produced in good yields under mild conditions without any assistance from heavy metals or acidic catalysts.

2.2.6. Phosphorylation

The concept of the activation of alcohols by the onium salt method was further extended to the phosphorylation of alcohols involving 2-alkyloxybenzoxazoles as intermediates[37]. It was hoped that the *N*-protonation of the 2-alkyloxybenzoxazole by certain phosphoric acid derivatives would result in an active intermediate, similar to 2-alkyloxybenzoxazolium salts, which would attack the phosphate anion formed at the same time. Many methods are known for the phosphorylation of alcohols, most of them involving activation of the phosphoryl group; methods based on activation of the alcohol have scarcely been reported[38]. Nevertheless the latter type of phosphorylation has the advantage of avoiding pyrophosphate formation.

When 2-alkyloxybenzoxazoles *(45)*, easily prepared from alcohols and 2-fluorobenzoxazole (Table 11), are treated with diphenyl hydrogen phosphate in refluxing benzene, the corresponding alkyl diphenyl phosphates *(46)* are obtained in good yields (Table 11). This method is seen to be superior in terms of reaction time, yields, and amount of the alcohols used when compared with former methods.

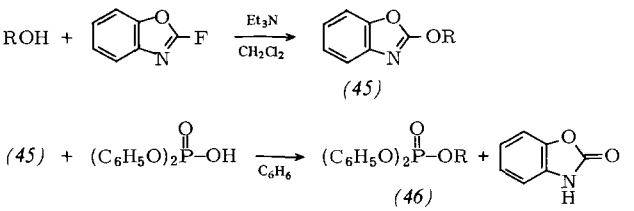


Table 11. Synthesis of 2-alkoxybenzoxazoles *(45)* from alcohols and 2-fluorobenzoxazole at room temperature and transformation of *(45)* into alkyl diphenyl phosphate *(46)*.

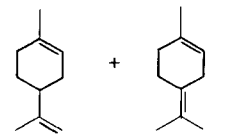
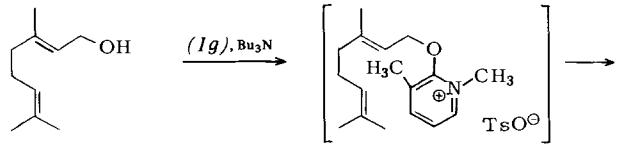
[a] RT = room temp., R = reflux.

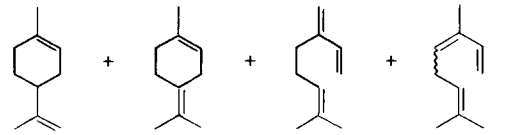


3. Intramolecular Dehydration

3.1. Biogenetic-Like Cyclization

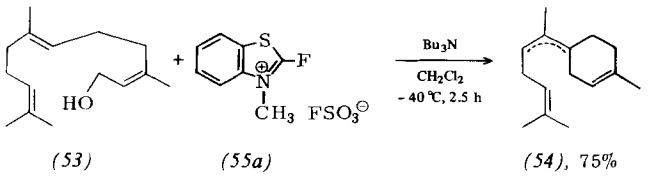


During the course of further investigation on the reaction of 2-fluoropyridinium salts and alcohols, 2-alkyloxypyridinium salts derived from the terpene alcohols nerol or geraniol were found to be unstable even at −78 °C, they are readily converted into hydrocarbon and 1-methyl-2-pyridone. For example, when nerol *(47)* is allowed to react with 1,3-dimethyl-2-fluoropyridinium tosylate *(1g)* and tri-*n*-butylamine in methylene chloride at −40 °C for 7 h, limonene *(48)* and terpinolene *(49)* are produced in 82% and 15% yield, respectively[39]. In the case of the reaction of geraniol *(50)*, uncyclized monoterpene hydrocarbons, myrcene *(51)* and ocimene *(52)*, were formed in smaller amounts. The *cis* configuration of the 2,3-double bond in the nerol moiety of the 2-neryloxypyridinium salt causes C-1 and the 6,7-double bond to be in close proximity and this leads to both the high reactivity and the high product selectivity. Thus no uncyclized product was detected when the reaction was carried out at low temperature. However, when the same reaction was undertaken at room temperature, myrcene and ocimene were also formed in *ca.* 10—15% yield along with the cyclized products.

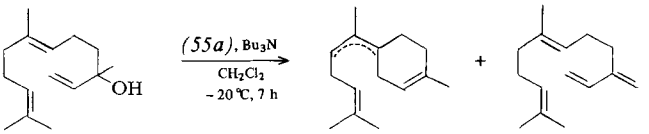


(47)

(48), 82% *(49)*, 15%



(50)



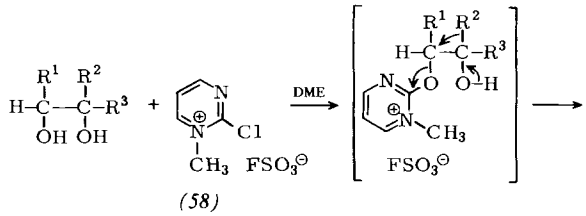
(48), 40% *(49)*, 4% *(51)*, 9% *(52)*, 9%

Application of this method to sesquiterpene alcohols was then examined[40]. In the first place the reaction of *trans,cis*-farnesol *(53)* with *(1g)* was tried, but the yield of cyclized product, bisabolene *(54)*, was low and many undetermined by-products were formed. Cyclization of *trans,cis*-farnesol using the onium salts such as 2-fluoro-3-methylbenzothiazolium fluorosulfate *(55a)* gave the best results (max. yield 75%). On the other hand, *trans,trans*-farnesol gave only a low yield of bisabolene (35%); a similar result is obtained in the reaction of geraniol.

(53) *(55a)* *(54)*, 75%

Using this method, nerolidol *(56)* was cyclized to bisabolene *(54)* in 79% yield, together with a small amount (less than 10%) of farnesene *(57)*.

(56) *(54)*, 79% *(57)*, < 10%



The allylic cation is more easily generated from nerolidol *(56)* than from farnesol *(53)*, so the competitive deprotonation would lead to farnesene. Naturally occurring terpenes are derived directly, or by way of stereospecific cyclizations and rearrangements, from the acyclic precursors such as geraniol or farnesol.

Non-enzymatic biogenetic-like conversion of such a precursor into the other terpenes has been of much interest and widely investigated[41]. However, most conversions of this kind involve the activation of hydroxyl group with protic acids or Lewis acids. Moreover, no method in a weakly basic medium has previously been reported, so the onium salt method provides a new entry among the biogenetic-like cyclization methods.

3.2. The Beckmann and Pinacol Rearrangements

The results of the cyclization studies on terpene alcohols suggest that the onium salts of 2-haloaza-arenes are useful reagents both for intramolecular dehydrations or rearrangements and for intermolecular reactions. Since such dehydrations or rearrangements are usually carried out in acidic media the utilization of the onium salt in weakly basic media could cause reactions to take a different course. These considerations prompted us to examine the pinacol and the Beckmann rearrangements as reactions usually carried out under strongly acidic conditions.

When a mixture of a pinacol and 2-chloro-1-methylpyrimidinium fluorosulfate *(58)* in dimethoxyethane is stirred at 0 °C for half an hour, and then refluxed for an additional half an hour, rearranged products (ketone or aldehyde) are obtained in good yield[42]. This is illustrated for phenylethanediol derivatives in Table 12.

(58)

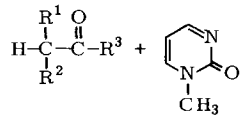


Table 12. Pinacol rearrangement with the 2-chloropyrimidinium salt *(58)* in 1,2-dimethoxyethane (DME).

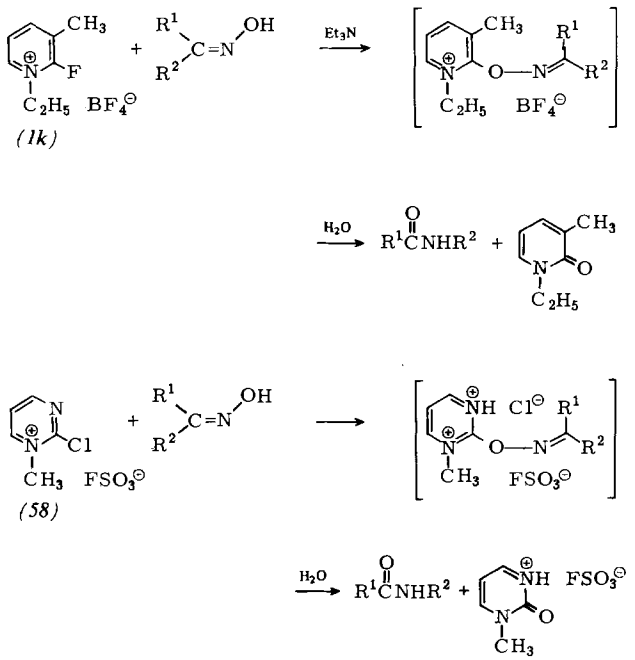
R^1	R^2	R^3	Yield [%]
C_6H_5	C_6H_5	H	54
C_6H_5	C_6H_5	CH_3	88
C_6H_5	C_6H_5	C_2H_5	73
C_6H_5	C_6H_5	C_6H_5	82
C_6H_5	$C_6H_5CH_2$	$C_6H_5CH_2$	60

Further, the pinacol rearrangement of trisubstituted ethanediol derivatives by the onium salt method involves elimination of the secondary hydroxyl group; the tertiary hydroxyl group is usually lost under acidic conditions. The peculiarity of this reaction may be explained by assuming that the 2-chloropyrimidinium salt *(58)* reacts mainly with the less hindered hydroxyl group of diols to form 2-(2-hydroxyethoxy)pyrimidinium salts, which in turn are immediately converted into the corresponding ketones with concomitant elimination of 1-methyl-2-pyrimidinone.

When oximes are treated at low temperature with 1-ethyl-2-fluoro-3-methylpyridinium tetrafluoroborate *(1k)* and triethylamine or with the 2-chloropyrimidinium salt *(58)* alone, they rearrange smoothly to the amides in high yields. The facility of rearrangement may be explained by assuming initial formation of *O*-(2-pyridinio)oximes or *O*-(2-pyrimidinio)oximes, which in turn rearrange to the amides on treatment with water (Table 13)[43]. Rearrangement proceeds particularly smoothly when the pyrimidinium salt *(58)* is used; oximes are simply mixed with *(58)* (even in the absence of tertiary amine).

Furthermore, the present method gives *N-tert*-butylbenzamide in high yield from pivalophenone oxime. This oxime rearranges to pivalanilide under the acidic conditions generally employed and to *N-tert*-butylbenzamide on heating with *p*-toluenesulfonyl chloride in alkaline solution[44].



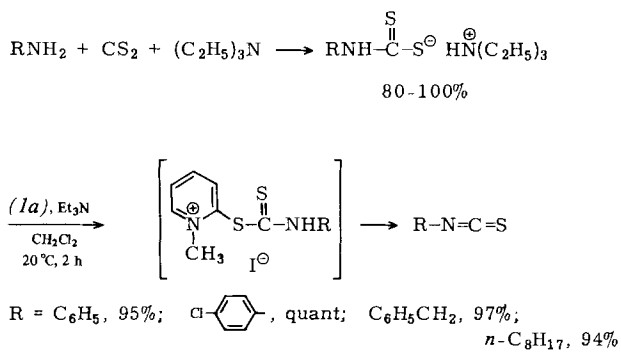


Table 13. Beckmann rearrangement of oximes with the onium salts *(1k)* (+Et_3N) and *(58)*.

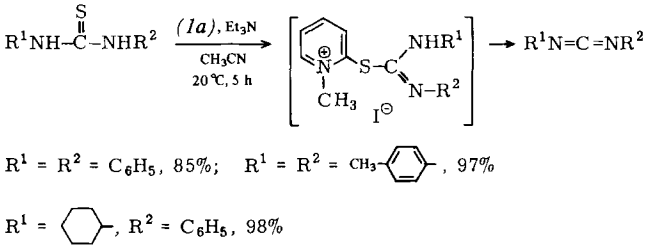
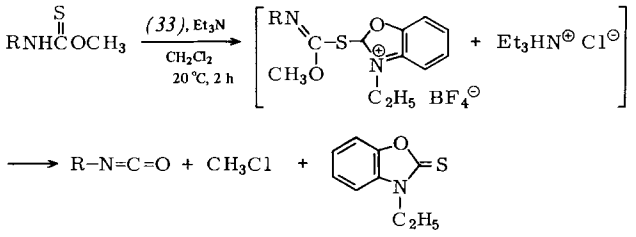
(58)	$(CH_2)_5$		94



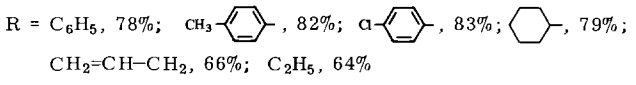
3.3. Preparation of Isothiocyanates and Carbodiimides

The ability of the sulfidopyridinium function to act as an effective leaving group was further demonstrated in the following preparation of isothiocyanate and carbodiimide.

When triethylammonium dithiocarbamate, easily prepared from amine, carbon disulfide, and triethylamine, is treated with the 2-chloropyridinium salt *(1a)* at room temperature, isothiocyanate is produced in high yield[45].



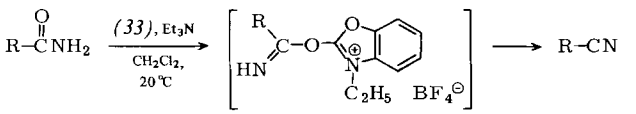
On treatment of *N,N'*-disubstituted thioureas with *(1a)* at room temperature in the presence of triethylamine, a similar β-elimination occurs smoothly to afford the corresponding carbodiimides in good yields[46].

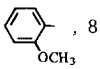


Carbodiimides are particularly important coupling reagents in the synthesis of peptides and nucleotides, and numerous publications have appeared which describe their preparation[47]. These involve, *e.g.*, catalytic conversion of isocyanates, dehydration of *N,N'*-disubstituted ureas, and desulfurization of thioureas with metal oxides and other metallic compounds, and also with alkaline hypochlorite. The new method is of quite general utility; aromatic and aliphatic carbodiimides are obtained by a simple procedure.

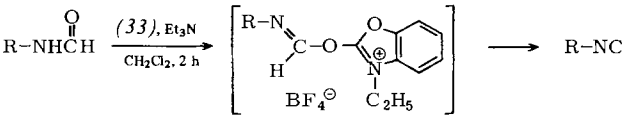
3.4. Preparation of Isocyanates

Methyl thiocarbamates are easily converted to the corresponding isocyanates in good yields on treatment with the more active onium salt, 2-chloro-1-ethylbenzoxazolium tetrafluoroborate *(33)*, in the presence of an equimolar amount of triethylamine[48]. The reaction proceeds *via* the initial attack of sulfur on the benzoxazolium salt to produce a 2-(iminomethylthio)benzoxazolium salt, which suffers nucleophilic attack by chloride ion at the methyl group. The method can be used for synthesis of both aliphatic and aromatic isocyanates at room temperature under neutral conditions. It also permits the preparation of allyl isocyanates which are accessible only in low yield by conventional methods[49].





R = C_6H_5, 78%; , 82%; , 83%; , 79%;
CH_2=CH–CH_2, 66%; C_2H_5, 64%



3.5. Preparation of Nitriles and Isocyanides

The 2-chlorobenzoxazolium salt *(33)* is very reactive; in the presence of triethylamine at room temperature it transforms carboxamides into nitriles[50].

R = C_6H_5, 88%;  , 81%;  , 78%; $C_6H_5CH_2$, 83%
n-C_6H_{13}, 73%

β-Elimination reactions of *N*-substituted formamides leading to isocyanide formation are also possible utilizing *(33)*. The reaction proceeds at room temperature under neutralization conditions. This isocyanide synthesis can be applied to

R = C_6H_5, 81%; 2,6-$Cl_2C_6H_3$, 69%; m-NO_2-C_6H_4, 86%;
$C_6H_5CH_2$, 82%; n-$C_{12}H_{25}$, 71%; n-C_6H_{13}–CH(CH_3), 78%

both aliphatic and aromatic formamides[51]. It is also applicable to the preparation of secondary alkyl isocyanides such as 1-methylheptyl isocyanide, which are not accessible by other methods[52].

3.6. Preparation of 1,2-Dichloroalkanes

The pronounced reactivity of 2-chlorobenzoxazolium salts such as *(33)* also enabled the following reactions to be carried out: Treatment of epoxides with *(33)* in the presence of tetraethylammonium chloride and triethylamine gives 1,2-dichloroalkanes in good yields (Table 14)[53]. The reaction probably proceeds *via* a chlorohydrin intermediate which is immediately converted into a 2-alkyloxybenzoxazolium salt. The salt is in turn attacked by chloride ion to give the 1,2-dichloroalkane.

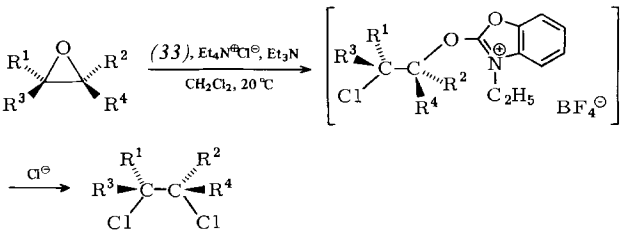


Table 14. Synthesis of 1,2-dichloroalkanes from epoxides.

R^1	R^2	R^3	R^4	t [h]	Yield [%]
C_6H_5	H	H	H	48	81
C_6H_5	H	H	C_6H_5	48	77 [a]
n-C_7H_{15}	H	H	H	48	75
p-$CH_3C_6H_4OCH_2$	H	H	H	12	95
n-$C_8H_{17}OCH_2$	H	H	H	12	84
$(CH_2)_4$		H	H	48	58 [b]

[a] DL:*meso* = 77:23. [b] *cis*:*trans* = 98:2.

Conventional preparations of 1,2-dichloroalkanes from 1,2-epoxides require prolonged heating in a solvent such as pyridine or chloroform for the completion of the reaction[54]. The transformation of cyclohexene oxide demonstrates the high stereospecificity of this reaction. *trans*-1,2-Dichloroalkane can generally be obtained directly from olefins and chlorine; the new method provides complementary effective and stereospecific route to the *cis* isomers.

3.7. Preparation of Ketones from α-Hydroxy Acids

Another example of the high reactivity of 2-chlorobenzoxazolium salts such as *(33)* is seen in the elimination of carbon monoxide and water from α-hydroxy carboxylic acids. When a mixture of α-hydroxy carboxylic acid and 2-chlorobenzoxazolium salt is added to a methylene chloride solution of triethylamine at room temperature, carbon monoxide is evolved rapidly, and the ketone is obtained in high yield (Table 15)[55].

The direct preparation of ketones from α-hydroxy carboxylic acids without using any oxidizing reagent was formerly unknown. Use of the onium salt *(33)* affords ketones in good yields under mild conditions.

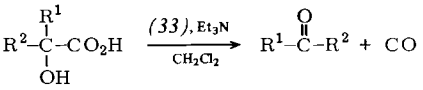

Table 15. Synthesis of ketones from α-hydroxy carboxylic acids.

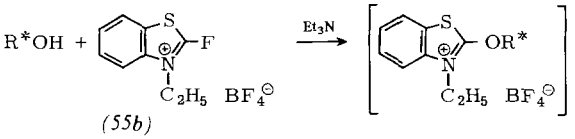

R^1	R^2	Yield [%]
C_6H_5	C_6H_5	83

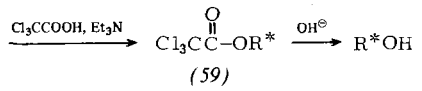
4. Preparation of Optically Active Substances



Structure-bioactivity relationships show that often only one enantiomer exhibits activity. Consequently, interest in the synthetic approach to a specific enantiomer of natural products has created a need for efficient and practical syntheses of optically active compounds. The fact that stereospecific reactions with inversion occur on use of the onium salts prompted us to examine the optical interconversion of chiral alcohols and the transformation of the alcohols into other derivatives.

4.1. Optical Interconversion of Enantiomeric Alcohols

Optically active 2-alkyloxybenzothiazolium salts, formed *in situ* from an optically active (secondary) alcohol and 2-fluorobenzothiazolium salt *(55b)*, react in the presence of triethylamine with a strong acid such as trichloroacetic acid to yield the ester *(59)*. This undergoes facile base-catalyzed hydrolysis to afford the enantiomer of the starting alcohol. Thus this sequence makes possible the interconversion of the

(55b)

(59)

Table 16. Interconversion of enantiomeric alcohols using the onium salt *(55b)*.

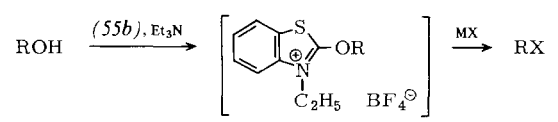
Starting material	$[\alpha]_D$ [°]	Product	$[\alpha]_D$ [°]
(*S*)-(+)-2-Butanol	+ 9.4	(*R*)-(−)-2-Butanol	− 7.8
(*R*)-(−)-2-Butanol	− 9.7	(*S*)-(+)-2-Butanol	+ 8.6
(*S*)-(+)-2-Octanol	+12.3	(*R*)-(−)-2-Octanol	−11.2
(*R*)-(−)-2-Octanol	−12.0	(*S*)-(+)-2-Octanol	+10.2
(*S*)-(+)-3-Nonanol	+ 9.6	(*R*)-(−)-3-Nonanol	− 7.4

enantiomeric secondary alcohols by a simple procedure (Table 16)[56]. For instance, (*S*)-(+)-2-octanol was converted into (*R*)-(−)-2-octanol in 70% overall yield.

4.2. Preparation of Alkyl Halides

The intermediate 2-alkyloxybenzothiazolium salt (see Section 4.1) also reacts with alkali metal halides to afford the alkyl halide in good yields (Table 17)[57].

Table 17. Synthesis of alkyl halides from alcohols. Isolated yields are given.



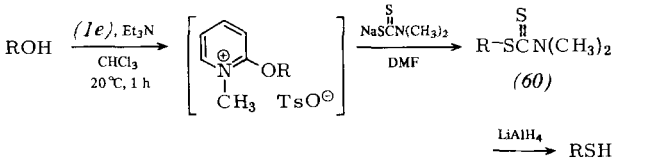
MX	RX	Yield [%]
NaI	$C_6H_5CH_2CH_2CH_2I$	92
LiBr	$C_6H_5CH_2CH_2CH_2Br$	90
LiCl	$C_6H_5CH_2CH_2CH_2Cl$	90
NaI	$C_6H_5CH_2CH_2I$	82
LiBr	$C_6H_5CH_2CH_2Br$	87
NaI	DL-$C_6H_5CH_2CH(CH_3)I$ [a]	75
LiBr	DL-$C_6H_5CH_2CH(CH_3)Br$ [a]	72
NaI	(*R*)-(−)-$C_6H_{13}CH(CH_3)I$ [b]	87
LiBr	(*S*)-(+)-$C_6H_{13}CH(CH_3)Br$ [c]	64
LiCl	(*R*)-(−)-$C_6H_{13}CH(CH_3)Cl$ [b]	56

[a] Starting material: DL-alcohol. [b] Starting material: (*S*)-(+)-alcohol. [c] Starting material: (*R*)-(−)-alcohol.

Table 18. Optical rotation of 2-halooctanes.

Alcohol [a]	2-Halooctane	$[\alpha]_D^{23}$ [b]	*c* [g/100 ml]
(*S*)-(+)-2-Octanol	(*R*)-(−)-2-Iodooctane	−53.1°	4.07
(*R*)-(−)-2-Octanol	(*S*)-(+)-2-Bromooctane	+39.9°	4.16
(*S*)-(+)-2-Octanol	(*R*)-(−)-2-Chlorooctane	−33.7°	17.0

[a] Our samples of (*S*)-(+)- and (*R*)-(−)-2-octanol had $[\alpha]_D^{20}$ (0.1 dm, neat) +9.9 and −9.7°, respectively. Literature values: +9.9 and −9.9°. [b] Optical rotation measurements recorded in a 0.1 dm tube in ether with an automatic polarimeter. Reported maximum rotations of (*R*)-(−)-2-halooctanes $[\alpha]_D^{20}$ (neat) are: −64.6 (I), −44.9 (Br), and −36.2° (Cl).

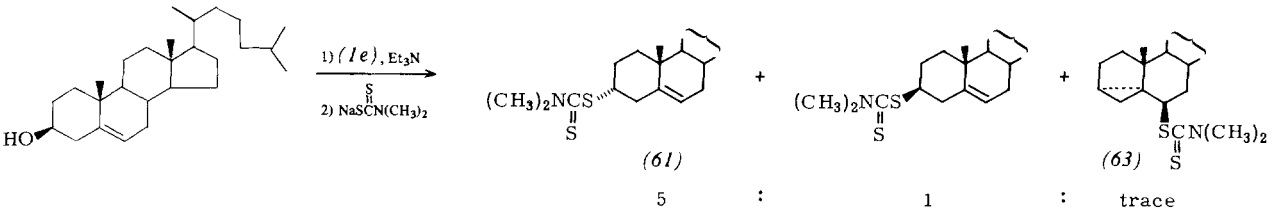


The stereochemical course of the reaction was exemplified by (*S*)-(+)- and (*R*)-(−)-2-octanol. The results shown in Table 18 clearly indicate that the benzothiazolium moiety of the salt is displaced by a halide ion with inversion of configuration to give 2-halooctane of high optical purity. Among the many examples of the preparation of optically active alkyl halides from alcohols, only a few (*e.g.* the reaction of tosylate carried out under strictly controlled experimental conditions)[58] have been found satisfactory in practice. Under the usual reaction conditions alkyl iodides in particular are generally attacked by iodide, thus resulting in racemization. The present halogenation method has several advantages over others with respect to the generality, yields, and the mildness of the reaction condition (low temperature, almost neutral medium, and equimolar amounts of the reagents, *etc.*). Side reactions and a halide ion exchange are minimized.

4.3. Preparation of Thiols

Thiols are widely used as versatile synthetic intermediates and many syntheses have been reported[59], most of them consisting of three steps: (i) conversion of alcohols into halides or tosylates; (ii) bimolecular substitution with sulfur-containing nucleophiles; and (iii) conversion of the intermediates into thiols. Although Walden inversion occurs in most of the methods, some stereochemical ambiguities remain to be resolved[60]. The utilization of the onium salts of azaarenes for the preparation of thiols appears promising, provided that a suitable combination of sulfur-containing nucleophiles and onium salts can be found.

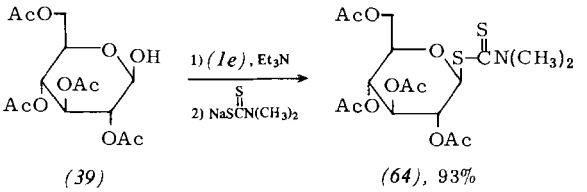
After screening several possible combinations, it was found that 1-fluoro-2-methylpyridinium tosylate *(1e)*/sodium *N,N*-dimethyldithiocarbamate is effective for this purpose. Thus various alcohols including steroids and carbohydrates have been successfully converted into the corresponding thiols in high yields with high stereospecificity[61]. The procedure consists of: (i) reaction of alcohols with *(1e)* to give 2-alkyloxypyridinium salts; (ii) S_N2 type reaction of these salts with sodium *N,N*-dimethyldithiocarbamate to give alkyl dithiocarbamates *(60)*; and (iii) reductive cleavage to thiols.



(60), R = *n*-$C_{12}H_{25}$, 97%; $C_6H_5CH_2$, 98%; $C_6H_5CH{=}CHCH_2$, 98%; DL-$C_6H_{13}CH(CH_3)$, 94%; product from (−)-menthol, 66%

(*R*)-(−)-2-Octanethiol was obtained with complete inversion of configuration from an optically active alcohol, *e.g.* (*S*)-(+)-2-octanol ($[\alpha]_D^{20}$ +9.9° (neat)), by treatment with *(1e)* and dithiocarbamate and subsequent reduction. The rotatory power of the thiol was $[\alpha]_D^{23} = -32.7°$ (1.74, C_2H_5OH).

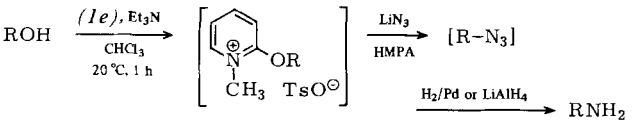
A clean inversion of configuration also occurred in the case of alicyclic alcohols. For instance, 3β-cholestanol could be converted into 3α-cholestanethiol in 97% overall yield.



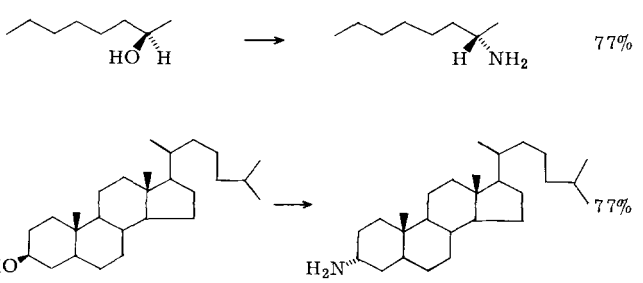
Similar treatment of 3β-cholesterol afforded a 5:1 mixture of isomeric dithiocarbamates (together 76%), where the major component was the α-isomer *(61)* (inversion) and a minor component was the β-isomer *(62)* (retention), both of which were converted into the corresponding thiols and their acetyl derivatives.

Since preparative methods for cholestenethiol using 3β-cholesteryl chloride and potassium thiocyanate[62], or 3β-cholesteryl tosylate and thiourea[63], give only the β-isomer, the formation of α-isomer with inversion according to this method seems of particular synthetic importance.

In allylic systems, *e.g.* cinnamyl alcohol, substitution takes place exclusively at the OH-substituted carbon atom; and no isomeric dithiocarbamate (S_N2') was detected.



Treatment of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose *(39)* with *(1e)* and sodium dithiocarbamate produces a single dithiocarbamate, the β-isomer *(64)*, formed with retention of configuration. The result can be explained by invoking participation of the neighboring acetoxy group *trans* to the leaving group.

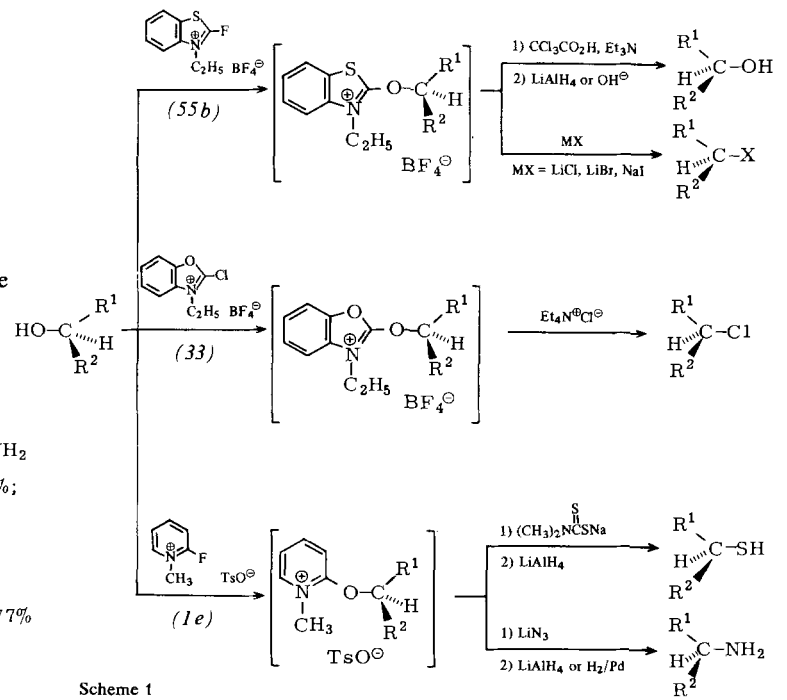


(39) *(64)*, 93%

4.4. Preparation of Primary Amines

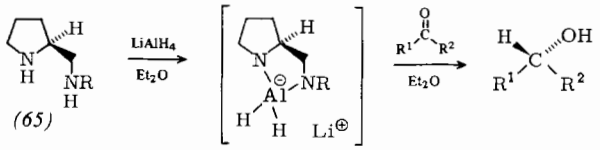
The last example utilizing the onium salt of azaarenes is the stereospecific synthesis of primary amines from alcohols.

R = n-$C_{12}H_{25}$, 94%; $C_6H_5CH_2$, 77%; $C_6H_5CH{=}CHCH_2$, 78%; DL-$C_6H_5CH(CH_3)$, 75%



Sterically controlled introduction of amino groups is of special synthetic importance, and extensive investigations have been conducted in recent years[64].

Among the various combinations of nitrogen-containing nucleophiles and onium salts examined, lithium azide/2-fluoro-1-methylpyridinium tosylate *(1e)* gave favorable results. Treatment of the intermediate 2-alkyloxypyridinium salt with potassium phthalimide, ammonia, and lithium diarylsulfenamide[64c] proved unsuccessful. The use of the 2-fluorobenzothiazolium salt *(55a)* instead of *(1e)* gave poor yields of alkyl azides. This method seems to have general applicability, since the conversion of alkyl azides into primary amines is known to be effected under a variety of mild reductive conditions, with most of the functional groups present in a molecule remaining intact[65].



4.5. Preparation of Secondary Alcohols by Asymmetric Reduction and Alkylation

We have described an effective and convenient method for the preparation of chiral halides, thiols, and amines from chiral secondary alcohols by utilizing the onium salts of aza-arenes. Thus various types of optically active compounds are accessible when an effective route to chiral secondary alcohols could be found. Hence, we have recently investigated the asymmetric reduction and alkylation of carbonyl compounds to chiral alcohols.

Scheme 1

For the asymmetric reduction of prochiral ketones, chiral hydride reagents *(66)*, prepared *in situ* from (*S*)-2-(anilinomethyl)pyrrolidine *(65a)* or (*S*)-2-(2,6-xylidinomethyl)pyrrolidine *(65b)* and $LiAlH_4$, were found to be efficient[66]. For example, acetophenone was reduced to 1-phenylethanol in 95% optical yield (enantiomeric excess). As shown in Table 19, these chiral hydride reagents afford higher optical yields than previously reported reagents of this kind[67-70].

(65)

(a), R = Ph;

(b), R = 

(66)

Although the precise mechanism of this asymmetric reduction is not clear, we assume that the high enantioselectivity (all the alcohols produced have mainly *S*-configuration except when THF was used as solvent) to be due to the following factors: (i) The diamines *(65)*, simple compounds having only one asymmetric carbon, produce the effective chiral environment on treatment with $LiAlH_4$. This may be due to the formation of

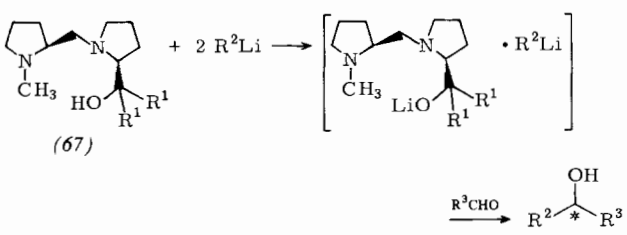


Table 19. Asymmetric reduction of ketones. Comparison of chiral reagents produced from $LiAlH_4$ and chiral ligands. (Values in parentheses: at −100 °C.) The enantiomeric excess is given.

sterically restricted *cis*-fused bicyclic hydride reagents, creating the additional chiral center on the nitrogen atom in the pyrrolidine ring. (ii) The reactivity of the two hydrogen atoms present in this chiral reagent is remarkably different; only one of them reacts with ketones, the other being subject to steric hindrance. (iii) The lithium ion, which presumably coordinates to the nitrogen atom of the pyrrolidine ring and/or the side chain in *(66)*, restricts the direction of approach of the ketones.

In contrast to the asymmetric reduction of carbonyl compounds where relatively high enantiomeric excess were realized, the enantiomeric excesses in the asymmetric alkylation of

(67)

organometallic reagents, such as Grignard reagents[71], alkyllithium[71b,72], organocopper[73] or alkylcadmium[74], with carbonyl compounds by using chiral ligand are very low (0–40%). However, the concept of the *cis*-fused five-membered ring system formed from the aminomethylpyrrolidine moiety was also found to be effective for the asymmetric alkylation of carbonyl compounds. Thus various optically active alcohols were obtained by the asymmetric reaction of alkyllithium with aldehydes using the dipyrrolidine derivative *(67)* as the chiral ligand (Table 20)[75].

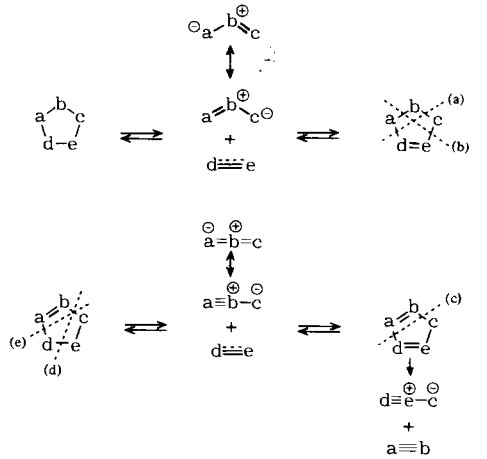
1,3-Dipolar Cycloreversions



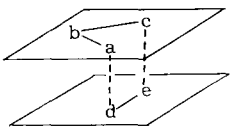
By Giorgio Bianchi, Carlo De Micheli, and Remo Gandolfi[*]

The 1,3-dipolar cycloreversion reaction represents a general scheme of fragmentation of pentaatomic heterocycles to produce 1,3-dipolar systems and dipolarophiles. This review summarizes cycloreversions which give rise to octet-stabilized 1,3-dipoles. The reaction can be either thermal or photochemical or electron impact induced. The aim of the article is to survey the published results, to emphasize the synthetic potential of this reaction, and to stimulate the study of its several not yet unambiguously defined mechanistic aspects.

1. General

The general concept of the 1,3-dipolar cycloadditions was recognized by *Huisgen* in the early 1960's[1]. Since then, an increasing number of researchers has produced an enormous amount of data on this branch of chemistry[2–11] and numerous examples have been found of the reverse reaction of 1,3-dipolar cycloaddition, *i.e.* [5→3+2][12] 1,3-dipolar cycloreversion. Scheme 1 exemplifies the cycloadditions of dipolarophiles with octet-stabilized[11] 1,3-dipoles of the allyl and propargyl-allenyl type and the corresponding cycloreversions[13].

Very often a [3+2]-cycloaddition/[3+2]-cycloreversion sequence generates a 1,3-dipole/dipolarophile couple differ-



Scheme 1. 1,3-Dipolar cycloadditions and cycloreversions. Above: reactions with 1,3-dipoles of allyl type. Below: Reactions with 1,3-dipoles of propargyl-allenyl type. In the reactant shown at top left of scheme, all [5→3+2]-fragmentations are *a priori* possible. (a)—(e), see text.

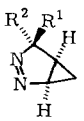
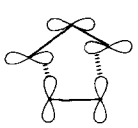
ent from the original reactants. This is the case when the cyclic adducts of Scheme 1 break down according to modes (a)—(e) ("1,3-dipole metathesis")[14]. This review will consider only the cycloreversions in which two σ bonds of the heterocycle are broken to give octet-stabilized 1,3-dipoles and double and triple bond dipolarophiles. Cycloreversions yielding vinylcarbenes, vinylazenes, ketocarbenes, ketoazenes, *etc.* as well as those giving equilibria such as azido-azomethines ⇌ tetrazoles, diazo-azomethines ⇌ triazoles, *etc.*[15-19] will not be treated.

Cycloreversions are induced thermally, photochemically, or by electron impact.

From the standpoint of orbital symmetry, thermal cycloreversions (from the ground state) are allowed[20] as suprafacial processes with regard to both fragments, and proceed *via* an aromatic (*Hückel*)[21] transition state. This $[_{\sigma}2_s + _{\sigma}2_s + _{\omega}2_s]$-concerted reaction takes place with some degree of nonsynchroneity in the σ bond cleavage. Experimental evidence for this type of mechanism has been found for anionic cycloreversions and for azides and nitrile imines (see Sections 2, 4, and 6); however, in some other instances a two-step mechanism involving a zwitterion (diazoalkanes, see Section 7) or a diradical (carbonyl oxides, see Section 12) has been advanced. As for [3+2]-cycloaddition[13,22], we consider the concerted mechanism the most plausible for the 1,3-dipolar cycloreversions too, especially for those processes in which addends are in equilibrium with adducts. The transition state geometry may vary according to the nature of the 1,3-dipole moiety. While for the reactions involving an allyl type 1,3-dipole *Huisgen*'s parallel-planes transition state *(1)* has received theoretical support from *ab initio* MO calculations[23], the same type of calculations have shown a one-plane transition state *(2)* to be most likely for 1,3-dipoles of propargyl-allenyl type[24].



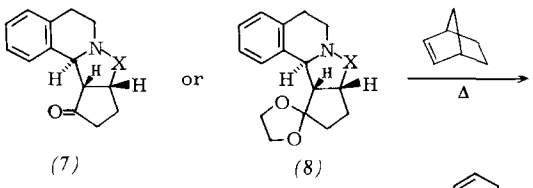
(1)



(2)

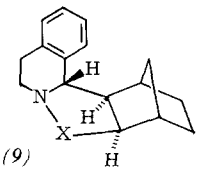
The great majority of photochemical cycloreversions takes place with the reactant in an excited singlet state[25-29]. Some of these reactions are known to be stereospecific[27,30-32]. A lack of stereospecificity may be explained in terms of photoinduced rearrangements of the final products[29,31]. No excited fragments have been detected and there is experimental evidence that the subsequent reactions of the photogenerated 1,3-dipoles take place in a thermally equilibrated ground state[25,33,34]. The efficiency of these liquid phase reactions varies, even though in some cases fairly high quantum yields (φ) have been measured (0.75 and 0.53, respectively) for extrusion of N_2 from *(3)* and *(4)* (313 nm, pentane)[30].

(3), R^1 = H, R^2 = CH_3
(4), R^1 = CH_3, R^2 = H



(5)

(6)

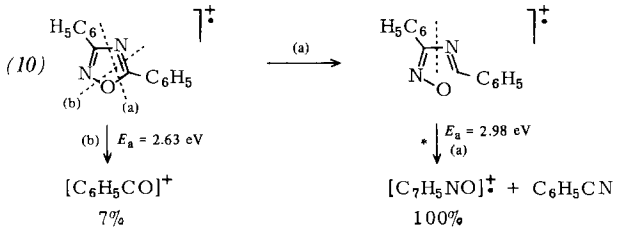


As far as the transition state geometry of the process is concerned, simple Woodward-Hoffmann orbital symmetry predictions require that, in a singlet excited state concerted fragmentation, one component has to react antarafacially as shown in *(5)*. This orientation is sterically unfavorable. However, no compelling experimental evidence exists for such a transition state structure. Some authors have proposed an alternative mechanism with a diradical such *(6)* as intermediate[35,36]. This latter hypothesis corresponds to a G_R type reaction (according to the Dougherty classification) with the system going from an excited surface (S_1) to the ground state surface (S_0). The diradical, where the two surfaces touch each other, provides a Born-Oppenheimer hole for direct passage from excited state to ground state[37]. For stereospecific cycloreversions some account should be taken of reactions of (vibrationally excited) hot ground state molecules. These originate from the excited state *via* a radiationless transition. This type of reaction is generally considered unimportant in dense media as a consequence of a very fast loss of excess vibrational energy. Yet, this reaction may become operative if a selective concentration of energy on the bonds to be broken occurs, and if the nuclei are moving toward fragmentation when the S_0 surface is reached[38,39]. Examples of possible hot ground state reactions are known[39,40].

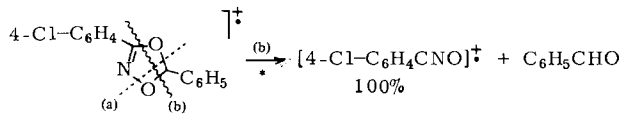
The most commonly encountered examples of thermal and photochemical cycloreversions are those with extrusion of small thermodynamically stable molecules such as CO_2 and N_2. Conjugation gain and steric strain relief on going from adducts to fragments are the most common and important factors favoring the cycloreversion process. The former reaction driving force finds clear support in the data reported in Scheme 2[41].

(7) *(8)*

(a), X = O; *(b)*, X = NC_6H_5



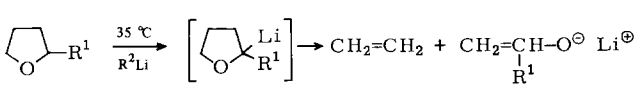
(9)



Scheme 2. Gain in conjugation energy as driving force for cycloreversion of *(7)* and *(8)*.

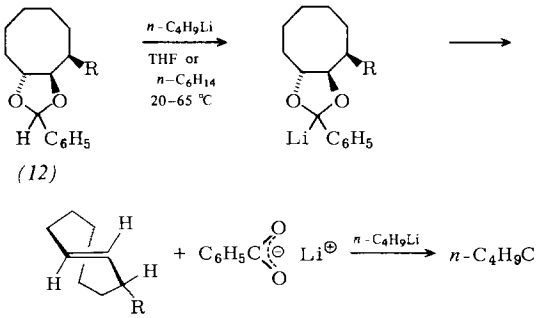
(7a) → *(9a)*, 9 h/ 80 °C/benzene 92% yield
(8a) → *(9a)*, 100 h/110 °C/toluene 10% yield
(7b) → *(9b)*, 100 h/140 °C/xylene 52% yield
(8b) 100 h/140 °C/xylene no reaction.

Numerous examples of electron impact induced 1,3-dipolar cycloreversion are known. Most of the five-membered heterocycles undergo this type of reaction. A very thorough mechanistic study of this type of reaction has been carried out by *Selva et al.* on 3,5-diaryl-1,2,4-oxadiazoles[42]. The radical ion $[C_7H_5NO]^+$ generated from *(10)* was shown to fragment further, to a slight extent as benzonitrile oxide and mainly as phenyl isocyanate, the rearrangement product of the 1,3-dipole[42a,b,43]. The process leading to the most abundant ion $[C_7H_5NO]^+$ [path (a)] is characterized by a higher activation energy [E_a = appearance potential − ionization potential] than that giving $[C_6H_5CO]^+$ [path (b)].



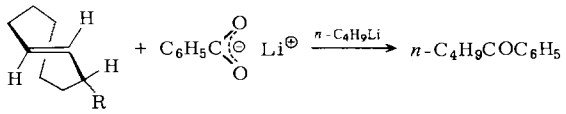
These results have been considered by the authors as good evidence for a stepwise cycloreversion in which there is a prior facile cleavage of the C–O bond [path (a)] requiring a smaller amount of energy than process (b)[42c,f]. Further investigations by the same authors, however, have shown that the ring cleavage can change from a stepwise to a concerted mechanism depending upon the substituents[42d]. In some instances, a completely different behavior of heterocycles towards thermal and electron impact induced cycloreversion has been observed. The 1,4,2-dioxazoline *(11)* fragments thermally exclusively by path (a) whereas cleavage (b) predominates on electron impact[44].

(11)

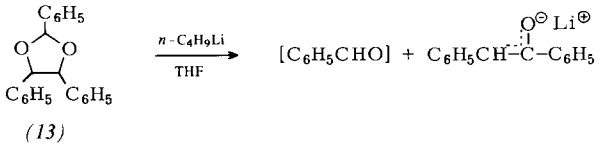


2. 1,3-Anionic Cycloreversions

The 1,3-anionic cycloreversion is particularly favored when the allyl or propargyl-allenyl anion fragment has a central carbon atom flanked by one or two electronegative atoms such as oxygen and sulfur[5,45]. This is because the negative charge is better stabilized on the triatomic anionic fragment, where it is localized at the two end atoms, than on the pentaatomic cycloanion, in which it is confined to the central C atom.

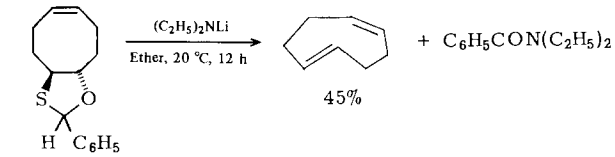


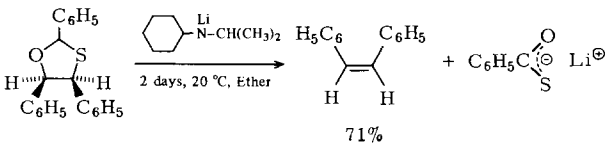
R^1 = H, R^2 = n-C_4H_9
R^1 = C_6H_5, R^2 = n-C_3H_7



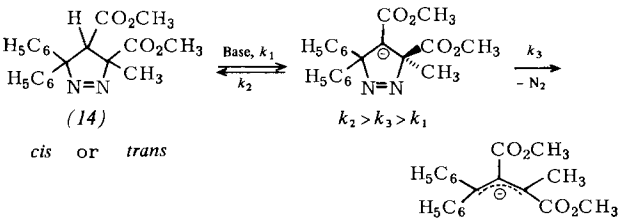
A cycloreversion reaction is often observed during slow metalation reactions with n-C_4H_9Li in tetrahydrofuran. The reaction is general for substituted tetrahydrofurans and is useful for the synthesis of enolates[46–48]. This reaction and all base-promoted fragmentations go through prior formation of an intermediate anion, which has been trapped or detected kinetically[47,49,50]. Cycloreversion proper follows. This type of mechanism applies to the transformation of cyclooctane-annelated 2-phenyl-1,3-dioxolanes *(12)* into *trans*-cyclooctenes derivatives in good yields[50,51]. However, the reaction is not generally applicable as shown by the fragmentation of *(13)*[50]. The undesired reactions encountered in the case of 1,3-dioxolanes can be avoided by using the 1,3-oxathiolanes. This is exemplified by the easy preparation of the highly strained *cis,trans*-1,5-cyclooctadiene and of *cis*-stilbene from the related precursors[52]. These compounds, however, were contaminated by traces of *cis,cis*-1,5-cyclooctadiene and *trans*-stilbene, respectively.

(12)



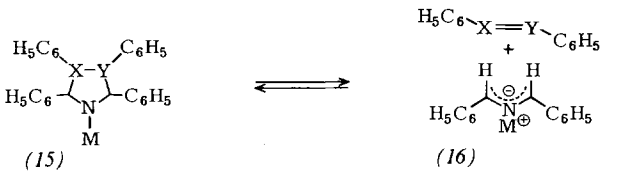


R = H, 73%
R = OH, 30%
R = OCH_3, 60%



(13)

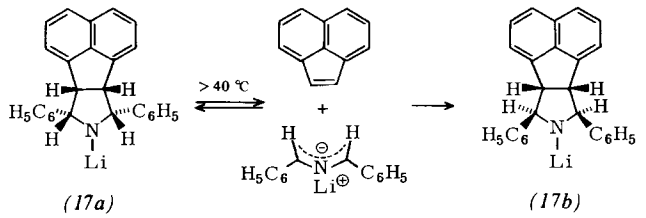
The authors do not explain whether these isomers are formed during the cycloreversion or afterwards. If the latter hypothesis were correct, the remarkable stereospecificity of the foregoing reactions suggests a concerted mechanism. The same mechanism was proposed by *Huisgen* for base-promoted extrusion of nitrogen from *cis*- and *trans*-*(14)* (sodium hydride in dimethylformamide at room temperature or sodium triphenylmethanide in tetrahydrofuran at $\geq -40\,^{\circ}C$). The rate of this reaction is $>10^{12}$ times greater than the thermal conversion of *(14)* ($>100\,^{\circ}C$) to cyclopropanes *via* the trimethylene species[49].



(14)

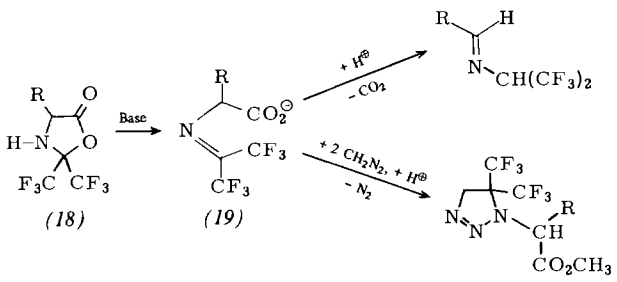
cis or *trans*

Examples of dynamic adduct ⇌ addends equilibria are those of 1,3-diphenyl-2-azaallyl anion *(16)* with various dipolarophiles. For instance, compound *(16a)* reacts with azobenzene at 20 °C to give high yields of the adduct *(15c)* which, however, at *ca.* 60 °C is in equilibrium with the addends[5]. The nature of the metals also plays a significant role, as evidenced by the fact that cycloreversion of *(15b)* is



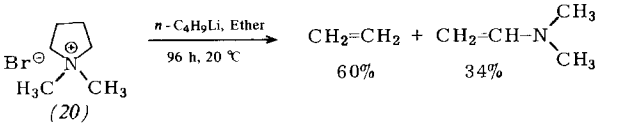
favored relative to *(15a)*[5]. This was rationalized on the basis of a hard-hard interaction between lithium cation and anion in *(15a)* and a soft-soft interaction between the potassium cation and the delocalized anion in *(16)*[45]. Quantitative transformation of the *"endo"* adduct *(17a)* into the stable *"exo"* isomer *(17b)*[5] is explained in terms of cycloreversion and subsequent cycloaddition[5]. Strain relief is probably the driving force of this reaction.

(15) *(16)*



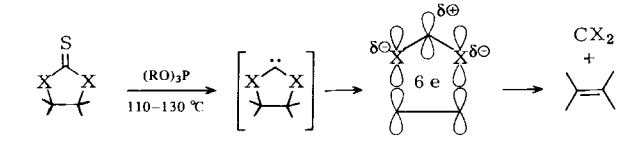
(a), X–Y = CH–CH, M = Li
(b), X–Y = CH–CH, M = K
(c), X–Y = N–N, M = Li

(a), M = Li
(b), M = K



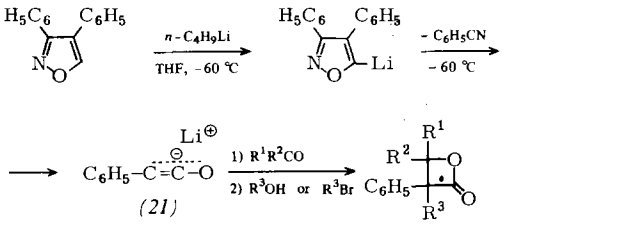
(17a) *(17b)*

The base-catalyzed fragmentations of 5-acyl-2-isoxazolines[53], 3-acyl- and 5-acyl-isoxazolidines[54,55], and 5-oxazolidones *(18)*[56] can be considered as examples of two-step cycloreversion. The intermediate *(19)* could be trapped by diazomethane.



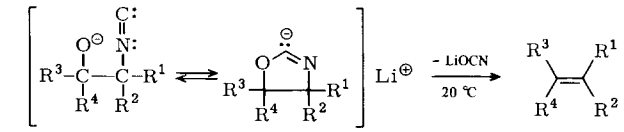
(18) *(19)*

The base-promoted fragmentations of cyclic amonium *(20)*[57] and sulfonium ions[58] and the stereospecific extrusion of CO_2 and CS_2 on reaction of 1,3-dioxolane- and 1,3-dithiolane-2-thiones with trialkyl phosphites to give alkenes[59] may be considered as further examples of anionic cycloreversions. In these cases, however, the 4π fragment extruded is electrically neutral.



(20)

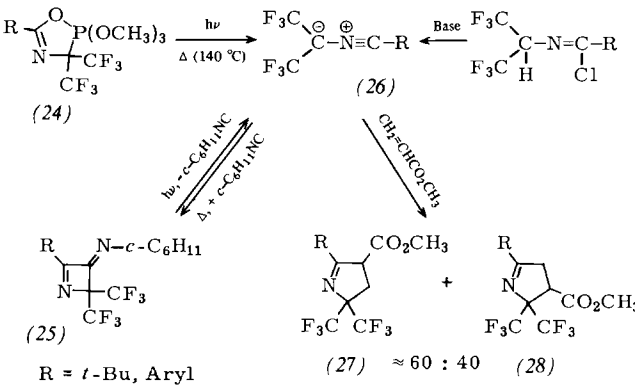
X = O, S



Cycloreversions leading to heteropropargyl-allenyl anions are less common[60-63]. The reaction of 3,4-diphenylisoxazole with strong bases permitted the first synthesis of the ynolate ion *(21)* which was converted into highly substituted β-lactones[62].

(21)

$R^1 = R^2 = CH_3$, $R^3 = C_6H_5CH_2$, 56%
$R^1 = R^2 = CH_3$, $R^3 = H$, 59%
$R^1 = H$, $R^2 = C_6H_5$, $R^3 = C_6H_5CH_2$, 69%



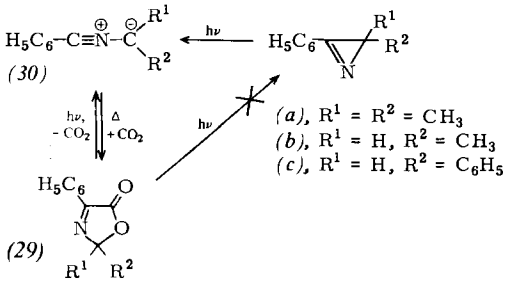
Oxazolinyl anions *(23)* exist in equilibrium with the 2-isocyano alkoxides *(22)* and are readily obtained by interaction of lithiated alkyl isocyanides with aldehydes or ketones at −70 °C. If one of the substituents is a vinyl or phenyl group the equilibrium is moved towards stereospecific fragmentation to give olefins[61].

(22) *(23)*

3. Nitrile Ylides

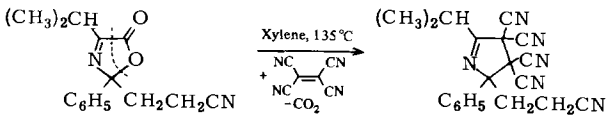
The nonisolable nitrile ylides *(26)* can be conveniently generated by thermolysis or photolysis of 1,4,2λ⁵-oxazaphospholines *(24)* with elimination of trimethyl phosphite and from 1-azetines *(25)* on extrusion of isocyanides[33]. The latter reaction represents a rare example of a [4→3+1] process. The ratio of regioisomers *(27)* and *(28)* found for trapping reactions of *(26)* with methyl acrylate was independent of the 1,3-dipolar precursors[33], suggesting that the photogenerated nitrile ylides *(26)* are electronically and vibrationally relaxed.

(24) *(26)*

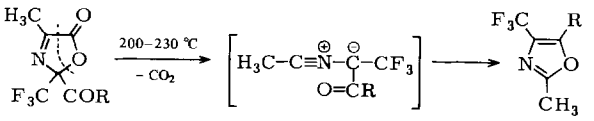


(25)

R = *t*-Bu, Aryl

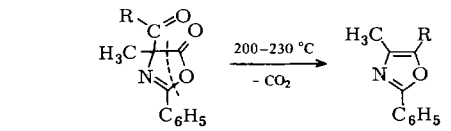


(27) ≈ 60 : 40 *(28)*

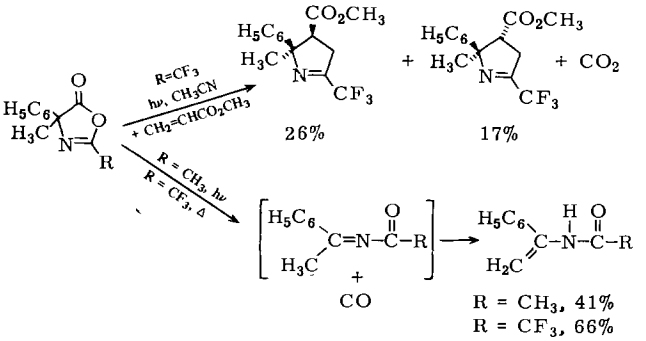


Photoextrusion of CO_2 from 3-oxazolin-5-ones *(29)*[25,64,65] was shown by *Padwa et al.* to occur from the excited singlet manifold since the reaction was not quenched by piperylene (triplet quencher) but was suppressed by xanthone (triplet sensitizer); xanthone absorbed more than 98% of the incident light[25]. The nitrile ylides *(30)* were trapped by electron poor CC double and triple bonds to give fairly good yields of 1-pyrrolines[25] and pyrroles[65]. At infinite dipolarophile (acry-

lonitrile) concentration the quantum yield for cycloaddition was 0.30 for reaction of compound *(29a)* at 253.7 nm. Although cycloaddition experiments with nitrile ylides *(30)* formed from 2*H*-azirines gave the same isomer distribution as that obtained from *(29)*, azirines are not intermediates in the transformation *(29)*→*(30)*[25].

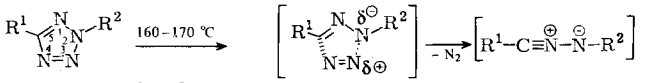


Several trisubstituted 3-oxazolin-5-ones undergo extrusion of CO_2 when heated at the appropriate temperatures[66-69].



R = C_6H_5, 94%
R = 4-NO_2-C_6H_4, 61%
R = CH_3, 26%

Photochemical[36] and thermal[66,67] extrusion of CO_2 is known also for trisubstituted 2-oxazolin-5-ones. The 1,3-dipolar cycloreversion is not the sole reaction reported for these latter compounds: in some instances [5→4+1]-cycloreversion with extrusion of CO was observed[36,68].

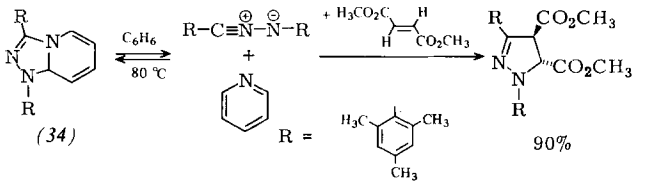


R = CH_3, C_6H_5, OCH_3, $CO_2C_2H_5$ 71–95%

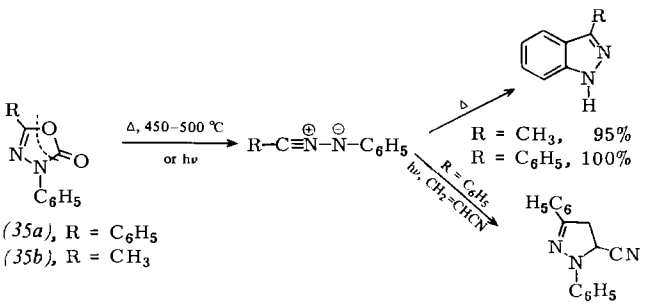
Cycloreversion to a nitrile ylide radical ion and a C=S fragment was detected in the mass spectra of 2,4-dimethyl-2-thiazoline[70].

4. Nitrile Imines

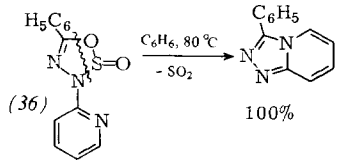
Thermolysis[34,71-73] and photolysis[34,73,74] of 2,5-diaryltetrazoles *(31)* represents a ready route to nitrile imines *(33)*[1,2]. The thermal decomposition of 2,5-diphenyltetrazole follows first order kinetics little influenced by the solvent polarities[72]: $E_a = 32.4$ kcal mol^{-1} and $\Delta S^{\neq} = -2.6$ cal K^{-1} mol^{-1}[71]. A transition state such as *(32)* in which N^2–N^3 bond has suffered more extensive heterolytic cleavage than N^4–C^5 was proposed by *Baldwin et al.* on the basis of Hammett ρ values of +1.16 and −0.23 for 2-aryl-5-phenyl- and 5-aryl-2-phenyltetrazoles, respectively[71].



(31) R¹, R² = Aryl *(32)* *(33)*



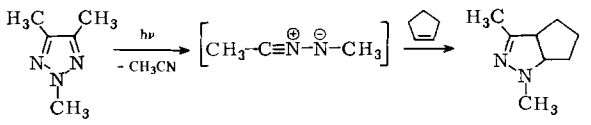
The same behavior has been observed for several other tetrazoles[75-80]. 5-Phenyl-2-(trimethylsilyl)tetrazole yields the nitrile imine above 190 °C[75], 5-phenyl-2-phthalimidotetrazole at *ca.* 80 °C[76], and 5-aryltetrazoles above 165 °C[77]. 2,5-Diphenyltetrazole was calculated to react 38 times faster than 5-phenyltetrazole in benzonitrile at 175 °C[77]. In the fragmentation of 2-methyl-5-phenyltetrazole higher temperatures are required (≥220 °C) and it has been reported that the extrusion of nitrogen competes with a second less important 1,3-dipolar cycloreversion to methyl azide and benzonitrile[78].



Photolytic studies on 5-phenyltetrazole[74] and 2-methyl-5-phenyltetrazole[80] gave results best explained by a 1,3-dipolar ring cleavage, although a different mechanism was proposed for the latter compound.

Dimesitylnitrile imine yields stable 1:1 adducts of type *(34)* with aromatic heterocycles such as pyridine, quinoline, and isoquinoline[81]. These adducts readily dissociate into reactants when heated and the newly formed nitrile imine can be trapped with dipolarophiles.

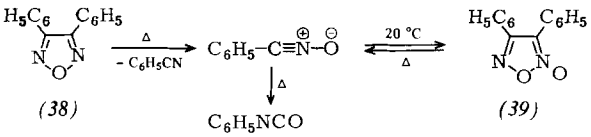
The extrusion of carbon dioxide and sulfur dioxide from 1,3,4-oxadiazol-2-ones *(35)*[82,83] and 1,2,3,4-oxathiadiazole *S*-oxides *(36)*[85], respectively, is of interest. 2,4-Diphenyl-1,3,4-oxadiazol-2-one *(35a)* is fairly stable up to about 300 °C[84]; however, it can be transformed by flash vacuum pyrolysis at 500 °C into 3-phenylindazole in nearly quantita-



(36) 100%

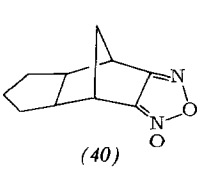
tive yield[82]. In contrast to its thermal stability, compound *(35a)* gives good yields of diphenylnitrile imine adducts when irradiated in absolute ethyl acetate in the presence of various dipolarophiles[83].

Analogously, 2,4,5-trimethyl-2*H*-1,2,3-triazole gave acetonitrile and the adduct *(37)* on irradiation in ether (Vycor filter) in the presence of an excess of cyclopentene[28]. The 2,4,5-triphenyl derivative, on the other hand, failed to react under the same conditions[28].



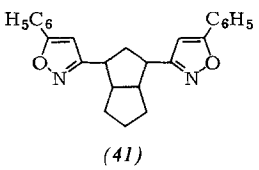
(37) 25%

Several heterocycles embodying the nitrile imine system in their rings undergo [3 + 2]-cycloreversion on electron impact. They include the previously cited 2,5-disubstituted tetrazoles[86] and 5-aryltetrazoles[87], the 1,3,4-Δ^2-oxadiazolines[88,89], the 1,3,4-Δ^2-thiadiazolines[88,89], and Δ^2-pyrazolines[89,90]. The charge is preferentially retained by the 1,3-dipole.

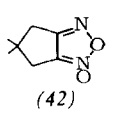


5. Nitrile Oxides, Nitrile Sulfides, and Nitrile Selenides

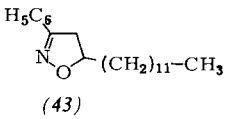
The thermal cleavage of 3,4-diphenylfurazan *(38)* and 3,4-diphenylfurazan *N*-oxide *(39)*, discovered at the end of the last century[91 93], are probably the first examples of 1,3-dipolar cycloreversions.



(38) (39)

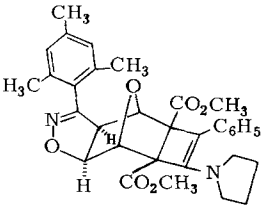


The cycloreversion of furazan *N*-oxides was recently used by *Boulton*[94], *Chapman*[95], and *Paton*[96b] to generate nitrile oxides as an alternative to more common methods[96a]. The reaction is favored by steric strain relief. For example, while *(40)* gives the adduct *(41)* on heating with excess phenylacetylene at 55 °C, compound *(42)* is recovered unchanged under the same reactions conditions[94]. Moreover,

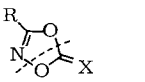


(40)

(41)

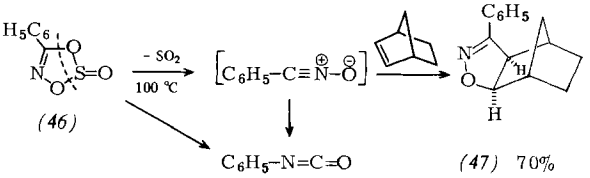


(42)



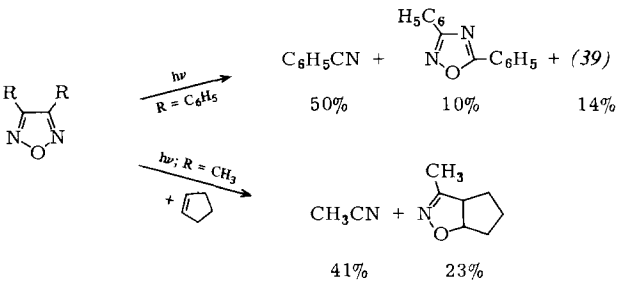
(43)

while sterically encumbered 3,4-bis(1-adamantyl)furazan *N*-oxide was found to undergo cycloreversion at *ca.* 77 °C[97], compound *(39)* requires much more drastic conditions and reacts with 1-tetradecene (as dipolarophile and solvent) only at 245 °C to give *(43)* in 82% yield[95]. It remains an open question whether the cycloreversion is concerted or proceeds as a two-step process *via* an intermediate dinitrosoalkene[96c].



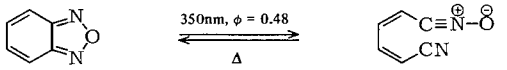
2-Isoxazolines and isoxazoles, which are readily prepared by reaction of nitrile oxides with alkenes and alkynes, are quite thermostable compounds. However, under the conditions of flash-vacuum pyrolysis at 600—650 °C, the 2-isoxazoline *(44)* gives a quantitative yield of 2,4,6-trimethylbenzonitrile oxide[98].

(44)



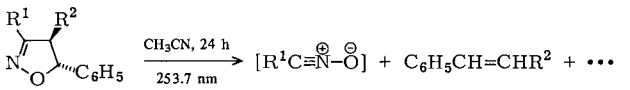
(45) X = O, S

(46) (47) 70%



Hydroxamic acids react with acid chlorides such as phosgene to give heterocycles *(45)* and *(46)* in high yields[99]. While in the case of *(45)* the thermal and photochemical elimination of CO_2 and COS gives the corresponding acylnitrene, which has been trapped with suitable scavengers[99], compound *(46)* undergoes thermal cycloreversion to benzonitrile oxide as a major fragmentation path. In fact when compound *(46)* was heated with an excess of norbornene, adduct *(47)* was obtained with some phenyl isocyanate[100].

Light irradiation of 3,4-diphenylfurazan alone in benzene (Pyrex filter)[101] and of 3,4-dimethylfurazan in ether (Vycor filter) in the presence of cyclopentene[28] yielded products in agreement with 1,3-dipolar cycloreversion processes. Under conditions such that added xanthone absorbed 99% of the incident light the 3,4-diphenylfurazan yielded benzonitrile at a rate of *ca.* 12% of that on direct irradiation[28]. The foregoing results suggest that the cleavage of the furazans occurs predominantly in a singlet excited state.



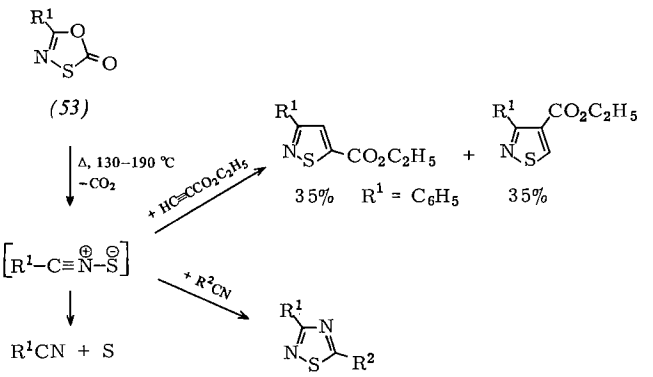
The benzofurazans behave similarly. Irradiation of benzofurazan *(48)* at room temperature in strongly polar solvents (*e.g.* H_2O) yielded exclusively *(49)*, detected and characterized by UV and IR spectroscopy[102] and trapped with dime-

thyl acetylenedicarboxylate[103]. Compound *(49)* undergoes thermal reconversion into *(48)*[102], k (20 °C) = 2×10^{-5} s^{-1}.

(48) *(49)*

Also, 2-isoxazolines *(50)* and particularly the 4,5-disubstituted derivatives are reported to undergo light-induced cycloreversion to nitrile oxides and alkenes in admixture with other compounds (see Scheme 3). Detailed mechanistic investigation showed that the reaction possibly takes place in a singlet excited state of the ketoxime group[29].

(50) *(51)* *(52)*



Scheme 3. Cycloreversion of substituted 2-isoxazolines *(50)*. Yields based on reacted starting material.

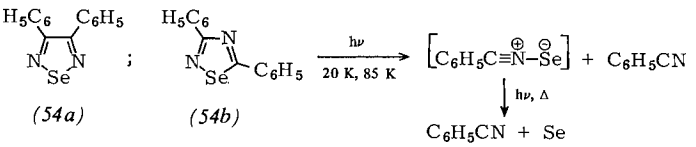
$R^1 = CH_3$, $R^2 = C_6H_5$	29% [b]	66% [c]	59%
$R^1 = R^2 = C_6H_5$	—	39% [d]	31%
$R^1 = C_6H_5$, $R^2 = H$	—	1.6%	24%

[a] Recovered. [b] Trapped with cyclopentene. [c] *cis:trans-(52)* = 1:1. [d] *cis:trans-(52)* = 2:1.

No examples of electron impact induced 1,3-dipolar cycloreversion have been reported for isoxazoles[104]. Conversely, this process is important for 2-isoxazolines[43,105] and several heterocycles containing the nitrile oxide moiety such as 1,2,4-oxadiazoles[42,108b], Δ^2-1,2,4-oxadiazolin-5-ones[106a], 1,4,2-oxathiazole 4-oxides[106b], 1,4,2-dioxazoles[44], furazan *N*-oxides[97,107], and furazans[101,108] with the positive charge retained preferentially in the 1.3-dipole fragment.

So far, the sole synthetically practical route to nitrile sulfides is the cycloelimination of CO_2 from 1,3,4-oxathiazol-2-ones *(53)*[109]. The 1,3-dipole was trapped by CC and CN triple bonds to give good yields of isothiazoles and 1,2,4-thiadiazoles, respectively[109].



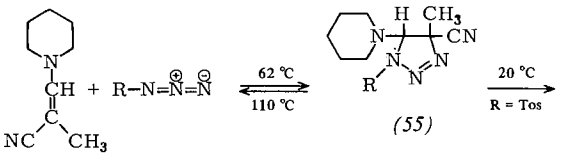
(53)

$R^1 = C_6H_5$, $R^2 = CO_2C_2H_5$, 88%
$R^1 = CO_2C_2H_5$, $R^2 = C_6H_5$, 33%

A yield of 22% of dimethyl 3-phenyl-4,5-isothiazoledicarboxylate was obtained on irradiation of 5-phenyl-1,3,4-oxathiazol-2-one (Pyrex filter) in neat dimethyl acetylenedicarboxylate as reagent and solvent[110]. Moreover, irradiation of 3,4-dimethyl (Vycor filter) and of 3,4-diphenyl-1,2,5-thiadiazole (Corex filter) in ether gave fair yields of the corresponding nitrile and sulfur[28].

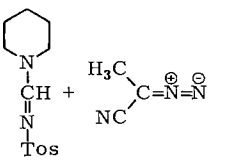
The nitrile sulfide radical ion was found to be the most abundant peak in the mass spectra of several 1,2,5- and 1,2,4-thiadiazole derivatives[108a,111]. In contrast to isoxazoles, the isothiazoles show extensive electron impact induced 1,3-dipolar cycloreversion[112].

A recent study on low temperatures photolysis of diphenylselenadiazoles such as *(54a)* and *(54b)* has shown (IR and UV spectroscopic detection) that a new type of 1,3-dipole, *viz.* benzonitrile selenide, occurs as intermediate. Attempts to trap the 1,3-dipole with dimethyl acetylenedicarboxylate were unsuccessful[113].



(54a) *(54b)*

The benzonitrile selenide radical ion has been also detected in the mass spectra of 1,2,5-selenadiazole derivatives[108a,114].

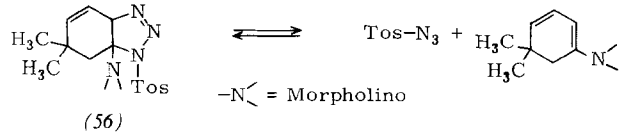


6. Azides

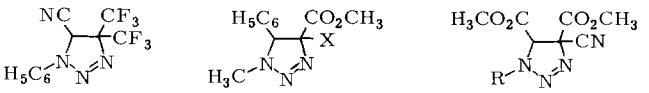
The reaction of Δ^1-1,2,3-triazolines to give azomethines or aziridines on extrusion of nitrogen has been widely studied[115]. However, triazolines undergo two other important fragmentation processes: 1,3-dipolar cycloreversions to azides and alkenes and to diazoalkanes and azomethines, respectively. For example, phenyl azide and β-piperidinomethacrylonitrile are in mobile equilibrium with adduct *(55a)*[116,117]. Below 62 °C, triazoline *(55a)* is favored over the addends, and after 10 days the reaction yield is quantitative, while at 110 °C the only ≤5% of same heterocycle is present[116].

(55)

(a), R = C_6H_5
(b), R = Tos



In the case of *(55b)* (not isolated) even at room temperature the equilibrium lies completely to the right with complete dissociation to diazoalkane and azomethine[116].

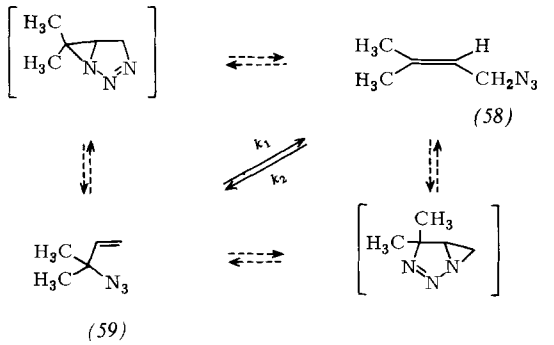


Adduct *(56)*, which can be isolated as a fairly stable solid at −20 °C, is in equilibrium with the products of [3+2]-cycloreversion in solution[118].

Cycloreversion was found to compete with aziridine formation in the case of compounds of type *(57)* at the temperatures indicated[119].

The foregoing examples show that both electron-rich and electron-poor conjugated double bonds are easily extruded from 1,2,3-triazolines.

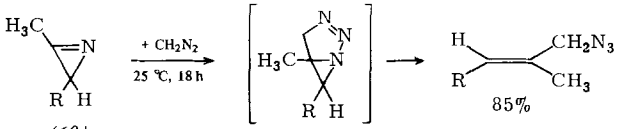
(56)



(57a), 110 °C (in $C_6H_5CH_3$)

(57b), X = CN, 80 °C (in C_6H_6); X = CO_2CH_3, 140 °C (in $(CH_3)_2C_6H_4$)

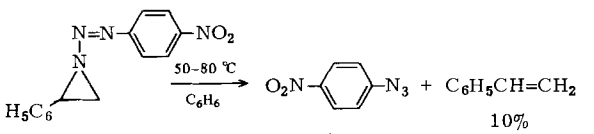
(57c), R = CH_3, 61 °C (in $CHCl_3$); R = $CH_2C_6H_5$, 80 °C (in C_6H_6)



Of interest is the equilibrium between the azides *(58)* and *(59)* [*(58)*:*(59)* ≈ 3:1 at 25 °C] which requires both 1,3- and 1,1-intramolecular dipolar cycloadditions and cyclorever-

(59)

Scheme 4



sions. As the rates constants k_1 and k_2 are only slightly sensitive to solvent polarity and no solvolysis processes were detected in 70% aqueous acetone, it was concluded that no ion pair is formed during the rearrangement[120]. The mechanism formulated in Scheme 4 finds further support in the results of the reactions of diazoalkanes with 2*H*-azirines such as *(60)*[121] and of the fragmentation of *N*-(4-nitrophenylazo)-2-phenylaziridine *(61)*[122].

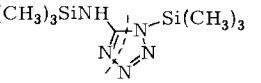
The 1,3-dipolar cycloreversion has also been observed in 2-tetrazolin-5-ones and found to be dependent on the substituents[123,124]. For the tetrazolinones *(62)* the activation energy was in the range 29—34 kcal mol^{-1} with activation entropy values of 0—7 cal K^{-1} mol^{-1}. The reaction rates were little influenced by solvent polarity but were increased by

(62)



the electronegativity of the isocyanate group ($\rho = +1.4$). These findings led *L'abbé et al.* to propose a concerted mechanism involving charge imbalance in the transition state of type *(63)*[123].

(63)

(64)

R^1 = CH_3, R^2 = C_6H_5

(65)

The thermal fragmentation of 2-tetrazolines *(64)* (at *ca.* 120 °C)[125] and of tetrazole *(65)* (at 150—160 °C)[75] are noteworthy examples of cycloreversions leading to azomethines and cyano compounds.

Tetrazolinones *(66)*[126], tetrazolinethiones, and tetrazolinimines *(67)*[127] undergo [3+2]-cycloreversion on electron impact. Pathway (a) is always dominant over pathway (b), and the positive charge has been found to be retained preferentially by the dipolarophilic group. This is often the base peak of the spectrum. In dialkyl-substituted tetrazolinones the pathways (a) and (b) can be neglected.

7. Diazoalkanes

The driving force for most of the known thermal and photochemical cycloreversions of 1-pyrazolines condensed with three- and four-membered carbocycles to give diazoalkanes and C=C dipolarophile systems is the relief of strain. It is not surprising, therefore, that the adducts of diazoalkanes with cyclopropenones *(68)*[128,129], with triafulvenes *(69)*[130], and with diphenylthiirene dioxide[131] are labile compounds which readily undergo intramolecular [5→3+2]cyclorever-

sion. However, the diazoalkane/cyclopropene adducts *(70)* are relatively stable and their cycloreversion properties depend largely on the substituents[26, 35, 128, 132, 133]. For instance, while compound *(70a)* cycloreverts smoothly at 80 °C[132c], *(70b)* undergoes cycloreversion at 0 °C and could not be isolated[132a]. In general, electron-withdrawing substituents attached to the incipient olefin moiety accelerate cycloreversion[132d].

(70c), R = CO_2CH_3

A clean photoinduced reaction of 2,3-diazabicyclo[3.1.0]hex-2-enes such as *(70c)* is exemplified by direct photolysis to give the diazoalkane indicated in the equation[128]. A more complex behavior has been found in the photolysis of compounds *(70d)—(70h)* and of 2,3-diazabicyclo[3.2.0]hept-2-enes *(73)* and *(74)*. The formation of the reaction products from *(70d)* and *(70e)* was rationalized as due to the two competitive processes (a) and (b)[35]. The 1,5-diradical *(71)* was considered the common intermediate for both processes. Diazoalkane *(72)* was detected by NMR.

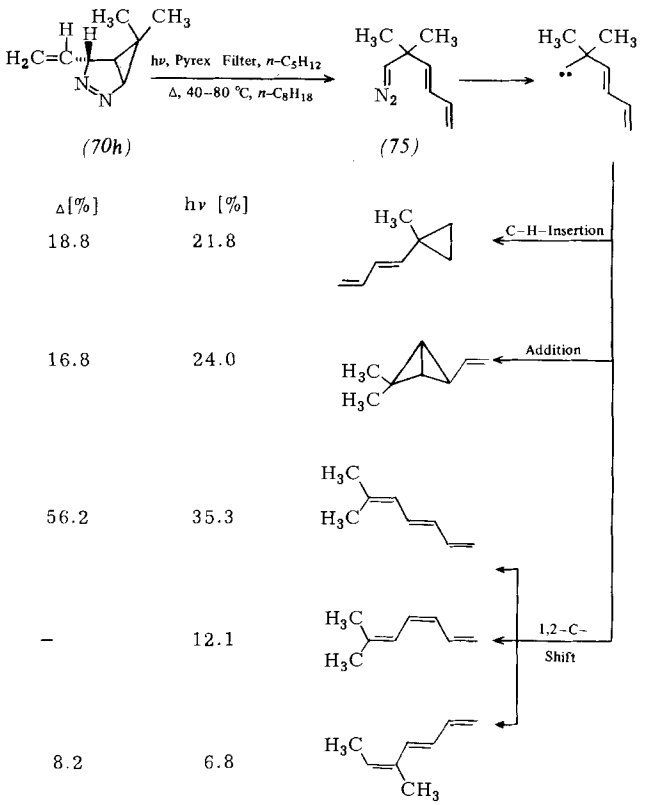
A similar reaction pattern was proposed for the direct ($\lambda > 300$ nm) and sensitized (acetophenone) photolysis of compound *(73)* where, however, cycloreversion [path (b), Scheme 5] is a minor process[26, 134]. By contrast, in the thermolytic fragmentation of *(73)* and *(74)* path (b) again prevails over path (a)[26, 135].

(73), R = H
(74), R = CH_3



Thermolysis and photolysis of *(70f)* and *(70g)* are stereospecific reactions initiated by a cycloreversion mechanism[30].

Schneider et al. recently showed that the cycloreversion mechanism may be the sole photochemical and thermal fragmentation route for 2,3-diazabicyclo[3.1.0]hex-2-enes *(70)*[133]. The authors were able to demonstrate that diazoalkane *(75)* is the sole primary product of *(70h)* on photochemical (and most probably also on thermal) treatment by trapping reactions and on the basis of spectroscopic detection. Thermodynamic data were also determined: the thermal cycloreversion of *(70h)* is characterized by $\Delta H^{\neq} = 24.8 \pm 1$ kcal mol^{-1} and $\Delta S^{\neq} = -1 \pm 2$ cal K^{-1} mol^{-1}.

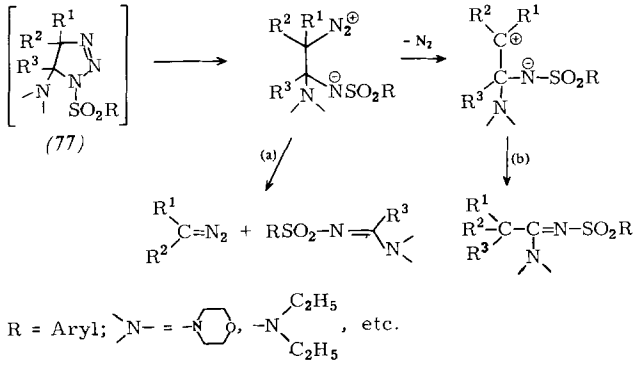
To our knowledge, no examples of cycloreversion have been reported for cyclopentane-condensed 1-pyrazolines[136]. Monocyclic 1-pyrazolines such as *(76)* are found to undergo 1,3-dipolar cycloreversion with difficulty[27, 31, 32, 137, 138].



(76)

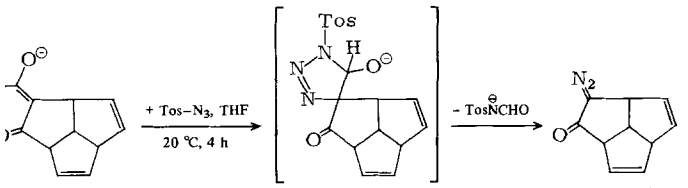
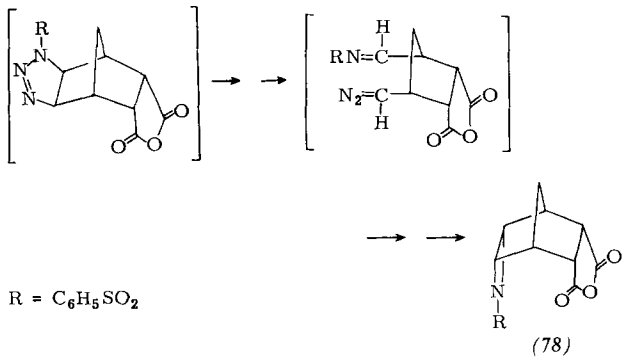
The photochemical process is a singlet state stereospecific reaction favored by short wavelengths and low pressures[27]. A vibrationally excited S_1 state was postulated as initiating the cycloreversion.



The pericyclic ring opening of 1,2,3-triazolines to give C=N dipolarophiles and diazoalkanes is also well documented[16, 128, 132a, 139–143]. For instance, sulfonyl azides react readily with enamines at room temperature to give the non-isolable 1,2,3-triazolines *(77)* whose decomposition by pathway (a) or (b) is determined by the substituents. 1,3-Dipolar cycloreversion [path (a)] was the only fragmentation path detected (except for R^3 = cyclopropyl) when $R^1 = R^2 = H$, $R^1 = H$ or alkyl and R^2 = formyl, acyl, vinyl and phenyl. This process is therefore a convenient route to α-diazo aldehydes[16, 140, 141].

(77)

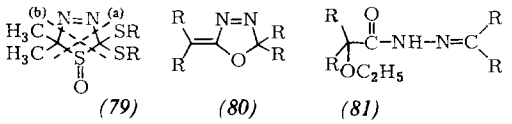


R = Aryl; $\rangle N-$ = , , etc.

Of great synthetic value is also the reaction of tosyl azide with the salts of β-carbonyl vinyl alcohols to give α-diazocarbonyl compounds[16] as exemplified by the synthesis of 3-diaza-2,3-dihydrotriquinacen-2-one[142].

100%

Specific fragmentation to diazoalkanes and C=N fragments was observed in the course of the reactions of the adducts of phosphono or phosphinyl azides with enol ethers[143a], tosyl azide with tetrakis(dimethylamino)allene[143b], tosyl azide with tetramethoxyethane[143c], and picryl azide with a vinylporphyrin[143d]. Such a fragmentation has also

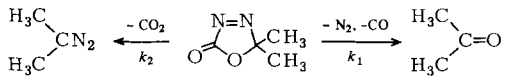


R = $C_6H_5SO_2$

(78)

been postulated to explain the frequently predominant formation of the *endo*-aziridines such as *(78)* in the reaction of benzenesulfonyl azide with norbornene derivatives[144].

Less common are cycloreversions leading to diazoalkanes and C=O[145–148], C=Se[150], C=S[149, 150], and N=P[151] double bonds. Only a few examples of these reactions can be mentioned. Sulfene-diazoalkane adducts dissociate at room temperature into their components. In some cases, both of the two possible decomposition pathways have been observed, as for the adduct *(79)*[149].

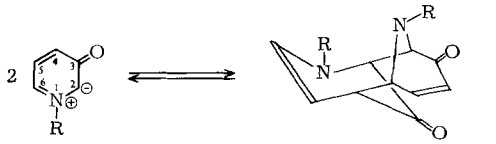


(79) *(80)* *(81)*

(a), 60%; *(b)*, 30% R = C_6H_5

Another example is the [3 + 2]-cycloadduct of diphenyldiazomethane and diphenylketene *(80)*, which undergoes cycloreversion when heated to 150 °C[147]. Photochemical cycloreversion of compounds *(80)* is a two-step process, as evidenced by the isolation of *(81)* when operating in absolute ethanol[147].

Finally, the thermal behavior of 5,5-dimethyl-5*H*-1,3,4-oxadiazol-2-one in methanol and carbon tetrachloride is of interest[148]. The compound decomposes by two potential routes. The great rate enhancement of cycloreversion induced by solvent polarity causes decomposition to 2-diazopropane and carbon dioxide to predominate in methanol.



84 °C, CCl_4 : $k_1 = 10^{-4}s^{-1}$, $k_2 = 0.25\times10^{-4}s^{-1}$

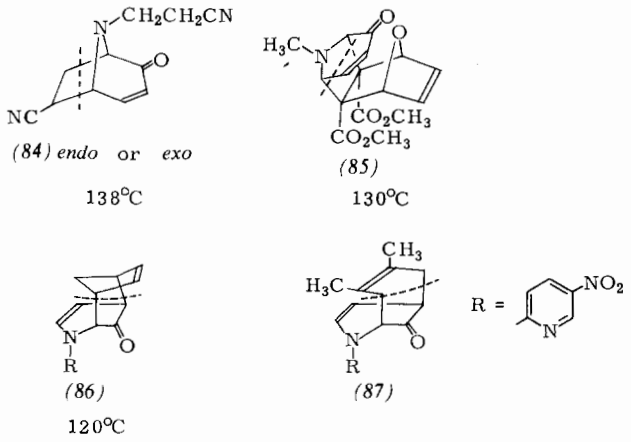
8. Azomethine Ylides



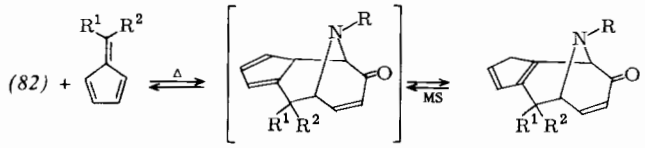
The 1,3-dipolar cycloadditions of a variety of pyridinium betaines with 2π, 4π, and 6π dipolarophiles have been extensively studied by *Katritzky et al.*[7]. A characteristic of almost all the azomethine ylides of type *(82)* is a dynamic equilibrium with the dimer *(83)* (the latter often as a mixture of two regioisomers)[7]. Dimers *(83)* also cyclorevert on electron impact, although in several cases the thermal process precedes the electron impact in the mass spectrometer[152].

(82) *(83)* + Regioisomer

Compounds *(82)* react as 1,5-dipole at the 2,4-position and as 1,3-dipole at the 2,6-position with dipolarophiles. Some of these adducts undergo cycloreversion: *(84)*[153], *(85)*[154], and *(86)* on heating[155] (at the temperature indicated), whereas compound *(87)* cycloreverts only on electron impact[155].

The conditions for the cycloreversion process are not always so drastic. The azomethine ylide 2-(2,4-dinitrophenyl)isoquinolinium-4-olate forms cycloadducts with *cis*-stilbene and with various heterodipolarophiles which could not

(84) endo or exo — 138°C

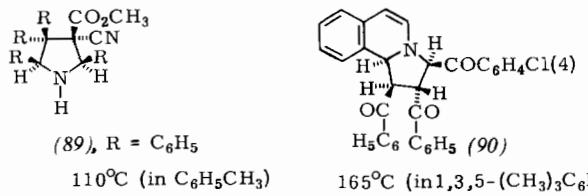


(85) — 130°C

(86) — 120°C

(87)

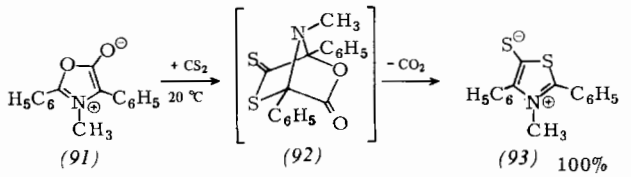
be isolated because they rapidly suffered 1,3-dipolar cycloreversion[156].



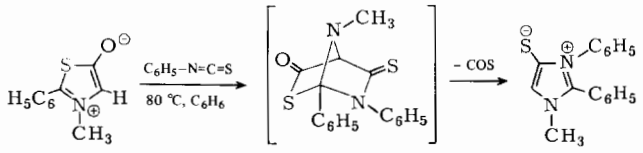
The cycloadducts *(88)* of fulvenes with the betaines *(82)* decompose in the mass spectrometer (MS) thus indicating a rare 1,3-dipolar cycloreversion following a 1,5-hydrogen shift[155].

(82) + (88)

$R^1 = R^2 = CH_3$
$R^1 = H,\ R^2 = 4\text{-}CH_3OC_6H_4$
$R^1 = H,\ R^2 = C_6H_5$



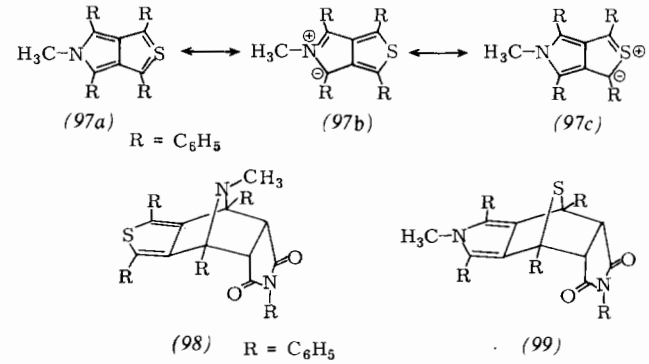
Compounds *(89)*[157] and *(90)*[158] are two examples of adducts of azomethine ylides whose 1,3-dipolar skeleton is not an integral part of an aromatic systems, for which thermal cycloreversion has been reported.



(89), R = C_6H_5 — 110°C (in $C_6H_5CH_3$)

(90) — 165°C (in 1,3,5-$(CH_3)_3C_6H_3$)

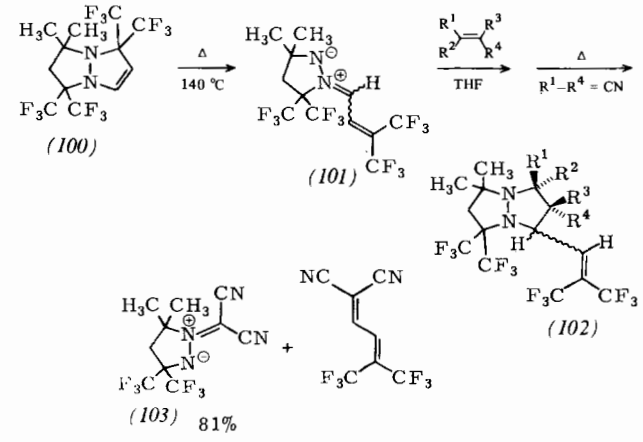
Particularly interesting is the easy synthesis of compounds *(93)*[159] and *(96)*[160] from the mesoionic oxazolone *(91)* and thiazolone *(94)*, respectively, *via* the nonisolable intermediates *(92)* and *(95)*. The intermediacy of compounds of type *(92)* (not yet isolated) has also been formulated for the reaction of *(91)* with C=C double bonds to give, on extrusion of CO_2, a new azomethine ylide system[1,2]. However, *(94)* reacts at room temperature with alkenes to give isolable adducts of type *(95)*. A great proclivity for COS extrusion on heating and on electron impact has expectedly been observed for these adducts[160].



(91) (92) (93) 100%

(94) (95) (96), 64%

Using a semiempirical MO approach (CNDO/2) in which d orbital participation was included, *Cava et al.* have found that the contribution of *(97b)* to the structure of thieno[3,4-*c*]pyrrole *(97)* is of greater importance than that of *(97c)*[161]. It does not come as a surprise, therefore, that *Cava*[161] and *Potts*[162] have found thieno[3,4-*c*]pyrrole to add alkenes at the azomethine ylide system to give compounds such as *(98)*. However, on heating, these adducts revert to the addends which finally give the thermodynamically more stable thiocarbonyl ylide adducts of type *(99)*.

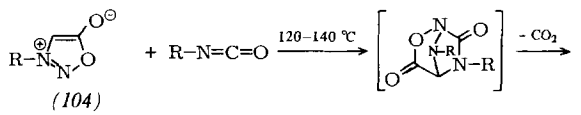


(97a) R = C_6H_5 (97b) (97c)

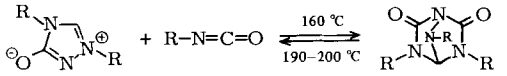
(98) R = C_6H_5 (99)

9. Azomethine Imines

The reaction of sydnones with alkenes represents a general synthesis of 2-pyrazolines[1,2]. The [3+2]-cycloadduct formed in the rate determining step spontaneously eliminates carbon dioxide by [3+2]-cycloreversion.



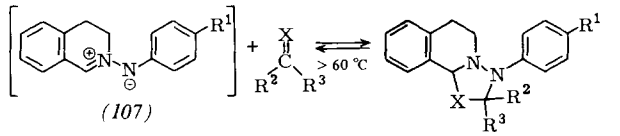
A case of 1,3-dipole metathesis has recently been described by *Burger et al.*[14]. The stable azomethine imine system *(101)* generated almost quantitatively from *(100)* gives [3+2]-cycloadducts *(102)* with numerous dipolarophiles. Those formed from *(101)* and dimethyl fumarate, dimethyl maleate, fumaronitrile, and ethenetetracarbonitrile in THF under reflux decompose particularly readily. *(102)*, R^1—R^4 = CN, transforms at ≈60 °C into a new stable azomethine imine *(103)* and 5,5,5-trifluoro-4-(trifluoromethyl)-1,3-pentadiene-1,1-dicarbonitrile.



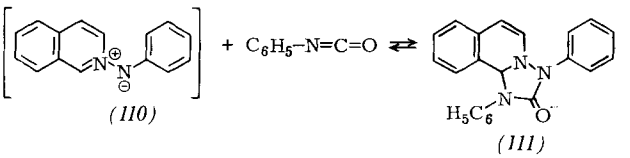
(100) (101) (102)

(103) 81%

Examples are known of equilibria between [3 + 2]-cycloadduct and 1,3-dipole + dipolarophile in which the dipolarophile is an heteromultiple bond. For instance, the 1,3-dipole *(104)* reacts with phenyl isocyanate to give the mesoionic triazolone *(105)*[163] which in the presence of an excess of phenyl isocyanate equilibrates with the cycloadduct *(106)*[164].

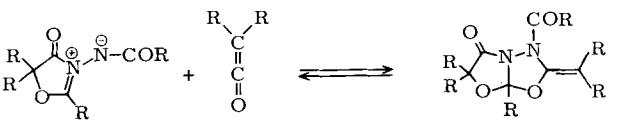


(104)

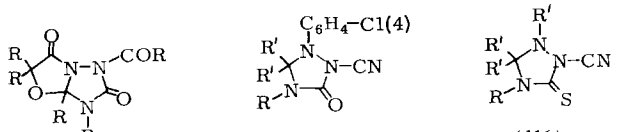


(105) R = C_6H_5 *(106)*

The thermolability of 1,3,4-oxadiazolidines *(108)*, particularly for $R^1 = NO_2$[165], and of 1,2,4-triazolidines *(109)*[166] and *(111)*[167] is easily detectable by reversible thermochromism on heating the substances in inert solvent.



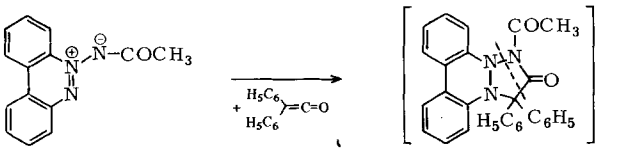
(107) *(108)*, X = O; *(109)*, X = N–CH_3



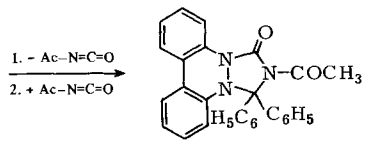
(110) *(111)*

In contrast to the isoquinolinio-*N*-anilide *(110)*, the 1,3-dipole *(107)* was trapped with phenyl isocyanate and isothiocyanate to give thermostable [3 + 2]-adducts[167].

The azomethine imine *(112)*, formed from dibenzoyldiazene and diphenylketene, reacts further with a second equivalent of the same diphenylketene to give the bicyclic compound *(113)* which is in equilibrium with the reactants at elevated temperature[168]. While compounds *(112)* reacts with phenyl isocyanate to give the stable [3 + 2]-adduct *(114)*[168] the 1,2,4-triazolidine-3-ones *(115)* and -3-thiones *(116)* are relatively unstable products, reverting to the reactants even in cold solution[169].



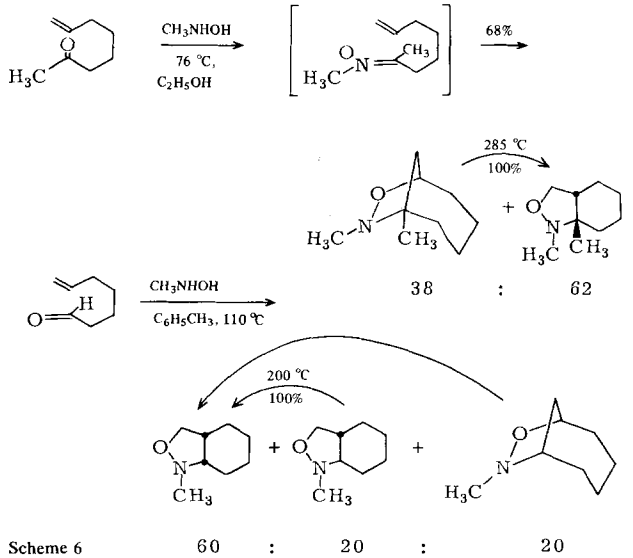
(112) *(113)*



(114) R = C_6H_5, R' = Aryl *(115)* *(116)*

A cycloreversion is probably involved in the reaction of the azimines such as benzo[*c*]cinnolinio-*N*-acetylimide *(117)* with diphenylketene to give a complex mixture of compounds in which the 1:1 adduct *(119)* is formed in 12% yield[170]. According to the authors, adduct *(118)* is unstable by virtue of its three saturated adjacent nitrogen atoms.

(117) *(118)*



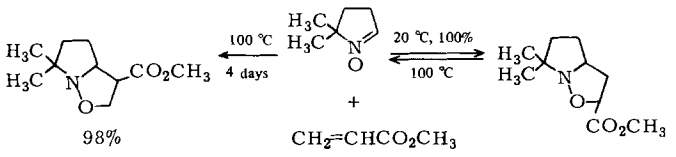
(119)

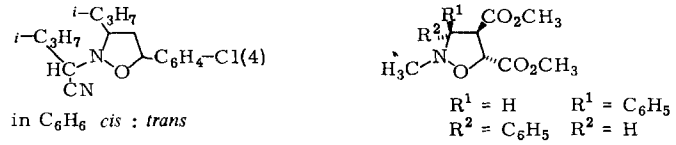
1,3-Dipolar cycloreversions have been also postulated in the reactions of some carbonyl ylides[171] or diazoalkanes[172] with azo derivatives.

An electron impact induced [4→3 + 1]-cycloreversion has been reported by *Deyrup* for 3-iminodiazetidines obtained from *(107)*, $R^1 = NO_2$, and *tert*-butyl isocyanide[173].

10. Nitrones (Azomethine Oxides)

Many isoxazolidines have been reported to undergo [3 + 2]-cycloreversion under mild reaction conditions. The reactions depicted in Scheme 6[174] represent typical examples of the occurrence of the dynamic equilibrium between polycyclic isoxazolidines and nitrone + alkene. Presumably, the easy [3 + 2]-cycloreversion found for these and similar systems is a consequence of the remarkable stability of nitrones.

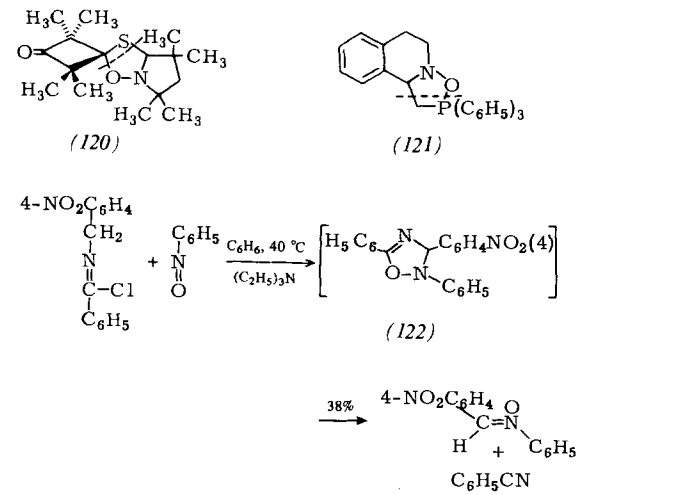




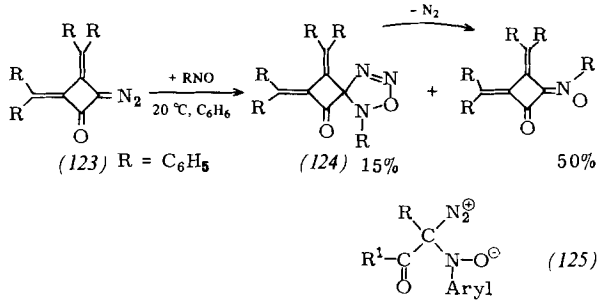
Scheme 6

As shown in Scheme 6, the correct choice of reaction conditions permits formation of a sole adduct. These reactions

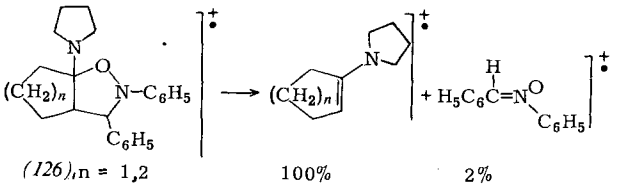
are interesting examples of 1,3-dipolar reactions in which the stereochemical and regiochemical course can be controlled. The synthetic importance of these reactions has already been widely discussed elsewhere[8, 175].



Even milder reaction conditions are required for [3+2]-cycloreversion of monocyclic isoxazolidines derived from nitrones and conjugated CC double bond systems[176–183] as exemplified in Scheme 7[176, 178, 180a].

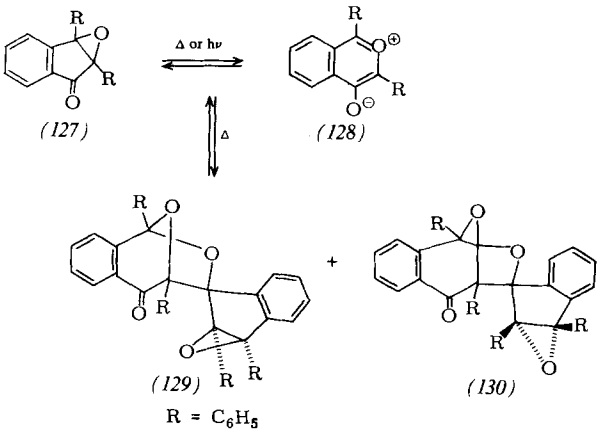


Scheme 7

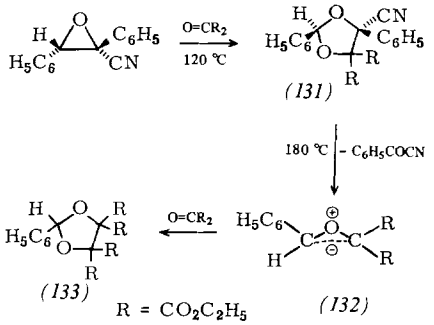


The rate-enhancing effect of carbonyl groups is evidenced by the adducts of 3,4-dihydroisoquinoline *N*-oxide with tricarbonyl(tropone)iron[41] and of *C*-benzoyl-*N*-phenylnitrone with α,β-unsaturated esters[55, 183] which both cyclorevert at room temperature. Of relevence in connection with the foregoing results is the fact that triphenylnitrone reacts with dimethyl maleate to give the corresponding isoxazolidine, whereas no adduct is obtainable with the more reactive dipolarophile dimethyl fumarate. In order to rationalize this observation, it has been suggested that, although the addends ⇌ adduct equilibrium is reached more easily with fumarate than in the addition with maleate, the equilibrium is nevertheless shifted mainly towards the reactants because of the greater thermodynamic stability of dimethyl fumarate[180a]. Cycloadducts of nitrones to heterodouble bonds also exhibit a great propensity to cycloreversion. Thus adduct *(120)* cycloreverts to the addends in solution at room temperature[184] and compound *(121)* requires a temperature of 100 °C to undergo cycloreversion[185], while the adduct *(122)* of a nitrile ylide and nitrosobenzene could not been even isolated[186].

Finally, the isolation of adduct *(124)* in the reaction of diazoketone *(123)* with nitrosobenzene is of interest[187]. This contradicts previously accepted mechanistic concepts invoking the zwitterionic intermediate *(125)*[188].

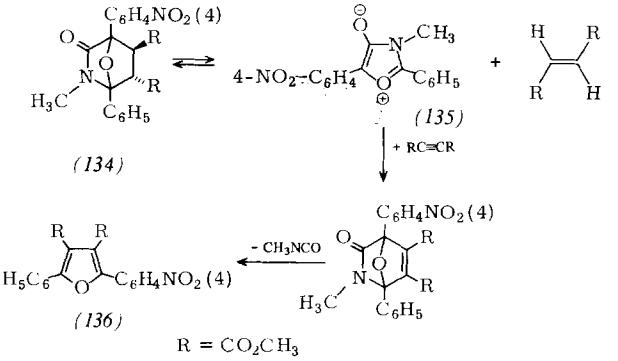


Electron bombardment also induces [3+2]-cycloreversion in isoxazolidines[189, 190]. The possibility of a prior thermal cycloreversion in the mass spectrometer has been ruled out by comparing the mass spectrum of the adducts *(126)* with those recorded for the related addends[189].

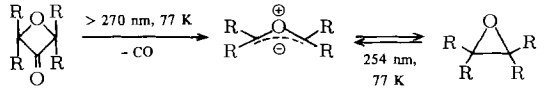


11. Carbonyl Ylides and Thiocarbonyl Ylides

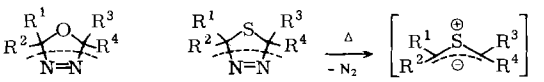
2,3-Diphenylindenone oxide *(127)*, which is in thermal (symmetry-forbidden disrotatory process) and photochemical equilibrium with the red benzopyrylium olate *(128)*, is converted by heat into *(129)* and *(130)* in benzene or diethyl



succinate as solvents. The two dimers undergo 1,3-dipolar cycloreversion, as proved by their thermochromism and by trapping *(128)* with dimethyl acetylenedicarboxylate[191]. The cycloadduct *(131)* obtained by heating a *trans*-stilbene oxide derivative with diethyl mesoxalate undergoes 1,3-dipolar cycloreversion to the carbonyl ylide *(132)* which adds afresh to diethyl mesoxalate to give *(133)*[192].



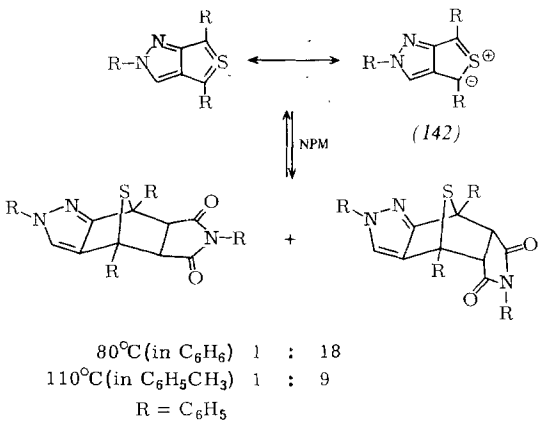
Hamaguchi and *Ibata* described trapping reactions of the thermally generated carbonyl ylide *(135)*; on heating to 200 °C in *o*-dichlorobenzene with a fivefold excess of dimethyl acetylenedicarboxylate the bicyclic compound *(134)*,



used as carbonyl ylide source, furnished the furan derivative *(136)* in quantitative yield together with large amounts of dimethyl fumarate[193].

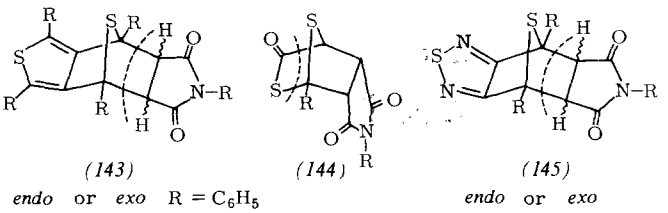
Do-Minh et al. reported an interesting [4→3+1]-photofragmentation of the tetraphenyl oxetanone *(137)* into carbonyl ylide *(138)* and carbon monoxide[194].

While photolysis of Δ^3-1,3,4-oxadiazolines *(139)* gives rise to a complex fragmentation pattern[195], thermolysis of the same class of heterocycles represents a convenient source of carbonyl ylides[2, 10, 196].



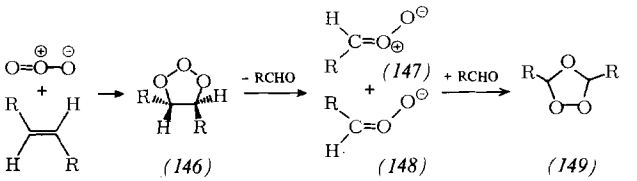
The thermal behavior of compounds *(140)* parallels that of compounds *(139)*. Temperatures in the range 40—100 °C suffice to generate the thiocarbonyl ylide *(141)* from *(140)*[2, 10]. Kinetic measurements of cycloreversion of few Δ^3-1,3,4-thiadiazolines permitted determination of the Arrhenius parameters; the enthalpy and entropy values were in the range 26.0—31.4 kcal mol^{-1} and 1.1—11.6 cal K^{-1} mol^{-1} respectively[197].

On irradiation, compounds *(140)* lose sulfur to give azines[198].



A dynamic equilibrium between adduct and addends is present in the reaction of the nonclassical thiophene system *(142)* with *N*-phenylmaleimide (NPM) (Scheme 8)[199].

Additional examples of systems undergoing [3+2]-cycloreversions to give thiocarbonyl ylides are *(143)*, *(144)*, and *(145)*; heating the polycyclic compound *(143)* to its melting

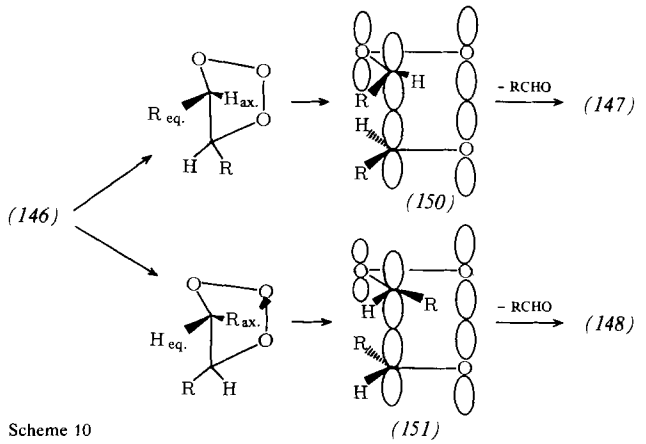


Scheme 8

point produces the addends[200], while the thermostable compounds *(144)*[201] and *(145)*[202] cyclorevert on electron bombardment.

12. Carbonyl Oxides and Ozone

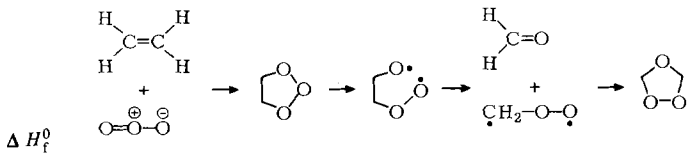
The present consensus of opinion[203-209] is that liquid phase ozonolysis of olefins occurs exclusively according to the modified Criegee mechanism (Scheme 9).



Scheme 9

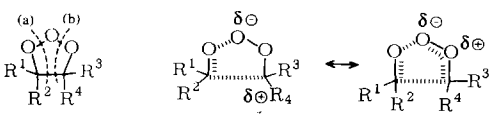
Thus the final ozonides *(149)* are formed in a two-step exothermic process[210] with prior 1,3-dipolar cycloreversion of primary ozonides *(146)* to give a mixture of *anti*- *(147)* and *syn*-carbonyl oxides *(148)* and a carbonyl compound. In general, these spontaneous 1,3-dipolar cycloreversions take place at very low temperatures; for example, in the case of *trans*-3-hexene the 1,2,3-trioxolane *(146)* (R = CH_3) cycloreverts at −100 °C with $k = 5.4 \times 10^{-4}$ s^{-1}[211].

In addition, the kinetically formed carbonyl oxides *(147)* and *(148)* tend to equilibrate[204, 207]. This process is favored by temperature and solvent polarity but disfavored by π-complexing substances which stabilize carbonyl oxides and by high concentrations of added aldehydes which trap the kinetically formed *syn* and *anti* carbonyl oxides.



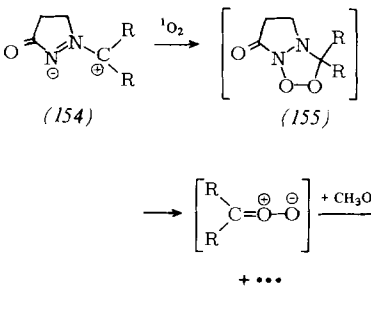
According to *Kuczkowski et al.*, the concerted cleavage of the 1,2,3-trioxolanes *(146)* should proceed *via* an envelope conformation of the molecule (Scheme 10)[212]. The substituent at the carbon atom destined to become part of the zwitterion can assume either an equatorial or an axial orienta-

tion, so as to give rise to final *anti- (147)* or *syn*-carbonyl oxide *(148)*, respectively. The energies involved in the two transition states *(150)* and *(151)* will be determined by the sum of interactions between substituents and lone pairs. This mechanism is supported by *ab initio* SCF MO calculations[213] from which $E_a = 11$ kcal mol^{-1} was estimated. This is in good agreement with the experimental values found for the cycloreversion of the primary ozonides of 1-hexene ($E_a = 7$ kcal mol^{-1})[214] and *trans*-3-hexene ($E_a = 8$ kcal mol^{-1})[211].



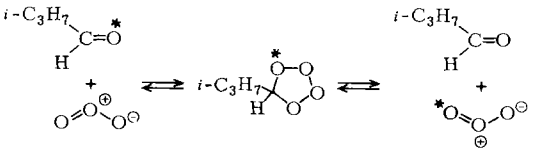
Scheme 10

By contrast, a nonconcerted cycloreversion has been proposed by *Goddard et al.*[215]. Calculated heats of formation (ΔH_f^0) are shown below the respective formulas[215].



As suggested by the authors, the intermediate carbonyl oxide should possess a singlet diradical structure lying, according to generalized valence bond and configuration interaction calculations, at an energy level lower by 27 kcal mol^{-1} than that of the zwitterionic structure of the same carbonyl oxide. *Criegee*, however, contended that singlet diradical carbonyl oxide should attack methanol at a C–H bond instead of the experimentally found O–H bond[203]. A nonconcerted diradical pathway was also proposed for the cycloreversion of 1,2,3-trioxolanes in the gas phase[216].

Unsymmetrically substituted 1,2,3-trioxolanes *(152)* cyclorevert in solution according to pathways (a) and (b)[217]. The direction of cleavage was found to be unaffected by temperature and solvent polarity but greatly influenced by substituents; the dominant carbonyl oxide obtained is that whose substituents are most capable of stabilizing a partial positive charge [see transition state *(153)* for path (a)].



The short-lived 1,2,3,4-dioxadiazolidines *(155)*, the probable intermediates of cycloaddition of azomethine imines *(154)* and excited singlet oxygen, undergo spontaneous cycloreversion[218]. The carbonyl oxides are trapped by methanol as methoxyhydroperoxides or by acetaldehyde as [3+2]-cycloadducts.

Two [3+2]-cycloreversion pathways, *viz.* fragmentation to carbonyl compounds and carbonyl oxides and to oxygen and carbonyl ylides, are to be seen in the mass spectra of 1,3,4-trioxolanes, albeit with low intensity[219].

Klopman and *Joiner* found that ^{18}O-labeled isobutyraldehyde in contact with ozone loses its label readily even at −78 °C. In order to rationalize the result the authors proposed a reversible type of [3+2]-cycloaddition of ozone with a carbonyl compound[220].

13. Conclusion

The examples selected here should illustrate the generality of the reaction in confirming, at least in part, a 1972 statement anticipating "a future growth in the scope of the retro 1,3-dipolar reaction comparable with that which has taken place for the forward reaction ..."[58].

Recent techniques will serve to increase the scope of this field; we consider flash thermolysis to be particularly promising. In the future it is to be hoped that more attention will be paid to exploring the synthetic possibilities of [3+2]-cycloreversion, and that a better understanding of the remaining mechanistic questions will soon be reached.

We are indebted to all who have provided us with examples of 1,3-dipolar cycloreversions; we wish to thank especially Nicholas Dennis, Alan R. Katritzky, Rolf Huisgen, Paolo Grünanger, Robert Carrié, Richard M. Kellogg, Kevin T. Potts, and Antonio Selva. Our thanks are also due to Silvana Bellaviti for carefully typing the manuscript.

New analytical methods (16)

Applications of SEPIL to the Solid State Defect Chemistry of Fluorites and Ultra-trace Inorganic Analysis

By John C. Wright, D. R. Tallant, F. J. Gustafson, M. V. Johnston, M. P. Miller, D. S. Moore, L. C. Porter, and J. R. Akse[*]

Although it has been recognized for many years that the spectra of lanthanoid ions can provide useful information about short range phenomena in the neighborhood of these ions in a solid material, lanthanoid spectroscopy has only infrequently been used for studying complex materials because of the problem of line-sorting the complex spectra that are obtained. The advent of convenient tuneable lasers has eliminated this problem. By *s*electively *e*xciting *p*robe *i*on *l*uminescence (SEPIL), it is possible to obtain fluorescence and excitation spectra from a single kind of crystallographic environment. Two applications of this method are discussed in this paper. The first application is the study of the defect chemistry of fluorite materials (compounds with CaF_2 lattice). It is shown how this method can provide unique information about the solid state chemistry, thus clarifying many of the unexplained behaviors of this important class of material. The second application shows how ultra-trace analysis can be carried out by causing an association between an analyte ion and a fluorescent probe ion. The unique crystal field levels of a probe ion associated with a particular analyte can be selectively excited so that traces of the ion to be analyzed can be detected with very high selectivity and with very low detection limits.

1. Introduction

The optical spectroscopy of lanthanoid-doped materials has been studied for many years[1]. Early efforts were concerned with understanding the physical mechanisms for the characteristic sharp line spectra and strong fluorescence of lanthanoids (rare earth metals)[2, 3]. The discovery that many lanthanoid compounds function very well as lasers[4] brought about a sudden surge in interest in the spectroscopy of this group of elements, particularly with a view to understanding the relaxation mechanisms and dynamic processes which determine the efficiency of the quantum electronic applications[5]. This work has led to a clearer understanding of both the static and dynamic aspects of lanthanoid spectroscopy and in many cases has furnished a degree of predictive power.

It was realized in the early spectroscopic studies that because the line positions and transition probabilities depend upon the immediate environment of the lanthanoid ion, one had at ones disposal a probe for the local crystal field[1]. By measuring the polarization of the transition, the line positions and/or the Zeeman splitting tensor, the local symmetry of a lanthanoid ion could be determined in many cases[2, 3, 6-10]. Some workers have succeeded in gaining information about the static and dynamic properties of lattice phonons[11-15] and about exciton propagation[16]. The majority of the work has been carried out on simple materials, usually single crystals in which the lanthanoid ion occupies a unique crystallographic site. Fundamental investigations of more complex materials have usually been avoided because of the difficulty in characterizing the site of the lanthanoid

ion or in interpreting the spectroscopic data. If a lanthanoid ion can occupy several different kinds of crystallographic sites, the spectroscopy is much more difficult since each lanthanoid site contributes a unique set of lines to the overall spectrum observed. Each line in the spectrum has to be studied individually in order to measure the polarization and the intensity as a function of the dopant concentration, the crystal treatment, the temperature, the symmetry of the Zeeman splittings, and/or the lifetime[7-10,17]. All of the lines can then be divided into groups that have the same behavior and correspond to the lanthanoid sites that are present. This process has been successfully used by a number of groups but it is generally time-consuming, tedious, and subject to error. Even after such a procedure is carried out, the results can still be ambiguous. Two groups studying $KCl:Sm^{2+}$ came to diametrically opposed views and wrote a series of passionate articles about their different conclusions[8,9].

In order to function efficiently as probes of short range order in more general situations where one is not dealing with simple materials, it is necessary to use techniques that can simplify the spectroscopy of a complex material (*i.e.* of a material where there are several environments encountered by a lanthanoid ion). A key idea for surmounting the problems was published in 1966 by *Voron'ko et al.*[18]. They used a mercury lamp and a monochromator with a 3 Å bandpass to selectively excite a specific absorption line of a specific lattice site of the lanthanoid ion and obtained fluorescence from that site alone. By exciting other absorption lines, they could obtain the fluorescence spectrum of each of the other sites. Using this method, they were able to classify the lines in the spectrum of $CaF_2:Er^{3+}$ into three different Er^{3+} sites. The method was not used for later studies, however, because the fluorescence intensities encountered with this excitation method were low and the bandwidth could not be made sufficiently narrow. The advent of tuneable dye lasers has eliminated these problems and made the selective excitation method quite practical[19,20]. In addition to obtaining fluorescence spectra from single sites by exciting a specific absorption line, one can also obtain single site excitation spectra by monitoring a specific fluorescence line as the laser excitation wavelength is changed. A complex absorption spectrum can therefore be split into the spectra of individual sites by monitoring different fluorescence transitions and obtaining excitation spectra. The problem of line classification then becomes quite simple (Fig. 1). Figure 1a shows the absorption spectrum of CaF_2:0.05 mol-% Er. This absorption spectrum is reproduced as the upper trace in Figures 1b—d. The bottom trace in these three figures is the excitation spectrum that results when different fluorescence lines are monitored. Figures 1b—d show how the absorption lines can be assigned to three lattice sites. The excitation line from the site shown in Figure 1d is in the same position as a line in Figure 1b, yet both excitation spectra can be obtained without interference from each other because the fluorescence lines monitored do not overlap.

We believe that selective laser excitation methods (also called site selective spectroscopy by later workers[21]) will extend the application of lanthanoid ions from studies aimed at understanding the spectroscopy of the lanthanoids to studies of more general interest where the lanthanoids are used as probes of short range environments in complex materials. In this paper, we present two examples of how the methods might be used—one example is a fundamental study of the solid state chemistry which occurs in charge compensated crystals, while the second example is the development of practical techniques for the ultra-trace analysis of inorganic ions.

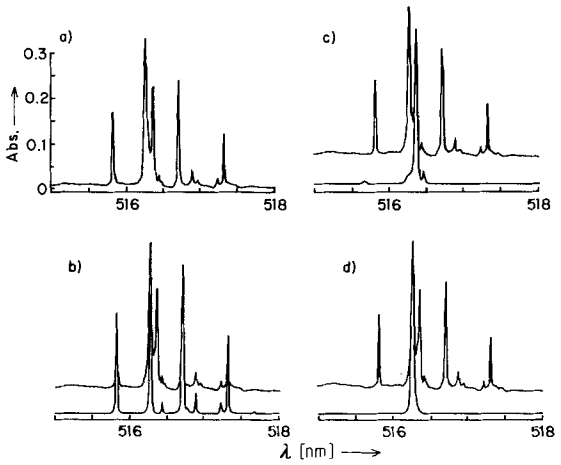

Fig. 1. a) Absorption spectrum of the $Z \rightarrow F(^4I_{15/2} \rightarrow {}^2H_{11/2})$ transition in CaF_2:0.05 mol-% Er^{3+}. This spectrum is reproduced as the top trace in Fig. 1b—d. b—d) Excitation spectrum of the Z→F transition obtained while monitoring the fluorescence line at 540.0 nm (b), 539.15 nm (c) or 537.98 nm (d).

2. Solid State Chemistry of Fluorites

One of the most important problems in materials science is the description of point defects. In most cases the defects in a material determine its overall properties[22-26]. Compounds having the fluorite structure have played an important role in understanding defects both because of their practical importance and their use as model systems. A great deal of work has been carried out with compounds having a fluorite structure, particularly as regards dielectric relaxation, ionic conductivity, thermal conductivity, diffuse and Bragg neutron scattering, diffusion, density measurements, NMR, ESR, ENDOR, UV, visible and IR spectroscopy[27-44]. In this paper, we shall restrict our discussion to the fluorites CaF_2, SrF_2, and BaF_2.

It is generally accepted that the predominant defects in CaF_2, SrF_2, and BaF_2 are fluoride interstitials (F_i')[45] and fluoride vacancies ($V_F^{\cdot}$) which exist in equal numbers because of charge neutrality requirements[23,46]. If trivalent cations like Er^{3+} are introduced into a lattice such as $CaF_2(Er_{Ca}^{\cdot})$, additional fluoride interstitial ions are required for charge compensation. There will be Coulombic interactions between $Er_{Ca}^{\cdot}$ and F_i' promoting association into single pairs $(Er_{Ca}^{\cdot} \cdot F_i')^x$ which can have different symmetries depending upon the relative positions of $Er_{Ca}^{\cdot}$ and F_i'. The two most important symmetries are tetragonal and trigonal[10]. The relative numbers of the different symmetry pairs is determined by the relative free energies of association and the temperature of the crystal[47]. In addition, the $Er_{Ca}^{\cdot}$ and F_i' can be distant from each other and occupy sites of cubic symmetry. The free F_i' that are found then force a decrease in the $V_F^{\cdot}$ concentration. The model can be described in terms of two equilibria analogous to solution equilibria.

$$\text{Perfect } CaF_2 \text{ lattice} \rightleftharpoons F_i' + V_F^{\cdot}$$
$$+$$
$$Er_{Ca}^{\cdot}$$
$$\downarrow\uparrow$$
$$(Er_{Ca}^{\cdot} \cdot F_i')$$

This simple model has been extensively employed in many studies with apparent success. Particularly convincing evidence was provided by EPR measurements, which conclusively identified the tetragonal and trigonal site symmetries expected for the lanthanoid ion in an associated pair and the cubic symmetry of the site expected for a lanthanoid in an unassociated pair[47,48]. ENDOR measurements identified the presence of the F_i' in the tetragonal and trigonal sites[49,50].

There were several observations however that did not agree even qualitatively with this model[50–52]. The ratio of associated pairs to non-associated pairs (or trigonal + tetragonal to cubic pairs) was measured by EPR spectroscopy as a function of the crystal temperature[53]. $CaF_2:Gd^{3+}$ samples were heated in an oxygen-free atmosphere until the distribution of site populations reached equilibrium and then were quenched rapidly to freeze the high temperature distribution. The simple model would predict that the ratio of associated to non-associated pairs would decrease as the effective crystal temperature was raised in order to maximize the entropy of the system. Instead, exactly the opposite behavior was observed: The number of associated pairs increased as the temperature was raised. The ratio was also measured as a function of the Gd^{3+} concentration[53–58]. According to the simple model the ratio of associated to non-associated pairs should increase as the dopant concentration is raised, but the measurements actually showed that the ratio decreases.

Problems were also encountered in the interpretation of Bragg neutron diffraction and diffuse neutron scattering data in highly doped samples of $CaF_2:Y^{3+}$. These experiments revealed two types of F_i' ions, those with distortions along the ⟨110⟩ direction and those with distortions in the ⟨111⟩ direction from the central (½, ½, ½) cubic position of a normal F_i' site[28,29]. Fluoride vacancies could also be observed. The relative concentrations of these three types of defects could be explained by postulating that the two types of F_i' ions and the $V_F^{\cdot}$ form a cluster designated as a 2:2:2 cluster since it contains two of each type of defects. There are also a number of variations in the structure and composition of this basic cluster. The $Y_{Ca}^{\cdot}$ ions in the sample could not be observed directly; though there was evidence from the diffuse neutron scattering measurements that the $Y_{Ca}^{\cdot}$ were only loosely associated with the clusters. It was further argued that the cation mobility in CaF_2 should be sufficiently small that one would not expect $Y_{Ca}^{\cdot}$ to cluster extensively[30,59]. If there is only a loose association of $Y_{Ca}^{\cdot}$ with the 2:2:2 clusters, the clusters would possess a net negative charge which would favor their dissociation. What stabilizes the formation of negatively charged clusters? Furthermore, the distance required between two F_i' with ⟨110⟩ distortions in the 2:2:2 cluster was 2.0 Å, much closer than the 2.3 Å separation expected theoretically[28–30]. In order to explain these two problems, *Catlow* proposed that an additional covalent interaction existed between F_i' which both stabilized the negatively charged 2:2:2 clusters and produced the 2.0 Å separation between F_i'[59]. We shall see later how *Catlow*'s proposal also explains the anomalous changes in the ratio of the associated to non-associated pairs.

2.1. Experiments on Selective Excitation in CaF_2

We have investigated materials having a fluorite lattice by the selective laser excitation technique. This technique is the only one that has permitted the examination of all the different sites occupied by a trivalent dopant. Most of our work has been concentrated on $CaF_2:Er^{3+}$[19,20,60–62], although we have found that SrF_2[63] and BaF_2[64] exhibit a similar behavior. The excitation spectrum that one observes for a CaF_2:0.2 mol-% Er^{3+} sample when fluorescence from all Er sites is monitored is shown in Figure 2. The lines in this excitation

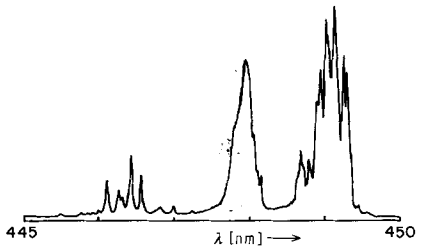

Fig. 2. Excitation spectrum of CaF_2:0.2 mol-% Er^{3+} that results on monitoring the fluorescence of all E→Z ($^4S_{3/2}\rightarrow{}^4I_{15/2}$) transitions with a broad bandwidth monochromator while a dye laser is scanned over the possible Z→H ($^4I_{15/2}\rightarrow{}^4F_{5/2}$) transitions.

spectrum can be divided into groups corresponding to the different Er sites by monitoring a single fluorescence line from an individual site. The single-site excitation spectra obtained in this way are shown in Figure 3. Each line in Figure 3 corresponds to a line of the excitation spectrum in Figure 2.

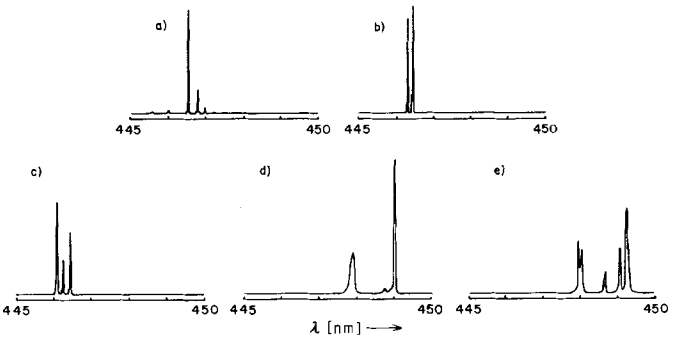

Fig. 3. Single site excitation spectra of CaF_2:0.2 mol-% Er^{3+} (see Fig. 2) [Z→H ($^4I_{15/2}\rightarrow{}^4F_{5/2}$) transitions]. The spectra are observed by monitoring the fluorescence at: a) 835.4 nm (A site), b) 835.8 nm (B site), c) 836.1 nm (C site), d) 843.1 nm (D(1a) site), e) 654.4 nm (D(2a) site).

Only two representative spectra (Fig. 3d and 3e) of the many that make up the bands shown in Figure 2 have been shown. It was possible to show that at least 15 sites contributed lines to the bands, 11 which had spectra similar to Figure 3d and four which had spectra similar to Figure 3e. The site whose spectrum is shown in Figure 3a corresponds to an Er^{3+} ion with a F_i' in the nearest possible interstitial position producing a tetragonal site symmetry. This identification could be made because *Rector et al.*[7] had previously shown that the lines from this site had a Zeeman splitting tensor that possessed tetragonal symmetry. Similarly, the spectrum in Figure 3b corresponds to an Er^{3+} ion with a F_i' that produces a

trigonal site symmetry. The spectra in Figures 3c—e were shown to correspond to different clusters of Er^{3+} ions whose symmetry remains undetermined. It is clear from Figure 2 that these clusters cause the dominant features in the overall spectrum at the 0.2 mol-% concentration level. A great deal of effort was spent in showing that clusters of Er^{3+} actually cause these spectral features, both because of their importance in the optical spectrum and because many workers did not believe that Er^{3+} clusters could be important[50-52] or in fact even be formed because of low Er^{3+} mobilities[59]. A prime reason for this disbelief was the inability of EPR measurements to identify any features that would correspond to Er^{3+} ion clusters[50]. It should, however, be pointed out that many optical spectroscopists have observed the lines and correctly assigned them to Er^{3+} clusters because of their rapid increase with dopant concentration[10,17-20,31-33,65]. In 1966, *Voron'ko et al.* were particularly successful in unraveling the optical spectrum into four sites which are essentially those represented in Figure 3[10] and in attributing two of the sites to clusters of Er^{3+} ions.

2.2. Proof of Clustering in Fluorites

Two experiments show quite conclusively that clusters of Er^{3+} ions are responsible for the features shown in Figures 3c—e. If a particular electronic multiplet within the $4f^n$ electron configuration of a particular lanthanoid ion is excited, resonant or non-resonant energy transfer can occur with another lanthanoid ion[60,66]. Non-resonant energy transfer is generally quite weak if the initial and final energy states differ by more than a few hundred cm^{-1}. However, if the two ions involved in the energy transfer are quite close to each other, as is the case for the clusters, the non-resonant energy transfer rate can become efficient. In fact, non-resonant energy transfer is generally the dominant non-radiative relaxation mechanism for the clusters. A series of measurements were performed on CaF_2 in order to determine how the transfer rate depends upon the energy mismatch between the initial and final energy states. The results are shown in Figure 4 as the isolated points. It can be seen that there is a strong dependence upon the energy mismatch. The multiphonon relaxation rate was also measured for CaF_2 as a function of the amount of energy lost by the non-radiative relaxation (line (a) in Figure 4). In this process, an excited electronic level can relax non-radiatively to a lower electronic level by dissipating the energy difference as lattice phonons. Although multiphonon relaxation is more rapid than non-resonant energy transfer for a particular value of energy dissipation, there are generally enough different electronic levels for two arbitrary lanthanoid ions that a combination of lower levels will lie closer in energy to an excited level than the gap appropriate for multiphonon relaxation. Non-resonant energy transfer is therefore very important in clusters. No energy transfer has been observed for the tetragonal and trigonal Er sites which are isolated from other Er ions.

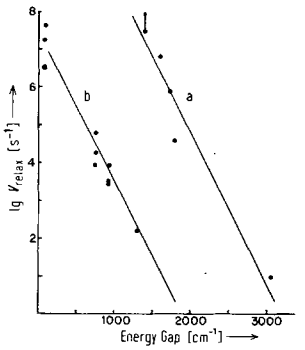

Fig. 4. The points of curve a represent the non-radiative rate for multiphonon relaxation as a function of the energy gap between the emitting level and the next lowest level. The points of curve b represent the non-radiative rate due to non-resonant energy transfer between two ions in a cluster. All of the data is for CaF_2 with Er^{3+} as dopant.

The energy transfer causes some interesting phenomena. Up-conversion of excitation energy can be particularly efficient if two ions in the clusters are excited[20,60]. One ion transfers its excitation energy to the neighboring excited ion and causes a fluorescence from a level much higher in energy than that originally pumped. Thus, one can visually observe green fluorescence from a $CaF_2:Er^{3+}$ crystal when the Er clusters are being excited in the red. If one monitors the green fluorescence, the red excitation spectrum obtained will only contain lines from the Er clusters. The single pairs (*i.e.* the tetragonal and trigonal sites) cannot undergo the energy transfer and consequently cannot produce the up-converted fluorescence. This method provides a convenient way in which to discriminate between the single ($Er_{Ca} \cdot F_i$) pairs and Er^{3+} clusters.

The second experiment which shows the presence of clusters involves the double doping of CaF_2 samples[61]. In a sample of CaF_2:0.2 mol-% Yb^{3+}, 0.01 mol-% Er^{3+}, the site distribution is determined by the Yb^{3+} concentration, which is large enough that the optical spectrum is dominated by the clusters. The Er^{3+} will also be distributed among the various possible sites, and some Er^{3+} ions will form mixed clusters with Yb^{3+}. The Er^{3+} concentration is sufficiently low that pure Er clusters are improbable. However, if one monitors the Er transitions, mixed Er—Yb clusters can be seen. The lines are shifted slightly from those observed in $CaF_2:Er^{3+}$ samples because Yb^{3+} has a different ionic radius from that of Er^{3+}. An example of the differences observed is shown in Figure 5. Since it is clear that Yb^{3+} is sufficiently close to Er^{3+} to affect the Er spectrum, it follows that these transitions must arise from clustering of the cation dopants.

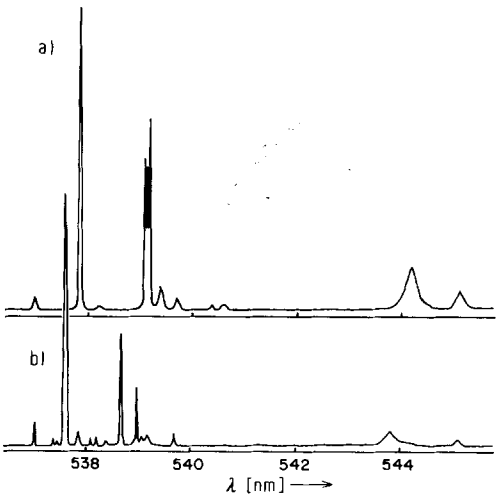

Fig. 5. Single site fluorescence spectrum for the $E \rightarrow Z(^4S_{3/2} \rightarrow {}^4I_{15/2})$ transition of the C site in a) $CaF_2:Er^{3+}$ and b) $CaF_2:Er^{3+}$, Yb^{3+}. Note the shift of the lines due to the influence of the Yb^{3+} on the clusters.

2.3. Concentration of Clusters

Secemski and *Low* pointed out that the observation of clustered ions in the optical spectrum does not necessarily mean that clusters are important[50]. The ions in the clusters may simply have much more favorable radiative transition probabilities and quantum efficiencies than single pairs and therefore may look brighter in the fluorescence spectra. Their actual concentration could still be quite low and thus might prevent EPR spectroscopic detection. The authors point out that transition probabilities for EPR are much simpler than for optical transitions. The measurement of the cluster concentrations therefore constitutes an important experimental step in solving the solid state chemistry of the fluorites.

The only technique that permits observation of the cluster species is optical spectroscopy. However, the relationship between the fluorescence intensity or absorption coefficient and concentration is complex. One can follow how any given site will change in samples of different concentrations but the transition probabilities must be known in order to determine an absolute concentration. The transition probability for an absorption transition can be obtained if that same transition can be observed in fluorescence where a fluorescence lifetime can be determined[6]. The fluorescence lifetime determines the total relaxation rate for the level. The radiative quantum efficiency must be measured in order to obtain the total radiative relaxation rate for the level. Finally, the radiative relaxation rate for a particular transition of interest can be derived by measuring what fraction that transition represents of the total fluorescence from the level[60]. The actual procedure for obtaining all the concentrations is more involved than described here (for further details see reference[61]). The results thus obtained are shown in Figure 6, where the site concentrations are plotted as a function of total dopant concentration in the system $CaF_2:Er^{3+}$. The C

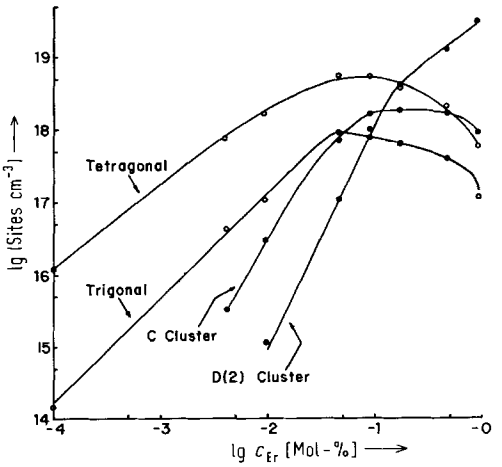

Fig. 6. Absolute concentrations of the Er sites in $CaF_2:Er^{3+}$ as a function of Er^{3+} dopant concentration.

and D(2) designations refer to Er clusters that have the spectra shown in Figures 3c and e. The concentration of the unassociated or cubic Er site does not appear in Figure 6 because it cannot be observed: electric dipole transitions are forbidden in a cubic crystal field[2]. It should be clear from this data that the clusters are a dominant feature of the site distribution at almost all commonly used dopant concentrations and must be included in any description of the solid state equilibria.

2.4. Discussion

As shown in Figure 6, at very low concentrations the single pair sites (the tetragonal and trigonal sites) change linearly with concentration. As soon as the clusters appear, the number of single pair sites changes more slowly until their absolute concentration actually begins to decrease. A decrease in the absolute concentration of any site is unexpected, since a simple equilibrium of defects will allow only changes in the rate of increase of a site population with dopant concentration, but never a decrease[61].

Our explanation for this behavior requires an extension of the simple model presented earlier[45,61].

$$\begin{array}{l}\text{Perfect } CaF_2 \text{ lattice} \rightleftharpoons F_i' + V_F^{\cdot} \\ \qquad\qquad\qquad\qquad + \\ \qquad\qquad\qquad\qquad Er_{Ca}^{\cdot} \\ \qquad\qquad\qquad\qquad \downarrow\uparrow \\ (Er_{Ca}\cdot F_i)^x + (Er_{Ca}\cdot F_i)^x \rightleftharpoons (2\,Er_{Ca}\cdot 2\,F_i)^x + \cdots \\ \qquad\qquad\qquad\qquad\qquad\qquad + \\ \qquad\qquad\qquad\qquad\qquad\qquad F_i' \\ \qquad\qquad\qquad\qquad\qquad\qquad \downarrow\uparrow \\ \qquad\qquad\qquad\qquad\qquad\qquad (2\,Er_{Ca}\cdot 3\,F_i)'\end{array}$$

The clustering has been shown explicitly as an additional equilibrium. The additional covalent interaction between F_i' ions that was proposed by *Catlow*[59] has been represented by an equilibrium in which $(2\,Er_{Ca}\cdot 3\,F_i)'$, a charged cluster, is formed. This last type of equilibrium is the key to the explanation of the anomalous behavior of CaF_2 and may well be the equilibrium that controls the solid state equilibria in the fluorites. At high temperatures, the $Er_{Ca}^{\cdot}$ and F_i' are both free to move about in the lattice. As the temperature is lowered, the $Er_{Ca}^{\cdot}$ lose mobility and the distribution becomes frozen. This event fixes the total number of $Er_{Ca}^{\cdot}$ that exist as single ions, dimers, trimers, *etc.* However, the F_i' are still mobile and can be distributed among the different $Er_{Ca}^{\cdot}$ sites to form different species. In particular, if the bonding of a F_i' to make a charged species like $(2\,Er_{Ca}\cdot 3\,F_i)'$ is very favorable, the concentration of free F_i' would be forced lower. However, the equilibrium between unassociated $Er_{Ca}^{\cdot}$ and the single associated pairs $(Er_{Ca}\cdot F_i)^x$ must follow a simple mass action relation

$$K = [F_i'][Er_{Ca}^{\cdot}]/[(Er_{Ca}\cdot F_i)^x]$$

which determines the ratio of unassociated to associated $Er_{Ca}^{\cdot}$. If $[F_i']$ is small because of the formation of $(2\,Er_{Ca}\cdot 3\,F_i)'$, the ratio $[Er_{Ca}^{\cdot}]/[(Er_{Ca}\cdot F_i)^x]$ will become large as the associated single pairs are forced to dissociate. Higher dopant concentrations produce more clusters which form the $(2\,Er_{Ca}\cdot 3\,F_i)'$ type of species that removes F_i' from the equilibria. Thus, the absolute concentrations of the tetragonal and trigonal sites will decrease, as is observed experimentally (Fig. 6). The same argument provides an explanation of the anomalous behavior observed in EPR measurements: the cubic site concentration increases relative to the associated single pair sites as the total dopant concentration is increased.

This model also provides an understanding of the temperature dependence observed by *Franklin* and *Marzullo*[53], who found that the concentration of cubic sites decreases relative to the concentration of tetragonal sites as the temperature of the sample is raised. At high temperatures, species such as $(2\,Er_{Ca}\cdot 3\,F_i)'$ will dissociate and raise the concentration of free F_i'. The free F_i' ions can then recombine with Er^{3+} ions in cubic sites to form the associated single pairs.

The results from Bragg neutron diffraction and the diffuse scattering experiments relate very directly to this model. The selective laser excitation studies showed clearly that contrary to some expectations, there is extensive clustering of Er^{3+} ions. The presence of several Er^{3+} ions in a cluster would help to stabilize it against the dissociation discussed for the (2:2:2) cluster model presented by *Cheetham et al.*[28,29], *Steele et al.*[30] and *Catlow*[59]. The cluster of Er^{3+} ions would be further stabilized by the additional covalent bonding of F_i' proposed by *Catlow*[59]. This interaction also produces the charged species which determines the defect equilibrium discussed.

This model is supported by density measurements carried out by *Franklin* as a function of dopant concentration[27]. *Franklin* observed that the density of $CaF_2:Gd^{3+}$ increased too rapidly with concentration to be explained by having a single Gd^{3+} charge compensated by a single F_i'. He suggested that HF from the atmosphere around the crystal during its growth had entered the lattice and formed associations with $(Gd_{Ca}\cdot F_i)^x$ pairs. No evidence could be found for the F H F groups that would be formed. However, the additional HF could be brought into the lattice in association with the cluster species and result in the anomalously high values for the density.

Although this model provides a self-consistent explanation for the behavior of CaF_2, it remains a speculative model that must be proven. We are presently engaged in experiments that will monitor the populations of all the sites as the temperature of the crystal is changed. We expect to see the population of species like $(2\,Er_{Ca}\cdot 3\,F_i)'$ decrease as the temperature is raised while the $(2\,Er_{Ca}\cdot 2\,F_i)^x$ and $(Er_{Ca}\cdot F_i)^x$ concentrations increase correspondingly. These experiments are not complete but it is clear that temperature changes cause large redistributions in site population.

3. Ultra-trace Chemical Analysis

When we began our experiments in selective laser excitation, we were struck by both the excellent signal/noise ratio and ability to selectively excite a specific site without interference from other sites. These two features are also of great importance for a good trace analysis method. One would like to have analytical methods that can measure very low concentrations with a high degree of selectivity for the analyte of interest. Could the trace analysis of lanthanoids be carried out using the laser methods? Our systems at that time were single crystals, not particularly interesting samples for an analytical determination. In order to use our selective laser excitation methods, we had to find a convenient way of incorporating lanthanoid analytes from a material of analytical interest into a material suitable for our methods.

3.1. Analysis of Lanthanoids

We found that coprecipitation from aqueous solution was a suitable way to incorporate analytes[67]. Treatment of a solution containing unknown amounts of different lanthanoid ions with $Ca(NO_3)_2$ and then with NH_4F leads to coprecipitation of the lanthanoids in the resulting CaF_2 microcrystals. We have measured the amount of coprecipitation that occurs as a function of the total amount of CaF_2 precipitated and have found that the distribution law for lanthanoid coprecipitation is very favorable. The precipitation therefore performs several functions:

1) it incorporates the analyte into a suitable matrix,
2) it serves as a preconcentration step,
3) it serves as a separation step, especially since other ions with much different ionic radii are not likely to coprecipitate.

Although it might be expected that the quality of the micro-crystals would be too poor to show sharp line structure, the lanthanoid transitions are reasonably sharp. An example of the excitation spectrum of a $CaF_2:Er^{3+}$ precipitate is shown in Figure 7a. There are lines from both the tetragonal

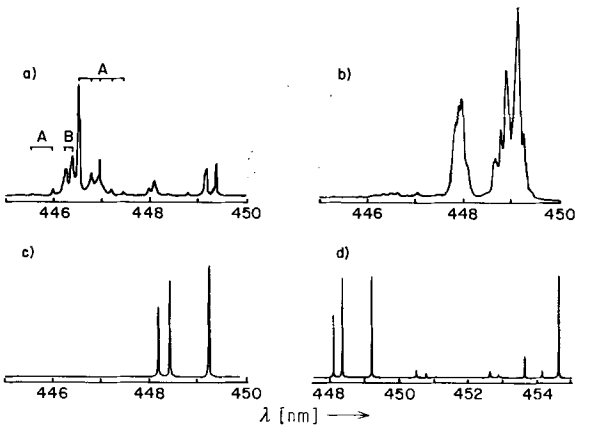

Fig. 7. Excitation spectra of the $Z\rightarrow H(^4I_{15/2}\rightarrow{}^4F_{5/2})$ transition for a $CaF_2:Er^{3+}$ precipitate dried at different temperatures. A monochromator with a very wide bandpass was used to monitor the fluorescence in order to include fluorescence from all the sites present. a) Room temperature (A, B see text), b) 350 °C, c) 500 °C, d) 1000 °C.

and trigonal Er sites present which are labeled A and B respectively. If the precipitate is dried at 350 °C, dramatic changes occur in the spectrum as shown in Figure 7b. Lines that have the same appearance as the cluster site lines shown in Figure 3e become prominent while the lines from single pair sites almost disappear. This behavior is quite unexpected and cannot be explained with any degree of certainty. It would appear to indicate that the Er^{3+} ions initially coprecipitate in isolated positions in the lattice and do not have sufficient mobility at room temperature to reach the equilibrium distribution. As the temperature is increased, they finally achieve sufficient mobility (in precipitates at least) to move and form clusters with each other. At higher temperatures (Fig. 7c), the spectrum changes once more. All the previously observed lines and bands disappear and are replaced by lines from a single site—labeled G1. The fluorescence intensity from this site is several orders of magnitude higher than those of the previously discussed sites. Other workers have studied CaF_2 under very similar conditions to ours and have discovered the reason for the appearance of the new

site[68-72]. The fluoride charge is compensated by oxygen anions instead of by fluoride ions, because F_i reacts with water vapor:

$$2F_i' + H_2O \rightarrow 2HF + O''$$

The oxygen anion replaces one of the nearest neighbor fluoride ions in the lattice and produces an Er site with trigonal symmetry. The spectrum continues to change as the precipitate is heated to 1000 °C (Fig. 7d). Lines associated with sites labeled G2, G3 and G4 increase in intensity up to 1000 °C but then become weaker again at higher temperatures. These sites are probably the result of additional oxygen incorporation. For example, the site labeled G4 is believed to result from replacement of seven nearest neighbor fluoride ions and the fluoride interstitial charge compensation by four oxygen anions[70]. At very much higher temperatures, the spectrum changes to that of CaO[67].

The sites that are present below 500 °C are of no analytical value. As one lowers the concentration of the rare earth in solution, the line intensities drop non-linearly at a rapid rate until they cannot be detected at a concentration of 1.25 μg/ml. It is assumed that the non-linear behavior is caused by the dissociation of the single pairs of $Er_{Ca}^{\cdot}$ and F_i' at very low concentrations. The lines of the single pairs disappear and are not replaced by spectra from the dissociated pairs because the cubic Er site of a dissociated pair does not have allowed electric dipole transitions. The temperature region between 500° and 700 °C is optimum for an analysis because the site distribution has collapsed into a single site which is intensely fluorescent and is stable against dissociation at very low concentrations. It is particularly advantageous to have only one site because the peak intensity is higher and the system becomes more insensitive to other influences that could change the site distribution.

Any lanthanoid that fluoresces in CaF_2 can be determined by the procedure described. In order to fluoresce, an ion must have excited electronic levels within the $4f^n$ electron configuration (transitions to other configurations have much broader lines because of the additional interactions with the lattice) and must have an excited electronic level whose non-radiative relaxation is slow in comparison with its radiative relaxation[5]. Of the 15 lanthanoid ions, only La, Ce, and Lu do not have excited electronic levels. (Ce actually has one excited level but it is too close to the ground state to be used.) Gd has many excited levels but they lie in the UV beyond 310 nm where it is difficult to obtain convenient tuneable lasers. The non-radiative relaxation rate is determined by the strength of multiphonon processes that convert electronic energy into vibrational energy. The rate for this process depends exponentially upon how much energy an excited level must dissipate in the lattice. If there is another electronic level that has a lower energy than the excited level, a non-radiative transition to the lower level can occur and the energy difference is dissipated as several phonons. Figure 4 describes the relationship between relaxation rate and the energy gap for CaF_2. If the typical radiative transition rate is 10^3 s^{-1}, an energy gap greater than 2600 cm^{-1} is required before a level will generate sufficient fluorescence. All lanthanoid ions having excited electronic levels—Pr^{3+}, Nd^{3+}, Pm^{3+}, Sm^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}, and Yb^{3+}—also have at least one level that can fluoresce efficiently. We have experimentally demonstrated the feasibility of analyzing all of these ions excepting Pm^{3+}, Gd^{3+}, and Yb^{3+}. Pm is radioactive, while Gd and Yb have electronic levels in a spectral region that is not accessible with our lasers. As will be discussed later, there are methods that can be used for the analysis of those ions which cannot be detected by this method, namely La^{3+}, Ce^{3+}, Gd^{3+}, Yb^{3+}, and Lu^{3+}.

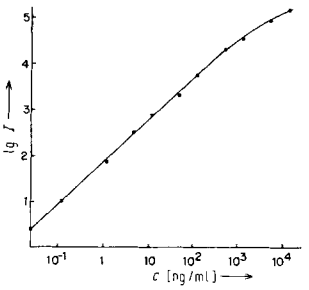

Fig. 8. Fluorescence intensity (I) of a $CaF_2:Er^{3+}$ precipitate as a function of Er^{3+} concentration (c) in the original solution (calibration curve).

The analytical working curve for Er analysis is shown in Figure 8. The concentrations are referenced to the original solution before precipitation. At high concentrations the curve becomes non-linear; at these concentrations additional lines also appear in the spectrum which have been proven to be associated with cluster formation (see later discussions). The spectrum of the cluster site is shown in Figure 9. Note the double line structure that is associated with exchange-splittings between the two lanthanoids. The change in the site distribution accompanying cluster formation causes the non-linearity of the calibration curve (Fig. 8) at high concentrations.

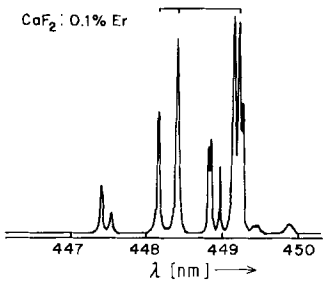

Fig. 9. Excitation spectrum of the $Z \rightarrow H(^4I_{15/2} \rightarrow {}^4F_{5/2})$ transition obtained with wide bandpass monitoring of a CaF_2:0.1 mol-% Er^{3+} precipitate. By comparing this spectrum with that in Figure 7c, the additional lines that are formed at high concentrations are readily recognizable. The three lines from Figure 7c are marked.

The limit of detection for this method depends upon the number of photons available from the laser excitation source. One of the advantages of a pulsed laser is the ability to use time resolution techniques or gating to discriminate between signal and background. The lanthanoids have relatively long fluorescence lifetimes, usually 200 μsec or longer, and discrimination becomes simple. On the other hand, the lifetimes are short enough to allow photomultiplier dark noise fluctuations to be greatly reduced by gating. Thus, the limit of detection is determined more by the excitation source intensity than by the fluctuations in source intensity and by the residual dark noise fluctuations. With currently available instru-

mentation a detection limit of 25 fg/ml (25×10^{-15} g/ml) of Er^{3+} can be achieved, calculated by extrapolation of the signal/noise ratio at 1 pg/ml. The absence of clean-room facilities prevented us from reaching the detection limit of the method experimentally. The instrumentation used by us included a N_2-pumped dye laser with an average power of 1 milliwatt and an uncooled S-20 photomultiplier. With a cooled photomultiplier and a laser power of a modest 50 milliwatts, the detection limit would be 25×10^{-18} g/ml.

The sources of interference in this method can be divided into different classes:

1) formation of other precipitates
2) changes in efficiency of coprecipitation
3) line-broadening
4) changes in site distribution
5) quenching of fluorescence.

The first class of interferences are obvious ones. If we assume the lanthanoid analytes are in solution as we begin the procedure, problems can arise if there are substances present which precipitate when either $Ca(NO_3)_2$ or NH_4F is added. Insoluble fluorides would provide the main problem since most anions that precipitate Ca will have already precipitated the lanthanoid ions. The insoluble fluorides include such compounds as SrF_2, PbF_2, BaF_2, and BiF_3. Generally if such substances are present in concentrations large enough to affect the amount of CaF_2 precipitate that is formed, this will cause more severe interferences of the other classes mentioned above. Interferences of class 2 have not been identified or studied.

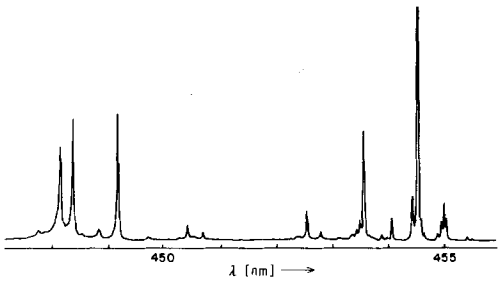

Fig. 10. Excitation spectrum of the $Z \rightarrow H(^4I_{15/2} \rightarrow {}^4F_{5/2})$ transition for a CaF_2:0.1 mol-% Er^{3+} precipitate after addition of 50 ppm of Na^+; for usual conditions see Figure 7c. It can be seen that Na^+ changes the spectrum and therefore acts as an interference.

We have examined examples of each kind of ion that can act as a potential interference. As typical monovalent cations, Li^+, Na^+ and K^+ were added to the lanthanoid-containing solution. Na^+ and Li^+ produce marked changes in the spectrum (Fig. 10). They affect the site distribution by accelerating charge compensation by oxygen anions instead of by fluoride anions. Additional lines appear in the spectrum that are probably associated with lanthanoid-ion sites which are compensated by the monovalent cation.

The spectrum obtained when K^+ is added to the solution is shown in Figure 11. The site distribution is completely changed, the intensity of the lines is dramatically lowered, the lines are broadened, and the background is increased. These changes are very severe and would drastically limit the applicability of the technique if they could not be eliminated. Traces of other ions have also been observed to severely change the site distribution.

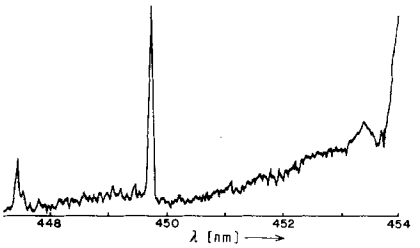

Fig. 11. Excitation spectrum of the $Z \rightarrow H(^4I_{15/2} \rightarrow {}^4F_{5/2})$ transition for a CaF_2:0.1 mol-% Er^{3+} precipitate after addition of 0.1 mol/l of K^+. Comparison with Figure 7c shows the profound influence of K^+.

We believe that these problems are best interpreted in terms of the solid state equilibria in the precipitated microcrystals. Any aliovalent ion that enters the lattice will require a charge compensation and must therefore affect all of the defect equilibria. If all the aliovalent ions are present at trace levels, the position of the defect equilibria can fluctuate as other trace contaminants enter the lattice. The situation is analogous to an unbuffered aqueous solution which can fluctuate in pH as trace quantities of different ions enter the solution. A buffer is required to fix the equilibria positions and remove the sensitivity to traces of other ions. Li and K were chosen to act as the solid state buffer. The solution containing $Ca(NO_3)_2$ and the lanthanoid analytes is treated with $LiNO_3$ and KNO_3 before the precipitation is carried out. The precipitate is heated at as low enough a temperature that only sites of type G1 are formed. This step eliminates the sensitivity of the system to any of the monovalent cations and has been made an integral part of the procedure. All of the results described in the following sections were obtained on adopting this procedure.

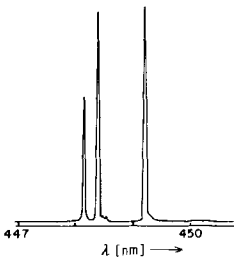

Fig. 12. Excitation spectrum of the $Z \rightarrow H(^4I_{15/2} \rightarrow {}^4F_{5/2})$ transition for a CaF_2:0.1 mol-% Er^{3+} precipitate after addition of 0.005 mol/l of Sr^{2+}. Comparison with Figure 7c shows the line-broadening effect of Sr^{2+} and the additional sites that appear.

Divalent cations do not interfere at low concentrations, but do so at higher concentrations (*ca.* 5×10^{-3} mol/l). An example of a spectrum obtained with $Sr(NO_3)_2$ present in the original solutions is shown in Figure 12. The lines are all broadened and therefore result in a lower measured intensity. Sr ions can enter the lattice substitutionally for Ca and cause disruptions in the lattice order because of their different ionic radii. The lanthanoid ions are therefore present in many different environments, resulting in both broadened lines and a background fluorescence.

Trivalent cations include the lanthanoid ions themselves and many other similar ions. The trivalent cations interfere at concentrations above *ca.* 10^{-5} mol/l by the same clustering mechanism that causes non-linearities in the working curve (see Fig. 8). This interference might be expected, because trivalent cations having properties similar to those of lanthanoid ions should cause a site distribution characteristic

of a higher lanthanoid concentration in the cation lattice. The lanthanoids themselves could cause additional interference by participating in energy transfer processes that quench the fluorescing level. These processes have a particularly strong influence if the two levels lie quite close to each other[66]. However, we have not found any evidence of lanthanoid fluorescence being quenched by other lanthanoids over the entire linear region of the working curve. This lack of interference by quenching means that all of the lanthanoids can be determined in a single sample without any need for prior separation.

Interference by transition metals does not generally occur until concentrations greater than *ca.* 10^{-4} mol/l are reached. Fe^{3+}, however, interferes particularly strongly and its concentration must be kept below *ca.* 4×10^{-6} mol/l. Interferences by transition metals belong to the class 5 interferences (quenching of lanthanoid fluorescence).

We have also examined a number of the common anions such as Br^-, Cl^-, SO_4^{2-}, NO_3^- and PO_4^{3-} and have not found any interference at concentrations below *ca.* 10^{-3} mol/l. We are presently extending our study of interferences to include many other ions. In addition, we are engaged in applying this technique to samples of geological interest in order to test whether interferences will arise which we had not anticipated and to demonstrate the practicability of the method in cases where lanthanoid analysis is important.

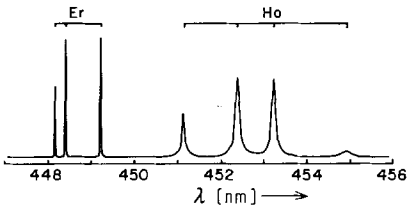

Fig. 13. Excitation spectrum of the $Z \rightarrow H(^4I_{15/2} \rightarrow {}^4F_{5/2})$ transition for a mixed precipitate of $CaF_2:Er^{3+}$, Ho^{3+}. The individual Er^{3+} and Ho^{3+} transitions are indicated. The bandwidth of the fluorescence monitor was sufficiently wide to include both the Ho^{3+} and Er^{3+} fluorescence.

The technique is highly selective regarding the analysis of specific lanthanoid ions. This selectivity is demonstrated for a CaF_2 precipitate containing Ho^{3+} and Er^{3+}, two lanthanoid ions with very similar energy levels. The spectrum in Figure 13 shows that the excitation transitions are close to each other. The fluorescence transitions are also quite close. However, the lines are all sufficiently sharp, so that either Ho or Er can be excited individually. The resulting fluorescence spectrum contains only transitions from the ion excited. The selectivity is ultimately limited by the weak vibronic sidebands that accompany any electronic transition[2,3]. The vibronic sidebands occur because the electronic states of the lanthanoids are loosely coupled to the lattice, and changes in the vibrational state of the lattice can happen simultaneously with an electronic change. Vibronic processes result in the absorption or emission of a lattice phonon. If the experiments are performed at low temperatures, as is usually the case in order to obtain narrow line profiles, then only phonon emission processes need to be considered. Vibronic sidebands are much weaker than the pure electronic transition and their shape reflects the density of phonon states at different energies and the amount of coupling between a phonon of particular symmetry and the electronic levels. The vibronic sideband for a single pure electronic transition in $CaF_2:Eu^{3+}$ is shown in Figure 14. The peak of the sideband is *ca.* 10^3 times weaker than the parent electronic transition shown on the right-hand side in Figure 14. This selectivity is available in both the excitation and fluorescence spectrum

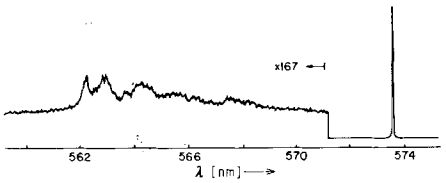

Fig. 14. The structure of the vibronic sideband for the $^7F_0 \rightarrow {}^5D_0$ transition of $CaF_2:Eu^{3+}$. The sensitivity at the lower wavelengths has been increased by a factor of 167 to make the vibronic sideband features visible.

and therefore results in a 10^6 rejection factor between ions that have close lines. If there are lines that lie outside of the region of vibronic sidebands (a region determined by the maximum phonon energy of the lattice; for CaF_2 this is *ca.* 370 cm^{-1}), the rejection factor is larger. This selectivity is more than adequate for performing multiple-ion analysis on samples containing all of the lanthanoids.

3.2. Analysis of Non-fluorescent Trivalent Ions

The clustering behavior that is observed at high lanthanoid concentrations suggests a way for extending the method to other ions that cannot fluoresce. If one wanted to perform a La^{3+} analysis (La^{3+} is a lanthanoid ion that has no excited electronic levels in the $4f^n$ electron configuration), a $CaF_2:Er^{3+}$ precipitate could be formed in the presence of a high Er^{3+} concentration and an unknown concentration of the La^{3+} analyte. Large numbers of Er^{3+} clusters would form, a few of which would also contain a La^{3+} ion. Since La^{3+} has a different ionic radius from Er^{3+}, the Er^{3+} ions in the clusters containing La^{3+} would have slightly different crystal field splittings from those of the Er^{3+} ions in pure Er^{3+} clusters. By selectively exciting the crystal field levels of the La^{3+}-containing clusters, one can obtain a spectrum of only these clusters. This procedure would establish a 1:1 relationship between the non-fluorescent and the fluorescent ion. The sensitivity of the technique depends upon how well one can measure the fluorescent ion. We have already seen that very low detection limits can be achieved by the methods described. The selectivity will depend upon how well the analyte's spectral lines can be resolved from the lines of other sites.

Naturally, this analytical method presents a problem. The success of the method rests upon the ability to discriminate between the weak lines of the clusters containing analytes and the much stronger lines of the pure clusters. Since the separations between the lines are not likely to be very large, one can expect that the lower detection limit is fixed by the selectivity of excitation. This limitation can be overcome by taking advantage of the efficient non-resonant energy transfer that occurs between ions in clusters. The rates of these processes for fluoride compensated clusters can be estimated from Figure 4. The energy mismatch can be estimated by constructing the double ion energy levels which show all the possible energy states for two ions. The double ion levels for Er are shown in Figure 15. The gap below the D level is large

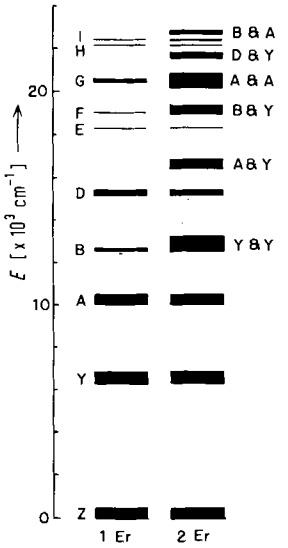

Fig. 15. Left: Electronic energy levels for a single Er^{3+} ion. Right: Possible levels for two Er^{3+} ions ("double ions").

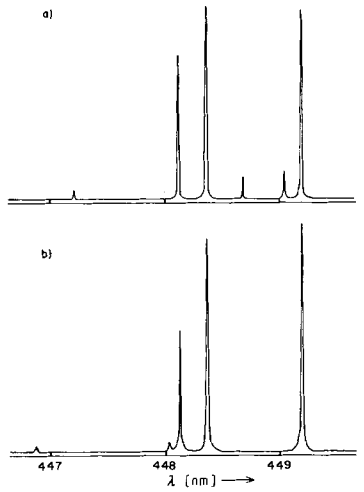

Fig. 16. Excitation spectrum of the $Z \rightarrow H(^4I_{15/2} \rightarrow {}^4F_{5/2})$ transition for a CaF_2 precipitate containing 0.02 mol-% Er^{3+} and a) 0.02 mol-% La^{3+} or b) 0.02 mol-% Ce^{3+}. The lines due to Er-La or Er-Ce clusters are seen by comparison with Figure 7c. A third line from the Er-Ce cluster is hidden by the line at 44.4 nm.

enough for D to fluoresce, while the gap below the E level is too small to allow efficient fluorescence. A cluster that contains two Er^{3+} ions should therefore not exhibit fluorescence from the E level but will fluoresce from the D level. If one of these Er^{3+} ions is replaced by a La^{3+} ion which has no electronic levels, the double ion levels of the Er-La dimer are identical to a single Er^{3+} ion's levels and both the E and D levels can fluoresce. The fluorescence spectrum from the E level can only contain contributions from the Er^{3+} ions that are paired with La^{3+}, while the fluorescence of the pure Er^{3+} cluster will be quenched.

Examples of typical excitation spectra for the detection of La^{3+} and Ce^{3+} are shown in Figure 16 when fluorescence from the E level is monitored with a wide bandpass instrument. Note the absence of lines from pure Er clusters. The relative line positions and intensities are similar to those of the pure Er cluster spectra shown in Figure 9 except that the exchange splittings are not observed and the line positions are shifted. There does not appear to be any simple correlation between the shifts and the ionic radius of the analyte. The technique retains the sensitivity of the direct lanthanoid method and can separate the different analyte peaks nicely by selective excitation. It has been used successfully for the analysis of Sc^{3+}, Y^{3+}, La^{3+}, Ce^{3+}, Gd^{3+}, and Lu^{3+} when Er^{3+} was used to monitor the fluorescence. These ions are the ones that could not be determined directly by the previously discussed method. The ions that can be determined directly will quench the Er^{3+} fluorescence if incorporated into a dimer and thus will not interfere in this method. Thus, this method is complementary to the direct method. All these studies are very new and there are still many factors which must be investigated. We are very pleased with these initial results and expect that the method will be suitable for practical applications.

3.3. Analysis of Non-fluorescent Ions Using Charge Compensation

The idea of achieving a 1:1 association between the analyte and a fluorescent ion, whose fluorescence is modified by the analyte, can be extended to other metal ions if one uses charge compensation to promote an association. In an arbitrary binary compound M_mX_n where the cation M is not trivalent, a trivalent lanthanoid dopant will require a charge compensation. This can be either an intrinsic compensation, such as a lattice vacancy, or an extrinsic compensation. There are several ways of achieving extrinsic compensation. If M is a divalent cation, the charge of the lanthanoid ion can be compensated by replacing another M ion by a monovalent cation. In this case only those monovalent cations are suitable whose ionic radii are close to that of the lanthanoid ion because both are substituting at the M ion lattice site. The charge of the lanthanoid ion can also be compensated by replacing an X ion by another anion that has one unit more negative charge. If M is a tetravalent cation, the lanthanoid ion can be compensated by replacing another M ion by a pentavalent cation with an ionic radius similar to that of the lanthanoid ion or by replacing an X ion by an anion with one unit smaller negative charge.

A less restrictive situation arises when a tertiary compound, $M_mA_nX_p$, is used. If M is again a non-trivalent ion which is replaced by a trivalent lanthanoid ion, the same kinds of charge compensation are possible as in the binary system. In addition, the A ion can be replaced by another ion which has a similar radius. Since the identity of A can be varied widely, the ions of most elements of the periodic systems are potential charge compensators. If M is a divalent cation and A is a cation, the lanthanoid ion can be charge compensated by replacing an A ion by an ion with one fewer positive charges. If M is a tetravalent cation, charge compensation is achieved by replacing A by an ion with one more positive charge.

Both the lanthanoid ion and its charge compensating ion have equal and opposite effective charges relative to the lattice and therefore tend to associate because of their Coulombic attraction. When the charge compensating ion enters the neighborhood of the lanthanoid ion, it changes the crystal fields at the lanthanoid site in a unique way. The new crystal field levels can be selectively excited or monitored in the presence of many other sites. If the charge compensator is an analyte, one can use the line positions to qualitatively indi-

cate the presence of the analyte and the line intensities to quantitatively measure its concentration. This method has been given the acronym SEPIL (*s*elective *e*xcitation of *p*robe *i*on *l*uminescence).

Procedures and guidelines had to be developed to aid the search for proper systems and techniques in order to put these ideas into practice. One of the first problems is the difficulty of carrying out a study of many materials, each of which can be prepared in different ways. Moreover, an arbitrary material generally contains several sites, each having their individual set of lines. Although selective excitation enables the lines in a spectrum to be classified according to the sites, the method requires a great deal of time, especially because one does not know where the lines are. Since the lines are sharp in both fluorescence and excitation, time must be spent at the beginning of studying a material, merely in order to determine the positions of the lines.

The problem of line sorting can be alleviated by using Eu^{3+} as the probe ion. Eu^{3+} has a singlet ground state ($^7F_0$) and a singlet excited state ($^5D_0$)[2]. Only one transition can occur between these two states in either fluorescence ($^5D_0 \rightarrow {}^7F_0$) or absorption ($^7F_0 \rightarrow {}^5D_0$). If one monitors the fluorescence from a material with a very wide bandpass so that all fluorescence can be seen and scans the excitation wavelength of a narrow bandwidth dye laser over the region of the $^7F_0 \rightarrow {}^5D_0$ transition, the resulting excitation spectrum will contain one line from each site. Thus in a single scan, one can obtain all of the information about the sites present in a material and an indication of their concentration. There is the possibility, however, that the lines for two sites accidentally appear at the same wavelength. Such an occurrence can be detected by reference to the many other transitions of Eu^{3+}. Of course it is not necessary to restrict the probe ion to Eu^{3+} after having carried out the initial experiments. A lanthanoid ion can be chosen which gives the best sensitivity and selectivity for the particular analysis.

There are a number of restrictions on the choice of material that can be used in guiding survey experiments to find suitable materials:

1) The short range order about a lanthanoid ion dopant must be sufficiently high that sharp line transitions occur.
2) Both the lanthanoid ion and the analyte ion must be incorporated into the lattice.
3) Both the lanthanoid ion and the analyte ion must be associated with each other.
4) The material must not quench fluorescence from the lanthanoid.

Our preliminary experiments have always been aimed at determining whether the particular material under study meets these requirements. If the material quenches fluorescence, there is little one can do with the material. In the preparation of a sample there are many variables which can affect whether a material meets the other requirements. These variables include the method of sample preparation (precipitation from solution, solid state reaction, cooling of a melt, molten flux reaction, solvent evaporation, *etc.*), the temperature of annealing, the type of reagents used and the valence state of the dopants, the method of incorporating the dopants (coprecipitation, diffusion, solid state reaction), the reaction vessel material used, and the atmosphere above the material during its preparation. Contamination must be carefully guarded against in the initial studies before one knows what ions a given material is sensitive to. Once a method of preparation is found which gives sharp lines and good intensities, different possible analytes are introduced into the material and the $^7F_0 \rightarrow {}^5D_0$ excitation spectrum is obtained to see if new sites are formed as a result of association between the lanthanoid ion and the analyte ion. The preparation variables, particularly the temperature of annealing and the type of reagents used, will also affect the association. The identification and development of suitable materials are therefore involved procedures. It is hoped that once experience has been gained on a number of representative materials, a more efficient method for obtaining suitable materials can be developed.

We have further restricted our survey experiments to materials that can be heated, so as to reduce the number of lattice defects, to permit diffusion of ions into association with each other, and to provide a range of annealing temperatures over which association can take place. We have used materials whose cations have ionic radii similar to those of the lanthanoids, and selected analyte ions whose ionic radii are close to the radius of the lattice ion which they replace.

The first example of a suitable system was $BaSO_4:Eu^{3+}$, PO_4^{3-}. $EuCl_3$ and Na_2SO_4 were added to a solution containing trace concentrations of PO_4^{3-} and $BaSO_4$ was precipitated by adding $BaCl_2$[73]. The Eu^{3+} and PO_4^{3-} coprecipitated with the $BaSO_4$. The excitation spectrum of the undried precipitate is complex and indicates the presence of at least 9 sites. There are two sites in the spectrum that are associated with presence of the PO_4^{3-} ions which compensate the Eu^{3+}-charge. The spectrum is poorly resolved however and cannot be easily used for PO_4^{3+} analysis. If the precipitate is heated, the spectrum and the site distribution change. The sites that correspond to associates with PO_4^{3-} disappear, as do many of the other sites. At higher temperatures between 800—1000 °C, the spectrum becomes sharper and a new, strong line appears that is proportional to the PO_4^{3-} concentration. The excitation spectra of a $BaSO_4$ precipitate ignited at 940 °C without and with the PO_4^{3-} analyte are shown in Figure 17a and b, respectively. The line at 578.2 nm corresponds to the site containing PO_4^{3-}. It should also be noted that the presence of PO_4^{3-} causes other sites to disappear, *e.g.* the site whose line appears at 574.9 nm. This effect is believed to be caused by the shift in the solid state equilibria that must occur when PO_4^{3-} is added (this will be discussed in more detail below).

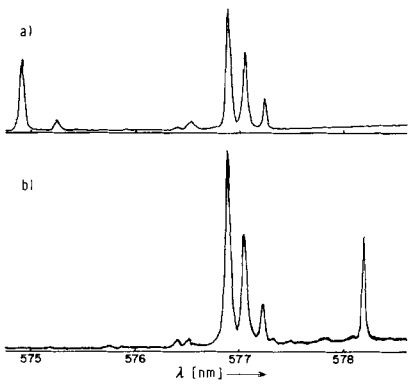

Fig. 17. The excitation spectrum of the $^7F_0 \rightarrow {}^5D_0$ transition of $BaSO_4:Eu^{3+}$ a) without PO_4^{3-} and b) with 4 ppm PO_4^{3-} in the Na_2SO_4 solution.

The methods described earlier in the paper can be used to isolate the transitions of the PO_4^{3-} site from those of the other sites in the spectrum. Remembering that the PO_4^{3-} line at 578.2 nm in Figure 17b represents a $^7F_0 \rightarrow {}^5D_0$ excitation transition that can equally well be observed in fluorescence ($^5D_0 \rightarrow {}^7F_0$), we can tune a monochromator to 578.2 nm and scan the dye laser wavelength over the spectral region of the electronic $^5D_2$-multiplet. The $^5D_2$ state, with $J=2$, will have $(2J+1)$ crystal field levels. The $^7F_0 \rightarrow {}^5D_2$ transition can therefore be expected to have five transitions for each site. The experimentally observed spectrum is shown in Figure 18. It contains exactly five lines, and there are no indications of lines from other sites as might be expected from the well-resolved lines of Figure 17. Thus Figure 18 demonstrates once again the high selectivity of the technique for specific analytes.

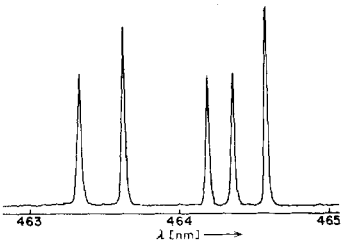

Fig. 18. Single site excitation spectrum of the $^7F_0 \rightarrow {}^5D_0$ transition in $BaSO_4$: EU^{3+}, PO_4^{3-} obtained by monitoring the $^5D_0 \rightarrow {}^7F_0$ transition at 578.2 nm for the PO_4^{3-} site.

Other systems have also been found that are suitable materials for this procedure. Two examples of such materials are shown in Figures 19 and 20: the $^7F_0 \rightarrow {}^5D_0$ excitation spectrum of $Ca_2Nb_2O_7:Eu^{3+}$ both undoped and doped with Zr^{4+}, and of $CdMoO_4:Eu^{3+}$ both undoped and doped with Nb^{5+}. In the spectra new lines appear that are characteristic of the presence of Zr^{4+} and Nb^{5+}, respectively, and can be used for their analysis. Other systems have been found that give analyte lines for Li^+, Na^+, V^{5+}, Ta^{5+}, Cu^+, Ag^+, Bi^{3+}, Sb^{5+}, As^{5+}, Hg^+, and S^{2-}. Work is continuing on these systems.

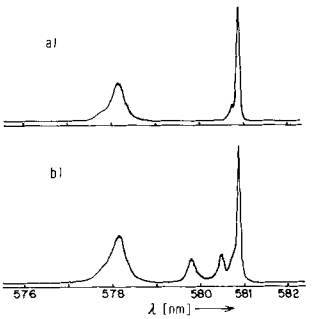

Fig. 19. $^7F_0 \rightarrow {}^5D_0$ excitation spectrum obtained by wide bandwidth monitoring of a $Ca_2Nb_2O_7$ sample containing a) Eu^{3+} and b) Eu^{3+} and Zr^{4+}.

The addition of an analyte ion to a system can have other effects. In many cases, lines characteristic of an analyte-lanthanoid site fail to appear, while lines for an intrinsically compensated lanthanoid site disappear upon adding a charge compensating ion. Such an example is shown in Figure 21 for $PbMoO_4:Eu^{3+}$. If no analyte ions are introduced as charge compensators, the two lines in the $^7F_0 \rightarrow {}^5D_0$ excitation spectrum of Figure 21a indicate there are two major sites intrinsic to the material. If As^{5+} is added for charge

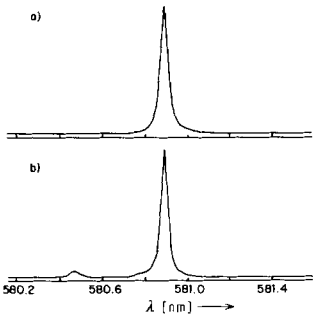

Fig. 20. The $^7F_0 \rightarrow {}^5D_0$ excitation spectrum obtained by wide bandwidth monitoring of a $CdMoO_4$ sample containing a) Eu^{3+} and b) Eu^{3+} and Nb^{5+}.

compensation, the intensity of the main line increases dramatically and the weaker line disappears. Clearly the As^{5+} has an effect on the site distribution—but no new lines are formed.

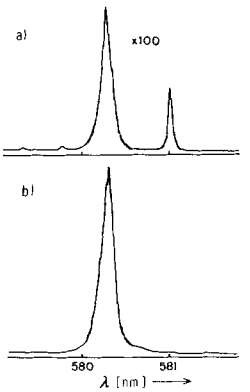

Fig. 21. $^7F_0 \rightarrow {}^5D_0$ excitation spectrum obtained by wide bandwidth monitoring of a $PbMoO_4$ sample containing a) Eu^{3+} and b) Eu^{3+} and As^{5+}.

Even more dramatic changes are observed in the case of $SrSO_4:Eu^{3+}$. Figure 22a shows the spectrum of $SrSO_4:Eu^{3+}$ without extrinsic charge compensation. The Eu^{3+} occupies one intrinsic site. If PO_4^{3-} is added as a charge compensator, a completely new set of lines forms and the intrinsic line disappears (Fig. 22b).

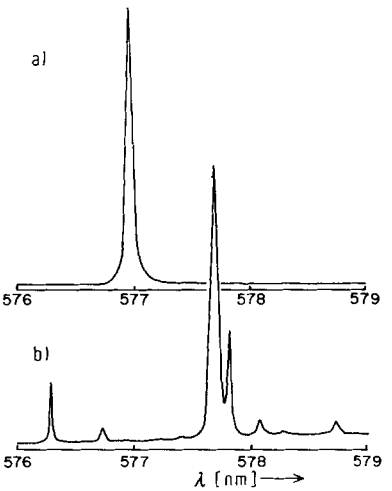

Fig. 22. $^7F_0 \rightarrow {}^5D_0$ excitation spectrum obtained by wide bandwidth monitoring of a $SrSO_4$ sample containing a) Eu^{3+} and b) Eu^{3+} and 5 μg/ml PO_4^{3-}.

All of the examples given are unsuitable for practical applications at the present time because the intensity of the

analyte lines is a non-linear function of concentration. At high concentrations the intensity becomes constant, while at low concentrations it plummets so rapidly that one cannot work below concentrations of about 50 ppb in most cases. If this problem were eliminated, the characteristics of the technique would be very similar to the excellent methods described earlier in Sections 2.1 and 2.2 for lanthanoid analysis.

In order to get an insight into the reasons for the observed behaviors, let us consider the solid state equilibria that should be involved in this problem. Assume we have a binary compound MX, in which M and X are divalent, and that the dominant defects of the compound are the Shottky defects, *i.e.* cation and anion vacancies. A trivalent lanthanoid ion, R^{3+}, and a trivalent anion analyte, A^{3-}, are present as dopants. The relevant equilibria are the following:

$$\begin{array}{lll} \text{MX perfect lattice} \rightleftharpoons & V_M'' & + \; V_X'' \\ & + & + \\ & 2R_M^{\cdot} & + \; 2A_X' \rightleftharpoons 2(R_M \cdot A_X)^x \\ & \downarrow\uparrow & \downarrow\uparrow \\ & (2R_M \cdot V_M)^x & (2A_X \cdot V_X)^x \end{array}$$

where the notation of *Kröger-Vink* has been used[45]. Notice the similarity between these equilibria and the familiar set of EDTA equilibria of analytical importance. The intrinsic vacancies V_M'' and V_X'' play the role of H^+ and OH^- which are formed on dissociation of the H_2O solvent. The $(2R_M \cdot V_M)^x$ species is analogous to the metal hydroxide complexes that form in aqueous solution, while the $(2A_X \cdot V_X)^x$ species is analogous to the different protonated species of the EDTA weak acid. The $(R_M \cdot A_X)^x$ species is the analytically important complex we are interested in observing and is analogous to the metal-EDTA chelate. It is well known that the key to using EDTA as a chelating agent lies in controlling the pH. Too acidic a solution results in an unfavorable conditional formation constant causing dissociation of the chelate, while too basic a solution precipitates the metal hydroxide. One might expect the same ideas would apply to the defect equilibria, where the V_M'' and V_X'' concentrations must be controlled. These concentrations were not controlled in the examples given. Addition of analyte ion would raise the concentration of V_X'' by an amount that depended upon the stability of the $(2A_X \cdot V_X)^x$ pair and, as a result, the concentration of V_M'' would decrease. The $(2R_M \cdot V_M)^x$ species would then tend to dissociate. The addition of analyte ions has two effects in this situation—the shift in defect equilibria and the formation of the analytically interesting $(R_M \cdot A_X)^x$ pairs. An analytical procedure, however, should have the relevant equilibria fixed at optimal values by suitable buffers while the analyte is added. It is believed that the failure to buffer the equilibria is the cause of the non-linear working curves and the plummeting of the intensity at low concentrations. The situation is analogous to the non-linear behavior that has been observed for the fluoride compensated lanthanoid ions in CaF_2; the kind of non-linearity is the same. We are presently studying the control of these equilibria by the atmosphere above the reaction vessel and by addition of other aliovalent ions.

This picture also enables a description of the different behavior observed in materials after addition of the analyte ion A^{3-}. If the equilibrium constant for the formation of $(R_M \cdot A_X)^x$ is much larger than the constants of the other equilibria, the addition of A^{3-} will lead to formation of the species $(R_M \cdot A_X)^x$ and force dissociation of the $(2R_M \cdot V_M)$ species. A behavior such as that shown in Figure 22 would then be observed. If the formation constants for both the species $(R_M \cdot A_X)^x$ and $(2R_M \cdot V_M)^x$ are large, addition of A^{3-} will cause new lines to form without destroying the lines from the intrinsic sites. A behavior such as that shown in Figures 19 and 20 might then be expected. If the formation constants of the $(R_M \cdot A_X)^x$ and $(2A_X \cdot V_X)^x$ species are small, the concentration of V_X'' will be raised as A^{3-} is added to the system; this will lower the V_M'' concentration and cause dissociation of $(2R_M \cdot V_M)^x$. In this case the system might behave similarly as shown in Figure 21.

The picture presented above is quite speculative and is not meant as a definitive explanation of experimental observations. It is certainly oversimplified and omits many important factors such as the interaction with other defects or impurities, the equilibria with atmospheric species and the reaction vessel, the distribution coefficients into the various phases, and the possibility of having several types of defects. It is certainly inadequate for explaining the complex behavior of the $BaSO_4$ system shown in Figure 17. Instead, the picture is meant to focus on the key parts of this method of analysis to provide a framework for organizing previous observations and guiding the ideas of future work. It is a tentative picture at best and can be expected to change appreciably as further work is done in this area.

3.4. Analysis with Pure Lanthanoid Compounds

There are other methods of causing an analyte ion to associate with a fluorescent probe ion. One of the simplest is to form a pure, fluorescent lanthanoid compound in the presence of an analyte ion. Anything that enters the lanthanoid lattice will have to perturb many lanthanoid ions and give rise to new lanthanoid sites which can be identified spectroscopically. Again, selectivity is the key to a successful technique. The site associated with an analyte ion must be measured in the presence of a much larger population of intrinsic sites. There is a severe limitation in the choice of lanthanoid as lattice cation, since rapid exciton migration to quenching ions and energy transfer processes prevent fluorescence from most pure materials[66]. Generally, fluorescence can be obtained from Eu^{3+}, Tb^{3+}, and Yb^{3+} compounds (and occasionally from Gd^{3+} compounds) whose large energy gaps prevent efficient energy transfer.

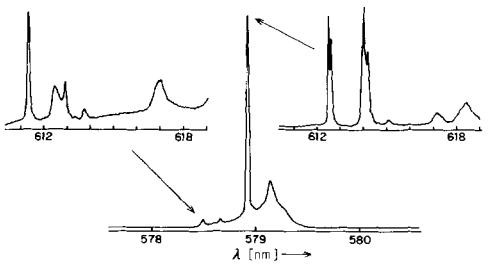

Fig. 23. Bottom: $^7F_0 \rightarrow {}^5D_0$ excitation spectrum of a $Eu_2(SO_4)_3$ sample formed from a solution containing 5×10^{-4} mol/l PO_4^{3-}. Top: Fluorescence spectra that result if the dye laser is tuned to either of the marked lines ($^5D_0 \rightarrow {}^7F_2$ transition).

$Eu_2(SO_4)_3$ (: PO_4^{3-}) was prepared by rapidly evaporating a solution of $Eu_2(SO_4)_3$ in the presence of PO_4^{3-}. The $^7F_0 \rightarrow {}^5D_0$ excitation spectrum of this material is shown in Figure 23 (below). It contains one very intense and sharp line and a band at higher wavelength whose intensity varies from sample to sample. Two additional weak lines appear at short wavelengths with intensities which are proportional to the PO_4^{3-} concentration. Although it would appear difficult to measure these lines at much smaller concentrations because of the very large intensity of the neighboring intrinsic peak, it is possible to selectively excite these lines and obtain fluorescence spectra that are free of fluorescence from the main intrinsic site. This is illustrated in Figure 23 (above left) for the weak line at 578.5 nm; also illustrated (above, right) is the spectrum obtained on excitation of the intrinsic line at 578.1 nm. The selective excitation allows one to follow the fluorescence of this PO_4^{3-} site down to 0.3 ppm PO_4^{3-}, at which point it is obscured by a background fluorescence.

A difficulty that was encountered in this work was the inability to selectively excite the PO_4^{3-} site using other excited levels. For example, if any of the lines occurring in the fluorescence shown in Figure 23 were monitored as an excitation spectrum of the $^7F_0 \rightarrow {}^5D_2$ transition was obtained, all of the excitation spectra would be identical. Excitation anywhere in the $^5D_2$-multiplet results in exactly the same fluorescence spectrum. This behaviour suggests that rapid energy transfer can occur from either the $^5D_2$ or $^5D_1$ excited states to the Eu^{3+} site which has the lowest $^5D_0$ energy, where it becomes trapped and must fluoresce. The lower part of Figure 23 shows that the PO_4^{3-} sites have $^5D_0$ states whose energy is higher than that of the other intrinsic sites (since they appear at shorter wavelength). Therefore they can transfer energy to the intrinsic sites. If the $^5D_0$ state is excited directly, this energy transfer between sites does not occur, probably because the density of phonon states available at these small energy differences is too small to allow efficient non-resonant energy transfer. This explanation immediately suggests that if the introduction of an analyte ion produces a Eu^{3+} site with a lower $^5D_0$ state than the intrinsic sites, energy transfer to this site should be very efficient and would greatly enhance the fluorescence intensity for such a site. Such a system might be of great analytical interest.

3.5. Analysis of Complexing Agents

Another method of achieving an association between a lanthanoid probe ion and an analyte ion is to form complexes of the two ions in aqueous solutions. One is again restricted in the choice of lanthanoid ions that can be used for such experiments since the high vibrational energies of water strongly favor multiphonon processes. Only the ions with very large energy gaps, such as Eu^{3+}, Tb^{3+}, and Gd^{3+}, can fluoresce.

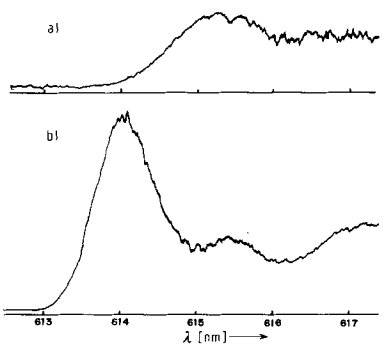

Fig. 24. $^5D_0 \rightarrow {}^7F_2$ fluorescence spectrum of a) a $Eu(NO_3)_3$ solution and b) of a $EuCl_3$ solution.

Figure 24a shows the $^5D_0 \rightarrow {}^7F_2$ fluorescence spectrum of a $EuCl_3$ solution while Figure 24b shows the $^5D_0 \rightarrow {}^7F_2$ fluorescence spectrum of a $Eu(NO_3)_3$ solution. Although the lines are quite broad, the $Eu(NO_3)_3$ fluorescence can be distinguished from the fluorescence of the uncomplexed Eu^{3+}. Figure 25 shows the $^7F_0 \rightarrow {}^5D_2$ excitation spectra of uncomplexed and complexed Eu^{3+}. Again the lines are broad but separated sufficiently enough to distinguish between complexed and uncomplexed Eu^{3+}. Thus despite the large linewidths of Eu^{3+} in solution, it is still possible to obtain good selectivity for NO_3^- because of the large separations of its lines in both the excitation and fluorescence spectra.

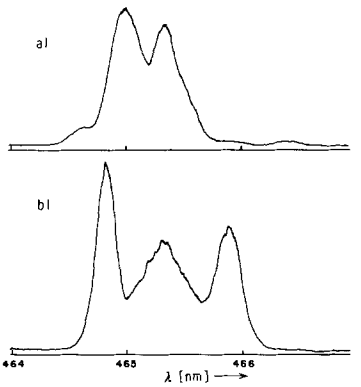

Fig. 25. $^7F_0 \rightarrow {}^5D_2$ excitation spectrum of a) a $EuCl_3$ solution and b) a $Eu(NO_3)_3$ solution.

4. Conclusions

In this paper, we have shown how the laser excitation techniques provide a way of obtaining direct information about the microscopic details of the clustering processes in fluorite materials. EPR methods have failed in this respect—for reasons which are still unknown. The many different bulk measurements that have been made require theoretical modeling in order to glean microscopic information, and they lack the selectivity required to study the many different kinds of sites. The selective excitation of lanthanoid probe ions offers a new approach to the problem. The sensitivity and selectivity of laser excitation methods provide a way of examining sites in a material whose concentrations differ by several orders of magnitude. It is expected that these advantages will result in laser and lanthanoid spectroscopy playing a far greater role in the quest to understand the basic chemical processes which control the solid state chemistry of a material.

We have also outlined a very different method of performing chemical measurements at the trace level. The direct excitation of a lanthanoid ion has resulted in the ability to detect 25 parts in 10^{15} of a lanthanoid in aqueous solution with very high selectivity for the specific lanthanoid of interest. We have shown how non-fluorescent ions can be measured with a similar sensitivity and selectivity by forcing the system

to dimerize and causing a 1:1 association between the non-fluorescent analyte ion and a fluorescent lanthanoid probe ion. Extension of this idea to other ions of the periodic system can be accomplished by using charge compensation to cause the 1:1 pairing between analyte ion and fluorescent lanthanoid ion. The procedures for lanthanoid analysis work quite nicely and we believe they presently constitute one of the best ways of performing analytical measurements on lanthanoids. There is still much work that needs to be done before practicable methods for the real analytical determination of other ions in the periodic system are available, but the method has great promise.

This paper has outlined two applications of the idea of using lanthanoid probe ions with selective laser excitation methods to study complex materials. We believe there are many applications that remain to be tried. The spectra of the lanthanoids provide information at the atomic level about the short range environments of a material, indeed with a sensitivity and selectivity that are difficult to match with other techniques. These are the very properties that modern researchers need in their effort to understand fundamental processes and to further improve the limits of detection.

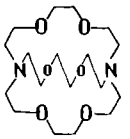
Multidentate Acyclic Neutral Ligands and Their Complexation

By Fritz Vögtle and Edwin Weber[*]



The properties of cyclic crown ethers are approximated by acyclic neutral ligands (podands), which are compared and contrasted with open-chain bioionophores and acidic chelating agents in this article. Variations of the *endo*-polarophilicity/*exo*-lipophilicity balance, complex stability, ion selectivity can often be accomplished more easily, with greater versatility, and at less expense with acyclic polyethers than with their cyclic counterparts; complexation and decomplexation are generally faster in acyclic systems; and the pseudocavity usually has greater conformational flexibility. Acyclic crown ethers and open-chain cryptands stiffened by rigid "terminal groups" containing donor atoms readily form crystalline complexes of alkali and alkaline earth metals. Some open-chain neutral ligands form helical conformations in their crystalline complexes. The observed coordination numbers and geometries are of theoretical interest. Attractive terminal group interactions lead to pseudocyclic species occupying a position intermediate between cyclic and acyclic ligands. It has recently proved possible to isolate crystalline complexes of alkali and alkaline earth metal ions with weakly donating oligo(ethylene glycol ethers) and with glycols; such complexes have also been obtained with sugars. Acyclic neutral ligands can serve as simple models of nigericin-type bioionophores and be used analytically in microelectrodes. The recently discovered crystalline stoichiometric complexes formed by some acyclic neutral ligands with guest molecules such as urea, thiourea, and water provide a fresh insight into weak interactions between neutral molecules and for the development of urea receptors.

1. Introduction[1]

Induced by formation of alkali metal ion complexes by dibenzo[18]crown-6 *(1)*[2], the range of available synthetic crown ethers[1] was first extended by variation of ring size and of donor atoms in the monocyclic representatives[3] and by the preparation of bi- [*e.g. (2)*] and oligocyclic cryptands[4][**]:

(1)

(2)

The *open-chain* bioionophores such as nigericin *(5)*[5] (see Table 1) which like the cyclic bioionophores nonactin and valinomycin[6] can complex alkali metal ions with a remarkable degree of selectivity[7] prompted the study of acyclic oligoethers. The exceptional properties of the cyclic crown ethers offer the only explanation for the dearth of work performed with simple acyclic neutral ligands of types *(3)* and *(4)* (A, B, C are any structural units, *vide infra*). The latter have the advantage of facile synthesis, which requires use of neither dilution principle[8] nor template effect[9] and is therefore inexpensive[10], of versatility of ligand structure[1b,1e], and of fast complex formation (see Section 4.2.5).

(3)

(4)

In order to demonstrate the importance of open-chain ligands of crown ether type (podands), we shall first consider corresponding natural ionophores and, for purposes of demarcation, the alkali metal ion complexes of "acidic" chelate-forming ligands.

2. Acyclic Ionophoric Antibiotics

Ionophoric antibiotics are lipid-soluble natural products which form complexes with alkali or alkaline earth metal ions and can thus influence the transport of ions through membranes[11]. They can be divided into several groups on the basis of structural features[6,7,12]:

a) *Peptides*[13], *acyclic* ionophoric antibiotics (gramicidin[14]; alamethicin[15]) with up to 20 amino acid units, and also *cyclic* ones (antamanide[16]);

b) *Polyenes*[17] and *polyethers,* including the *open-chain* nigericin antibiotics, nigericin *(5)*[5], grisorixin *(6)*[18], dianemycin *(7)*[19], monensin *(8)*[20], X-206 *(9)*[21], X-537 A *(10)*[22] (see Table 1), and *cyclic* macrolide *esters* of the actin series (nonactin to tetranactin)[23];

c) *Depsipeptides*[12] (valinomycin, enniatin, monamycin, beauvericin), *i.e.* ester amides. They usually have cyclic structures, frequently with unusual ring sizes, which may contain uncommon amino acids.

Most of the acyclic (or pseudocyclic, *vide infra*) ionophores have a polyether structure. Of physiological[24] and clinical importance[25] are their selectivities for various cations[7]:

[**] We propose the following rule in the interest of systematic use of the terms crown ether, coronand, cryptand, and podand: *coronands* are taken to mean medio- and macro*mono*cyclic compounds with any heteroatoms. *Cryptands* are *bi-* and *poly*cyclic compounds with any heteroatoms, *podands* are acyclic coronand and cryptand analogs with any heteroatoms. The term *crown ether* is used for coronands having only oxygen as heteroatom.

While the open-chain nigericin *(5)* (like most cyclic ionophores) shows a preference, *e.g.* for $K^{\oplus}$ over $Na^{\oplus}$[26], the order $Na^{\oplus} > K^{\oplus}$ applies to monensin *(8)*, also in biological systems[26,27].

On complexation, acyclic antibiotics (*e.g.* nigericin) wrap themselves around the cation like a *pseudocyclic* species. As with cyclic ligands[28], this enclosure of the ions occurs in such a way that polar regions (ether, carbonyl oxygens) of the ligands are directed inward (*endo*-hydrophilic or *endo*-polarophilic) towards the cation; the periphery of the complex therefore consists of lipophilic regions (CH_2 groups, alkyl groups, aliphatic rings) making the complex *exo*-lipophilic and thus soluble in lipophilic media (organic solvents, biological membranes). The generally flexible open-chain bioionophore changes its conformation on complexation; it usually becomes less mobile. This affects, *e.g.* the rate of complexation and of the dissociation of the complex into its components[12]. In the case of monobasic acids, the pseudocyclic species are stabilized by terminal group interactions, in the complex and in the free ligand[29,30]. In the latter case, the pseudocavity is usually occupied by an additional water molecule[6,12].

Monensin *(8)*[20], nigericin *(5)*[5], grisorixin *(6)*[18], X-537 A *(10)*[22], alborixin *(11)*[31], and emericid *(12)*[32] (Table 1) are well characterized carboxylic antibiotics. They all possess an acyclic primary structure but may adopt cyclic tertiary structures as a result of hydrogen bonding. X-ray structure analyses[20b] show the free acid monensin *(8)* to exist in a cyclic arrangement with two intramolecular H bonds between the C=O group and a water molecule which holds the two ends of the chain together (Fig. 1a). Complexation of an $Ag^{\oplus}$ ion leads to differing H bonding[33]; however, the C=O does not coordinate the central ion according to X-ray structure analyses[20c] (see Fig. 1b). In the free ligands, the water molecules bound by H bonds appear to play an important role in complexation, in that they affect the hydration sphere of the central ion[12].

Table 1. Important acyclic ionophoric antibiotics. Coordinated oxygen atoms are shown in bold type.

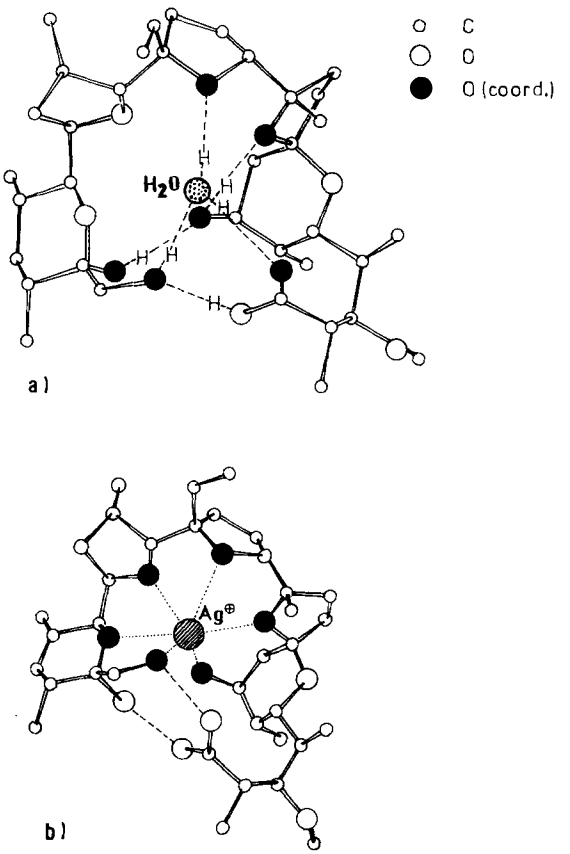

Fig. 1. a) Structure of monensin *(8)*-monohydrate. H-bonds shown as dashed lines. b) Fine structure of the monensin-$Ag^{\oplus}$ complex. Metal/oxygen contacts shown as dotted lines. Two H bonds (dashed) are responsible for the pseudocyclic ligand conformation [28].

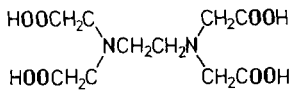
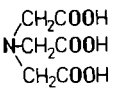


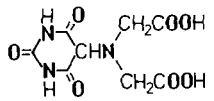
The silver salts of the ionophoric antibiotics nigericin *(5)*[5b] and grisorixin *(6)*[18b] resemble the monensin-$Ag^{\oplus}$ salt[20c], except that the silver ion is coordinated by the C=O group.

The $Ba^{2\oplus}$ complex of X-537 A *(10)* crystallizes as an aggregate of two molecules of antibiotic, one $Ba^{2\oplus}$ ion, and one molecule of water of solvation[34]. Six oxygen atoms of one ionophore molecule and two of the other coordinate the cation. In the dimeric $Ag^{\oplus}$ complex of X-537A, the $Ag^{\oplus}$ ions are enclosed in almost cylindrical fashion by the ligands, with each ion being fixed to five oxygen atoms and one phenyl ring[22b]. As in monensin, the C=O groups are not joined directly to the $Ag^{\oplus}$ ion.

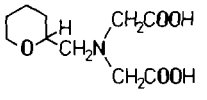


3. Chelates: Alkali Metal Complexes of (Potentially) Acidic Acyclic Ligands

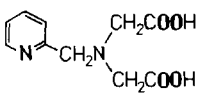
In contrast to the "classical" heavy metal complexes[35], stable coordination compounds of Group I and II elements with synthetic acyclic *neutral* ligand molecules were apparently unknown until the sixties. Crystalline products of alkali metal hydroxides and alkoxides and 1,3-diketones, *o*-nitrophenol, and salicylaldehyde all have chelate structures[36].



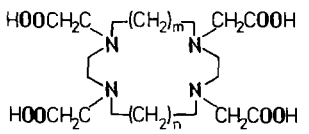
A climax was reached in the complex chemistry of protic "chelating agents"[37] on preparation of "complexones" [ethylenediaminetetraacetic acid (EDTA) *(13)*, nitrilotriacetic acid (NTA) *(14)*, *etc.*][38], which preferentially bond to alkaline earth metal ions. Uramildiacetic acid *(15)* can also form stable complexes with univalent metal ions in aqueous solution (stability sequence: $K^{\oplus} < Na^{\oplus} < Li^{\oplus} < Tl^{\oplus} < H^{\oplus}$)[39]. However, $M^{2\oplus}$ ions (except $Be^{2\oplus}$) are complexed better by EDTA than by uramildiacetic acid. Complexones having heterocyclic ether oxygen[40] or amine nitrogen donor centers[41], such as *(16)* and *(17)*, permit further variation in the stability sequence.



(13)

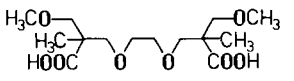


(14)

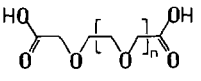


(15)

(16)

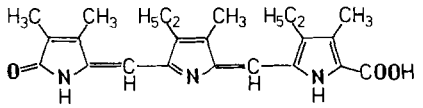


(17)



(18a–c): n,m = 2,3

Among the four-armed ligands of the same type as tetraazacycloalkane-*N,N',N'',N'''*-tetraacetic acid *(18)*[42], whose complexing properties depend on ring size, *(18a)*, $n=m=2$, having a pK value of 15.85, is the strongest complexing agent known for $Ca^{2\oplus}$. In the case of *(18b)*, $n=2$, $m=3$, the stability of the $Sr^{2\oplus}$ complex (pK = 11.70) is very noticeable, while *(18c)*, $n=m=3$, is able to discriminate between $Mg^{2\oplus}$ and $Ca^{2\oplus}$.



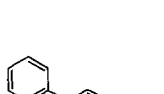
In the presence of pyridine or triphenylphosphane, 2,9-bis(methoxymethyl)-2,9-dimethyl-4,7-dioxa-1,10-decanedioic acid *(19)* forms crystalline dimeric chelates with $Cu^{2\oplus}$ ions; the ether oxygen atoms play an important role in their formation[43]. Unsubstituted oligo(ethylene glycol) dicarboxylic acids *(20)* are found by pH titrimetry to show various stability sequences with alkaline earth metal ions, depending upon the number of ether oxygen atoms present ($n=0$–3)[44].

(19)

(20): n = 0-3

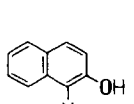
(21)

Sodium chloride and some other alkali metal halides could be precipitated from aqueous solution as coordination compounds with *rac-p,p'*-diamino-2,3-diphenylbutane[45]. Furthermore, the $NH_4^{\oplus}$, alkali metal, alkaline earth metal, and heavy metal "salts" of oxotripyrrene-2-carboxylic acid *(21)* have also been ascribed chelate character[46].

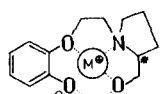


Alkali metal complexes with phosphane oxides as ligands have been examined by X-ray structure analysis[47]: in the NaBr complex of *P,P'*-methylenebis(diphenylphosphane oxide) the $Na^{\oplus}$ ion is located in a trigonal-prismatic environment of six oxygen atoms of the phosphane oxide[48]. IR studies suggest partly electrostatic bonding between $Na^{\oplus}$ and O. The smaller Li atom is accordingly coordinated by a tetrahedral arrangement of only four oxygen atoms in the LiI-triphenylphosphane oxide complex[49]. Analogous arsenic ligands form complexes of only modest stability with alkali and alkaline earth metal halides[48].

A roughly octahedral environment of O coordination sites is found in the $NaClO_4$ complex of bis[*N,N'*-ethylenebis(salicylideniminato)copper(II)][50]: two O donors are contributed by the chelating $ClO_4^{\ominus}$ ion and two by each of the tetradentate ligands in the Cu complex, which are fixed in sandwich fashion above and below the $Na^{\oplus}$ ion. Chelation of the $Na^{\oplus}$ ion is again regarded as the principal feature of the bonding in this complex.



8-Hydroxyquinoline *(22)*, isonitrosoacetophenone *(23)*, and 1-nitroso-2-naphthol *(24)*, on the other hand, can probably form *true* (*i.e.* nonprotic) coordination compounds[51].



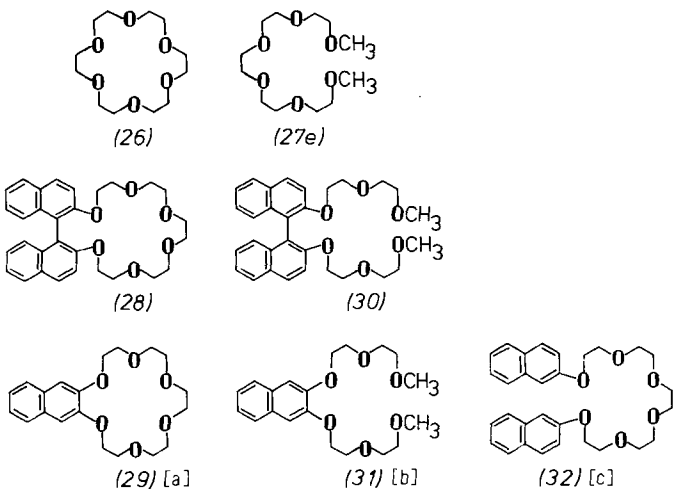
(22)

(23)

(24)

(25)

Another acidic complex ligand is a chiral dihydroxy compound, called "semicrown" by *Wudl*, which forms complex salts of type *(25)* with alkali metal ions[52]; it yields a stable crystalline salt with $Li^{\oplus}$. The optically active ligand exhibits cation-specific ORD curves, suggesting that the $Li^{\oplus}$ and $Na^{\oplus}$ ions are probably enclosed; this appears impossible with larger ions.



4. Synthetic Acyclic Neutral Ligands (Podands)

4.1. Classical Glyme Compounds (Oligoethylene Glycol Dimethyl Ethers) and Their Relatives

On going from cyclic [18]crown-6 *(26)* to open-chain, and yet also hexadentate, pentaethylene glycol dimethyl ether ("pentaglyme") *(27e)* (Table 2) an approximately 10^4-fold drop in stability (complexation constant K_s[1b,4]) is observed for complexation of $K^{\oplus}$ ions (*ca.* 10^3 for $Na^{\oplus}$)[53]. This corresponds to a drop in the enthalpy of complexation ΔG^0 of *ca.* 25 kJ/mol (6 kcal/mol)[54].

This tendency is also observed for *tert*-butylammonium as guest ion in cyclic crown ethers *(28)* and *(29)* and the corresponding glyme analogues *(30)*—*(32)*[55].

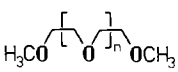


Table 2. Comparison of some crown ethers and their acyclic analogues.

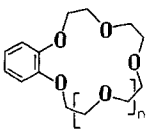

[a] $K_E = 26$ (with tBuNH$_3^{\oplus}$ClO$_4^{\ominus}$). [b] $K_E = 0.026$ (with tBuNH$_3^{\oplus}$ClO$_4^{\ominus}$), 4.5 (with tBuNH$_3^{\oplus}$PF$_6^{\ominus}$). [c] $K_E = 0.0738$ (with tBuNH$_3^{\oplus}$PF$_6^{\ominus}$).

The extraction constants K_E (solvent $CDCl_3/D_2O$) show that *(29)* complexes *ca.* 10^3 more strongly with tBuNH$_3^{\oplus}$ than with *(31)* whose donor centers only partly converge. Compound *(31)* has complexation properties some $10^{1.5}$ better than *(32)* with terminal naphthyl groups since there are no longer any (mutually linked) rigid groups able to enforce convergence of donor atoms. The difference in complex stability between the cyclic compound *(28)* and its acyclic analog (360:40) seems remarkably small compared with *(26)*/*(27e) (vide supra)*; apparently, the binaphthyl hinge permits extensive perturbation of planarity (and convergence) of individual coordination sites. Thus it may be concluded that enforced convergence of the binding sites in these simple systems, *i.e.* a stiffening of the ligand backbone favoring coordination, considerably increases complex stability. The modest difference between the cyclic compound *(28)* and the acyclic analogue *(30)* also suggests that a detailed examination of the readily preparable open-chain neutral ligand might be a rewarding object of study.

The difference in complex stability which can result on ring closure—retaining the nature and geometry of donor atoms—is denoted as the *"macrocyclic effect"*[4,53a,56]. Although this effect was originally explained in terms of entropy factors which oppose complete enclosure of cations by acyclic polyethers[56], studies on macrocyclic tetramine[57] and tetrasulfide systems[58] showed that thermodynamic parameters (ΔH), coupled with ligand solvation effects, often play a greater role in the origin of the macrocyclic effect[59]. Polarographic determinations of $\log K_s$, ΔH, and ΔS for the interaction between heavy metal ions such as $Pb^{2\oplus}$ with [18]crown-6 *(26)* or tetraglyme *(27d)*, $n = 3$, in aqueous solution showed the cycle *(26)* to be some 10^4 times more stable than the open-chain ligand[60]. The macrocyclic effect was attributed largely to entropy effects in this case. Measurement of complex stability constants of some oligoethylene glycol dimethyl ethers *(27)* of various chain lengths for $Na^{\oplus}$, $K^{\oplus}$, $Cs^{\oplus}$, $Tl^{\oplus}$[61] (potentiometric and conductometric, in CH_3OH) revealed that an increase in the number of coordination sites (ether O atoms) raises the stability constants and the $K^{\oplus}/Na^{\oplus}$ selectivity; replacement of the two methoxy chain ends by primary carboxamide groups or ester groups impairs the complexation properties of the ligands.

(27a)-*(27i)*: n = 0-8
(27k): n = 21

(33a): n = 1
(33b): n = 2

In keeping with the low stability constants—even in low-polarity organic solvents—*crystalline alkali metal complexes* of such "simple" acyclic oligoethylene glycol ethers *(27)*, the glymes, were unknown until very recently[62]; this also applies to ligands containing polyether chains of up to ten oxygen atoms which are bent by and also partly stiffened by inclusion of *ortho*-substituted aryl groups[61].

The stoichiometries and specific structures of the resulting ion pair/glyme compounds were determined in tetrahydrofuran (THF) by titration of difluorenylbarium with glymes of various chain lengths[63]. Like [18]crown-6 *(26)* and monobenzo[18]crown-6 *(33b)*, glyme-7[64] *(27f)*, $n = 5$, and glyme-9 *(27h)*, $n = 7$, give 1:1 complexes between the ligand and difluorenylbarium. It can be shown from the optical spectra that these complexes are mixed intimate/loose ion pairs of the type fluorenyl$^{\ominus}$Ba$^{2\oplus}$/glyme/fluorenyl$^{\ominus}$[65]. The ability of glyme-5 *(27d)*, $n = 3$, like monobenzo[15]crown-5 *(33a)* to form a stable 2:1 complex with difluorenylbarium suggests that a ligand such as glyme-10 *(27i)*, $n = 8$, should have adequate bonding sites for construction of an entirely separate 1:1 ion pair complex. Such an ion pair also results on coordination of difluorenylbarium with glyme-23 *(27k)*; two $Ba^{2\oplus}$, $(\text{fluorenyl})_2^{2\ominus}$ units may possibly be complexed to this glyme.

Numerous publications have already appeared concerning the synthesis and structure of crystalline glyme complexes with transition metal ions, *e.g.* $Fe^{2\oplus}$, $Mn^{2\oplus}$, $Co^{2\oplus}$, $Ni^{2\oplus}$, $Cu^{2\oplus}$[66], and with mercury[67] and cadmium salts[68], including some X-ray structure analyses[69]. While several molecules of *dimethoxyethane (27a)* (monoglyme) are usually required (generally three[66,69]) for complexation, dinuclear complexes are also formed by suitably long polyether chains[67c]. X-ray structure analysis[67a] of the complex of *tetraethylene glycol dimethyl ether (27d)* (TGM) with $HgCl_2$ (1:1 stoichiometry) indicates the following ligand conformation[70]:

CH_3–O–CH_2–CH_2–O–CH_2–CH_2–O–CH_2–CH_2–O–CH_2–CH_2–O–CH_3 *(27d)*

ap sc ap ap (−)sc ap ap sc ap ap (−)sc ap

All the H_2C–O bonds are thus antiperiplanar *(ap)*, and the CH_2–CH_2 bonds in the adjacent unit alternately synclinal *(sc)* and (−)-synclinal [(−)*sc*]. The ligand is fixed in a circular geometry but does not form a closed circle (see Fig. 2a). The five oxygen atoms, which are almost coplanar and all directed inward, closely embrace the $Hg^{2\oplus}$ ion (2.78—2.98 Å).

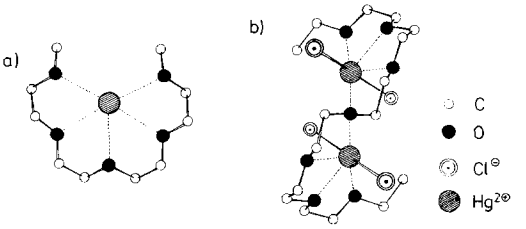

Fig. 2. Interactions between the O and Hg atoms in the $HgCl_2$ complexes of (a) TGM *(27d)* and (b) HGE *(27l)* [67a, c].

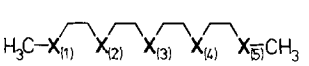
In the corresponding *tetraethylene glycol diethyl ether* (TGE)/$HgCl_2$ complex[67b] very similar Hg—O distances and angles are found in the interior of the chain. An *sc* arrangement occurs at only one end of the chain, thus avoiding steric hindrance of the ethano groups in the *ap/ap* conformation.

Hexaethylene glycol diethyl ether (27l) (HGE) can utilize its seven coordination sites to bond two $Hg^{2\oplus}$ ions at relatively short distance (Hg—O, 2.66—2.91 Å); the HGE molecule exhibits the following conformation in the complex[67c]:

CH_3–CH_2–O–CH_2–CH_2–O–CH_2–CH_2–O–CH_2–CH_2–O–

ap ap sc ap ap (−)sc ap ap sc sc sc

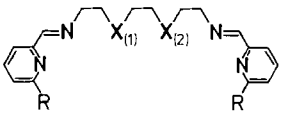
–CH_2–CH_2–O–CH_2–CH_2–O–CH_2–CH_2–O–CH_2–CH_3



sc ap ap (−)sc ap ap sc ap ap *(27l)*

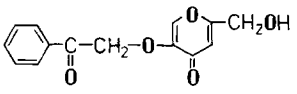
The adjacency of two *sc/sc* sequences at the central O atom is remarkable; it effects a separation into two coordination moieties of four coplanar oxygen atoms, each occupied by one $Hg^{2\oplus}$ ion. The central O atom is involved in coordination to both Hg ions (see Fig. 2b).

Similar structural units are found in the complex of tetraethylene glycol dimethyl ether *(27d)* (TGM) with $CdCl_2$[68]. However, owing to the smaller number of donor sites available (five per glyme molecule) additional Cl bridging ligands are required; each bridge holds together two ligands over a total of four $Cd^{2\oplus}$ ions.



While glyme complexes of $Hg^{2\oplus}$ salts are relatively easy to obtain the preparation of corresponding coordination compounds with the softer[71] $Hg^{\oplus}$ ions runs into difficulties owing to disproportionation to Hg^0 and $Hg^{2\oplus}$[72]. However, a crystalline complex of composition $Hg_2(diglyme)_2(NO_3)_2$ has recently been isolated; it can be kept for some time under a protective gas but on heating (65 °C) the organic ligand *(27b)* is completely eliminated[73]. Corresponding $Hg^{\oplus}$ complexes of sulfide ligands proved to be more stable[74].

New combinations of sulfur and oxygen donor centers in oxathiapentadecanes of general type *(34a)* should be particularly suitable for complexation of heavy metal ions, especially $Ag^{\oplus}$, $Hg^{2\oplus}$[75].



(34a): $X_1, X_2, X_3, X_4, X_5 = O, S$

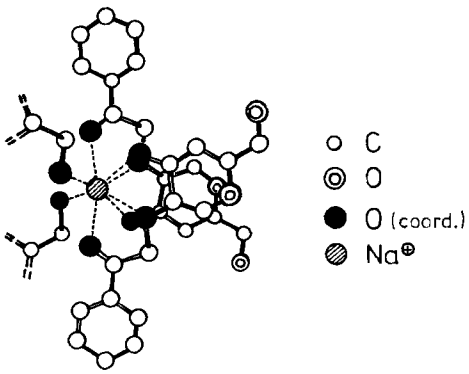
(34b): $X_1, X_5 = N; X_2, X_4 = S; X_3 = O$

(35): $X_1, X_2 = O, S$; $R = H, CH_3$

Complexation of transition metal ions ($Cu^{2\oplus}$, $Ni^{2\oplus}$, $Co^{2\oplus}$, $Zn^{2\oplus}$, $Pd^{2\oplus}$ and $Ag^{2\oplus}$) with the open chain sulfur-, oxygen-, and nitrogen-containing ligand 8-oxa-5,11-dithia-2,14-diazapentadecane *(34b)* has also been studied[76]. Alkali metal complexes of this "heteroglyme" appear—as expected from the low tendency of the soft sulfur atom to coordinate the hard Group I elements[77]—to play only a subordinate role. The same applies to the many open-chain multidentate Schiff base ligands *(35)* which readily form complexes with Fe, Co, Cu, Pd, Pt, Ru, *etc.*[78].

(36)

More than 25 years ago, *phenacyl kojate (36)* was found to form crystalline 2:1 complexes with sodium halides in methanol[79]. Their structures[80] (see Fig. 3) resemble those of the [18]crown-6 complexes of the corresponding sodium salts[81]: six oxygen donor centers (from two phenacyl kojate units) are grouped in planar fashion around the sodium ion; in contrast to the crown ether complex, however, four of them come from a carbonyl group. The crystal structure is held together by H bonds between CO and OH groups and by H...O interactions. The Na···O distances lie between 2.56 and 2.68 Å[82].



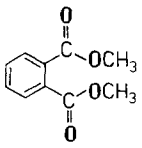


Fig. 3. Crystal structure of the complex formed by phenacyl kojate *(36)* with NaCl[80].

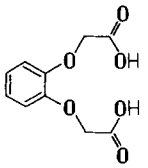
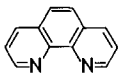


Alkali metal salts have been known for some time to form complexes with 1,4-*dioxane*[83]; however, these complexes

have poor thermal stability and exhibit high dioxane vapor pressures even at 300 K. Although some of them are isolable in crystalline form from aqueous solution they generally lose their dioxane to the air. The coordination compounds of $NaClO_4$, $NaBF_4$, NaI with dioxane, like the $AgClO_4$ complex, possess a cubic structure with the metal ion in an octahedral environment of dioxane oxygen atoms at distances of 2.43—2.46 Å. The perchlorate ion at the center of the unit cell can undergo free rotation, and the dioxane molecules rotate about their O—O axes. Ions of the higher alkali metals are too voluminous to form stable crystal structures.



Dimethyl phthalate (37) acts as a bidentate neutral ligand towards various divalent cations such as $Mg^{2\oplus}$, $Ca^{2\oplus}$, $Mn^{2\oplus}$, $Fe^{2\oplus}$, $Co^{2\oplus}$, $Ni^{2\oplus}$, and $Zn^{2\oplus}$[84]. In the resulting complexes, the metal ions are each bonded by three dimethyl phthalate molecules *via* the carbonyl groups, with the coordinating carbonyl oxygens forming a regular octahedron. It is important for these complexes to have a large counterion (*e.g.* $InCl_4^{\ominus}$); they decompose completely in the presence of water.

(37)

(38)

(39)

A remarkably stable 2:1 complex is formed by *O,O'-catecholdiacetic acid (38)* and KCl[85]. It has a complicated layer structure stabilized by H bonds in which the $K^{\oplus}$ ions are enclosed in sandwich fashion by ten O atoms (four ether and six carbonyl oxygens) in an irregular pentagonal-antiprismatic arrangement (Fig. 4).

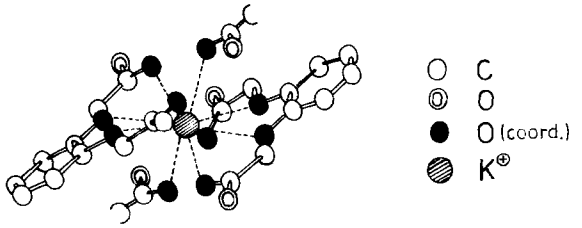


Fig. 4. Structure of the complex of *O,O'*-catecholdiacetic acid with KCl [85].

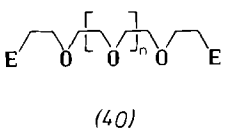
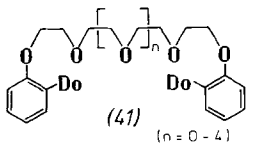
No such coordination compounds can be obtained with Li, Na, Cs, and NH_4 salts. The observed "precipitation selectivity" towards $K^{\oplus}$, which exceeds that of $NaB(C_6H_5)_4$, is unusual since all the other known precipitation reagents for $K^{\oplus}$ also respond to $NH_4^{\oplus}$, $Cs^{\oplus}$, and $Rb^{\oplus}$[86].



Work by *P. Pfeiffer*, who isolated crystalline complexes of *1,10-phenanthroline (39)* with, *e.g.* $LiClO_4$, $NaClO_4$, $AgNO_3$, $TlNO_3$, $Ca(ClO_4)_2$, $Sr(ClO_4)_2$, and $Ba(ClO_4)_2$ as long ago as 1938[87], seems to have been forgotten. The complexes are precipitated from aqueous/alcoholic solution and can be recrystallized without decomposition. The Li complex forms particularly readily, while the Na salts show little tendency to undergo complexation and no corresponding K compound could be obtained at the time. The results were recently reconsidered and an interpretation based on the influence of the counterion and on protonated intermediates proposed[88a]. At roughly the same time, alkali metal complexes of phenanthroline and of *bipyridine*, including some with potassium salts, were obtained in independent studies[88b].

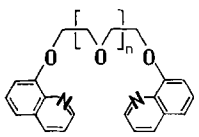
The tendency of certain heterocycles to favor $Li^{\oplus}$ over ions of the higher alkali metals is also apparent from the solubility series of the chlorides of $Na^{\oplus}$, $K^{\oplus}$, $Rb^{\oplus}$, and $Cs^{\oplus}$ in *pyridine*, in which all these salts except LiCl are practically insoluble[89]. The situation can be modified by stepwise addition of water. This is the basis of a separation of lithium ions from other alkali metal ions and from $Ba^{2\oplus}$ which was developed as long ago as 1908[90].



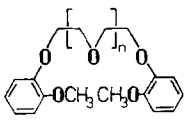
4.2. Acyclic Crown Ethers and Coronands

4.2.1. Terminal Group Concept

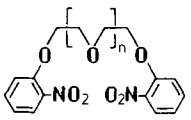
Attachment of rigid (*e.g.* aromatic) *terminal groups* (*E*) bearing donor centers (Do) [cf. *(40)*] to oligoethylene glycol units ("terminal group concept")[91] affords neutral ligands *(41)* which readily form stable crystalline complexes with alkali and alkaline earth metal ions[92] in the same way as the cyclic crown ethers. Apart from complexes of Na, K, Ca, *etc.*, it is also possible to obtain such compounds of lanthanoids, uranyl, Zn, Hg, Mg, and Ag salts, as well as ammonium ion complexes.



(40)



(41)



Suitable terminal groups (*E*) are 8-quinolyloxy, *(42)*, *o*-methoxyphenoxy *(43)*, *o*-nitrophenoxy groups *(44)*, among many others[91,92].

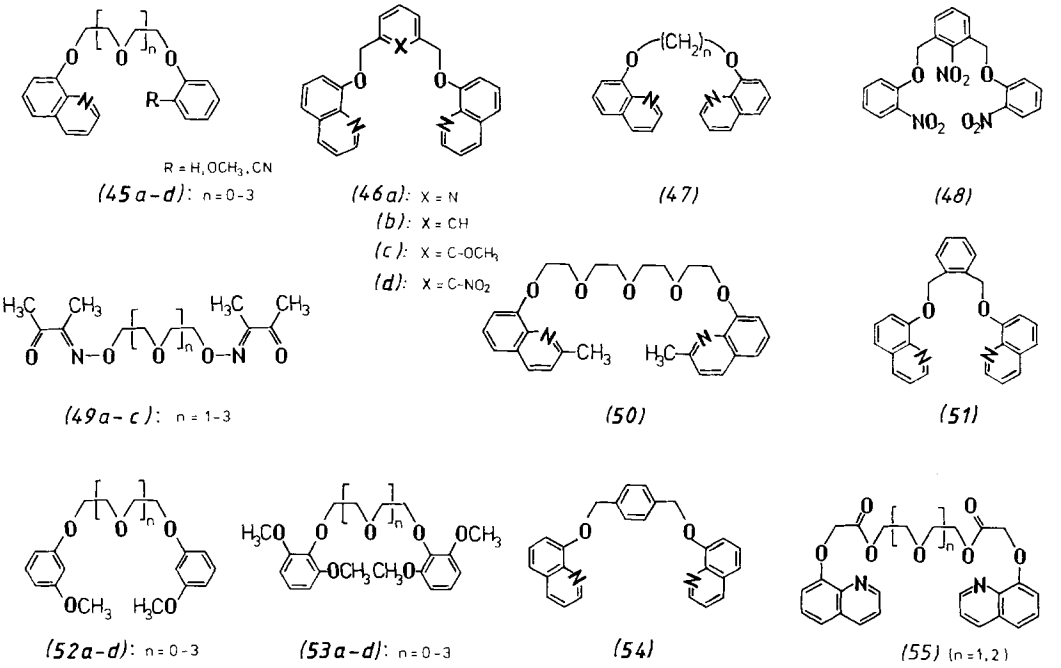
(42a–g): n = 0–6

(43a–d): n = 0–3

(44a–d) n = 0–3

Synthesis of unsymmetrical open-chain ligands such as *(45)* permits almost any intramolecular combination of weak and strong donor terminal groups.

The terminal groups function as anchoring points with locally fixed donor centers on which the cation can take hold; a certain number of donor sites remains a prerequisite for complex formation. Structures such as *(47)* in which the terminal groups are isolated from one another by a polymethylene chain show only limited ability to form crystalline alkali metal complexes although the distance between the quinolyl units was modified by variation of *n*[92,93a].



Apart from the terminal group donor effect, geometrical and steric factors also play a role[91,92]: the compounds *(46c)*, X = C—OCH_3, *(46d)*, X = C—NO_2, and *(48)* bearing an adequate number of proven donor atoms neither form crystalline complexes with alkali metal salts nor do they transfer alkali metal permanganates into organic phases. Complexation

is apparently blocked by substituents (which in principle are capable of coordination[93b]) projecting into the pseudocavity.

Among the neutral ligands having diacetylmonoxime terminal groups *(49)*[94], the *E* configuration of the oxime appears to interfere with the formation of crystalline complexes.

tion is also retained on recrystallization of the complex (from methanol/ethyl acetate).

The tetrasubstituted ligand *(53)* forms not only 1:1 complexes[95a]: transition from 1:1 stoichiometry in the *(53a)*-$LiClO_4$ complex to 3:2 stoichiometry (ligand:salt) in the *(53a)*-sodium complex can be rationalized in terms of the greater radius of the sodium ion, which precludes complete

On the other hand, no steric hindrance of crystalline complex formation by the methyl groups is observed in the quinaldine compound *(50)*; this is easily rationalized in terms of the helical structure of the ligand in the complex (see Section 4.2.3). The *ortho*-phenylene compound *(51)* can also form stable complexes of the ligands *(43)*, *(52)* (with positionally isomeric methoxy terminal group), and *(53)*, which contain only oxygen as donor centers; only the *o*-methoxy derivatives give crystalline alkali metal salt complexes under comparable conditions[95a].

Terminal groups can also be attached by way of ester groups instead of ether functions [cf. *(55)*]; in some cases, transesterification was observed on attempted isolation of crystalline alkali metal complexes in methanol as solvent[95b].

4.2.2. Stoichiometry of the Crystalline Complexes

Stable crystalline complexes are obtained not only with Group I and II metals[91,92,95a] but also with transition metal ions ($Zn^{2\oplus}$, $Cd^{2\oplus}$, $Hg^{2\oplus}$, $Ag^{\oplus}$, $Co^{2\oplus}$, $Ni^{2\oplus}$) and lanthanoid and actinoid ions ($Pr^{3\oplus}$, $Nd^{3\oplus}$, $UO_2^{2\oplus}$) and with ammonium salts[92,95b]: however, many cations remain to be studied.

In spite of less strictly stipulated "cavity geometry", complexes of exactly stoichiometric composition are generally formed—even in the presence of a large excess of one component of the complex[92]. For example, the ligand *(42d)* always gives a 1:1 complex with KSCN regardless of whether the molar ratio of ligand to salt is 2:1 or 1:2. This composienclosure by a single ligand molecule. The fact that the *(53b)*-sodium and *(53b)*-potassium complex also exhibit 2:1 stoichiometry requires a different explanation, particularly since the ligand *(43b)*, which bears a single *o*-substituent on each side, forms a 1:1 sodium complex. In this case, mutual steric hindrance in the 1,2,6-positions rules out the availability of the methoxy groups in the optimum cation region—as manifested, *e.g.*, by chemical shift differences in the ^{1}H-NMR spectra of the complexes—with the result that a further ligand molecule is required for occupation of the free coordination sites on the metal ion.

The proposed structures are also supported by features of the IR spectra of these complexes. In general, interpretable changes in the IR absorptions of crown ether complexes relative to the free ligands are conspicuous in the region of the mostly strong bands of the original salt[2,96]. Above all, these include the absorptions of inorganic anions such as $NO_3^{\ominus}$, $SCN^{\ominus}$, $ClO_4^{\ominus}$, $BF_4^{\ominus}$, and also those of complexed ammonium ion[97]. This also applies to complexes of open-chain crown ethers[95].

Some of the complexes contain H_2O in stoichiometric proportions[91,92], as revealed by the appearance of more or less sharp OH bonds in the IR spectra[95]. The question whether the H_2O molecules are in coordinational contact with the complexed cation or exist as free water of crystallization in the crystal lattice[98] will only be conclusively settled by X-ray structure studies *(vide infra)*. This also applies to the extent of participation of anions in coordination[99], which has been explained in such a way for some complexes.

4.2.3. X-Ray Structure Analyses of Crystalline Complexes

Right at the start of our investigations[92], model considerations of the structure of the ligand *(42d)*, $n=3$, equipped with 8-quinolyloxy terminal groups, suggested that on participation of all seven heteroatoms in coordination of the metal ion a screw-shaped, and thus chiral, arrangement of the ligand skeleton should result; mutual hindrance of the α- and β-hydrogen atoms on the quinoline ring is the reason for the lack of coplanarity of the donor centers. The ability of ligand *(42d)* to effectively wrap around a "fitting" cation in helical-chiral fashion is demonstrated by a consideration of space-filling atomic and spherical ion models[100]. In this respect, *(42d)* is a model substance for acylic ionophores, *e.g.*, for open-chain gramicidins and nigericins (cf. Section 2).

An X-ray structure analysis has been performed on the *(42d)*-RbI complex[101] which crystallizes in beautiful platelets. It confirms the expected participation of all seven heteroatoms (5O, 2N) in complexation and affords the first proof of a *helical-chiral* arrangement of a synthetic open chain ionophore around an alkali-metal ion (Fig. 5b): plus and minus helices are present in equal amounts. However, the iodide ions are not included in the coordination sphere of the central ion; nor are they in direct contact with any heteroatoms of the quinolyl ether.

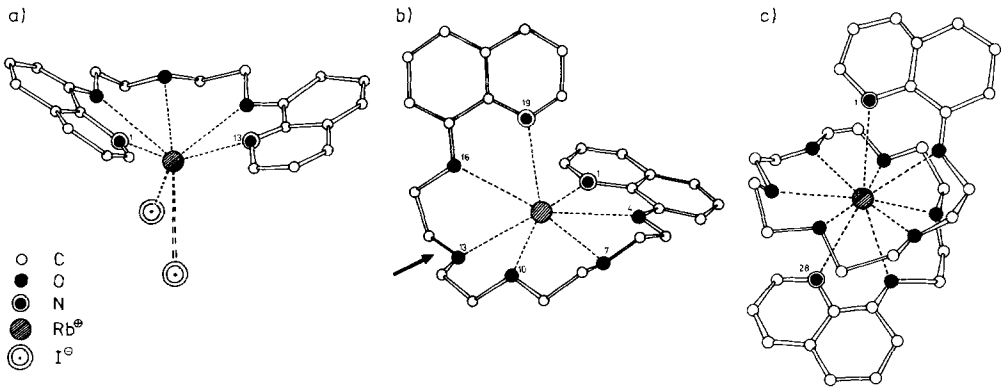


Fig. 5. Structures of some $Rb^{\oplus}$ complexes of open-chain neutral ligands: (a) *(42b)*-RbI with planar wrapping around the cation; (b) *(42d)*-RbI with helical wrapping of ligand around the cation; and (c) *(42g)*-RbI with spherical wrapping around the cation.

The bond lengths and angles between the heteroatoms (O, N) and the $Rb^{\oplus}$ ion admittedly deviate from one another but can nevertheless be regarded as approximately symmetric with regard to an axis shown joining the $Rb^{\oplus}$ ion and the O(10) atom in Figure 5b. Whereas the $Rb^{\oplus}\ldots O$ distances in the dibenzo[18]crown-6-RbSCN complex (2.861—2.939 Å) largely correspond to the sum of atomic and ionic radii (2.87 Å)[102], the bond lengths in the *(42d)*-RbI complex show some remarkable differences: the $Rb^{\oplus}\ldots O(10)$ distance of 2.88 Å closely approaches the ideal value (2.87 Å); the distances $Rb^{\oplus}\ldots O(7)$ and $Rb^{\oplus}\ldots O(13)$ of 2.99 and 2.94 Å, respectively, show considerable extension. Even greater extension is observed with the bond lengths between $Rb^{\oplus}$ and O(4) and O(16), which have values of 3.07 and 3.09 Å. The most likely cause of such deviations in bond lengths lies in the differing donor strengths of aliphatic or aromatic oxygen atoms, rather than contributions by steric hindrance of the polyether chain. In contrast, the $Rb^{\oplus}\ldots N$ distances of 2.91 Å for N(1) and 2.96 Å for N(19) are very close to the value of 2.97 Å calculated from the atomic and ionic radii.

The angle formed by two adjacent donor sites with $Rb^{\oplus}$ as apex can be divided into three categories (see Fig. 5b): $O\ldots Rb\ldots O$ angles having values of 54—59° are determined by the conformational arrangement, *i.e.* the specific geometry of the $O-CH_2-CH_2-O$ fragments within the polyether chain. The $N\ldots Rb\ldots O$ angles of 52 and 53 are laid down by the atomic arrangement in the 8-quinolyloxy group while the angle of 77° between $Rb^{\oplus}$ and the two quinoline N atoms results from the acyclic structure of the ligand.

In the complexes of cyclic crown ethers the oxygen atoms coordinated around the metal ion are usually coplanar; in the ideal case, the complexed cation is located in this plane at the center of the ring[28]. If the relative sizes of cation and cavity are less favorable then the metal ion may be displaced somewhat from the "crown ether plane"[103].

In *(42d)* the chain bearing the oxygen and nitrogen donors is too long to enclose the $Rb^{\oplus}$ in a plane. Nevertheless, the major part of the donor atoms is fixed in a plane in this complex (Fig. 5b). This applies to atoms N(1), O(4), O(7), O(10), and O(13). In this region of the ligand the conformational angles at the C—C bonds are expectedly synclinal *(sc)* and those at the C—O bonds antiperiplanar *(ap)*. In order to avoid collision of the two terminal quinoline units, the dihedral angle at bonds C(12)—O(13)—C(14)—C(15) is *sp* instead of *ap* (see arrow in Fig. 5b). As a result, the heteroatoms O(16) and N(19) are displaced, together with the attached quinolyl group, from the plane formed by the other five donor sites, and the $Rb^{\oplus}$ ion is shifted by 0.748 Å towards the other quinolyl group; this imparts the particular (helical) structure to the complex.

The helical arrangement of the *(42d)*-RbI complex is replaced in the RbI complex of the ligand *(42b)*, $n=1$, shorter by two oxyethyl units, by an approximately *planar* arrangement (folded like a butterfly) having mirror symmetry (Fig. 5a)[104]. X-ray structure analysis of the RbI complex shows this neutral ligand to be pentadentate. Differences in O—Rb distances can also be seen here. However, the coordinative bonds of the ether oxygen atoms to the central ion are even longer than in *(42d)*-RbI and deviate considerably in the extreme case for the central O atom (3.18 Å) from the calculated value of 2.87 Å. The Rb...N distances of 2.98 Å closely

approach the calculated value of 2.97 Å. The coordination sphere of the $Rb^{\oplus}$ which, in contrast to the case of *(42d)*, is not saturated by five donor sites, is filled alternately by two iodine atoms per ligand unit participating in complexation.

Spherical wrapping around a rubidium ion was ascertained in the RbI complex of the *decadentate* linear polyether *(42g)*, $n=6$, by X-ray structure analysis (Fig. 5c)[105a]: All the heteroatoms lie approximately on the surface of a sphere of radius *ca.* 3 Å, whose poles are occupied by the two quinoline nitrogen atoms. Starting from one of the nitrogen donor sites, the ligand chain runs to the equator of the sphere which it encircles and then proceeds to the other pole. The $Rb^{\oplus}$ ion is tenfold coordinated if the $Rb^{\oplus}\ldots N$ and $Rb^{\oplus}\ldots O$ contacts of 3.371 and 3.147 Å are included. Similar values are known for highly coordinated $Rb^{\oplus}$ but other $Rb^{\oplus}$-polyether complexes with smaller ligands show normal values (cf. Fig. 5a, b). The iodide ions lie in cavities between the "spheres" of the $Rb^{\oplus}$ complexes where they are held by weak van der Waals forces. For this reason they are statistically twofold disordered.

X-ray structure analysis of the *(50)*-RbI complex[104] revealed a significant difference in the ligand conformation, compared with the *(42d)*-RbI complex (Fig. 5b). While a discontinuous helix having a somewhat bent but coordinated quinoline terminal group is present in the latter, the likewise heptadentate diquinaldine ligand *(50)* is arranged as a *continuous* helix in its complex (see Fig. 6a). This can be explained by assuming the methyl groups of the quinaldine units to sterically hinder planar inclusion of the cation at the terminal group, thus inducing a helical wrapping which then continues. In the analogous quinoline ligand *(42d)*, on the other hand, a planar geometry is sterically feasible at one of the quinolyloxy termini which remains coplanar until steric hindrance occurs on addition of the second quinolyl group so that this latter group is kinked (see Fig. 5b).

ion chain structures (Fig. 6c)[104]: the two carbonyl groups of any one ligand molecule do not coordinate the potassium ion held tightly by the five intramolecular ether oxygen donor centers but instead the potassium ion of the preceding and the following ligand. This observation is compatible with the high entropy of complexation found for the sodium ion *(vide infra)* which can be interpreted both as cyclization and as polymerization entropy.

As shown by the X-ray structure analysis of the complex of phenylglycine ethyl ester-hydrotrifluoromethanesulfonate with the double phosphane oxide *O,O'*-(3-oxapentamethylenedioxy)bis(triphenylphosphane oxide) (Fig. 7), the phosphane oxide moiety can be utilized both as donor terminal group and as a structural unit enhancing the lipophilic properties of podands[107].

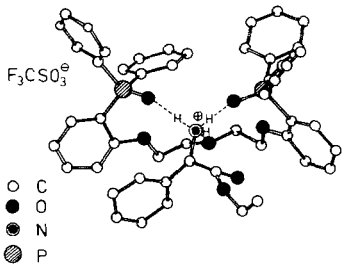

Fig. 7. Stereochemistry of the phenylglycine ethyl ester-hydrotrifluoromethanesulfonate complex of *O,O'*-(3-oxapentamethylenedioxy)bis(triphenylphosphane oxide).

4.2.4. NMR Studies on Complexation in Solution

The line shape and position of the signals in the ^{1}H-NMR spectra of complexing agents are generally modified by their contact with metal ions[108a]. In the case of acyclic ligands, too, ^{1}H-NMR spectroscopy proved extremely useful[65] for

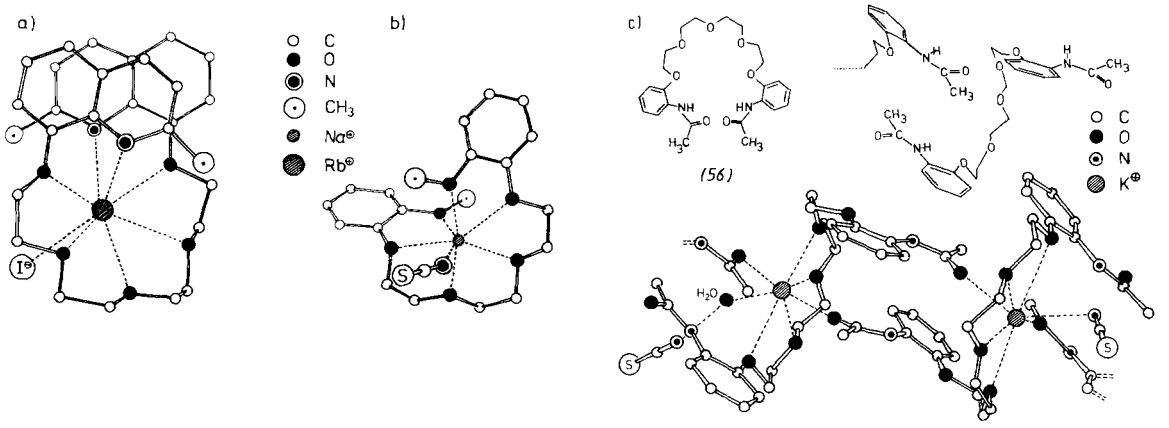

Fig. 6. Geometry of the alkali metal ion complexes of the open-chain ligands (a) *(50)*, (b) *(43c)*, and (c) *(56)*.

The ligand also forms a continuous helix in the *(43c)*-NaSCN complex[106], with a OCH_3 group above or below the other benzene ring[104]. The central sodium ion coordinates to all six oxygen atoms and to the $SCN^{\ominus}$ ion lying above the helix (see Fig. 6b).

X-ray structure analysis of the 1:1 KSCN complex of the amide ligand *(56)* unexpectedly shows polymeric ligand-cat-

recognizing complexation at certain bonding sites[108b] and for analysis of ion pair equilibria in solution, particularly when complexation has no effect on the optical spectra[109].

For example, in a 1:1 mixture of fluorenyllithium and ethylene glycol dimethyl ether (DME) *(27a)* in deuterated benzene, the signals of the CH_2 protons are shifted upfield by 1.22 pm and those of the CH_3 groups by 0.76 ppm[110]. A

similar situation is observed when higher glymes or crown ethers complex with fluorenyl ion pairs[111]. Differences in the NMR spectra are also observed when glymes form complexes with paramagnetic ion pairs[109].

In the ^{1}H-NMR spectra of the complexes of podands with stiffened terminal groups, pronounced changes are observed in the splitting pattern and in the chemical shifts of the aromatic part[92,95,112]: the 8-quinolyloxy unit of ligand *(42d)* absorbs in three separate characteristic signal groups around $\delta = 7.40$, 8.10, and 8.90[92]. In the $K^{\oplus}$ complex the shape of these resonance signals has changed considerably; even more noticeable is their pronounced upfield shift ($\delta = 0.52$ ppm) which affects mainly the pyridine protons and indicates participation of the quinoline nitrogen in coordination of the $K^{\oplus}$ ion. The absorptions of the methylene protons are generally affected much less by complexation (increasingly less towards the center of the chain); apart from further splitting of the multiplet structure, the absorptions of methylene protons close to the ends of the chains merely experience a slight partial upfield shift. The heptadentate helical structure of the RbI complex of *(42d)* (cf. Fig. 5b) established by X-ray crystal structure analysis is in full accord with the upfield shift found for the heterocyclic terminal groups[100].

The RbI complex of the quinoline ligand *(42b)* containing two oxyethyl units less fails to show any sign of helicity in its NMR spectrum[112]. Containing a total of five donor atoms, the ligand is too short to overlap in a helical fashion in solution or in its crystals (see Fig. 5a).

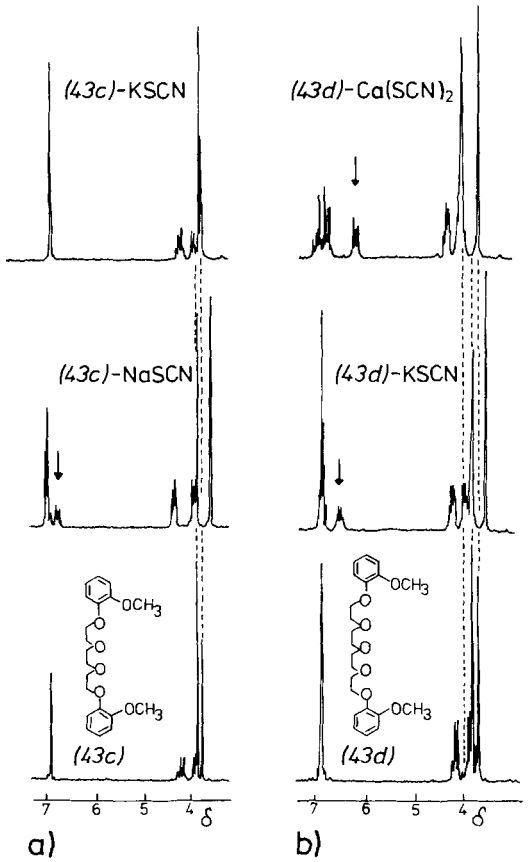

Fig. 8. ^{1}H-NMR spectra (sections) of the free ligands *(43c)* and *(43d)* and of some of their complexes. The OCH_3 region is dashed; arrows mark upfield shifts of aromatic protons.

The OCH_3 group in the ligands *(43)* and *(53)* which possess methoxyphenyl terminal groups is even better suited as an NMR probe for determining the structure of the complex in solution[95a] (see Fig. 8): while the OCH_3 protons generally exhibit an upfield shift in the $Na^{\oplus}$ complexes of *(43c)*, owing to partial overlap of the two aromatic terminal groups, the $K^{\oplus}$ ion leads to disappearance of overlap (cf. Fig. 8a). No upfield shift is observed since the larger $K^{\oplus}$ ion is no longer sufficiently enclosed by the inadequately long ligands in order to form a helix.

However, in the ligand *(43d)* containing one oxyethyl unit more, not only the $Na^{\oplus}$ ion but also the larger $K^{\oplus}$ ion leads to helical overlapping of the terminal groups (see Fig. 8b). The small ion $Ca^{2\oplus}$ permit an even closer enclosure of the cation with a helical structure showing more pronounced overlapping than in the potassium complex.

The helical complexes of type *(46a)* having central pyridine unit and aromatic or heteroaromatic terminal groups exhibit temperature dependent ^{1}H-NMR and ^{13}C-NMR spectra[113]. In the case of the NaSCN complex of the quinaldine analogue of *(46a)*, lowering of the temperature leads to broadening of the CH_2 absorption, which can be interpreted in terms of slowing down of the racemization (fast at room temperature) of the plus to the minus helix and *vice versa* (cf. Fig. 9). A free enthalpy of activation of $\Delta G_c^{\ddagger} \approx 41$ kJ/mol (≈ 9.8 kcal/mol) is calculated for this racemization process.

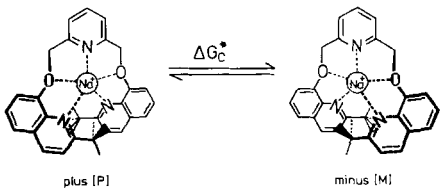

Fig. 9. Configurational interconversion [P]⇌[M] of the complex of NaSCN with the quinaldine analogue of *(46a)*.

The $Mg(ClO_4)_2$ complex of this ligand shows considerable broadening of the OCH_2 signals at room temperature as a consequence of its tighter helical structure (small cation with high charge density).

Measurements of ^{13}C-NMR shifts and spin-lattice relaxation times are attracting increasing interest in the study of alkali metal ion complexation by open chain neutral ligands[114].

In the future, a better understanding of complexation/decomplexation processes and their temperature dependence should result from NMR spectroscopy of the complexed cations, *e.g.* with the aid of ^{23}Na nuclear magnetic resonance[115] *(vide infra)*.

4.2.5. Thermodynamics and Kinetics of Complexation in Solution

Because they have model character for the transport of cations through biological membranes[116], the thermodynamics and kinetics of the complexation of $Na^{\oplus}$, $K^{\oplus}$, $Rb^{\oplus}$, $Cs^{2\oplus}$, and $Mg^{2\oplus}$ ions have been examined for various podands[117,118]. Changes in UV absorption of the two linear quinolyl ethers *(42d)*, $n = 3$, and *(46a)* (in methanol) on continuous addition of metal ions reveal the existence of two

nonequivalent bonding sites for alkali metals ions, with stability constants between 10^3 and 10^4 l mol^{-1} for K_1 and between 10^2 and 10^3 l mol^{-1} for K_2[117]. Stepwise bonding of $Na^{\oplus}$ and $K^{\oplus}$ ions induces a hypso- and hypochromic shift of the absorption maximum of the ligands. In methanol, the 1:1 and 1:2 complexes of the quinoline ligands *(42d)* with $Na^{\oplus}$ and $K^{\oplus}$ exhibit comparable stability. The stability constants are largely independent of ionic radius, as is apparent from the relatively small discrimination factor $K_1(Na^{\oplus})/K_1(K^{\oplus})=0.5$; this is a consequence of the flexibility of the tetraethylene glycol chain which can readily adapt to the various ions (cf. Fig. 10a). Introduction of a bridging pyridine ring into the ether chain increases the rigidity of the system, as is manifested in a greater cation selectivity [$K_1(Na^{\oplus})/K_1(K^{\oplus})=12$] of ligand *(46a)* (Fig. 10b).

In order to gain further information about the specific contribution of the 8-quinolyloxy terminal groups to complexation, studies were conducted on the coordination behavior towards $Mg^{2\oplus}$ since it has long been known that 8-hydroxyquinoline *(22)* forms stable chelates with $Mg^{2\oplus}$[119] whereas the classical oxygen-containing crown ethers show little tendency to complex $Mg^{2\oplus}$ ions[1a, 7a, 53, 120]. Stoichiometric titrations show that *(42d)* has four bonding sites for $Mg^{2\oplus}$ and that *(42d)*-$Mg^{2\oplus}$ complexes are considerably more stable in methanol than complexes of corresponding alkali metal ions. The four bonding sites are apparently non-equivalent, and the conformation of the polyether molecule changes several times on successive complexation.

Far lower K_s values are found for nitro groups in *(44d)*, $n=3$, with poor selectivity towards $Na^{\oplus}$ and increasing selectivity towards $Rb^{\oplus}$ (Fig. 10c), as well as the unsymmetrical compound *(45d)*, $n=3$, with phenyl (R = H) and quinoline at the ends of the chains (Fig. 10a). Atypical behavior is seen with *(79b)*, $n=1$ (see Section 4.3.3) with pronounced peak selectivity for $K^{\oplus}$ and very low tendency to complex other ions, as well as with the acidic ligand *(61a)* (see Section 4.2.8) with plateau selectivity towards $K^{\oplus}$ and $Rb^{\oplus}$ ($\log K_2 \approx 3$) and very low stability of the $Cs^{\oplus}$ complex.

The *meta*- and *para*-phenylene system, *(46b)* and *(54)*, respectively, having 8-quinolyloxy terminal groups, was compared with the corresponding ligand *(46a)* containing pyridine as central units: whereas *(46a)* exhibits high peak selectivity for $Na^{\oplus}$ ions at comparably high complex stability *(vide supra)*, the complexes of the two phenylene compounds with all ions show much lower K_s constants.

The fluorescence spectrum of *(54)* contains a pronounced band at *ca.* 300 nm whose intensity can be selectively modified by cations: $Rb^{\oplus}$ ions with optimum adaptation of host and guest[121] have a strong quenching effect on this fluorescence band. Thus an electronic interaction of the *para*-phenylene π-electron system can be deduced with the cation[122].

The *changes in entropy* (ΔS^0) on complexation of the open-chain ligands with several cations are, *e.g.*, -170 for *(42d)* with $Li^{\oplus}$, and -59 J K^{-1} mol^{-1} for $Na^{\oplus}$. ΔS *increases* sharply with increasing ionic size from $Li^{\oplus}$ to $Cs^{\oplus}$ while ΔH decreases along the same series. The ionic radius-dependent increase in entropy can be interpreted as being due to differing conformational changes on complexation of variously sized ions, since the rise in the ΔS curve apparently opposes expulsion of solvent molecules from the solvation sheath of the ions—which should lead to the opposite sequence of ΔS with increasing ionic size.

This finding appears all the more remarkable in view of the *decrease* in ΔS with increasing ionic radius observed with crown ethers such as [18]crown-6 *(26)* or [2.2.2]cryptand *(2)*[123]. This appears to reflect the replacement of the solvent molecules by the ligand, while the increase in entropy with open-chain ligands suggests entropy-controlled complexation.

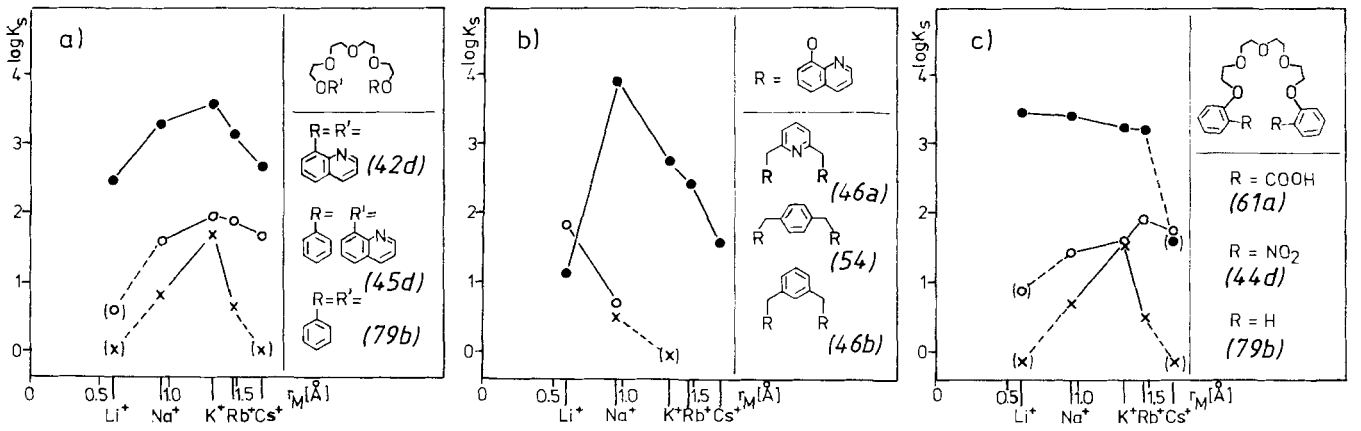

Fig. 10. Stability constants ($\log K_s$) of various podand-alkali metal ion complexes as function of ionic radius. (a) Stepwise loss of donor terminal groups; (b) ligands with stiffened chain; (c) variation of terminal group.

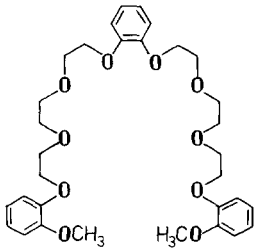
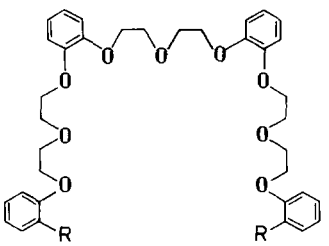
^{23}Na-NMR studies on the thermodynamics of complexation of the open-chain ligand *(56)* with $Na^{\oplus}$ in pyridine as solvent afforded $\Delta H^0=-17$ kcal/mol (-71 kJ/mol), $\Delta S^0=-48$ cal K^{-1} mol^{-1} (-201 J K^{-1} mol^{-1})[124]. The strongly negative ΔS^0 value suggests an entropy of cyclization or/and polymerization (see Fig. 6c for X-ray structure analysis). Complexation compells the ligand to adopt a particular conformation in which most or all of the oxygen donor centers form bonds to the included $Na^{\oplus}$ ion, accounting for the relatively large change in enthalpy. Complexation of *(56)* in solution is enthalpy-driven. It is seen from ^{23}Na-NMR studies that the interaction is best described by a successive



wrapping of the heptadentate ligand *(56)* around the sodium ion.

Kinetic data for the complexation/decomposition equilibria of $K^{\oplus}$ ions with *(42d)* and of $Na^{\oplus}$ ions with *(46a)* in methanol were obtained[117,118] from temperature jump relaxation experiments[125], which initially showed the occurrence of a simple reaction $A + B \rightleftharpoons AB$. The experimentally determined rate constants $k_{1,2}$ for recombination between $Na^{\oplus}$ and *(46a)*, and of $K^{\oplus}$ with *(42d)*, of 4×10^8 and 1×10^8 $mol^{-1}\ s^{-1}$, respectively, are relatively high[125]; nevertheless, they are more than one power of ten lower than the value of 5×10^9 $mol^{-1}\ s^{-1}$ expected for diffusion-controlled recombination of alkali-metal ions with uncharged monodentate ligands in methanol[126,127]. The reduced rate of complex formation can be rationalized as a consequence of stepwise displacement of solvent molecules from the inner coordination sphere of the metal ion by coordinating oxygen atoms of the polydentate ligand. In order to account for the high overall rate, each individual substitution process must occur at a rate of about $10^9\ s^{-1}$. Values of this order have been reported for the recombination of alkali metal ions with acidic chelating agents such as ethylenediaminetetraacetic acid *(13)* and nitrilotriacetic acid *(14)*[128].



That the sum of the individual substitutions is the rate-determining step of complexation is underlined by comparison of $k_{1,2}$ for *(42d)* and *(46a)*: the flexible heptadentate ligand *(42d)* complexes $Na^{\oplus}$ and $K^{\oplus}$ four times as slowly as the more rigid pyridine-containing ligand *(46a)* which has only five coordination sites and accordingly cannot embrace a metal ion so completely. Overall, however, complexation in both cases is sufficiently fast to satisfy the demands formulated by *Eigen et al.*[129] for a carrier molecule[12].

4.2.6. Long-Chain Multidentate Acyclic Ligands

Long-chain multidentate podands of types *(57)* and *(58)*[130] are of interest because they might be able to form helical *endo*-polarophilic/*exo*-lipophilic "ion channels". Such multiply wound spiral structures which participate in ion transport through membranes[131] by the channel or pore mechanism[11,13] have been detected for several biomolecules such as gramicidin[132]. Model studies on synthetic channel-forming ionophores should provide an insight into possible transport mechanisms.

(57)

(58a): R = OCH_3
(58b): R = NO_2

All the ligands *(57)* and *(58)* qualitatively show pronounced solid/liquid phase transfer for inorganic salts; $KMnO_4$ is readily transferred into organic phases. That salts such as NaSCN, KSCN, NH_4SCN, $UO_2(NO_3)_2$ are complexed, follows from shifts and splitting of signals in the ^1H-NMR spectra; as with the shorter chain and more rigid ligands (cf. Section 4.2.4) this suggests helical structures. A number of crystalline alkali and alkaline earth metal salt complexes, including some with 1:2 ligand/salt stoichiometry, have been isolated[130]; an X-ray structure analysis has been published for the complex of *(58b)* with KSCN (Fig. 11)[105b]: in contrast to spherical wrapping of the decadentate ligand *(42g)* around the $Rb^{\oplus}$ ion[105a], the polyether *(58b)* is wrapped in an S-shaped manner in the *dinuclear* KSCN complex with a $K^{\oplus}SCN^{\ominus}$ ion pair located in each half-loop[105b]. The arrangement of the ligand in the complex is stabilized by coordination to $K^{\oplus}$, with double coordination of O(17) (cf. $Hg^{2\oplus}$-HGE complex, Section 4.1) and O(1), O(18), probably playing an important role. Interestingly, the nitro group is rotated relative to the phenoxy group by $-42\,°C$. Partial rotation through $-13°$ can be explained as due to steric repulsion between an oxygen atom of the nitro group and the *ortho*-situated ether oxygen atom; any twisting in excess of this figure is possibly due to an improvement of coordination of the nitro-oxygen atoms with $K^{\oplus}$. Formation of a dinuclear complex appears to be generally favored by double coordination of the terminal nitro groups. For example, a 1:1 complex of $K^{\oplus}$ could be isolated with the analogous ligand having 2,6-dimethoxyphenoxy in place of *ortho*-nitrophenoxy groups, while the smaller $Na^{\oplus}$ ion gave a 1:2 complex[130].

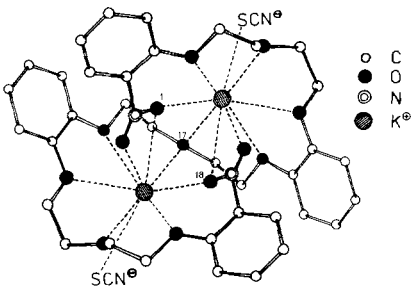


Fig. 11. Structure of the dinuclear KSCN complex of *(58b)*.

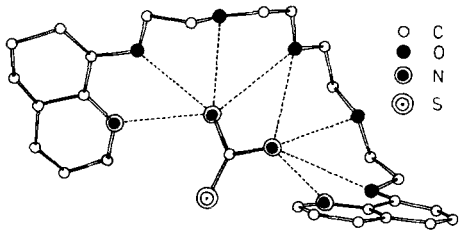
We have no detailed knowledge about the structure of the 1:1 complexes of these ligands; however, it can be assumed that helices with several turns may be present[133] which could comply with the pore concept of ion transport through membranes[11].

4.2.7. Neutral-Molecule Complexes of Acyclic Ligands

In 1970, *Pedersen* discovered that crown ethers not only complex metal ions but also enter into "coordinative" interaction with neutral molecules such as urea and thiourea[134]. Owing to the sometimes complicated stoichiometry, the complexes were initially regarded as adducts of the channel inclusion type[135]. Meanwhile, however, numerous substrate complexes of cyclic crown ethers have been found to have uniform stoichiometry, for example those with dimethyl acetylenedicarboxylate[136a] or CH-acid compounds such as CH_3CN[136b,136d], malononitrile[136c], and others[136d], or with NH-acid compounds such as benzenesulfonamide[137a] or phenylhydrazines[137b] as guest molecules.

We found that open-chain ligands like *(42d)* and *(43d)* are capable of forming stable crystalline 1:1 adducts with neutral guest molecules[138]. Crystalline urea and thiourea complexes can be formed, *e.g.* simply by uniting methanolic solutions of the substrates and an acyclic crown ether such as *(42d)*. The colorless adducts can be recrystallized unchanged from acetone. Elemental analyses confirm an exact 1:1 stoichiometry; it is also obtained when the dissolved components are mixed in various stoichiometric ratios. It may be concluded from the stoichiometry that we are not dealing with inclusion adducts in which the urea molecules form a crystalline host lattice with channel-like cavities[135], because such channel adducts are always found to have stoichiometries corresponding to five to six thiourea or urea molecules for one guest molecule (such as paraffins, *etc.*)[139].

X-ray structure analysis[140] of the crystals formed by *(42d)* and thiourea establishes the presence of crown-ether type 1:1 complexes (Fig. 12a): the NH terminal groups of the thiourea remarkably coordinate with all seven donor sites of the acyclic ligand, involving bifurcated H bonds.



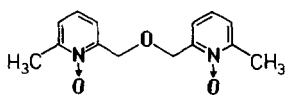


Fig. 12a. Crystal structure of the complex of *(42d)* with thiourea.

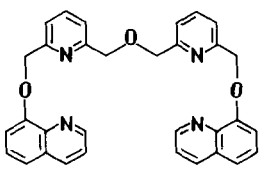

An analogous 1:1 complex is formed between thiourea and the heptadentate neutral ligand *(43d)*; an X-ray analysis has been performed[104].

It is characteristic that the non-crown type compound *(47)* shows deviating behavior; the 1:2 stoichiometry common for quinoline[141] is found with one thiourea molecule per heteroarene. The podands *(60)*, which contain two pyridine rings as central unit and are therefore fairly rigid, form crystalline complexes of alkali, alkaline earth, and transition metal ions, and also of urea and thiourea, with unusual ease[142]. The clearly observable, upfield shifts in the ^{1}H-NMR spectra indicate strong face-to-face overlapping of the end groups.

In this context it was found that classical neutral transition metal ligands such as phenanthroline *(39)* form crystalline stoichiometric 1:1 complexes with alkali metal salts[88b] and with urea[88c].

(59)

(60)

An interesting 1:2 complex of the double pyridine *N*-oxide *(59)* and water has also been isolated[142]; X-ray structure analysis (Fig. 12b)[104] showed that two of the ligand molecules are pseudocyclized *via* two H_2O molecules (H bonding) with the *N*-oxide oxygen atoms, while in the resulting pseudocavity two other water molecules are linked, again by H bonds, to each other and to the pyridine *N*-oxide oxygen atoms. Both the pseudocyclization *via* bridging water molecules and the coordination of water in the cycle show a remarkable analogy to H_2O bonding in bioionophores (Fig. 1a) and in cyclodextrins[143].

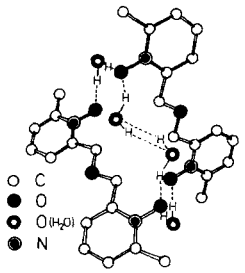

Fig. 12b. Pseudocyclization and H bonding in the H_2O complex of the podand *(59)*.

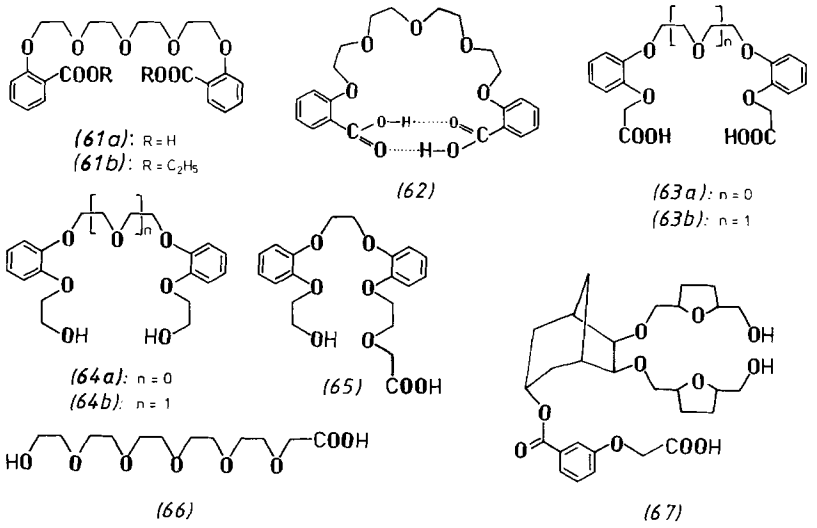
Thus it has been demonstrated that podands, like the coronands, are suitable for complexation of neutral substrate molecules and therefore also have the character of receptor models[144]; in the case of urea as guest molecule this is of great clinical interest owing to the possibility of accelerating dialysis. The design of improved urea receptors will utilize the kind of bonding first observed in podand-urea complexes.



4.2.8. Interaction between Terminal Groups

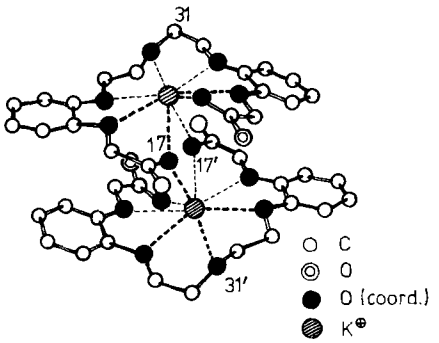
The dicarboxylic acid *(61a)*[91] differs from the ligands having neutral donor terminal groups described so far in several properties: in spite of the comparatively high acidity, the carboxy protons have not been removed in the crystalline KSCN and $Ca(SCN)_2$ complexes, a fact substantiated by IR spectroscopy and interpreted with the aid of an attractive intramolecular terminal group interaction of the kind shown in *(62)*[91].

In this respect, *(61a)* can serve as a model for biotic acyclic carboxylic ionophores[12,116], in which the ligand conformation is enforced in pseudocyclic manner by similar strong intramolecular H bonds, partly *via* interposed water molecules[145]. Antibiotics belonging to the nigericin group (see Section 2) are very appropriate examples.

The open-chain dicarboxylic ligand *(63b)*[146a] behaves analogously. It also forms a series of crystalline alkali metal ion complexes, *e.g.* with KCl, KBr, KI, NaBr, RbSCN, Na- and K-picrate, in which the acid acts as neutral ligand. A crystal structure analysis is available for the K-picrate complex[146a] (see Fig. 13).

Contrary to expectation, no head-to-tail H bonds are observed. Instead, the principal feature is the dimeric centrosymmetric structure of the complex cation. In this structure, each individual ligand is arranged spirally and its conformation is fixed by one $K^{\oplus}$ ion each. One carbonyl oxygen of the monomer [O(17), O(17')] serves as bridging atom and is further coordinated to a second $K^{\oplus}$ ion (see Fig. 13). In this way, irregular eightfold coordination of potassium is achieved, with K...O distances between 2.29 and 2.93 Å; the two $K^{\oplus}$ ions are separated by 4.74 Å in the dimeric complex.

Significantly modified torsional angles are observed at the O(31) atom (see Fig. 13) (152 and 75°; normal values, 180 and 60°, respectively); this is responsible for the helical pitch of the ligand. The picrate ions do not participate in coordination of $K^{\oplus}$ but are bonded to one carboxy H each of the dimer *via* H bonds (not shown) and are also close to a benzene ring of a second complex unit.



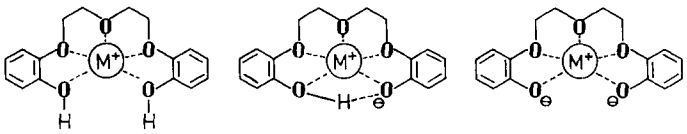


Fig. 13. Crystal structure of the complex of *(63b)* with K-picrate.

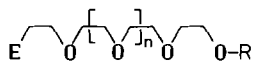
On reduction of the carboxy ligand *(63a)*, the open-chain polyether diol *(64a)* results which forms a crystalline 1:1 complex with NaSCN and a 2:1 complex with KSCN[146b]. Crystal structure analyses of the two complexes revealed heptadentate coordination of $Na^{\oplus}$ in the sodium complex and decadentate coordination of $K^{\oplus}$ on the potassium complex. In the dimeric 1:1 NaSCN complex, one of the two hydroxy oxygen atoms of ligand *(63a)* bonds alternately to the adjacent metal ion. The seventh coordination site is occupied by the $SCN^{\ominus}$ ion. In the 2:1 KSCN complex, two ligand units are grouped around one $K^{\oplus}$ ion in such a way that a pseudo-twofold symmetry axis is generated. Five of the total of six oxygen atoms of each ligand make up the tenfold coordination of the central ion. Specific H bonds are apparently one reason for the difference in the structures. While H bonds exist between the $SCN^{\ominus}$ ions and the two hydroxy groups of *one* ligand in the NaSCN complex, two hydroxy groups (one of which is uncoordinated) from *different* ligands are linked by H bonds in the KSCN complex.

Pseudocyclization by *intramolecular* H bonds is postulated for the complexes of the "acidic" ligands *(65)* and *(66)* on the basis of their ability to transport alkali metal ions through a liquid membrane of 1-hexanol[147]. That *(65)* permits considerably better transport than *(66)* is interpreted by assuming the benzene ring to permit greater stability of the pseudocyclic conformation in the complex (cf. Section 4.1) and to lead to better solubility of the salts in 1-hexanol. Moreover, *(64a)*, which does not contain a carboxy group, also transports alkali metals only poorly. The carboxy group therefore seems to be essential for ion transport (see also Section 4.3.2).

It was recently shown that open-chain ligands having tetrahydrofuran units such as *(67)* effect efficient transport of $Ca^{2\oplus}$ across lipophilic layers[148].

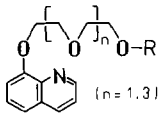
(68) *(69)* *(70)*

Acyclic "neutral" ligands with "acid" phenolic terminal groups can form several kinds of alkali and alkaline earth metal salt complexes[149]: complexes *(68)* neutralized by inorganic counterions, such as arise from open-chain crown ethers, and—after loss of one or both protons—acid complexes *(69)* and *(70)*, in which the ligands serve as mono- and dianions, respectively.



Special interactions between terminal groups are to be expected when nucleic bases such as adenine, thymine, *etc.* are attached to the ends of oligoethylene glycol ethers[150].

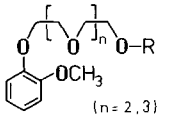
4.3. Weakly Complexing Acyclic Neutral Ligands



There is still a lack of systematic studies in the transition region between glymes *(27)* and open-chain crown ethers *(40)*, *i.e.* on those podands which bear just *one strong* donor group at the end of one chain or *several weaker* donor terminal groups.

4.3.1. Oligoethylene Glycol Ethers Bearing only One Strong Terminal Group

In ligand skeletons *(71)* having one strong donor terminal group (*E*), the other end of the chain can be weakly coordinated without the complex loosing its crystallinity[151].



(71)

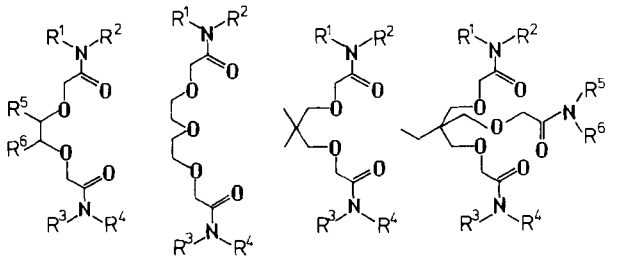
(n = 1, 3)

(72a): R = 1-Naphthyl
(72b): R = Phenyl
(72c): R = Methyl

(n = 2, 3)

(73a): R = 1-Naphthyl
(73b): R = Phenyl
(73c): R = Methyl

Thus the tetra- to hexadentate neutral ligands *(72a)*—*(72c)*[151] containing a good coordinating group such as an 8-quinolyloxy group on the one side and a poor coordinating group such as naphthoxy, phenoxy, or methoxy group on the other still give readily crystalline complexes with various salts. Just a single effective terminal group also permits isolation of crystalline alkali metal ion complexes of *(73a)*—*(73c)*[151]. The short chain of the oligoethylene glycol moiety is remarkable—as with the ligands having two strong donor terminal groups[91,92,95], it need only have $n>1$ and possess four donor atoms.



The flexible chain segment attached to the rigid donor terminal group (*E*) in *(71)* is apparently able to wrap around the cation after anchoring to the metal ion in a favorable planar arrangement; a second donor terminal group is then no longer necessary for formation of crystalline complexes. However, such an additional group may well enhance its stability and, above all, raise its complex constant.

Information about the geometry of the donor-free ends of the chains of the complexes in solution is provided by comparison of the ^{1}H-NMR spectra of the naphthyl ether *(72a)*, $n=2$, and the phenyl ether *(72b)*, $n=2$[151]: while the former exhibits a strong upfield shift of the α- and β-quinoline protons on transition from the free ligand to the complex, only the signal of the α-quinoline proton shows an upfield shift in the complex of *(72b)*. Since spatial proximity of the naphthyl/phenyl and quinolyl group can be deduced in both cases from the chemical shift, the difference should be related to the greater anisotropic region of the naphthalene ring; a change in the mutual orientation of the ends of the chains might also be responsible for the difference[152].

Suitable choice of donor terminal groups (*E*) on the one side and lipophilic chain termini on the other side of a ligand skeleton should open the way to further ligand/complex topologies with almost infinitely variable lipophilic/hydrophilic balance and complex stability constants and complexation kinetics[118], which is important for some applications[25].

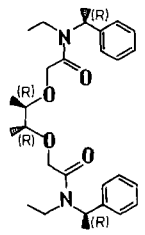
4.3.2. Ionophores of Dioxasuberamide Type with Lipophilic Chain Termini

The acyclic compounds *(74a)* and *(74b)*[153] of the same type as dioxasuberamide and its homologue *(75)*, $R^1=R^2=R^3=R^4=C_6H_5$[154], are suitable sensors for potentiometric activity determinations of $Na^{\oplus}$, $Ba^{2\oplus}$, $Ca^{2\oplus}$, and of other ions of Groups IA and IIA[155]. The cation selectivity is dependent mainly upon molecular structure (nature and number of coordination sites, nature of the chain termini, *etc.*)[7b,156], apart from the choice of measuring medium. In

(74) *(75)* *(76)* *(77)*

(74a), $R^1=R^2=R^3=R^4=CH_2C_6H_5$, $R^5=R^6=H$
(74b), $R^1=R^3=$ Propyl, $R^2=R^4=$ Neopentyl, $R^5=R^6=H$
(74c), $R^1=R^2=R^3=R^4=C_6H_5$, $R^5=R^6=H$
(74d), $R^1=R^3=CH_3$, $R^2=R^4=H_3CCH_2OOC(CH_2)_{11}$–, $R^5=R^6=CH_3$
(74e), $R^1=R^2=R^3=R^4=$ Propyl, $R^5=R^6=H$
(74f), $R^1=R^2=R^3=R^4=$ Propyl, R^5—R^6 = —$(CH_2)_4$—

general, divalent cations are increasingly preferred over monovalent cations with increasing dielectric constant of the membrane phase[156]. An increase in the polarity of the ligand skeleton has a similar effect, with the result that small cations are preferred over bulkier ones of the same charge[7a,7b,153,157].



For example, the following selectivity sequences are found for the ligands *(74c)* and *(74d)* by potentiometry on liquid membrane electrodes[158]:

(74c): $Ba^{2\oplus}>Sr^{2\oplus}\gtrsim Ca^{2\oplus}>Mg^{2\oplus}$;
$Na^{\oplus}\gtrsim K^{\oplus}>Rb^{\oplus}>NH_4^{\oplus}>Cs^{\oplus}>Li^{\oplus}$
(74d): $Ca^{2\oplus}>Sr^{2\oplus}>Ba^{2\oplus}>Mg^{2\oplus}$;
$Li^{\oplus}>Na^{\oplus}\gtrsim Cs^{\oplus}>Rb^{\oplus}\gtrsim K^{\oplus}\gtrsim NH_4^{\oplus}$

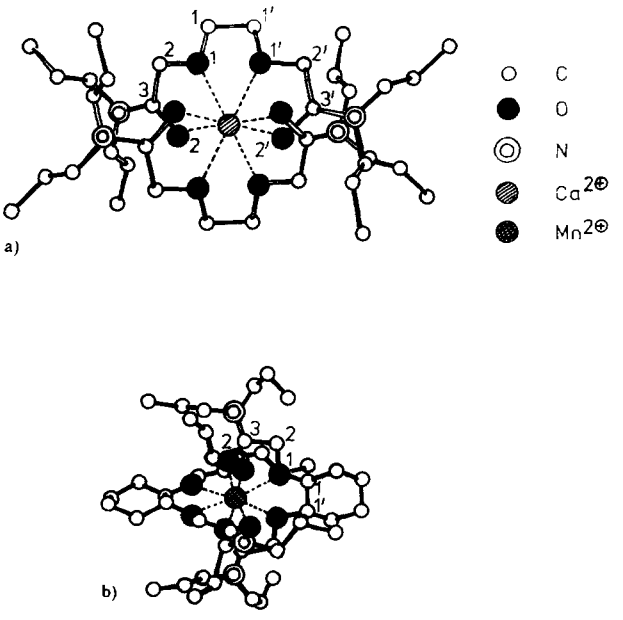
Comparative measurements in the dioxasuberamide series with ligand-impregnated PVC membranes show *(74a)* to be a $Na^{\oplus}$-selective ionophore[155a], *(74b)* a $Ca^{2\oplus}$-selective ionophore[7b], and *(75)* a $Ba^{2\oplus}$-selective ionophore[156]. It recently also proved possible to tailor a ligand of similar structure for $Li^{\oplus}$, *viz.* *(76)*, $R^1=R^3=CH_3$, $R^2=R^4=$ heptyl[159]. Paying due attention to the coordination number/donor atom relation[160], the same kind of ligand could also be adapted to fit the $Na^{\oplus}$ ion by addition of another donor arm ("tripod", cf. Section 5.2). This $Na^{\oplus}$ ionophore *(77)*, $R^1=R^3=R^5=CH_3$, $R^2=R^4=R^6=$ heptyl[161] discriminates against $K^{\oplus}$ ions considerably more strongly ($K^{Pot}_{NaK}=4.4\times10^{-3}$ in *o*-NPOE[161]) than the $Na^{\oplus}$-selective ligand *(74a)* ($K^{Pot}_{NaK}=2\times10^{-1}$, in DBE[156], PVC matrix) and can therefore be used for intracellular studies under physiological conditions[162].

Ion carriers such as *(78)* having C_2 symmetry, which possess four centers of chirality, exhibit enantiomer-selective electromotive properties on incorporation into suitable mem-

branes[163] and accumulate one enantiomer, *e.g.* of α-phenylethylammonium ions, on transport across membranes[164].

(78)

Although these comparatively lipophilic ligands are conceived as ion carriers for liquid membrane sensors[165] and therefore do not have high K_s values, but require fast complexation kinetics in the interest of fast equilibration[154,166], the complex stabilities nevertheless suffice for formation of some crystalline complexes of alkali- and alkaline earth metal salts[158]. The isolated complexes usually require additional water molecules for construction of a stable crystal lattice. Coordinative participation of the carbonyl oxygen atoms[167], which could be substantiated by ^{13}C-NMR spectroscopy for the dissolved state[114a,c], could also be established for the solid state by IR spectroscopy and by crystal structure analyses recently carried out on the $CaCl_2$ and $MnBr_2$ complexes of the ligands *(74e)* and *(74f)*[168]: in both cases the metal ion is coordinated to four ether oxygen atoms and four carbonyl groups of a pair of symmetrically equivalent ligands (Fig. 14). In spite of differing demands of the two metal ions [$r(Ca^{2\oplus})=0.99$ Å, $r(Mn^{2\oplus})=0.80$ Å] the coordination geometries are essentially similar. A trigonal dodecahedron is present in both cases, with the four ether oxygens and the four carbonyl oxygens respectively at the corners of a distorted square. The measured O-metal ion distances are longer for the ether oxygens than for the carbonyl groups, with the latter actually shorter than the calculated ion/atom contacts. The O...Ca distances in the *(74e)*-$CaCl_2$ complex (Fig. 14a) are 2.462 and 2.364 Å (sum of ionic radii 2.39 Å), and



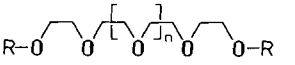


Fig. 14. Geometry (a) in the complex of *(74e)* with $CaCl_2$ and (b) in that of *(74f)* with $MnBr_2$ [168].

the O...Mn distances in the *(74f)*-$MgBr_2$ complex (Fig. 14b) are 2.370 and 2.185 Å (additive value 2.20 Å). The torsional angles show the atomic sequences C(1'), C(1), O(1), C(2), C(3), and O(2) of both ligands to be almost planar.

In contrast to the crystals of *(74e)*-$CaCl_2$ (2:1 stoichiometry), there are two kinds of $Mn^{2\oplus}$ in different geometrical sites in the packing of the crystals of *(74f)*-$MnBr_2$ (1:1 stoichiometry). One kind is coordinated pairwise by ligand molecules while the other is surrounded by a square plane of bromide ions.

4.3.3. Glyme Analogues with Donor-Free Rigid Ends

The simplification of "open-chain crown ethers" *(40)*[91,92] by stepwise worsening of the donating properties of the chain ends in *(71)*[151] raises the question whether podands devoid of donor terminal groups—such as *(79)*—might not also form crystalline complexes with alkali and alkaline earth metal salts (for heavy metal complexes, see Section 4.1).

(79a): R = 1-Naphthyl (n = 1 - 4)
(79b): R = Phenyl

Careful crystallization experiments with the polyethers *(79a)* and *(79b)* having two donor-free but rigid aryl groups as the chain termini and at least five ether oxygen atoms ($n \geq 1$) indeed afforded a series of crystalline complexes with alkaline earth, and also alkali metal ions[169].

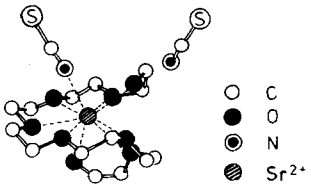
As with the ligands bearing donor terminal groups[92], the formation of a pseudocycle or a helix during complexation in solution can be deduced from the upfield shift observed in the ^{1}H-NMR spectra for the aromatic and aliphatic protons[169] (cf. Section 4.2.4 and 4.3.1). Given a sufficiently long chain (above six CH_2CH_2O units), complexation can only be recognized from the upfield shift of the aliphatic protons. In these cases the aryl ether oxygen atoms may possibly no longer participate in coordination of the metal ion.

If the chain of *(79a)* and *(79b)* is shortened to just four or less CH_2CH_2O units, then no crystalline complexes are obtained under the experimental conditions employed, in accord with previous findings[2,92]. Thus the ligands *(79a)* and *(79b)* mark the limits of crystallizability of crown ether-type complexes. These ligands (with short chains) belong to the simplest and most inexpensive ligands available[10].

Recently, even the long-known *oligoethylene glycol dimethyl ethers* (glymes) *(27)* (Section 4.1) without rigid terminal groups but having a certain minimum number of chain members, *e.g.* hexaglyme *(27f)*, $n=5$, heptaglyme *(27g)*, $n=6$, have been found to form crystalline complexes with alkali/alkaline earth metal ions[169]. Previous attempts to prepare such compounds had all failed[2,92]. Thus it has been demonstrated that glymes not only interact with solvents and cations (solvation/association effects)[65] but also form stoichiometric crystalline complexes whose study (X-ray structure analysis) appears of fundamental importance.

Similar stoichiometric 1:1 neutral complexes with alkali and alkaline earth metal salts have meanwhile also been isolated[172] with the corresponding non-alkylated oligoethylene

glycols[170] and even with *ethylene glycol* itself[171]. Compounds having free OH groups do not seem to require a complexing central portion in order to form crystalline complexes.



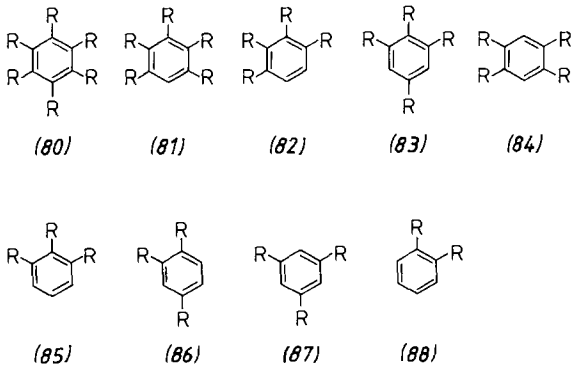


Fig. 15. Structure of the complex of heptaethylene glycol with $Sr(SCN)_2$.

An X-ray structure analysis is available for the heptaethylene glycol-$Sr(SCN)_2$ 1:1 complex (Fig. 15); it reveals an interesting coordination geometry[173]: all eight oxygen atoms of the glycol coordinate to the metal ion; in addition, one of the two $SCN^{\ominus}$ ions is also bonded to $Sr^{2\oplus}$ *via* a nitrogen atom. As in other podands having a similar number of donor atoms (see Section 4.2.3) the ligand chain in this complex is wrapped in helical fashion around the central ion. The Sr...O bond lengths vary between 2.56 and 2.73 Å, with the terminal oxygen atoms showing the shortest Sr...O distances.

(a), R = n-$C_4H_9(OCH_2CH_2)_3SCH_2$; *(b)*, R = $CH_3(OCH_2CH_2)_2SCH_2$; *(c)*, R = CH_3SCH_2; *(d)*, R = n-$C_4H_9SCH_2$; *(e)*, R = n-$C_{12}H_{25}SCH_2$; *(f)*, R = $C_6H_5SCH_2$; *(g)*, R = 2,6-$(CH_3)_2C_6H_3SCH_2$; *(h)*, R = $C_6H_5CH_2SCH_2$; *(i)*, R = β-Naphthyl-SCH_2; *(k)*, R = $C_6H_5OCH_2$; *(l)*, R = *o*-CHO—C_6H_4—OCH_2; *(m)*, R = *o*-CH_3CO—C_6H_4; *(n)*, R = C_6H_5—N=N—*p*-C_6H_4—OCH_2; *(o)*, R = 8-Quinolyl-OCH_2; *(p)*, R = 8-Quinolyl-$OCH_2CH_2COOCH_2$; *(q)*, R = C_6H_5S

ring by way of sulfur atoms[174]. These compounds, which are reminiscent of octopi, exhibit striking phase transfer properties towards metal ions (cf. Fig. 16). *(80a)* transfers a large proportion of alkali metal picrate (Mg, Ca, Sr, Ba) from, *e.g.*, 10^{-4} N aqueous solution into dichloromethane; almost all the salt is transferred into the organic phase in the case of alkali metal picrate solutions (Li, Na, K, Rb, Cs)[175].

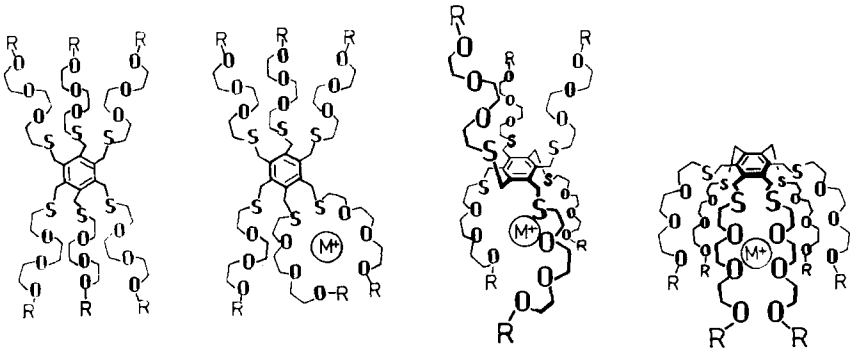

Fig. 16. Interaction between octopus-like ligands *(80a)* and cations $M^{\oplus}$.

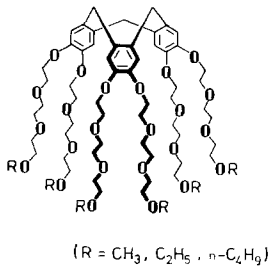
5. Acyclic Neutral Ligands Having Many Arms (Oligo/Polypodands)

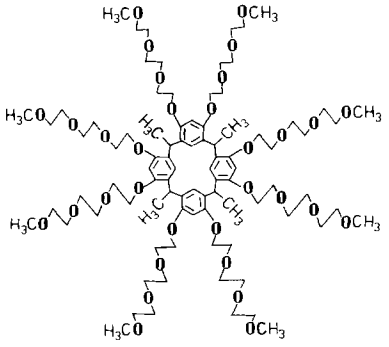
5.1. Ligands without Donor Terminal Groups

Many-armed neutral ligands—polypodands[*]—are of interest for several reasons[1]: the high number of donor atoms holds promise of powerful and versatile complexation; there is also a possibility of discovering novel stereochemical arrangements and complex geometries. Such molecular skeletons should also permit a wide range of variation of lipophilic/hydrophilic balance of both ligands and complexes.



The first compounds described were *(80)*—*(88)* which bear several donor-containing "tentacles" attached to a benzene

Phase transfer is greatly restricted on reduction of the number of donor sites, whether by shortening of the tentacles as in *(80b)* or by reduction of their number as in *(81)*—*(88)*.



Similar phase transfer properties are shown by the hexapodands *(89)*[176] derived from cyclotriveratrylene. While *(89)* can form an "octopus-like" complexation cavity, the conformationally more rigid *(90)*[176] is unable to do so; its phase transfer activity is therefore very modest.

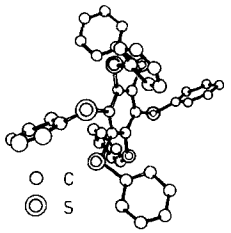
The oxygen-free hexasubstituted benzenes *(80c)*—*(80g)*[177] examined for sake of comparison are naturally unable to act as ligands towards metal ions[174]. However, as was subsequently demonstrated for various examples [*(80h)*, *(80k)*, *(80q)*[178]; *(80l)*—*(80p)*[179]], they form a new type of stoichiometric inclusion compound by acting as host molecules ("hexahosts") for neutral organic molecules such as acetone, dioxane, diglyme, trichloroethanol, dimethylformamide, dimethylacetamide, tetramethylurea, hexamethyl-

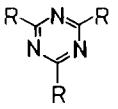
[*] Having already denoted podands as open-chain analogs of coronands and cryptands (see Footnote [**] on p. 753), we classify them as *di-*, *tri-*, *tetra-*, ... *poly*-podands according to the *number* of donor "arms".

(89)

(90)

phosphoric triamide, pyridine, lutidine, collidine, toluene, styrene, cyclohexane, and other hydrocarbons[135d, 178]; their precise structure has yet to be elucidated. Since decomposition of the adducts, which are stable at room temperature, is greatly accelerated by a drop in pressure, a channel structure would appear likely[178]. An X-ray structure analysis has been performed on the CCl_4 clathrate of the host molecule *(80q)* containing fewer benzylic CH_2 groups (Fig. 17)[180]. As is typical of hexasubstituted benzenes[181], the SC_6H_5 side arms point alternately upwards and downwards out of the plane of the central benzene ring and give rise to three-dimensional *inter*molecular cavities in the crystal lattice which are occupied by the CCl_4 guest molecules (1:2 stoichiometry). CCl_3CH_3 and CCl_3SCl can also be incorporated into host lattice in the same ratio, whereas CCl_3Br and CCl_3NO_3 give 1:1 adducts[180, 182].





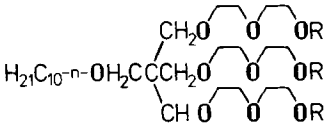


Fig. 17. Geometry of the "hexahost" *(80q)* in the CCl_4 clathrate [180].

A remarkable degree of *guest selectivity* is found for the hexahosts on recrystallization from solvent mixtures (*e.g. o*- and *p*-xylene in equimolar amounts)[183]. Which of the two isomers is preferentially complexed depends primarily on the structure of the host[135e]. *(80h)* and *(80i)* favor inclusion of *p*-xylene, while *(80f)* and *(80k)* take up more of the *o*-isomer. An *o/p* ratio of 90:10 is found for hexakis(phenylthiomethyl)benzene *(80f)*.

Interest also attaches to adduct formation between some "octopus molecules" bearing donor terminal groups with crown ethers such as [12]crown-4, [15]crown-5, [18]crown-6, and crown ether-cation complexes (cascade complexing)[179]. X-ray structure analyses should reveal whether these are intramolecular compounds or whether the guest molecules are accommodated in cavities in the crystal lattice.

Open-chain crown ether fragments without donor end groups have been attached to the triazine system *via* N atoms, and the resulting tri- and hexapodands *(91)* examined with respect to their phase-transfer behavior[184] (cf. Section 6). Once again, phase transfer depends upon the number of polyether arms and upon the length of the terminal alkyl groups (cf. [174]). Corresponding modifications have been performed on *pentaerythritol* as links for polyether "tentacles" *(92)*[184].

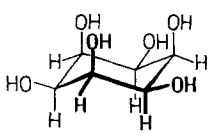
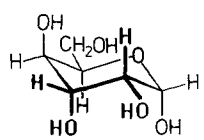
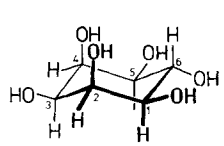
Oxygen-free polyamines of the many-armed "cascade molecule" type *(93)*[185] are of interest as chelating agents in metalation reactions[186] or as polyfunctional hydrolysis catalysts[187]. Crystalline stoichiometric alkali metal salt complexes of permethylated polyamines such as *(94)* are known[186].



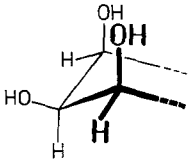
(93)



(94)



Complexation of *carbohydrates* (cyclitols, sugars) with alkali metal ions has been studied by paper electrophoresis[188] and by NMR spectroscopy[189]: the electrophoretic investigations carried on from the observation that many polyols migrate towards the cathod on paper electrophoresis in supporting electrolytes containing acetates of various metals[190]. Among the polyols examined, *cis*-inositol *(95)* showed the greatest mobility in solutions of all the metal acetates used, the effect being most pronounced in the presence of $Ca^{2\oplus}$, $Sr^{2\oplus}$, and $Ba^{2\oplus}$ ions[189]. This is not very surprising in view of



(95)

(97)

(96)

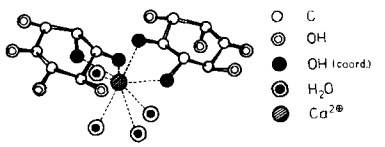
(98)

the four potential complex bonding sites—three jointly acting axial OH groups and three *a-e-a* arrangements of O atoms. *epi*-Inositol *(96)* having only an *a-e-a* orientation of OH groups, exhibit only about one third of the mobility of *cis*-inositol under comparable conditions.

Other cyclitols and sugars, *e.g.* α-gulose *(97)* having an OH group arrangement resembling that of *(98)*, behave correspondingly. Worthy of note is the specificity difference between the series $Ca^{2\oplus}$, $Sr^{2\oplus}$, $Ba^{2\oplus}$, $La^{3\oplus}$, which are suitable for both *cis-(95)* and *epi*-inositol *(96)*, and small ions ($r = 0.6$—0.8 Å) such as $Mn^{2\oplus}$, $Fe^{3\oplus}$, $Ni^{2\oplus}$, $Co^{2\oplus}$, $Cu^{2\oplus}$, $Zn^{2\oplus}$, $Mg^{2\oplus}$, which are effective only in solutions of *cis*-inositol[189a]. This suggests that the latter cations coordinate only to the three axial OH groups of *(95)*. Even smaller cations ($Be^{2\oplus}$, $Al^{3\oplus}$, $Li^{\oplus}$) have no effect at all on electrophoretic mobility.

Addition of $CaCl_2$ to a solution of *epi*-inositol *(96)* effects significant changes in the NMR spectra[189a,b]: all signals are shifted downfield, with that of H(3) being shifted most (0.32 ppm in 2 M $CaCl_2$). The diamagnetic shifts are dependent upon the charge of the complexed cation and its bond strength. $La^{3\oplus}$ ions accordingly cause larger shifts and $Na^{\oplus}$ smaller shifts than $Ca^{2\oplus}$ ions[191]. The stability constants of the complex formed can thus be roughly estimated from the shift data[189a,b].

The stereochemistry was elucidated by X-ray structure analysis of some hydrated $CaBr_2$ complexes (see Fig. 18) which could be isolated in crystalline form by evaporation of equimolar amounts of the components in aqueous solution[192]; in these complexes the $Ca^{2\oplus}$ ions are located in a square-antiprismatic environment of eight oxygen atoms contributed to varying extents by several ligand molecules (three in the case of galactose, two for inositol) and by water participating in coordination (3 to 4 molecules).



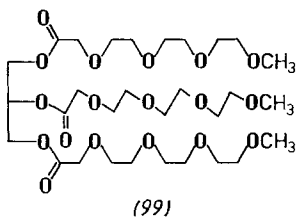


Fig. 18. Coordination sphere of the $Ca^{2\oplus}$ ion in the inositol-$CaBr_2$ complex [192a].

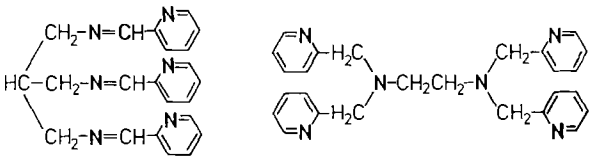
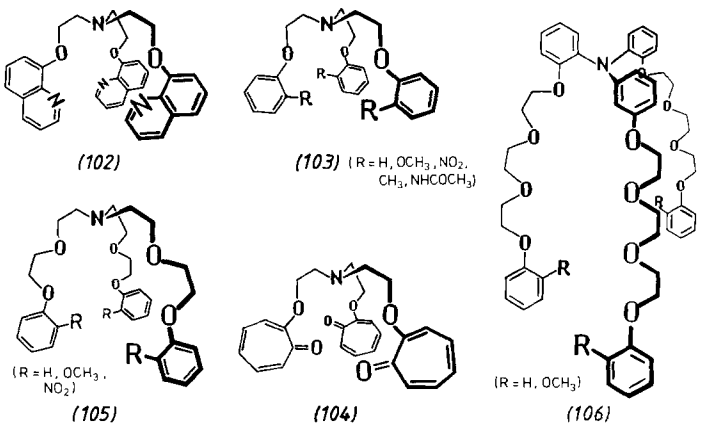
Several bonding and torsional angles show characteristic deviations relative to those in uncomplexed sugars. Such changes in conformation may be involved in biological $Ca^{2\oplus}$ transport[193] or in the reversible fixation of $Ca^{2\oplus}$ ions in carbohydrate compartments in membrane surfaces[194].



(99)



In this connection, there would appear to be a variety of interesting applications for the recently synthesized "hydrophilic lipids" of type *(99)*, in which the fatty acid residues are replaced completely or partly by oligoethylene glycol ether chains; given a sufficient number of ether oxygen atoms, these substances become so hydrophilic that they dissolve in water[195].

5.2. Polypodands Having Donor Terminal Groups (Acyclic Cryptands, Tetrapodands)

Although many-armed ligand skeletons with neutral coordinating terminal groups *(100)*[196], *(101)*[197] have long been known[78a], particularly for complexation of heavy metal ions, acyclic ligands having cryptand properties for elements of Groups I and II have only recently become available[198] by combination of the polypodand (octopus molecule)[174] and terminal group concepts[91,92].

(100) *(101)*

(102) *(103)* *(105)* *(104)* *(106)*

These neutral ligands *(102)*—*(105)*, which have been designated *open-chain cryptands*, do indeed exhibit cryptand-analogous complexation and phase transfer behavior[198]: $KMnO_4$ and aqueous Na- and K-picrate are more readily taken up in organic phases than with dibenzo[18]crown-6 *(1)*. A series of crystalline complexes can be isolated with salts such as NaSCN, KSCN, RbI, NH_4SCN, $Ni(ClO_4)_2$, H_2PtCl_6, BaI_2, $Th(NO_3)_3$, $Cu(ClO_4)_2$, *etc.*[118,198].

The KSCN complex of the three-armed, decadentate neutral ligand *(105)*, $R = OCH_3$, which is the first alkali metal complex of an open-chain cryptand to be examined by X-ray structure analysis, exhibits a novel complexation geometry (Fig. 19)[104]: all ten donor centers including the three OCH_3 terminal groups participate in coordination of the metal ion, which is located at the center of the pseudocavity. In order to attain this coordination, the three arms wrap around the cation in a propeller-like fashion. Owing to the complete screening of the cation, there is no point of attack for the anion. The $SCN^{\ominus}$ ion is therefore outside the lipophilic periphery of the cation complex, as in the bicyclic cryptands.

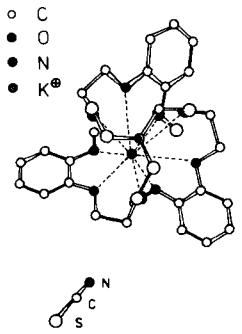


Fig. 19. Structure of the KSCN complex of *(105)*, R = OCH_3 ("open-chain cryptand").

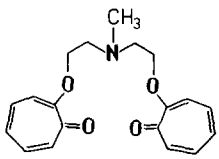
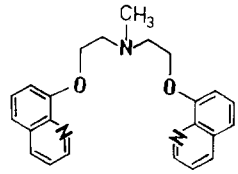
Of all the acyclic ligands studied so far[198], *(102)* exhibits the highest complex constant for alkali metal ions (in methanol/water); not only its preference for $Na^{\oplus}$ ($\log K = 2.7$) over $K^{\oplus}$ ($\log K = 2.0$) and $Li^{\oplus}$ ($\log K < 2$) but also its high selectivity for divalent cations, especially $Ba^{2\oplus}$ ($\log K = 3.2$) and $Sr^{2\oplus}$ ($\log K = 2.7$), warrant mention. The even higher complex constant of the pseudocryptand *(104)*, having three tropolone ether terminal groups, for these divalent cations (*e.g.* $\log K(Ba^{2\oplus}) = 3.6$, $\log K(Sr^{2\oplus}) = 3.3$, but $\log K(K^{\oplus})$ and $\log K(Na^{\oplus}) < 2$) is also striking. Accordingly, we were able to prepare a BaI_2 complex, but no KSCN complex, of *(104)*. On the other hand, the complex stabilities with the smaller ions $Li^{\oplus}$ (<2) and $Ca^{2\oplus}$ (<2) are significantly lower. These ligand selectivities can be rationalized with the aid of space-filling models, and apparently arise from the inability of the pseudocavity to contrast sufficiently to ensure ubiquitous intimate contact with the small cations owing to steric constraints. Only *(102)* shows a $\log K$ value >2 for $Mg^{2\oplus}$. Parallels between ligand cavity size and complexation strength can also be deduced from the ^{1}H-NMR spectra of the complexes (anisotropic upfield shift)[198].



The reaction of tris(chloroethyl)amine with salicylate ions does not lead to the expected ether, as in the dipod system [cf. *(61a)*[91]], but instead, as shown by preliminary results of X-ray structure analyses[104], to the tris(salicyclic ester) having free phenolic OH groups which forms colored neutral complexes soluble in organic media, even with heavy metal ions.

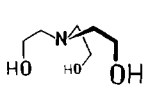
The benzo-annelated tripodand *(106)*, R = OCH_3[199], has been found to give 1:1 complexes with KI, RbI, and BaI_2, and a 1:2 complex with $Ba(SCN)_2$; corresponding complexation experiments with *(106)*, R = H, were unsuccessful, thus underscoring the favorable effect of the terminal groups in this system too. For constant chain length but different terminal groups the contribution of the terminal groups to complexation in the tripodand series *(105)* was found to increase in the following order[199]: phenyl < 2-NO_2-phenyl ≤ CH_3 ≤ 2-CH_3O-phenyl ≤ 8-quinolyl.



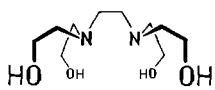
The complex stabilities measured for the tetrapodands *(107)* and *(108)* with various terminal groups were generally somewhat lower than for the analogous tripodands *(102)* and *(104)*[200]. The four large terminal groups probably offer steric hindrance to complexation of small cations.

The ethylenediamine system and the tropolone end group in *(108)* appear to complement each others particularly well[200]: in methanol/water (88:12), a value of $\log K_s = 2.5$ is found for $Na^{\oplus}$ ions and 2.7, 3.0, and 3.1 for $Ca^{2\oplus}$, $Sr^{2\oplus}$, and $Ba^{2\oplus}$ ions (cf. [198]).

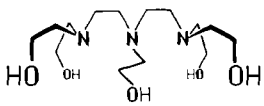
Also of interest in this connection is a comparison of the tropolone compound *(108)* with the corresponding dipodand *(109)*. Although the latter is a stronger complex ligand than the dipodand molecule *(110)* with quinoline terminal group, it is significantly weaker than the corresponding tetrapodand *(108)*[200].



(109)



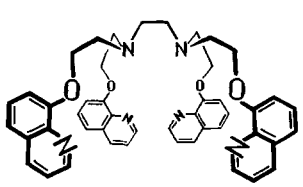
(110)



Further studies will show whether the attachment of *additional* tentacles (pentapodands ... octapodands) gives rise to a further (selective) enhancement of complexing ability (*e.g.* towards divalent ions). It may be that a *lengthening* of the arms of the polypodands proves more favorable on account of the less extensive steric hindrance.

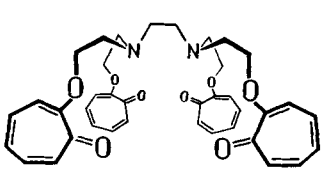
(111)

(112)



(113)

The strict 1:1 stoichiometry recently found for the alkali/alkaline earth metal complexes of nitrilotriethanol *(111)* and of the corresponding tetra- and pentapodands *(112)* and *(113)*[201] is worthy of note: these are examples of fundamental, facile recognition and selectivity processes on a molecular level[144].



6. Use of Open-Chain Neutral Ligands for Phase Transfer Catalysis

While the phase transfer properties of cyclic crown ethers and cryptands have found wide application in chemical synthesis[202], only few results of this kind have so far been reported for open-chain neutral ligands.

The phase transfer efficiency of open-chain neutral ligands of type *(42d)* and *(80a)* was compared with that of cyclic and bicyclic crown ethers and cryptands[175a] with the aid of the standardized phase transfer reaction of benzyl chloride with potassium acetate in acetonitrile as solvent. It was found that each ligand generates a *naked anion* characteristic for its particular system. Further investigations will show to what extent this result, obtained for $K^{\oplus}$ and acetonitrile as solvent, is valid for other systems.

(107)

(108)

Comparison with the noncatalyzed reaction shows that equilibria with characteristic product yields are attained in all cases. They vary between several percent and almost 100%. The time of equilibration also depends upon the type of ligand, varying between a few hours and several days.

This and similar substitution reactions with other potassium salts (in acetonitrile or benzene) have also been carried out with glymes of various chain lengths *(27)* and analogous compounds[10]: it was found that the efficiency of the oligoethylene glycol dimethyl ethers increases with concentration, that at the same concentration (in mol/l) the longer-chain ethylene glycol ethers are more effective than the shorter chain ones, and that a certain minimum chain length is necessary for significant catalytic properties. Diglyme *(27b)* and triglyme *(27c)* therefore exhibit only slight effects. At equal concentration, the open chain ethers are somewhat inferior to the macrocyclic crown ethers, *e.g.* [18]crown-6. This can be compensated by increasing the concentration.

In the *triazine* series *(91)*, phase transfer activity peaks at *(91b)* and falls on shortening of the alkyl group [*(91a)*] or if the number of arms is reduced to three [*(91c)*, *(91d)*][184]. Compound *(91b)* resembles typical trialkylphosphonium catalysts in its phase transfer efficiency[203] and is hardly inferior to the alkyl-substituted cryptands[204]. Whereas *(91b)* proved to be a good phase transfer catalyst in all the reactions studied, the efficiency of the pentaerythritol derivatives *(92)* is highly dependent upon the kind of reaction being catalyzed[184].

During the etherification of glycols or mixtures of glycols of various degrees of oligomerization or polymerization with methyl chloride or dimethyl sulfate in a solid/liquid two phase system (sodium hydroxide/benzene; light petroleum or xylene were used in some cases), the glycol appears to initially act like a phase transfer catalyst by enclosing the sodium ion; as the reaction proceeds it is released by the resulting ether[205]. Anion transfer from solid to solution is promoted to a greater extent by triethylene glycol than would be expected from a potentially tetradentate ligand.

Non-linear relationships between the chain length of oligoethylene glycol ether *(27)* and the complex stability were also observed on complexation of aryldiazonium ions[206]: the complex stability increases with the number of donor atoms up to a certain length (heptaglyme) and then falls abruptly at *octaglyme (27h)*. A further increase in the number of ether oxygen atoms leads to a renewed rise in complex stability. Since the complex constant of [18]crown-6 towards the same diazonium ion is only about five times greater than that of the dimethyl ether of Carbowax-1000[207], the possibility opens up of using this less expensive glyme mixture as phase transfer catalyst in the reaction of aryldiazonium salts[206b]. Aryldiazonium salts experience photochemical stabilization on complexation with glymes (and crown ethers)[206a]. Interestingly, triglyme *(27c)* exerts a stabilizing effect comparable with that of [15]crown-5.

7. Outlook

A new chapter of complex chemistry with neutral organic ligands has begun. Parallel to the cyclic and polycyclic series attempts should be made in the case of podands to create pseudocavities, by means of specifically interacting terminal groups, which resemble those in bioionophores. These cavities may possibly simulate the ionic channel structure and the bactericidal properties of the bioionophores. The incorporation of chiral structural elements into oligopodands also appears a rewarding aim. Such molecules could also be of interest as chiral additives for enantioselective syntheses[208]. Helical enclosure of metal ions such as $Li^{\oplus}$ by chiral ligands in organolithium compounds may effect a higher optical induction than the reagents examined so far[209].

The synthesis of new topologies of acyclic crown ethers and cryptands— also for simple glycols—and their testing as phase transfer catalysts in chemical reactions with ions is just a matter of time[210]. There is no lack of expectation, some rather speculative, in chemistry and other branches of science and technology, such as photography, vulcanization techniques, petroleum engineering, electroplating, reaction engineering[211]. The comparatively low price of open-chain crown compounds should further their large-scale commercial utilization[10]. Considerable progress has already been made in the construction of multielectrode systems doped with open-chain neutral ligands for simultaneous determination of the concentration of several cations, *e.g.* in blood and serum[25].

Mutually comparable physico-chemical studies (ΔH, ΔG, ΔS, ΔK_s, k) of host-guest interactions between simple ligands and simple guest ions or molecules could contribute much to our understanding of passive and active ion transport[11,12,116,131], the mode of action of biological ionophores[7c], and drug/receptor, enzyme/substrate, and antigen/antibody interaction[144,212]. Since the salt balance is of vital importance for organisms (blood coagulation, sugar balance, muscle contraction, kidney function, *etc.*)[24a] and specific modifications play an important role in pathological concentration changes (cancer, gout, *etc.*) and the action of drugs (*e.g.* digitalis)[213], further research into neutral ligand complexation appears of general interest and practical value in numerous fields of application.

We are indebted to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for support of our own work. Thanks are also due to Ms. B. Jendrny for her assistence.

[64] The number following the designation glyme shows—by analogy with crown ether nomenclature, according to a proposal by *J. Smid* [65]—the total number of O atoms in the glyme molecule. In the other conventional names such as di-, tri-, and tetraglyme the numbers refer to the sum of the CH_2CH_2O units.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

1,1′-Trimethylenebis(η^5-3-*tert*-butylcyclopentadienyl)-titanium(IV) Dichloride, a Chiral *ansa*-Titanocene Derivative[**]

By *Horst Schnutenhaus* and *Hans H. Brintzinger*[*]

Chiral organometallic compounds are of interest as stereoselective catalysts, especially for asymmetric reactions with prochiral olefins. With titanocene derivatives, from which catalysts for various olefin reactions can be obtained, chirality can be introduced in principle by multiple substitution at the ring ligands[1]. However, in order to be used as stereospecific catalysts, *e.g.* for olefin hydrogenation, compounds of this type have to retain their configurational stability even upon exchange of both equatorial ligands, which invariably occurs in catalytic reaction sequences[2]. Titanocene derivatives with configurational stability vis-à-vis exchange of equatorial ligands and with a high degree of stereorigidity can be obtained by introduction of ring substituents into a metallocene framework, in which both cyclopentadienyl rings are covalently connected by a $(CH_2)_n$ bridge[3]. We wish to report the synthesis of such a chiral titanocene derivative, the title compound *(1)*, and its resolution by way of a diastereomeric (*S*)-binaphtholate.

Reaction of the anion of *tert*-butylcyclopentadiene[4] with one half equivalent of 1,3-dibromopropane in anhydrous tetrahydrofuran (THF) under an atmosphere of nitrogen at $-10\,^\circ C$ affords 1,3-bis(3-*tert*-butylcyclopentadienyl)propane, which is aromatized without isolation and allowed to react with one equivalent of titanium(III) chloride. Subsequently, oxidation to the Ti^{IV} derivative is achieved by addition of 6 N aqueous hydrochloric acid. The crude product can be purified, albeit with considerable loss of yield, by high-pressure liquid-chromatography on silica gel (Lichrosorb SL 100, E. Merck & Co.) with toluene as eluent. The red-brown compound *(1)* is obtained as the main fraction[5]. In the ^{1}H-NMR spectrum of *(1)* (in $CDCl_3$, rel. $\delta(CHCl_3)=7.25$) a sharp multiplet at $\delta=6.05$—6.40 is attributed to six cyclopentadienyl protons, a somewhat broadened multiplet at $\delta=2.15$—2.35 to six methylene protons of the $(CH_2)_3$ bridge and a sharp singlet at $\delta=1.40$ to 18 *tert*-butyl protons. The occurrence of only one *t*-Bu signal confirms the steric uniformity of the product obtained. Apparently, the formation of isomers with 1,2-disubstituted or *meso*-coordinated ring ligands is suppressed by the substantial steric requirements of the *tert*-butyl groups.

In order to resolve the racemic mixture of *(1)*, the crude product is allowed to react with (*S*)-(−)-1,1′-bi-2-naphthol[6] in the presence of sodium or sodium amide in toluene for 24 h at 60 °C. The reaction products are separated by high-pressure liquid-chromatography of the solution on a reversed-phase-adsorbent (Lichrosorb RP18, E. Merck & Co.) with methanol as eluent. Besides small amounts of unbridged $(t\text{-}BuC_5H_4)_2Ti(O_2C_{20}H_{12})$ and of doubly bridged $\{(CH_2)_3\}_2(t\text{-}BuC_5H_2)_2Ti(O_2C_{20}H_{12})$, one obtains as main fraction the desired compound $(CH_2)_3(t\text{-}BuC_5H_3)_2Ti(O_2C_{20}H_{12})$ *(2)*[7]. In the ^{1}H-NMR spectrum of *(2)*, the expected multiplets of the binaphtholate protons are observed at $\delta=7.87$—7.78 and 7.22—6.95, the multiplets of the cyclopentadienyl protons at $\delta=6.53$—6.12 and 5.17, and the signals of the methylene bridge at $\delta=1.26$ and 1.22 (1:2). The *tert*-butyl groups give rise to one singlet at $\delta=0.96$. The equivalence of both *tert*-butyl groups documents, also for the diastereomeric product *(2)*, a stereochemical uniformity, *i.e.* the absence of substitutional or configurational isomers and indicates that the molecule has, at least on the NMR timescale, the expected axially symmetric structure (see Fig. 1). The specific rotation of *(2)* is found to be $[\alpha]_{577}^{20}=+590^\circ$ ($c=0.8$ g/100 ml diethyl ether); this value remains unchanged after repeated chromatographic purification. The visible part of the CD spectrum of *(2)* shows positive maxima at 480 and 365 nm, a minimum at 445 nm, and a crossover to negative $\Delta\varepsilon$ values at 305 nm.

Interestingly, the high-pressure liquid-chromatographic separation of the reaction product of *(1)* with (*S*)-1,1′-bi-2-naphthol yields only one of the possible diastereomers of *(2)*. Probably, the formation of *(2)* is highly stereoselective. A molecular model (Fig. 1) shows that for the 1*R*,1′*R* enantiomer[8] as well as for the *meso*-form of *(1)*, the introduction

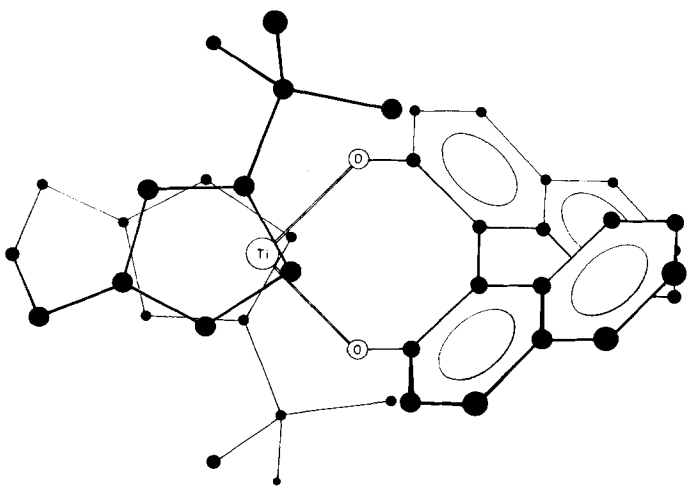

Fig. 1. Molecular model of 1*S*,1′*S*-trimethylenebis(3-*tert*-butylcyclopentadienyl)titanium(IV) (*S*)-1,1′-bi-2-naphtholate *(2)* (projected on TiO_2 plane, height of C atoms above and below this plane indicated by size of dark spheres) [8]

[**] *ansa*-Metallocenes, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and by research funds of the University of Konstanz. We wish to thank Dipl.-Chem. *M. Böhme* for help with the chromatographic separations.—Part 1: *J. Smith, J. von Seyerl, G. Huttner, H. H. Brintzinger*, J. Organomet. Chem. *173*, 175 (1979).

of the (*S*)-binaphthol ligand is opposed by substantial steric repulsion between the *tert*-butyl groups of the titanocene framework and the H atoms in the 3-position of the naphthol ligand; only for the 1*S*,1′*S* enantiomer of *(1)* does the equidirectional helicity of the titanocene framework permit an uninhibited introduction of the (*S*)-binaphthol ligand.

On reaction with HCl in diethyl ether at 0 °C the diastereomer *(2)* is converted into (*S*)-binaphthol and one of the enantiomers of *(1)*, whose specific rotations are $[\alpha]_{435.8}^{20} = -127°$ and $[\alpha]_{365.4}^{20} = +253°$ ($c = 0.16$ g/100 ml diethyl ether). The CD spectrum, with positive maxima at 475 and 330 nm, a negative double maximum at 395 and 415 nm, and with a cross-over to negative $\Delta\varepsilon$ values at 305 nm corresponds—with a shift of one of the bands to shorter wavelengths—largely to the CD spectrum of the binaphtholate derivative *(2)*.

The correspondence of the CD spectra of *(2)* and *(1)* is in accord with our original expectation, *viz.* that an exchange of equatorial ligands would leave the configuration of the chiral *ansa*-titanocene framework unchanged. Based on this assumption, and on the structure of the diastereomer *(2)* represented in Fig. 1, we can assign to the finally obtained enantiomer of *(1)* a 1*S*,1′*S*-configuration.

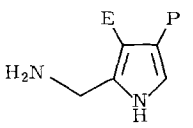
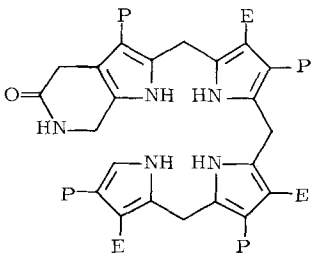
[6] For the resolution of 1,1′-bi-2-naphthol, the procedure reported by *J. Jacques, C. Fouquey, R. Viterbo* (Tetrahedron Lett. *1971*, 4617) was modified by reacting 1,1′-bi-2-naphthol and $POCl_3$ in the presence of pyridine, and by a direct reduction of the unmethylated phosphoric acid ester of *(S)*-1,1′-bi-2-naphthol with $LiAlH_4$. A similar procedure has recently been reported by *E. P. Kyba, G. W. Gokel, F. de Jong, K. Koga, L. R. Sousa, M. G. Siegel, L. Kaplan, G. D. Y. Sogah, D. J. Cram*, J. Organic Chem. *42*, 4173 (1977).



[7] Mass spectrum with molecular ion $[(CH_2)_3(C_4H_9\ \ C_5H_3)_2Ti(O_2C_{20}H_{12})]^+$ and fragment ion $[(CH_2)_3(C_4H_9\ \ C_5H_3)_2Ti-2H]^+$.

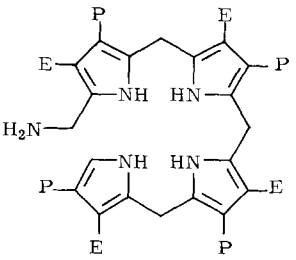
[8] For a stereochemical description of the substituted *ansa*-titanocene framework, we follow the extension of the Cahn-Ingold-Prelog notation to substituted metallocenes as proposed by *Schlögl*[3]. For the compounds under consideration here, the configuration of the complete ligand framework is unambiguously described by denoting the configuration of one of the ring atoms in each ring, in our case *e.g.* that of the bridgehead atoms 1 and 1′.

Enzymatic Formation of Uroporphyrinogen I and III from a Substituted Bilane[**]

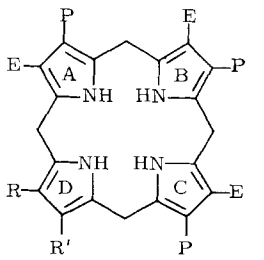


By *Peter Kammerer, Gertrud Wörner*, and *Gerhard Müller*[*]

All natural porphyrins, chlorins, isobacteriochlorins, and corrins are derived from uroporphyrinogen (uro'gen) III. This compound has an arrangement of side chains on ring D opposite to that of uro'gen I. Enzymatic transformation of four molecules of porphobilinogen *(1)* into uro'gen III is catalyzed by "porphobilinogenase"[1]. This enzyme system consists of two enzymes, *viz.* uroporphyrinogen I synthase (porphobilinogen deaminase) and the thermally labile uroporphyrinogen III cosynthase (isomerase). Only the deaminase catalyzes formation of uro'gen I. The uro'gen III:I ratio is determined on enzymatic uro'gen formation by means of the isomerase content of the porphobilinogenase preparation[1]. It was recently deduced from experiments on unlabeled[2] and ^{14}C-labeled[3] bilane *(3)* that the first steps of uro'gen I and uro'gen III synthesis are the same. Accordingly, uro'gen III is formed by isomerization on ring closure of the bilane *(3)* which arises by formal "head-to-tail" condensation of four molecules of *(1)*. NMR spectroscopic studies by *Battersby et al.*[3c] with ^{13}C-labeled bilanes revealed that *(3)* is transformed into uro'gen III by intramolecular rearrangement of the unit forming ring D. Other workers assumed, on the basis of extensive experiments with di- and tripyrrolylmethanes, that isomerization is the first step of enzymatic formation of uro'gen III and arises by "head-to-head" condensation of the first two units of *(1)*[1,4].—Our enzymatic studies have shown that the bilane *(3)* is converted into uro'gen III by "porphobilinogenase".



(1)



E = $-CH_2-COOH$
P = $-CH_2-CH_2-COOH$

(2)

(3)

Uro'gen I, R = P, R′ = E
Uro'gen III, R = E, R′ = P

Alkaline hydrolysis (1 M KOH, 48 h, 30 °C) of the lactam *(2)* (see [2] for synthesis) gives the bilane *(3)*[2], from which uro'gen I is obtained almost exclusively (contains <3% uro'gen III; overall yield *ca.* 70% after 16 h at 37 °C) by chemical cyclocondensation (phosphate buffer, pH = 7—8). The porphobilinogenase preparations from cell extracts of *Clostridium tetanomorphum* were enriched by ammonium sulfate fractionation (30–50% saturation) and on Sephadex DEAE A-25 and were free from porphyrinogen[5]. The uro'gens obtained chemically or enzymatically were dehydrogenated to the uroporphyrins and quantitatively determined according to *Cornford*[6]. For isomer analysis, the uroporphyrins were fixed to Sephadex DEAE A-25, esterified with CH_3OH/H_2SO_4, and isolated as octamethyl esters[5]. After decarboxylation, the resulting coproporphyrins (see [2]) were analyzed by TLC according to *Frydman et al.*[4a] and the coproporphyrin tetrapropyl esters (after esterification of the coproporphyrins with 1-propanol/H_2SO_4) by HPLC (Merck Hibar column; Li Chrosorb RP-18, 5 μm; acetoni-

trile/water 83:17, v/v)[7]. Quantitative determination of the isomeric composition was by HPLC.

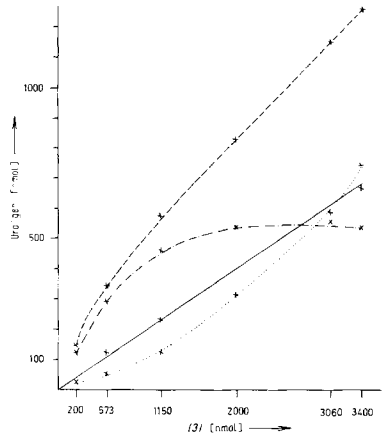

Fig. 1. Chemical and enzymatic formation of uroporphyrinogen as function of concentration of bilane *(3)*. The incubation mixtures contain 1600 mg of protein in 80 ml of 52 mM phosphate buffer, pH = 7.7, as well as the amounts of bilane given, based on unhydrolyzed lactam *(2)*; after hydrolysis of *(2)* the mixture is neutralized with NaH_2PO_4. Incubation: 1 h, 37 °C.—Chemically formed uro'gen I (contains <3% uro'gen III); bilane and protein were incubated separately for this purpose (each 80 ml, see above) and combined after uro'gen dehydrogenation. Enzymatically formed uro'gen: --- total amount, -·-·- uro'gen III, ····· uro'gen I.

The results of Figures 1 and 2 and Table 1 clearly demonstrate that bilane *(3)* is a substrate of "porphobilinogenase". Enzymatic cyclization of *(3)* gives far higher yields than chemical cyclization. Since the content of uro'gen III is proportional to the amount of cosynthase in the porphobilinogenase preparation[1], the highest uro'gen III contents (up to 90%) arise at low bilane concentrations; the total amount of uro'gen III reaches a limiting value at high bilane concentrations. More uro'gen I than III is formed in this region (Fig. 1). Expectedly, the uro'gen III:I ratio increases on incubation with substrate saturation when increasing amounts of "porphobilinogenase" are employed (Fig. 2). The results ob-

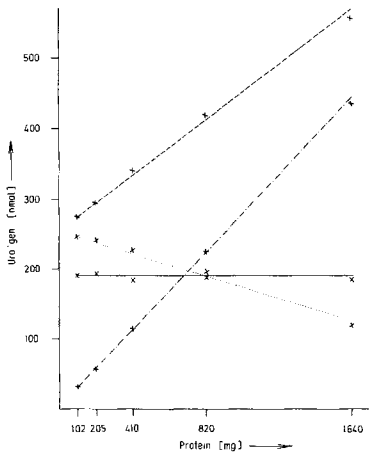

Fig. 2. Uroporphyrinogen formation as function of porphobilinogenase concentration. The incubation mixtures contained 925 nmol of bilane *(3)* (see Fig. 1) in 80 ml of 52 mM phosphate buffer, pH = 7.7, as well as the amounts of protein given. Incubation: 1 h, 37 °C. Enzymatically formed uro'gen: ----- total amount, -·-·- uro'gen III, ····· uro'gen I.——— Chemically formed uro'gen (98% type I) produced under same conditions (see Fig. 1).

tained with enzyme preparations heated for various lengths of time to denature the cosynthase (Table 1) also show conclusively that the "porphobilinogenase" catalyzes both isomerization and cyclization. The deaminase expectedly cata-

Table 1. Formation of uroporphyrinogen I and III from 450 nmol of bilane *(3)* (see Fig. 1) and porphobilinogenase preparations (500 mg of protein in 65 ml of 52 mM phosphate buffer pH = 7.7) which had previously been heated to 60 °C for time *t*. Incubation: 1 h, 37 °C.

Heating *t* [min]	Uro'gen isolated [nmol]	[%]	I : III
—	221	49.1	23 : 77
15	222	49.3	59 : 41

[8] Separation of deaminase and cosynthase (isomerase) can be accomplished on AH-Sepharose 4B with 0.06 M Tris/HCl buffer, pH = 7.2, + increasing amounts of NaCl; the deaminase is eluted by 0.2 M NaCl buffer solutions and the cosynthase by 0.3 M NaCl buffer solutions. *G. Gunzer,* Dissertation, Universität Stuttgart 1978.

[9] After conclusion of the present investigation *A. R. Battersby, C. J. R. Fookes, G. W. J. Matcham, E. McDonald, K. E. Gustafson-Potter,* J. Chem. Soc. Chem. Commun. *1979*, 316 as well as *G. Burton, P. E. Fagerness, S. Hosozawa, P. M. Jordan, A. I. Scott, ibid. 1979*, 202 reported ^{13}C-NMR-studies on enzymatic formation of uroporphyrinogen III. Despite differing interpretation of the results, both groups show that the final product of the deaminase reaction is a tetrapyrrole that is not identical with bilane *(3)*. Since *(3)* is a substrate of "porphobilinogenase" (deaminase + cosynthase) (see above), the deaminase must catalyze a further reaction of bilane *(3)* along the pathway *(3)*→uro'gen III.

Complexes with Chiral Alkylcyclopentadienyl Ligands for Homogeneous Catalytic Asymmetric Hydrogenation of 2-Phenyl-1-butene

By *E. Cesarotti, R. Ugo,* and *H. B. Kagan*[*]

Homogeneous asymmetric hydrogenation of double bonds by metal complexes with chiral ligands such as phosphanes,

amines, and alcohols has been a subject of intense research whereas very little attention has been paid to the use of optically active hydrocarbon ligands.

We have focused our attention on the η^5-cyclopentadienyl ligand and its derivatives which not only form well characterized complexes with many metals but have also been used in catalysts for various organic reactions (hydrogenation[1a], hydroformylation[1b], polymerization[1c]) and for stoichiometric organic reactions such as those related to hydrozirconation[2]. Titanium(IV) complexes with the menthyl- and neomenthylcyclopentadienyl ligands[3] show appreciable catalytic activity for the hydrogenation of simple olefins, including 2-phenyl-1-butene *(1)*, in the presence of a reducing agent, such as "Red-Al" $[Li(H_2Al(OCH_2CH_2OCH_3)_2)]$ acting as a cocatalyst[4].

We have now found that on hydrogenation of the prochiral olefin *(1)* to 2-phenylbutane *(2)* in the presence of one of the catalysts *(3)—(6)*, the (*R*)- or (*S*)-enantiomer predominates in the product (Table 1).

$$\underset{(1)}{H_3C{-}CH_2{-}CPh{=}CH_2} \rightarrow \underset{(2)}{H_3C{-}CH_2{-}CHPh{-}CH_3}$$

Table 1. Asymmetric hydrogenation of *(1)* to *(2)* with the catalysts *(3)—(6)*. Pentane (5 ml, solvent), *(1)* (4 mmol), "Red-Al" as cocatalyst in toluene, and the catalyst in tetrahydrofuran (THF) are introduced in that order with a syringe into a thermostated reactor: *(1)*/Red-Al/catalyst = 75/6/1. $p = 1$ atm, $T = 20\,^\circ C$; 100% conversion [a].

	Catalyst [b]	Product *(2)*	$[\alpha]_D$ [°] [c]	e.e. [%] [d]
(3)	$(\eta^5\text{-MCp})_2TiCl_2$	(*S*)-(+)	$+3.2 \pm 0.3$	14.9
(4)	$(\eta^5\text{-NMCp})_2TiCl_2$	(*R*)-(−)	-1.6 ± 0.3	7.0
(5)	$(\eta^5\text{-MCp})(\eta^5\text{-Cp})TiCl_2$	(*S*)-(+)	$+1.9 \pm 0.3$	8.4
(6)	$(\eta^5\text{-NMCp})(\eta^5\text{-Cp})TiCl_2$	(*R*)-(−)	-2.3 ± 0.3	10.0

[a] The hydrogen uptake was measured with a gas burette and monitored by GLC of the reaction mixture; no isomerization products were detected. [b] MCp = (−)-menthylcyclopentadienyl; NMCp = (+)-neomenthylcyclopentadienyl. [c] After each introduction of air the reaction mixture was evaporated down and vacuum-distilled. The distilled samples were separated by preparative GLC (instrument: Carlo Erba GT 200 with one SS column (¼″ × 2.5 m); 20% Carbowax 1500 on Chromosorb W 60/80; helium; $T_i = 150\,^\circ C$; $T_0 = 100\,^\circ C$). *(2)* was collected in a liquid nitrogen trap. The $[\alpha]_D$ values ($c = 6$, EtOH) of a distilled sample and of one separated by GLC were in agreement (±0.3). [d] Enantiomeric excess: mean values from at least three determinations. $[\alpha]_D$ of (*S*)-(+)-*(2)* = +22.7° ($c = 1$, EtOH, 95%); *J. Cymerman Craig, W. E. Pereira, B. Halpern, J. W. Westley*, Tetrahedron *27*, 1173 (1971).

The catalysts *(3)* and *(5)* with (−)-menthylcyclopentadienyl lead to (*S*)-(+)-*(2)*, whereas the catalysts *(4)* and *(6)* with (+)-neomenthylcyclopentadienyl give (*R*)-(−)-*(2)*. Whether one or two chiral alkylpentadienyl groups are present has hardly any effect on the enantiomeric excess.

The enantiomeric excess obtained with catalyst *(3)* is comparable with that found for metal complexes of chiral phosphanes[5]. A higher asymmetric induction has also been observed with special complexes[6].

However, hydrogenation of *(1)* with the chiral complex *(7)* as catalyst did not lead to optically active *(2)*[7].

$$[\eta^5\text{-}C_6H_5CH(CH_3)C_5H_4](\eta^5\text{-}C_5H_5)Zr(CH_3)_2 \qquad (7)$$

Our titanium compounds *(3)—(6)* prove to be inactive towards olefins with donor groups such as CN, COR, COOR. Studies on other simple prochiral olefins should reveal the manner in which these relatively flat and rigid ligands effect preferential formation of one enantiomer.

$S_5N_6(CH_2)_4$—The First Spirocyclic $1'\lambda^6$-Thiacyclopentane Derivative of a Sulfur-Nitrogen Compound[**]

By *Herbert W. Roesky, Cornelia Graf, M. N. S. Rao, Bernt Krebs*, and *Gerald Henkel*[*]

The presence of sulfur atoms of coordination number 2 in the basket-like compound S_5N_6[1] should permit derivatization. Formal dialkyl substitution at the S atom of the "handle" in the molecular skeleton of S_5N_6 can be accomplished by reaction of $S_4N_4Cl_2$ *(1)* with thiacyclopentane *S,S*-bis(trimethylsilylimide) *(2)*[2]. Compound *(1)* is accessible by reaction of S_4N_4 with chlorine[3].

(1) *(2)* *(3)*

The spirocyclic product *(3)* was isolated as yellow crystals which are stable towards air and moisture. On heating to 150 °C a red coloration is observed, and explosive decomposition occurs at 151 °C (we detected only fragments of the new compound in the mass spectrum). It fails to dissolve without decomposition in all the usual solvents; hence no ^{1}H-NMR investigation has yet proved successful.

X-ray structure analysis of *(3)* (monoclinic, space group $P2_1/c$, $a = 7.056(2)$, $b = 13.272(4)$, $c = 11.660(3)$ Å, $\beta = 101.57(3)°$, $Z = 4$; four-circle diffractometer data, $R = 3.4\%$) proves the spiro-linkage of the thiacyclopentane ring to S1 of the bicyclic SN skeleton (Fig. 1).

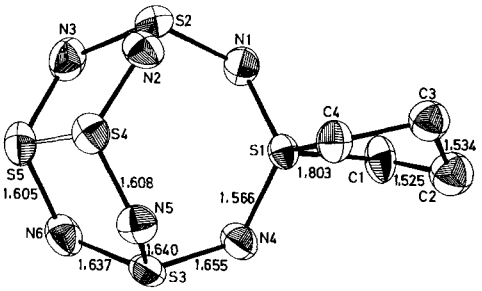

Fig. 1. Molecular structure of $S_5N_6(CH_2)_4$ in the crystal with bond lengths (σSN and σSC = 0.003, σCC = 0.010 Å) and vibrational ellipsoids (50% probability).

The eight-membered ring without S1, N1, and N4 has a conformation analogous to that of the S_4N_4 molecule; the other two rings (S1—N1—S2—N2—S4—N5—S3—N4 and S1—N1—S2—N3—S5—N6—S3—N4) have a crown shape comparable with that of the S_8 molecule. The distance of 2.454(1) Å between S4 and S5 corresponds to a transannular interaction. This contact is stronger than in S_4N_4 (2.58 Å) but weaker than in S_5N_6 (2.425(2) Å)[1] and in $S_5N_6(CH_3)_2$ (2.433(3) Å)[4]. Neglecting the $S(CH_2)_4$ five-membered ring, the molecule of *(3)* has C_s symmetry. The bond lengths averaged over both halves of the molecule are shown in Figure 1; bond angles S—N—S 121.1(2)—125.3(2), N—S(trivalent)—N 104.0(2)—111.0(2). N—S(divalent)—N 118.4(2)—119.2(2), N—S(tetravalent)—N 124.1(2)°.

Procedure

A solution of *(2)* (5 mmol) in CH_3CN (25 ml) is added dropwise to a cooled (−5 to −10 °C) and stirred solution of *(1)* (5 mmol) in CH_3CN (50 ml). A grayish-brown precipitate appears on slow warming of the reaction mixture to room temperature (12 h). The product is purified by dissolving samples of *ca.* 50 mg in a mixture of CH_2Cl_2 (30 ml) and CH_3CN (10 ml). After removing part of the CH_2Cl_2 (25 ml) the solution is allowed to stand in a refrigerator, whereupon yellow crystals of *(3)* precipitate. The yield is 40% (before recrystallization).

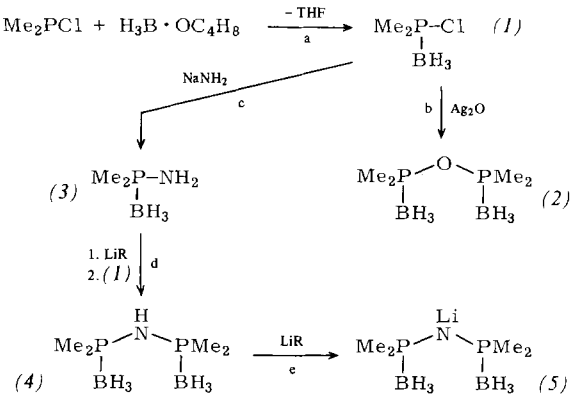
Chemistry of the $H_3B(CH_3)_2P$ Group[**]: Unusual Properties of Some Simple Reference Compounds

By *Hubert Schmidbaur* and *Erwin Weiss*[*]

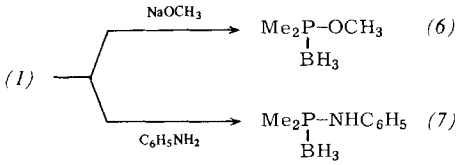


The trimethylsilyl group Me_3Si— confers synthetically, technically, and analytically valuable properties on a variety of compounds. Its advantages as a protecting and leaving group and as an inert and hydrophobic synthetic moiety having influence on the solubility, volatility and surface nature of substances were soon recognized and rapidly led to a wide spectrum of practical applications.

It appears inapposite at first sight to expect similar properties of the isoelectronic $Me_2(H_3B)P$-group, since the otherwise typical lability of the BH-function and the formal charges would suggest such substances to have a completely different character. We have found, however, that 1) all $Me_2(H_3B)P$ compounds analogous to the Me_3Si parent compounds can exist, that these 2) are surprisingly thermally and chemically stable and 3) open up access to a variety of derivatives by substitution reactions.

The chlorophosphaneborane *(1)* corresponding to chloro(trimethyl)silane is readily and quantitatively obtainable (route a) from inexpensive starting materials; the stable, distillable liquid is only slightly sensitive to moisture[1].

The compound *(2)* analogous to disiloxane can be prepared from *(1)* by controlled hydrolysis or—better—with Ag_2O (route b); its air- and water-stable crystals, m.p. 74 °C, are sublimable without decomposition.



Ammonolysis of *(1)* with NH_3 in diethyl ether or the reaction with $NaNH_2$ (route c) leads quantitatively to the analog of (unstable![2]) amino(trimethyl)silane; the product *(3)* is a deliquescent crystalline substance at room temperature which loses neither NH_3 nor H_2 spontaneously and can be distilled without decomposition. After metalation with *n*-C_4H_9Li in pentane, the reaction (route d) with further *(1)* affords the compound *(4)* corresponding to disilazane; like *(2)* it is air- and water-stable, can be sublimed, and can be metalated once again at the NH group (route e), giving the important versatile reagent *(5)*[3].

Reaction of *(1)* with $NaOCH_3$ in diethyl ether/methanol quantitatively affords the methoxyphosphaneborane *(6)*, whose aromatic odor is reminiscent of that of the corresponding silyl ether. The CH_3O— moiety in *(6)* is readily replaceable by other RO groups. On reaction with aniline in diethyl ether, *(1)* is completely converted into *(7)* already at room temperature. Other amines give analogous products.

The structure and composition of all the named compounds was confirmed by complete elemental analyses and spectroscopic investigations [MS, IR, NMR, ^1H, ^{13}C, ^{31}P].

[**] Part 1.

The unusual properties of these prototypes deserve comment: it is a little-known fact that the BH_3 group in phosphaneboranes has, for much discussed but still unclear reasons[4], lost its hydride activity to such an extent that it is even stable towards acids and bases[5]. According to our findings the monofunctional derivatives behave similarly and thus the $H_3B(CH_3)_2P$ group proves to be a relatively inert and readily exchangeable substituent. It is apparent then that many of the known reactions of $(CH_3)_3Si$ compounds can be accomplished with the corresponding $H_3B(CH_3)_2P$ compounds, but the products have a characteristically higher polarity.

Experimental

(1): A 1 M THF solution of $BH_3 \cdot C_4H_8O$ (63 ml, 63 mmol) is added to 6.0 g (62.7 mmol) Me_2PCl at 0 °C. The solvent is removed at 20 mbar/20 °C and the residue distilled at 0.1 mbar/20 °C; colorless liquid[1].

(2): To a solution of *(1)* (0.46 g, 4.2 mmol) in THF (15 ml) is added Ag_2O (0.48 g, 2.1 mmol) and the mixture stirred in a sealed vessel for one week at 20 °C. All volatile components are removed at 0.1 mbar/20 °C, and the residue washed with pentane (5 ml) and sublimed at 60 °C/10^{-4} mbar. Yield 66%; m.p. 74 °C.

(3): *(1)* (2.96 g, 26.8 mmol) is added to a solution of $NaNH_2$ (1.10 g, 20.2 mmol) in THF (10 ml) at −78 °C. The mixture is warmed up and stirred for 1 h. Workup as in the case of *(2)* gives *(3)* in 68% yield.—The same product is obtained on passage of NH_3 into a solution of *(1)* (5.00 g, 45.3 mmol) in ether (75 ml) at 0 °C. After filtration from precipitated NH_4Cl and removal of solvent, *(3)* is obtained in 98% yield; m.p. 29 °C.

(4): One equivalent of *t*-BuLi in pentane is added to a suspension of *(3)* (2.33 g, 25.6 mmol) in pentane (20 ml) at 0 °C and the mixture stirred for 12 h at 20 °C. *(1)* (2.80 g, 25.6 mmol) is then added at 0 °C and stirring continued for a further 4 h at 20 °C. Removal of solvent, washing with 2 × 10 ml water, and crystallization from toluene affords *(4)* in 47% yield; m.p. 164 °C.

(6): To a solution of $CH_3ONa \cdot CH_3OH$ (0.93 g, 10.8 mmol) in ether (10 ml) is added 1.19 g (10.8 mmol) of *(1)* at 0 °C and the mixture is stirred for 1 h. Workup as for *(1)* affords *(6)* in 73.5% yield; colorless liquid.

NMR data of the new $H_3B(CH_3)_2P$ compounds; coupling constants in Hz.

Synthesis and Crystal Structure of a Salt Containing the Anion $[H_3B(CH_3)_2P{\cdots}CH{\cdots}P(CH_3)_2BH_3]^-$; Precursors and Related Compounds[**]

By *Hubert Schmidbaur, Erwin Weiss,* and *Beate Zimmer-Gasser*[*]

Phosphaneboranes R_3PBH_3 are relatively inert owing to the reduction in polarity of their HB and BP structural elements by specific bonding in the H_3BP group. CH_3 groups (R = Me) in such compounds, however, have distinct acidic character due to the stability of the corresponding ylide bases[1]. This effect ought to be much more pronounced in compounds of the type $[R_2(H_3B)P]_2CH_2$ and thus enable metalation at the central atom.

Starting from the bisphosphane *(1)*[2] and the borane adduct $H_3B \cdot OC_4H_8$, we have now synthesized *(2)*, which crystallizes in the form of stacked hexagonal scales (a crystal structure analysis could not be carried out because of the extreme thinness of the flakes). Conversion into a metalated derivative was accomplished by reaction with alkyllithium in an inert solvent, and a crystalline Li-complex salt *(3)* could be isolated by precipitation with tetramethylethylenediamine (TMEDA).

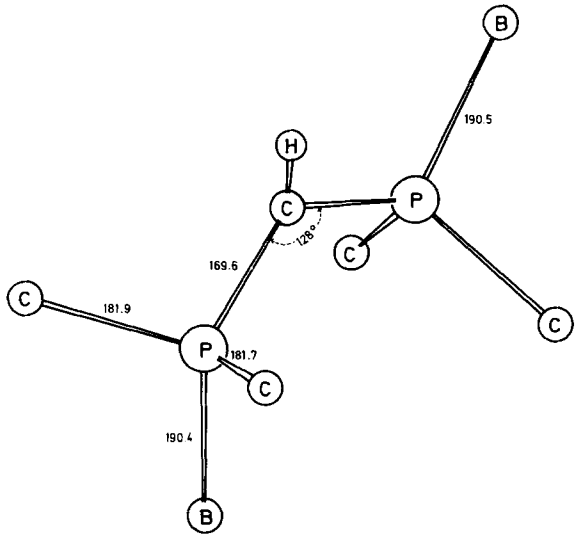
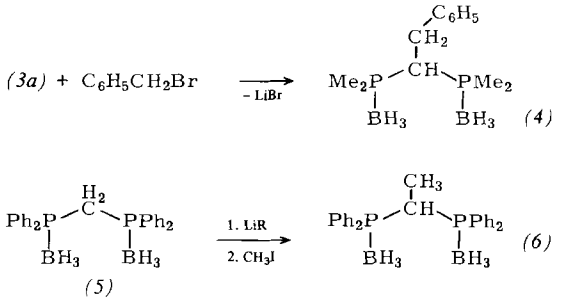
[**] Chemistry of the $H_3B(CH_3)_2P$ Group, Part 2.—Part 1: [4].

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/1010-0782 $ 02.50/0

In order to confirm the proposed structure and to gain a closer insight into the characteristic geometries of $Me_2(H_3B)P$ compounds in general, an X-ray structure analysis was carried out on *(3)*[3]. As expected, independent ions are present in the crystal. In the anion (Fig. 1) both P atoms show a tetrahedral ligand arrangement PC_3B. The bond lengths in the angular (128.6°) PCP bridge are almost equal and distinctly shorter than the terminal PC bonds, thus proving the ylidic nature of the bridge. The lengths of the outer PC and PB bonds differ only slightly, so that the overall shape of the $H_3B(CH_3)_2P$ group does in fact closely resemble that of the isosteric $(CH_3)_3Si$ group[4]. Details can be correlated with the structure of $(Me_3Si)_2NH$.





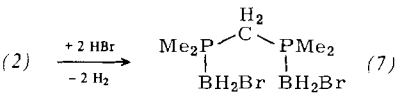


Fig. 1. Structure of the anion in the crystal of the complex salt *(3)*. Bond lengths in Å.

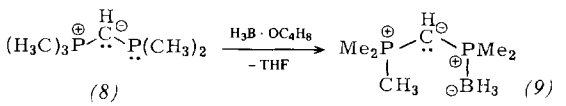

(3) is attacked by alkyl halides at the central C-atom, *e.g.* reaction with benzyl bromide leads to the crystalline product *(4)*. The already well-known[5] phenyl homolog of *(2)* can be alkylated in a similar way *via* the Li-salt [*(5)*→*(6)*].

In contrast to the metalation, the halogenation of *(2)* takes place at the B-atom. Thus, reaction with two equivalents of HBr affords the difunctional haloborane *(7)*, which readily undergoes further reaction.

The phosphino-substituted ylide *(8)*[6] leads to a molecule isosteric with the anion in *(3)* since it reacts with $H_3B \cdot OC_4H_8$ at the P-atom to give the phosphaneborane *(9)*. The formal

replacement of one B-atom in *(3)* by a C-atom determines the neutral character of *(9)*, which now has only four alternating charges.

The composition and structure of all the new compounds have been confirmed by elemental analysis and by IR, NMR, and mass spectrometry.

Experimental

(2): To a solution of *(1)* (2.73 g, 20.8 mmol) in THF (50 ml) is added two equivalents of $H_3B \cdot C_4H_8O$ (46.5 ml of a 0.9 M THF solution). After 30 minutes' stirring at 20 °C, filtration, removal of solvent and crystallization from THF affords 2.85 g (84%) of *(2)*; m.p. 145 °C.

NMR data of the new phosphaneboranes; coupling constants in Hz.

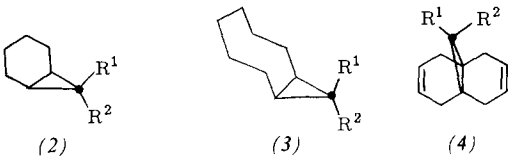
Direct ^{13}C-NMR Spectroscopic Observation of Cyclopropylidene Bromolithiocarbenoids

By *Dieter Seebach, Herbert Siegel, Klaus Müllen,* and *Kurt Hiltbrunner*[*]



The first detection of a halolithiocarbenoid by *Köbrich* and *Trapp*[1a] was followed by initially extensive mechanistic studies[1b] while the preparative scope of this class of substances, which are stable only at very low temperatures, was not fully appreciated until the 1970's[2]. The geminal position of the positive (metal) and negative (halogen) leaving group, *i.e.* the joint acceptor and donor properties of the C atom of compounds such as *(1)*, leads to the versatile and surprisingly stereoselective[3] reaction behavior shown in Scheme 1. In spite of, or precisely because of, the plethora of chemical results available the nature of the bond in intermediates like *(1)* is still unclear; they have hitherto escaped direct observation in the temperature range[4] in which the reactions mentioned take place.

We have successfully examined by ^{13}C-NMR spectroscopy the carbenoids *(2b)—(4b)* generated in an NMR sample tube in tetrahydrofuran solution at −100 °C from the ^{13}C-labeled (●) dibromides[5] *(2a)—(4a)* and *n*-butyllithium (solution in hexane).

Scheme 1. Acceptor and donor reactivity of bromocarbenoids *(1)*.

For comparison we also determined the ^{13}C-(●)-NMR shifts of the corresponding Br/Br, Br/H, Li/H, and H/H compounds *(2a, c—e)—(4a, c—e)*. All the data are compiled in Table 1. The signals of the lithium derivatives are on average *ca.* 8 ppm wide at −100 °C and are without structure; they become sharper at higher temperature. Chemical proof of the identity of the organometallic species was provided by protonation (in the sample tube and on a preparative scale[7]) to the corresponding CH compounds *(2c, e)—(4c, e)* and their NMR analysis and isolation. In the case of *(3b)*, the rearrangement[8] to the 1,2-cyclononadiene ($\delta C^2 = 208$[9]) which occurs on warming could be monitored: the signal of *(3b)* became increasingly sharp at −80 and −70 °C, and reached normal line width (as for solvent signals) at −60 °C; at the same time it loses intensity in favor of the allene-C^2 signal.

(a): $R^1 = R^2 = Br$
(b): $R^1 = Li$, $R^2 = Br$
(c): $R^1 = H$, $R^2 = Br$
(d): $R^1 = H$, $R^2 = Li$
(e): $R^1 = R^2 = H$

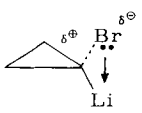


Table 1. ^{13}C-NMR shifts of the 90% ^{13}C-labeled (●) compounds *(2)—(4)* in δ values relative to TMS. Temperature −100 °C, solvent C_4H_8O/C_4D_8O (9:1); Varian XL-100 spectrometer, 25 MHz measuring frequency; FT recording technique up to 2500 pulses.

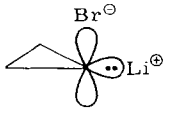
	Chemical shift or shift difference						
Compound	*(a)*	*(b)*	*(c)*	$\Delta\delta_{bc}$	*(d)*	*(e)*	$\Delta\delta_{de}$
(2)	40.1	87.0	24.5	62.5	10.0	9.6	0.4
(3)	37.9	80.7	24.9	55.8	10.8	10.3	0.5
(4) [6]	53.8	102.0	35.4	66.6	11.8	11.8	0.0



The *pronounced downfield shift* $\Delta\delta_{bc}$ of the Li/Br carbenoid C atoms (●) by values of up to 67 relative to the H/Br compounds is surprising (cf. Table 1): large shift differences are not normally found for the saturated (sp^3) C atom between CH and CLi derivatives[10,11], as is confirmed by the cyclopropanes *(2d, e)—(4d, e)* ($\Delta\delta_{de}$ in Table 1). The observed deshielding is also unexpectedly large in comparison

[*] Prof. Dr. D. Seebach, Dr. H. Siegel, Prof. Dr. K. Müllen [**], K. Hiltbrunner
Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule

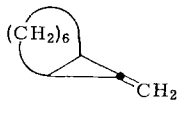
[**] Present address: Institut für Organische Chemie der Universität, Greinstrasse 4, D-5000 Köln 4 (Germany)



with sulfur- and phosphorus-substituted carbanionoid centers[13] ($\Delta\delta$ *ca.* -10 to $+10$). Replacement of H by Br leads in the Li derivatives *(2)—(4)* ($\Delta\delta_{bd}=70$—90) to a four- to five-fold greater downfield shift than that in the H compounds ($\Delta\delta_{ce}=14$—24). Thus it may be concluded that considerable weakening *(5a)* of the CBr bond[14] or even rehybridization *(5b)* have taken place in the cyclopropylidene carbenoids, cf. (●) shift in *(6)*[12] and *(7)*[15]. Further studies[12] (variation of halogen and metal, measurement of ^{13}C-^{13}C coupling constants, *etc.*) are necessary to obtain more precise information[16].

[16] *(5b)* could be regarded as the LiBr complex of singlet cyclopropylidene whose carbene C is calculated to have a charge of -0.21 [*R. Gleiter, R. Hoffmann*, J. Am. Chem. Soc. *90*, 5457 (1968)]. The well-documented destabilization on going from pyramidal to planar-trigonal arrangement of atoms in the three-membered rings appears at first sight to disfavor formulation *(5b)* based on the geometry [*P. W. Dillan, G. R. Underwood*, J. Am. Chem. Soc. 99, 2435 (1977); *D. J. Pasto, M. Haley, D. M. Chipman, ibid. 100*, 5272 (1978)] of cyclopropylidene.

^{13}C-NMR Spectra of Tribromomethyllithium and 1,1-Dibromoethyllithium

By *Herbert Siegel, Kurt Hiltbrunner*, and *Dieter Seebach*[*]

After addition of *n*-butyllithium to a solution of ^{13}C-labeled tetrabromomethane[1] [*(1a)*, $\delta=-29.8$] in tetrahydrofuran, *i.e.* after bromine/lithium exchange to give *(1b)*, at $-100\,^\circ C$ in an NMR sample tube[2], the ^{13}C-NMR spectrum shown in Figure 1A is observed. Almost the entire intensity of the label appears in three stable (at least for several hours) low-field signals: a quartet (q_1, $J=43$ Hz) at $\delta=101.5$, a sharp singlet (s) at $\delta=144.1$, and a second quartet (q_2, $J=40$ Hz) at $\delta=152.2$. Addition of methanol immediately quenches all three resonances. On warming to $-80\,^\circ C$, q_1 disappears in favor of q_2, which concomitantly becomes less structured: at $-70\,^\circ C$ only s is still present; its intensity decreases on further warming but reaches zero only at $-40\,^\circ C$[3]. Addition of methanol at $-70\,^\circ C$ to the solution displaying only the singlet does not lead to tribromomethane [*(1c)*, $\delta_{^{13}C}=9.7$]; the hydrolysis product characteristic[4] of tribromomethyllithium *(1b)* is formed only so long as the two other signals are visible.

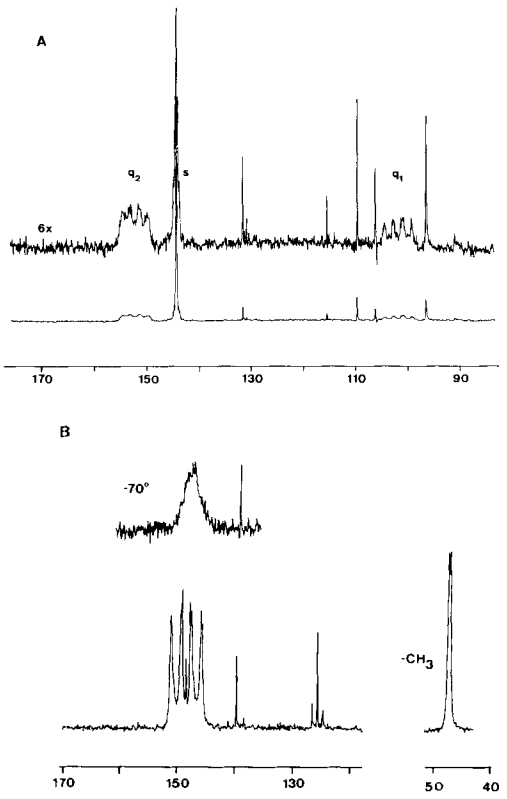

Fig. 1. ^{13}C-NMR spectra (H-decoupled) of solutions of *(1b)*, A, and *(2b)*, B, in THF/perdeuterio-THF (9:1) at $-100\,^\circ C$. As in the text, the shifts are given as δ values relative to TMS. Varian XL 100 spectrometer, FT mode.

Figure 1B shows the *sole* low-field signal obtained in the same way for 1,1,1-tribromoethane [*(2a)*, 90% $^{13}CBr_3$, 20% $^{13}CH_3$; produced from *(1b)* and labeled iodomethane]: it is a 45 Hz quartet having 8 Hz of fine structure ($J_{^{13}C^{13}C}$). As in the case of *(1b)*, warming to $-80\,^\circ C$ leads to a loss of structure; however, no singlet occurs even at high temperatures.

[*] Prof. Dr. D. Seebach, Dr. H. Siegel, K. Hiltbrunner
Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)

The signal can still be observed—with reduced intensity—at $-40\,^{\circ}C$. On renewed cooling to $-100\,^{\circ}C$ it reassumes a quartet structure. *(2b)* reacts with methanol to give 1,1-dibromoethane *(2c)*.

Br_3CR CH_3-CBr_2R

(1) *(2)*

(a): R = Br, *(b)*: R = Li, *(c)*: R = H

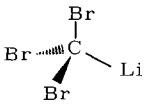

Table 1. Chemical shifts and coupling constants of *(2a)*—*(2c)*.

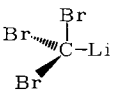
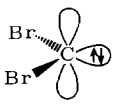
	δC^1	$J_{C,C}$ [Hz]	δC^2	$J_{C,H}$ [Hz]
(2a)	31.5	38	49.4	132
(2b)	147.0	8	45.4	127
(2c)	40.1	37	31.8	180 (C^1)
				131 (C^2)



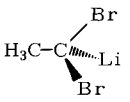
As with the cyclopropylidene derivatives[2], the ^{13}C-NMR signals of the bromolithiocarbenoids *(1b)* and *(2b)* presently being studied appear at *unexpectedly low field:* replacement of H by Li in tribromomethane and of Br by Li in tetrabromomethane causes a downfield shift (q_2) of $\Delta\delta = 142$ and 182 (Table 1 lists the data of the ethanes recorded in THF).

Three species are present in the solution of *(1b)*. As with *(2b)*, two of them show a 1:1:1:1 quartet coupling with one ^7Li atom (nuclear spin $^3/_2$). This is the first proof of non-ionized *organolithium compounds* which are *monomeric* on the NMR time scale. The coupling constants $J_{^7Li,^{13}C}$ of 40—45 Hz are *three to four times greater* than for RLi aggregates[5]; on the other hand, the C-C coupling constant falls from a value lying in the typical sp^3-sp^3 range (30—40 Hz) to about one fifth of that value (smallest $J_{^{13}C,^{13}C}$ ever measured in an ethane) on going from the haloalkane *(2a)* to the carbenoid *(2b)*[6].

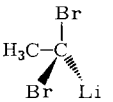
Shifts and coupling constants indicate unusual bonding. It follows from the loss of quartet structure on warming (cf. also[2]) that the C–Li bond participates in faster and faster dynamic processes on the NMR time scale.



(3a)



(3b)



(3c)

(3d)

(4b)

The quartet signal q_1 of *(1b)* could be assigned to a normal tetrahedral structure *(3a)* with strongly polarized Br–C bonds; the greater downfield shift of the thermally more stable q_2 species could be explained in terms of structures such as *(3b)* or *(3c)*, in which stepwise[7] release of LiBr from the carbenoid C atom has led to a distortion towards sp^2 geometry, *(3b)*, or to a linear arrangement[8], *(3c)*, in which a bromide ion has migrated from the carbon to the lithium. *(3b)* and *(3c)* may be regarded as LiBr complexes of dibromocarbene *(3d)*, to which we assign the no longer Li-coupled s signal[9]. A much smaller shift is expected for free tribromomethyl anion or an O ylide[9a,10]. The loss of the s species by reaction between -70 and $-40\,^{\circ}C$ is compatible with the observation[4] of an exothermal reaction[11] in this temperature range.—Assuming the "normal" rules to apply, then the small C-C coupling constant of the ethane derivative *(2b)* indicates that the tetrahedral geometry *(4a)* is so distorted at the carbenoid center, see *(4b)*, that the C–C bond assumes considerably enhanced p character.

[11] Besides insoluble carbon-like solids, we found the reaction products to contain the dimer of *(3d)*, tetrabromoethylene.

Detonation of Benzyl(triethyl)ammonium Permanganate

By *Horst Jäger, Johann Lütolf*, and *Max W. Meyer*[*]

When preparing benzyl(triethyl)ammonium permanganate *(1)* according to a recently published precedure[1] we witnessed a violent explosion on drying the crystalline compound at $80\,^{\circ}C/1$ torr.

The data given by *Schäfer et al.*[1] on the oxidation of hydrocarbons with *(1)* could be confirmed experimentally, but the data regarding the stability and shock resistance of this reagent are inconsistent with our observations.

[*] Dr. H. H. Jäger, J. Lütolf, Dr. M. W. Meyer
Ciba-Geigy AG, CH-4002 Basel (Switzerland)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/1010-0786 $ 02.50/0

On warming at a rate of 4 °C/min in a sealed testing vessel (Mettler thermoanalyzer TA 2000) benzyl(triethyl)ammonium permanganate explodes violently at *ca.* 120 °C with liberation of about 350 kJ/mol heat. The compound also decomposes violently at lower temperatures, but only after expiration of a certain induction time dependent upon the temperature (autocatalytic decomposition)—*e.g.* 2g-amounts of *(1)* in an open vessel ignite spontaneously after 14 h at 60 °C, or after only 28 min at 90 °C. At 50 °C no measurable exothermic reaction could be observed within 92 h.

Benzyl(ethyl)ammonium permanganate is sensitive to impact (class 3; 49 Nm).

It is recommended that benzyl(triethyl)ammonium permanganate should not be kept in storage and that room temperature should not be exceeded on drying it *in vacuo*[2].

Stability of Benzyl(triethyl)ammonium Permanganate

By *H.-Jürgen Schmidt* and *Hans J. Schäfer*[*]

We recently reported on the oxidation of hydrocarbons and ethers with benzyl(triethyl)ammonium permanganate *(1)*[1]. Crystalline *(1)* is less stable than we assumed on the basis of our previous observations—insensitive to hammer blows, stable on heating for 5 minutes to 100 °C[1]. We confirm the findings of *Jäger et al.*[2] regarding the thermal instability and sensitivity to shock and support their recommendations[2] for the handling of this reagent.

Benzyl(triethyl)ammonium permanganate decomposes violently after 7 min at 100 °C, and explodes after 25 min at 90 °C or 90 min at 80 °C. On thermal decomposition in a steel cylinder with a jet diameter of 2 mm (using the procedure for testing thermal sensitivity by heating sample in steel cylinders, as developed by the Materials Research Establishment of the Federal Republic of Germany)[3] the steel casing is shattered. The violet salt *(1)* is sensitive to heavy blows (30 Nm)[3].

300 g of benzyl(triethyl)ammonium permanganate, prepared from benzyl(triethyl)ammonium chloride[4] (m.p. 198—199 °C, from ethyl acetate/methanol) and commercially available potassium permanganate, has been dried over Sicapent (Merck) by us for 1 week at 40 °C.

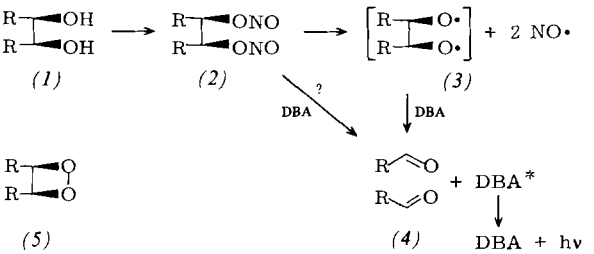
Preparation and Chemiluminescence of *cis*-1,2-Cyclobutylene Dinitrite[**]



By *Nobutaka Suzuki*[*]

Two alternative mechanisms have been proposed for the chemiluminescence of simple 1,2-dioxetanes: the concerted (Route A) and the stepwise (radical) mechanism (Route B, C)[1].

Since organic nitrites react *via* radical intermediates[2] they should permit investigation of the chemiluminescence mechanism of 1,2-dioxetanes with 1,2-dinitrites. We have prepared the dinitrite *(2a)* (in spite of its extreme instability to hydrolysis) and the dinitrites *(2b)* and *(2c)* and tested their chemiluminescence in the presence of sensitizers. A solution of *(2)* (1.7×10^{-2} M) and 9,10-dibromo- or 9,10-diphenylanthracene (DBA or DPA: 1×10^{-4} to 2×10^{-2} M) in 2 ml DMSO (dried over CaH_2) under argon showed a weak light emission when heated to 140 °C; the maximum quantum yield of chemiluminescence was *ca.* 10^{-6} einstein/mol[2]. The identity of the aldehyde *(4)* formed on heating was confirmed by GLC, IR and ^{1}H-NMR spectroscopy on authentic samples.

The emission of light, though small, during thermal decomposition of *(2)* to *(4)* is an interesting phenomenon. Thus, *(2)* directly yields an electronically excited aldehyde *(4*)*, or it initially forms a diradical *(3)*, which then transforms into the electronically excited aldehyde *(4*)*[3]. These results suggest that most of the light emission from the 1,2-dioxetane *(5)* corresponding to the dinitrite *(2)* may be produced by the concerted mechanism, and not by the diradical mechanism.

(a), –R–R– = $-(CH_2)_2-$; *(b)*, –R–R– = $-(CH_2)_4-$; *(c)*, R = CH_3

Experimental

The dinitrites *(2)* are prepared under argon as follows: A solution of *(1)* (10.2 mmol) in saturated aqueous $NaNO_2$ (10 ml) is cooled in an ice/salt bath (−7 to −10 °C). Concentrated HCl (1.6 ml, 19.4 mmol; ρ = 1.187) is then added by means of an injector with a Teflon needle at such a rate that the temperature of the reaction mixture does not exceed

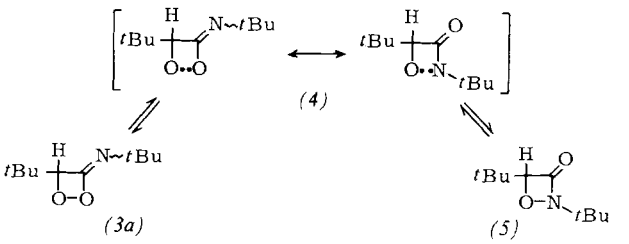
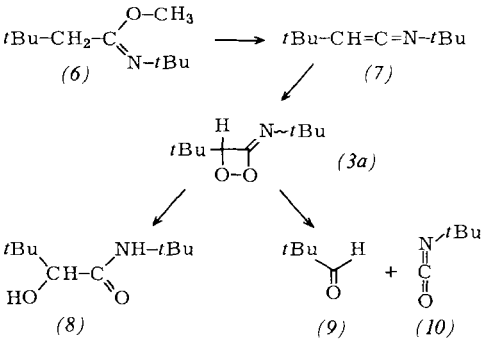
A 3-Imino-1,2-dioxetane *via* Singlet Oxygenation of a Ketenimine[**]



By *Waldemar Adam, Ottorino De Lucchi, Helmut Quast, Rautgundis Recktenwald*, and *Faris Yany*[*]

The synthesis of stable 1,2-dioxetanes *(1)* has been abundantly documented and extensively utilized for the mechanistic exploration of chemi-energized electronic excitation[1]. The considerably less stable α-peroxylactones *(2)*, which are

(1) *(2)* *(3)*



the postulated reaction intermediates in luciferin bioluminescence, produce electronic excitation through the novel electron exchange mechanism (CIEEL, *i.e.* chemically initiated electron exchange luminescence)[2]. They have also been isolated and characterized. We have now synthesized and characterized 4-*tert*-butyl-3-*tert*-butylimino-1,2-dioxetane *(3a)* as the first compound of type *(3)*. Besides assessing its thermal stability and chemi-energization efficiency, we thought that *(3a)* might isomerize to *(5)*; this reaction would proceed *via* the elusive 1,4-dioxyl radical *(4)*[3].

(4) *(3a)* *(5)*

Heating of the *N*-*tert*-butyl imidate *(6)* together with an excess of methyllithium in ether or *tert*-butyllithium in hexane effected demethanolation, affording high yields of the ketenimine *(7)*[4]. Tetraphenylporphyrin-sensitized photo-oxygenation of *(7)* (0.02 M solution in $CFCl_3$, CH_2Cl_2, or xylene at $-78\,^{\circ}C$, 150-W sodium street lamp, continuous purging with a slow stream of dry oxygen) led to complete consumption of *(7)* within 50 min.

Subambient ^{1}H-NMR monitoring confirmed the presence of a thermally labile product, which exhibited proton resonances at $\delta = 1.22$ (9H, s), 1.60 (9H, s), and 5.59 (1H, s), consistent with structure *(3a)*. On warm-up to *ca.* $30\,^{\circ}C$, the sole products were 2,2-dimethylpropanal *(9)* and *tert*-butyl isocyanate *(10)*. So far we have no evidence for formation of the oxazetidinone *(5)*[5]. On flash distillation of a CH_2Cl_2 solution, the iminodioxetane *(3a)* codistilled with the solvent, showing that a monomeric material was on hand; however, extensive decomposition into aldehyde and isocyanate occurred. Isolation of *(3a)* in pure form was not attempted in view of its inherent explosive nature. Iodometric titration confirms that *(3a)* is formed in *ca.* 95% yield. Reaction with NaI in acetone/acetic acid gave the expected *N*-*tert*-butyl 2-hydroxy-3,3-dimethylbutyramide *(8)*[6].

(6) *(7)* *(3a)* *(8)* *(9)* *(10)*

These experimental facts clearly establish the proposed 3-imino-1,2-dioxetane structure *(3a)* for the singlet oxygenation product of the ketenimine *(7)*. Furthermore, although no direct chemiluminescence could be observed in the decomposition of *(3a)*, in the presence of fluorescers such as rubrene, pyrene, 9,10-diphenyl- or 9,10-dibromoanthracene, appreciably enhanced chemiluminescence was detected. In view of the thermal instability of *(3a)* (half-lives are of the order of a few seconds at $0\,^{\circ}C$), it was difficult to quantitatively estimate the singlet and triplet excitation yields[8]. However, our qualitative observations reveal that the excitation yields are much lower (*ca.* 1000-fold) than those ob-

served for the α-peroxylactones *(2)* and that the electron exchange mechanism does not operate[2].

On the basis of our preliminary results, we conclude that the 3-imino-1,2-dioxetanes *(3)* are thermally much less stable than the α-peroxylactones and are inefficient sources for chemi-energizing electronically excited products. In this context, it is of interest that the 3-imino-1,2-dioxetanes *(3)* derived from *N*-phenyl- and *N*-*p*-tolyl-diphenylketenimines and *N*-*p*-tolyl-*tert*-butylketenimine *via* singlet oxygenation were too unstable for ^{1}H-NMR observation even at −60 °C; only the carbonyl compound and isocyanate produced by fragmentation could be detected.

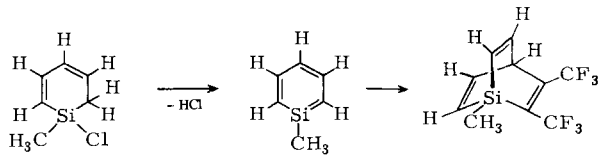
1,4-Di-*tert*-butylsilabenzene: Generation and Trapping Reactions

By *Gottfried Märkl* and *Peter Hofmeister*[*]



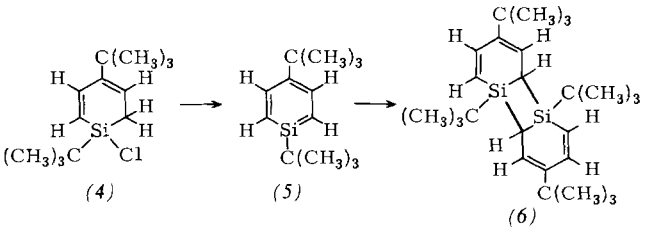
Now that the heteroatom homologues of pyridine have proved to be stable aromatic compounds, increasing attention is being turned to the question whether the higher homologues of benzene, *i. e.* silabenzene and germabenzene, are capable of existence.

Theoretical calculations on silabenzene have been performed by *Dewar et al.* (MINDO/3)[1], by *Schlegel et al.* (*ab initio*, GAUSSIAN 70 and FORCE program, STO 3G basis set)[2], and by *Blustin* (*ab initio*, Frost's Floating Spherical Gaussian Orbital (FSGO) Model)[3]. These studies give values of bond lengths and angles showing some degree of divergence; calculations by *Dewar et al.* and *Schlegel et al.* show silabenzene to have a singlet ground state and an aromatic stabilization energy of an order comparable with that of benzene.

According to the *ab initio* calculations, silabenzene exhibits strong polarization with a low electron density on silicon and an enhanced electron density in positions 2, 4, and 6—as expected from the electronegativities $\chi_C = 2.50$ (2.55) and $\chi_{Si} = 1.74$ (1.90).

The problems encountered in the silabenzene system are therefore due mainly to its pronounced electrophilic reactivity, arising from the δ^+ character of silicon. The silabenzene ring must be synthesized under conditions avoiding the presence and/or formation of nucleophiles capable of addition to the Si=C bond.

Barton et al.[4] have presented evidence supporting the formation of 1-methyl-1-silabenzene *(2)*, on elimination of HCl from *(1)* with the sterically hindered base $LiN(Si(CH_3)_3)_2$, by trapping of *(2)* with hexafluoro-2-butyne to give the 1-silabarrelene derivative *(3)*.

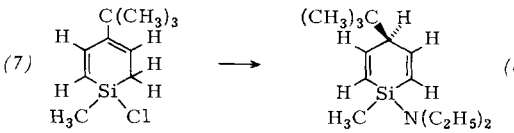


(1) *(2)* *(3)*

Simultaneous formation of 1-[*N*,*N*-bis(trimethylsilyl)amino]-1-methyl-1-sila-2,4-cyclohexadiene suggests that the elimination is accompanied by substitution at the silicon atom.

Starting from 1,1-di-*n*-butyl-4-*tert*-butyl-4-methoxy-1,4-dihydrostannin, we have prepared 1,4-di-*tert*-butyl-1-chloro-1-sila-2,4-cyclohexadiene *(4)* by a method resembling one which we recently described[5].

The sole product of reaction, apart from LiCl, of *(4)* with lithium diisopropylamide in *n*-pentane at 0 °C is a colorless crystalline compound, m.p. 204 °C, shown by analytical and spectroscopic data (Tables 1 and 2) to be the dimeric silabenzene *(6)*, having a 1,3-disilacyclobutane structure, which was predicted by *Dewar et al.*[1].



(4) *(5)* *(6)*

Is 1,4-di-*tert*-butylsilabenzene *(5)* an intermediate of dimer formation?

No diisopropylamine substitution product is formed on hydrogen chloride elimination; in contrast to the case with *(1)*, the steric effect of the *tert*-butyl group attached to silicon prevents both substitution of *(4)* by $LiN(iPr)_2$ and the conceivable addition of $LiN(iPr)_2$ or $HN(iPr)_2$ to the Si=C double bond of *(5)*.

This result rules out formation of *(6)* by a pathway other than dimerization of intermediate silabenzene *(5)*. The Si—C double bond of *(5)* thus behaves in an entirely analogous manner to silaethenes, which likewise dimerize to 1,3-disilacyclobutanes[6].

Support for elimination of HCl from *(4)* to give *(5)* is also provided by the reaction of 4-*tert*-butyl-1-chloro-1-methylsila-2,4-cyclohexadiene *(7)* with lithium diethylamide which, in contrast to *(4)*, gives almost exclusively the substitution product, which then isomerizes to the 2,5-diene *(8)*.

(7) *(8)*

Formation of *(5)* from *(4)* is proved just as unequivocally by the reaction of *(4)* with $LiN(iPr)_2$ in *n*-pentane in the presence of 1,3-dienes (1,3-butadiene, isoprene, 2,3-dimethyl-1,3-

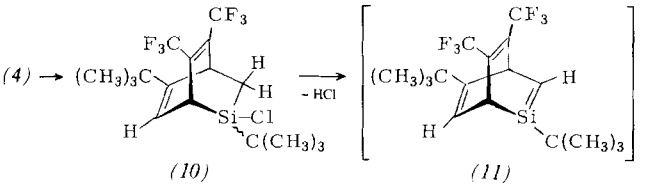
butadiene) at 0 to −20 °C. Given a large excess of diene (diene/*n*-pentane = 1:1 v/v), the [4+2]cycloadducts *(9)* are obtained; dimerization of *(5)* to *(6)* can be completely suppressed under these conditions.

The Diels-Alder adducts *(9)* are identified by analytical and spectroscopic data (Table 1). On electron impact induced retro-Diels-Alder reaction, the adducts form the silabenzene derivative *(5)* with high intensity (Table 2).



(9a), R = R' = H; *(9b)*, R = H, R' = CH_3; *(9c)*, R = R' = CH_3

The silabenzene *(5)* reacts as a dienophile towards 1,3-dienes and therefore resembles silaethenes in its chemical behavior; trapping reactions with 2,3-dimethyl-1,3-butadiene have been described for the latter[7].

Attempts to trap 1,4-di-*tert*-butylsilabenzene *(5)* as a diene (with inclusion of the Si=C bond) by reaction with dienophiles—by analogy with formation of 1-silabarrelene *(3)*[4]—have so far been unsuccessful.

In the presence of *(4)* the dienophile hexafluorobutyne reacts immediately, even at −100 °C, with $LiN(iPr)_2$ [or $LiN(Si(CH_3)_3)_2$] to give brown insoluble products, and the starting material *(4)* is recovered. Reactions of *(4)* with lithium amides in the presence of diethyl acetylenedicarboxylate, azodicarboxylic esters, and 2-butyne follow a similar course.

Steric hindrance could be responsible for the complete failure of attempts to trap *(5)* with alkyne dienophiles, which

(10) *(11)*

contrasts with the results of *Barton et al.*[4]; however, *(4)* does react smoothly at 60—100 °C with hexafluorobutyne to give the 2,3-dihydro-2-silabarrelene derivative *(10)* which can be dehydrochlorinated with $Li(iPr)_2$ to the spontaneously dimerizing 2-silabarrelene derivative *(11)*.

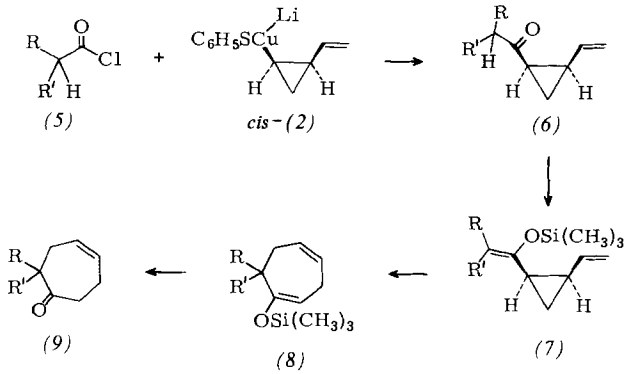
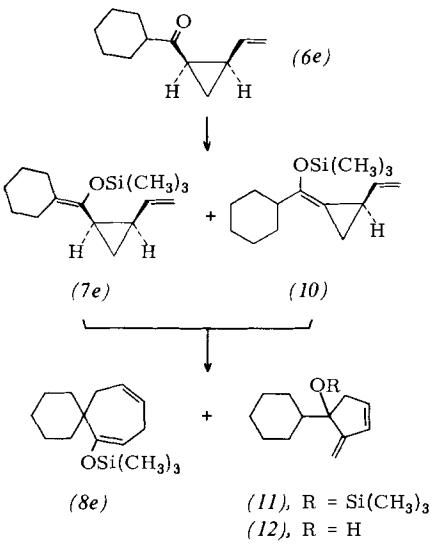
Synthesis of *cis*-2-Vinylcyclopropyl Ketones; a New Synthesis of 4-Cycloheptenones[**]



By *Edward Piers* and *Hans-Ulrich Reissig*[*]

Although the thermal (Cope) rearrangement of 1,2-divinylcyclopropane systems has been studied quite extensively from a mechanistic point of view[1], it is only recently that this type of transformation has been investigated with synthetic methodology in mind[2]. Our previous work in this area involved the development of new seven-membered ring annelation processes, in which the key steps entailed thermal rearrangement of α,β-unsaturated β-(2-vinylcyclopropyl) ketones[2b-d]. The latter compounds were prepared by reaction of β-iodoenones with lithium phenylthio(2-vinylcyclopropyl)cuprate reagents. For example, treatment of *(1)* with the cuprate *(2)* (mixture of epimers), followed by thermal rearrangement of the initially formed products *(3)*, yielded spiro[4,6]-undeca-6,9-dien-1-one *(4)* (84%)[2b].

(1) *(3)* *(4)*



We report here on a potentially important extension of this type of methodology, involving (a) the reaction of acyl chlorides *(5)*[3] with *cis-(2)* to produce the ketones *(6)*, (b) the conversion of *(6)* into silyl enol ethers *(7)*, and (c) the thermal rearrangement of *(7)* into the cycloheptadiene derivatives *(8)*. The silyl enol ether moiety in the rearrangement products *(8)* can be removed by hydrolysis [to give the cycloheptenones *(9)*]; it should be noted however that this functionality is itself synthetically very versatile[4] (see experimental procedure).

(5) *cis-(2)* *(6)* *(7)* *(8)* *(9)*

(a), R R′ = $-(CH_2)_3-$; *(b)*, R—R′ = $-(CH_2)_4-$; *(c)*, R,R′ = H, n-C_4H_9; *(d)*, R,R′ = H, C_6H_5; *(e)*, R R′ = $(CH_2)_5$

Although conversion of *(5e)* into *(6e)* can also be carried out smoothly and efficiently (87% yield), subjection of *(6e)* to the lithium diisopropylamide/trimethylsilyl chloride sequence produces, in addition to the expected product *(7e)*, the isomer *(10)* (*ca.* 1:1)[8]. Thermolysis (150 °C, 30 min) of the mixture leads to *(8e)* + *(11)*[9], and hydrolysis to *(9e)* + *(12)* (*ca.* 4:3).

(6e) *(7e)* *(10)* *(8e)* *(11)*, R = $Si(CH_3)_3$ *(12)*, R = H

Experimental

Reduction of 1,1-dibromo-2-vinylcyclopropane[5] with zinc in ether/acetic acid affords a mixture (47%) of *cis*- and *trans*-1-bromo-2-vinylcyclopropane (ratio 5:1, respectively), from which the pure *cis* isomer[2e,6] can be isolated by column chromatography (silica gel). Treatment of the *cis* isomer with 1.1—1.2 equivalents of *tert*-butyllithium in ether (−78 °C, 2 h), followed by successive addition of tetrahydrofuran (THF) and copper benzenethiolate[7] (1 equivalent) affords a reddish-brown solution of *cis-(2)*. When the latter is allowed to react with 0.66 equivalents of *(5a)* (−78 °C, 5 min; −20 °C, 1 h; 20 °C, 1 h), the ketone *(6a)* is obtained in 93% yield. Conversion of *(6a)* into *(7a)* ($LiN(iPr)_2$, THF, −78 °C; $(CH_3)_3SiCl$, $(C_2H_5)_3N$, −78 °C to +20 °C), followed by thermal rearrangement (neat, 100—110 °C, 30 min) of *(7a)*, affords 5-(trimethylsiloxy)spiro[3.6]deca-5,8-diene *(8a)* (87%). Hydrolysis (1 N HCl in methanol, 20 °C, 1 h) of this material gives the corresponding ketone *(9a)* (91%) in 74% overall yield. *(5b)*—*(5d)* react in a very similar fashion; the overall yields are 70, 74 and 29%, respectively.

Phase Transfer Catalyzed Synthesis of Ferrocene Derivatives[**]

By *MartaAlišová* and *Howard Alper*[*]

Phase transfer catalysis[1] is a valuable synthetic technique in transition metal organometallic chemistry, both for stoichiometric[2] and catalytic[3] reactions. This communication describes the first synthesis of metallocenes by phase transfer catalysis. This reaction proceeds rapidly, and occurs under very gentle conditions; it is also exceedingly simple, both in execution and work-up. Furthermore, the use of metallic sodium or potassium normally required to generate the cyclopentadiene anion is unnecessary, and rigorously dry conditions are not necessary either.

(a), R = H; *(b)*, R = CH_3; *(c)*, R = $C_6H_5CH_2$; *(d)*, R = n-C_3H_7; *(e)*, R = c-C_6H_{11}

Treatment of a tetrahydrofuran solution of cyclopentadiene *(1a)* with potassium hydroxide, ferrous chloride, and [18]crown-6 as the phase transfer catalyst (room temperature, one hour) affords ferrocene *(2a)*; the yield is 60%. Similar reaction of the substituted cyclopentadienes *(1b)—(1e)* gave the corresponding 1,1′-disubstituted ferrocenes *(2b)—(2e)* (in 45, 55, 40, and 65% yields, respectively). The physical data (m.p. or b.p., IR, NMR, and mass spectra) are in excellent accord with those given in the literature[4]. Other crown ethers (*e.g.* dibenzo[18]crown-6) may also be used, but work-up of the reaction is not as simple as with [18]crown-6. Less than 12% ferrocene was formed when the reaction of cyclopentadiene with ferrous chloride and potassium hydroxide was effected in the absence of the crown ether catalyst. The yields of ferrocenes obtained by the solid/liquid phase transfer reaction described above are much higher than the yields realized using liquid/liquid phase transfer catalysis [*(1)*, aqueous NaOH, $FeCl_2$, benzene, $PhCH_2N(C_2H_5)_3^+Cl^-$].

Procedure

To a tetrahydrofuran solution (60 ml) of *(1a)* (30 mmol) was added [18]crown-6 (15 mmol) followed by potassium hydroxide (2.5 g). After stirring the solution for 15 minutes, ferrous chloride (15 mmol) was added portionwise (over 5 minutes) and the resulting mixture was stirred vigorously for 25—40 min. The solution was transferred to a separatory funnel containing water and benzene. The benzene layer was washed with water, dried ($MgSO_4$), and concentrated to give the crude metallocene *(2a)*. Pure metallocene was then obtained by crystallization or by chromatography (Al_2O_3, hexane/benzene 5:1).

Regiospecific Nucleophilic Attack at the γ-Position of 1-(2,6-Dimethyl-4-oxo-1,4-dihydro-1-pyridyl)pyridinium Compounds; Novel Synthesis of 4-Substituted Pyridines[**]

By *Alan R. Katritzky, Hector Beltrami, James G. Keay, David N. Rogers, Michael P. Sammes, Christopher W. F. Leung,* and *Cheuk Man Lee*[*]

We designed the substituent 2,6-dimethyl-4-oxo-1,4-dihydro-1-pyridyl [see *(1)*] which (i) could be attached to a pyridine nitrogen in two high-yield stages[1a], (ii) sterically shields the α-positions while activating the γ-position to nucleophilic attack [*(1)*→*(2)*], and (iii) then acts as a leaving group to rearomatize the 4-substituted dihydropyridine ring [*(2)*→*(3)*]. The success of this strategy was illustrated by the preparation of a series of 4-arylpyridines using Grignard reagents as the attacking nucleophile[1b]. We have now considerably extended this work and here illustrate the scope of application of the method to carbon, sulfur and nitrogen nucleophiles by reference to the novel preparations of five classes of compounds [*(3a)—(3e)*].

(a), Nu = Alkyl; *(b)*, Nu = CRR′COAlkyl; *(c)*, Nu = CRR′NO_2; *(d)*, Nu = SAlkyl or SAryl; *(e)*, Nu = 1-benzimidazolyl or 1-benzotriazolyl

[**] Synthetic Applications of N ·N Linked Heterocycles, Part 6.—Part 5: see Ref. [1b].

a) 4-Alkylpyridines (3a): The cation *(1)* reacts with ethyl-, *n*-propyl-, isopropyl-, and *n*-butylmagnesium bromide directly [without isolation of the intermediate *(2a)*] to give the corresponding 4-alkylpyridines *(3a)* (average yield 82%). Other methods for the synthesis of *(3a), e.g.* by alkylation of 4-picoline[2], from 4-cyanopyridine *via* ketones[3] or according to *Arens'* procedure[4] are less generally applicable, tedious, and/or give poorer yields.

b) α-(4-Pyridyl)alkyl ketones (3b): Addition of the salt *(1)* to the lithium enolates of ketones in tetrahydrofuran gives the corresponding dihydro-intermediates *(2b)* which can be isolated by chromatography on Al_2O_3[5]. On boiling under reflux in CCl_4 in the presence of azobis(isobutyronitrile), the intermediates *(2b)* are decomposed in high yield into a readily separable mixture of *(3b)* and *(4)*. In this way *inter alia* diethyl ketone, methyl isobutyl ketone, pinacolone, benzyl methyl ketone, cyclohexanone, 2-methylcyclohexanone, cycloheptanone, acetophenone, and propiophenone were converted into *(2b)* and *(3b)*: average yields 81% and 85%, respectively. Previously the only practical route to *(3b)* has been the acylation of 4-alkylpyridines[6]; this restricts considerably the type of compound that can be prepared.

c) 4-(α-Nitroalkyl)pyridines (3c): Sodium derivatives of nitroethane, 2-nitropropane and 2-nitro-1-phenylpropane react with *(1)* in ethanol to give the intermediates *(2c)* (average yield 85%). Photolysis of *(2c)* in $CHCl_3$ in the presence of benzoyl peroxide gives *(3c)* (average yield 52%). Previous methods for the synthesis of *(3c)* involved nitration of alkylpyridines under acidic[7a] or basic conditions[7b]. The yields are usually 50—70%; a prerequisite, however, is that the corresponding 4-alkylpyridine must be available.

d) 4-Alkylthio- and 4-arylthio-pyridines (3d): The anions benzyl-, ethoxycarbonylmethyl-, furfuryl-, and *p*-chlorophenyl-thiolate in aqueous solution react with *(1)* to give the intermediates *(2d)* (average yield 72%). Decomposition of these adducts in refluxing carbon tetrachloride, with or without the addition of a free radical initiator gives *(3d)* (average yield 90%).

e) 4-(1-Benzimidazolyl)- and 4-(1-benzotriazolyl)pyridines (3e): The anions of benzimidazole and benzotriazole add in acetonitrile to *(1)* to give *(2e)* (average yield 74%). Photolytic decomposition in $CHCl_3$ in the presence of benzoyl peroxide and subsequent chromatography (Al_2O_3-$CHCl_3$) give *(3e)* (average yield 65%). Compounds of this type have been previously prepared by diverse methods which suffer from the number of stages involved, lack of generality, and/or poor yields, and all require 4-substituted pyridines as starting materials[8].

The method described here is of considerable potential for the synthesis of a wide variety of 4-substituted pyridines. Compounds of the type *(3a)*[9], *(3b)* and *(3c)*, bearing a 2- and/or 3-methyl group in the pyridinium ring, have already been obtained. In none of the reactions presently reported was any 2-substitution detected. Harder nucleophiles, however, attack at the α-position[10].

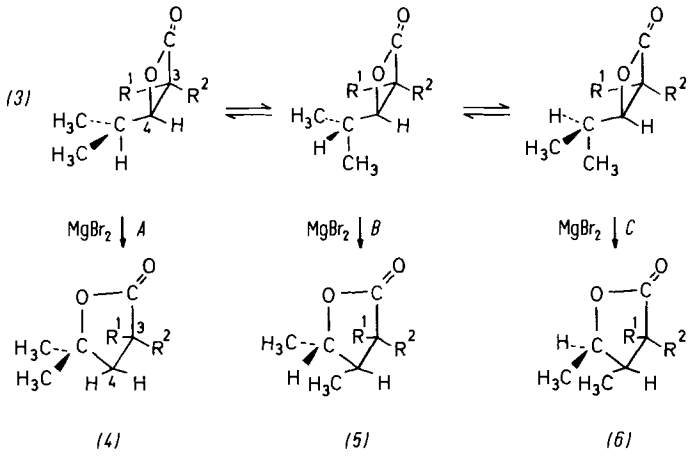
Stereospecific Synthesis of γ-Lactones by Dyotropic Wagner-Meerwein Rearrangement

By *Johann Mulzer* and *Gisela Brüntrup*[*]

The enormous relief of strain on going from a four- to a five-membered ring (*ca.* 22 kcal mol^{-1})[1] and the resulting driving force for ring expansion has so far been exploited only for the synthesis of carbocyclic compounds[2]. We report the ring expansion of 2-oxetanones (β-lactones) like *(1)* and *(3)* to 2-oxolanones (γ-lactones) like *(2)* and *(4)*—*(6)*. This isomerization, which is initiated by ethereal $MgBr_2$ and proceeds in a manner formally resembling a Wagner-Meerwein rearrangement[3], is of preparative interest because (i) it is quantitative, stereospecific, and can be run under extremely mild conditions; (ii) the required β-lactones are readily prepared in sterically pure form, *via* the 3-hydroxycarboxylic acids, from aldehydes and carboxylic acids[4]; and (iii) γ-lactones are of great importance in synthetic, analytical, and natural products chemistry.

(1) *(2)*



Scheme 1. R^1, R^2, see Table 1.

The steric course of the rearrangement of 4-*tert*-butyl-β-lactones *(1)* is shown in Scheme 1. The migrating CH_3 group and the C–O bond to be broken are in *anti* position, as is often observed in Wagner-Meerwein rearrangements[3]; as a result the configuration at the 3,4 bond is retained. The same stereospecificity is observed in the case of the 4-isopropyl-β-lactones *(3a)* and *(3b)* (Scheme 2). However, two additional problems are encountered: (i) CH_3- or H shift and (ii) control over the new chiral center at C-5. The three reaction pathways conceivable for *(3a)* and *(3b)*, *i.e. A* (H shift), *B* and *C* (CH_3 shift), are shown in Scheme 2. The relative contribution of *A, B,* and *C* is highly dependent upon the configuration of *(3)*. In the *trans* derivative *(3a)* the isopropyl group has almost unrestricted conformational mobility, and H shift predominates in this case (78% *A*). In the *cis*-lactone *(3b)*, however, steric hindrance occurs between the 3-phenyl and an isopropyl methyl group in the case of pathways *A* and *B*. Thus route *C* is adopted to an extent of >98% (TLC analysis), and *(6b)* is formed exclusively. Hence in this rearrangement all three stereocenters of the resulting γ-lactone are under complete control.

The stereospecificity of the ring expansion with respect to the C^3–C^4 axis is incompatible with a classical Wagner-

(6a) [b]	H	C_6H_5	90—100/0.1	1770
(6b)	C_6H_5	H	90—100/0.1	1770

[a] Yield 94—98%; all compounds gave correct CH analyses. The configurational assignment of the γ-lactones was based on ^{1}H-NMR spectra; thus we found that in *cis-trans* isomeric γ-lactones always $J_{3,4\text{-}cis} < J_{3,4\text{-}trans}$ and $\tau(cis\text{-}4\text{-}CH_3) > \tau(trans\text{-}4\text{-}CH_3)$. Cf. also *D. Sawostianoff, M. Pfau,* Bull. Soc. Chim. Fr. *1967*, 4162.

[b] Yield *(4a)* + *(5a)* + *(6a)* = 97%.

Meerwein carbenium-ion mechanism because such a process should involve at least partial rotation about the C^3—C^4 bond in the case of the *cis*-lactones *(1b)* and *(3b)*. We therefore assume that ring opening and migration of CH_3 or H are part of a concerted dyotropic rearrangement[5]. This assumption is further supported by two experimental results: (i) the reaction of *(1a)* with isopropylmagnesium bromide gives not only the Grignard adduct at the carbonyl group (5-hydroxy-2,6,6-trimethyl-4-phenyl-3-heptanone) but also considerable amounts of *(2a)*. The $MgBr_2$ generated in the Schlenck equilibrium[6] initiates the ring expansion of *(1a)*; if a carbenium ion were an intermediate it should be trapped by the organometallic species. (ii) In the reaction of 1 equiv. of $MgBr_2$ with *cis*-3-methyl-4-phenyl-2-oxetanone ring expansion cannot occur; instead, decarboxylation gives a quantitative yield of *trans*-1-phenylpropene. The carbenium ion apparently formed in this case decomposes *via* rotation and CO_2 elimination, *i.e.* reactions which are not observed with ring-expanding β-lactones.

Procedure

3.2 M $MgBr_2$-ether (1.55 ml, 4.9 mmol) is added to a water-cooled stirred solution of *(1a)* (1.00 g, 4.90 mmol) in anhydrous ether (10 ml). After 5 min, water (10 ml) is added and crystalline *(2a)* (98%) is isolated from the dried ether phase.

Cobalt(I)-phthalocyanine Anion as Vitamin B_{12s} Model: Selectivity in Reactions with Electrophiles

By *Heiner Eckert* and *Annette Schier*[*]

In order to understand vitamin B_{12}-catalyzed reactions[1,2] and to ascertain the scope of the cobalt(I)-phthalocyanine anion $[Co^IPc]^-$ as a stable reagent in synthetic chemistry (protecting group technique for syntheses of peptides[3a] and β-lactam antibiotics[3b], intermediate in the production of blue dyes[3c]), it is important to know the selectivity of this anion towards functional groups. Owing to the extremely high reactivity of cobal(I)amine[4] and its model compounds cobal(I)oxime[4] and $[Co^IPc]^-$[5] towards alkyl halides they are designated as "supernucleophiles".

We have now found that the cobalt(I)-phthalocyanine anion (as lithium salt $Li[Co^IPc]$) behaves as a supernucleophile in nucleophilic substitution of acyl compounds *(2a)* and *(2b)* (reaction *b*), while no nucleophilic additions (reaction *a*) were observed with carbonyl compounds *(1)*, including those with cumulated double bonds. Vinyl and aryl halides such as *(2c)* and *(2d)* do not undergo nucleophilic substitution (see Scheme 1 and Table 1).

Scheme 1. Reactions of compounds A with the cobalt(I)-phthalocyanine anion. See text for details.

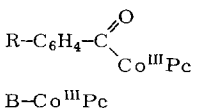
[a] Gravimetrically as Co^{II}Pc after air-oxidation. [b] See text. [c] Gravimetrically as n-butyraldehyde 2,4-dinitrophenylhydrazone together with 17% of 2-ethyl-2-hexenal 2,4-dinitrophenylhydrazone. [d] Gravimetrically as benzaldehyde 2,4-dinitrophenylhydrazone. [e] Neither A nor products thereof were detected. [f] 91% of triphenyl isocyanurate. [g] Volumetrically according to *Mohr*. [h] 8% of *(2b)* were isolated after 3 h, and 5% after 96 h. [i] Gravimetrically as benzoic acid. [j] Product mixture, principal component $C_6H_5\ NO$ (from IR). [k] Reduction products not yet elucidated. [l] MeCN as reactant and solvent.

(1a), *(1b)*, and *(1c)* do not react with [Co^{I}Pc]$^{-}$ according to path *a*, neither under standard conditions for aldol condensations and Michael additions nor on 48 h refluxing in methanol. The aldehydes can be recovered as 2,4-dinitrophenylhydrazones; *(1a)* forms 17% of the aldol condensation product within 144 h. Nor does a Cannizzaro reaction occur under these conditions—thus indicating the low basicity of the supernucleophile [Co^{I}Pc]$^{-}$. Only on reaction of benzaldehyde *(1b)* with [Co^{I}Pc]$^{-}$ in 1,4-butanediol (150—170 °C, 72 h) can 30% of benzyl alcohol be isolated.



Likewise, no addition (reaction *a*) to the cumulated double bonds of phenyl isocyanate *(1d)* and carbon dioxide *(1e)* took place; *(1d)* undergoes quantitative trimerization to triphenyl isocyanurate.

In contrast, [Co^{I}Pc]$^{-}$ reacts very fast with p-toluoyl chloride *(2a)* and benzoic anhydride *(2b)*, reaction with *(2a)* being at least 10^3 times faster than with *(2b)*. This behavior accords with the basicity of the leaving groups chloride and benzoate in an addition-elimination reaction. The acylated complexes p-toluoyl- and benzoyl-cobalt(III)phthalocyanine

(2)

(a), R = p-CH_3, X = Cl
(b), R = H, X = $OCOC_6H_5$

B–Co^{III}Pc

(type B–Co^{III}–Pc) have been characterized by elemental analysis and IR spectra (ν(C=O) = 1740 cm^{-1}). The complexes, LiCl, and Li-benzoate can be isolated in quantitative yield.

2-Bromoallyl benzoate *(2c)* and chlorobenzene *(2d)* are completely inert toward nucleophilic attack by [Co^{I}Pc]$^{-}$ and are recovered quantitatively. The fact that no substitution occurs at the sp^2 carbon is a further criterion for the S_N2 character of the nucleophilic substitution reactions of [Co^{I}Pc]$^{-}$ with alkyl halides[5b].

The acidic compounds phenol *(3a)* and diethyl malonate *(3b)* do not react according to path *c*, but can be recovered quantitatively.

Nitrobenzene *(4a)* is reduced very fast, according to reaction *d*, to nitrosobenzene, which itself, like 1-chloro-4-nitrosobenzene, can be slowly reduced further by [Co^{I}Pc]$^{-}$. The nitrile group in acetonitrile is not attacked by [Co^{I}Pc]$^{-}$.

The CoPc complexes were obtained in quantitative yields as organo-Co^{III}Pc (reaction *b*), or Co^{II}Pc (reaction *d*), or, after air-oxidation of the unchanged [Co^{I}Pc]$^{-}$, as Co^{II}Pc (non-occurrence of reactions *a* and *c*) in quantitative yield.

These results show that the cobalt(I)-phthalocyanine anion [Co^{I}Pc]$^{-}$ differs from cobal(I)amine[2,6] and other strong nucleophiles by not undergoing nucleophilic additions; instead, as far as has been determined, it reacts only *via* nucleophilic substitution, with the exception of the reduction of nitro- and nitroso compounds. Thus [Co^{I}Pc]$^{-}$ resembles nucleophiles such as I^{-} in its selective behavior, but is considerably more reactive (relative logarithmic nucleophilic character of I^{-}: $n = 7.42$[7]; that of [Co^{I}Pc]$^{-}$ is $n = 10.8$[5a]). [Co^{I}Pc]$^{-}$ is thus to be regarded as a very strong soft[7] nucleophile (high polarizability of the $3d_{z^2}$ orbital of Co^{I}) with low basicity.

The selectivity for substitution reactions together with the strong nucleophilicity, the low reduction potential (−0.37 V[8]), and the extremely high stability recommend use of cobalt(I)-phthalocyanine anion, in spite of its high molecular weight (571), as a reagent for removal of β-halogenated alkyl protecting groups from sensitive systems[3b,9] such as penicillin and cephalosporin derivatives[3b].

Isopropyl Carboxylates—A New Class of Insect Pheromones

By *Wittko Francke, A. R. Levinson, T.-L. Jen*, and *H. Z. Levinson*[*]

The hide beetle *Dermestes maculatus* (Deg.), which feeds on animal tissues and animal products both as larva and as imago, causes considerable damage to stored products[1]. We have identified the pheromone bouquet of this beetle as a basis for biotechnological pest control (see Table 1).

In an exocrine abdominal gland absent in females, sexually mature males produce a series of sex-specific volatile compounds showing high biological activity[2]. GC-MS studies on pentane extracts[3] of prepared glands were initially concerned with a group of four closely related substances. The most volatile component of this group ($M_r = 242$) has a molecular weight two units higher than that of the other three compounds, which are transformed into the first-mentioned one on catalytic hydrogenation.

The ions observed at $m/z = 102$ (14%) and 115 (11.5%) in the mass spectrum of this substance are typical products of a McLafferty rearrangement and, in conjunction with intense fragments at $M^+ - 41$ (22%) and $M^+ - 42$ (28.5%), indicate the propyl ester of a carboxylic acid with 12 carbon atoms[4]. In fact, isopropyl laurate showed the same gas chromatographic retention time as the natural product and an identical mass spectrum.

Thus it had also been established that the other three components must be unbranched isopropyl dodecenoates. The principal component was isolated by preparative gas chromatography[5] and afforded heptanal as the major product on micro-ozonolysis; synthetic isopropyl *Z*-5-dodecenoate proved to be identical with the natural product. Identification of the other two compounds of mass 240 as isopropyl *Z*-7- and *Z*-9-dodecenoate was accomplished by comparison of their gas chromatographic retention times and mass spectra[6] with those of authentic compounds prepared from the corresponding alkenols[7] by oxidation and esterification (see Table 1).

Table 1. Quantitative composition of the isopropyl ester pheromone bouquet of male hide beetle *Dermestes maculatus* (Deg.). The weights refer to an individual insect (total *ca.* 0.9 μg).

Carboxylic acid	Type	Weight [ng]
Lauric acid	C_{12}	*ca.* 2.5
Z-5-Dodecenoic acid	*Z*-5-C_{12}	300
Z-7-Dodecenoic acid	*Z*-7-C_{12}	1
Lauroleic acid	*Z*-9-C_{12}	*ca.* 0.1
Myristic acid	C_{14}	25
Z-5-Tetradecenoic acid	*Z*-5-C_{14}	50
Z-7-Tetradecenoic acid	*Z*-7-C_{14}	100

The Kováts indices $I_{WG11,\,150\,°C}$[8] of the isopropyl esters of all straight-chain dodecenoic acids are listed in Table 2: index differences of one unit can be distinguished on co-injection at comparable concentration; the working temperature must be reduced for smaller differences. It is seen that, on steady shift of the double bond from position 2 to 11, the initially more rapidly eluting *Z* compounds are "overtaken" by the *E* isomers. Isopropyl *Z*-6- and *E*-6-dodecenoate appear simultaneously; the ester of *Z*-5-dodecenoic acid is eluted faster than all other isopropyl dodecenoates.

Table 2. Kováts indices (*I*) of unbranched isopropyl dodecenoates on WG 11 at 150 °C [8].

E-4	1866	*Z*-7	1876	*E*-3	1885.5	*E*-2	1970

Four other sex-specific substances found in the glands of male hide beetles contained two CH_2 groups more than the compounds previously identified. Gas chromatographic retention times and mass spectra[6] were in agreement with synthetic samples of methyl myristate and isopropyl *Z*-5-, *Z*-7-, and *Z*-9-tetradecenoate.

In the same way the isopropyl esters of palmitic, palmitoleic, and oleic acids were also detected as male-specific components of the gland extract.

Table 1 shows a quantitative composition of this pheromone bouquet, which is the most extensive yet identified in beetles. A mixture of synthetic substances in the same ratio exhibited similar electro- and behavioral-physiological activities as did pentane extract of the abdominal glands of male hide beetles. The isopropyl carboxylates now found for the first time in insects thus constitute a new class of pheromones.

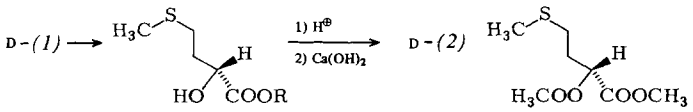
Enantioselective Synthesis of the Hydroxy-Analogues of D- and L-Methionine

By *Axel Kleemann, Bernd Lehmann,* and *Jürgen Martens*[*]

The calcium salt D,L-*(2)* of D,L-2-hydroxy-4-(methylthio)butyric acid ("hydroxy-analogue of methionine") is used, like D,L-methione D,L-*(1)*, for supplementing mixed feeds and for special diets. While the nutritional equivalence of D-*(1)* and L-*(1)* has been established experimentally[1], corresponding studies on D-*(2)* and L-*(2)* have yet to be performed.



D-*(1)*, X = H, Y = COOH
L-*(1)*, X = COOH, Y = H

D-*(2)*, X = H, Y = COO
L-*(2)*, X = COO, Y = H

We have now prepared these enantiomers for the first time. Diazotization of D-methionine D-*(1)* (by analogy with ref. [2]) gave D-2-hydroxy-4-(methylthio)butyric acid D-*(3)* which was purified *via* the dicyclohexylammonium salt D-*(4)* ($[\alpha]_D^{25} = +22.2°$ ($c = 1$, ethanol, m.p. 127—129 °C) and transformed into the salt D-*(2)* with aqueous calcium hydroxide (no racemization) ($[\alpha]_D^{25} = +24.3$ ($c = 1$, H_2O)). L-*(2)* was obtained analogously from L-*(1)*. Apart from the rotations ((L-*(2)*: $[\alpha]_D^{25} = -25.3°$ ($c = 1$, H_2O); L-*(4)*: $[\alpha]_D^{25} = -22.5°$ ($c = 1$, ethanol)) all the physical data of L-*(2)*, L-*(3)*, and L-*(4)* agree with those of the D-series.

D-*(3)*, R = H
D-*(4)*, R = $(c\text{-}C_6H_{11})_2NH_2$

D-*(5)*

The enantiomeric purity of D-*(3)* was examined (i) by comparison with D-*(3)* obtained by a biochemical route and (ii) by NMR spectroscopy of the derivative D-*(5)*.

(i) The acid D-*(3)* produced by microorganisms[3] affords a salt D-*(4)* having $[\alpha]_D^{25} = +22.2°$ ($c = 1$, ethanol) and m.p. 128—129 °C. The mixed melting point recorded with chemically synthesized D-*(4)* showed no depression.

(ii) The methyl D,L- and D-2-acetoxy-4-(methylthio)butyrates D,L-*(5)* and D-*(5)*, respectively, produced from D,L-*(3)* and D-*(3)* were examined by ^{1}H-NMR spectroscopy[4]. The signals of the methine protons of D,L-*(5)* at 60 and 80 MHz can be separated by addition of the optically active shift reagent Eu(opt)$_3$. On irradiation at the resonance frequency of the neighboring methylene protons ("homo-decoupling"), the methine protons of the enantiomers each appear as singlets at $\delta = 6.48$ and 6.37 (1:1).—In the case of D-*(5)*, the methine proton was found to give a triplet at $\delta = 6.53$ and a singlet at $\delta = 6.53$ with Eu(opt)$_3$, without and with decoupling, respectively. Thus no L enantiomer can be detected in D-*(5)*. On mixing of D-*(5)* with D,L-*(5)* (1:1) and with Eu(opt)$_3$, the decoupled spectrum expectedly shows two signals for the methine proton at 6.50 and 6.37 (3:1).

Procedure

D-*(1)* (596.9 g, 4 mol) is dissolved in 10% sulfuric acid (3430 g) and treated at 0—5 °C with an ice-cooled solution of sodium nitrite (345 g, 5 mol) in water (500 ml). The mixture is allowed to warm overnight to 20—25 °C and then extracted four times with ether (600 ml). The ethereal phase is dried over sodium sulfate and the solvent stripped off; residue, 96.3 g (14.4%) crude D-*(3)* as oil. D-*(4)* crystallizes on addition of dicyclohexylamine to the ethereal solution of D-*(3)*. Repeated recrystallization from ethyl acetate/light petroleum gives 100.2 g (52.4%) of analytically pure[5] D-*(4)*. Hydrolysis of D-*(4)* with dilute sulfuric acid and work-up as above leads to pure D-*(3)*. This residue is taken up in water (100 ml) and treated with calcium hydroxide (9.9 g) in water (100 ml). After treatment with activated charcoal, the solution is evaporated to dryness in a water-pump vacuum; yield 45.4 g (88% of D-*(2)*).

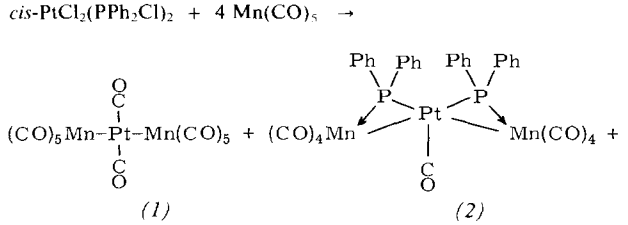
Synthesis and Crystal Structure of a Chiral Complex Containing a Non-linear Heterotrimetal Chain: $PtMn_2(\mu_2\text{-}PPh_2)_2(CO)_9$[1]

By *Pierre Braunstein, Dominique Matt, Odile Bars,* and *Daniel Grandjean*[*]



The course of reaction between metal carbonyl anions and square planar substrates of the type ML_2Cl_2 (M = Pd, Pt) depends markedly on the nature of L[2]. Thus *cis*-PtL_2Cl_2, where L = pyridine, reacts with $Mn(CO)_5^-$[3] to give a trimetallic complex containing the linear arrangement

[Mn–Pt(py)$_2$–Mn], whereas when L = PEt_3 or PPh_3 the homopentametallic clusters $Pt_5(CO)(\mu_2\text{-}CO)_5L_4$[4] are formed.

We have now found that when L = PPh_2Cl, the complexes *(1)* and *(2)* with two new heterotrimetallic [Mn–Pt–Mn] chains can be generated[5] (see Experimental procedure).

(1) *(2)*

The mass spectrum of *(1)* shows the molecular ion at *m/e* = 641 (based on ^{195}Pt). According to dipole moment measurements the three metal atoms are linearly arranged. The ^{31}P-NMR spectrum of *(2)* contains a singlet with two ^{195}Pt-satellites ($\delta = 161$ rel. to H_3PO_4 ext., $^1J(P\text{-}Pt) = 2265$ Hz, in CD_2Cl_2), indicating that the phosphorus atoms are attached to the Pt atom[6]. Although the mass spectrum contains the molecular peak (*m/e* = 927), the molecular structure of *(2)* cannot be unequivocally derived from these data since, according to the 16–18 electron rule, either a closed or an open structure could be envisaged.

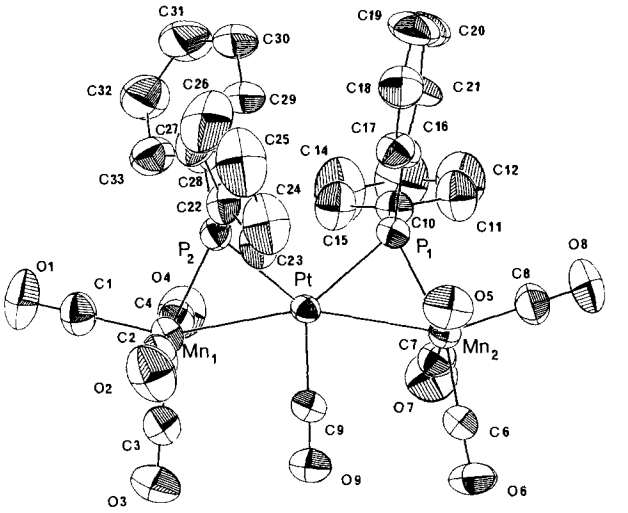

Fig. 1. Structure of *(2)*. Important bond lengths [pm] and angles [°]: Pt–Mn(1): 274.1(1); Pt–Mn(2): 274.7(1); P(2)–Mn(2): 223.7(2); P(1)–Mn(2): 224.1(3); P(1)–Pt: 230.5(2); P(2)–Pt: 231.9(3).
P(1)–Pt–P(2): 101.08(11); Mn(1)–Pt–P(2): 51.65(8); Mn(2)–Pt–P(1): 51.77(8); Mn(1)–Pt–Mn(2): 159.56(4).

As was shown by a single crystal X-ray structure analysis (Fig. 1)[7], each Mn atom is bonded to four terminal CO groups, to the Pt atom, and to a P atom bridging the Pt–Mn bond. (The use of PR_2Cl ligands to form PR_2-bridged metal-metal bonds is already known [8].) The Mn(1)–Pt–Mn(2) angle is 159.56°(4). The CO group which is bonded to the Pt atom is nearly in the plane of the metal atoms[9]. P(1) and P(2) are located on opposite sides of this plane (+0.59 Å (P1) and −0.36 Å (P2)).

The molecule *(2)* has no element of symmetry and thus is chiral. This chirality is inherent in the Mn(1)P(2)PtP(1)Mn(2) framework. Complexes like *(2)*, with a heterotrimetallic *bent* chain containing a Pt atom, were previously unknown. To our knowledge *(2)* is the first *neutral* complex with a nonlinear heterotrimetallic chain and chiral framework; the only other formally comparable species $Rh[Fe(PPh_2)(CO)_2(\pi\text{-}CH_3C_5H_4)]_2^+$[10] has a bent Fe–Rh–Fe chain and a chiral framework, but it is not neutral.

Experimental

All reactions and operations must be carried out under nitrogen. The solvents are dried and distilled under nitrogen before use. A tetrahydrofuran solution (40 ml) of $NaMn(CO)_5$ [prepared from $Mn_2(CO)_{10}$ (1.60 g, 4 mmol)] is filtered and added to a suspension of *cis*-$Pt(PPh_2Cl)_2Cl_2$ (1.41 g, 2 mmol) in THF (50 ml) at 0 °C. The dark-red mixture is then stirred for 2 h at room temperature. The residue obtained after filtration and evaporation under reduced pressure is chromatographed on a silica gel column (Kieselgel 60, Merck). Elution with pentane gives a red solution of *(1)*, affording analytically pure claret-colored needles on crystallization at −78 °C; yield 0.04 g (3% based on Pt), m.p. 60 °C (decomp.), ν(CO) in KBr: 2066 s, 2046 s, 2022 s, 1994 sh, 1984 vs, 1967 vs cm^{-1}. Further elution with pentane gives a more concentrated red solution from which orange-red analytically pure crystals of *(2)* can be obtained at −10 °C; yield: 0.20 g (11%), m.p. 171–172 °C, ν(CO) in KBr: 2069 s, 2050 s, 2000 sh, 1990 vs, 1970 vs, 1945 vs cm^{-1}. Elution with toluene/pentane mixtures gives products which have not yet been characterized.

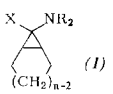
The Morpholino Group as Stereoindicator in Aminobicyclo[4.1.0]heptanes[**]



By *Elmar Vilsmaier* and *Wolfgang Tröger*[*]

The *exo-endo* assignment of aminobicyclo[*n*.1.0]alkanes *(1)*, especially those with two bridge substituents, is difficult if they are prepared from haloenamines ($n = 3$[2,4]; $n = 4$[4,6]) and nucleophiles. Among the compounds *(1)* synthesized in this way, the stereochemistry has been established by X-ray structure analysis [*(1a)*[5]] or from the ^1H-NMR coupling

d	3	*exo*-H	*endo*-$N(CH_3)_2$
e	4	Pyrrolidino	Pyrrolidino
f	4	OCH_3	Pyrrolidino

(2) *(3)* *(4)*

We have found the reaction of *S,S*-dimethyl(2-morpholino-2-cycloheptenyl)sulfonium fluorosulfonate *(2)*[1] with nucleophiles H–X and a base to provide a new entry to bicyclo[4.1.0]heptanes *(1)*, NR_2 = morpholino, $n=4$. Moreover, it was also found that the morpholino group in *(1)* permits facile ^{1}H-NMR spectroscopic assignment of *(1)* [see *(3)* and *(4)*].

Reaction of the sulfonium salt *(2)* and morpholine gives 7,7-dimorpholinobicyclo[4.1.0]heptane *(3g)*. A dimorpholinocycloheptene constitution can be ruled out on the basis of the IR (no C=C bond) and the ^{13}C-NMR spectrum (no signals with $\delta>90$ ppm). The ^{1}H-NMR spectrum (Table 1) shows an AA'XX' system for the protons of one morpholine ring and an ABXY system for the other. On heating ([D_5]nitrobenzene) the ABXY system coalesces at 125 °C ($\Delta G^{\neq}=80.9$ kJ/mol); at 210 °C these morpholine protons also show an AA'XX' system. The AA'XX' system of the protons belonging to the other morpholine ring recorded at room temperature does not coalesce on cooling to −40 °C (CD_2Cl_2).

In the case of morpholines bearing an achiral *N*-substituent, the ring protons appear as an AA'XX' system owing to fast rotation and inversion[7]. However, an ABXY system is to be expected if rotation[7,8] or inversion[7,8] are hindered. The ABXY pattern of *(3g)* resembles the low-temperature spectrum of *N*-methylmorpholine[7] (−40 °C, slow ring inversion) in shape and coupling constants. Owing to the steric situation in *(3g)*, the AA'XX' signal system must accordingly be assigned to the *exo*-morpholino and the ABXY system to the *endo*-morpholino group[9].

The dipyrrolidine compound analogous to *(3g)*, *i.e.* *(1e)*, affords *(1a)*[5] on treatment with aqueous hydrochloric acid and *(1f)* [no structure reported][6] with methanol. By analogy we obtained *(4h)* from *(3g)* and aqueous hydrochloric acid and *(4i)* with methanol/H^+. Both compounds exhibit an AA'XX' pattern (Fig. 1a) for the morpholine protons. We

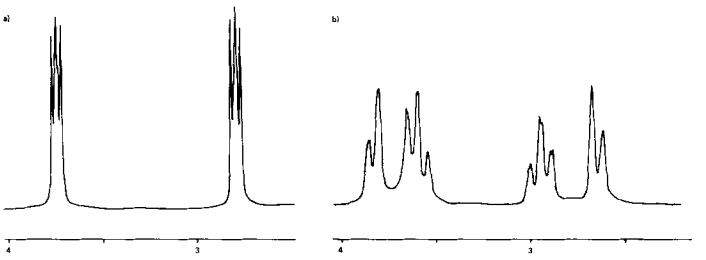

Fig. 1. ^{1}H-NMR morpholine signals of 7-morpholinobicyclo[4.1.0]heptan-7-ols. a) *(4h)* and b) *(3h)*; 200 MHz, $CDCl_3$, δ values.

obtained isomers of *(4h)* and *(4i)* by reaction of *(2)* with $OH^{\ominus}$ and $CH_3O^{\ominus}$. These isomers each give only an ABXY system for the morpholine protons (Fig. 1b). Thus it is possible to assign the *endo*-morpholine configuration to *(3h)* and *(3i)* and the *exo*-morpholine configuration to *(4h)* and *(4i)*.

We attribute the formation of *(3h)* and *(3i)* from *(2)* to steric effects of substitution. The isomerization of *(3h)* and *(3i)* to *(4h)* and *(4i)* even by traces of acid in chloroform can readily be followed by ^{1}H-NMR spectroscopy. Thus, the unexpected formation of *(1a)* from *(1e)* and of *(4h)* and *(4i)* from *(3g)* with acid is probably the result of thermodynamically controlled isomerization.

Hence introduction of the morpholino group in place of the previously used dimethylamino, pyrrolidino, and piperidino groups in 7-aminobicyclo[4.1.0]heptanes permits facile *exo-endo* assignment of the bridge substituents by ^{1}H-NMR spectroscopy.

Procedure

Synthesis of *(3g)*: Compound *(2)*[1] (34.1 g, 0.1 mol) is refluxed with morpholine (17.4 g, 0.2 mol) in anhydrous acetonitrile (80 ml) for 1.5 h. After removal of solvent *in vacuo*, the residue is extracted twice with ether (2 × 100 ml) and the ethereal phase is vacuum distilled; yield: 19.2 g (72%) of *(3g)*, b.p. 80—86 °C/0.02 torr.

Synthesis of *(3h)*: A solution of *(2)* (3.4 g, 10 mmol) and sodium carbonate (1.0 g, 10 mmol) in water (50 ml) is cov-

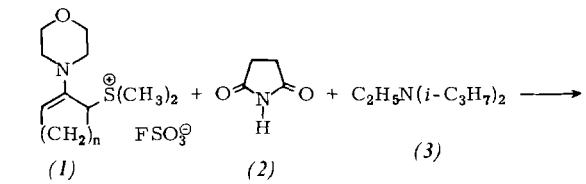
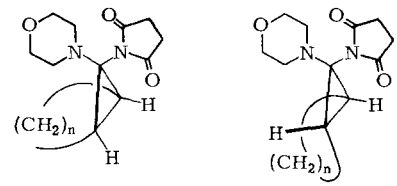
[9] AA'XX' and ABXY signal patterns can also be clearly distinguished in the 90 and 60 MHz spectrum. We attribute the ABXY pattern to hindered rotation around the C N bond; the coupling constants found require the presence of essentially a single conformation at fast ring and N inversion.



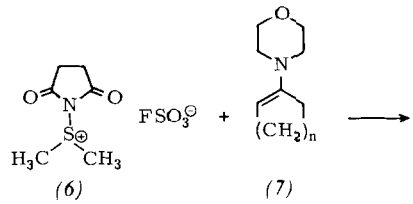
Morpholino(succinimido)bicyclo[*n*.1.0]alkanes from Enaminosulfonium Salts[**]

By *Elmar Vilsmaier* and *Claus Michael Klein*[*]



Starting from the enaminosulfonium salt *(1b)* and nucleophiles, we have prepared 7-morpholinobicyclo[4.1.0]heptanes whose stereochemistry can be determined by ^{1}H-NMR spectroscopy[1], and now wish to report about application of this method of synthesis and structural assignment to morpholinobicyclo[*n*.1.0]alkanes of various ring sizes taking succinimide as nucleophile.

Enaminosulfonium salts *(1a—e)* are treated with succinimide *(2)* in the presence of diisopropylethylamine *(3)* in anhydrous acetonitrile. After removal of the solvent and washing with aqueous potassium hydroxide solution (5%), colorless crystals are obtained in each case. On the basis of their ^{1}H-NMR, ^{13}C-NMR, and IR spectra, we assign the morpholino(succinimido)bicyclo[*n*.1.0]alkane structure *(4)* to these products. Compounds *(4)* can also be prepared by direct reaction of an enamine *(7)* with the succinimidosulfonium salt *(6)*[12], for *(6)* and *(7)* give an equimolar mixture of *(1)* and *(2)*.



The ^{1}H-NMR spectra of 7-morpholinobicyclo[4.1.0]heptanes recorded at room temperature contain an AA'XX' system for *exo*-morpholine and an ABXY system for *endo*-morpholine[1]. Compounds *(4a—c)* give only an ABXY system which coalesces to an AA'XX' system above 120 °C (Table 1). Thus the morpholino group also proves to be a stereoindicator in these bicyclic systems; the *endo*-morpholino structure is to be assigned to compounds *(4a—c)*[3]. The coalescence temperature (T_c) is expectedly much lower for *(4d)* and *(4e)*.

(1) *(2)* *(3)*

(4) *(5)*

(6) *(7)*

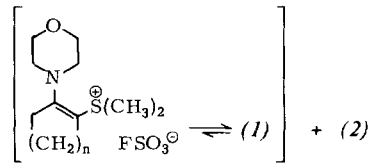


Table 1. Spectroscopic data of the morpholino(succinimido)bicyclo[*n*.1.0]alkanes of types *(4)* and *(5)*. δ values, solvent $CDCl_3$. T_c = coalescence temperature (in $C_2D_2Cl_4$).

[a] J [Hz]: J_{AB} = 11.5—14, J_{XY} = 9.6—11.6, $J_{AX} \approx 3$, $J_{BX} \approx 1$, J_{AY} = 10.3—11.9, $J_{BY} \approx 1.5$. [b] Above T_c, singlet at δ = 2.6; below T_c form of an AA'BB' system. [c] Typical morpholine signal. [d] At −50 °C. [e] Complex splitting of NCH$_2$ protons owing to chirality; coalescence detectable only for OCH$_2$ signal.

A rotation barrier can also be detected for the succinimidocyclopropane bond of *(4a—e)* by ^{1}H-NMR spectroscopy. Transition from the AA'BB' signal system to the singlet takes place just above room temperature. The ring size has only a slight effect on this process, thus indicating the uniform *exo* position of the succinimido group. Hence the *endo*-morpholine structures *(4d)* and *(4e)* are assigned to the compounds obtained by reaction of *(6)* with *(7d)* and *(7e)* respectively[4].

[**] Enaminosulfonium Salts, Part 4.—Part 3: [1].

Depending upon the procedure adopted, two isomeric bicyclo[8.1.0]undecanes can be obtained from *(6)* and *(7e)*. Direct addition of *(3)* to a mixture of *(6)* and *(7e)* gives a colorless precipitate which proves to be pure *(4e)*. *cis*-Linkage of the two rings follows from the five signals observed for the ten-membered ring in the ^{13}C-NMR spectra [plane of symmetry in *(4)*]. If *(6)* and *(7e)* are allowed to stand for 48 h prior to addition of *(3)*, then 10% of *(4e)* is accompanied by 39% of an isomer. The *trans* product *(5e)* was deduced from the ^{13}C-NMR spectrum; the lack of symmetry in *(5e)* requires the occurrence of 11 signals for the 11 C atoms of the bicyclic system. Owing to chirality, *(5e)* shows a complex ^{1}H-NMR spectrum in the region of the morpholine NCH_2 protons; the OCH_2 signal corresponds to that of a normal morpholine molecule. In contrast to the situation in *(4e)*, the spectrum does not change down to $-20\,^\circ$C (Table 1). The purity of *(4e)* (>99%) and of *(5e)* (≈95%) was established by HPLC[5].

We assume that the compounds *(4a—e)* arise from *(1)* *via* bicyclic iminium salts (cf. [6]). They are preferentially attacked from the *exo* side (cf. [7]) and lead to the *endo*-morpholino bicyclic compounds *(4)*.

Procedure

Synthesis of *(4)*: To a stirred suspension of *S,S*-dimethylsuccinimidosulfonium fluorosulfate *(6)* (1.3 g, 5 mmol) in anhydrous acetonitrile (5 ml) is added compound *(7)* (5 mmol) at $-10\,^\circ$C. After 30 min at $-10\,^\circ$C, compound *(3)* (0.64 g, 5 mmol) is added. With *(7a—c)* the mixture is refluxed for 24 h, the solvent then being removed under vacuum and the residue washed twice with 5% aqueous KOH (2 × 30 ml) before being rubbed with pentane (20 ml) and dried in a vacuum. With *(7d—e)* stirring is continued for 18 h after addition of amine and the crystals filtered off under suction. They are successively washed with pentane (10 ml) and 5% aqueous KOH (30 ml), and then dried in a vacuum. A further crop of *(4d)* can be obtained by concentration of the acetonitrile solution.

Oxidative Removal of the Benzyl Ether Protecting Group by Homogeneous Electron Transfer[1]

By *Werner Schmidt* and *Eberhard Steckhan*[*]

We recently reported the mild oxidative deprotection of *p*-methoxybenzyl ethers by homogeneous electron transfer with the tris(*p*-bromophenyl)amine cation radical, thus providing a convenient alternative to the usual reductive deprotection[2]. Internal electrochemical regeneration of the electron transfer agent permits use of only catalytic amounts of the reagent.

The benzyl ether function, however, is not attacked by this electron transfer agent.

We have now found a simple and relatively mild method for the oxidative removal of the benzyl ether protecting group with electron transfer agents of type *(2)*, whose cation radicals have a higher oxidation potential than the tris(*p*-bromophenyl)amine cation radical. A route is thus opened up for the selective protection and selective liberation of primary and secondary hydroxy functions (see [3]).

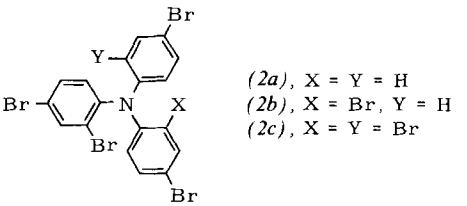

Table 1. Oxidative debenzylation of the ethers *(1)* by homogeneous electron transfer according to methods 1 and 2 (see Procedure).

[a] In the presence of 2,6-dimethylpyridine. [b] In the presence of $NaHCO_3$. [c] Recovered benzyl ether *(1)*. [d] Material yield.

We have examined the cation radicals of the triarylamines *(2a)—(2c)* (synthesis, see [4]) having redox potentials of +1.42 *(2a)*, +1.56 *(2b)* and +1.74 V *(2c)*, measured against the normal hydrogen electrode (NHE), as electron transfer agents for the oxidative debenzylation of the ethers *(1a)—(1d)*.

In the preparative reaction the cation radical $(2)^{\cdot\oplus}$ can either be used in molar amounts as its readily obtainable[4] stable hexachloroantimonate (method 1) or it can be electrochemically generated and regenerated from catalytic amounts of *(2)* during the course of the reaction (method 2). In the presence of bases such as 2,6-dimethylpyridine or $NaHCO_3$ the reaction is considerably accelerated (see Table 1).

Benzyl octyl ether *(1a)* is a suitable example with which to monitor the effectiveness of the electron transfer agents. Owing to an inadequate redox potential, the cation radicals of

(2a) and *(2b)* lead to only incomplete conversion of the benzyl ether *(1a)* according to method 2. The concentration of the benzyl ether cation radical in the electron transfer equilibrium is apparently so low that the follow-up chemical reactions are unable to shift the equilibrium sufficiently in favor of the products[5]. On the other hand, owing to the increased steady state concentration of the benzyl ether cation radical, *(2b)* leads by method 1 to complete conversion and almost quantitative yields of alcohol. *(2c)*, with a still higher redox potential, leads to excellent yields of alcohols in both methods, even in the absence of bases. The electrochemically determined irreversible oxidation potentials of the isomeric ethers *(1a)* (+2.50 V) and *(1b)* (+2.46 *vs.* NHE) differ by 40 mV. This potential difference is responsible for the fact that the secondary ether *(1b)* is quantitatively cleaved by the agent *(2b)* even according to method 2. Deprotection of benzyl 2-ethyl-3-hydroxyhexyl ether *(1d)* by the cation radical of *(2c)* leads to only moderate yields of the alcohol, since the oxidizing agent apparently attacks the secondary function in a side reaction.

From these findings it can be concluded that if the deprotection of alcohols is carried out in the presence of other oxidation-labile groups, a maximum selectivity is reached when the benzyl ether protecting group is removed from primary alcohols with *(2b)* according to method 1, whereas in the case of secondary alcohols method 2 can also be employed. In the absence of oxidation-labile functions *(2c)* is superior as electron transfer agent owing to its higher rate of reaction and ease of preparation.

General procedure

Method 1: A solution of the triarylammoniumyl hexachloroantimonate in CH_3CN is added dropwise to the solution of *(1)* (2 mmol) and 2,6-dimethylpyridine (0.212 g, 2 mmol) or $NaHCO_3$ (0.5 g, 6 mmol) in CH_3CN[6] until conversion of *(1)* is complete (GC control). On using *(2a)* or *(2b)* *ca.* 5 to 6 mmol, of the cation radical salt is necessary, on using *(2c)* *ca.* 8 mmol. The alcohols are isolated and identified as described in [2].

Method 2: In a divided beaker-type glass cell (20 °C, Pt anode, Pt cathode) a solution of *(2)* (2 mmol) in CH_3CN[6]/CH_2Cl_2 (5:1; 0.2 M $LiClO_4$) is used as anolyte; the catholyte consists of CH_3CN/1.0 M $LiClO_4$. After application of the redox potential of *(2a)*, *(2b)*, or *(2c)* the intense color of the cation radical appears. On addition of *(1)* (5 mmol) and 2,6-dimethylpyridine (0.535 g, 5 mmol) or $NaHCO_3$ (0.5 g, 6 mmol) the solution first decolorizes. After reappearance of the color of the cation radical and complete conversion (GC control) of *(1)* (consumption of *ca.* 0.020 F) the electrolysis is stopped.

Selective Deprotection of Primary and Secondary Hydroxy Functions by Homogeneous Electron Transfer[1]

By *Werner Schmidt* and *Eberhard Steckhan*[*]

Both benzyl ether[2] and *p*-methoxybenzyl ether protecting groups[3] can be removed oxidatively if differently substituted triarylamine cation radicals are used as electron transfer agents. Owing to the ease of internal electrochemical regeneration of the agent only catalytic amounts of triarylamine are necessary. The *p*-methoxybenzyl ether group can be removed with the radical cation of tris(*p*-bromophenyl)amine *(9)*[3], whereas the benzyl ether function is not attacked by this agent. Removal of the benzyl ether function can, however, be achieved with the cation radicals of the amines *(10)*[2] and *(11)*[2]. We have now exploited this behavior for the directed functionalization and selective liberation of primary and secondary hydroxy functions.

This new method is a convenient and effective alternative for the directed protection/deprotection of primary and secondary hydroxy functions by cathodic cleavage of a 10-oxo-9-phenyl-9,10-dihydro-9-anthryl ether in the presence of a substituted benzyl ether[4], particularly in the case of reduction-labile compounds.

The efficiency of the method is demonstrated in Scheme 1 using as example the selective bromination of the primary and secondary OH groups in 2-ethyl-1,3-hexanediol *(1)*. The reaction sequence a, b, c, has also been effected with 1,3-butanediol: The yields (selectivities) were 75 (90), 69 and 90 (100%), respectively.

Scheme 1. Selective bromination of primary and secondary hydroxy groups of *(1)*. The material yields are given. An = *p*-methoxybenzyl, Bz = benzyl, Et = ethyl, Pr = *n*-propyl. For reaction steps a—e, see *Experimental*.

Orléans-Ring 23, D-4400 Münster (Germany)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/1010-0802 $ 02.50/0

Since the oxidative removal of benzyl ether functions by homogeneous electron transfer both with molar amounts of triarylamine cation radicals (method 1)[2, 3] and with catalytic amounts of triarylamine and internal electrochemical generation and regeneration of the cation radical (method 2, indirect electrolysis)[2, 3] leads to comparably good results, only one method was used for every step in each case. In this way 3-(bromomethyl)-4-heptanol *(8)* could be prepared isomerically pure in a material yield of 50% *via* five steps from *(1)*. We obtained 3-bromo-2-ethyl-1-hexanol *(4)* in 61% yield *via* three steps. For comparison: In the reaction of *(1)* with molar amounts of Ph_3PBr_2 a 1:1 mixture of the bromo alcohols *(4)* and *(8)* was formed in a yield of 93%, together with 5% dibromo compound. In the case of these bromo alcohols all attempts at separation failed.

The completely selective removal of the *p*-methoxybenzyl ether protecting group in the presence of the benzyl ether protecting group offers new possibilities, especially in carbohydrate chemistry. Other methods for the removal are much less selective or even non-selective. For example, direct anodic oxidation[5] of *(5)* leads, despite potential control, to cleavage of both *p*-methoxybenzyl ether and benzyl ether. Moreover, the anode becomes passivated, the yields are poor, and the products contain numerous impurities[6].

Experimental[8]

(2) from *(1)* (Step *a*): To a solution of *(1)* (14.62 g, 100 mmol) in anhydrous dioxane (100 ml) is added 2.3 g (100 mmol) of Na and the mixture heated (reflux, stirring) for 4 h at 100 °C. After cooling to 30 °C, anisyl chloride (17.16 g, 110 mmol) is added dropwise. The mixture is treated with ether, neutralized with 2 N HCl, extracted three times with water and the ethereal phase dried over $MgSO_4$. Bulb-to-bulb distillation at 120 °C/0.05 torr furnishes 21.9 g (83%) of *(2)*. According to the ^{1}H-NMR spectrum the selectivity is at least 95%.

(5) from *(2)* (Step *b*): *(2)* (9.32 g, 35 mmol) is allowed to react with NaH in anhydrous dimethylformamide (DMF) and benzyl chloride, as described in [5c]. Bulb-to-bulb distillation at 140 °C/0.05 torr gives 9.29 g (75%) of *(5)*.

(6) from *(5)* and *(4)* from *(3)* (Step *c*): *(5)* (0.99 g, 3 mmol) or *(3)* (1.65 g, 5 mmol) is allowed to react with *(9)* (0.48 g, 1 mmol) and *(12)* (0.321 g, 3 mmol or 0.535 g, 5 mmol) according to the procedure described in [3], method 2. Bulb-to-bulb distillation affords 0.67 g (95%) of *(6)* or 0.87 g (84%) of *(4)*, respectively. Gas chromatographic and spectroscopic selectivity checking show that the benzyl ether function in *(6)* is completely retained.

(7) from *(6)* and *(3)* from *(2)* (Step *d*): *(6)* (0.43 g, 2 mmol) or *(2)* (1.33 g, 5 mmol) is brominated with Ph_3PBr_2 in anhydrous DMF according to the procedure given in [7]. Bulb-to-bulb distillation gives 0.55 g (92%) *(7)* or 1.45 g (88%) *(3)*, respectively.

(8) from *(7)* (Step *e1*): *(7)* (0.48 g, 1.6 mmol) is cleaved with *(10)*$^{\oplus}$$SbCl_6^{\ominus}$ (8.4 g, 8 mmol) and $NaHCO_3$ (0.5 g, 6 mmol) according to the method given in [2], method 1. Bulb-to-bulb distillation gives 0.31 g (92%) of *(8)*.

(1) from *(6)* (Step *e2*): *(6)* (0.24 g, 1 mmol) is cleaved with *(11)* (0.064 g, 0.1 mmol) and *(12)* (0.107 g, 1 mmol) according to the method in [2], method 2. Bulb-to-bulb distillation gives 0.11 g (74%) of *(1)*.

BOOK REVIEWS

Solvent Effects in Organic Chemistry. Monographs in Modern Chemistry, Vol. 3, *C. Reichardt*. Verlag Chemie, Weinheim 1979. xi, 355 pp., 45 figs., 69 tables, linen, DM 108.00.

It is only recently that chemists have become aware of the great importance of solvents in all areas of organic chemistry. The reactivity series obtained in the mass spectrometer (*i.e.* in the absence of solvent), the activation of organometallic compounds by complexing ligands and the use of chiral solvents indicate pathways that lead beyond the questionings of previous decades. It is therefore greatly to be welcomed that the monograph "Solvent Effects in Organic Chemistry", the second edition of which appeared in 1973, is now available in a completely revised version. The relevant information, which is not easy to retrieve, has been evaluated (over 1200 references) and is presented in the proven format for organic chemists who are inclined toward the mechanistic and preparative aspects.

After an introduction to the physicochemical fundamentals of the interaction between solvent and solute (31 pages), where topics such as selective and micellar solvations are treated at reasonable length, there is a classification of solvents on this basis (19 pages), *e.g.* according to their polarity and their acceptor and donor properties (for electrons and hydrogen bonds).

The next two chapters are a fund of impressive examples of solvent effects on equilibria (25 pages) and in particular on reaction rates (109 pages), which can only be found to a limited extent from the subject index. These chapters will provide a wealth of new ideas for any organic chemist active in research or production.

The effects on acid-base and tautomeric equilibria, which to a certain extent have been known for a long time, are considered from modern viewpoints and amplified with recent examples. Among the qualitative and quantitative aspects the (in part) unexpectedly drastic solvent effects on S_N, E1,

and E2 reactions are discussed, where frequently specific solvations decide the issue. However, this chapter also includes a thorough discussion of the considerably weaker effects in radical and pericyclic reactions, together with their mechanistic consequences. The chapter has 451 references.

A further chapter (45 pages) deals with solvent effects on spectral properties. Starting with solvatochromism phenomena (UV/VIS), the author describes effects on IR, NMR, and ESR spectra, by which it is also often possible to detect specific solvations. This provides a logical transition to linear "free energy relationships" (54 pages), which are mainly derived from spectroscopic data for given model systems and which, possibly just because of their empirical nature, range over an astonishingly wide field of chemical reactivity. Here too the book shows the use and limitations of the Z and E_T values and AN and DN values, together with the value of multiparametric equations, some of which have only recently been developed.

An appendix gives brief information about the purification and possible applications of solvents, their spectroscopic and other physical data, and also their toxicity.

No other work currently available presents the confusing multiplicity of solvent effects as thoroughly, comprehensively, and critically as this one. Furthermore, it is intended for the organic chemist who wants to interpret these effects or to use them in planning his reactions. It is hoped that the high price will not hinder a wide readership of this book.

Siegfried Hünig [NB 481 IE]

Organometallic Mechanisms and Catalysis. By *J. K. Kochi.* Academic Press, New York 1978. xvii, 623 pp., $ 59.50.

It isn't very often that a reviewer has the good luck to be asked to write a critique about a book which he intended to purchase and I was, therefore, delighted when this volume landed on my desk—particularly in view of the price.

Organometallic chemistry and homogeneous catalysis can no longer be ignored by conventional organic and inorganic chemists: many organometallic compounds have either found direct practical application (*e.g.* organotin- and organolead compounds) or are routinely used as stoichiometric reagents in organic synthesis (*e.g.* organolithium- and organomagnesium compounds) or are involved as intermediates in metal catalyzed organic transformations some of which now form the basis of large industrial processes (*e.g.* organocobalt- and organonickel compounds in the hydroformylation and hydrocyanation of alkenes).

Although a number of reaction- or metal-specific books and reviews are available, it has become clear in the last few years that the role of organometallic species in organic synthesis could be profitably discussed from a unifying mechanistic standpoint and it is to fill this need that this book has been written.

Has the author succeeded? On the whole I think he has. He is certainly to be admired for not capitulating before the sheer volume of the material to be discussed. The book is divided into three related sections: part one deals with oxidation-reduction processes in which the metal undergoes a discrete change in oxidation state, part two is devoted to the chemistry of organometallic compounds with emphasis on reactions leading to cleavage of the metal-carbon bond, and part three is concerned with charge transfer interactions.

This arrangement enables a surprising amount of information to be classified while avoiding the frequently artificial distinction between main group- and transition-metal organometallic compounds. A first-class index makes it easy to find relevant material. The main difficulty facing the author is that concrete evidence is often lacking for many of the catalytic processes being considered and, in spite of his good intentions, the discussion all too often becomes metal-specific and generalizations have to be followed by a disclaimer. The most desirable effect which this book could have would be to stimulate further work towards greater mechanistic uniformity.

The book will be of greatest interest to chemists involved directly with organometallic compounds and catalysis but it should also be very profitable reading for all preparative organic chemists. Its greatest service will be to act as an orientation point in classifying new information. For me at least it will now be easier to keep an eye on what is happening in the wood while at the same time tending some of the trees.

P. W. Jolly [NB 477 IE]

The Chemistry of Functional Groups. The Chemistry of Diazonium and Diazo Groups. Edited by *S. Patai.* John Wiley & Sons, New York 1978. Part 1, xiv, 510 pp.; Part 2, xiv, pp. 511—1069; bound, together $ 130.00.

The last comprehensive survey of diazo and diazonium compounds (*H. Zollinger:* Diazo and Azo Chemistry) was published in 1961; the pertinent chapters of Houben-Weyl (10/3 and 10/4) were written in 1965 and 1968. The present two-volume work in the series "Chemistry of Functional Groups" is therefore most welcome.

Diazonium ions and diazo compounds do have a number of interfaces (they are related by acid-base equilibria in the aliphatic series), but differ greatly in their reactions. The two classes of compounds are therefore considered together in some of the chapters, but separately in others. The work opens with a theoretical survey (*J. B. Moffat*) which also embraces diazirines and diimides. Three chapters are concerned with the synthesis of diazonium salts (14, *K. Schank*) and of diazoalkanes and their carbonyl, phosphoryl, and sulfonyl derivatives (15, 17, *M. Regitz*). Further chapters are devoted to acid-base equilibria (2, *V. Štěrba;* 6, *J. F. McGarrity*), structural problems (3, *S. Sorriso;* 7, *H. M. Niemeyer*), and analytical procedures (5, *D. A. Ben-Efraim*). The section on thermochemistry (4, *R. Shaw*) does not appear very successful, being based on a value for the heat of formation of diazomethane which is most probably incorrect. Mechanistic questions are discussed with particular emphasis on photochemistry (9, *W. Ando*), electrochemistry (10, *J. Fry*), substituent effects (11, *E. S. Lewis*), kinetics (12, *A. F. Hegarty*), rearrangements (13, *D. Whittaker*), and the use of isotopes (16, *P. J. Smith* and *K. C. Westaway*). Special attention is focused on the synthetic application of diazonium salts (8, *D. S. Wulfman*) and diazo compounds (18, *D. S. Wulfman, G. Linstumelle,* and *C. F. Cooper*) by two large chapters with *ca.* 2400 references. This is where the chemist engaged in preparative work will gain well-founded information and critical suggestions concerning, for example, the choice of catalyst in the decomposition of diazo compounds.

Repetition is bound to occur in a book written by 19 authors (*e.g.* the Wolff rearrangement is mentioned in Chapters 3, 9, 13, and 18); and yet new aspects are often revealed precisely by such repetition. Some information turns up in unexpected places, *e.g.* ^{13}C-NMR data of diazo compounds in Chapters 11 and 16, but not in Chapter 5 and regrettably not in the index. Typographical errors are rare (*e.g.* pp. 374, 413, 607, 629, 726, 851, 855, 909, 932); errors of fact are even rarer (the statement on p. 13 that diazirine is more stable than diazomethane contradicts the heats of formation compiled in Tables 10 and 11; classification of the photochemical Bamford-Stev-

ens reaction as "photolysis of aliphatic diazonium ions" in Chapter 9 is surprising; the hypothesis of "hot" cations is attributed to the wrong authors on p. 574). Interspersion of an occasional *bon mot* provides amusement between formulae and tables: "It is not clear whether the catalyst plays an active role or represents a retreat to the chemistry of (Paracelsus) von Hohenheim" (p. 910). The subject index (24 pages) is comparatively exhaustive; the author index (66 pages) provides a visible measure of the relative ranking of the pundits (*Regitz* is a clear winner with 11.8 cm).

The high quality of most of the contributions, the high information content, and the careful editing recommend these volumes not only to subscribers to the series but to a wide circle of organic chemists engaged in mechanistic and preparative work.

Bonding Properties of Cyclopropane and Their Chemical Consequences

By Armin de Meijere[*]

Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday

Among the cyclic compounds of carbon, cyclopropane and its derivatives are outstanding by virtue of their unusual structural, spectroscopic, and chemical properties. The cyclopropane ring more closely resembles the C=C double bond than the cyclobutane ring: it is a small ring with "double bond character". Cyclopropyl and vinyl groups interact with neighboring π-electron systems and p-electron centers; both cyclopropane derivatives and olefins form metal complexes, and add strong acids, halogens, and ozone; they both undergo catalytic hydrogenation and cycloadditions. While distinct differences in reactivity do exist—the double bond usually being more reactive than the three-membered ring—there are no fundamental differences in behavior.—Although cyclopropane derivatives have been known for more than 90 years, intensive studies have been limited to the past 25 years. The development of carbene chemistry has rendered cyclopropane derivatives far more readily accessible. In recent years, the synthetic potential of the small-ring function has been increasingly exploited. A considerable number of newly developed methods utilizing this approach clearly demonstrates that the reactivity of the cyclopropene ring, like that of the C=C double bond, qualify it as a "functional carbon group". This development is in full swing; we may therefore justifiably devote considerable effort to the study of cyclopropane chemistry.

1. The Chemical Bond in the Cyclopropane Ring

Olefins and cyclopropane derivatives are related in many ways[1]. The reason for this lies in the similarity of bonding in the C=C double bond and in the three-membered carbon ring. There are two equivalent descriptions for each system. According to the MO model of *Walsh*[2] (see Fig. 1), three occupied molecular orbitals (MOs) determine the nature of the C—C bonds of the three-membered ring. Of these, the orbit-

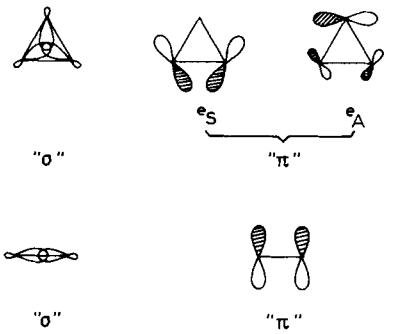

Fig. 1. Molecular orbital (MO) description of bonding in cyclopropane and ethylene.

al of lowest energy (σ) is a linear combination of three sp^2-hybrid atomic orbitals (AOs), while the other two (e_S and e_A) are equal-energy linear combinations of three p-AOs differing only in their symmetry properties. This picture is strongly reminiscent of the commonest description of a C=C double bond by two occupied MOs, one linear combination each of two sp^2 AOs (σ-MO) and two p AOs (π-MO) (see Fig. 1). By analogy with the latter MOs, the Walsh e_S and e_A orbitals are also called π or "quasi π" orbitals of the three-membered ring.

The second kind of theoretical description is the valence bond (VB) model of cyclopropane, due originally to *Förster*[3] and refined by *Coulson*[4]. The C—C bonds are described as resulting from the overlapping of two sp^5-hybrid orbitals at each C atom (see Fig. 2). Since the directions of

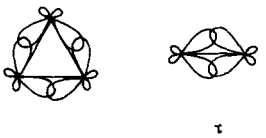

Fig. 2. Valence bond (VB) model of cyclopropane and ethylene.

the orbitals cannot coincide with the directions of bonding, but are directed outwards relative to the latter, the bonds create the impression of being bent. However, this merely expresses the experimentally established fact[5] that the density of the bonding electrons is greatest off the C—C connecting line. In the more common MO model this fact is reflected by the e_S and e_A orbitals in which the overlap region of the p AOs also lies off the C—C connecting lines (see Fig. 3)[6].

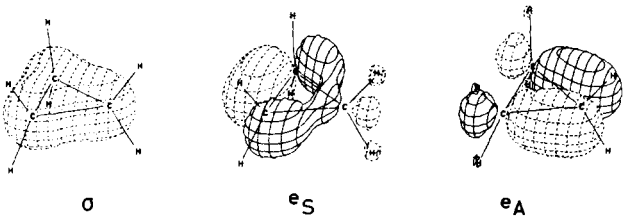

Fig. 3. Electron density distribution in the occupied molecular orbitals of cyclopropane responsible for the C—C bonds (according to [6]).

Another common feature of the two models is the participation of sp^2 hybrid orbitals of the C atoms in C—H bond formation. This is substantiated by experimental facts: for instance, the cyclopropyl C—H bonds (like vinylic C—H bonds) are shorter than normal aliphatic C—H bonds[7], and the ^{13}C-H coupling constants found for cyclopropane derivatives indicate 32% s character of the C—H bonding orbitals[8].

Furthermore, the C=C double bond can also be described, according to *Pauling*, by bent bonds[9]. As in the three-membered ring, the so-called "τ bonds" arise by overlapping of sp^5 hybrid orbitals of the C atoms off the C—C connecting line (see Fig. 2). For cyclopropane and ethylene, we have two completely equivalent models which can be transformed mathematically into each other[10]. The physical and chemical consequences can be explained equally well in principle by either model. However, the σ,π description of the double bond and the three-membered ring is more convenient for quantum mechanical calculations.

These analogies in bonding properties help us to understand similarities in chemical behavior; the regions of high electron density off the C—C connecting lines determine their reactivity towards electrophilic reagents[1, 11, 12]. This is also the reason why both of the bond systems can undergo electronic interaction with π or p-electron centers. It leads to an effect usually designated as conjugation, which is generally manifested in the physical and chemical properties of the corresponding compound. In the case of the C=C double bond, conjugation effects are known for systems containing in its immediate vicinity
a double bond or, more generally,
a CX multiple bond,
a cyclopropane ring,
a carbanion center,
a radical center, or
a carbenium ion center.

In principle, an interaction effect should be expected for combinations of each of these five groups with a cyclopropane ring. It is the intention of this article to describe model compounds with characteristic properties and thereby show how far this prediction is fulfilled.

It should first be mentioned that the extent of interaction in conjugated systems with a double bond and with a three-membered ring is highly dependent upon their conformation. In general, the interaction energy, and hence also the effect of conjugation on physical and chemical properties, is greatest when the axes of the mutually interacting orbitals are parallel to each other because the overlap between the orbitals is then at a maximum. Open-chain conjugated systems therefore preferentially adopt a conformation permitting such maximum interaction. Thus over 95% of the molecules of 1,3-butadiene exist in the antiperiplanar (*s-trans*) conformation having a planar carbon skeleton[13, 14]; the allyl anion, the allyl radical, and the allyl cation[15] are planar.

Owing to the special kind of anisotropic electron distribution in the cyclopropane ring (*vide supra*), its interaction with a suitable neighboring group is at a maximum when the p-orbital axis of the neighboring group is arranged parallel to the plane of the three-membered ring. For vinylcyclopropane, for instance, this is the case in the antiperiplanar con-

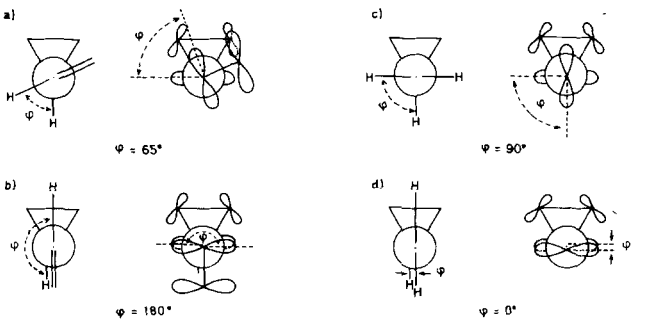

Fig. 4. Conformations of vinylcyclopropane: a) synclinal (*gauche*); b) antiperiplanar (*s-trans*). Conformations of the cyclopropylmethyl cation: c) perpendicular; d) bisected.

formation (see Fig. 4) and for the cyclopropylmethyl cation in the o-called bisected conformation.

The interaction energy in a system with a three-membered ring and a double bond is apparently lower than in one with

two conjugated double bonds because the more stable antiperiplanar conformation of vinylcyclopropane predominates only to the extent of 75% in the liquid and gaseous phase, corresponding to an energy difference of 4.6 kJ/mol relative to the less stable synclinal (*gauche*) form[16]. The maximum stabilization energy of a system with conjugated double bond and three-membered ring would correspond to the energy difference between the antiperiplanar form and a 90° conformation; this energy difference is somewhat greater than 4.6 kJ/mol (*vide infra*). In contrast, the energy difference between the lowest-energy bisected conformation of the cyclopropylmethyl cation and the energetically least favorable perpendicular conformation is much greater at 60—70 kJ/mol[17,18]. The gain in energy experienced by such a cation in an optimum geometry is of the same order of magnitude as the stabilization energy of an allyl or benzyl cation[19] relative to a primary alkyl carbenium ion. Thus the ability of the cyclopropyl group to stabilize a center of positive charge is comparable with, or even greater than, that of the vinyl and the phenyl group[20].

On comparing the vinyl and the phenyl group on the one hand with the cyclopropyl group on the other, it is essential to bear in mind a difference in geometry, which can play an important role primarily in conformationally rigid systems: as a rule, the four substituents attached to the two carbon atoms of a double bond are located in a plane (S) including the carbon atoms and oriented perpendicular to the plane (O) of the π-orbital axes (interplanar angle $\alpha = 90°$; cf. Fig. 5); however, four substituents attached to two C atoms of a cyclopropane ring define, together with the C atoms, two distinct planes (S^1 and S^2) enclosing an angle of *ca.* 120° and forming angles of *ca.* 60° with the plane of the three-membered ring, and thus also with that of the p-orbital axes (O) ($\alpha \approx 60°$, cf. Fig. 5).

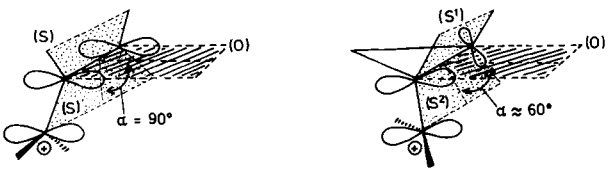

Fig. 5. Geometrical differences in the allyl and the cyclopropylmethyl cation at maximum orbital overlap [α = interplanar angle].

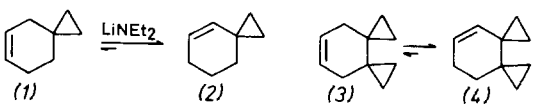
The modern description of the bonding properties of cyclopropane provides a theoretical basis for the classical concept of ring strain[21], which has been invoked to explain various typical reactions of small ring compounds: according to present-day ideas, ring strain is an expression of the sum of all bond energies in a molecule. The experimental value can be obtained for any cycloalkane from the difference between its heat of combustion and that of a long-chain unstrained *n*-alkane[22] with the same number of CH_2 groups (see Table 1). This definition is less misleading and yet more comprehensive that the original one proposed by *A. von Baeyer*[21], which assumed that only the C valence angles deviating from tetrahedral angles give rise to a strain in small rings which increases with decreasing ring size. In fact, we nowadays distinguish three causes of ring strain and thus three components contributing to the total strain: deformation of bond angles gives rise to angular strain (von Baeyer strain) and an eclipsed or at least imperfectly staggered arrangement of CH_2 groups causes torsional strain (Pitzer strain); the third contribution is due to transannular van der Waals interaction of nonbonded atoms.

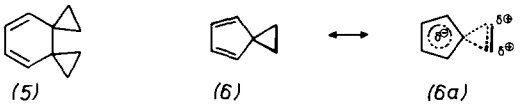
Table 1. Strain energy of lower cycloalkanes $(CH_2)_n$ and ethylene.



Cpd.	*n*	Bond angle deformation per CH_2 group	Heat of combustion per CH_2 group $\Delta H_{comb.}/n$ [kJ/mol]	Strain energy per molecule $\Delta H_{comb.} - n \cdot 6586$ [kJ/mol]
Ethylene	2	109.5°	705.4	93.6
Cyclopropane	3	49.5°	697.1	115.5
Cyclobutane	4	19.5° [a]	686.2	110.4
Cyclopentane	5	1.5° [a]	664.0	27.0
Cyclohexane	6	0°	658.6	0.0
n-Alkane	∞	0°	658.6	0.0

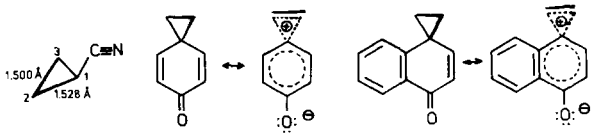
[a] Calculated for a planar ring, as assumed by *A. von Baeyer* [21].

The values of the strain energy (Table 1) show that the thermodynamic stability of a cyclopropane ring is lower than that of a C=C double bond; accordingly, cyclopropane derivatives are often observed to rearrange to more stable olefins on acid catalysis[11,23] or thermally at sufficiently high temperatures[24,25]. Nevertheless, three-membered rings show a pronounced tendency of formation; for example, certain eliminations leading to olefins can be applied with comparable success to the synthesis of cyclopropane derivatives from homologous substrates (γ-elimination)[26]. The numerous methods for generating carbenes[27] and their additions to C=C double bonds have greatly increased the possible preparations of three-membered rings[28]. The recently developed generation of dichlorocarbene from chloroform and concentrated aqueous sodium hydroxide under phase transfer catalysis[29] has reduced the expenditure of effort and financial resources to such an extent that two of the principle obstacles on the way to an industrial utilization of cyclopropane chemistry have been removed.



2. Effects of Conjugation between Cyclopropane and Multiple Bonds

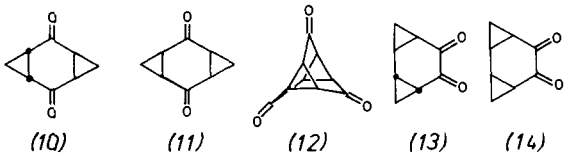
Staley has estimated from the position of the equilibrium which is established in the presence of strong bases between spiro[2.5]oct-5-ene *(1)* and spiro[2.5]oct-4-ene *(2)* at room temperature that conjugation between the C=C double bond and the cyclopropane ring effects a stabilization of *ca.* 5.0 kJ/mol[30]. Dispiro[2.0.2.4]dec-8-ene *(3)* can accordingly undergo more than 80% rearrangement to the more stable conjugated isomer *(4)*[31].



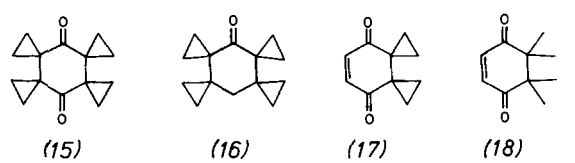
Conjugation in compounds of types *(2)* and *(4)* is manifested not only in their greater thermodynamic stability but also in their UV, NMR, IR, and PE spectra. The bathochromic shift of the longest wavelength UV absorption band

of a 1,3-diene chromophore is *ca.* 15 nm per three-membered ring, given optimum conformation of the system, as is almost accomplished in dispiro[2.0.2.4]deca-7,9-diene *(5)*[31,32]. For spiro[2.4]hepta-4,6-diene *(6)*, having the vinylcyclopropane units fixed in the antiperiplanar conformation in the planar

(5) *(6)* *(6a)*



five-membered ring[33], *Clark* and *Fiato* have deduced partial delocalization of the cyclopropyl bond electrons into the five-membered ring [as in *(6a)*] from the exceptional downfield position of the NMR signals due to the cyclopropyl protons[34]. However, this assumption could not be confirmed by way of the bond lengths of *(6)*. In the five-membered ring they correspond to those of cyclopentadiene and in the three-membered ring to those of cyclopropane[33]. The electron-donating capacity of the cyclopropyl group apparently becomes effective only when stimulated by electron withdrawal by a π-acceptor substituent, such as a polar CX multiple bond[35]. Thus a significant lengthening of the C^1—C^2 bond, and a corresponding shortening of the C^2—C^3 bond have been determined experimentally for cyclopropanecarbonitrile *(7)*, just as predicted theoretically on the basis of the Walsh MO model[36]. (The C—C bond length in cyclopropane is 1.510 Å.)

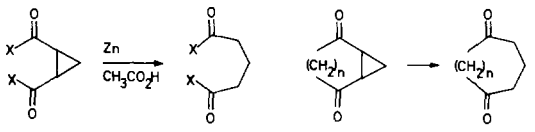


(7) *(8)* *(8a)* *(9)* *(9a)*

Thus it appears reasonable that the ^{1}H-NMR and UV data of spiro[2.5]octa-4,7-dien-6-one *(8)*[37] and its benzo derivative *(9)*[38] are best interpreted in terms of a significant contribution of the zwitterionic resonance structures *(8a)* and *(9a)*[38].

The magnitude of the bathochromic shift of the n-π^* band in the UV spectrum[39] and the shift of the νC=O band to lower wave numbers in the IR spectrum[40] of cyclopropyl ketones as an expression of the conjugation between the cyclopropyl and the carbonyl group is critically dependent upon the geometry of the system[41]. In cyclopropyl-conjugated diketones, the effect of through-space and through-bond interaction between the carbonyl groups is also important; the data collected for compounds *(10)*—*(18)* are impressive illustrations (see Tables 2).

(10) *(11)* *(12)* *(13)* *(14)*



(15) *(16)* *(17)* *(18)*

Table 2. Selected UV and IR data of some cyclopropyl-conjugated cyclohexanediones and reference systems.

Compound	UV, n-π^* (EtOH) λ_{max} [nm] (ε_{max})	IR (KBr) νC=O [cm^{-1}]	Ref.

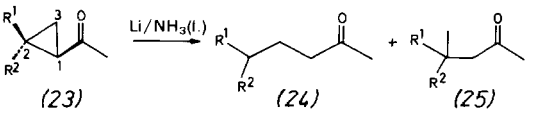
(18)	365	1682	[46]

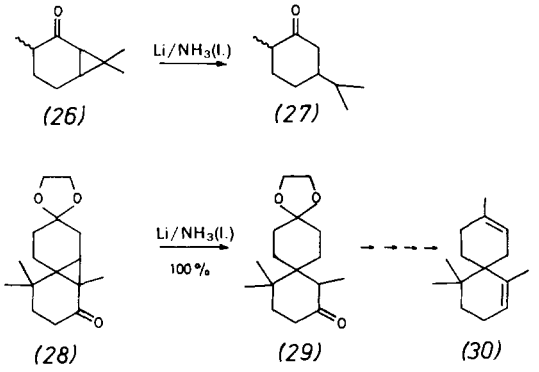


[a] Not measured.

The particularly facile reductive cleavage of the cyclopropyl C—C bond in 1,4-dicarbonyl compounds of types *(19)* and *(21)* may be regarded as a chemical consequence of cyclopropyl-carbonyl conjugation and of the low C—C bond energy. This mode of reaction, which leads to 1,5-dicarbonyl compounds *(20)* and *(22)*[47], can be used to advantage, *e.g.*, for ring expansion[48].

(19) *(20)* *(21)* *(22)*

Reductive ring cleavage of conjugated cyclopropyl monoketones can also be accomplished with lithium in liquid ammonia[49]. In monocyclic conformationally mobile systems such as *(23)*, the type of substitution will determine which of the cyclopropyl bonds overlaps with the π orbital of the C=O group in the energetically most favorable conformation and is thus preferentially opened (see Scheme 1)[50]. In annelated bicyclic systems the fixed geometry leads to a stereoselective ring opening, which has been successfully utilized to reduce (+)-caran-2-one *(26)* to (−)-carvomenthane *(27)*[51] and to produce the intermediate *(29)* from *(28)* in a total synthesis of the spirosesquiterpene (+)-α-chamigrene *(30)*[52].



(23) *(24)* *(25)*

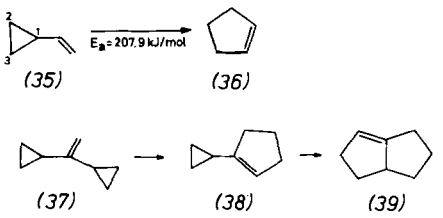
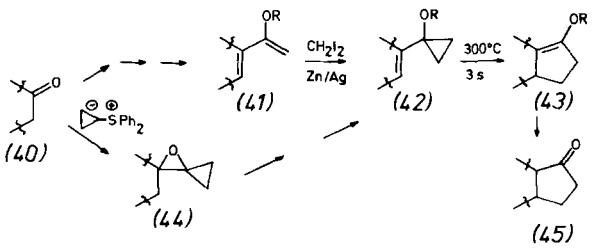
(c), $R^1=H$, $R^2=CH_3$	6	:	94

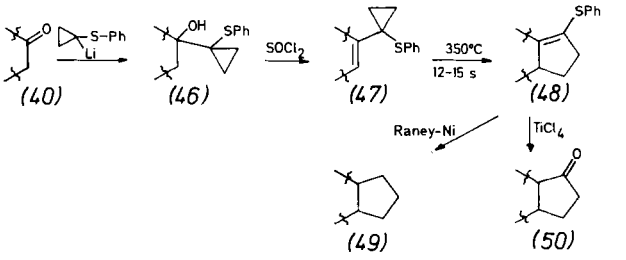
Scheme 1. Ring opening of cyclopropyl methyl ketones *(23)* depending upon type of substitution [50].



In protonated cyclopropyl ketones *(31)*, the electron-donating capacity of the cyclopropyl group is exploited by a neighboring carbenium ion center. In keeping with their cyclopropylmethyl cation structure (see Section 6), compounds

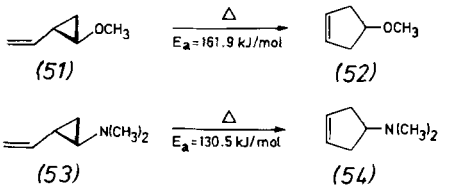


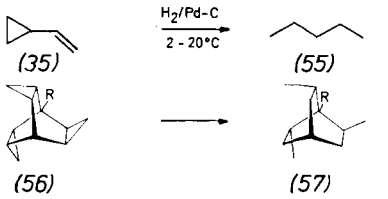
(31) form homoallyl systems *(32)* by ring opening; this mode of reaction is the basis of a synthetic method for 1,4-diketones *(34)* which result from trapping of *(32)* with water and subsequent oxidation[53].



Conjugation of C=C double bonds with cyclopropyl groups also affects chemical properties. The simplest compound of this kind, vinylcyclopropane *(35)*, undergoes a relatively facile and uniform thermal rearrangement (Arrhenius activation energy $E_a = 207.9$ kJ/mol) to cyclopentene *(36)*[54]; numerous substituted vinylcyclopropanes[24,25] behave analogously [*e.g. (37)→(38)→(39)*] provided they are not fixed in

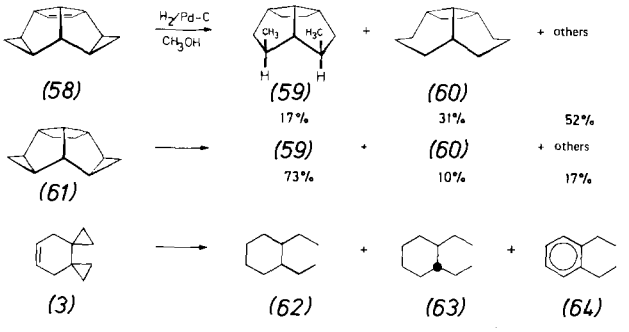
an antiperiplanar or anticlinal conformation that is unfavorable for this ring closure. This kind of rearrangement serves as the principle underlying techniques of fusing cyclopentane rings onto cyclic ketones *(40)* (see Scheme 2)[55,56]. The decisive intermediates are 1-vinylcyclopropyl trimethylsilyl ethers *(42)*, obtained according to *Conia et al.*[55] by Simmons-Smith cyclopropanation of 2-trimethylsilyloxy-1,3-dienes *(41)* or according to *Trost et al.*[56] *via* the oxaspiropentanes *(44)*.





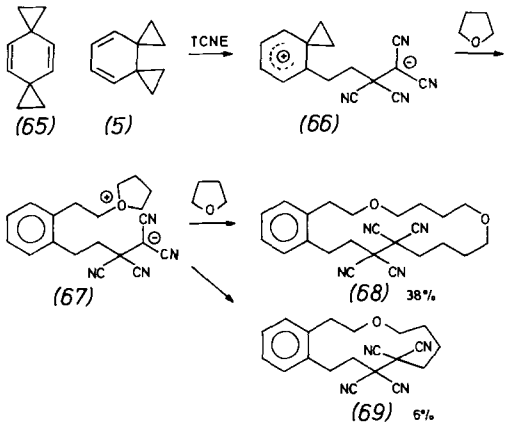
Scheme 2. Methods of fusing cyclopentane to cyclic ketones *(40)*, R = $(CH_3)_3Si$.

Being stereocontrolled, the alternative method *via* the phenylthio-substituted systems *(47)* and *(48)* also developed by *Trost et al.*[57] may be advantageous. The trimethylsiloxy and phenylthio groups in *(42)* and *(47)*, respectively, facilitate thermal rearrangement as compared to the parent system.

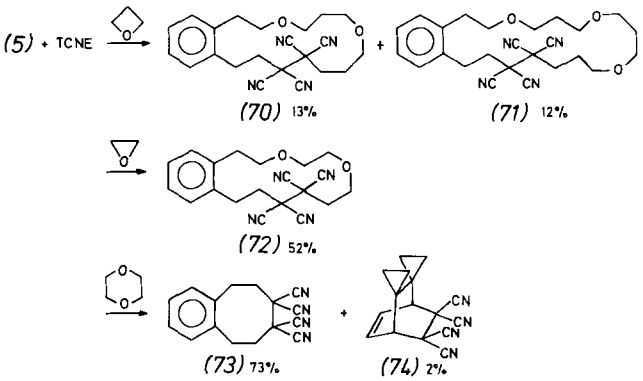


A comparable effect is observed with a methoxy ($E_a = 161.9$ kJ/mol) or a dimethylamino group ($E_a = 130.5$ kJ/mol) in position 2 of the vinylcyclopropane [see *(51)* and *(53)*][58].

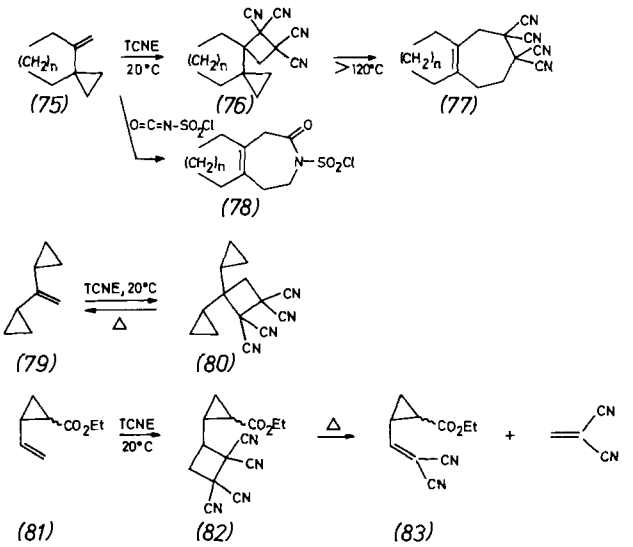
On catalytic hydrogenation, vinyl-conjugated cyclopropyl groups are generally more readily cleaved than isolated ones[59]; moreover, vinyl as well as carbonyl and phenyl groups lead to regioselective opening of the C^1—C^2 bond, while it is mainly the C^2—C^3 bond which is opened in the case of alkyl-substituted cyclopropanes[60].



Vinylcyclopropane *(35)* is hydrogenated to *n*-pentane *(55)* over palladium in methanol at 2—20 °C and at normal pressure[61]; in contrast, the trishomobarrelene derivatives *(56)* undergo hydrogenation to the stereochemically interesting 2,6,7-trimethylbicyclo[2.2.2]octyl derivatives *(57)* (R = ethyl, 1-methylcyclopropyl, methoxy) only at elevated hydrogen pressure (≥5 bar) in the presence of platinum dioxide/glacial acetic acid[62]. In oligocyclic systems having essentially rigid geometry, however, non-conjugated C=C double bonds may also affect the regioselectivity and ease of cyclopropyl ring opening. The unsaturated pentacycle *(58)* takes up hydrogen far more rapidly than the corresponding saturated pentacycle *(61)*, and gives a much higher proportion of the fully unexpected[59,60] product *(60)*[63] than does *(61)*. Compound *(3)* completely fails to give the expected[59,60] 1,1,2,2-tetramethylcyclohexane, but instead affords *cis*- *(62)* and *trans*-1,2-diethylcyclohexane *(63)*, as well as 1,2-diethylbenzene *(64)* alongside a small amount of saturated dispiro[2.0.2.4]decane[64].

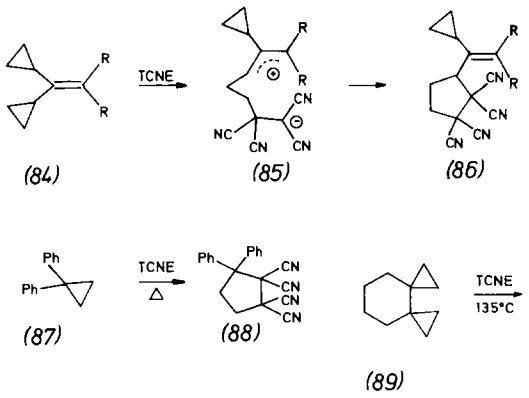


Thus in molecules such as *(58)* and *(3)* the olefinic group is the better "ligand" for the catalyst surface, and therefore plays a major role in determining how the overall molecule is adsorbed on the catalyst surface and which cyclopropyl bond subsequently undergoes preferential cleavage.



The interaction between the bonding orbitals of a cyclopropyl group and the π orbitals of neighboring C=C double bonds raises the energy of the highest occupied MO (HOMO) of such a conjugated system. This corresponds to a lowering of the π-ionization potential, as has been established by photoelectron spectroscopy for the compounds *(2)*, *(4)*, *(5)*[31], *(6)*[65], *(65)*[66], and other examples[67]. The ionization potential of dispirodecadiene *(5)* is especially low at 7.74 eV. This is apparently responsible for the unusual mode of reaction of *(5)* with tetracyanoethylene (TCNE).

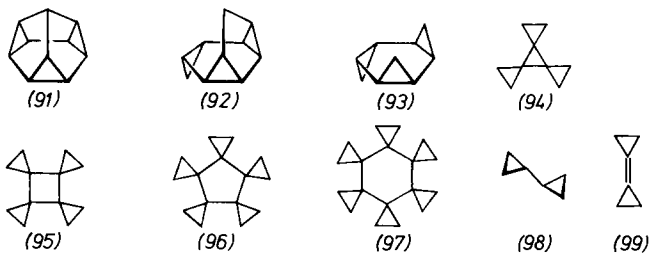
The major product (38%) of a reaction in tetrahydrofuran (THF) at room temperature is the 1:1:2 cycloadduct *(68)* of *(5)*, TCNE, and THF[68]. Since TCNE readily takes up an electron to form the radical anion[69], electron transfer from *(5)* to TCNE is probably the initial step of this reaction. After recombination of the pair of radical ions from *(5)* and TCNE the zwitterion *(66)* is formed, which ultimately cyclizes to the 18-membered ring *(68)* after incorporation of two molecules of THF *via (67)* and a further intermediate. Careful work-up of the reaction mixture afforded a further product (6%)[70] shown by its ^{1}H-NMR spectrum to have the structure *(69)* with a 13-membered ring, which must have arisen by cyclization of *(67)*. This reaction can be extended to the preparation of further macrocyclic ethers. In the presence of an excess of oxetane, *(5)* and TCNE give a mixture of *(70)* (13%) and *(71)* (12%) having a 16- and a 20-membered ring, respectively, in addition to polymeric material[70]. Similarly, the more highly strained oxirane is cyclooligomerized by *(66)* even at $-20\,^{\circ}C$: the major product (52% yield) is 11,12-benzo-1,4-dioxa-11-cyclotetradecene-7,7,8,8-tetracarbonitrile *(72)*[70].



In contrast, the strain-free cyclic ether dioxane does not participate in the reaction; as a polar solvent it instead prolongs the lifetime of the zwitterion *(66)* and permits its cyclization to the benzocyclooctene derivative *(73)* (73% yield)[70]. The bicyclo[2.2.2]octene derivative *(74)* is formed merely as a by-product (2%) by normal Diels-Alder addition to the 1,3-diene unit in *(5)*. In contrast, this "normal" type of adduct is formed exclusively with all dienophiles[71-73] which are not also sufficiently strong oxidizing agents for *(5)*, like TCNE or certain substituted *p*-benzoquinones[73]. Compound *(73)* is formally a $[_{\sigma}2+_{\sigma}2+_{\sigma}2]$cycloadduct of TCNE and the synperiplanar-fixed bicyclopropyl unit. Analogous additions of TCNE to synperiplanar-fixed vinylcyclopropane systems have also been reported[74, 75].

Unlike *(5)*, however, the spirovinylcyclopropanes *(75)*, $n=1$ or 2, initially react by way of a [2+2]cycloaddition to give isolable cyclobutane derivatives *(76)*, which rearrange to cycloheptene derivatives *(77)* only at elevated temperature[75]. Prior electron transfer is not essential in this case because chlorosulfonyl isocyanate reacts analogously with *(75)* to give the seven-membered ring *(78)*[76] whereas this cyclophile gives a normal Diels-Alder adduct of type *(74)* with *(5)*[77]. Instead it is the conformation of the vinylcyclopropane system which is of prime importance. The adducts *(80)* and *(82)* of the sterically undefined cyclopropylethylenes

(79) and *(81)*[78] undergo exclusive cycloreversion to *(79)* and *(83)* on heating[75].

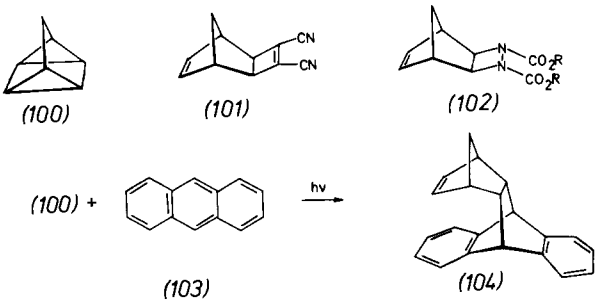


(84) *(85)* *(86)* *(87)* *(88)* *(89)* *(90)*

Cyclopropylethylenes having a sufficiently low ionization potential, such as *(84)*, R = cyclopropyl or phenyl, react like *(5)* in the initial steps; however, the zwitterion *(85)* preferentially cyclizes to the cyclopentane derivative *(86)*[79]. As shown by the examples *(88)*[80] and *(90)*[81], TCNE also undergoes cycloaddition to phenyl- and cyclopropyl-conjugated cyclopropanes such as *(87)* and *(89)*, probably without intermediate formation of radical ions.

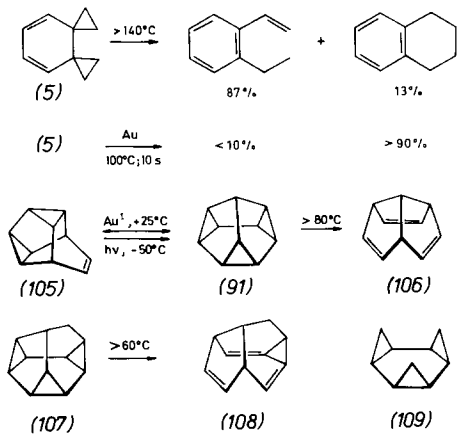
Further transformation of such tetracarbonitriles, formed by TCNE addition to olefins and cyclopropanes, has hardly been utilized so far in spite of the potential they offer. Thus under alkaline conditions, *(72)* can readily be hydrolyzed to the tetracarboxylic acid[70]; in the absence of acid-labile groups, acid-catalyzed hydrolysis with simultaneous decarboxylation is possible[82].

3. Cyclopropyl-Cyclopropyl Interaction



Although the electronic interaction between neighboring cyclopropyl groups does not appear to exert any substantial effect on the UV/VIS spectrum of corresponding compounds[31,83,84], it is manifested in the PE spectra in accord with theoretical concepts. Of particular value for such studies were compounds such as *(3)*, *(4)*, *(5)*, *(89)*[31], the tris-σ-homobenzenes *(91)*[85], *(92)*[86], and [*n*]rotanes *(94)*—*(97)*[87]

(91) *(92)* *(93)* *(94)* *(95)* *(96)* *(97)* *(98)* *(99)*

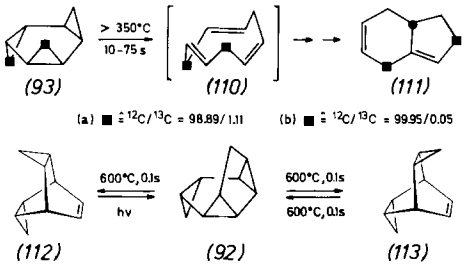


containing bicyclopropyl groups in uniformly defined conformations. However, comparable information was also provided by the PE spectrum of bicyclopropyl *(98)* which exists in two equilibrium conformations[88]. The resonance integrals serving as a measure for the interaction between neighboring 2p atomic orbitals of conjugated cyclopropyl groups vary from $\beta = -1.50$ eV for *(95)* through $\beta = -1.73$ eV for *(91)*, *(92)*, *(93)*, *(98)* up to $\beta = -2.05$ for *(94)*. The highest value, $\beta = -2.14$ eV, was found for bicyclopropylidene *(99)*[87], because the distance between the two cyclopropyl groups in this compound is smaller than in all other systems owing to the linkage *via* a double bond.

The proximity of two cyclopropyl groups is surely a determining factor in the cycloaddition of TCNE to a three-membered ring of *(89)* to give *(90)*[81]; however, bicyclopropyl *(98)* does not react under comparable conditions. The same unusual type of cycloaddition as that of TCNE to the bicyclopropyl unit of *(5)* to give *(66)* has so far been found for only one other class of compounds: quadricyclane *(100)*[89] and quadricyclane derivatives[90] react with dicyanoacetylene, azodicarboxylate, or other reactive dienophiles to form cycloadducts of the type *(101)*[89a] and *(102)*[89b], respectively. A photochemical $[_\pi 4 + _\sigma 2 + _\sigma 2]$cycloaddition of anthracene *(103)* to *(100)* giving *(104)* has also been reported[91].

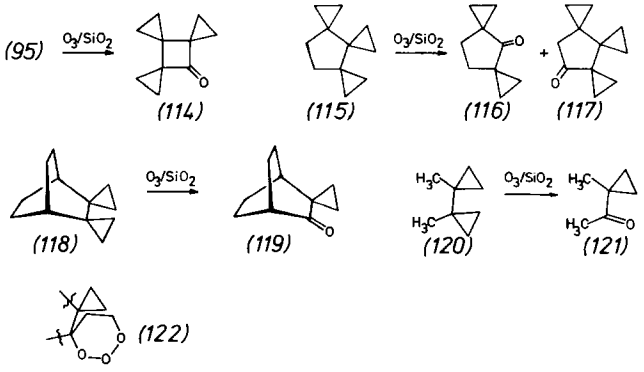
(100) *(101)* *(102)* *(100)* + *(103)* *(104)*

Uncatalyzed and catalyzed thermal rearrangements of *(5)* and *(91)*—*(93)* are also determined by the proximity of cyclopropyl groups in various ways. While the purely thermal reaction of *(5)*—probably *via* intermediate diradicals—yields 87% *o*-ethylstyrene and only 13% tetralin[71], the gold-catalyzed reaction[92] gives more that 90% tetralin, the product of a bicyclopropyl group cyclization. The same kind of rearrangement is catalyzed by gold and gold(I) complexes in the case of diademane *(91)*; in the presence of dicyclopentadienegold(I) chloride, *(91)* isomerizes even a room temperature to snoutene *(105)*[92] from which it is in turn formed by photochemical interamolecular $[_\pi 2 + _\sigma 2]$cycloaddition[83b,93].



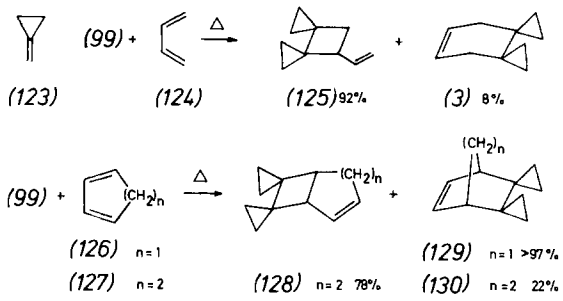
(5) *(5)* *(105)* *(91)* *(106)* *(107)* *(108)* *(109)*

In the absence of catalyst, however, *(91)* rearranges above 80 °C with cleavage of all its three-membered rings to triquinacene *(106)*[83b,94]. This type of cycloreversion, which has an activation energy of only 132.2 kJ/mol[95] in the case of *(91)*, is common to all *cis*-tris-σ-homobenzene derivatives[96]. All experimental evidence indicates a concerted $[_\sigma 2_s + _\sigma 2_s + _\sigma 2_s]$cy-



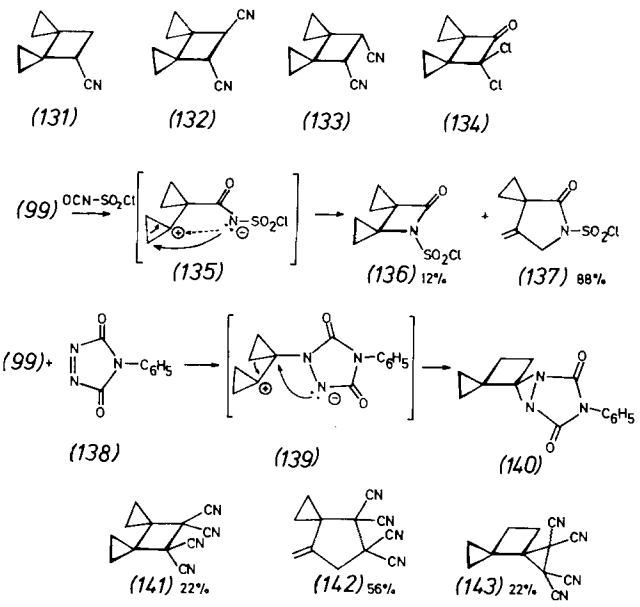
cloreversion. If the three cyclically conjugated cyclopropyl groups of a *cis*-tris-σ-homobenzene are better oriented for overlap of the Walsh orbitals than in *(91)*, as is the case in 1,6-homodiademane *(107)*[93,97], the isomerization proceeds even more readily ($E_a = 118.4$ kJ/mol). Thence it could be estimated that the hitherto unknown parent hydrocarbon *(109)* should just be stable at room temperature[97].

Although the overlap between neighboring p orbitals in two out of three bicyclopropyl groups is very small in *trans*-tris-σ-homobenzene *(93)*, it rearranges formally according to the same scheme; however, this reaction requires an activation energy of 175.7 kJ/mol[98]. Thus, under the conditions employed, the initial product, *viz.* the highly strained *cis,trans,trans*-1,4,7-cyclononatriene *(110)*[98b], could not be



isolated but detected only by the isotopic labeling pattern in the final product *(111b)* from *(93b)*[98a]. Only when an additional bridge is present, as in *(92)* does the system avoid the excessive strain energy in the bridged intermediates of type *(110)* and instead undergoes $[_\sigma 2 + _\pi 2]$cycloreversion probably proceeding *via* diradicals at higher temperatures, giving the isomeric bishomobarrelenes *(112)* and *(113)*[99], from which it was in turn generated photochemically[99] and thermally[100].

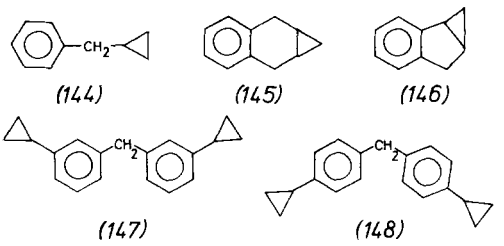
Although the [*n*]rotanes *(94)*—*(97)* would appear predestined for a number of interesting chemical transformations, hardly anything of this kind is known about them. This is partly due to the tedious synthetic pathways leading to them before more convenient alternative approaches were developed[101]. The [4]rotane *(95)* obtainable by dimerization of the bicyclopropylidene *(99)*, which is now readily accessible[102], undergoes oxidative degradation to trispiro[2.0.2.0.2.1]decan-10-one *(114)* by ozone on silica gel[103]. It is not the ring strain of a spiro[2.3]hexane system which plays a crucial role, but instead the activation of a spirocyclopropyl group by at least one neighboring cyclopropyl group, for the hydrocarbons *(115)*, *(118)*, and *(120)* are degraded analogously to the ketones *(116)* [alongside *(117)*], *(119)*, and *(121)*, respectively[103]. Moreover, this mode of reaction is not



a consequence of an initial silica gel-catalyzed isomerization to an olefin[103]; rather the ozone directly attacks a cyclopropyl C—C bond, possibly with cycloaddition to give a rather unstable 1,2,3-trioxane of type *(122)*, as has been proved for highly strained σ bonds[104].

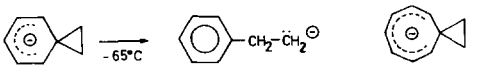
Because of the double bond-like properties of the cyclopropane ring (see Section 1), methylenecyclopropane *(123)* and bicyclopropylidene *(99)* sometimes react like cumulenes. The ready dimerization of *(123)*[105] and *(99)*[106] are pertinent examples. Cycloadditions of the more reactive compound *(99)*[106] to double bonds of other reactants provide an entry

to compounds having spirobicyclopropyl groups. Reaction with conjugated dienes such as 1,3-butadiene *(124)* and 1,3-cyclohexadiene *(127)* give mainly the cyclobutane derivatives *(125)* and *(128)*, respectively, together with the [2+4]cycloadducts *(3)* and *(130)*[107]. Only cyclopentadiene *(126)* reacts with *(99)* to give exclusively the formal [2+4]adduct *(129)*[107]. Compound *(99)* does not add to electron-rich olefins[108], but very readily to some double bond systems bearing strong electron acceptors as substituents. Thus *(99)* reacts with acrylonitrile to give the cyclobutanecarbonitrile derivative *(131)*, and with fumaronitrile to give a mixture of the isomers *(132)* and *(133)*; dichloroketene forms the "normal" [2+2]adduct *(134)*[108]. In contrast, chlorosulfonyl iso-



cyanate affords, alongside a small amount of *(136)*, mainly *(137)*, possibly by cyclopropylallyl rearrangement of the intermediate zwitterion *(135)*. *N*-Phenyltriazolinedione behaves differently: the intermediate *(139)* apparently undergoes cyclopropylmethyl-cyclobutyl ring expansion and sub-

sequent cyclization to the four-membered ring derivatives *(140)*. TCNE experiences all three kinds of addition, as shown by the products *(141)*, *(142)* (major product), and *(143)*[108]. Simple methylenecyclopropanes also undergo a formally analogous reaction[109].

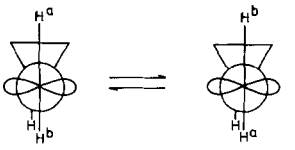


4. Stabilization of Carbanions by Cyclopropyl Groups

Owing to its bonding properties, a cyclopropyl group should, in principle, have a mesomeric and an inductive stabilizing effect on a carbanion[110]. However, *Perkins et al.* have deduced from measurements of hydrogen/deuterium exchange rates for benzylcyclopropane *(144)*, 3,4-benzobicyclo[4.1.0]heptene *(145)*, 2,3-benzobicyclo[3.1.0]hexene *(146)*, and reference compounds that the benzyl anions obtained from *(144)*, *(145)*, and *(146)* are, at best, only slightly more stable than the corresponding anions having no α-cyclopropyl groups[111]. This conclusion, *i. e.* that cyclopropyl substituents have hardly any effect on the stability of carbanions was confirmed by *Streitwieser*[112] on the basis of the kinetic acidities of *(147)* and *(148)*.

(144) *(145)* *(146)* *(147)* *(148)*

The widely differing stabilities of the spiro[2.5]octadienyl *(149)* and spiro[2.7]decatrienyl anion *(151)* reported by *Staley et al.*[113] also convincingly demonstrate the cyclopropyl group to be a poor π-electron acceptor but a very good π donor: the anion *(149)* in which the cyclopropyl group is spiro-linked to a 6 π system and in which it can only act as an ac-

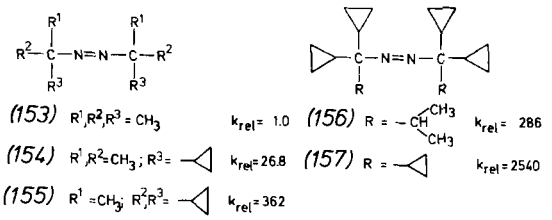


(149) *(150)* *(151)*

ceptor undergoes fast rearrangement at as low a temperature as −65 °C to the aromatic phenethyl anion *(150)*. In contrast, *(151)* in which the spirocyclopropyl group acts as a π donor, as in spiro[2.4]heptadiene *(6)*, is itself already "aromatic" according to the ring current criterion[113b] and therefore stable up to −30 °C.

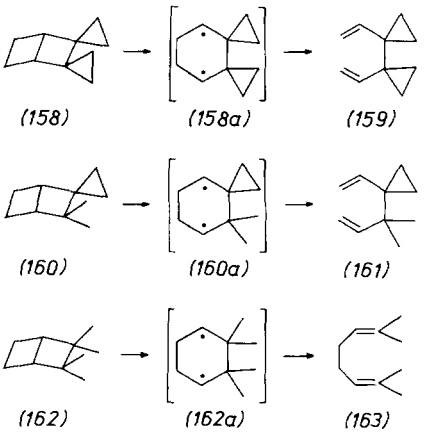
5. Relative Stabilities of Cyclopropylmethyl Radicals

Although studies on the generation and transformation of cyclopropylmethyl radicals and their relative stabilities are not very numerous[114], they are far better represented than those on cyclopropylcarbanions. This would indicate that cyclopropyl-substituted radicals have a greater potential.



ESR studies have shown that cyclopropylmethyl radicals prefer the bisected conformation *(152)* with optimum overlap between the radical p orbital and the cyclopropyl Walsh orbital[115]; however, the CH_2 rotation responsible for the exchange process *(152a)*⇌*(152b)* is subject to a barrier of only <12.5 kJ/mol[115]. This is much smaller than in the case of

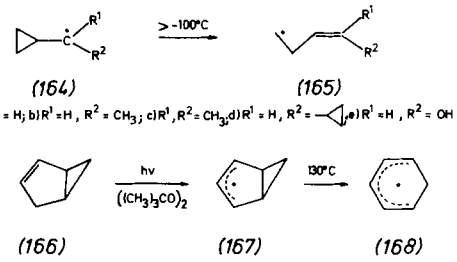
(152a) *(152b)*



the cyclopropylmethyl cation[17,18] indicating that a radical is stabilized less by an α-cyclopropyl substituent than a carbenium ion.

Kinetic studies on the decomposition of azoalkanes *(153)*—*(157)* led *Martin* and *Timberlake* to essentially the same conclusion[116]. Any replacement of a methyl by a cy-

clopropyl group in *(153)* increases the rate of thermolysis, on average by a factor of 14. The steric influence due to the difference in sizes of these groups plays a subordinate role, as shown by comparison of the values obtained for *(156)* and *(157)*. However, in the case of *(155)*, *(156)*, and *(157)*, apparently not all the cyclopropyl groups can simultaneously adopt an optimum conformation for interaction with the incipient radical center in the transition state.

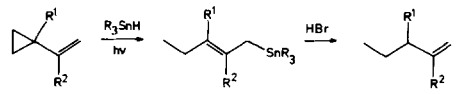


This difficulty is largely avoided in the bicyclo[2.2.0]hexane derivatives *(158)*, *(160)*, and *(162)*: their thermolysis leads initially to conformationally uniform 1,4-cyclohexanediyls *(158a)*, *(160a)*, and *(162a)*, respectively[117]. It was estimated from the differences in activation energy for the over-

(158) *(158a)* *(159)*
(160) *(160a)* *(161)*
(162) *(162a)* *(163)*

all reactions leading to *(159)*, *(161)*, and *(163)* that the stabilization energy of a cyclopropylmethyl radical with an optimum conformation is *ca.* 12 kJ/mol[117].

Simple cyclopropylmethyl radicals *(164)*—generated from methylcyclopropanes by hydrogen abstraction with *tert*-butoxy radicals—undergo very fast rearrangement to homoallyl radicals *(165)*, in some cases even at *ca.* −100 °C[118]. In contrast, the bicyclo[3.1.0]hexenyl radical *(167)* generated in the



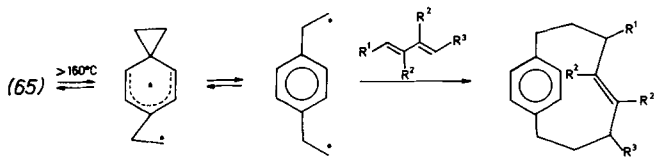
(164) (165)

a) $R^1,R^2 = H$; b) $R^1 = H$, $R^2 = CH_3$; c) $R^1,R^2 = CH_3$; d) $R^1 = H$, $R^2 =$; e) $R^1 = H$, $R^2 = OH$

(166) (167) (168)

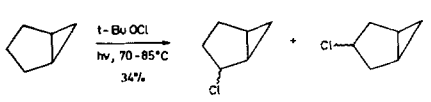
same way from *(166)* is stable up to at least +70 °C; it isomerizes to the cyclohexadienyl radical *(168)* only at +150 °C[119].

The facile ring cleavage of cyclopropylmethyl radicals is the basis of a method for the chemospecific reductive ring opening of vinylcyclopropanes *(169)*. Photochemically initiated hydrostannylation leads *via* 1,4-addition to trialkylal-



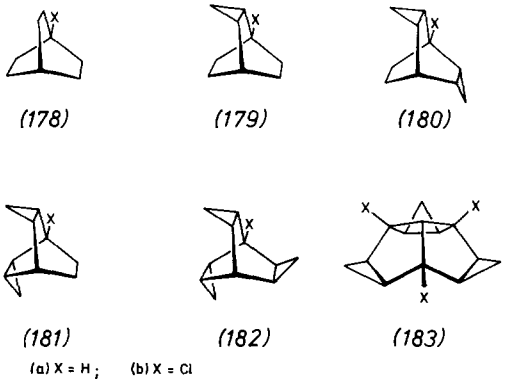
(169) (170) (171)

$R^1,R^2 = H, CH_3$ R = CH_3, n-Bu



lylstannanes *(170)* which are transformed by hydrogen bromide into the alkenes *(171)* in more than 80% yield[120].

Dispiro[2.2.2.2]deca-4,9-diene *(65)* is an interesting special case. The second step of its double ring cleavage *via (172)* to the diradical *(173)*, which is fast above 160 °C, belongs to the class of cyclopropylmethyl to homoallyl rearrangements; the yield of the [8]paracyclophane derivatives *(174)* (30—84%) on cycloaddition of *(173)* or *(172)* to conjugated dienes are surprisingly high[121].

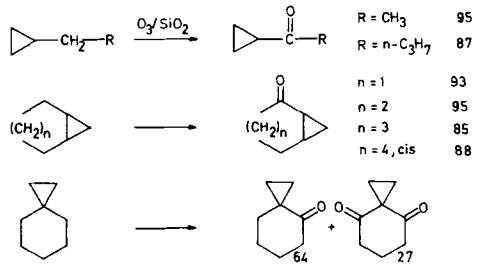


(172) (173) (174)

In spite of the pronounced tendency of α-cyclopropyl-substituted radicals to undergo ring opening, cyclopropyl hydrocarbons can be selectively derivatized by free radical attack. For instance, comparatively mild chlorination can be accomplished with *tert*-butyl hypochlorite on irradiation, especially at low temperatures[122–124]. Thus, at 70—85 °C, bicyclo[3.1.0]hexane *(175)* gives a mixture of 78% of *(176)* and 22% of *(177)* in 34% yield[122a]. Low temperature photochlorination (−40 °C) of the hydrocarbons *(179a)—(182a)* gave good yields of the bridgehead chlorides *(179b)—(182b)* completely free of secondary products due to rearrangement of the radical intermediate[18,123].

(175) (176) 78% (177) 22%

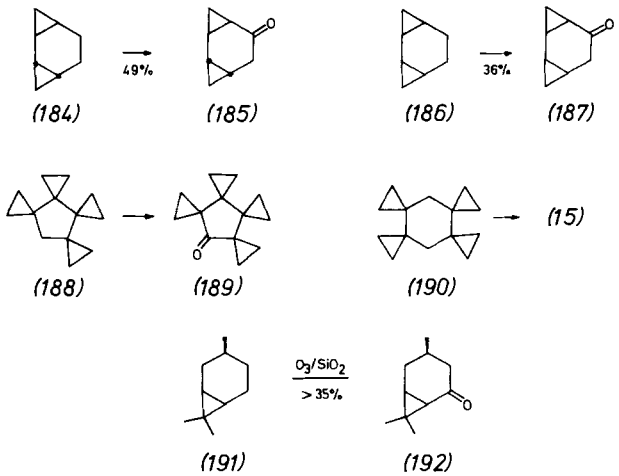
The same applies to the preparation of the trichloride *(183b)* from *(183a)*[124]. Even in tricyclo[3.2.2.0^{2,4}]nonane *(179a)*, bridgehead attack is favored by a factor of more than



(178) (179) (180)

(181) (182) (183)

(a) X = H; (b) X = Cl



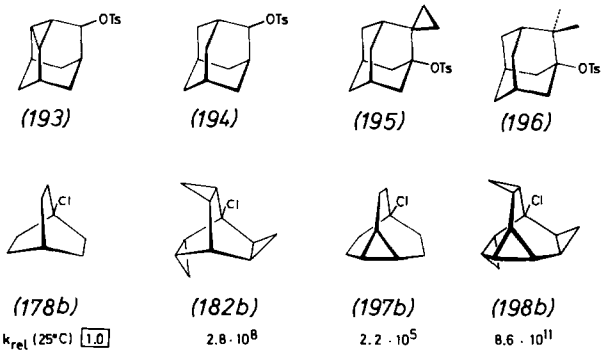
2 relative to bicyclo[2.2.2]octane *(178a)*; it becomes more and more dominant as the number of α-annelated cyclopropane rings increases, and is practically the only reaction in trishomobarrelene *(182a)*. This is due not only to the weak yet definite radical stabilization by α-cyclopropyl groups; the strong electron donating effect of the cyclopropane ring on electron-deficient centers (see Section 6) also plays a role since the transition state of hydrogen abstraction by *tert*-butoxy radicals (and by electronegative radicals in general) exhibits partial charge separation[125].

This combined effect also becomes operative on attack of C—H bonds by ozone; it is responsible for the selective oxidation[103,127] of sites adjacent to a cyclopropane ring on dry ozonation[126], for ozone behaves as a dipolar 1,3-diradical[128]. This new method for the synthesis of cyclopropyl ketones from cyclopropyl hydrocarbons (see Scheme 3) is a

Scheme 3. Relative yields of α-ketones on ozonation of cyclopropyl hydrocarbons as percentages (without considering unreacted starting material).

convenient addition to the list of previous reactions[28]. The method also provides an entry to compounds which are otherwise inaccessible or accessible only with difficulty. Ex-

amples of such compounds are *exo- (185)* and *endo*-tricyclo[5.1.0.0^{2,4}]octan-5-one *(187)* from *(184)* and *(186)*, respectively, and the monoketone *(189)* and the diketone *(15)* as convenient precursors of [5]- *(96)*[129] and [6]rotane *(97)*[127b].



The new one-step preparation of *cis*-caran-5-one *(192)* from *cis*-carane *(191)*[130] is faster and gives better yields than other multistep procedures[131]. Further applications of this oxidation in the field of terpenes are conceivable and would appear promising.

6. Electron-Donating Effect of the Cyclopropyl Group

Undoubtedly the most versatile and hence most interesting "cyclopropyl function" results on combination of the three-membered carbocycle with a neighboring electron-deficient center. Several reviews[1,132–135] witness to the wealth of publications about such systems. The basis of a directed synthetic application of this function is, *inter alia*, a detailed knowledge of structure/stability and structure/reactivity relationships of cationic cyclopropylmethyl systems.

Studies by several research groups, especially those on systems of uniform, defined conformation, have revealed the relationship between the stability of a cyclopropylmethyl cation and its conformation[17,18,136–138].

In the didehydroadamantyl derivative *(193)* we see a system of this kind in the bisected conformation (see Fig. 4) with a parallel arrangement of the interacting orbitals. Therefore, *(93)* solvolyzes 2.5×10^8 times faster than 2-adamantyl tosylate *(194)*[136a] under the same conditions. For a perpendicular orientation of the cyclopropane Walsh orbital and the carbenium ion p orbital, such as encountered in the adamantane-2-spirocyclopropane system *(195)*, the solvolysis rate is reduced by a factor of 365 relative to the reference system *(196)*, *i.e.* the cyclopropyl group has an inductive electron-attracting effect in this case and destabilizes the intermediate carbenium ion[17]. The overall range of rate ratios of $\approx 10^{11}$ between *(193)/(194)* and *(195)/(196)* corresponds to a

difference in free energy of $\Delta G_{298} \approx 68$ kJ/mol between the bisected ($\varphi = 0°$) and the perpendicular ($\varphi = 90°$) conformation of the cyclopropylmethyl cation.

Essentially rigid intermediate conformations ($\varphi = 50$—$60°$) are found in the bridgehead cations of the polycyclic systems *(179)*—*(182)* and *(198)*. The S_N1 solvolysis rates of all the bridgehead chlorides *(179b)*—*(182b)* and *(198b)* are accordingly much higher that those of the reference compounds *(178b)* and *(197b)* which do not contain cyclopropyl groups in an α position relative to the bridgehead[18,138]. Owing to the cumulative effect of three such groups, the ratios of *(182b)* to *(178b)* and of *(198b)* to *(197b)* are particularly large at 2.8×10^8 and 3.9×10^6, respectively. Although it is a bridgehead chloride, *(198b)* is some 1.6×10^5 times more reactive than *tert*-butyl chloride: *(198)* thus exhibits the greatest bridgehead reactivity found so far for any system[139].

Detailed analysis of the solvolysis rates of *(178b)*—*(182b)*, paying due attention to all relevant structural factors, has shown that the dependence of the relative stabilization energy E_φ of a cyclopropylmethyl cation upon the torsional angle φ is reproduced very well by the $\cos^2 \varphi$ function

$$E_\varphi = E_{\varphi=0} \cos^2 \varphi$$

where $E_\varphi = 75$ kJ/mol[18]. Apart from the value for maximum stabilization ($E_{\varphi=0}$) the function exactly corresponds to the curve calculated for this angular dependence by the CNDO method[140] (see Fig. 6).

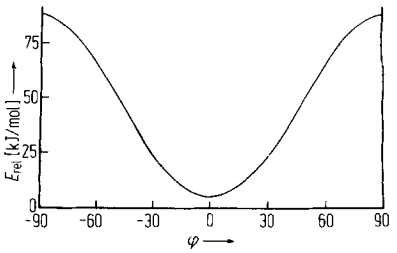


Fig. 6. Change in energy of a cyclopropylmethyl cation with conformation calculated by the CNDO method (φ = torsional angle, see Fig. 4) (according to [140]).

As a logical consequence of the enhanced bridgehead reactivity of *(179b)*—*(182b)* and *(198b)*, the corresponding "free" bridgehead cations can be readily generated[18] by

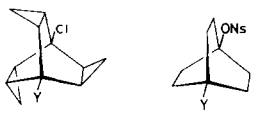

Table 3. Examples of known bridgehead derivatives of trishomobarrelene *(182)* and trishomobullvalene *(198)*. Isolated yields given.

present-day techniques[141]. Their ^{1}H- and ^{13}C-NMR spectroscopic data suggest considerable delocalization of the positive charge into the cyclopropyl groups, as has been demonstrated for cyclopropylmethyl cations in other conformations[142]. The cations can generally be efficiently trapped by nucleophilic reagents, regenerating bridgehead derivatives. In no case was skeletal rearrangement observed. Thus, on use of suitable reagents, nucleophilic substitution reactions provide access to almost any bridgehead derivative, especially of the trishomobarrelene *(182)* and the trishomobullvalene system *(198)* (see Table 3).

Unlike trishomobullvalene *(198a)*, trishomobarrelene *(182a)* has two equivalent reactive bridgehead sites; it therefore preferentially forms 1,5-dichlorotrishomobarrelene *(199a)* on treatment with an excess of *tert*-butyl hypochlorite[123]. Owing to the inductive effect of the second chlorine substituent, *(199a)* is significantly less reactive than the monochloride *(182b)*[123]. The logarithms of the solvolysis rates of a series of 5-substituted 1-chlorotrishomobarrelenes *(199a)—(199i)*[147]; correlate well with the inductive substit-

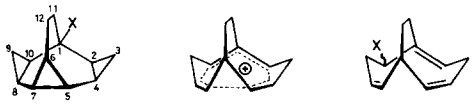
uent constants σ_{CH_2} of the Taft equation[148], and even better with the σ_q^I constants introduced by *Grob*[149]. The slope of the regression line, *i.e.* the reaction constant ρ_q^I (at 25 °C), is *ca.* 50% greater than that for 4-substituted 1-bicyclo[2.2.2]octyl *p*-nitrobenzenesulfonates *(200)*[150]. Hence the ability to transmit inductive substituent effects must be considerably greater for cyclopropane C—C σ bonds that for normal C—C σ bonds, as would be expected from their greater p character[10]. In contrast, transmission of mesomeric effects by the cyclopropane ring is much poorer than by a C=C double bond[151].

With regard to the results obtained for *(199a)—(199i)*, the substantially stronger electron withdrawal of a carbenium ion center should also be efficiently transmitted through the cyclopropyl C—C bonds in this system. This may be the reason why it has been impossible so far to generate the trishomobarrelene dication *(203)* from any of the dihalides *(201)*. In all cases only the monohalomonocations *(202)* were detectable[152] although, according to MINDO/3 calculations[153], the extent of stabilization for *(203)* with respect to

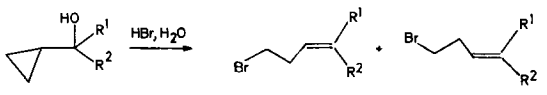


(201) *(202)* *(203)*

(204) *(205)* *(206)*

the known bicyclo[2.2.2]octyl dication *(204)*[154] should be the same as that for the monocation *(205)* relative to the kinetically unstable *(206)*[155].

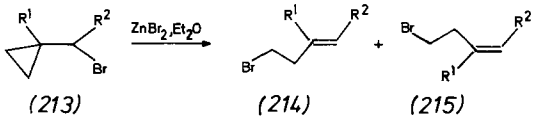
Cationic cyclopropylmethyl systems in general are known[132–134] to rearrange to homoallyl systems *via* ring opening or to cyclobutyl systems *via* ring expansion[156]. Neither of these types of rearrangement occurs in the bridgehead cyclopropylmethyl systems mentioned above, apparently because of extensive ring strain in the potential products. The dihydro-*exo,exo*-bishomobullvalene system *(207)*[157] is an exception, since the reaction of the alcohol *(207b)* with thionyl chloride in the presence of diethylaminomethyl-polystyrene even at room temperature yields a rearranged chloride shown by its ^{1}H- and ^{13}C-NMR spectra[158] to have the structure *(209c)*.



(207) *(208)* *(209)*

(a) X = H ; (b) X = OH ; (c) X = Cl

Apparently the intermediate carbenium ion behaves, like *(208)*, as a bridged trishomocycloheptatrienyl cation which is attacked by the nucleophile preferentially in positions 2 and 10, respectively.



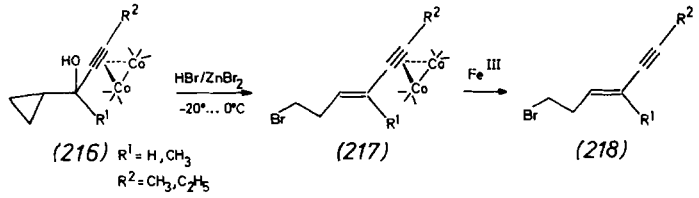
Therefore *(209)* is the result of a threefold cyclopropylmethylhomoallyl rearrangement. This type of reaction plays a major role in the synthetic utilization of the cyclopropyl ring function (see above). *Julia*'s olefin synthesis[159] is a classical example of these methods; it has found wide application in the preparation of isoprenoids[160–162].

(210) *(211)* *(212)*

(a) R^1 = Alkyl, R^2 = H
(b) R^1 = Alkyl, R^2 = CH_3

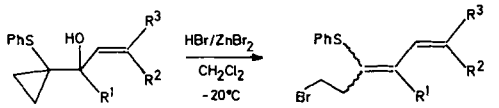
90–95% 5–10%

(213) *(214)* *(215)*



R^1 = CH_3, C_2H_5
R^2 = Alkyl, Alkenyl

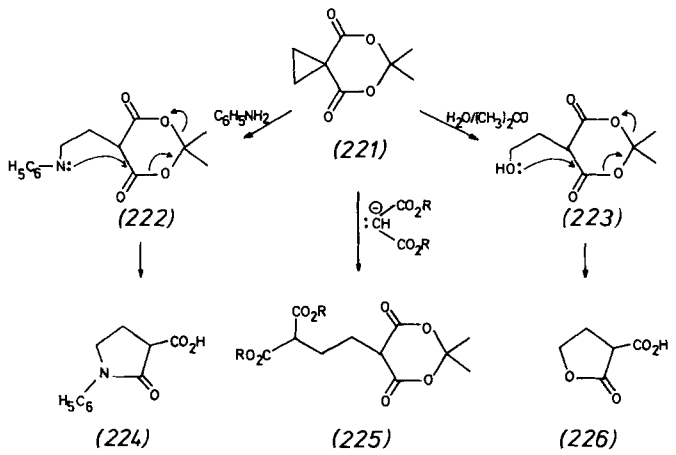
96–97% 3–4%



According to the original procedure[159a,b] a cyclopropylmethanol *(210)* is treated with 48% hydrobromic acid; secondary alcohols *(210a)* give the (*E*)-configurated olefins *(211a)* with 90 to 95% stereoselectivity. Treatment of tertiary alcohols *(210b)* with magnesium halides in ether also give the (*E*)-olefins *(211b)* in excellent yields[160]. On the other hand, the modified procedure of *Johnson et al.*[161] leads to trisubstituted (*E*)-olefins *(214)* stereoselectively upon treatment of the secondary cyclopropylmethyl bromides *(213)* with zinc bromide in ether. Stereoselectivity is also observed if one of the two alkyl groups in *(210)* carries a phenylsulfonyl group[159e].

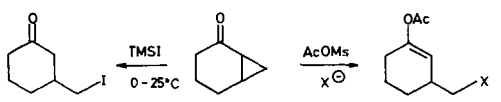
Interesting variants of the *Julia* method are the stereoselective production of conjugated enynes *(218)* as precursors for conjugated *E,Z*-dienes from alkynylcyclopropylmethanols *via* their dicobaltcarbonyl complexes *(216)* as interme-

diates[163], as well as the acid-catalyzed rearrangement of (phenylthiocyclopropyl)vinylmethanols *(219)* to functionalized conjugated dienes *(220)*, which are versatile intermediates in synthesis[164].



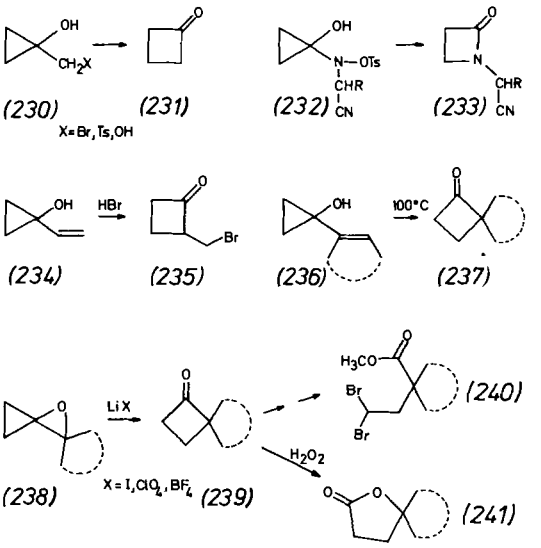
(216) $R^1 = H, CH_3$; $R^2 = CH_3, C_2H_5$ *(217)* *(218)*

(219) *(220)*



The "homologous Michael reaction", *i.e.* the ring opening of cyclopropylcarbonyl compounds by nucleophiles, which has been developed extensively in recent years[165,166], is derived from the same reaction principle. If sufficiently activated by two electron-withdrawing groups (especially as in *(221)*), such compounds can add various nucleophilic reagents[167]. The primary adducts of primary amines (*e.g.* *(222)*) or water *(223)* readily cyclize to the five-membered heterocycles *(224)* and *(226)* respectively, which, like the adducts of carbanions [*e.g.* *(225)*], can serve as intermediates in the synthesis of natural products[165].

(222) *(221)* *(223)*



(224) *(225)* *(226)*

Monoactivated cyclopropanes do not react the same way except in special cases[165]. Nucleophilic additions to such systems do, however, occur smoothly with the assistance of an electrophile[168–171] (see Section 2[53]). In this way, cyclo-

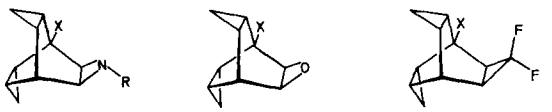
(227) *(228)* *(229)*

propyl ketones are cleaved under mild conditions by trimethylsilyliodide (TMSI) to γ-iodoketones [*e.g.* *(228)*→*(227)*[170]] or by acetylmethanesulfonate (AcOMs) together with nucleophiles to give δ-substituted enol acetates [*e.g.* *(228)*→*(229)*][171].

(230) *(231)* *(232)* *(233)* *(234)* *(235)* *(236)* *(237)* *(238)* *(239)* *(240)* *(241)*

These are a few examples only for the various possibilities of the cyclopropylmethyl homoallyl ring opening reaction. Nonetheless the second type of cyclopropylmethyl rearrangement, *i.e.* the ring expansion to cyclobutane derivatives, was essential for a number of new synthetic reactions[172–175]. All the (1-hydroxycyclopropyl)methyl derivatives *(230)* yield cyclobutanone *(231)* under appropriate conditions[172]. A β-lactam synthesis developed by *Wasserman et al.* [*e.g.* *(232)*→*(233)*] is based on the same reaction principle[173]. 1-Vinylcyclopropanol *(234)* reacts with electrophilic reagents to yield derivatives of 2-methylcyclobutanone, *e.g.* *(235)*[174]. 1-Vinylcyclopropanols *(236)* can also be rearranged thermally to cyclobutanones *(237)*[172]. The greatest flexibility is offered by the oxaspiropentanes *(238)*—readily available according to *Trost et al.*[56,57,175] from aldehydes and ketones—because of their rearrangements to cyclobutanones *(239)*, which can be utilized in the synthesis of a variety of compounds such as *(240)* and *(241)*[175].

The wide spectrum of possible applications of electron-deficient cyclopropylmethyl groups has only been suggested by these examples. Finally, it should be pointed out how the electron-donating ability of the cyclopropyl group can be utilized in mechanistic problems. *Tidwell et al.* have carefully investigated electrophilic additions to alkenes and observed that the rate enhancement by a cyclopropyl substituent is proportional to the amount of positive charge localized on the α-carbon atom in the transition state[176]. In a reversed sense, the cyclopropyl substituent can therefore be used as a sensitive probe into the transition state structure of an electrophilic addition[176].



7. Heterocyclic Analogues of Cyclopropane

While discussing the characteristics of the cyclopropane ring one is automatically tempted to compare them with those of simple heterocyclic three-membered rings, especially since their bonding properties can be described by the same model as that used for the cyclopropane ring[2,177]. As far as the chemistry of aziridines and oxiranes is concerned, reference is made to the relevant handbooks[178]. In this context, only the interesting question about the electron-donating ability of aziridyl and oxiryl groups, which has remained

unanswered for a long time in spite of elaborate studies[179/181], will be discussed briefly.

Previous kinetic and mechanistic investigations on aziridylmethyl[179,180a] and oxirylmethyl derivatives[181a] did not give a clear-cut picture, because in all cases so far ring opening reactions and neighboring group participation of the heteroatom played an important role. In contrast to this, the 1-chloro-3-methyl-3-azatrishomobarrelene *(242b)* and the 1-chloro-3-oxatrishomobarrelene *(243b)* solvolyze exclusively to unrearranged bridgehead derivatives *(242c, d)* and *(243c, d)*[182], respectively. Their solvolysis rates therefore yield reliable information pertaining to the question of how an intact three-membered heterocycle influences the relative stability of an adjacent carbenium ion center.

Taking into account all the structural details, the exact analysis of the rate data (see Table 4) shows that in these systems with their rigid conformations the electron-donating ability of an unsubstituted aziridyl group is about 13 times weaker than that of a cyclopropyl group, whereas the oxiryl group even exhibits a strong electron-withdrawing effect. The decreasing donating ability of the hetero-three-membered rings correlates with the increasing electronegativity of the heteroatoms, which lowers the energy of its highest occupied Walsh molecular orbital[184]. Electron-withdrawing substituents at the cyclopropyl group as in *(244b)* act in the same way (see Table 4)[182].

(242) R = CH_3 *(243)* *(244)*

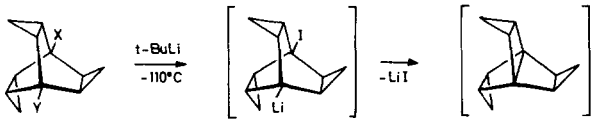
[a] Calculated for a hypothetical model showing the same degree of skeletal twisting in its transition state as found for *(182b)* (see [18]). [b] Calculated from the value for the *N*-methyl compound with a factor of 10^{-1} to account for the methyl group [183].

8. Outlook

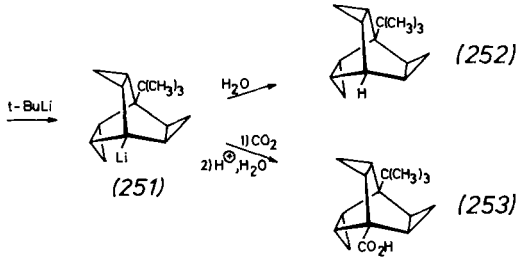
It is obvious that the aspects of small ring chemistry presented here cannot be discussed extensively, and they have not even been completely investigated yet. New polycyclic small ring compounds which have already been prepared or only trapped as short-lived intermediates will help to delineate the limits of the carbon atom's bonding ability and the possibilities of reactivity enhancement by ring strain. This is exemplified by the molecules *(245)—(249)*. In the so-called small ring propellanes *(245)—(247)* the p character of the central C—C single bond must be unusually high because all four bonds on the two quaternary carbons are arranged as in an "inverted" tetrahedron[185,186]. Like the π bonds in olefins, these central bonds therefore easily add a variety of reagents. However, the most important factor determining the reactivity of these propellanes is the high total strain energy, which is largely liberated upon opening the central bond. In this way, the [3.2.1]propellane *(245)*[187] with a strain energy *(SE)* of about 250 kJ/mol[188] rapidly adds halogens, acids, and even atmospheric oxygen. So far the [2.2.1]propellane *(246)*[189] and the [2.2.2] parent system[190] (*SE* about 330 kJ/mol[191] in each case) have only been postulated as intermediates based on the isolation of their addition products.

(245) *(246)* *(247)*



(248) *(249)*

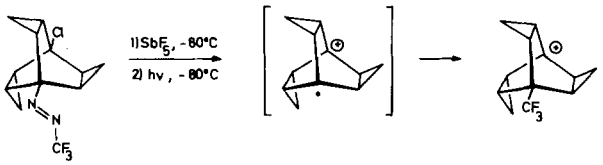
However, one cannot generally relate a high total strain energy of a molecule to its thermal instability and draw conclusions about its ability to exist at room temperature. For instance, *(245)* is thermally quite stable although it adds electrophiles quite easily. This difference is even more pronounced in the case of barettane *(248)* with $SE \geq 449$ kJ/mol[191]: in the presence of a catalyst *(248)* adds hydrogen extremely rapidly to the most highly strained σ bonds of its two bicyclo[2.1.0]pentane units; yet, on the other hand, it is completely stable up to 200 °C[192]. In contrast to the isomeric diademane *(91)* (*SE* about 427 kJ/mol)[191], *(248)* does not have a low energy reaction path to a thermodynamically more stable rearrangement product at its disposal.



The still hypothetical propellane *(249)* seems to approach the limits of what is conceivable on the basis of current bonding theory. Its three bicyclopentane units which all share the same central bond contribute to a total strain energy of at least 670 kJ/mol[191], the portion of about 328 kJ/mol which would be released upon opening the central bond very closely resembles the energy of a normal C—C single bond. It remains questionable, therefore, whether *(249)* can exist at all with a central "bond", even if one takes into account that a certain stabilizing interaction may occur between the bridgehead p orbitals and the cyclopropyl Walsh orbitals.

Nevertheless, there are experimental findings which suggest an intermediacy of *(249)* or its diradical or zwitterionic equivalent respectively[193]. The 1-*tert*-butyl derivative *(250)* is formed at −110 °C from 1,5-diiodotrishomobarrelene *(201d)* and *tert*-butyllithium after aqueous work-up. Since a direct *tert*-butylation of *(201d)* can be excluded—though the more reactive 1-iodotrishomobarrelene is smoothly metalated under the same conditions it does not yield a trace of *(252)*—it is more probable that in fact *(249)* is formed *via (250)*.

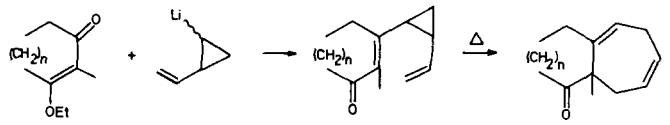
An addition of *tert*-butyllithium to the central bond in *(249)*, which would be reasonable in view of its high strain energy, leads to *(252)*, the intermediacy of which was proved by its carboxylation to *(253)*. Final proof for the intermediate formation of the symmetrical *(249)*, which would be possible, for instance, by use of a trishomobarrelene derivative *(201e)*



(201) (d) X = Y = I (e) X ≠ Y (250) (249)

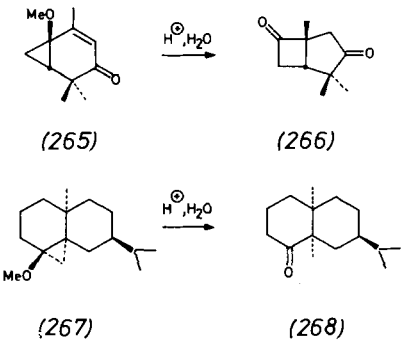
(251) (252) (253)

with two different leaving groups in optically active form[194], is still pending.



Better chances for a direct spectroscopic proof should exist for the radical cation *(255)* which is closely related to *(249)*, because the substantial cation-stabilizing effect of the cyclopropyl group (*vide supra*) comes into play and the conceivable "bond" between the two bridgeheads[195] would be a one-electron bond and thereby longer than that in *(249)*. It is an open question what the lifetime of *(255)* may be, if it occurs as an intermediate in the sequence *(254)*→*(257)*[193]. In this case, the use of optically active starting material[196] would again be of help.

(254) (255) (256)

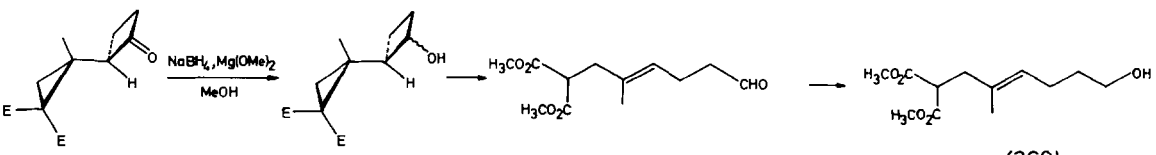


Thus more and more new model compounds can be conceived which will provide ever more detailed knowledge about the "bonding properties of the cyclopropane ring and their chemical consequences". The development of new synthons, which utilize these properties, will build upon that knowledge. Even nowadays, synthetic applications of the small ring functions are beginning to play a major role.

(261) constitutes a useful method for the annelation of cycloheptane rings[198].

(261) (262) (263) (264)

Wenkert et al. demonstrated an elegant utilization of the methoxycyclopropyl function in important steps of the total synthesis of (+)-grandisol [*(265)*→*(266)*], of (−)-valeranone [*(265)*→*(268)*], and of other sesquiterpenes[199].



(265) (266) (267) (268)

These and many other examples[200,165,163] point the way for the directed utilization of three-membered ring synthons.

The authors' own work cited in this article was only made possible by the dedication and ingenuity of a group of enthusiastic co-workers. Their namens are given in the relevant references. Particular thanks go to Professor W. Lüttke, Göttingen, for provision of excellent working conditions during the decisive initial phase. Financial support by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the State of Lower Saxony, and Hoechst AG, Frankfurt/Main, and BASF AG, Ludwigshafen, is gratefully acknowledged.

(257) E = $CO_2C(CH_3)_3$ (258) (259) (260)

Systems of type *(257)* can be constructed by standard methods, *e.g.* from α,β-unsaturated carbonyl compounds. Their fragmentation, accompanied by a strain energy release of about 230 kJ/mol, proceed under mild conditions and stereospecifically to give 1,6- and 1,7-difunctionalized molecules such as *(259)* and *(260)*, which can serve as starting materials for the syntheses of acyclic terpenes[197].

The thermal rearrangement of the adducts *(263)* of 2-vinylcyclopropyllithium *(262)* to 3-alkoxy-2-cycloalkenones

Conformational Analysis by Photoelectron Spectroscopy

By Martin Klessinger and Paul Rademacher[*]

Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday

The conformation of organic molecules may be determined by means of photoelectron (PE) spectroscopy if there are orbital interactions present which depend on a dihedral angle. Straightforward application of the method requires that all ionization bands of interest can be assigned unambiguously and that inductive effects and secondary orbital interactions do not occur or can be accounted for appropriately. In many cases, this method complements conventional methods of conformational analysis. PE conformational analysis is particularly suited to compounds containing vicinal lone pairs or π systems.

1. Introduction

In order to completely describe the structure of an organic molecule one has to specify not only the *constitution* and the *configuration,* but also the *conformation.* While the constitution merely indicates which atoms are connected, different spatial arrangements of the bonds with respect to a given atom or group of atoms (*e.g.* a C=C double bond, a ring, *etc.*) lead to different configurations which may be converted into each other only by breaking and reforming one or several bonds.

According to *Barton*[1] the conformations of a molecule of given constitution and configuration "are those arrangements in space of the atoms of the molecule which are not superposable upon each other". A molecule can therefore assume an infinite number of conformations by varying its bond lengths and bond angles. In practice, however, only those arrangements of atoms are usually considered as different conformations which are obtained by rotation about single bonds. Different conformations are populated according to their energy contents. While the few "stable" conformations of a molecule are of principal interest, energy rich forms may be of special importance in connection with chemical reactivity.

As the various stable conformers of a molecule can be interconverted by means of relatively low-energy processes (rotation about single bonds, inversion of nonplanar groups), they may be isolated at room temperature only in exceptional cases. The borderline between conformational and configurational isomerism is not rigid; a value of 80 kJ/mol may be assumed for practical purposes.

Conformational analysis as a branch of stereochemistry is concerned with physical and chemical properties of different conformers of a given molecule. The principles of conformational analysis[2,3], the historical development[3,4], as well as experimental[3] and theoretical[3,5] methods have been dealt

with extensively in a number of monographs and review papers.

Geometry and symmetry of a given conformer may be obtained by static methods, primarily by diffraction methods and spectroscopic methods such as IR/Raman and NMR spectroscopy, but also by the measurement of dipole moments. Activation energies of conformational interconversions are determined by means of dynamic methods such as calorimetry, acoustic relaxation, as well as microwave spectroscopy for barriers of 2—20 kJ/mol and especially dynamic NMR spectroscopy for barriers of 20—100 kJ/mol. A great number of interesting conformational problems in organic chemistry has been solved particularly by this last method in recent years.

Owing to the complexity of the internal motion of polyatomic organic molecules, the elucidation of the conformational properties of a given compound will often require a combination of various experimental and theoretical methods; complete potential energy diagrams for internal rotations and ring inversions as well as so-called conformational maps of molecules with several possibilities of internal conversion may be derived only by theoretical methods.

2. Theoretical Foundations of Conformational Analysis by PE Spectroscopy

2.1. The Koopmans Approximation

Photoelectron (PE) spectroscopy[6] permits the determination of vertical ionization potentials $IP(i)$, which according to *Koopmans'* theorem[7]

$$IP(i) = -\varepsilon_i \tag{1}$$

may be set equal to negative orbital energies $-\varepsilon_i$. PE spectroscopy is therefore suitable for the investigation of orbital interactions[8]. It was realized quite early that orbital interactions and therefore also PE spectra may be conformation-dependent[9].

Conformational analysis by PE spectroscopy is based upon the validity of *Koopmans'* theorem or *Koopmans'* approximation[10] as well as upon the possibility of assigning the observed ionization bands to distinct orbitals. For large organic molecules an unambiguous assignment can usually be given only for a few bands at lower energies which are well separated from neighboring bands.

Within this energy range *Koopmans'* theorem is valid to a fairly good approximation: each ionization potential corresponds to an orbital energy and *vice versa* since a single product of orbitals is a sufficiently accurate wave function of the system; it is only at higher energies that an adequate description of an ionic state will also require orbital products which, within the simple MO model, correspond to excited configurations of the ion. Due to this configuration interaction (CI) more states may appear than are to be expected from the orbital energies, so that the intensity of an ionization may be distributed as shown in Figure 1 over several bands as a result of so-called shake-up and shake-off processes[13].

Furthermore, correlation and reorganization effects which arise from changes in the number of electron pairs and from changes in the effective field for the individual electrons re-

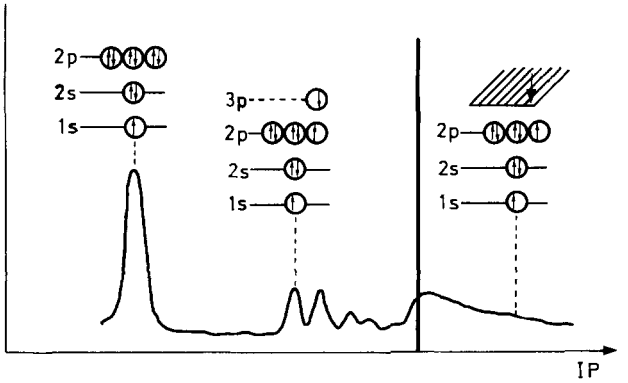

Fig. 1. Schematic representation of a PE spectrum including shake-up and shake-off processes for a core ionization of a neon atom. The solid vertical line represents the ionization limit.

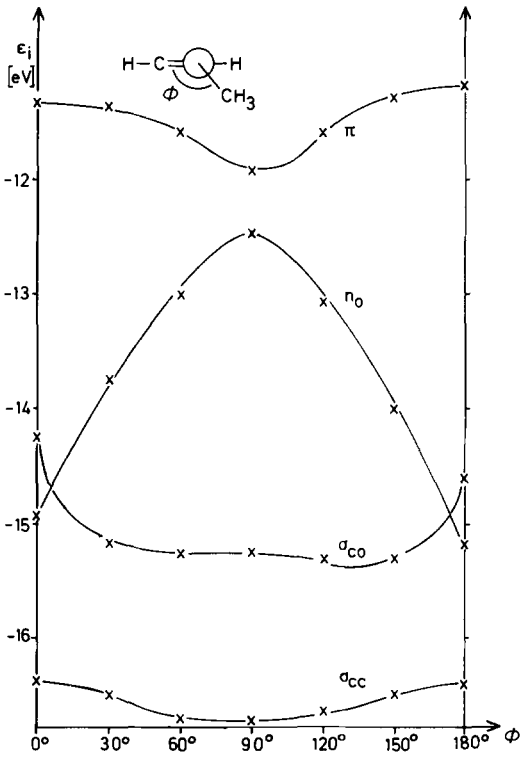
spectively more or less cancel each other for valence electrons[11,12]. Deviations from *Koopmans'* approximation are observed mainly in the case of ionizations from strongly localized orbitals[14] as a consequence of electron reorganization. However, even these deviations may be neglected if only relative orbital energies for different conformers are of interest, and if the character of the corresponding orbital does not change on going from one conformer to the other. In the following it is therefore assumed that an interpretation of the PE spectra based on the assumption of the validity of *Koopmans'* theorem is justified.

2.2. Orbital Interactions

2.2.1. Calculation of Orbital Energies as Functions of Dihedral Angles

The orbital energies for different conformations of a molecule may in principle be calculated by varying one (or sev-



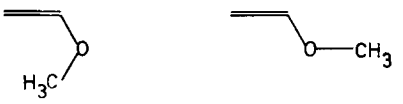


Fig. 2. Calculated energies (CNDO/S) of the four highest occupied orbitals of methyl vinyl ether *(1)* and their dependence on the dihedral angle ϕ. *(1a)*, $\phi = 0°$; *(1b)*, $\phi = 180°$.

eral) dihedral angles and simultaneously readjusting all other geometric parameters. Thus for methyl vinyl ether *(1)* the orbital energies are obtained as functions of the dihedral angle ϕ as shown in Figure 2[15]. Such calculations make it possible to decide which ionization potentials may be used for conformational analysis. However, if the dihedral angle is to be determined by comparing the observed difference ΔIP of ionization potentials with the calculated difference $\Delta\varepsilon$ of orbital energies an extremely high accuracy of calculation is required. In such cases an empirical parametrization of the theoretically determined relation between ΔIP and the dihedral angle ϕ is preferable[16] (cf. Section 3.2).

2.2.2. Orbital Interactions between Molecular Fragments

One of the main disadvantages of the direct calculation of orbital energies may be seen in the fact that this method, although making possible predictions of the conformational dependence of orbital energies, in general does not explain the origin of the orbital interactions. Thus it is not obvious from the calculated orbital energies in Figure 2 why ΔIP should differ for the planar *syn- (1a)* and *anti* conformer *(1b)* of methyl vinyl ether.

(1a), $\Phi = 0°$ *(1b)*, $\Phi = 180°$

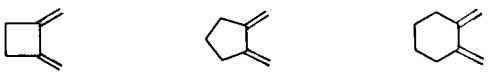
Detailed information about conformation-dependent orbital interactions is obtained on starting from orbitals localized in subsystems or fragments of the molecule, *e.g.* in the case of methyl vinyl ether *(1)* from the orbitals of the vinyl group and the oxygen lone pair as well as the methyl group. An SCF calculation based on such localized fragment orbitals yields the same results as a conventional SCF calculation based on AOs, but as these results are expressed in terms of fragment orbitals it is immediately seen which orbitals interact with each other and to what extent.

For the interpretation of the orbital interactions it is furthermore very illustrative to split the orbital interactions into two parts, which may be called "inductive" and "conjugative" interactions, and which are obtained by first considering the orbitals of one fragment in the field of all the other fragments and taking into account the bonding interactions between the fragments only in a second step. Within the LCFO-SCF-MO method (LCFO = *l*inear *c*ombination of *f*ragment *o*rbitals)[17] which has been especially developed for the interpretation of PE spectra, the inductive effects of the first step may be evaluated quantitatively on the basis of the generalized product functions approach[18] together with the strong orthogonality condition[19] which is automatically satisfied if the ZDO approximation is being applied. This procedure makes it possible to determine the conjugative interactions using for the orbital energies of the fragments experimental ionization potentials and electron affinities corrected by the calculated inductive perturbations. Interactions of fragment orbitals can thus be evaluated directly and in very good agreement with experimental data. The method was first developed within the π approximation and applied to the interaction of π systems[20], and afterwards extended to include σ systems[21], where *e.g.* in the case of the union of two methane fragments to yield ethane, changes in the number of nuclei and electrons have to be taken into account.

Calculations according to the LCFO method show that in general only very few antibonding orbitals of the fragments are needed for a sufficiently accurate description of the combined system. For unpolar systems, as *e.g.* for the interaction of the π systems of two unsaturated alternant hydrocarbons or for the interaction of two alkyl groups, all antibonding orbitals may be neglected. In this case the LCFO model reduces to the interaction of bonding (or occupied) orbitals and becomes identical with the LCBO model in the HMO approximation, which was first introduced by *Hall*[22] and which in a great number of different investigations has proved very useful for the interpretation of PE spectra[23].

2.2.3. Summary and Examples

The results of calculations based on the LCFO method may be taken as a justification of the LCBO method, but at the same time they indicate clearly the limits of this approach. These results can be summarized as follows:



The influence of conformational effects on the PE spectrum may be discussed on the basis of the LCBO model by means of angularly dependent orbital interactions, if

a) inductive perturbations of the fragment orbitals,
b) secondary orbitals interactions, and
c) interactions with unoccupied orbitals

either do not occur or else can be taken into account appropriately. Points b) and c) are of special importance as they can also be angularly dependent.

Some examples may illustrate these three points:

For 1,2-dimethylenecyclobutane *(2)*[24] and 1,2-dimethylenecyclopentane *(3)*[25] the difference $\Delta IP_{1,2}$ of the first two ionization potentials, which could be assigned to π orbitals, is about the same as for 1,3-cyclohexadiene[26]; these compounds contain a coplanar π system. For 1,2-dimethylenecyclohexane *(4)*[27] on the other hand $\Delta IP_{1,2}$ is only half that

(2) *(3)* *(4)*

value, as the chair conformation of the cyclohexane ring leads to a dihedral angle $\phi \approx 55°$ between the double bonds and therefore to a reduced conjugative interaction. The simple LCBO model is applicable and leads to $\Delta IP_{1,2} = 2\beta = 2\beta_0 \cos\phi$, if $\beta = \beta_0 \cos\phi$ is the angle-dependent resonance integral for the π-π interaction; the inductive effect can be estimated, from a comparison of the mean value of the π bands of 1,2-dimethylenecyclohexane with the first ionization potential of methylenecyclohexane[28], to be ≈ 0.3 eV.

In methyl vinyl ether *(1)* the difference between the splitting $\Delta IP_{1,2}$ for the *syn (1a)* and the *anti* conformer *(1b)* may be explained by secondary orbital interactions as shown in Figure 3: through-space interactions between the π_{CH_3} and π_{CC} orbitals destabilize the second MO, which is essentially the lone pair n_O of the oxygen, and stabilize the highest MO, which is predominantly π_{CC} in character. As this interaction is larger for the *syn* conformer than for the *anti* conformer for

geometrical reasons, $\Delta IP_{1,2}$ is smaller for the former than for the latter[29].

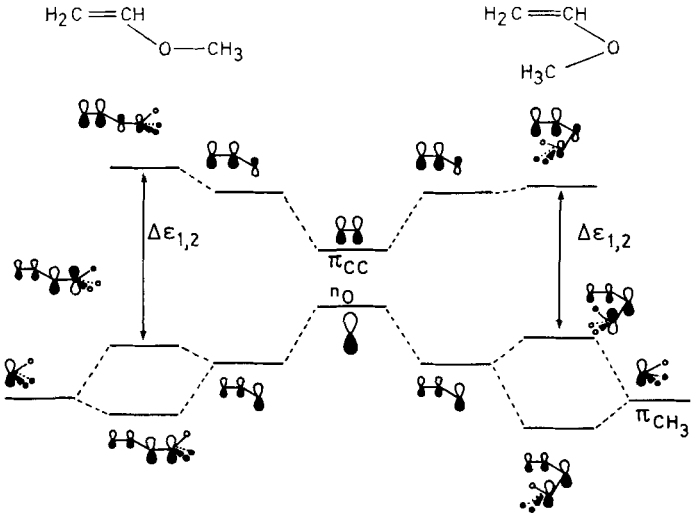


Fig. 3. Orbital interaction diagram of methyl vinyl ether *(1)* in the LCBO approximation. Center: energies of the π_{CC} and n_O orbitals without ($\phi=90°$) and with interaction ($\phi=0°$ or 180°). Left: influence of the π_{CH_3} orbital in the *anti* form *(1b)* ($\phi=180°$). Right: with additional through-space π_{CC}/π_{CH_3} interactions in the *syn* form *(1a)* ($\phi=0°$).

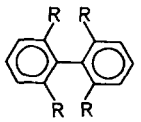
Finally, α,β-unsaturated carbonyl compounds[30] illustrate the inapplicability of the LCBO model as a result of interactions with antibonding orbitals. This may be seen from the fact that in contrast to expectations based on the LCBO model, the first ionization potential is higher for acrolein than for ethylene, corresponding to a stabilization of the π_{CC} MO due to the interaction with the lower lying π_{CO} MO.

3. Conformational Analysis by PE Spectroscopy



Conformation-dependent interactions are observed primarily between neighboring atoms. The corresponding orbitals may be lone-pair orbitals or p orbitals of π systems. PE spectroscopy may therefore be used to study conformational problems which can be interpreted by

a) n/n interactions,
b) π/π interactions, and
c) n/π interactions.

3.1. Biphenyls

The first example of a systematic conformational analysis by PE spectroscopy was presented by *Maier* and *Turner* in their study of biphenyls[9].

In the crystalline state, the two benzene rings of biphenyl *(5)* are coplanar, with an optimal delocalization of π electrons. In the gase phase, however, biphenyl is not planar but twisted with respect to the central CC bond by *ca.* 45°. The magnitude of this twisting depends on the substituents: for

(5) R = H

(6) R ≠ H

ortho substitution as in *(6)* the barrier to internal rotation can be large enough (≥80 kJ/mol) to permit the isolation of different conformers (atropisomerism)[31].

From Figure 4 it is seen that the pairwise splittings of the occupied MOs π_1 to π_6 of *(5)*, which may be constructed schematically from the π MOs of benzene, show different variations with the torsional angle ϕ. As expected, the effects are largest for the pair π_3 and π_6, for which the LCBO method yields

$$\Delta\varepsilon=\varepsilon(\pi_6)-\varepsilon(\pi_3)=2B\cos\phi \qquad (2)$$

for the splitting, with $2B$ being the maximal value for coplanar arrangement of the benzene rings ($\phi=0°$).

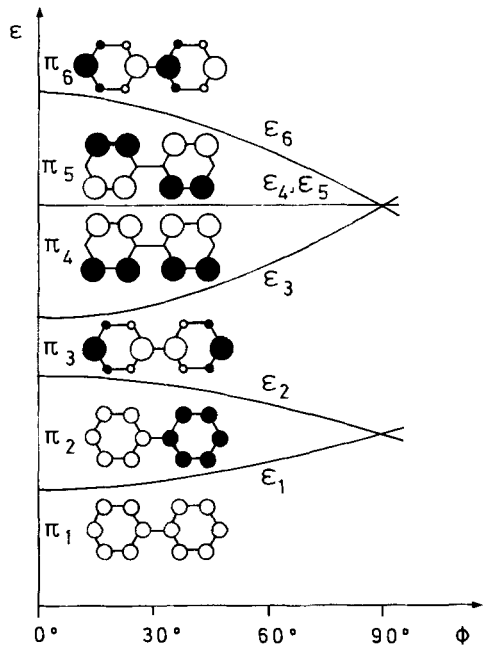


Fig. 4. Schematic representation of the occupied π MOs π_1 to π_6 of biphenyl *(5)* and the variation of the orbital energies ε_1 to ε_6 with the torsional angle ϕ.

Maier and *Turner* proved the validity of this relation using biphenyls of known structure, for which they obtained values of $\Delta IP=IP(\pi_6)-IP(\pi_3)$ and $\cos\phi$ which clearly confirm the linear relation of eq. (2). From this calibration line, torsional angles ϕ of a large number of biphenyls could be determined from their PE spectra.

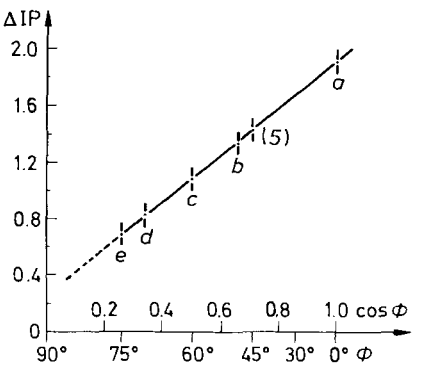

Fig. 5. Splitting $\Delta IP=IP(\pi_6)-IP(\pi_3)$ corresponding to the π MOs π_3 and π_6 for biphenyls of known conformation as a function of $\cos\phi$. *(5)*, biphenyl; *a*, fluorene; *b*, 2-fluoro-; *c*, 2,2'-difluoro-; *d*, perfluoro-; *e*, 2,2'-dibromobiphenyl.

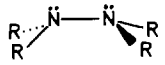
As far as experimental data are available, the values of ϕ thus obtained are in excellent agreement with the result of other methods.

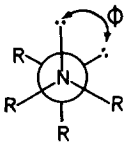
The straight line shown in Figure 5 may be expressed as

$$\Delta IP = 1.65 \cos\phi + 0.35 \text{ [eV]} \quad (3)$$



In contrast to eq. (2), this line does not pass through the origin of the coordinate system. This is due to secondary interactions between π and σ orbitals, which cannot be neglected, especially for large torsional angles.

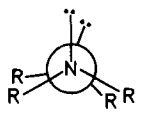
This method was applied analogously to the conformational analysis of related systems like bipyridyls[9], bithienyls[32], and bipyrroyls[33].



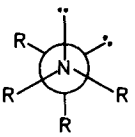
3.2. Systems with n/n Interactions

3.2.1. Hydrazines

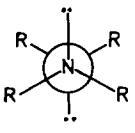
Hydrazines *(7)* are the simplest possible compounds with vicinal lone pairs of electrons. The unusual conformational



(7)



properties of such systems have been the subject of numerous theoretical and experimental investigations[34–38]. In particular, the preference for the *gauche* conformation ($\phi \approx 90°$) by the parent compound N_2H_4 and nearly all open-chain derivatives *(7)* was difficult to rationalize for a long time[35]. This property is not due to a specific "repulsion" or "attraction" of the lone-pair electrons, but results from the interaction with vicinal antibonding orbitals (n/σ*- or n/π* interaction)[36].



Undoubtedly, the most interesting aspect of the conformation of hydrazines is the magnitude of the torsional angle ϕ. The conformers *(7a)*, *(7b)*, and *(7c)* may be distinguished by

syn (C_{2v})
(7a)

gauche (C_2)
(7b)

anti (C_{2h})
(7c)

their symmetry. According to experimental[34] and theoretical[36] results for hydrazine and methylhydrazine, *(7b)* corresponds to the minimum of the torsional potential, while *(7a)* as well as *(7c)* are related with maxima of approximately 50 and 15 kJ/mol. Substituents obviously have only minor effects upon the torsional potential curve. Thus structure determinations and spectroscopic investigations on *(7)* with R = H, CH_3, CF_3, and SiH_3 always yielded *gauche* forms as stable conformers[34,39]. The only exception is tetrafluorohydrazine, for which an *anti/gauche* mixture has been observed[34].

The accurate experimental determination of ϕ for *(7)* is a very tedious task and usually necessitates complete structure analysis, since methods such as IR and NMR spectroscopy reveal at most the symmetry of *(7)* but not the value of the angle ϕ.

Substantial progress in this field was achieved on introduction of PE spectroscopy, which provided elegant solutions to many interesting conformational problems of hydrazines[16,40–51]. The procedure is based upon the correlation of the splitting ΔIP of the ionization potentials of the lone-pair electrons with the torsional angle ϕ. The two n MOs of *(7)*, n_+ and n_-, are obtained by linear combination of the n orbitals n_1 and n_2 (approximately sp^3-hybridized orbitals) localized on the nitrogen atoms:

$$n_+ = (n_1 + n_2)/\sqrt{2} \quad (4)$$
$$n_- = (n_1 - n_2)/\sqrt{2}$$

The variation of the orbital energies $\varepsilon(n_+)$ and $\varepsilon(n_-)$ on internal rotation as calculated by quantum chemical methods is drawn schematically in Figure 6.

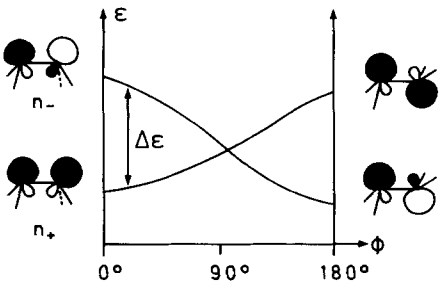


Fig. 6. Variation of the orbitals energies $\varepsilon(n_+)$ and $\varepsilon(n_-)$ of hydrazines with the torsional angle ϕ.

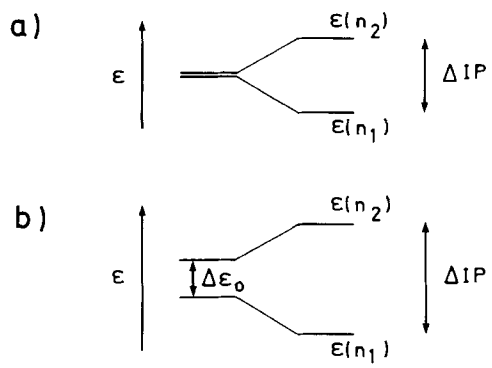
From these results a value of $\Delta IP = 0$ is to be expected for $\phi \approx 90°$, *i.e.* for the perpendicular arrangement of n_1 and n_2 with minimal overlap, while at 0° and 180° maximum values should be observed for ΔIP. Although the correlation between $\Delta IP = -\Delta\varepsilon = \varepsilon(n_+) - \varepsilon(n_-)$ and ϕ is undoubtedly affected by the substituents R and other structural parameters, it is justifiable, to a good approximation, to use a single relation similar to eq. (3) in all cases[16]. From the data of hydrazines of known structure, the relation

$$\Delta IP = 2.20 \cos\phi - 0.25 \text{ [eV]} \quad (5)$$

was obtained.

For unsymmetric hydrazines, n_+ and n_- may differ in energy due to the non-equivalence of n_1 and n_2, even in the case of vanishing interaction, by an amount $\Delta\varepsilon_0$ (Fig. 7)



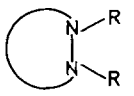


Fig. 7. Splitting $\Delta\varepsilon$ for the n orbitals of (a) symmetrically and (b) unsymmetrically substituted hydrazines *(7)*.

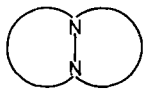
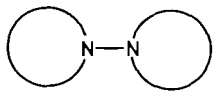
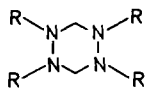


which has to be subtracted from the measured ΔIP prior to use of eq. (5)[16,42–44].

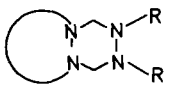
With the correspondingly corrected ΔIP values angles between *ca.* 90 and *ca.* 100° are obtained for acyclic hydrazines in all cases, definitely indicating the *gauche* conformation of these compounds.



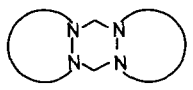
Equation (5) has been applied not only to acyclic hydrazines *(7)* but also to cyclic *(8)* and bicyclic *(9)* compounds and to bi(cycloamines) *(10)*, as well as to molecules containing two or three hydrazine groups *(11)—(14)*. Thus a variety



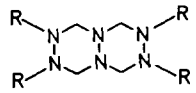
(8)



(9)

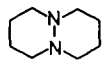


(10)

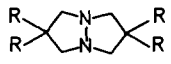


(11)

(12)

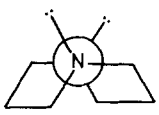


(13)

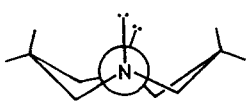


(14)

of different conformational problems could be solved. In this review only a few typical examples will be considered.

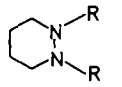


For cyclic *(8)* and bicyclic hydrazines *(9)*, ΔIP values up to 2.4 eV have been observed[40,41,43,45,47,48], indicating large deviations from 90°: 1,6-diazabicyclo[4.4.0]decane *(15)* and the central hydrazine fragment of 1,3,4,6,8,9-hexaazabicyclo[4.4.0]decane *(14)*, R = H, show the largest splittings of n orbitals with $\Delta\varepsilon = -2.35$ and -2.40 eV respectively[48], corresponding to their inversion symmetry ($\phi = 180°$), which is also indicated by their vibrational spectra[52]. Similarly large values can only be found for *syn*-fixed hydrazines ($\phi \approx 0°$).



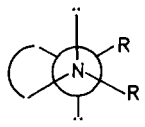
(15)

(16), R = H
(17), R = CH_3



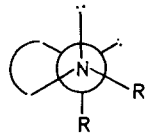
(16)

(17)

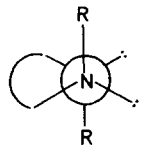


For the 1,5-diazabicyclo[3.3.0]octanes *(16)* and *(17)* ΔIP values of 1.57 and 2.21 eV respectively were measured[40,48]. The *syn* conformation of both compounds was revealed by NMR studies[53]; for *(16)* a structural analysis by gas phase electron diffraction yielded $\phi = 38°$[54]. According to the larger ΔIP values, *(17)* should therefore possess a torsional angle of approximately 0°, which obviously is enforced by the respulsion of the *endo* methyl groups. From eq. (5), $\Delta\varepsilon = 2.05$ eV results for $\phi = 0°$. That this value is exceeded may be due to a nearly coplanar arrangement of the bonds at the nitrogens in *(17)*, which leads to a larger overlap between n_1 and n_2 than sp^3 hybridization. In addition, stronger n/σ interactions are also to be expected at $\phi = 0°$.

Cyclic compounds of type *(8)* have been studied extensively[40,41,43,45,47,48]. Apart from the folding of the ring, particular interest attaches to the arrangement of substituents, the influence of double bonds and the possible existence of conformational mixtures. Moreover, extensive NMR data are available for these compounds. Hexahydropyridazines *(18)* have recently been reviewed by *Nelsen*[55].

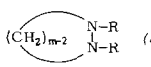


(18)



Three conformations (EE, EA, and AA) always have to be considered for compounds of type *(8)*[56]. While the EE form with diequatorial substituents is easily identified from the

EE
$\Phi \approx 180°$



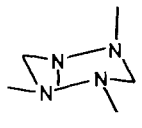
EA
$\Phi \approx 60°$

AA
$\Phi \approx 60°$

large splitting of the n ionization bands, any distinction between the other two forms is difficult due to the similarity of the values of ϕ especially for six-membered rings. Thus PE and NMR spectroscopy are seen to be complementary in these studies: the latter method clearly reveals the EA form, but cannot distinguish between the EE and AA forms. Some results are listed in Table 1.

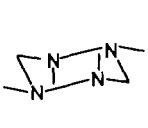
Table 1. Conformations of cyclic hydrazines of type *(8)*.

(8)



m	R	$\Delta\varepsilon$ [eV]		EE	EA	AA	Ref.
3	CH_3	−0.59			100% *trans*		[48]
4	CH_3	−2.12		100%			[45, 48]
	i-C_3H_7	−2.02,	0.6	much		little	[48]
5	H	0.44,	−1.45	little		much	[40, 48]
	CH_3	−2.22,	0.70	much		little	[40, 48]
	C_2H_5	0.88				100%	[40]
	i-C_3H_7	0.99				100%	[40]
6	H	0.70				100%	[40]
	CH_3	−2.32,	0.77	much	little [a]		[40, 48]
	C_2H_5	0.67			100% [a]		[43]
7	CH_3	0.54			100% [a]		[43]

[a] Decision between EA and AA is not possible on the basis of the spectra (see text).



A very impressive example of the efficiency of PE spectroscopic conformational analysis is provided by 1,2,4,5-tetramethylhexahydro-1,2,4,5-tetrazine *(11)*, R = CH_3[48]. NMR studies by *Anderson* and *Roberts*[57] indicated a conformation

(11a)

(11b)

(11c)

with two axial and two equatorial methyl groups. A distinction between the three possibilities *(11a)—(11c)* is immediately possible on the basis of the PE spectrum: The four n-ionization bands of nearly equal intensity could be assigned in pairs to the diequatorial and the diaxial *N,N'*-dimethylhydrazine fragment with $\Delta\varepsilon = -2.47$ eV ($\phi \approx 180°$) and 0.55 eV ($\phi = 70°$), respectively[48].

A detailed analysis of the PE spectra of *(11)* as well as of bi- and tricyclic derivatives with annelated five- and six-membered rings (*(12)* and *(13)*) also considers 1,3- and 1,4-interactions of n orbitals[50]. While the bicyclic compounds *(12)*, like *(11)*, prefer diequatorial-diaxial forms, the tricyclic compounds preferentially adopt tetraequatorial conformations[50,51].

The *N,N'*-connected bi(cycloamines) of type *(10)* exhibit an interesting conformational change with increasing ring size (Table 2)[40,43,45,48,49].

Table 2. Population of the *anti*- and *gauche* conformation of *N,N'*-bi(cycloamines) of type *(10)*.

(10)

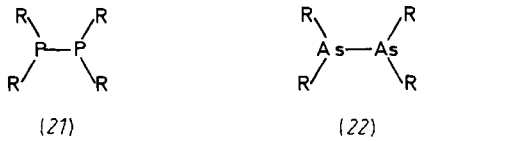
m	*anti* [%]	*gauche* [%]	ϕ *(gauche)*
3	100		
4	40	60	64°
5	50	50	99°
6		100	94°

According to vibrational spectroscopy and gas phase electron diffraction[58], the smallest compound, 1,1'-biaziridine ($m = 3$), exhibits an *anti* form with inversion symmetry and thus differs from the isoelectronic bicyclopropyl, which forms a mixture of *gauche*- and *anti* form[59]. For $m \geqq 6$ these compounds exist in a *gauche* form analogous to those of open-chain hydrazines *(7)*.

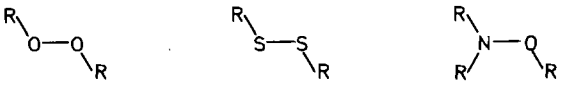
The *anti*- and *gauche* forms of the four-membered and the five-membered ring compound apparently have similar stabilities and therefore exist as mixtures. This behavior can be understood by considering the repulsion of the α-methylene hydrogens between the rings in the gauche form, which is alleviated by the greater flexibility (folding) of the rings only for $m \geqq 6$.

3.2.2. Hydrazobenzenes

The success of the conformational analysis of hydrazines by PE spectroscopy also stimulated the analysis of hydrazobenzenes *(19)*[60]. Conjugation between n- and π-electrons



(19) *(20)*



requires that the orientation of the phenyl groups be taken into account as well. A comparison of the spectra of *(19)* with those of the corresponding anilines *(20)* as well as MINDO/2 calculations and studies of molecular models revealed a systematic correlation of the splittings of the first two and the fourth and fifth ionization bands with the dihedral angle ϕ. It was found that the preferred conformation of hydrazobenzenes in the gas phase has the phenyl groups in *anti* positions, unless the geometry of a cyclic system forces the molecule into another conformation.

3.2.3. Other Compounds with Vicinal Lone Pairs

Apart from hydrazines *(7)*, other compounds with vicinal lone pairs like diphosphanes *(21)*[61-65], diarsanes *(22)*[61], peroxides *(23)*[66-70], disulfides *(24)*[71-74], and hydroxylamines *(25)*[75] have also been studied; due mainly to the smaller structural variety of these compounds, however, not nearly so many examples are known. In the case of *(23)* and *(24)*, the situation is complicated by the two electron lone pairs of

(21) *(22)*

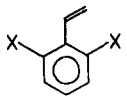
(23) *(24)* *(25)*

each oxygen or sulfur atom and for *(25)* by the nonequivalence of the interacting n orbitals.

Studies on open-chain and cyclic peroxides as well as on ozonides suggest a relation analogous to eq. (5) between the splitting of the first two n ionization bands and the twisting with respect to the O—O bond[70]. In disulfides too, the two highest occupied MOs apparently show a sufficiently systematic dependence on the torsional angle to permit their conformational analysis[71-74].

In the case of hydroxylamines, the position of *N*-substituents of isoxazolidines *(26)* and tetrahydro-1,2-oxazines *(27)* could be determined from their PE spectra[75].

(26) *(27)*



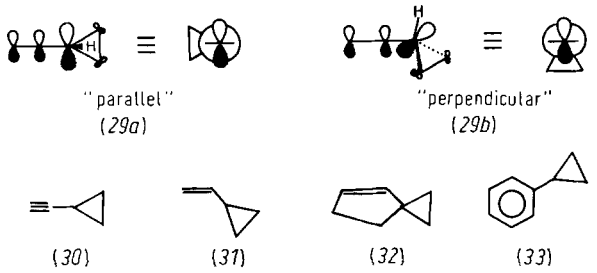
3.3. Systems with π/π Interactions

3.3.1. Dienes and Styrenes

Historically, conformation-dependent orbital interactions were first investigated for biphenyls (see Section 3.1).

The simplest compounds with π/π interactions are 1,3-dienes which generally have a coplanar arrangement of double bonds[76]. For planar systems such as 1,3-butadiene[77] or 1,3-cyclohexadiene[26,78] the difference between the two π-ionization bands is approximately $\Delta IP_{1,2} = 2.5$ eV, independent of the *s-cis* or *s-trans* conformation; for 1,2-dimethylenecyclobutane *(2)* and related compounds, 2,3-substitution and particularly secondary through-space interactions with π_{CH_2} orbitals reduce the value to $\Delta IP_{1,2} = 1.9$ eV[24]. 1,2-Dimethylenecyclohexane *(4)*, on the other hand, prefers a chair conformation with a dihedral angle of $\phi \approx 55°$[79] (see Section 2.2.3).

The interactions between a phenyl and a vinyl group in the styrene derivatives *(28)* were discussed in detail by *Maier* and *Turner*[81]; an approximately linear correlation exists be-



(28)

tween $\cos\phi$ (ϕ = angle of torsion) and the size (calculated e.g. from van der Waals radii) of the substituents X in the *o,o'*-positions, which prevent the coplanar arrangement of the vinyl and phenyl groups.

3.3.2. Cyclopropyl Compounds

The ability of the cyclopropane ring to undergo conjugative interaction with neighboring π centers justifies the treatment of vinyl- *(31)* and phenylcyclopropane *(33)* as systems with π/π interactions. For the vinylcyclopropyl system a parallel *(29a)* and a perpendicular conformation *(29b)* are characterized by maximal and minimal interaction, respec-

tively[82]. The two arrangements which correspond to both these conformations can be observed simultaneously in the spectrum of ethynylcyclopropane *(30)*[83]; $\Delta IP = 2.60$ eV for the parallel arrangement corresponds to the value observed for butadiene, whereas $\Delta IP = 1.50$ eV is found for the perpendicular arrangement. For vinylcyclopropane *(31)* and for the sterically fixed derivative spiro[2.4]hept-4-ene *(32)*, values of $\Delta IP = 2.55$ eV and $\Delta IP = 2.57$ eV have been obtained[84]; for *(31)* a second conformer was not observed at room temperature, and in the case of phenylcyclopropane *(33)* no bands of a second conformer could be detected even at higher temperatures.

The larger number of interacting orbitals makes matters more complicated for two neighboring cyclopropane rings. However, in the case of sterically fixed bicyclopropyl deriva-

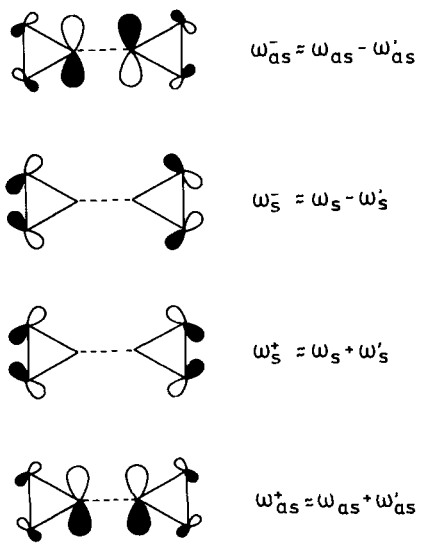


Fig. 8. Walsh orbitals of the bicyclopropyl system *(35)*.

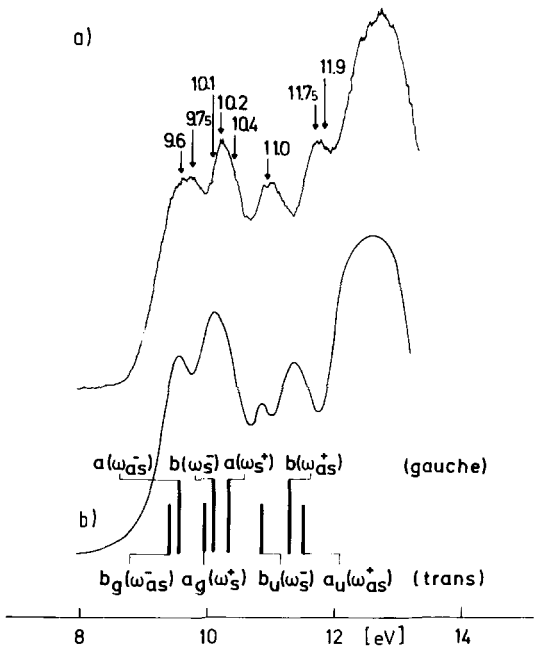
(34)

(35)

tives such as *(34)* the first four PE bands could be assigned to the combinations ω_{as}^{-}, ω_{s}^{-}, ω_{s}^{+}, and ω_{as}^{+} of Walsh orbitals shown in Figure 8[85]. For bicyclopropyl *(35)* in the gas phase a *trans* ($\phi = 90°$) and a *gauche* conformer ($\phi = 30$–$40°$) were found in the ratio 40:60[59], so that in the region between 9 and 11 eV a total of eight PE bands is to be expected, corresponding to ionizations from Walsh orbitals. This marks the limits of conformational analysis by PE spectroscopy: the spectra become too complicated. Nevertheless, a theoretical spectrum based on MINDO/2 results for a mixture of conformers in the above mentioned ratio and assuming Lorentzian curves with a half-width of 0.5 eV is in very good agreement with the observed spectrum (Fig. 9)[86].



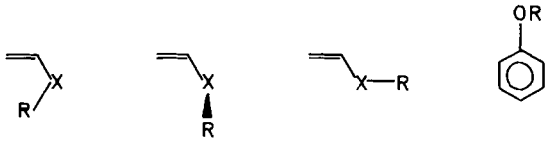


Fig. 9. PE spectrum of bicyclopropyl *(35)*; (a) experimental and (b) calculated for a 40:60 *gauche/trans* ratio assuming Lorentzian curves.

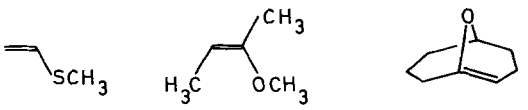
3.4. Systems with n/π Interactions

The principal systems with n/π interactions are vinyl ethers *(36)*, X = O, and vinyl sulfides *(36)*, X = S, as well as the corresponding aryl compounds. The conformations of these compounds have been studied intensively by numerous methods, affording differing results. Thus all the methods indicate that alkyl vinyl ethers and sulfides can exist in a second conformation in addition to the stable *syn* conformation *(36a)*. In the case of the alkyl vinyl ethers, however, there is some doubt whether this is a non-planar gauche conformation, as was concluded from gas phase electron diffraction[87,88] and microwave measurements[89], or a planar *anti* form, as was inferred from the IR spectrum[90], whereas for the alkyl vinyl sulfides different electron diffraction studies[88,91] gave contradictory results for the ratio of the *syn-(36a)* and *anti* form *(36c)* and therefore for the energy difference of these two conformations.

For aryl ethers *(37)*, IR[90,92] and microwave spectra[93] reveal only a planar form, whereas electron diffraction studies[94] and measurements of dipole moments and Kerr constants[95] were interpreted in terms of contributions from nonplanar conformers.



(36a) *(36b)* *(36c)* *(37)*

Information on equilibria between different conformers are obtained by variable temperature PE spectroscopy, as was first shown by *Ames* and *Turner*[62] as well as by *Schweig et al.*[96]. The following examples show that this method is particularly suitable for the investigation of the compounds in question and for deciding in a very simple way between the contradictory results of other investigations.

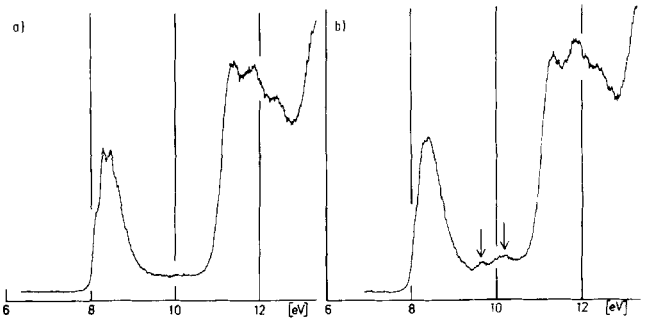
3.4.1. Alkyl Vinyl Ethers and Alkyl Vinyl Sulfides

The PE spectrum of methyl vinyl sulfide *(38)* has been investigated in the temperature range of 20—600 °C by *Schweig et al.*[95] and has been interpreted on the basis of a temperature-

(38) *(39)* *(40)*

dependent equilibrium between a *syn*- and a *gauche* conformer; the energy difference between the two is estimated as 9.6 ± 0.8 kJ/mol, corresponding to a ratio of 94:6 of *syn*- to *gauche* conformer at room temperature.

Sterically hindered and unhindered alkyl vinyl ethers behave differently[15]: at higher temperatures (*Z*)-2-methoxy-2-butene *(39)* gave two new bands at 9.6 and 10.1 eV (Fig. 10) which have been assigned to a nonplanar *gauche* conformation *(36b)* just like the band at 10.4 eV in the case of isopropyl vinyl ether (*(36)*, X = O, R = *i*-C_3H_7). For methyl vinyl ether *(1)*, on the other hand, no new bands appear between 10 and 12 eV, but from changes in the shape of the second band it was concluded that a new ionization appeared at 12.35 eV, corresponding to a larger splitting ΔIP for the less



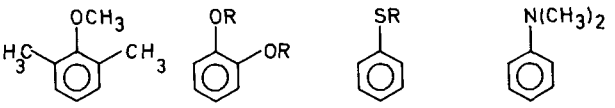


Fig. 10. PE spectrum of (Z)-2-methoxy-2-butene *(39)* at (a) 293 and (b) 508 K; the additional bands of the *gauche* conformation appearing at higher temperatures are marked by arrows.

stable conformer. In connection with the orbital correlation diagram of Figure 2, this shows that in sterically unhindered alkyl vinyl ethers the *syn* conformation predominates over the *anti* conformation, which is approximately 9 ± 3 kJ/mol less stable, whereas in sterically hindered ethers the most stable form is the *anti* conformation, with a nonplanar *gauche* form being 12 ± 1 kJ/mol less stable[15]. These results can be explained quite naturally by assuming strong steric repulsions to occur in the *syn* conformation if the alkyl group is particularly bulky or if the vinyl group carries substituents.

In the case of 9-oxabicyclo[3.3.1]non-1-ene *(40)* and the corresponding sulfur compound *Batich, Heilbronner, et al.*[97] deduced a deviation from coplanarity of the vinyl ether or vinyl sulfide system, respectively, of approximately 70–75° or 75–80° by carefully applying the LCBO model and assuming the angular dependence of the interaction term to be of the form $B = B_0 \cos\phi$.

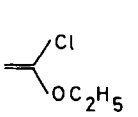
3.4.2. Alkyl Aryl Ethers and Alkyl Aryl Sulfides

The PE spectra of alkyl aryl ethers *(37)* suggest that sterically hindered compounds such as 2,6-dimethylanisole *(41)*[98] or *tert*-butyl phenyl ether *(37)*, R = *t*-Bu, occur in a nonplanar conformation which is expected to show up as a second, less stable form in the case of sterically nonhindered compounds like anisole *(37)*, R = CH_3. Qualitative considerations of orbital interactions[29] and quantum chemical calculations[99] strongly suggest that, in contrast to the results for alkyl vinyl ethers, the 90° twisted form also corresponds to a potential energy minimum. That the alkyl aryl ethers do indeed assume either a planar or a perpendicular conformation, so that the dihedral angle cannot assume arbitrary values depending on the size of the alkyl group, is seen from a plot of the ionization potential $IP(n_O)$ corresponding to the oxygen lone pair against the ionization potential of the corresponding alkyl iodides: all points lie on a straight line except that for the *tert*-butyl derivative, *i.e.* only the *tert*-butyl ether is sterically hindered and assumes a perpendicular conformation; in all other cases the variation of $IP(n_O)$ is due solely to the inductive effect of the alkyl group[29].

(41) *(42)* *(43)* *(44)*

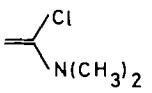
While one methyl group in position 2 does not alter the conformation of alkyl aryl ethers, PE measurements show that in the gas phase *o*-dimethoxybenzene *(42)* exists predominantly in a nonplanar conformation, whereas in the crystalline state most *o*-dimethoxybenzenes are planar[100]. For the alkyl aryl sulfides, on the other hand, PE measurements always reveal a nonplanar form in addition to the planar conformation. The importance of this nonplanar form increases with increasing size of the alkyl group[98]. In the case of *N*,*N*-dimethylaniline *(44)* just one methyl group in the *o*-position is sufficient for a twisted conformation to predominate, whereas for *N*-methylaniline both *o*-positions have to be substituted in order to force the molecule into such a conformation[101].

4. Scope of the Method



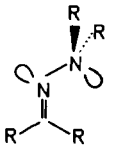
4.1. Assignment of PE Spectra

PE spectroscopy may be applied successfully to conformational problems only if the spectrum is sufficiently simple in the region of interest, for cogent conclusions about the magnitude of orbital interactions and hence about the conformation of a molecule may be obtained from the spectrum only if it is possible to unequivocally assign ionization bands to the orbitals in question. Bicyclopropyl *(35)* has been mentioned as an example of a compound whose PE spectrum is so complex as to reach the limits of the method (Section 3.3.2).

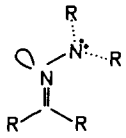


A reliable interpretation of the PE spectrum will usually be possible even in difficult cases by quantum chemical calculations of various degrees of sophistication; moreover progress in experimental techniques may provide new criteria for assignment. Thus, in the case of tetramethyldiphosphane *(21)*, $R = CH_3$, which is known to be a mixture of two conformers, the band at 8.75 eV was originally assigned to the two n orbitals of the energy-rich conformer corresponding to minimal interaction of the n orbitals in a perpendicular conformation ($\phi = 90°$). Measurements at higher temperatures as well as the angular dependence of the PE spectrum and its simulation by Gaussian curves showed that it is not the second but the first band which is due to two different ionizations[65]: it stems from the n_- orbitals of the two conformers, so that $\Delta IP = 0.6$ eV is obtained for the energy-rich conformation corresponding to a *gauche* form with $\phi = 60°$.

4.2. Secondary Orbital Interactions



Secondary orbital interactions can also make conformational analysis by PE spectroscopy difficult or even impossible. Thus an attempt to extend the results obtained for the enol ethers *(36)* to the α-chloro derivatives *(45)* and *(46)* was unsuccessful; the experimental ΔIP values are not related to the data of the stable conformers of the unsubstituted compounds. Simple calculations show that ΔIP becomes not only much smaller but also nearly conformationally independent as a result of possible interactions between the π_{CC} as well as the n_O orbitals and the lone-pair orbital of the chlorine[102].



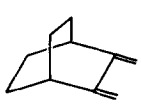
(45)

(46)

(47a)

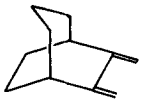
(47b)

Similar difficulties are observed for hydrazones, for which two stable conformations *(47a)* and *(47b)* are to be expected with the lone pair of the amino nitrogen interacting either with the lone pair of the imino nitrogen or with the π electrons of the C=N bond. As a consequence of these two possible interactions, the energy difference for the two highest orbitals is almost independent of the conformation; only the energy of the third orbital, with an ionization energy expected to lie in a region where unambiguous assignments become difficult, exhibits a marked dependence on the dihedral angle[103].



4.3. Other Geometric Changes

Finally it should be noted that other geometric changes may also influence the orbital energies and thus counterfeit changes in the dihedral angle. Thus, on assuming a planar π system for dimethylenenorbornadiene *(48)*, dihedral angles $\phi = 10°$ and $\phi = 20°$, respectively, were derived for dimethylenebicyclooctane *(49)* and the corresponding nonane *(50)* from the relation $\Delta IP_{1,2} = 2\beta_0 \cos\phi$[27]; however, all attempts to prove the nonplanarity of these π systems by other methods failed. Finally, force field calculations suggested that the π systems of all three compounds *(48)*—*(50)* are coplanar, but that the overall geometry of the butadiene fragment is determined by the bicyclic part of the molecule[80].



The dependence of the π orbital energies on the geometry of the butadiene fragment, which was demonstrated by *ab-*

(48)

(49)

(50)

initio calculations[24], as well as the linear relation between $\Delta IP_{1,2}$ and the bond angles determined by the force field calculations, suggest that the splitting of the first two ionization potentials of *(49)* and *(50)* is smaller than that of *(48)* not because of a deviation of the π system from coplanarity, but rather because of changes in CCC bond angles[80].

5. Summary and Outlook

In this review only compounds with neighboring n and π electrons were treated. However, interactions between more distant orbitals (*e.g.* 1,3- and 1,4-interactions) can of course also be conformationally dependent. In such cases we cannot expect a simple relation like eq. (2) and (3) to exist between conformational angle and ionization potentials, since through-bond interactions involving suitable "relay orbitals" always have to be taken into account in addition to the direct through-space mechanism. Studies on di- and trioxanes as well as the corresponding thianes by *Sweigart* and *Turner*[104] and those on cyclic 1,3- and 1,4-diamines by *Nelsen* and *Buschek*[105] can be regarded as pilot investigations in this field. Since a distinction between only few conformations is often all that is required for non-aromatic heterocycles, PE spectroscopy is expected to provide valuable information in these cases too.

Summarizing, we should like to state that PE spectroscopy has proved to be a very simple and fast method of conformational analysis, particularly in connection with MO calculations or qualitative MO considerations, and that further interesting applications of this method are to be expected in the future.

In all applications, however, it should always be examined whether and to what extent secondary orbital interactions may affect an expected simple relation between dihedral angle and ionization potentials, and whether geometric changes other than rotations around single bonds have to be considered.

Our thanks are due to our co-workers quoted in the references to our own contributions. We are greatly indebted to our esteemed teacher Professor Lüttke for kindling our interest in problems of molecular structure. This work was supported by the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung in Nordrhein-Westfalen, and the Fonds der Chemischen Industrie.

Catalytic Reactions with Hydrosilane and Carbon Monoxide

New synthetic methods (30)

By Shinji Murai and Noboru Sonoda[*]

The reagent hydrosilane/carbon monoxide opens up new possibilities for organic synthesis. Four cases will be discussed: 1. The reaction of olefins with hydrosilane (trialkylsilane) and carbon monoxide in the presence of Co, Ru, and Rh complexes leads to enol silyl ethers having one more carbon atom than the olefins. 2. Cyclic ethers undergo carbonylative ring opening to ω-siloxyaldehydes when reacted with hydrosilane and carbon monoxide in the presence of $Co_2(CO)_8$ as catalyst. 3. Aldehydes are catalytically converted into the next higher α-siloxyaldehydes or 1,2-bis(siloxy)alkenes depending on the reaction conditions used. 4. The reaction of alkyl acetates proceeds in various ways depending on the nature of the alkyl group; enol silyl ethers or alkenes are obtained.—Mechanisms for these $Co_2(CO)_8$ catalyzed reactions using hydrosilane and carbon monoxide are discussed in which $HCo(CO)_n$ or $R_3SiCo(CO)_nL$ function as catalytically active agents. With these species there are four types of catalytic cycles.—The synthetic possibilities of these catalytic reactions have still not been fully explored.

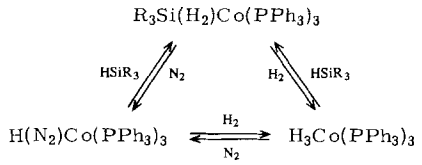
1. Introduction

The hydroformylation of olefins with molecular hydrogen and carbon monoxide to produce aldehydes has been extensively studied for almost forty years; the interest attached to homogeneous catalysis and the growing industrial importance of such reactions are continually stimulating new investigations.

A naive idea occurred to us about four years ago: what happens if a hydrosilane ($HSiR_3$) is employed in place of molecular hydrogen in the hydroformylation? The idea was based on the known similarity in reactivity between molecular hydrogen and hydrosilanes toward transition metal complexes (cf. Section 2.1). A few months later, clean but rather puzzling reactions were found. For example, the $Co_2(CO)_8$ catalyzed reaction of cyclohexene with a hydrosilane and carbon monoxide gave a silyl ether of cyclohexanecarbaldehyde-enol *(vide infra)*. This finding led to the discovery of a series of new catalyzed reactions using hydrosilane and carbon monoxide, opening up a new field embracing organosilicon chemistry, homogeneous catalysis, and synthetic organic chemistry.

Not only olefins but also various oxygenated compounds such as cyclic ethers and carbonyl compounds have been found to react with hydrosilane and carbon monoxide in the presence of group VIII transition metal complexes. In most cases $Co_2(CO)_8$ has been used as catalyst. Both olefins and oxygenated compounds incorporate carbon monoxide and the silyl moiety to give stable *O*-silylated derivatives of usually unstable or otherwise inaccessible hydroxy compounds such as enols, hydroxy aldehydes, or ene-diols.

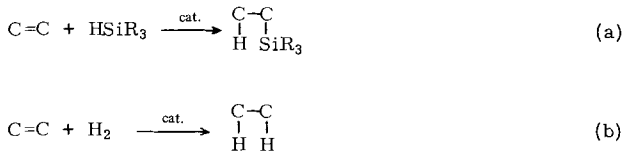
In this article we present a survey of these new catalytic reactions, almost all of which were discovered in our laboratory. Emphasis will be laid on the basic features of the reactions and hence on the possible role of the catalytic agents. We shall also focus attention on the unsolved problems in this area, for these reactions are still in an early stage of development.



2. Catalytic Reactions of Olefins with Hydrosilane and Carbon Monoxide

2.1. Similarity in Reactivity of Hydrosilanes and Molecular Hydrogen toward Transition Metal Complexes

It is interesting to note that reactions of hydrosilanes ($HSiR_3$) with transition metal complexes parallel those of

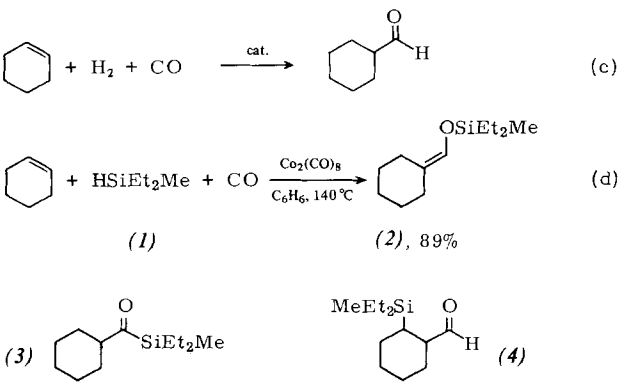


[*] Prof. Dr. S. Murai, Prof. Dr. N. Sonoda
Department of Petroleum Chemistry, Faculty of Engineering
Osaka University, Suita, Osaka 565 (Japan)

molecular hydrogen. Both hydrosilanes[1] and molecular hydrogen[2] undergo oxidative addition[3] to group VIII metal

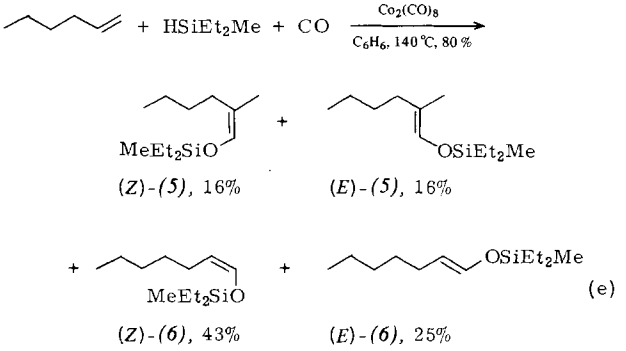
Scheme 1. Similarity of hydrosilane and molecular hydrogen. R = OEt.

complexes. The reactions[4] shown in Scheme 1 may serve as illustrative examples of the similar behavior of hydrosilanes and molecular hydrogen. Catalytic hydrosilylation[1,5], *i.e.* the addition of hydrosilanes to unsaturated compounds with



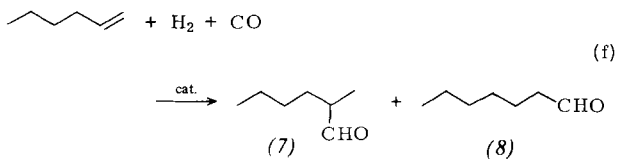
the aid of transition metal complexes [eq. (a)], is formally analogous to catalytic hydrogenation [eq. (b)][2]. Mechanistically, these two reactions seem to be very closely related[1,2].

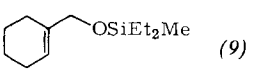
Various attempts have been made at the insertion of carbon monoxide into the Si—H bond[6] or into silicon-transition metal bonds[7], but all have proven unsuccessful. This parallels the fact that no definite example of carbonyl insertion into a hydrogen-transition metal bond has been recorded[8], although this reaction to give formylmetal complexes is suggested to be important as the initial step in the Fischer-Tropsch synthesis[8a] or in the Union Carbide ethylene glycol synthesis[9]. In this context, the copper(II) catalyzed insertion of cyclohexyl isocyanide, which is isoelectronic to carbon monoxide, into the Si—H bond of triethylsilane[10] is very intriguing. Carbon monoxide, however, does not react with the silane under the same conditions[11].



2.2. Reaction of Olefins with Hydrosilanes and Carbon Monoxide Catalyzed by $Co_2(CO)_8$

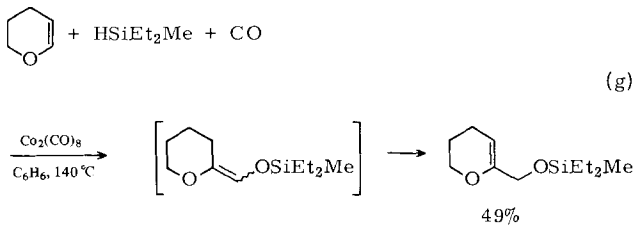
The well known Roelen reaction (so-called hydroformylation or oxo reaction)[12] involves addition of hydrogen and carbon monoxide to olefins [eq. (c)]. The similarity between hydrosilanes and molecular hydrogen in transition metal reactions urged us to study the reaction of olefins with hydrosilanes and carbon monoxide in the presence of various





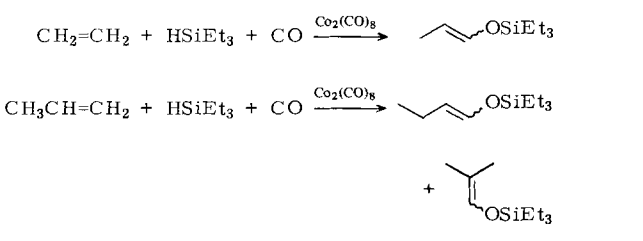
transition metal complexes[14–16]. The important works of *Colleuille*[17], as well as those of *Chalk* and *Harrod*[6,18], will be referred to at the end of this section.

As shown in eq. (d), the reaction of diethyl(methyl)silane *(1)* and carbon monoxide in the presence of a catalytic amount of $Co_2(CO)_8$ gives [diethyl(methyl)siloxymethylene]cyclohexane *(2)*, an enol silyl ether, as sole product and no trace of the acylsilane *(3)* or the β-silyl aldehyde *(4)*, as would be expected as products by direct formal analogy with the Roelen reaction[11,14,15]. Similarly, the (siloxymethylene)cycloalkanes of type *(2)* were obtained from cyclopentene (48%), cycloheptene (74%), and cyclooctene (69%)[14,15]. The reaction conditions were: catalyst 0.2—0.4 mmol, olefin 30—200 mmol, $HSiEt_2Me$ *(1)* 10 mmol, initial pressure of CO 50—80 bar at 25 °C, reaction temperature 140 °C, 20 h. Since two reaction sites are available in a terminal olefin, four isomers of siloxymethylene derivatives (regio- and stereoisomers) are expected in this case. All these isomers have been obtained (80%) and characterized in the $Co_2(CO)_8$ catalyzed reaction of 1-hexene[11,16] [eq. (e)].



The regioisomers *(5)* and *(6)* may correspond to those [*(7)* and *(8)*] obtained by the Roelen reaction[12] [eq. (f)]. Methyl acrylate, a terminal olefin having an electron withdrawing group, also gave a mixture of four isomeric enol silyl ethers[11]. When the reaction was carried out at higher temperatures or with higher concentrations of catalyst, migration of the double bond in the product took place. The reaction of cyclohexene at 200 °C gave 1-(siloxymethyl)cyclohexene *(9)* in addition to *(2)* in a ratio 1:5[15].

When migration of the double bond gives the more stable isomer, complete isomerization is observed as in eq. (g)[11].



So far, we have examined only a few types of olefins. Besides olefins, there still remain dienes and acetylenes to be studied. The effective range of transition metal complexes as catalysts has been studied and will be discussed in Section

(g)

2.3. While the reactivity of the H—H bond in H_2 obviously cannot be changed, that of the Si—H bond can be varied by changing the substituents on the silicon atom. This is one of the interesting aspects of the reactions using hydrosilanes. The reactivity of the hydrosilanes ($HSiR^1R^2R^3$ where R^n = H, alkyl, aryl, alkoxy, halogen *etc.*) in hydrosilylation depends upon the substituents[1,5]. A brief examination of the reactivity of hydrosilanes has been made for the $Co_2(CO)_8$ catalyzed reaction of cyclohexene [eq. (d)][15]. In this particular case the trialkylsilanes (alkyl = Me and/or Et) appear to be the reaction partners of choice. Although hydrosilanes having alkoxy or chloro groups proved to be very reactive, the reactions were complex and gave mixtures of many products whose structures have not yet been clarified. Diethyl(methyl)silane *(1)* was used exclusively in the present study because it is easy to handle (b.p. 76 °C, very stable towards water and oxygen). Moreover, the NMR spectrum of a compound containing an Et_2MeSi group(s) shows nice sharp singlet(s) due to the methyl group(s). This is of great experimental utility, because it enables the purity of a product or the number of the products formed to be ascertained immediately.

Pioneering work on the $Co_2(CO)_8$ catalyzed reactions of olefins with hydrosilanes and carbon monoxide has also been carried out independently by *Colleuille* and his results have appeared in the patent literature[17]; we first became aware of this only very recently. Although details for the characterization of products are not given, as is usual in patents, it has been clearly demonstrated that the corresponding enol triethylsilyl ethers were obtained from ethylene (44%), propene (70%), 1-butene (27%), isobutene (44%), cyclohexene (87%), and norbornene (65%) on using $HSiEt_3$ and CO. With exception of the reaction with propene, however, in all the cases mentioned considerable amounts of unidentified by-products (1 to 0.15:1) were obtained which could not be separated from the enol silyl ethers by fractional distillation. These by-products are likely to be double bond-isomers similar to *(9)* and/or hexaethyldisiloxane. No comment is made about the presence of stereoisomers, as in the reaction of 1-hexene [eq. (e)]. *Chalk* and *Harrod* have also reported the $Co_2(CO)_8$ catalyzed reaction of ethylene with $HSiEt_3$ and CO to give 1-(triethylsiloxy)-1-propene[6,8]. Both groups of workers reported that the reaction of 1-hexene was too complex, which is in contrast to our findings.

2.3. Catalysts

A search for good catalysts for a certain reaction will never be complete since there are numerous possible combinations of metals, ligands, additives, reactants, and reaction conditions. Even for the Roelen reaction[12], which has forty years of history, the research in this field is still in progress. So far, we have examined the catalytic activity of various transition metal complexes only for the reaction of 1-hexene according to eq. (e).

For this particular reaction the following complexes show little or no catalytic activity[11]: $CuCl_2$, Cu_2Cl_2, $W(CO)_6$, $Mn_2(CO)_{10}$, $Fe(CO)_5$, $Fe_2(CO)_9$, $Fe(CO)_4PPh_3$, $RuCl_2(PPh_3)_3$, Rh_2O_3, $IrCl(CO)(PPh_3)_2$, $Ni(CO)_4$, $Ni(CO)_2(PPh_3)_2$, $Ni(acac)_2$, $PdCl_2(PPh_3)_2$, $Pd(PPh_3)_4$, Pd-black, H_2PtCl_6, Pt-black. The effective complexes found are listed in Table 1[11,16].

Table 1. Reaction of 1-hexene with $HSiEt_2Me$ and CO to give the linear isomer *(6)* and the branched isomer *(5)* [a].

Catalyst (mmol)	Yield *(5)* + *(6)* [%]	Rel. Yield *(6)* [%] [*(6)*/(*(5)* + *(6)*)] × 100
$Ru_3(CO)_{12}$ (0.4)	40	89
$Co_2(CO)_8$ (0.4)	57	68 (55) [b]
$Co_2(CO)_8$ (0.4) [c]	80	68
$Co_2(CO)_8$ (0.4) + Ph_3P (1.0)	77	83 (90) [b]
$Co_2(CO)_8$ (0.4) + *n*-Bu_3P (1.0)	18	92 (62) [b]
$RhCl(PPh_3)_3$ (0.4)	41	82
$RhCl(PPh_3)_3$ (0.4) + Et_3N (1.0)	88	79

[a] Reaction conditions: 1-hexene (30 mmol), $HSiEt_2Me$ (10 mmol), CO (50 bar, initial pressure at 25 °C), catalyst (as given), solvent (benzene, 20 ml), 140 °C, 20 h. [b] For comparison: Relative yield of linear isomer in the Roelen reaction [19] [eq. (f)] in (%), [*(8)*/(*(7)* + *(8)*)] × 100. [c] 200 mmol 1-hexene.

These effective complexes for the reaction of 1-hexene were also tested in the reaction of cyclohexene [eq. (e)]; the results are shown in Table 2. Interestingly, whereas $Co_2(CO)_8$ was more effective for cyclohexene, $Ru_3(CO)_{12}$ and $RhCl(PPh_3)_3$ were more effective in the case of 1-hexene. Further investigations in this area should open up the possibility of selective reaction of different double bonds in one molecule.

Table 2. Reaction of cyclohexene with $HSiEt_2Me$ and CO [a].

Catalyst (mmol)	Yield of *(2)* [%]
$Ru_3(CO)_{12}$ (0.2)	1.4
$Co_2(CO)_8$ (0.2)	71
$Co_2(CO)_8$ (0.4) [b]	89
$RhCl(PPh_3)_3$ (0.2)	0.5
$RhCl(PPh_3)_3$ (0.2) + Et_3N (1.0)	30

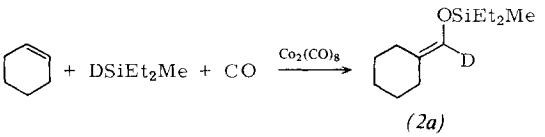
[a] Reaction conditions: cyclohexene (30 mmol), $HSiEt_2Me$ (10 mmol), CO (80 bar, initial pressure at 25 °C), catalyst (as given), solvent (benzene, 20 ml), 140 °C, 20 h. [b] Cyclohexene (200 mmol), CO (50 bar, initial pressure at 25 °C).

Since the present reaction requires the activation of both hydrosilane and carbon monoxide, it seems of interest to compare these results with those of hydrosilylation[1,5] and the Roelen reaction[12]. The effective catalysts found for the reaction of 1-hexene with $HSiEt_2Me$ and CO, *i.e.* $Ru_3(CO)_{12}$,

$Co_2(CO)_8$, and $RhCl(PPh_3)_3$, are known to be active in the Roelen reaction. The latter two complexes are also effective in hydrosilylation[1]. However, among the complexes which show little or no activity in the present reaction there are some which are effective catalysts for the Roelen reaction [for example, Rh_2O_3 and $IrCl(CO)(PPh_3)_3$][12] and for hydrosilylation [$PdCl_2(PPh_3)_2$, H_2PtCl_6, *etc.*][1]. A tentative conclusion that could be drawn here is that an effective catalyst in the present reaction may also be effective as a catalyst in both the Roelen reaction and in hydrosilylation[20]. However, more extensive studies are obviously necessary in this field.

It is noteworthy that the change in regioselectivity of the reaction of 1-hexene [eq. (e), Table 1], is similar to that observed in the Roelen reaction [eq. (f)] when using $Co_2(CO)_8$/PR_3 as catalyst[16]. This implies that the interaction of 1-hexene with $HCo(CO)_3$ is also important as initial step in the reaction using hydrosilane and carbon monoxide (cf. Section 2.5).

2.4. Reaction Conditions



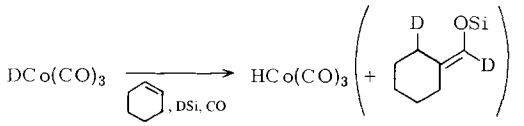
The effects of a change in reaction conditions have been examined for the $Co_2(CO)_8$ catalyzed reaction of 1-hexene with $HSiEt_2Me$ and CO [eq. (e)]. The reaction conditions described in footnote [a] of Table 1 have been regarded as the standard conditions. Under these standard conditions *(5)* and *(6)* were obtained in a combined yield of 57%. Some of the more important results[11] will be summarized below.

The combined yield of *(5)* and *(6)* markedly increases on using a higher molar ratio of 1-hexene to hydrosilane: The yields were 7, 57, and 80% at olefin/hydrosilane ratios of 1:1, 3:1 and 20:1, respectively. Good yields were obtained with $Co_2(CO)_8$:hydrosilane in the molar ratio 1:25. The use of smaller amounts of catalyst gave lower yields, while the use of a higher catalyst: hydrosilane ratio (1:10) resulted in the formation of a hydrosilylation product (n-$C_6H_{13}SiEt_2Me$) at the expense of the enol silyl ethers *(5)* and *(6)*. The effect of CO pressure was examined in the range between 3 and 150 bar (initial pressure at 25 °C). The yield increased from 14% at 3 bar to 68% at 80 bar and remained almost unchanged at higher pressures. The best results for the reaction of 1-hexene were obtained at a reaction temperature of 140 °C. The yields of the enol silyl ethers decreased with decreasing temperature, and no reaction took place below 80 °C. At 200 °C, migration of the double bond in the products took place to some extent. The distribution of the four isomers [(*Z*)- and (*E*)-*(5)* (branched), (*Z*)- and (*E*)-*(6)* (linear)], and hence the proportion of linear isomers, did not change significantly under the various reaction conditions described above. Nor did changes in the reaction time have any influence on the distribution. The reactions were almost complete within 7 h under the standard conditions.

2.5. Mechanistic Aspects

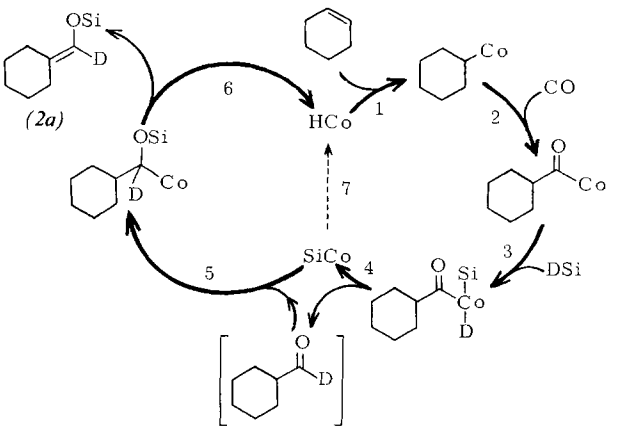
The mechanism of the catalyzed reaction of olefins with hydrosilane and carbon monoxide is one of the most intriguing problems. An understanding of the mechanism is, however, essential for further development of new reactions. On the basis of the arguments outlined below, we propose here the mechanism given in Scheme 2 for the $Co_2(CO)_8$ catalyzed reaction of cyclohexene with $DSiEt_2Me$ and CO.

While it is obvious that the carbon and oxygen atoms of carbon monoxide are incorporated into the oxymethylene group of the product, the enol silyl ethers, it is much more difficult to establish which hydrogen atom in the product stems from the hydrosilane used in the reaction. To clarify



(2a)

this problem we carried out the reaction of cyclohexene with $DSiEt_2Me$ and CO using $Co_2(CO)_8$ as a catalyst[11]: the deuterium was found predominantly (91%) in the vinylic position of the product *(2a)*.



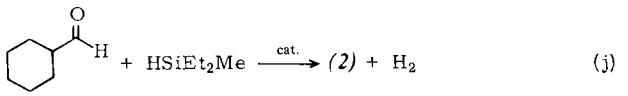
Initiation:

$$Co_2(CO)_8 + DSiEt_2Me \longrightarrow DCo(CO)_4 + MeEt_2SiCo(CO)_4$$

The first catalytic cycle:

Succeeding catalytic cycles:

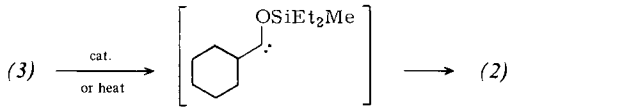
Scheme 2. $Co_2(CO)_8$ catalyzed reaction of cyclohexene with $DSiEt_2Me$ and CO. (The step *(7)* is not involved in the catalytic cycle; see text.) Abbreviations: SiCo *etc.* = $MeEt_2SiCo(CO)_n$, *etc.*, $n = 3$ or 4.



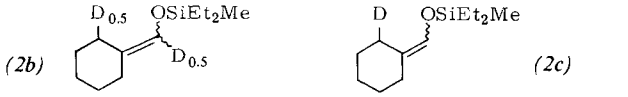
The course of the deuterium incorporation may be best explained in terms of the catalytic cycle shown in Scheme 2. For simplicity, the alkyl groups on the silicon and the CO ligands on the cobalt have been omitted. The most important reactions of hydrosilanes with $Co_2(CO)_8$ have been studied by *Chalk* and *Harrod*[6] and later by *Baay* and *MacDiarmid*[21]. The reaction of $HSiR_3$ with $Co_2(CO)_8$ takes place smoothly even at room temperature to give $HCo(CO)_4$ and $R_3SiCo(CO)_4$ [eq. (h)]. In the presence of excess amounts of the hydrosilane, the former reacts with the silane with evolution of molecular hydrogen [eq. (i)]. The catalytic cycle may

$$HSiR_3 + Co_2(CO)_8 \rightarrow HCo(CO)_4 + R_3SiCo(CO)_4 \quad (h)$$

$$HSiR_3 + HCo(CO)_4 \rightarrow R_3SiCo(CO)_4 + H_2 \quad (i)$$

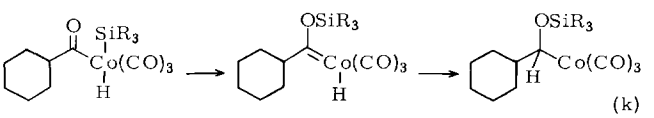


start by the insertion of olefin into the H—Co bond (Step 1). This is in agreement with the observed similarity of the product linearities with those in the Roelen reaction (Section 2.3) and with the fact that better yields of the product have been obtained at higher concentrations of olefin (Section 2.4), suggesting competition between insertion (Step 1) and hydrogen evolution [eq. (i)]. Although the reaction with $DSiEt_2Me$ proceeds primarily *via* $DCo(CO)_4$, this catalytically active species may be converted into $HCo(CO)_3$ in the first catalytic cycle (Scheme 2). In the second and all succeeding catalytic cycles the reaction of the olefin is catalyzed by $HCo(CO)_3$ (Step 1) which is repeatedly regenerated by β-elimination in the product-forming step (Step 6). Thus, the deuterium taken up in the oxidative addition (Step 3) moves to the acyl position of the intermediate aldehyde in the reductive elimination step (Step 4), and finally appears at the vinylic position of the enol silyl ether *(2a)* (Step 6). The possible intermediacy of an aldehyde will be discussed later.

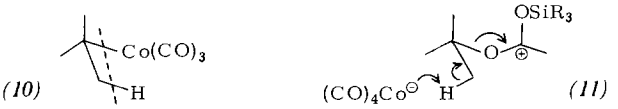


This deuterium labeling experiment clearly rules out the following two alternative mechanisms. The first one involves intervention of molecular hydrogen and is represented by two successive reactions [eq. (c) and (j)]. At first glance, it might be surmised that the present reaction involves the well

(j)

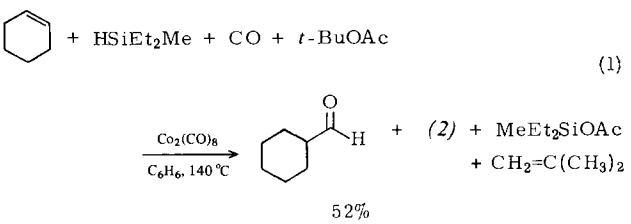


known Roelen reaction[12] [eq. (c)] utilizing molecular hydrogen which could be generated *in situ* by dehydrogenative silylation[5] [eq. (j)] of the aldehyde thus formed. The second alternative mechanism involves initial formation of an acylsilane such as *(3)* as an intermediate, followed by Brook rearrangement[22] to give *(2)*. This mechanism has been proposed by *Chalk* and *Harrod* to account for their observations[18].

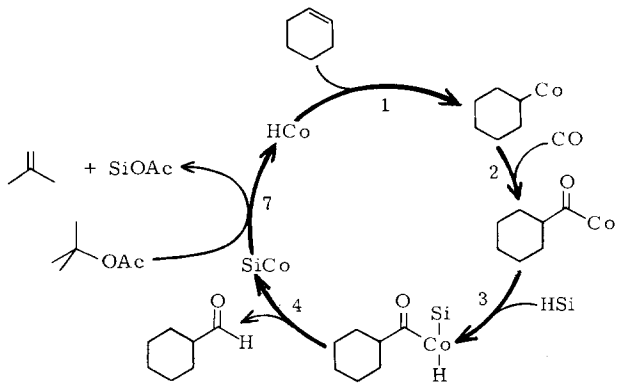


According to the first or the second alternative mechanism the reaction using $DSiEt_2Me$ should afford *(2b)* or *(2c)*, respectively[23]. However, the formation of *(2a) (vide supra)* is observed.

In the proposed mechanism (Scheme 2), the C—Co bond is first cleaved in the reductive elimination step (Step 4)—giving an aldehyde—and is then reformed again in the subsequent step (Step 5). Whether an aldehyde is first formed as an intermediate or not may be an important question[24], for a more direct path *via* a carbene-metal complex, in which the C—Co bond remains unbroken—with no aldehyde being produced [eq. (k)][25]—is also conceivable.



(k)



In order to decide which mechanism is operating, one could attempt to isolate the aldehyde. Examination of Scheme 2 suggests that introduction of an efficient by-path (Step 7) to convert the silyl(carbonyl)cobalt compound (SiCo in the Scheme) into $HCo(CO)_3$ (HCo in the Scheme) would leave the aldehyde intact without breaking the catalytic cycle. It occurred to us that *tert*-butyl acetate would be suitable for this purpose. The conversion could be expected to proceed *via (10)* or *(11)* (see Section 3.4).

Indeed, cyclohexanecarboxaldehyde was obtained in 52% yield when the $Co_2(CO)_8$ catalyzed reaction of cyclohexene (90 mmol) with $HSiEt_2Me$ (10 mmol) and CO (50 bar) was carried out in the presence of *tert*-butyl acetate (30 mmol) in benzene at 140 °C for 20 h[11]. The enol silyl ether *(2)* (20%), diethyl(methyl)silyl acetate, and isobutene were also formed [eq. (l)]. For this reaction we suggest the catalytic cycle

shown in Scheme 3, and that an aldehyde is formed as intermediate in the reaction (d); but further verification of Scheme 3 is required, since the possible intervention of the carbene complex [eq. (k)] is still not out of the question.

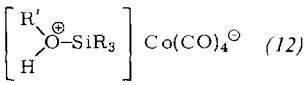
Scheme 3. Formation of an aldehyde from cyclohexene. (The numbering of the steps and abbreviations correspond to those in Scheme 2.)

It should be noted that the formation of an aldehyde according to eq. (l) is a new type of hydroformylation of an olefin and differs from the Roelen[12] or Reppe reactions[13]. It is hoped that still better trapping agents than *tert*-butyl acetate will be found.

There are still many unsettled questions regarding the mechanism. Above all, a detailed knowledge of the numerous steps involved and of the structures of the catalytically

effective intermediates is still lacking. A further interesting question is whether the mechanism suggested above is also valid or not for reactions with other catalysts, such as Rh and Ru complexes.

3. $Co_2(CO)_8$ Catalyzed Reactions of Oxygenated Compounds with Hydrosilane and Carbon monoxide



3.1. Reactivity of Silyl(carbonyl)cobalt Compounds

Reaction of a hydrosilane with $Co_2(CO)_8$ gives $HCo(CO)_4$ and $R_3SiCo(CO)_4$, [eq. (h)]. As we have already seen, $HCo(CO)_4$ is important in the catalyzed reaction of olefins. It has now been found that there are other reactions of hydrosilane and carbon monoxide in which $R_3SiCo(CO)_4$ seems to play the key role as catalyst. In these reactions, the catalytic cycles evidently begin with interaction between the substrates and $R_3SiCo(CO)_4$ and terminate with the regeneration of this compound. The substrates may be oxygenated organic compounds such as cyclic ethers, aldehydes, and esters. These compounds incorporate carbon monoxide and form siloxyaldehydes or enol silyl ethers having one or two more carbon atom(s). So far, we have studied these reactions only with $Co_2(CO)_8$ as catalyst (or catalyst precursor). Before discussing such reactions, it may be appropriate to take a brief look at the characteristic reactivity of $R_3SiCo(CO)_4$[27].

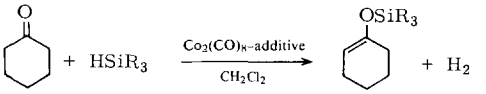
Trialkylsilyl(tetracarbonyl)cobalt, $R_3SiCo(CO)_4$, may be obtained by the reaction of hydrosilane with $Co_2(CO)_8$ as shown in eqs (h) and (i) and can be isolated by distillation or by crystallization when desired[6,21,28,29]. The most important property of these silyl(carbonyl)cobalt compounds is perhaps that they are very susceptible toward nucleophilic attack at the silicon atom even by weak bases such as alcohols [eq. (m)][21,29]. Since the stereochemistry of this reaction involves

$$R'OH + R_3SiCo(CO)_4 \rightarrow R'OSiR_3 + HCo(CO)_4 \qquad (m)$$

inversion at the silicon atom[29] the reaction most likely proceeds *via* the intermediate *(12)*[30]. Aprotic bases such as ter-

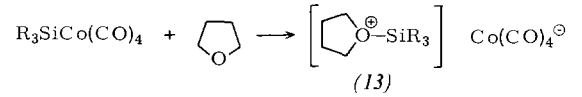
(12)

tiary amines or phosphanes react similarly[27]. For example, the reaction of trimethylsilyl(tetracarbonyl)cobalt with trimethylphosphane gives a silylphosphonium salt [eq. (n)] and not a phosphanecobalt complex obtainable by ligand exchange[31]. Strong bases such as MeLi and MeMgBr substi-



$$Me_3P + Me_3SiCo(CO)_4 \rightarrow [Me_3P{-}SiMe_3]^+[Co(CO)_4]^- \qquad (n)$$

tute triphenylsilyl(tetracarbonyl)cobalt[32] at the silicon atom, while PhLi attacks at the carbonyl ligand[33].

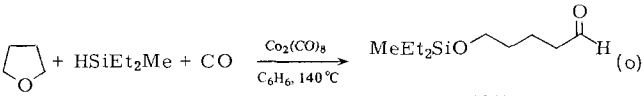


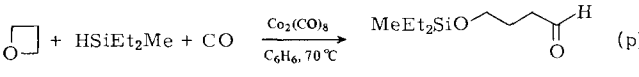
$Co_2(CO)_8$ is known to catalyze the silylation of alcohols, carboxylic acids, and amides[30]. In these silylations, the ac-

$$EtOH + HSiEt_3 \xrightarrow{\text{cat. } Co_2(CO)_8} EtOSiEt_3 + H_2$$

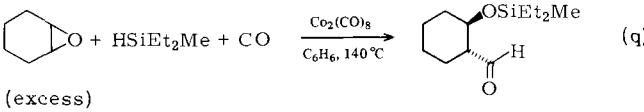
tive catalyst must be $Et_3SiCo(CO)_4$, which is generated by the reaction (h); it silylates the alcohol according to eq. (m), and is regenerated in the subsequent reaction (i) with evolution of molecular hydrogen. Recently, *Sakurai, Miyoshi,* and *Nakadaira* have found that the dehydrogenative silylation of ketones with hydrosilanes is effectively catalyzed by a $Co_2(CO)_8$-additive (additive: amines, phosphanes *etc.*)[34]. Again, silyl(carbonyl)cobalt must play an important role in

this useful reaction. *Chalk* has reported that $Co_2(CO)_8$ in the presence of a twofold or greater excess of $HSiEt_3$ catalyzes the cationic polymerization of tetrahydrofuran, an oxetane, and propylene oxide[30]. A silyloxonium ion of type *(13)* has been postulated[30] as intermediate.

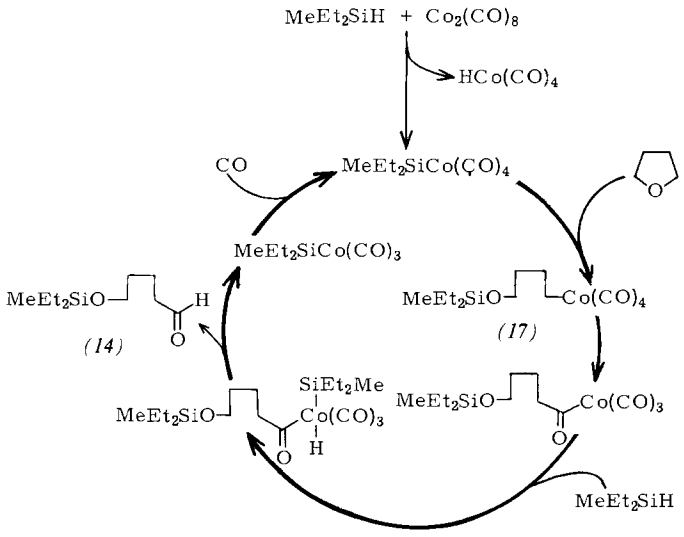




(13)

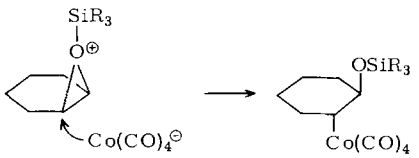


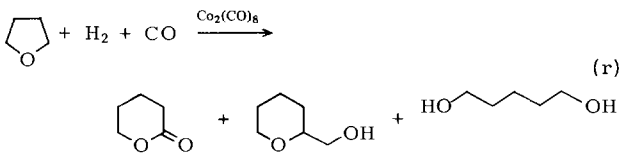
These examples imply that the central silicon atom in $R_3SiCo(CO)_4$ is strongly acidic and strongly electrophilic.



3.2. Catalytic Reactions of Cyclic Ethers with Hydrosilane and Carbon Monoxide

The reaction of cyclic ethers (tetrahydrofuran, oxetane, and 1,2-epoxycyclohexane) with $HSiEt_2Me$ and CO using $Co_2(CO)_8$ as catalyst has been found to give ω-[diethyl(methyl)siloxy]aldehydes[35]. The reaction conditions were: cyclic ether (3—5 equiv.), $HSiEt_2Me$ (1 equiv.), CO with initial pressure of 60 bar at 25 °C, $Co_2(CO)_8$ (0.02 equiv.), in benzene at 70—140 °C for 20 h. For the synthesis of the ω-siloxyaldehydes *(14)* to *(16)* excess amounts of cyclic ether are essential (see Section 3.3). The reaction appears to be limited to three-, four-, and five-membered cyclic ethers. Neither tetrahydropyran nor diethyl ether reacted under these conditions. Interestingly, diethyl ether could even be used as a solvent in the reaction of tetrahydrofuran. The enhanced reactivity of tetrahydrofuran toward $R_3SiCo(CO)_4$ has been known for some time[30,36].

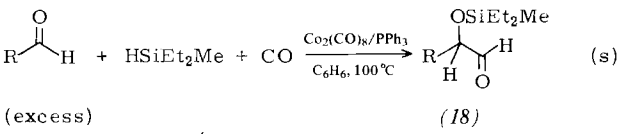




Scheme 4. $Co_2(CO)_8$ catalyzed reaction of THF with $HSiEt_2Me$ and CO.

Although a detailed reaction mechanism has not as yet been formulated, the catalytic cycle shown in Scheme 4 would appear to account for the present carbonylative ring opening. Two important aspects of this mechanism are: firstly, $R_3SiCo(CO)_4$, and not $HCo(CO)_4$, undergoes initial interaction with the cyclic ether, and is later regenerated; secondly, the well known high affinity of the organosilyl group for the oxygen atom[37] could be regarded as the important driving force for formation of the intermediate having a C—Co bond like *(17)*. In other words, Scheme 4 illustrates a new method for the formation of a carbon-transition metal bond; the carbonyl insertion is made possible by using the strong affinity of silicon for oxygen.

The ring-opening of tetrahydrofuran to the alkylcobalt complex *(17)* could proceed *via* the oxonium ion *(13)*. In this context, the configuration of the product *(16)* from 1,2-epoxycyclohexane is very interesting. The *trans* configuration of *(16)* could be understood by assuming an S_N2-type ring-opening of the oxonium ion intermediate.

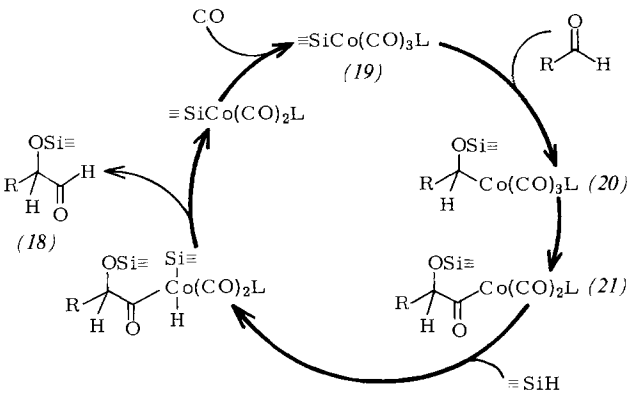


In contrast to reaction (o), the Roelen reaction[12] of tetrahydrofuran with $Co_2(CO)_8$ as a catalyst gives several products [eq. (r)][38].

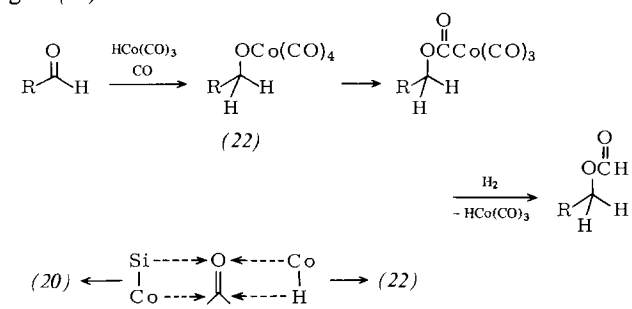
3.3. Catalytic Reactions of Aldehydes with Hydrosilane and Carbon Monoxide

We have tested whether the above described new entry to intermediates having a C—Co bond is also applicable to aldehydes, and have revealed unique catalytic reactions in which interaction of the carbonyl group of an aldehyde with $R_3SiCo(CO)_4$ seems to be the key step.

Reaction of 3 equivalents of aldehyde with 1 equiv. of $HSiEt_2Me$ and CO (50 bar) in the presence of 0.04 equiv. of $Co_2(CO)_8PPh_3$ (1:1) in benzene at 100 °C for 20 h, afforded the α-siloxyaldehydes *(18)* having one more carbon atom [eq. (s)][39]. The yields of *(18)* were 49% (R = *n*-C_3H_7), 50% (R = *n*-C_6H_{13}), and 54% (R = cyclohexyl). Although it is not



(s)



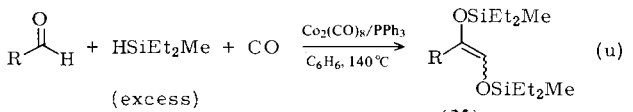
always necessary to use PPh_3 as a co-catalyst, it was found effective in suppressing the simple hydrosilylation of aldehydes [eq. (t)].

$$RCHO + HSiEt_2Me \xrightarrow{cat.} RCH_2OSiEt_2Me \qquad (t)$$

We suggest the catalytic cycle shown in Scheme 5 for the reaction (s). Here also, the active catalyst is a silyl(carbonyl)cobalt compound, $MeEt_2SiCo(CO)_3L$ (L = CO or PPh_3) *(19)*, and this reacts with the aldehyde to give the α-siloxyalkylcobalt *(20)*. The strong affinity between silicon and oxygen forces bond formation between the carbonyl carbon and the cobalt atom. In contrast, under the conditions of the Roelen reaction[12] (H_2 and CO) aldehydes are known to give formates. This implies that the interaction of aldehydes with $HCo(CO)_n$ (*n* = 3 or 4) takes place in the opposite direction to give *(22)*[40].

Scheme 5. $Co_2(CO)_8/PPh_3$ catalyzed conversion of a aldehyde to the next higher α-siloxyaldehyde using $MeEt_2SiH$ and CO. (The substituents on the silicon are not shown.) L = CO or PPh_3.

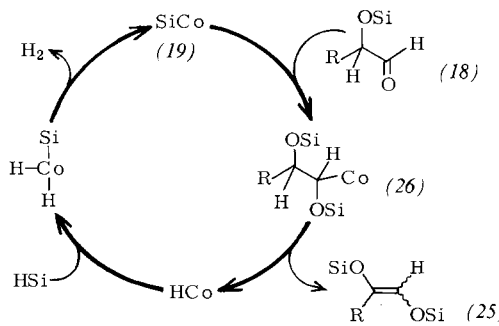
Insertion of carbon monoxide into the C—Co bond of *(20)* takes place to give the acylcobalt *(21)*. Very recently, inser-



tion of carbon monoxide into an α-siloxyalkylmanganese complex having similar structure to *(20)* has been reported[41]. Such reactions involving α-hydroxyalkylmetal compounds are very important with regard to the mechanism of the Fischer-Tropsch reaction[8a] and the Union Carbide ethylene glycol synthesis[9] in which α-hydroxyalkylmetal compounds [*(23)* and *(24)*, respectively] are thought to play a key role.

(23) *(24)*

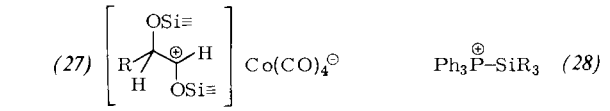
Two significant aspects of the reaction (s) may be worth mentioning. Firstly, the reaction (s) represents the first definite example of a catalytic reaction in which carbonylation with carbon monoxide takes place directly at the carbon of a carbonyl group. To our knowledge no reaction of this type, except for a few equivocal ones[42], has so far been reported, probably because no appropriate entry to the required α-hydroxyalkylmetal precursor has been available. Secondly, so far as we know, reaction (s) (Scheme 5) constitutes the first example of the interception of a plausible intermediate of carbonyl hydrosilylation [*e.g.* (t)], viz. of the compound *(20)*.



To obtain the α-siloxyaldehydes *(18)* by reaction (s), it is essential to use the starting aldehydes in excess over the hydrosilane; otherwise, the yields of *(18)* decrease. This implies that the catalyst species $R_3SiCo(CO)_3L$ *(19)* can react not only with the starting aldehydes but also with the α-siloxyaldehydes *(18)* that are formed. Thus, the $Co_2(CO)_8/PPh_3$ catalyzed reaction of an aldehyde with an excess of $HSiEt_2Me$ (1:3) and CO gave a different product, the 1,2-bis(siloxy)al-

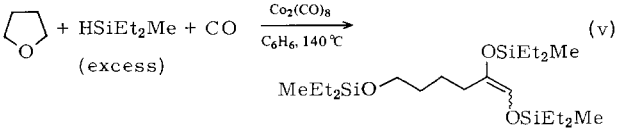
(u)

(25)



kene *(25)* was obtained instead of *(18)* [eq. (u)][43]. The yields were 67% (R = *n*-C_3H_7), 66% (R = *n*-C_6H_{13}), and 37% (R = cyclohexyl). Apparently, *(25)* may have been obtained as a result of dehydrogenative silylation of the initially formed *(18)*. Scheme 6 shows the simplified catalytic cycle for the conversion of *(18)* into *(25)*; the active catalyst *(19)* is regenerated, similarly as in reaction (i), with evolution of molecular hydrogen. The overall reaction (u) may be regarded as a combi-

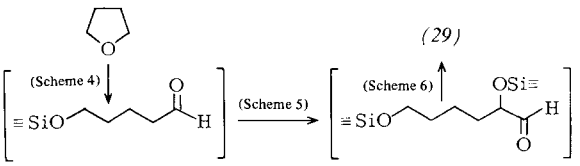
Scheme 6. Catalytic conversion of α-siloxyaldehydes *(18)* into 1,2-bis(siloxy)alkenes. (The substituents on the silicon are not shown. For simplicity, the ligands on the cobalt whose number may possibly change during the cycle are also not shown.) Abbreviations: SiCo *etc.* = $MeEt_2SiCo(CO)_nL$ *etc.*; *n* = 3 or 4, L = CO or PPh_3.



nation of the catalytic cycles given in Schemes 5 and 6. The use of PPh_3 was essential in these cases to suppress reaction (t).

Instead of the mechanisms shown in Schemes 5 and 6 some alternative ones could be suggested in which ionic species such as *(27)* or *(28)* could play a role. These possibilities remain open.

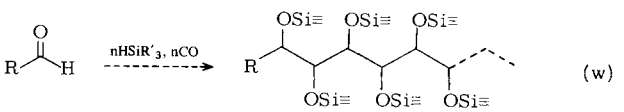
(27) *(28)*



Since the product from tetrahydrofuran is the aldehyde *(14)* [see eq. (o)], it can be expected that the use of excess amounts of $HSiEt_2Me$ will convert it into the corresponding 1,2,6-tris(siloxy)hexene *(29)*. This is indeed the case, as is shown in eq. (v)[43]. In this reaction, it was unnecessary to use

(v)

(29), 89%



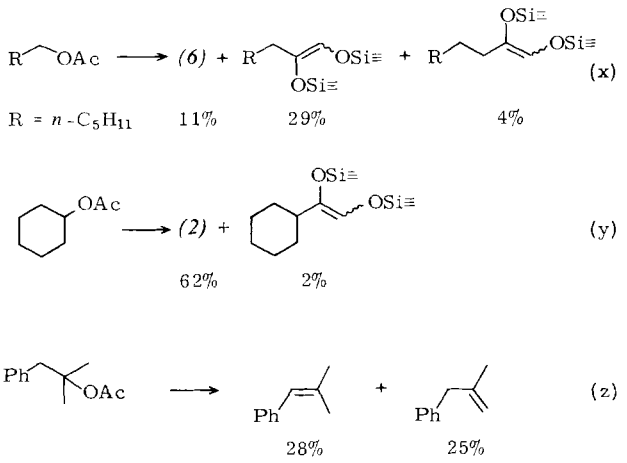
PPh_3 as a co-catalyst since the starting material was not an aldehyde [cf. reactions (s), (t), and (u)]. The course of the reaction (v) may be explained by a sequence of three catalytic cycles corresponding to Schemes 4, 5, and 6. The route from tetrahydrofuran to the product *(29)* is possibly very long, most likely involving more than a dozen steps. By using

(29)

excess amounts of $HSiEt_2Me$, oxetane gave a product similar to *(29)*, but 1,2-epoxycyclohexane unexpectedly afforded *(2)* as the major product[11].

A fascinating possibility could be envisaged on considering this type of C—C bond forming reaction with carbon monoxide. If one could carbonylate the α-siloxyaldehyde *(18)* in the same manner as in eq. (s), one would obtain a higher α,β-bis(siloxy)aldehyde. By repeating this process, one would in principle be able to "copolymerize" hydrosilane and carbon monoxide to persilylated polyhydroxymethylenes *(30)* [eq. (w)][44]. However, various other problems still have to be solved before seriously attempting this "copolymerization".

(w)



(30)

3.4. Catalyzed Reactions of Alkyl Acetates with Hydrosilane and Carbon Monoxide

There are many promising candidates available as partners for a catalyzed reaction with hydrosilane and carbon

monoxide. The reactions of oxygenated compounds such as esters, acid anhydrides, ketones, enones, acetals, ketals, and orthoesters as well as those of organic halides would be of great interest. So far, only a few substrates have been examined; some preliminary results of experiments with alkyl acetates are described below[11].

Alkyl acetates were allowed to react with $HSiEt_2Me$ (3:1) and CO (50 bar) in the presence of $Co_2(CO)_8$ in benzene at 140 °C for 20 h [eq. (x)—(z)].

Although not shown in eqs. (x)—(z), a silyl acetate $MeEt_2SiOAc$ was obtained in all cases. From the primary alkyl acetate [eq. (x)], only a trace amount of the branched isomers *(5)* was obtained, thus indicating little isomerization of the intermediary *n*-hexyl(carbonyl)cobalt compound under these reaction conditions. Interestingly, up to three molecules of carbon monoxide have been incorporated [eq. (x)]. The reaction of the secondary alkyl acetate [eq. (y)] seems to be promising as a synthetic reaction. In the plausible catalytic cycle of reaction (z), $H(CO)_4Co$ is very likely to arise in the product forming step. This process has already been formulated for step 7 in Schemes 2 and 3. In the present reaction (z), $HCo(CO)_4$ can be converted into a silyl(carbonyl)cobalt compound [eq. (z)].

4. Outlook

There are four types of catalytic cycles or overall catalytic transformations for the reaction with hydrosilane and carbon monoxide. One cycle begins with $HCo(CO)_4$ ("HCo"), another with a silyl(carbonyl)cobalt compound ("SiCo"); both terminate with regeneration of the same initial catalyst species in the product forming step [Scheme 2 for "HCo"; and Schemes 4 and 5 for "SiCo"]. In the other two catalytic cycles or overall catalytic transformations, regeneration of the initial catalyst species occurs after the product is formed [Scheme 3 for "HCo"; and the transformation (u) outlined by Schemes 5 and 6 for "SiCo"]. Availability of the two catalyst species, "HCo" and "SiCo", and hence of the four types of catalytic cycles or catalytic transformations provides a unique opportunity for designing a reaction. Moreover, in planning a new reaction, it will also be of great help to recall the close analogy between the reaction patterns of "SiCo" described in this paper and those of the well studied Me_3SiX, where X is a soft base such as CN, N_3, SR, I *etc.*[37,45].

From the synthetic point of view, the new catalyzed reactions have not as yet been fully explored. It should be noted, however, that the products obtained are *O*-silyl ethers of hydroxy compounds which are otherwise unstable or hardly accessible, *i.e.* enols, enediols, and α- and ω-hydroxyaldehydes. The synthetic utility of enol silyl ethers was first demonstrated by our research group[46] and has now been well established[37,45,47].

We wish to express our sincere gratitude to our able former students: Dr. Y. Seki (now at Kagawa University) for his conceptual and experimental contributions, Messrs. A Hidaka, I. Yamamoto, Y. Agari, S. Makino, and M. Fukutani for their skill and insight, and also to our present students (T. Kato, Y. Hatayama, and N. Chatani). We thank Prof. K. Kawamoto (Kagawa University) for valuable discussions.

Pino* in [1], Chapters 1—3; c) In the present paper, we use the term "Roelen reaction" for the catalyzed reactions of organic compounds with H_2 and CO. The term "oxo reaction" is not recommended because many "oxo reactions" do not give oxo (*i.e.* carbonyl) compounds [12b]. The popular term "hydroformylation", introduced by *H. Adkins* and *G. Krsek* [J. Am. Chem. Soc. *71*, 3051 (1949)], may also be confusing since it has, unfortunately, often been used not only to show the type of transformation (the addition of a hydrogen atom and a formyl group) but, improperly, to indicate the reactants (H_2 and CO). In the present paper, the term "hydroformylation" will be used only in the context of its original meaning, *i.e.* to show the type of transformation. Besides hydroformylation by the Roelen reaction (H_2 and CO), hydroformylation has also been observed in the Reppe reaction (H_2O and CO) [13] and in the reaction dealt with here ($HSiR_3$ and CO), see Section 2.5.

[23] Details will be published later.

[24] A control experiment, in which *n*-heptanal did not give the enol silyl ethers *(6)* but afforded n-$C_7H_{15}OSiEt_2Me$ under the standard reaction conditions, led us to suggest that an aldehyde might not be an intermediate [14]. Later, we found that this conversion into the alkoxysilane was complete before the temperature of the reaction vessel reached at 140 °C. When *n*-heptanal was injected under pressure at 140 °C, the enol silyl ethers *(6)* were found among the products [11].

[25] The silyl group migration to give the metal-carbene complex finds its topological analog in the known rearrangement of α-silyl ketones to enol silyl ethers [22b]. Hydrogen migration to a carbene ligand similar to that in eq. (k) has been suggested in some reactions [26].

Neurophysins: Molecular and Cellular Aspects[**]

By Roger Acher[*]

Neurophysins are linear cystine-rich proteins containing 93—95 amino acid residues which like the neurohypophysial hormones oxytocin and vasopressin are formed in the hypothalamus and travel from there to the hypophysial posterior lobe. A species usually contains two (or three) neurophysins which differ only slightly in chain length and/or sequence. Many observations suggest that both oxytocin and one of the neurophysins as well as vasopressin and the other neurophysin have a common precursor whose long chain is split into neurophysin and hormone. It can be shown on rats having considerable diabetes insipidus that a single gene controls the biosynthesis of the vasopressin and one of the neurophysins.

1. Neurosecretion and Neurohormones: First Investigations

The history of the neurophysins cannot be dissociated from that of neuroendocrinology. In fact, the early efforts of biochemists to purify the "posterior lobe hormones" of the pituitary, the activities of which have been known since the beginning of this century, were paralleled by cytologists' studies aimed at identifying the cells synthesizing these substances and at elucidating the secretory mechanism involved.

It was *Ernst Scharrer*[1] who in 1928, on the basis of his observations in certain hypothalamic neurons of a teleost fish, *Phoxinus laevis* (Fig. 1), for the first time clearly proposed the concept of neurosecretion. At the time, this idea was indeed revolutionary, nerve cells being considered as highly specialized for the conduction of nervous impulses and totally different from regular gland cells. For a long time thereafter, the posterior pituitary was interpreted as an autonomic endo-

[**] This review is dedicated to the memory of Ernst Scharrer, who some fifty years ago discovered neurosecretion.

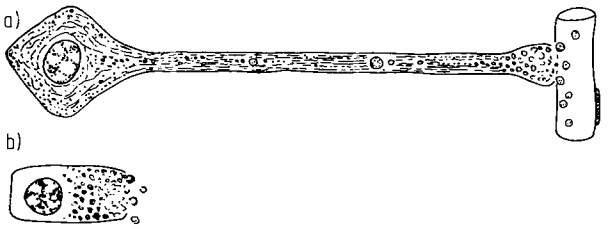

Fig. 1. The neurosecretory cell (a) can be considered as either a nerve cell with the characteristics of a gland cell (b), or a gland cell having acquired the characteristics of a nerve cell. In fact, it is a neuron which has very early undergone a second differentiation. The secretory granules have to be transported along a particularly long pathway from the site of their synthesis (perikaryon) to the site of their release (after [12]).

crine gland, and the synthesis of its hormones was attributed to special glial cells, the pituicytes, present in this lobe[2].

Only after the introduction by *Bargmann*[3] of the chrome hematoxylin phloxin method—originally intended by *Gomori*[4] for the demonstration of the β cells of the islets of Langerhans—was it possible to demonstrate the presence of secretory granules throughout the entire neurosecretory neuron. In 1951, *Bargmann* and *Scharrer*[5] definitely established that the perikarya of the supraoptic and paraventricular nuclei of the hypothalamus of higher vertebrates (corresponding to the preoptic nuclei of fishes and amphibians) synthesize a substance, called neurosecretory material, which is transported by axoplasmic flow to the posterior lobe where it

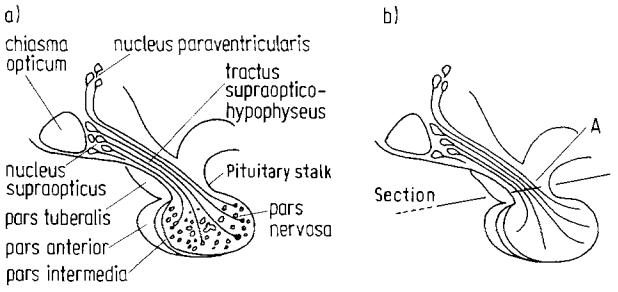

Fig. 2. Effects of severance of the pituitary stalk in the dog. Diagram of hypothalamo-hypophysial system, (a) of normal dog, and (b) of operated dog. The neurosecretory material originating in the supraoptic and paraventricular nuclei "migrates" along the axons and accumulates in the posterior lobe. After stalk sectioning neurosecretory material accumulates at the proximal stump of the axons (in A) (after [12]).

is stored and eventually released (Fig. 2). Thus the concept of a hypothalamic-neurohypophysial secretory system became established, involving a long intracellular route of transport in the course of which the possibility of modification of the initial product cannot be excluded. The fact that the presence of active principles demonstrated in various experiments generally coincided with that of the substance stainable by the Gomori technique led to the conclusion that the neurosecretory material represents either a substance associated with these hormones or the hormones themselves.

In the area of chemical characterization, the first papers by *Abel et al.*[6] between 1920 and 1930, suggested that the oxytocic, pressor and antidiuretic activities of the posterior pituitary belong to a single hormone. Later, two contradictory concepts were defended by different laboratories: the ones maintaining to have isolated a substance of high molecular weight possessing oxytocic as well as pressor activities, the others having succeeded in obtaining substances with either the one or the other activity possessing a very low molecular weight, of the order of 1000. The investigations of *Rosenfeld*[7], based on ultracentrifugation, suggested that the activities are due to one or two proteins with a molecular weight of the order of 20000 to 30000, but that substances of low molecular weight appear after treatment of the extracts with hot 0.25% acetic acid. In 1942, *Van Dyke et al.*[8] extracted frozen glands at low temperature and, after fractional precipitation with sodium chloride, obtained a protein considered to be pure and endowed with oxytocic, galactogogic, pressor and antidiuretic activities in ratios corresponding to those in the posterior lobe. *Van Dyke*[8] dismissed the possibility of the absorption of small active molecules by an inert protein on the basis of several experiments the two principal ones of which were as follows:

Free-boundary electrophoresis does not dissociate the activities from the protein, the unfolding of the protein as a film 8 Å thick leads to inactivation, whereas if the activities belonged to separate peptides, they would have to be always present, be it in the surrounding fluid or associated with the denatured protein. The liberation of active peptides would require cleavages which in the case of extracts are artificial, but which could be physiological at the time of secretion. Nevertheless, *Kamm*[9], followed by *Du Vigneaud*[10], *Fromageot*[11] and their collaborators, in 1953, isolated from acetone-treated glands ("acetone powder") by extraction with hot 0.25% acetic acid two fractions, one with oxytocic and galactogogic, the other with pressor and antidiuretic activities. This then presented the problem of determining the natural form of the hormones, protein or peptides, and of clarifying the relationships between the different active principles.

Moreover, the intracellular localization of the hormones and the endocrine significance of the substance stainable with the Gomori technique remained to be established. The Gomori reaction with chrome hematoxylin is not specific for a given chemical substance, but rather constitutes a staining process; not only can certain other neurosecretory systems, *i.e.* those of invertebrates[12], be demonstrated by this method, but also different endocrine cell types, *e.g.* the β cells of the islets of Langerhans. Thus the chemical nature of the stainable substance cannot be determined in this way. Despite the fact that *Hild* and *Zetler*[13] suggested that one is dealing with a phosphatide soluble in organic solvents and not with hormonal proteins or peptides, the histochemical studies of *Sloper et al.*[14] showed that the "Gomori-positive" granules stain equally well with performic acid/alcian blue, which are specific for cystine and cysteine, and that consequently the material has to be either a protein or a peptide rich in these amino acids. This applies specifically to the neurohypophysial peptide hormones or to the proteins with which they are associated, *i.e.* the neurophysins. It was, therefore, particularly interesting to find that the neurophysins, be they alone or in association with the hormones, stain with the Gomori method[15].

Since the first review on the neurophysins by *Acher* and *Fromageot*[11] several monographs on this subject have been published (see *e.g.* [16, 17]). Furthermore, the proceedings of a symposium on "Neurophysins: carriers of peptide hormones" has appeared as a separate volume[18].

2. The Reversible Neurophysin-Neurohypophysial Hormone Complex

Without denying the existence of small peptides endowed with hormonal activity, the followers of the unitary theory considered them as degradation products formed in the course of purification of the active protein. In fact, the posterior lobe extracts obtained at cold temperature appeared to be devoid of these small molecules. Besides, the possibility of non-covalent binding between a protein and peptides, at the time visualized as purely fortuitous, seemed hardly plausible, since the different protein preparations possessed specific reproducible activities and in ratios corresponding to the glandular content.

Since the active protein could play the role of a common precursor for oxytocin and vasopressin, it seemed to us important to elucidate the mechanism of formation of the peptides from a macromolecule[19,20]. The material obtained, under the conditions of *Van Dyke,* from fresh or acetone dried glands had all the characteristics described, namely: oxytocic and pressor activities of 18 U/mg, a sedimentation constant of 2.6—2.8 S, and a diffusion constant of 8.5×10^{-7} cm^2 s^{-1}, from which it could be concluded that the molecular weight was close to 30000. Based on this value, the estimated activities appeared in the neighborhood of 500 U per μmol, *i.e.* about equal to those of 1 μmol of oxytocin and 1 μmol of vasopressin. It was tempting to assume a stoichiometric relationship between the putative precursor and the active peptides. What then became a primary task was the rigorous verification of the homogeneity of the active protein. In the electrophoresis experiments of *Van Dyke*[8] the protein activities were not separated; this was accomplished by *Irving* and *Du Vigneaud*[21] who used the juice pressed from freshly slaughtered glands that had been immediately frozen and then ground up in the cold in the laboratory. This suggests that, under conditions of apparently weak proteolysis, the pressor principle migrates more quickly towards the cathode than the oxytocic principle.

We first carried out the free-boundary electrophoresis of the Van Dyke protein at low temperature (so as to minimize hydrolysis), and quantitatively determined the activities and the nitrogen content in the three parts of the U-shaped cell. Under conditions where the yields of the active principles and of nitrogen were of the order of 90—95% at the end of the experiment, the pressor activity per mg nitrogen was 5 times higher on the cathode side than on the anode side. The electrophoretic dissociation thus accomplished was then further exploited by subjecting the material to electrodialysis which separated proteins from small peptides. On using an electrodialyzer with three compartments separated by cellophane membranes and a current of only 12—15 mA (so as to avoid heating), it was possible to collect, from the active protein placed in the central compartment, practically all of the oxytocic and pressor activities in the cathode compartment. 90% of the nitrogen was recovered from the original, *i.e.* central compartment, the protein having remained there[19,20]. The only constituents identified in the cathode compartment were oxytocin and vasopressin, thus indicating that the entire activities of the protein complex were due to these peptides associated with the protein by non-covalent bonds. The quantitative dissociation of the active protein into three components was obtained likewise, either by counter-current distribution (Fig. 3) or by treatment with 5% trichloracetic acid,

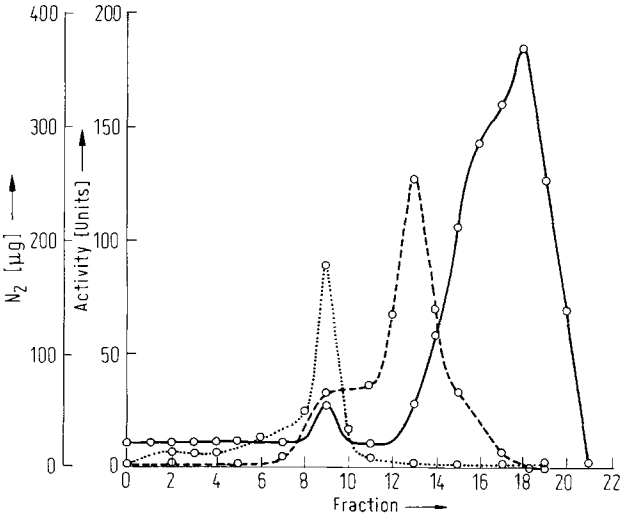

Fig. 3. Separation of the components of the neurophysin-neurohypophysial hormone complex by counter-current distribution in the system *sec*-butanol/0.5% trichloroacetic acid. ···· vasopressin activity, ---- oxytocin activity, —— nitrogen.

which precipitates the protein but leaves the peptides in the supernatant fluid (Fig. 4). This latter method opened the way to the simultaneous purification of the two hormones: the

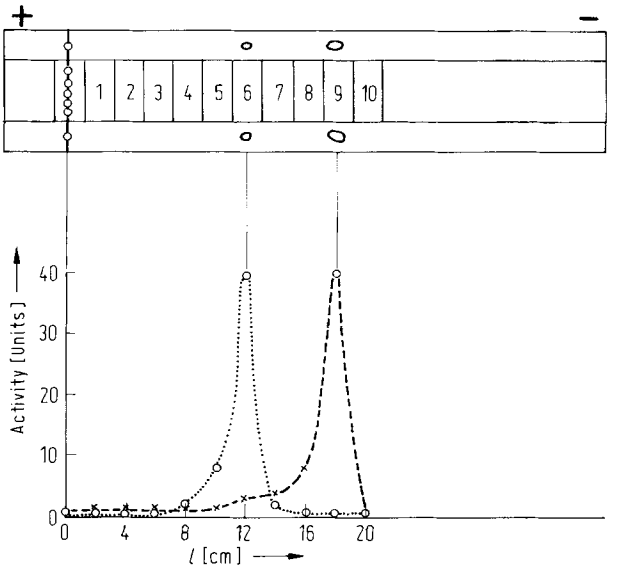

Fig. 4. Identification by paper electrophoresis of oxytocin and arginine vasopressin in the cathodic material obtained after electrodialysis of the supernate resulting from the dissociation of the "active" complex by 5% trichloroacetic acid. Below: activity test; ···· oxytocin activity, ---- vasopressin activity. *l* = migration towards cathode (after [20]).

protein-peptide complex was first separated from the extract by fractionated precipitation; after dissociation of the complex with trichloracetic acid, oxytocin and vasopressin were isolated by chromatography on an ion-exchange column[22] (Fig. 5).

We have proposed the term *neurophysin* for the protein which seems to be specifically associated with the hor-

Right-hand ordinate: oxytocin (OX-) and vasopressin (VP-) activity [units] (after [22]).

mone[19]. This specificity was confirmed by the reconstitution of the complex from its components, neurophysin, oxytocin and vasopressin, at the same ratio as that observed in the initial complex[23]. Furthermore, "hybrid" complexes were obtained with the neurophysin from one species and the hormones from another; mammalian neurophysins were thus used as selective adsorbents in the purification of active principles of lower vertebrates[24].

Neurophysin-hormone complexes were prepared from the glands of various mammalian species and it seems that this type of association is general among vertebrates. In the case of the whiting-pout[25], the precipitation of the complex required a higher sodium chloride concentration than in mammals. This might suggest a different constitution of the neurophysins of lower vertebrates or a degradation. In general, the yield in these species was increased by the addition of bovine neurophysin to the extracts.

3. Characterization of Neurophysins

3.1. Purification of Neurophysins

In spite of the fact that a certain heterogeneity of the neurophysin became apparent in the course of the counter-current distribution (Fig. 3) and paper electrophoresis experiments at alkaline pH, the protein separated from the complex seemed to correspond to a single molecular species in the course of ultracentrifugation. However, during starch-gel electrophoresis at pH 8.1, *Hope*[16] observed that the neurophysin isolated under our conditions contained several constituents. He attributed a part of these to proteolytic degradation occurring during the extraction at pH 4.0, and recommended acid extraction by means of 0.1 N hydrochloric acid in order to denature the proteolytic enzymes irreversibly. However, under these conditions, some contaminating proteins of higher molecular weight are extracted together with the complex and must be eliminated by a supplementary step of molecular sieving. *Hope*[16] recognized the presence of two major components and one minor component in the neurophysins of beef and pig and proposed for them the names Neurophysin I, II, *etc.*, in the order of their decreasing mobility toward the anode. This nomenclature, thus far accepted, can however suggest erroneous homologies between one species and another, since the number and mobility of the components vary in each species and since it is difficult to distinguish the authentic molecular species from degradation products. Thus one observed several neurophysins in the sheep although only one major protein can be detected[26, 26a, 27, 27a]. Polymorphism has been noted in several mammals, including man[28] and rat[29]; however, it is important to note that in the guinea pig, *Sachs et al.*[30] demonstrated only a single neurophysin.

In the meantime at least two sequentially different neurophysins have also been found in guinea pig[42a].

The purification of neurophysins is primarily accomplished by following two kinds of procedures which differ essentially in the first steps. In general, the initial material is an acetone powder of posterior lobes, but it can consist of fresh or frozen glands. An essential factor seems to be the speed with which the glands are removed after death. In the first process[20, 27], the powder is extracted at 4 °C with 0.01 N sulfuric acid, the pH being about 4. Under these conditions, the major part of the extracted material consists of the neurophysin-neurohypophysial hormone complex, which is then purified by fractionated precipitation with sodium chloride at pH 3.9 (Table 1).

After removal of the salts, the complex is dissociated into the proteins and peptide hormones by gel filtration on Sephadex G-25 with 0.2 M acetic acid. The proteins consist essentially of neurophysins, which are then separated by chromatography on a basic ion-exchanger, diethylaminoethyl-Sephadex A-50, using a gradient ionic strength (0.2—1 M pyridine acetate buffers) (Fig. 6). Under these conditions two well

Table 1. Neurophysin-neurohypophysial hormones complexes from mammalian species. OX = oxytocin, VP = vasopressin. The amount by weight of the complex is referred to the powder.

Species	Posterior pituitary powder Activities [U/mg] OX	VP	VP/OX	Complex Activities [U/mg] OX	VP	VP/OX	Weight [g/100 g]	Yield in activities [%]	
Ox	1.0	1.1	1.1	18—20	18—20	1.0	1.5	27	30
Calf (new born)	0.4	1.0	2.5	9	21	2.3	3.0	61	67
Sheep	0.8	0.8	1.0	18	18	1.0	4.2	92	90
Pig	1.4	1.4	1.0	18	18	1.0	1.5	19	19
Horse	0.9	0.8	0.9	20	10	0.5	0.8	18	10
Whale	0.5	2.5	5.0	5	20	4.0	6.0	47	57
Rat	1.2	1.4	1.2						
Rabbit	0.9	1.7	1.9						

separated fractions are obtained: Fraction A in the case of beef, sheep, and pig contains a neurophysin which, according to the nature of the amino acids in positions 2, 3, 6 and 7, we call MSEL-neurophysin (cf. Table 2). This material, depending on the conditions of preparation of the acetone powder, may contain derivatives truncated by several residues at the N- and C-terminus. Fraction B usually contains a second type of neurophysin (VLDV-neurophysin), as well as degradation products that have not yet been clearly identified.

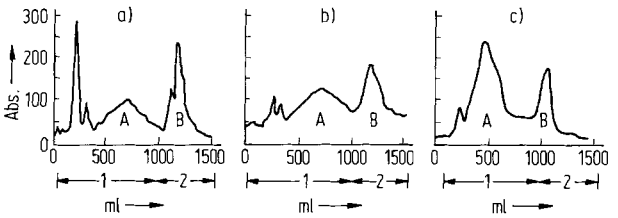

Fig. 6. Isolation of a) bovine, b) equine and c) ovine MSEL-neurophysins by gradient chromatography on DEAE-Sephadex A-50. Ordinate: absorption at 700 nm (Folin). A, B see text. 1: 0.2 M→0.4 M; 2: 0.4 M→1.0 M. pH = 5.9 (after [27]).

In the second procedure used by *Hope et al.*[16], *Breslow*[17] and *Watkins*[26], the extraction of the acetone powder is carried out with 0.1 N HCl at a pH of about 2.0. Neutralization to pH 7.0 leads to formation of a precipitate which can be separated by centrifugation. Readjustment of the pH to 3.9 and precipitation with sodium chloride furnishes a material containing the complex together with contaminating proteins of higher molecular weight. The peptide fraction of the extract is separated off by gel filtration on Sephadex G-25 in 0.1 M formic acid; the protein fraction is then passed through a gel of Sephadex G-75 once again so as to remove the proteins of higher molecular weight. The "neurophysin" fraction is then chromatographed on the basic ion-exchanger diethylaminoethyl-Sephadex A-50 at a constant pH of 8.1 (Tris-HCl) with increasing sodium chloride gradient. Two or three fractions are thus separated, from which at least three components possessing different electrophoretic mobilities can be isolated by repeated chromatography. Nevertheless, so far only two distinct neurophysins have been identified beyond doubt by means of sequential analysis of proteins from beef, pig and sheep glands. Other purification procedures, including selective extraction, isoelectric focusing or affinity chromatography on "immobilized" hormones, have been tried occasionally, but have thus far not been used extensively.

3.2. Amino Acid Sequence of the Neurophysins

The molecular weight of the neurophysins is still under discussion. By ultracentrifugation at pH 4.8, *Hope et al.* obtained values of 19000 and 21000, respectively, for bovine neurophysins I and II[16]. On assuming a molecular weight of 25000—30000 for the complex one could roughly calculate that one molecule of neurophysin is associated with one molecule of oxytocin and one molecule of arginine vasopressin. If the molecular weight is measured by molecular sieving on Sephadex G-75 at pH 7.0, values of the order of 15000—20000 are obtained, both for the complex as well as the "crude" or purified neurophysins[26,31,32]. In contrast, the molecular weight determinations by electrophoresis on polyacrylamide gel in the presence of sodium dodecyl sulfate give lower values of the order of 12500 for the neurophysins[32]. Finally, sequential analysis of the peptides furnished by trypsin hydrolysis of the oxidized neurophysins has revealed that the molecular weight of the monomer lies around 10000. A "dimerization" might therefore easily occur at pH 4 to 8, yielding associations stable in the course of molecular sieving or of ultracentrifugation.

Another interpretation might be that the molecular weights evaluated by ultracentrifugation or by gel filtration are too high owing to the unusual conformation of the molecule[44a].

Table 2. Amino acid sequence of the MSEL neurophysins of sheep [34, 34a], ox [34, 34a], pig [37, 37a, b], horse [37c] and whale [37d].

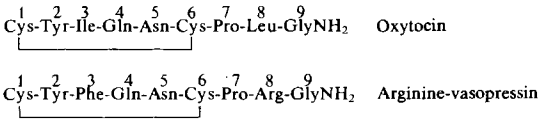
The neurophysins isolated thus far are acid proteins having isoelectric points between 4 and 5. They are distinguished from other proteins by a very high content of cystine (seven disulfide bridges for a chain of 93—95 residues) and proline (seven to eight residues) and by a very low content of aromatic amino acids: they do not contain tryptophan, and have only one tyrosine residue, and two to four phenylalanine residues per molecule. This explains the atypical absorption spectrum in the ultraviolet with a 260/280 nm absorbance ratio greater than unity.

According to *Hope et al.*[16] the three neurophysins demonstrable in beef and pig glands all possess an N-terminal alanine. A comparable result was then obtained for the three components of sheep[26]. On the other hand, in the case of the beef neurophysins, amino acid analyses have shown that neurophysin I contains histidine but no methionine, whereas neurophysins II and C contain methionine but no histidine[16]. In the pig, none of the three neurophysins contains histidine and only two of them contain methionine. The presence or absence of methionine often serves for the distinction of the different neurophysins in a given species.

The actual data concerning complete amino acid sequences of neurophysins are so far limited to those of beef, sheep, pig, horse and whale. N-terminal sequences are known for the neurophysins of rat, dog, cod and man. It seems that every species possesses at least two neurophysins which differ essentially from each other by the N- and C-terminal sequences. Consequently, it has been proposed to distinguish between two families, the MSEL-neurophysins and the VLDV-neurophysins, according to the residues in positions 2, 3, 6 and 7[33]. All neurophysins are single-chained polypeptides of 93—95 amino acids.

The MSEL-neurophysins are actually the best known. The complete amino acid sequences that have so far been determined are collected in Table 2. The amino acid sequence proposed by *Walter et al.*[35,36] for beef MSEL-neurophysin would appear by way of analogy[38] to be less likely than the sequence in Table 2. The amino acid sequence suggested by *Chauvet et al.*[34] for beef MSEL-neurophysin has been confirmed by *Wuu* and *Crumm*[34b].

The MSEL-neurophysins characterized up to now (ox, sheep, pig, horse and whale) consist of a single polypeptide chain of 95 residues. A large N-terminal part (residues 1—88) is nearly invariant since substitutions occur only once in position 36 (valine in all, except methionine in whale) and position 48 (asparagine in all, except isoleucine in sheep). In contrast, for the C-terminal part of the chain, variations can be observed in positions 89, 90, 91, 92 and 95. In the ox, a microheterogeneity is found in position 89, since two forms of MSEL-neurophysins are found, one with isoleucine, the other with valine.



Except for position 90 in which glycine or serine is found, the "mutable" positions of the C-terminal sequence are occupied by hydrophobic residues. Curiously, positions 89 and 95 seem related since both are occupied either by alanine (pig, horse, whale) or by isoleucine or valine (ox and sheep).

The five species examined belong to three orders of eutherian mammals: Artiodactyla (ox, sheep, pig), Perissodactyla (horse) and Cetacea (whale). These orders diverged about 70—80 million years ago. If the sheep is taken as reference, the percentage of substitutions between two different orders is 4—5%. The "drift" of MSEL-neurophysin in the course of evolution is small when compared with those of hemoglobin chains (12—20%). On the other hand, the close resemblance between ox and sheep MSEL-neurophysins is reminiscent of the similarity found for several pituitary polypeptide hormones (Table 3). A "neutral" drift is hard to imagine because both species (which belong to the suborder Ruminantia) diverged perhaps 30 million years ago and the number of substitutions is not proportional to time.

All the MSEL-neurophysins contain 14 cysteine residues per molecule (monomer) which form seven disulfide bonds; a certain mode of bonding has been suggested in the case of the ox protein[39], but since the sequence from which it was deduced is questionable, the definite location of the disulfide bridges still remains unclear.

The VLDV-neurophysins seem less abundant than the MSEL-neurophysins and the proportion of them appears to vary from species to species, so that their characterization is less advanced. The complete amino acid sequence of pig VLDV-neurophysin (neurophysin II) has been indicated[40]. The N-terminal sequences of VLDV-neurophysins from ox (neurophysin I)[41], man (neurophysin I)[42], rat (neurophysin II)[42a] and dog (neurophysin I)[42b] are known. VLDV-neu-

Table 3. Amino acid sequence of the neurohypophysial hormones.

	Asn	Leu	Aspargtocin	Ile	Arg	Vasotocin (?)

rophysins contain 93 residues per molecule and 14 cysteine residues, *i. e.* they resemble the MSEL-neurophysins.

The complete amino acid sequences of pig[40a] and ox[40a,41a] VLDV-neurophysins have recently been published (Table 4)[40a]. The sequence for bovine VLDV-neurophysin in Table 4 differs from that published by *Schlesinger et al.*[41a]

Table 4. Amino acid sequence of porcine and bovine VLDV-neurophysin. The arrangement of the tryptic peptides (pig: T1—T7; ox: T1—T6) has been determined with overlapping peptides which were obtained with the protease from Staphylococcus (S1—S5) and by sequencing (N-terminal sequence) (after [40a]).

by the C-terminal residue: glutamine instead of leucine. Table 5 compares the five MSEL-neurophysins and the two VLDV-neurophysins known to date. The homology between the MSEL- and VLDV-neurophysins of the same species is about 80%. The homology within the MSEL-family (five species) ranges from 95 to 99%. The two types of neurophysins have now been recognized also in man[40b]; so the duality exists in all the mammalian species investigated.

The two families of neurophysins have in common a long central sequence of about 65 residues (between positions 10 to 75) and seem to differ mainly in their N-terminal and C-terminal sequences. This fact strongly suggests that the origin of the polymorphism is duplication. On the other hand an internal homology between two parts of the same chain has led to the hypothesis that the chain is formed by partial duplication of a primitive gene coding for 55—60 residues and fusion of the daughter genes[41].

Table 5. Comparison of MSEL and VLDV neurophysins. Upper series: Sequence of the MSEL neurophysins of sheep, ox, pig, horse and whale. Lower series: Sequence of the VLDV neurophysins of pig and ox. Interchanged amino acids within the two groups are given (after [40a]).

3.3. Conformation of the Neurophysins

The three-dimensional structure of the neurophysins has not yet been determined. The CD spectrum of beef MSEL- and VLDV-neurophysins are very similar and suggest a small percentage of α-helix (about 5%) but a very high percentage of β-structure (about 40%)[17,43]. The marked accessibility of the disulfide bonds to reducing agents in the absence of urea[44,44a] suggests a conformation of low compactness. In the absence of urea, routinely used to unfold proteins, the seven disulfide bonds of the molecule are entirely reduced by dithiothreitol, which could be explained if the protein had a naturally extended structure. Its cleavability by enzymes leads to the same conclusion: the protein with its seven disulfide bonds intact is split by trypsin or chymotrypsin in practically the same way as in the unfolded state after reduction and alkylation[44a]. This extended (or easily extendable) conformation can be explained by the great number of proline residues, which for proteins of animal origin is most uncommon.

Molecular weight determinations in the absence of dissociating agents suggest that at pH 3 to 8 two subunits are associated to form a dimer, and even more aggregated forms could exist. It seems probable that the binding of the hor-

mones takes place on the dimer, but the latter's conformation is still unknown.

4. Interactions between Neurophysins and Neurohypophysial Hormones

The relatively small size of the neurophysins and especially of the neurohypophysial hormones, which belong to the smallest biologically active peptides, makes the complex a particularly simple model for the study of protein-protein interactions. Besides, the association is not followed by a chemical modification, as for example in proteolysis, which would complicate the observations. A very large spectrum of synthetic analogues of the hormones (over 300) has been prepared, primarily due to the efforts of *du Vigneaud, Boissonnas* and their co-workers, and it has been possible to determine the residues that intervene in the association. Though complexes of beef neurophysin with arginine vasopressin have been obtained in crystalline form by *Hope et al.*[16], the crystals have thus far not lent themselves for a radiocrystallographic X-ray study, so the three-dimensional structure of the complex has not yet been established. Indirect information is obtainable, however, from equilibrium dialysis studies as well as from variations in ultraviolet absorbance, circular dichroism, and nuclear magnetic resonance following the binding of the hormones to the neurophysins.

4.1. Stoichiometry of the Association

According to the experiments of *Breslow*[17,45] the changes in the CD spectrum reach their maximum when one mole of oxytocin or one mole of lysine vasopressin is combined with one mole of monomeric neurophysin (molecular weight of 10000) (Fig. 7—9). By means of an equilibrium dialysis study at pH 7.4 using labeled oxytocin, lysine vasopressin and beef neurophysin II (MSEL-neurophysin), *Breslow* and *Walter*[46] found that the binding of the two hormones is

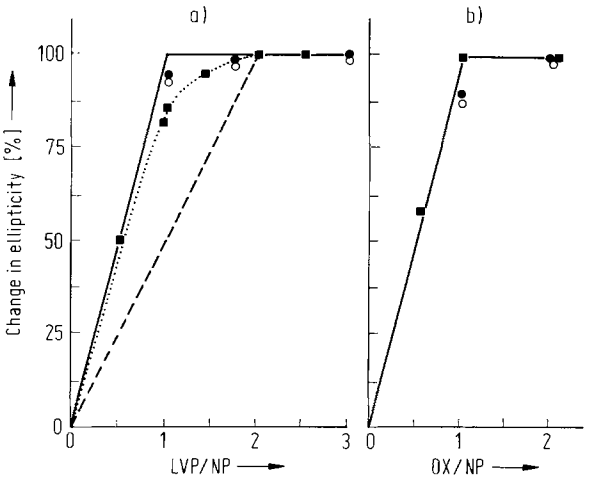

Fig. 7. Alteration of CD spectrum on titration of native or nitrated bovine neurophysin II (MSEL-neurophysin, NP) with a) lysine-vasopressin (LVP) and (b) oxytocin (OX). Results are expressed as the percentage of the total change in ellipticity generated by different hormone/protein ratios, where the total change is defined as the ellipticity of the saturated protein minus the sum of its isolated components. — One high affinity site, ···· one site with $K = 2 \times 10^5$, ---- two equal high affinity sites. • 280 nm, native bovine NP-II; ○ 245 nm, native bovine NP-II; ▪ 350 nm, nitrated bovine NP-II (after [45]).

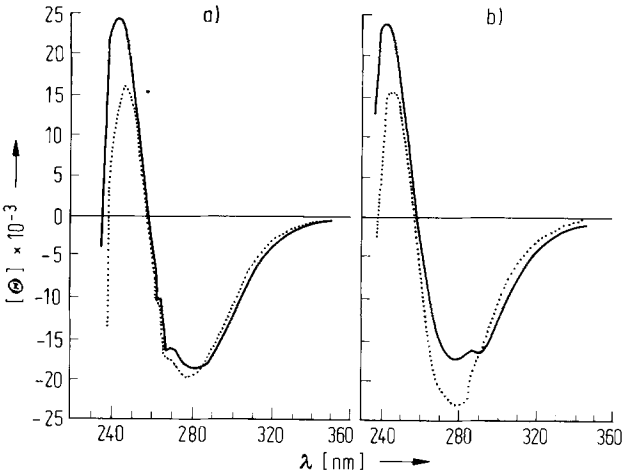

Fig. 8. Near-ultraviolet CD spectra of bovine neurophysin II (MSEL-neurophysin) in the presence of a) 1×10^{-3} M *S*-methyl-Cys-Phe-IleNH$_2$ and b) Met-Tyr-PheNH$_2$. — observed, ···· theoretical. "Theoretical" curves represent calculated spectra for a solution of bovine neurophysin II that is 1×10^{-3} M in the appropriate peptide with neglection of interactions (after [43]).

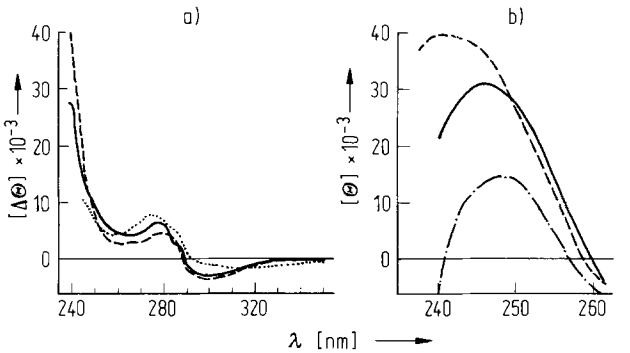

Fig. 9. a) Difference CD spectrum obtained by subtracting the CD spectra of the individual components of the mixture from the spectrum of the protein-peptide complex. Spectra obtained in the presence of oxytocin (—) or of lysine-vasopressin (– – –) represent 100% saturation of protein with hormone. Spectra obtained in the presence of *S*-methyl-Cys-Tyr-PheNH$_2$ (····) represent 90% saturation of the protein. b) Direct circular dichroism spectra of neurophysin II alone (–·–·–) and in the presence of 2 equivalents of oxytocin (—) or lysine-vasopressin (– – –) (after [45]).

competitive, with association constants of 1.2×10^4 M^{-1} for oxytocin and 8×10^3 M^{-1} for lysine vasopressin. Moreover, the authors point out that the affinities for neurophysin I (VLDV-neurophysin) are similar, so that it is not possible to demonstrate the specificity of association of one neurophysin with one given hormone.

On the other hand, the competition and the very similar association constants suggest that the binding sites of the neurophysin for the hormones largely overlap and are perhaps even identical; one direct deduction from this is that the binding sites of the hormones comprise especially the residues which they have in common (seven residues out of nine). The interpretation by *Breslow* and *Walter* does not take into account the fact that, at the pH at which the binding takes place, neurophysin is likely to be present in the form of a dimer, and assumes implicitly that each monomer fixes its ligand in an independent manner. However, the existence of cooperative effects in the binding process has recently been evoked[47,48]. If one assumes a stoichiometric relationship of 1:1 for neurophysin and hormone, one is led to reckon with a separate binding site in each monomer, and to identify the residues that constitute it. The relative instability

of the complexes, shown by the weak association constants, makes it difficult to identify the shielded residues as was possible in the case of the associations of trypsin or chymotrypsin with the pancreatic Kunitz inhibitor[49,50].

4.2. Binding Site of the Hormones

Beef neurophysins bind not only the mammalian neurohypophysial hormones (oxytocin, arginine vasopressin, lysine vasopressin) but also the six active peptides found in the other classes of vertebrates (see Table 3). All these hormones are nonapeptides, in which only the amino acids in positions 3, 4 and 8 vary[24]. The investigations carried out to date have mainly demonstrated the role of the first, second and third amino acid residues of the hormones in the binding to the neurophysins.

Amino Acid Residue No. 1: Acher, Chauvet and *Olivry*[20] had observed that dialysis at pH 2.75 against 0.1 M acetic acid leads to dissociation of the complex, permitting the passage of the hormones from the dialysis sac, whereas the same procedure against water elicits practically no dissociation. This observation suggested the existence of ionic binding between hormones and neurophysins. Since active peptides possess all their carboxy groups in amide form, the only possible group with a charge at the pH of fixation is the α-amino group, which in all cases belongs to a cysteine residue.

The discovery by *du Vigneaud et al.*[51] that this group is not only unnecessary for hormonal activity, but that its suppression even leads to an increase in activity, has naturally led to the examination of the binding of deamino-oxytocin to neurophysin. *Stoufer, Hope* and *du Vigneaud*[52] observed that deamino-oxytocin, in contrast to oxytocin, does not associate itself with beef neurophysins if these are precipitated at pH 3.9 with sodium chloride, nor does it accumulate in the sac containing the neurophysins if these are dialyzed against a solution containing the peptide.

These observations were confirmed by *Breslow* and *Abrash*[53] who have shown that the side chain of the cysteine in position 1 could be lengthened without disturbing the binding since 1-homocysteine oxytocin attaches itself to the protein as well as the oxytocin. Subsequently, *Breslow et al.*[54,55] observed that tripeptide analogues of the N-terminal sequence, which contain *S*-methylcysteine or methionine in position 1, were likewise bound, whereas the replacement by glycine reduces the association constant thirty-fold. The nature of the amino acid in position 1 does not seem to be exactly defined, but the presence of methylene groups in the β- and γ-position, participating in hydrophobic bonds, and certainly that of an α-amino group, implicated in the electrostatic binding, seem necessary.—It must be pointed out that the deamino-hormones are active, but substitution of the first residue causes inactivation.

Amino Acid Residue No. 2: Oxytocin containing the hydrophobic aliphatic isoleucine or glycine residue instead of tyrosine in position 2 is not bound whereas the 2-phenylalanine oxytocin is[53]. The presence of one aromatic amino acid in position 2 thus seems essential and this has been confirmed with the aid of di- and tri-peptides[54,55]. These data would suggest the necessity of precise hydrophobic contacts and perhaps the existence of π-π interactions. Finally, D-tyrosine oxytocin is not bound[53].

Tyrosine-2 is present in all known neurohypophysial hormones and this constancy probably indicates a participation in the association with the protein receptors of the cellular membranes.

Amino Acid Residue No. 3: Residue No. 3 is isoleucine in all known neurohypophysial hormones with the exception of vasopressin in which phenylalanine occupies this position. The oxytocin with glycine in position 3 has an affinity thirty-fold smaller[53]. Likewise, a glycine residue in position 3 of tri- and tetrapeptides reduces the binding affinity[55]. It would seem then that the presence of a hydrophobic aliphatic or aromatic amino acid in position 3 is necessary for binding with neurophysin.

Interestingly, the presence of isoleucine in position 3 seems essential for a marked association of hormones with the uterine receptor, while phenylalanine favors the renal receptor. The antidiuretic specialization of mammalian arginine vasopressin, derived from the arginine vasotocin of the other vertebrates, has come about during evolution precisely by this substitution[24].

Amino Acid Residues Nos. 4—9: Residues 4 to 9 do not appear to be essential for the binding with the neurophysins. The 4-glycine oxytocin binds almost as well as oxytocin[53], and so does the 5-valine oxytocin[46]. Replacement of glycinamide in position 9 by glycine reduces the fixation by 50%[46]. Position 8 is occupied by leucine in oxytocin, and by lysine or arginine in the vasopressins without giving rise to a marked difference in binding power. Finally, the tripeptide *S*-methyl-Cys-Tyr-PheNH_2, an analogue of the sequence of the first three residues of vasopressin, binds with mononitro-neurophysin II of beef with two-thirds of the free energy of oxytocin or lysine vasopressin[45]. Hence, it would seem that fixation to neurophysins implicates essentially the first three residues of the nonapeptides, whereas the activities of the hormones tolerate only very slight variations of sequence, and particularly no "truncation". The zone of interaction between the peptide and the protein is thus extremely limited in comparison with other known models of binary protein-protein association. The weak association constants are in agreement with a relatively small number of contacts, but location of the site of "anchorage" of the peptide is still not possible because of a lack of direct structural data.

4.3. Binding Site of Neurophysins

The identification of certain amino acid residues of hormones associating with neurophysins has led to the search for the protein residues that serve them as binding partners. Thus, a carboxyl group implicated in ionic binding has received particular attention; in addition the single tyrosine (tyrosine-49) present in all neurophysins has been studied in detail.

4.3.1. Aspartic Acid-30, Glutamic Acids-31 and -47

The participation of at least one carboxyl group in the association is shown by the fact that blockage of the acidic residues of the neurophysins furnishes a derivative that no longer binds the hormones[32]. According to the degree of proton displacement accompanying the binding of oxytocin or lysine vasopressin to beef neurophysin II, this binding carbox-

yl group can be assigned a pK value of 4.3[17]. This would indicate binding at a side chain rather than at the free terminal α-carboxy group of the protein (pK = 3—3.5). In fact, there exist variations in length and sequence in the C-terminal region of the chain[34] which make binding at this site unlikely. *Walter* and *Hoffman*[56] announced that they were able to couple the α-amino group of arginine vasopressin with a carboxy group of neurophysin II covalently, with the aid of a water soluble carbodiimide, and to identify the residue involved as Asp-30 or Glu-31. Either one of these could, in the non-covalent complex, be linked by ionic binding with the amino group of the hormone. However, *Breslow*[45] suggested the participation of Glu-47 on the basis of molecular models. In fact, localization of the acidic residue intervening in the electrostatic binding has not yet been definitely established.

4.3.2. Tyrosine-49

All neurophysins analyzed up to now possess a single tyrosine residue in position 49. The ease of detection of this amino acid by ultraviolet spectroscopy, circular dichroism, and nuclear magnetic resonance, has focused attention on Tyr-49 as a residue playing an essential role in the binding of the protein. The first observation supporting this participation was made by *Furth* and *Hope*[57] who transformed the residue to mononitrotyrosine by treatment with tetranitromethane, and showed that the absorption spectrum of the nitrotyrosine changed during the binding of arginine vasopressin in a manner which suggested a lowering of its pK_a value. The lowering of the pK was attributed to the approach of a positively charged group, the guanidine group in arginine-8, or approach of a positively charged group of the protein following a change in the conformation. The authors also suggested that the environment of the nitrotyrosine became more hydrophobic after the association. *Breslow* and *Weis*[43] repeated this experiment using CD measurements and spectrophotometric titration. The results indicated that the arginine vasopressin lowered the pK_a of the nitrotyrosine from 7.45 to 6.85 and produced changes in the ellipticity of the tyrosine. Since these alterations were brought about also by oxytocin or by analogues involving the sequence of the first three residues of the hormones, they could not be due to arginine-8. According to NMR investigations by *Breslow et al.*[58,59] the *ortho* and *meta* protons of Tyr-49 are affected by the association with the tripeptide *S*-methyl-Cys-Phe-IleNH_2, thus confirming that the environment of this residue is modified by the binding. Application of the nuclear Overhauser effect to this system established that the changes in the environment of Tyr-49 on complex formation are attributable to the approach of the peptide residue in position 2[59]. In the case of the above mentioned tripeptide, the intensity of the phenylalanine ring proton resonances decreases after irradiation in the presence of neurophysin II; this is not observed in the absence of neurophysin II. The effect occurs also in the case of hormones with tyrosine in position 2. It would appear that the changes are not due to a stacking, one above the other, of the phenol rings of Tyr-49 of the neurophysin and Tyr-2 of the hormones, but rather to the fact that Tyr-49, masked in the free protein perhaps by a phenylalanine residue, is displaced from this position, either directly by Tyr-2 or by a more general change in conformation[45]. The finding that Tyr-49 can be di-nitrated[45] or acetylated[57] without effect on the binding capacity, does not speak in favor of stacking between Tyr-49 and Tyr-2. In fact, the Tyr-49 of neurophysin would not be in direct contact with the Tyr-2 of the hormone, but in its immediate vicinity. The essential conclusions of *Breslow* and her group have subsequently been confirmed by other investigators[60].

4.4. Conformational Changes during Binding

The fact that the association between hormones and neurophysins favors precipitation by sodium chloride[52] and markedly increases the sedimentation constant[55] can be interpreted either in terms of a modification of the tertiary structure of the protein, or of a displacement of the equilibrium towards dimerization. It is actually difficult to distinguish between the effects of the interaction between hormone and monomer and those of the interaction between two monomers. It is also unclear whether these two interactions are independent of each other. If this were the case, the protein would possess, aside from the binding site for the hormone, a binding site for the second subunit (for the structure of the neurophysins cf. Sections 3.2 and 3.3).

The nature of the contacts and the possible conformational changes resulting from the interaction between hormone and neurophysin are a matter of speculation. Since the side chains of residues 1, 2 and 3 of the hormones are implicated, one can suppose that the disulfide bridge 1—6 and the phenol ring of the invariant tyrosine-2 are affected. *Breslow*[17,43,45,61], attributes the effects measured by analysis of the circular dichroism spectra of free and associated bovine neurophysin II to the following phenomena:

(1) the increase in ellipticity at 195 nm and 240 nm to a disturbance of the disulfide bonds in the course of association,
(2) the increase in ellipticity centered near 280 nm to a disturbance of the tyrosine of the hormone, with perhaps a small contribution by the tyrosine of the protein[43],
(3) the variations in the far-ultraviolet spectrum to changes in the tertiary structure of the protein, or to direct disturbances of different chromophores by the bound peptide.

The shifts of the amino acid residues of the protein, with the exception of the change in orientation of Tyr-49 (see Section 4.3.2), cannot actually be determined.

On the other hand, the possibility should be considered that the decrease in binding affinity between pH 6 and pH 2 may be the consequence of a carboxyl-dependent change in protein conformation[61a]. From measurements of temperature-jump relaxation it has recently been deduced that oxytocin and vasopressin bind with greater affinity to the neurophysin dimer than the monomer and that the binding of oxytocin and vasopressin in neurophysin dimer at pH 7.4 is nearly identical for each hormone[62a].

5. The Possible Common Precursor of Neurophysins and Neurohypophysial Hormones

The stoichiometric association of neurohypophysial hormones and neurophysins may be fortuitous, and the complexes isolated by extraction may be artefacts. Nevertheless, there are a number of arguments indicating that the two

types of substances are already associated in the secretory granules. One must consider the possibility that cleavage of an inactive protein precursor furnishes one neurophysin and one active peptide which remain associated. This happens *e.g.* in the cleavage of ribonuclease into peptide S and truncated protein by subtilisin. However, this hypothesis, which would account for a certain number of cytological and biochemical observations, has not yet been proven (Fig. 10).

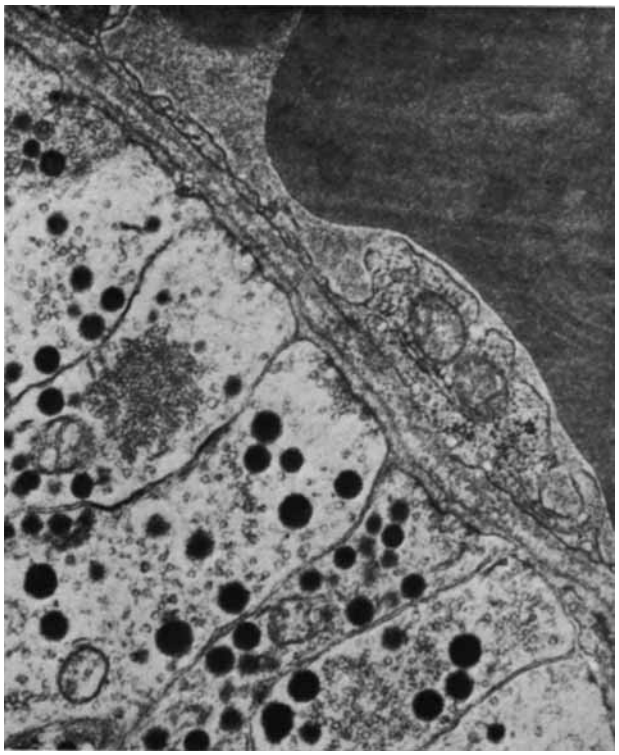

Fig. 10. Neurohypophysial terminals abutting a capillary containing (upper right) a red blood cell. The arrangement is conventional with the terminal regions of the neurons separated from the fenestrated capillary wall by the parenchymal and endothelial basement membranes. Terminals show evidence of secretory activity: paucity of large electron-dense neurosecretory granules and abundance of microvesicles (synaptic vesicles) (after [80]).

In the neurohypophysis of mammals, among which most species have been studied from different points of view, one finds generally two hormones, oxytocin and arginine vasopressin, which very often occur in roughly equal proportions. It is reasonable to assume that the two putative protein precursors would have similar though only slightly different sequences, and consequently, if the neurophysins represent inactive ballast, that they ought to exist in the gland in the same numbers as the hormones and probably in equivalent proportions. In fact, this argument is difficult to substantiate because, on the one hand the actual number of distinct neurophysins can be established only by sequential studies, and on the other hand the proportions can be affected by degradation or selective secretion.

5.1. Biosynthesis of Neurophysins and Hormones

There are a number of data proving that the neurohypophysial hormones and the neurophysins are synthesized in cell bodies located in the hypothalamus. Destruction of the supraoptic and paraventricular nuclei leads to the disappearance of the two types of substances, as determined by their biological activities and cytochemical reactions.

Sachs et al.[62] have studied the biosynthesis of vasopressin. They injected cysteine labeled with ^{35}S into the third ventricle of dogs and removed the hypothalamus 1.5 h later. One half of the tissue, examined right away, contained proteins but practically no vasopressin. The other half, after incubation for 4.5 h in a medium containing puromycin (which blocks the synthesis) and unlabeled cystein, yielded a significant amount of labeled vasopressin. These experiments suggest the biosynthesis of an inactive macromolecular precursor which is subsequently split to yield active vasopressin. *Sachs* assumed that the precursor is formed on the ribosomes of the perikarya of the hypothalamic nuclei and that the "maturation" (cleavage) takes place in the secretory granules during their axonal transport to the neurohypophysis. On the other hand, *Sachs et al.*[63] demonstrated on the dog hypothalamus, after infusion of labeled cysteine, the presence of a labeled neurophysin whose molecular weight (determined by molecular sieving), electrophoretic mobility (on cellulose acetate) and immunological characteristics were very similar to those of bovine neurophysins.

During subcellular fractionation, the labeled protein followed the vasopressin; in the case of animals kept alive for 10—21 days with free access to water, the protein could be recovered from the posterior lobe. Incubation of the latter *in vitro* with a high content of K^+ led to simultaneous secretion of vasopressin and labeled protein. *In vivo*, simultaneous se-

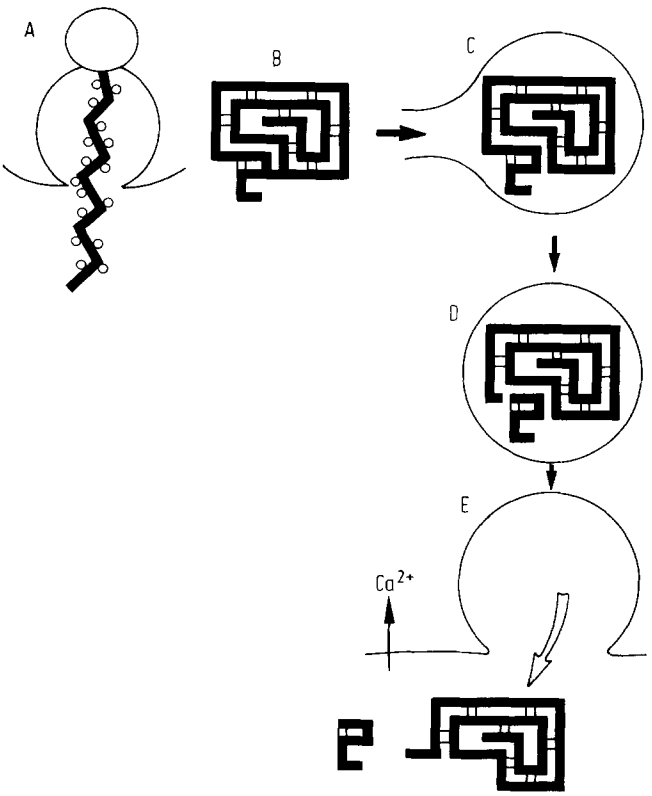

Fig. 11. A model for the biosynthesis, transport, and release of posterior pituitary hormones and neurophysins. A: synthesis of precursor in rough endoplasmic reticulum; B: folding of precursor; C: formation of neurosecretory granules in the Golgi apparatus; D: axonal transport (2—3 mm/h); hormone bound to neurophysin within granules; E: exocytosis; depolarization of the neuronal plasma membrane by propagated action potential; release of hormone and of neurophysin (possible conformational change) (after [16]).

cretion of the two substances and their release into the circulation occurred in dogs subjected to a severe hemorrhage. These experiments would indicate that the biosynthesis and secretion of vasopressin and of one neurophysin are parallel events.

Recently, *Gainer et al.*[63a] have shown that [^{35}S]-cysteine injected adjacent to the supraoptic nucleus of the rat is rapidly incorporated into a 20000-dalton protein which, in time is converted into a 12000-dalton labeled protein, neurophysin, and several small peptides including possibly oxytocin and vasopressin.

Brownstein et al.[63b] have also shown that two putative neurophysin precursors (pI 5.4 and 6.1) with molecular weights of about 20000, and two "intermediates" (pI 5.1 and 5.6) with molecular weights of about 17000, extracted from supraoptic nuclei, bind specifically to anti-rat neurophysin antiserum.

The localization of the neurophysins and the neurohypophysial hormones within the neurons seems to confirm the parallelism and favors the hypothesis of the common precursor (cf. Fig. 11).

5.2. Intracellular Localization of Neurophysins and Hormones

5.2.1. Localization in the Neurons by Immunocytological Methods

The identification of neurophysins in the perikarya of the supraoptic nucleus of the rat by immunofluorescence was accomplished by *Hope*[16] using anti-pig neurophysin II. Furthermore, in dog with anti-pig neurophysin he could demonstrate by this technique the transport of the neurosecretory material by axoplasmic flow in the hypophysial stalk of the dog: twenty hours after constriction of the stalk, he observed an accumulation of immunofluorescent material in the proximal, but not in the distal portion[16] (Fig. 12). In the rat it was even possible to estimate the speed of transport of a labeled protein similar to a neurophysin to be 2—3 mm/h[64].

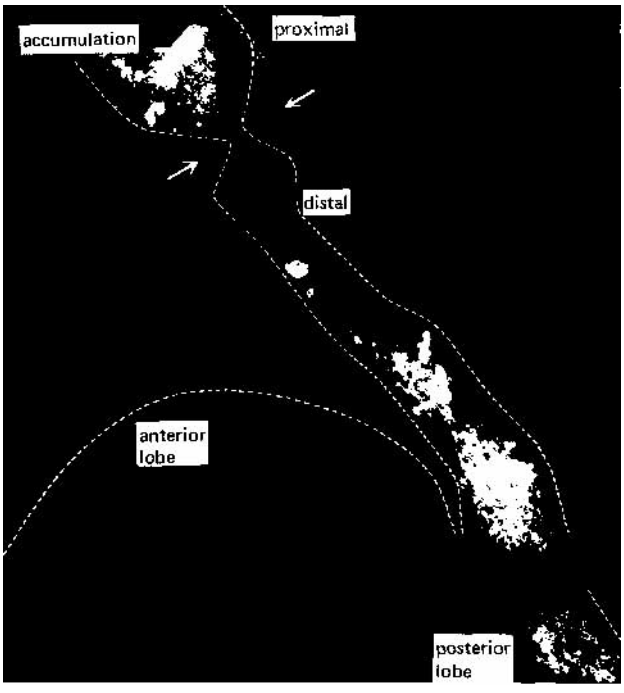

Fig. 12. The distribution of neurophysin immunofluorescence in the neurohypophysial stalk both proximal and distal to the site of a constriction. Note accumulation of fluorescence proximal to the point of constriction (arrows), its absence from axons in the tract immediately distal to the constriction, and its depletion in the proximal neurohypophysis (after [81]).

The intracellular distribution of neurophysins in the hypothalamus and posterior lobe of normal rats (Long-Evans) and of rats with a vasopressin deficiency and considerable diabetes insipidus (Brattleboro strain) has been examined by *Sokol et al.*[64a] using the immunoperoxidase technique (Fig. 13). In the homozygous Brattleboro rats, in contrast to normal rats, about 50% of the magnocellular neurons of the supraoptic and paraventricular nuclei lacked immunoreactive neurophysin. It was suggested that the neurons deficient in vasopressin also lacked neurophysin, which once again speaks in favor of a common biosynthesis.

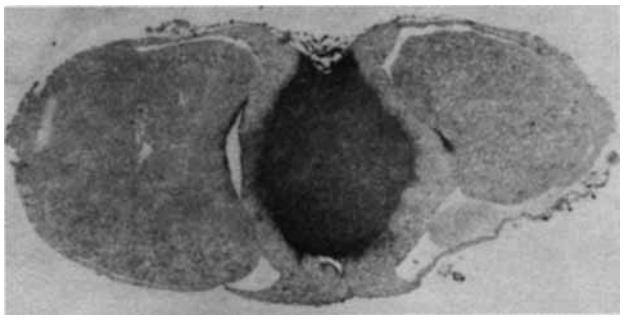

Fig. 13. Low power photomicrograph of mouse pituitary gland sectioned coronally. Immunoperoxidase stain using anti-human estrogen-stimulated neurophysin. There is heavy staining throughout the posterior lobe. The intermediate and the large anterior lobes are essentially free of reaction products (after [82]).

5.2.2. Localization within Neurosecretory Granules

After isolation of secretory granules from bovine posterior lobes by prolonged ultracentrifugation in a density gradient of sucrose it could be demonstrated by electrophoresis that the two major components of the bovine neurophysin, as also the two hormones, are present in about the same ratio[65]. *Dean* and *Hope*[65] found that the two neurophysins represent about 50% of the "granular" proteins. Furthermore, the two neurophysins were simultaneously present in each of the 15 glands individually examined, thus ruling out a genetic heterogeneity. The amino acid content of the crude "granular" neurophysin corresponds to that of a mixture of neurophysins I and II in equal proportions[65]. In addition, the distribution of oxytocin and vasopressin in the sucrose gradient suggests that the two hormones are stored in separate granules[65]. Moreover, neurophysin I is presumably present in the granules containing oxytocin, and neurophysin II in those containing vasopressin[66]. The existence of two categories of granules each possessing one type of hormone and one type of neurophysin also supports the hypothesis of a common precursor of the two substances. In the pig, lysine vasopressin is associated within the granules with neurophysin I[67]. This neurophysin (which is a truncated MSEL-neurophysin) is diminished selectively during the dehydration of the animal which leads to the secretion of lysine vasopressin[68]. All of the available data suggests affiliation of the MSEL-neurophysin with vasopressin, and it is interesting to note that in the bovine fetus the excess of vasopressin (in re-

lation to oxytocin) in the posterior lobe is accompanied by an excess of MSEL-neurophysin[38]. The simultaneous release of one hormone and one type of corresponding neurophysin can be explained by the mechanism of exocytosis[69]. The fact that the neurophysins of one species do not reveal a particular specificity of binding vis-à-vis the one or the other hormone leads one to think that the association does not have a biological significance related to the transport of the material but rather that it results from a juxtaposition due to the phenomenon of biosynthesis.

In the higher vertebrates the neurons terminating in the neurohypophysis have their origins in two hypothalamic regions, the supraoptic and paraventricular nuclei, which made it possible to assume a specialization whereby each of them would synthesize one hormone. However, recent investigations do not speak in favor of such a specialization[70,71]. This does not weaken the hypothesis of "one neuron-one hormone", since each nucleus may contain both types of neurons, a situation that is supported by the cytological analysis of Brattleboro rats which, being afflicted by hereditary diabetes insipidus, show a dispersion of neurons with and without granules[72].

5.3.3. Common Genetic Control of Vasopressin and One Neurophysin

One mutant of rats known as "Brattleboro strain" presents a hereditary diabetes insipidus caused by a deficiency either in the biosynthesis of vasopressin or in its liberation from an inactive precursor[73,74]. This deficiency affects only a single gene, and the heterozygous animals manifest a control over diuresis intermediary between that of normal animals and homozygous mutants. It is, therefore, important to verify if the absence of vasopressin is accompanied by a deficiency in one neurophysin. In the normal rat, three neurophysins (I or A, II or B, III or C) have been detected by means of polyacrylamide gel electrophoresis[75,76]. By injection of [^{35}S]-Cysteine before sacrifice, *Pickering et al.* observed that the ratio between the quantities of radioactivity incorporated in neurophysins I and II is very close to that of the amounts of vasopressin and oxytocin present in the gland[75]. On the other hand, in the homozygous Brattleboro rat, neurophysin I is absent, and in the heterozygote its quantity is lower than that of neurophysin II. *Pickering et al.*[29,75] concluded from this observation that vasopressin is synthesized with neurophysin I (or A) and oxytocin with neurophysin II (or B). *Pickering* attempted to determine the respective quantities of neurophysin I and II by using antiserums. Even though the specificity is imperfect—the antiserum for neurophysin I also precipitates 20% of neurophysin II — he concluded that vasopressin and neurophysin I (or A) are present in the gland in approximately equivalent amounts. These data argue in favor of the existence of a provasopressin which, by cleavage, gives rise to vasopressin and neurophysin I; this is in agreement with the conclusions of *Sachs et al.*[62,63].

Sunde and *Sokol*[76] also compared the neurophysins of the normal rat with those of the Brattleboro homozygote by polyacrylamide gel electrophoresis and likewise observed the disappearance of neurophysin I (neurophysin A of *Pickering*) in the strain manifesting diabetes insipidus. In spite of this, according to their experimental results neurophysin II (B) and neurophysin III (C) are present in equal proportions. The authors have examined the molar ratios of vasopressin/neurophysin I and oxytocin/neurophysin II + neurophysin III and have found the values to be 0.91 and 1.8 for the normal rat, and (0.0) and 1.77 for the Brattleboro homozygote. Furthermore, in the dehydration experiments, where the amount of vasopressin in the posterior lobe of the rat is considerably reduced, the molar ratio vasopressin/neurophysin I is 1.37 for the control animal (free access to water) and 1.31 for the animal deprived of water for three days. Even if the ratio between oxytocin and neurophysins II + III is debatable, that between vasopressin and neurophysin I appears, by way of contrast, to be very constant. It remains open whether rat neurophysin I belongs to the MSEL- or VLDV-family of neurophysins.

The sum total of observations made on the Brattleboro rat would indicate that a single gene controls the biosynthesis of vasopressin and of one neurophysin and that the two substances could be fragments derived from a common protein precursor.

6. Conclusions

The problem of the biosynthesis of the neurohypophysial hormones extrapolates to the more general topic of the biosynthesis of polypeptide hormones, and in a still broader sense to that of protein secretion. Since the work of *Steiner et al.*[77] one knows that most of the polypeptide hormones are synthesized in the form of an inactive precursor of larger size: thus proinsulin, proparathormone, proglucagon, the progastrins, *etc.*, have been characterized, in small quantity, in the secretory cells. One is dealing here with a general characteristic concerning the secretory proteins since one has equally been able to identify a proalbumin, proenzymes, *etc.* Furthermore, it has recently been observed that the proproteins are themselves cleavage products of very short-lived chemical compounds which are called pre-proproteins. *Habener et al.*[78]—inspired by experiments on pre-proparathormone—have proposed a general scheme of the biosynthesis and conversion. The initial protein chain, resulting from the transcription of messenger RNA, leaves the ribosome at its NH_2-terminus and penetrates the membrane of a cistern of the endoplasmic reticulum. An N-terminal sequence consisting of about 20 amino-acid residues, generally hydrophobic, represents the "perforator" of the membrane which is itself hydrophobic, and the rest of the chain can then penetrate the canal thus formed. The N-terminal sequence, called pre-peptide, becomes detached from the chain after 1—2 min, probably by enzymatic action. The isolation of the preproprotein and the characterization of the N-terminal sequence require microtechniques (radioactive labeling, special degradation procedures) that can be applied to quantities of the order of a nanomol. It was in this way that the sequences of the prepeptides of pre-proparathormone[78] and of pre-proinsulin[79] were determined.

Inside the cistern the chains, once liberated from the ribosome, acquire the native conformation of the prohormone. At the ends of the cisterns, vesicles detach themselves which then become fused to form secretory granules. Inside these granules a second proteolytic cleavage converts the prohormone into the hormone. Despite the fact that the enzymes responsible for these cleavages have not yet been isolated, they

seem to have a "trypsin-like" specificity. The life span of the prohormone in the granule is of the order of 1—2 h; in the case of insulin, for example, 95% of the proinsulin is converted into the active hormone whereby a peptide (peptide C) is liberated. The secretory granules reach the secretory pole of the cell and probably their entire content is discharged from the cell by the phenomenon of exocytosis (Fig. 14).

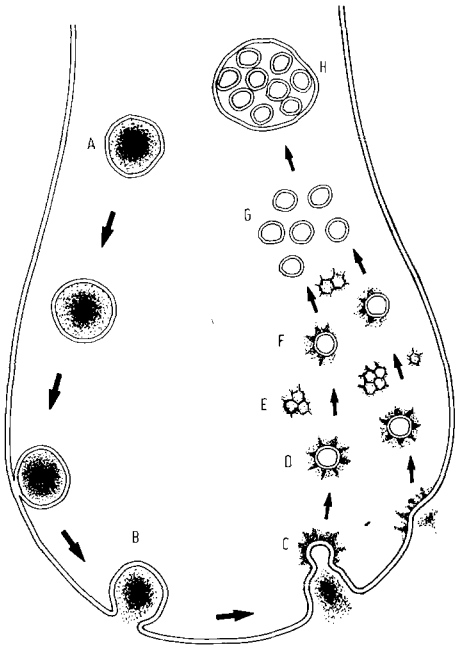

Fig. 14. Scheme depicting exocytosis-vesiculation sequence suggested to operate in neurohypophysial terminals. Contents of neurosecretory granules (A) are emptied directly into extracellular space by exocytosis (B). Granule membrane is retrieved from terminal surface by micropinocytosis-like activity (vesiculation), producing coated caveolae (C) which pinch off as coated microvesicles (D) and then shed coat fragments (E) to become partially coated microvesicles (F) and, finally, smooth (synaptic) microvesicles (G). These in turn are incorporated in lysosomal bodies (H) (after [80]).

This general scheme can also be accepted in the special case of neurosecretion; the neurosecretory neurons function like gland cells[80]. However, here the axoplasmic pathway for the transport of the granules from the cell body in the hypothalamus to the axon terminal in the neurohypophysis is particularly long and the transformations which the proteins undergo within the granules ("maturation") can be especially important. It seems reasonable to assume that the hormonal nonapeptides of the neurohypophysis are synthesized in the form of much longer chains, and that a sequence of cleavages, similar to those observed in several other polypeptide hormones, leads to active stable compounds which one can isolate in relatively important amounts. The simultaneous presence of hormones and neurophysins in the perikarya of the neurosecretory neurons, as revealed by the immunocytological technique; their close association within the granules, proved by the isolation of the latter and by chemical characterization; the indirect demonstration, by the incorporation of labeled amino acids, of the existence of a macromolecular precursor of vasopressin; the simultaneous disappearance of vasopressin and one neurophysin as a consequence of a unique mutation in the rat: all these observations provide a very strong argument in favor of the existence of a common precursor yielding one hormone and one neurophysin by cleavage.

The author is indebted to Prof. Bertha Scharrer for her help in the composition of the manuscript.

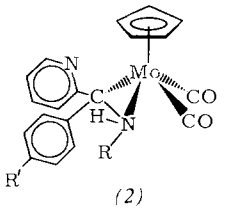
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

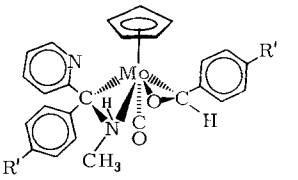
Synthesis and X-Ray Structure Analysis of a Mo Complex with η^2-Coordinated Benzaldehyde; Transformation of a CO Ligand by Double α-Addition[**]

By *Henri Brunner, Joachim Wachter, Ivan Bernal,* and *Michael Creswick*[*]



The chelate complexes *(1)*[1], accessible from the Schiff bases of 2-pyridinecarbaldehyde and $C_5H_5Mo(CO)_3Cl$ react with an excess of C_6H_5Li or *p*-$R'C_6H_4MgBr$ under ring contraction to give the neutral complexes *(2)*[2]. Reaction of the *N*-methyl compound *(1)* (R = CH_3) with *p*-$R'C_6H_4MgBr$ (R' = H, CH_3) in the molar ratio 1:2 does not stop at the stage of *(2)* but leads to *(3)* by reduction of a CO group. Whereas in the formation of a carbene ligand from a M—C≡O group the nucleophile adds to the C atom and the electrophile to the O atom[3], the transformation of a C≡O ligand into η^2-benzaldehyde, established for *(3a)* by X-ray structure analysis, requires double α-addition.

In the solid state *(3a)* occurs in two isomeric forms which can be separated manually. Both contain in the IR spectrum (KBr) the ν_{C-O} band at 1830 cm^{-1}; however, they differ in the frequency of the N—H stretching vibrations [*(3a')* 3203 cm^{-1}, *(3a'')* 3181 cm^{-1}]. The molecular structure of *(3a')* in the crystal (Fig. 1), determined by X-ray crystallography, is



(1)

R = CH_3, C_6H_5, $CH(CH_3)_2$, $CH_2C_6H_5$, $CH(CH_3)C_6H_5$

(2)

R' = H, CH_3, OCH_3, Cl

(3a), R' = H, *(3b)*, R' = CH_3

in accord with the ^{1}H- and ^{13}C-NMR spectra measured in solution at −10 °C (Table 1). Compared with *(2)*, in *(3a)* the δ(^{13}C) values for the MoCN three-membered ring (Δ = −23) and the CO group (Δ = +13) are shifted appreciably. In *(3b)* the *p*-CH_3 signals are nonequivalent.

At room temperature, the orange solutions of *(3)* in chloroform, benzene, and acetone soon turn blue with formation of extremely air sensitive and thermolabile complexes of still unknown structure.

The orange rhombs of *(3a')* crystallize in the space group $P\bar{1}$, $Z = 2$, cell constants $a = 9.035(6)$, $b = 12.314(6)$, $c = 13.220(5)$ Å, $\alpha = 65.91(4)$, $\beta = 71.40(4)$, $\gamma = 72.42(4)°$; $V = 1246.97$ Å^3, $\varrho_{calc} = 1.311$ g·cm^{-3}. From 3154 measured reflections (MoK_α radiation, $\lambda = 0.71073$ Å) 2128 with $I > 2\sigma(I)$ were used for the refinement of the structure [*R*(F) value 4.59%].

Table 1. NMR data of complexes *(3a)* and *(3b)* ($CDCl_3$ solution, TMS int.) [a].

^{1}H-NMR	$C_6H_4CH_3$		NCH_3 ($J_{NH\ CH_3}$)	C_5H_5	CH	NH	H5	C_5H_4N H4, H3	H6	C_6H_4R'
(3a)			^{2}2.63 (5.5)	^{1}4.76	^{1}5.22	^{m}6.30 [b]	^{m}6.49	^{m}6.98	^{m}8.39	^{m}7.32

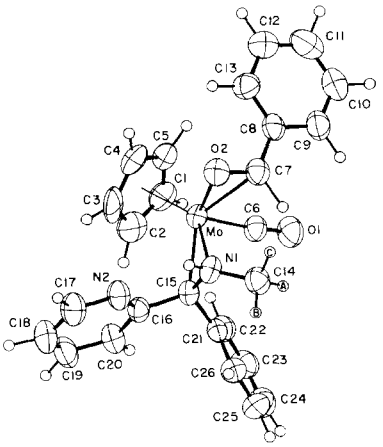

Fig. 1. ORTEP diagram of *(3a')*. Bond lengths: Mo–C6 1.900(11), C6–O1 1.182(13), Mo–C7 2.258(14), C7–O2 1.333(12), Mo–O2 2.071(8), Mo–N1 2.137(9), N1–C15 1.436(17), Mo–C15 2.203(9), Mo–Cp (average) 2.35(3) Å; bond angles: C7–Mo–O2 35.4, Mo–C7–O2 64.5, N1–Mo–C15 38.7, Mo–N1–C15 73.2, Mo–C6–O1 171.7, C6–Mo–C7 69.7, C6–Mo–O2 104.6, C6–Mo–N1 93.4, C6–Mo–C15 88.9°.

Similarly as in *(2)*, in the MoCN three-membered ring of *(3a')* the pyridyl substituent at C15 and the hydrogen atom at N1 lie at the side of the C_5H_5 ring; a hydrogen bridge is formed between N1 and N2[2]. The C_6H_5 substituent at the MoCO three-membered ring is also orientated to the C_5H_5 ring. The plane of the C_5H_5 ring forms angles of 60.36 and 33.58° with the planes of the MoCN and MoCO three-membered rings, whereby in the MoCN ring C15 and in the MoCO ring O2 are closer to the C_5H_5 plane. With an angle of 77.56° the planes of both three-membered rings are nearly perpendicular to each other. With 110.6(8)° the angle C16—C15—C21 is close to the tetrahedral angle. The η^2-bonding of the benzaldehyde in *(3a')* corresponds to the coordination of formaldehyde in $Os(\eta^2\text{-}CH_2O)(CO)_2(PPh_3)_2$[4] and benzaldehyde in $Ni(PPh_3)_2(\eta^2\text{-}C_6H_5CHO)$[5]. Considering the η^2-benzaldehyde a two-electron ligand and the η^2-aminomethyl group a three-electron ligand, *(3a')* can be regarded as a derivative of $C_5H_5Mo(CO)_2(NO)$[6].

Procedure

A solution of $p\text{-}R'C_6H_4MgBr$ ($R'=H$ or CH_3) (11.6 mmol) in 50 ml THF is added dropwise to a suspension of 2.2 g (5.9 mmol) *(1)* ($R=CH_3$) in 100 ml THF at room temperature. After refluxing for 30 minutes the solvent is evaporated off and the residue dissolved in 15 ml benzene. On chromatography on SiO_2 (column 3 × 20 cm) with benzene two very weak zones develop. These are discarded. Thereafter a broad greenish-blue zone develops which contains *(3a)*, *(3b)* and their subsequent reaction products; this is eluted with benzene/ether (1:1). Recrystallization at −35 °C from 100 ml acetone and 20 ml ether affords red orange crystals in 23–25% yield. On further recrystallization from ether/pentane (10:1) analytically pure compounds can be obtained: orange rhombs of *(3a')* (dec. 155 °C, $\nu_{NH}=3203\ cm^{-1}$)[7], red prisms of *(3a'')* (dec. 154 °C, $\nu_{NH}=3181\ cm^{-1}$), and red prisms of *(3b)* (dec. 170 °C, $\nu_{NH}=3181\ cm^{-1}$), respectively.

Thermodynamically Controlled Stereoselective Synthesis of Geissoschizine[**]

By *Werner Benson* and *Ekkehard Winterfeldt*[*]

Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday

We have previously described a total synthesis[1] of the biogenetically important alkaloid[2] geissoschizine *(1)*. The stereoselective methylene-lactam rearrangement of amino acids of type *(2)* may be regarded as the key reaction, which affords the *E*-configurated lactam *(3a)* as main product.

[*] Prof. Dr. E. Winterfeldt, Dipl.-Chem. W. Benson
Institut für Organische Chemie der Universität
Schneiderberg 1 B, D-3000 Hannover (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Wi 206/30).

The *Z*-configurated lactam *(4a)* formed as by-product proved to be stable under the reaction conditions, so a chromatographic separation was necessary. In an attempt to avoid this separation step we have studied the possibilities of *E-Z* isomerization.

Whereas in the case of unsaturated C^{15}-unsubstituted lactams [see *(3b)*] only the desired *E*-configuration is formed under kinetically controlled conditions[3] and is thermodynamically stable, in the case of the geissoschizine intermediate *(3a)* competing formation of the *Z*-isomer *(4a)* takes place by steric interaction between CH_3 and R [see conformation *(3')*]. This interaction would be minimized in the conformation *(3'')*—a conformation which however is not populated, unless forcefully so by bonding between R and the indole *N*-atom. This is achieved by treatment of the lactamic acid *(4b)* with trifluoroacetic anhydride. This ring closure is in fact accompanied by a spontaneous isomerization of the double bond with formation of the *E*-configurated dilactam *(5)*. Regioselective ring-opening of the dilactam with sodium methoxide in methanol leads to the lactamate *(3a)* in quantitative yield.

The synthesis becomes stereoconvergent through the intermediate *(5)*. The mixture of the lactamates *(3a)* and *(4a)* is hydrolyzed to the mixture of the lactamic acids, which then cyclize to the single dilactam *(5)* in very high yields. All the steps give excellent yields and can be carried out without resorting to isolation and purification of the intermediates. *(3a)* is cleanly converted into geissoschizine *(1)* by "Borch reduction" and formylation (see [1]).

Experimental

Hydrolysis of *(4a)* to the lactamic acid *(4b)*: NaOH (300 mg) and water (5 ml) were added to a solution of *(4a)* (200 mg, 0.6 mmol) in methanol (10 ml) and the mixture stirred overnight at room temperature. After acidification with 2 M citric acid and extraction of *(4b)* with dichloromethane, the extract was dried over $MgSO_4$ and then evaporated to dryness: 185 mg (96.5%) *(4b)*.—A mixture of *(4b)* (185 mg), dichloromethane (5 ml) and trifluoroacetic acid (20 ml) under nitrogen was stirred overnight at room temperature. After evaporation to dryness the product *(5)* was recrystallized from ether: 150 mg (86%), m.p. 195 °C[4].

Ring-opening to *(3a)*: A mixture of *(5)* (150 mg) and a 2% solution of sodium methoxide in anhydrous methanol (20 ml) was stirred for 1 h at room temperature in the absence of moisture. After addition of 2 M citric acid solution and extraction with dichloromethane the extract was washed with saturated sodium hydrogen carbonate and saturated sodium chloride solutions, dried over $MgSO_4$ and evaporated to dryness. The product *(3a)* was recrystallized from ether: 155 mg (93.6%).

Enantioselective Synthesis of α-Methyl-α-aminocarboxylic Acids by Alkylation of the Lactim Ether of *cyclo*-(L-Ala-L-Ala)[**]

By *Ulrich Schöllkopf, Wolfgang Hartwig,* and *Ulrich Groth*[*]

Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday

Optically active amino acids are of special interest in pure and applied organic chemistry. Asymmetric amino acid syntheses are of preparative importance, but only when they are simple to perform and give high optical yields (>90%). In the case of stoichiometric asymmetric syntheses the chiral agent ought to be recoverable and/or readily available in the "chiral pool".

We recently reported the asymmetric synthesis of α-methyl-α-aminocarboxylic acids [type *(7)*] by alkylation of *N*-1-chirally substituted 4-methylimidazolin-5-one[1a]. In the search for further synthetic routes we have now found that the base-induced alkylation of (3*S*,6*S*)-(+)-2,5-dimethoxy-3,6-dimethyl-3,6-dihydropyrazine *(3)* proceeds with high asymmetric induction (cf. Table 1). The diastereoselectivity

[**] Asymmetric Syntheses *via* Heterocyclic Intermediates, Part 2.—Part 1: [1a].

of the alkylation can be determined, either ^{1}H-NMR spectroscopically at the stage of the alkylation product *(6)* or polarimetrically or NMR spectroscopically with chiral shift reagents at the stage of the α-methyl-α-aminocarboxylate *(7)* or α-methyl-α-amino acid.

We obtained 3,6-dihydropyrazine *(3)* by reaction of *cyclo*-(L-Ala-L-Ala) *(2)*[2] with trimethyloxonium tetrafluoroborate. This reaction proceeds without racemization. The lithiation of *(3)* to *(4)* can be smoothly performed at −70 °C (in tetrahydrofuran) with butyllithium or lithium diisopropylamide (LDA). Double metalation at C-3, which would lead to an antiaromatic 8π electron system, does not take place[3]. The alkylation products *(6)* are hydrolyzable with 0.5 N hydrochloric acid even at room temperature. The esters *(1)* and *(7)* can be separated, for instance, by distillation.

In the alkylation *(4)*→*(6)*, the *R*-configuration is induced at C-6, *i.e.* the alkyl moiety prefers the *trans*-position to the methyl group at C-3. For example, (*R*)-(−)-α-methylphenylalanine[1b] is obtained from *(6a) via* the ester *(7a)*. In *(6a)* the *R*-configuration at C-6 is recognizable in the ^{1}H-NMR spectrum: 3-H absorbs at relatively high field strengths (δ = 3.17) because it is situated in the shielding anisotropic region of the phenyl group, which probably lies in a π-complex fashion over the heterocycle[4]. We attribute the high asymmetric induction to the fact that one of the two diastereotopic sides of the probably planar anion of *(4)* is relatively strongly shielded by the methyl group.

Experimental

(2): After washing with ether, the crude product obtained according to [2a] is *ca.* 90% optically pure. Crystallization twice from water yielded almost optically pure *(2)*; $[\alpha]_D^{25}$ = 26.4° (*c* = 1.3, H_2O); after drying in a vacuum over P_2O_5, m.p. 289 °C.

(3): A mixture of *(2)* (14.2 g, 0.1 mol) in anhydrous CH_2Cl_2 (300 ml) and trimethyloxonium tetrafluoroborate was vigorously stirred or shaken for 34 h at room temperature[5]. A buffer solution, consisting of NaH_2PO_4 (40.0 g, 0.3 mol) and Na_2HPO_4 (113.7 g, 0.8 mol) in 500 ml water, was added to the ice-cold mixture, the organic phase was separated off and the aqueous phase extracted three times with CH_2Cl_2. The combined extracts were dried over $MgSO_4$ and then evaporated to dryness at 10 torr; yield 14.9 g (88%) of almost optically pure *(3)*, b.p. ≈75 °C/8—10 torr; $[\alpha]_D^{20}$ = +82.6° (*c* = 1.0, ethanol)[6]; IR (film): ν = 1685 cm^{-1} (N=C); ^{1}H-NMR ($CDCl_3$): δ = 1.33 (d, CH_3), 4.04 (q, further split with $J_{1,4}$, CH).

Alkylation of *(3)* to *(6):* A solution of butyllithium (10 mmol, 6.4 ml of a 1.55 N solution in hexane) (or 10 mmol lithium diisopropylamide in a little THF) is cooled to −70 °C and then added dropwise to a solution of *(3)* (1.7 g, 10 mmol) in anhydrous THF (20 ml) at −70 °C. The mixture is stirred for 10 min at this temperature, treated with a solution of *(5)* (10 mmol) in THF (10 mmol) and stirring continued for 2—10 h. The mixture is allowed to warm to room temperature, the solvent removed at 10 torr, the residue treated with 10 ml water (and if necessary 5 g common salt), extracted three times with 30 ml of ether or CH_2Cl_2, the extracts combined, dried over $MgSO_4$ and worked-up in the usual way. Diastereomeric ratios (cf. Table 1) were determined on the crude product. The compounds *(6)* were purified by bulb-to-bulb distillation; example: *(6a)*, b.p. 115—120 °C/0.6 torr; IR (film): ν = 1680 cm^{-1} (N=C); ^{1}H-NMR ($CDCl_3$): δ = 3.62 and 3.60 (each s, OCH_3), 1.44 (s, 6-CH_3), 1.16 and 0.40 (each d, *J* = 7 Hz, 3-CH_3 for *trans-(6a)* and *cis-(6a)*[7], intensity ratio ≈28:1), 3.17 (q, *J* = 7 Hz, 3-H), 3.11 and 2.74 (AB, *J* = 14 Hz, CH_2).

Hydrolysis of *(6)* to *(7):* A suspension of *(6)* (10 mmol) in 0.5 N hydrochloric acid was stirred for 20 min—2 h at room temperature. The solvent was removed in a vacuum (50 °C), the residue [*(7)*·HCl] taken up in a *ca.* 10 ml water, covered with 30 ml ether and treated with conc. ammonia solution (1.6 ml) with vigorous stirring at 0 °C (danger of racemization of recovered *(1)*!). After separation of the ether phase, the aqueous phase was treated with 2 g sodium chloride, extracted five times with ether and the combined extracts dried over sodium sulfate. In the case of water-insoluble esters *(7)*, after hydrolysis the mixture was treated with dilute ammonia solution, extracted twice with ether, and potassium carbonate was added to the aqueous phase. After further extraction with ether the combined ether phases were dried over sodium sulfate. After removal of ether, *(1)* and *(7)* were separated by bulb-to-bulb distillation; example: *(7a)*, b.p. 50—55 °C/0.6 torr [*(1)* was separated in the forerun]; IR (film): ν = 1600 (br., NH_2), 1725 (C=O), 3200, 3320, and 3380 cm^{-1} (NH_2); ^{1}H-NMR ($CDCl_3$): δ = 3.66 (s, OCH_3), 3.13 and 2.78 (AB, CH_2), 1.37 (s, CH_3).

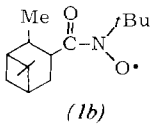
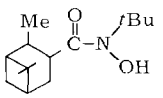
Enantioselective Oxidation by a Chiral Acylaminyl Oxide



By *Corrado Berti* and *M. John Perkins*[*]

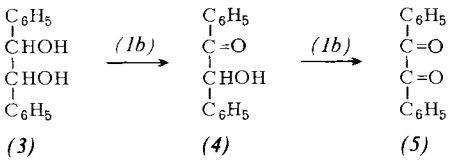
Dedicated to Dr. Robert S. Cahn on the occasion of his 80th birthday



The literature contains relatively few instances of asymmetric induction in atom transfer from carbon, presumably because chirality is lost in the derived carbon radical. However enantioselectivity has been observed, and constitutes a

(1a)

(1b)



(2)

[*] Prof. Dr. M. J. Perkins, Dr. C. Berti

simple procedure for obtaining materials enriched in one enantiomer[1]. The present report extends this principle to oxidations with chiral nitroxides (aminyl oxides), *i.e.* radicals of the type RR'NO•.

It has been demonstrated that isolable acyl(*tert*-butyl)aminyl oxides *(1)* are sufficiently reactive to behave as mild selective homolytic oxidizing agents, *e.g.* towards phenols and allylic alcohols[2]. Unlike *Fremy*'s radical $(K^+ {}^-O_3S)_2NO•$[3] they may be employed in non-polar solvents. We recently found that as sensitive compound as Vitamin A alcohol can be oxidized to retinal in *ca.* 90% yield by the radical *(1a)*; there is negligible competition from radical attack on the conjugated pentaene unit, or on the product aldehyde[4].

(3) *(4)* *(5)*

We have now isolated the chiral acylaminyl oxide *(1b)*, and found that it will effect enantioselective oxidation of benzoin *(4)*. Reaction of benzoin with *ca.* 1.5 molar equivalents of *(1b)* in benzene gives benzil *(5)* (*ca.* 0.6 equiv.) together with unreacted benzoin *(4)* (*ca.* 0.4 equiv.) which has $[\alpha]_D^{25}$ $(CHCl_3) = 14°$. This corresponds to an enantiomeric excess of *ca.* 7%[5]. In view of the separation between the radical center and the chiral substituent in *(1b)* the effect seems encouragingly large. The substrate initially selected for study was *meso*-dihydrobenzoin, *meso-(3)*, since it was envisaged that selectivity might be enhanced by hydrogen-bond association with the carbonyl group of the aminyl oxide. In this case, although benzoin *(4)* could be isolated, which was substantially enriched in one isomer, (e.e. *ca.* 15%), the yield was very low (<10%) since the rate of oxidation of benzoin *(4)* to benzil *(5)* proved to be greater than the rate of oxidation of dihydrobenzoin *(3)* to benzoin *(4)*.

The aminyl oxide *(1b)*, a blue oil which is readily prepared from (−)-3-pinanecarboxylic acid *via* the hydroxamic acid *(2)* ($[\alpha]_D^{25}$ (1 g/100 ml $CHCl_3$) = −49°; m.p. 157—158 °C) following a well-established procedure[6], is regarded as the prototype for a series of chiral aminyl oxide oxidizing agents. Manipulation of both reactivity and enantioselectivity by varying the acyl group and by replacing *tert*-butyl with a chiral alkyl group should be straightforward.

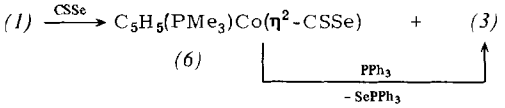
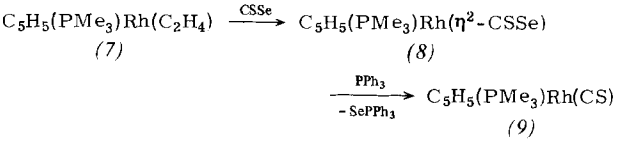
Thiocarbonyl-Metal Complexes from CSSe[1]



By *Helmut Werner* and *Oswald Kolb*[*]

In the carbon disulfide complex *(2)*, which is formed on reaction of $C_5H_5Co(PMe_3)_2$ *(1)* with CS_2[2], the η^2-CS_2 ligand is tightly bound. Hence, all attempts to obtain the corresponding thiocarbonyl complex *(3)*, as in the case of other CS_2-metal complexes[3] by reaction of *(2)* with PMe_3 or PPh_3, have met without success[4].



(1) reacts with COS to give $C_5H_5(PMe_3)Co(CO)$ in almost quantitative yield[5]. Possibly the complex *(4)* analogous to *(2)* is formed as labile intermediate, which then undergoes further reaction with the PMe_3 present in the solution with elimination of a sulfur atom to give *(5)*.

Should this be the case, then—assuming an analogous reaction course—the thiocarbonyl complex *(3)* ought to be formed from CSSe and *(1)* *via* the intermediate *(6)*. This expectation is only partially fulfilled. On reaction of *(1)* with thiocarbonyl selenide at −20 °C in toluene a mixture of *(3)* and *(6)* is obtained, which owing to the difference in solubility of the complexes in hexane [*(3)* is readily soluble and *(6)* is only sparingly soluble] can be easily separated. *(6)* reacts with PPh_3 in benzene (50 °C, 1 h) to give *(3)* in quantitative yield.

CSSe is also a very suitable source of CS for the preparation of other thiocarbonyl complexes. Thus, replacement of the ethylene ligand in *(7)*[6] by CSSe (benzene, 50 °C, 5 h) leads to *(8)*[4], which reacts with PPh_3 (benzene, 50 °C, 45 min) to give *(9)* in quantitative yield. The triphenylphosphane complex $C_5H_5(PPh_3)Rh(CS)$ analogous to *(9)* was recently synthesized starting from $(PPh_3)_2Rh(CS)Cl$ and NaC_5H_5[7].

The use of CSSe opens a new synthetic route to thiocarbonyl-metal complexes, which hitherto were mainly obtained from CS_2 or $CSCl_2$[8]. CSSe is of particular advantage if the potential alternative metal-(η^2-CS_2) compound is kinetically inert toward PPh_3 or other sulfur-abstracting agents.

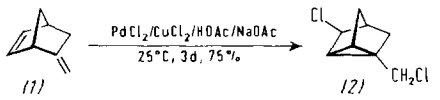
Cyclic Systems by Palladium-Catalyzed Oxidation of Diolefins[**]

By *Andreas Heumann, Marius Reglier*, and *Bernard Waegell*[*]

The direct catalytic oxidation of olefins (except ethylene[1]) in the presence of palladium salts has only recently acquired importance in synthetic organic chemistry[2]. With the system $PdCl_2/CuCl_2$/buffered acetic acid it is possible to add chlorine and the acetoxy group[4] to strained olefins such as norbornene[3a] or apopinene[3b].

We have found that not only compounds from the norbornene series but also monocyclic and acyclic hydrocarbons—providing they contain two double bonds—can be oxidized selectively and in good yields with palladium salts. The reaction is of general utility [examples: *(1)*, *endo-(6)*, *(10)*, 5-methylenecyclooctene[5]] and proceeds according to the following Scheme:



On addition of $CuCl_2$ (2 mol per mol olefin) the reaction becomes catalytic with regard to the palladium salt ($PdCl_2$ 0.03 mol-%); the use of buffered (NaOAc) acetic acid as solvent facilitates the isolation of various types of disubstituted final products. The second double bond in the substrate stabilizes the intermediary (and often isolable) Pd-σ-complex and, moreover, is inserted into the C—Pd bond. C–C coupling, *i.e.* cyclization, occurs and the σ-π complex affords a new σ-complex which can readily react by β-elimination or reductive elimination to give the metal-free final products.

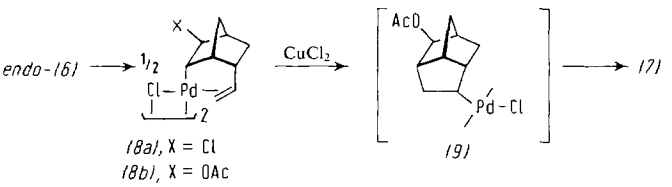
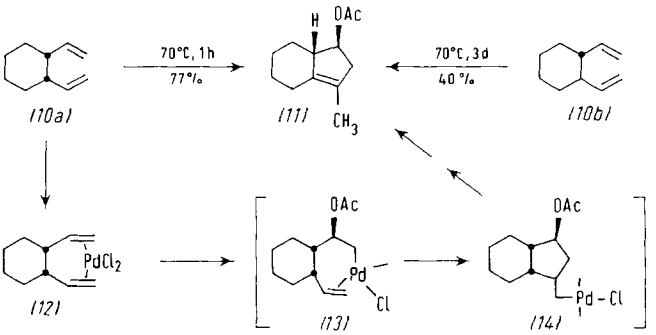
Under these conditions 5-methylenenorbornene *(1)* furnishes only the dichlorinated nortricyclene derivative *(2)*[6].



This selective dichlorination is the result of a $PdCl_2/CuCl_2$ catalysis; $CuCl_2$ alone catalyzes only the addition of HCl or HOAc to give *(3)*, *(4)*, and *(5)*.

Reaction of the structurally related 5-vinylnorbornene *(6)* (*exo*/*endo* = 24/76) with $PdCl_2/CuCl_2$/HOAc/NaOAc leads to the isomeric brendane derivatives *(7a)* and *(7b)* in the ratio 7:3; noncyclized chlorides are also formed.



The structures of the compounds *(7)*[7] were confirmed by degradation to the known 2-brendanone[8]; the position of the chlorine can be assigned by mechanistic considerations.

The base-catalyzed cleavage of HCl from *(7)* leads to 4-brenden-2-ol[9]. The complexes *(8a)* and *(8b)* can be isolated[10], and, at 80 °C, form the same products *(7)*.

A formal α,ω'-cyclization is observed on oxidation of *cis*- and *trans*-1,2-divinylcyclohexane *(10a)* and *(10b)* to the bicyclo[4.3.0]non-6-ene derivative *(11)*.

The formation of the isomer *(11)* can be regarded as a sequence of several stereoselective steps proceeding *via* the intermediates *(13)* and *(14)*[2]. Apparently, the *cis*-isomer *(10a)* has the "correct" stereochemistry; according to model considerations, however, the *trans*-isomer *(10b)* should also yield palladium complexes relatively easily. It can be seen that the

chosen models lead not only to synthetically interesting reactions but also give an insight into the reaction mechanism[5].

Experimental

Synthesis of *(11)*: A suspension of $PdCl_2$ (50 mg, 0.28 mmol), anhydrous $CuCl_2$ (2.7 g, 20 mmol) and sodium acetate (800 mg, 10 mmol) in glacial acetic acid (25 ml) is treated with *(10a)* (1.36 g, 10 mmol) and the stirred mixture is warmed to 70 °C for 1 h. After addition of 25 ml of water the mixture is cooled and extracted with pentane (4 × 15 ml). The combined pentane extracts are washed until neutral (1 × $NaHCO_3/H_2O$, 1 × $NaCl/H_2O$) and dried over $MgSO_4$. After removal of solvent in a rotary evaporator the crude product is distilled *in vacuo* (bulb-to-bulb, 80 °C/10 torr); yield 1.5 g (77%) *(11)*[11].

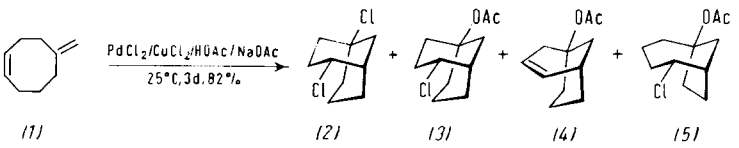
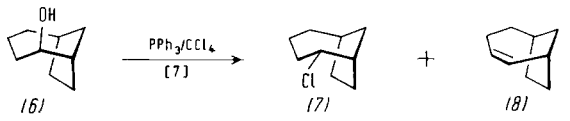
Mechanistic Aspects of the Palladium-Catalyzed Cyclization of 5-Methylenecyclooctene[**]

By *Andreas Heumann, Marius Reglier,* and *Bernard Waegell*[*]

The palladium-catalyzed cyclization of diolefins represents a simple and direct method for the preparation of substituted bi- and poly-cyclic systems[1]. We report here on a further reaction of this kind, the cyclization of 5-methylenecyclooctene *(1)*, which is readily accessible in four steps from 1,5-cyclooctadiene. Cyclization of *(1)* in the presence of $PdCl_2$ (3 mol-%), $CuCl_2$ [2 mol per mol *(1)*] and HOAc/NaOAc affords the products *(2)* to *(5)* in the ratio 8:35:20:22 (Table 1)[2]. This reaction enables not only the preparation of relatively complex systems from readily accessible olefins but also an insight into the mechanism of this metal-catalyzed oxidative cyclization. The structures were assigned on the basis of the following findings: On base-catalyzed HCl-elimination, hydrolysis, and subsequent hydrogenation the reaction mixture afforded bicyclo[3.3.1]nonan-1-ol[3] and bicyclo[4.2.1]nonan-1-ol[4]. The *endo* configuration of the 4-chloro substituents in *(2)* and *(3)* can be unequivocally assigned by the chemical shift and the coupling constants of the CHX proton[5]. In contrast, the mobility of the C_4-bridge in the bicyclo[4.2.1]nonane system leads to almost identical multiplicities of the CHX protons in the NMR spectra of the 5-*endo*- and 5-*exo*-compounds[6]. Comparison of the CHX signals of *(5)* and of the *endo*-2-chlorobicyclo[4.2.1]nonane *(7)* obtained from *(6)*[6] (Table 1) showed that *(5)* is most probably the *endo* isomer.





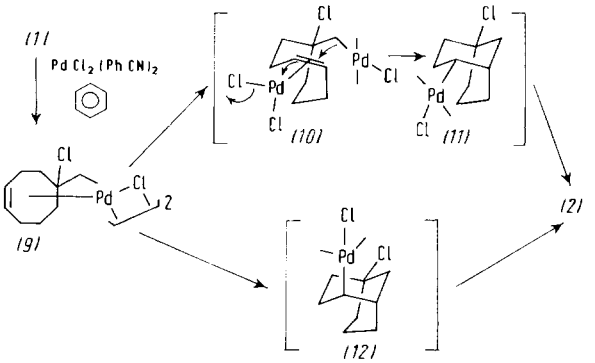


Table 1. Characteristic spectral data of the compounds *(1)*—*(5)* and *(7)*. ^{1}H-NMR in $CDCl_3$, IR in $CHCl_3$.

(1), ^{1}H-NMR: δ = 4.79 (s, 2 H, C=CH_2), 5.56—5.72 (m, 2 H, CH=CH)
(2), ^{1}H-NMR: δ = 4.24 (m, J_1 = 4, J_2 = 8, J_3 = 14 Hz, 1 H, CHCl)
(3), IR: 1720 cm^{-1}; ^{1}H-NMR: δ = 4.24 (m, J_1 = 4.5, J_2 = 9, J_3 = 13 Hz, 1 H, CHCl), 1.96 (s, 3 H, OAc)
(4), IR: 1720 cm^{-1}; ^{1}H-NMR: δ = 5.48—5.82 (m, 2 H, CH=CH), 1.98 (s, 3 H, OAc)
(5), IR: 1730 cm^{-1}; ^{1}H-NMR: δ = 4.04 (d, t, J_1 = J_2 = 4.5, J_3 = 9 Hz, 1 H, CHCl), 1.98 (s, 3 H, OAc)
(7), ^{1}H-NMR: δ = 4.05 (d, t, J_1 = J_2 = 4.5, J_3 = 9 Hz, 1 H, CHCl)

The reaction of *(1)* reveals the paramount importance of the reactivity of the C—Pd bond. In the reaction of *(1)* with $PdCl_2(PhCN)_2$ in benzene we were able to isolate the σ-π complex *(9)* by simple filtration and oxidatively cyclize it to the products *(2)*—*(5)*.

From the structure of *(9)* one could expect during the cyclization step a reaction behavior similar to that of the corre-

[**] This work was supported by the Délégation Générale à la Recherche Scientifique et Technique (DGRST: décision d'aide n° 77.7.0755). We are grateful to Hüls, Marl, for supplying the 1,5-cyclooctadiene.

sponding 1-methyl-4-cyclooctenyl derivatives[8]; however the exclusive isolation of *endo* derivative and the absence of diacetates are only difficultly reconcilable with an ionic mechanism. It would appear to us that an intermolecular catalyzed cyclization *via (10)* and *(11)* is possible; this reaction is formally comparable with the transannular amination of *N*-ethoxycarbonyl-8-azabicyclo[5.1.0]oct-3-ene to *N*-ethoxycarbonylnortropidine[9]. There is little likelihood, however, that the carbon bonded to palladium in *(10)*, which is much less nucleophilic than the N-atom in the reference compound[9], is capable of effecting formation of the intermediary complex *(11)*. Rather, *(2)* should be formed *via* a *(cis)* insertion to give *(12)* and oxidative cleavage with $CuCl_2$ with reversal of configuration. That the $CuCl_2$-catalyzed oxidation of the C—Pd bond could be a similar process has only recently been shown on singly deuterated olefins[10].

The bridgehead acetates *(3)—(5)* are formed analogously [*(4)* is formed by β-elimination] but it is still unclear at which stage the Cl is replaced by OAc.

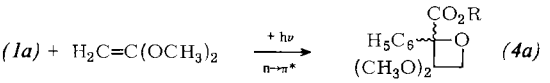
Unusually High Asymmetric Induction in the Photochemical Formation of Oxetanes[**]

By *Hans Gotthardt* and *Wolfgang Lenz*[*]



Asymmetric reactions giving products with high optical purity are of special interest in synthetic chemistry. We report here on the asymmetric induction in the photochemical formation of oxetanes according to *Paterno-Büchi*[1].

The optically active phenylglyoxylic acid (−)-menthyl ester *(1a)*[2] (0.025 M in benzene) combines with 2,3-dimethyl-2-butene (0.060 M) on irradiation[3], presumably *via* the intermediate *(2a)*, to give an oily (23.7:76.3)-mixture of the diastereomeric oxetanecarboxylates *(3a)*[4] in 90% yield as a result of a formal [2+2]-photocycloaddition. We have been able to isolate the main component in pure crystal form by gas chromatographic separation[5]. Subsequent hydrolysis with potassium hydroxide/dicyclohexano[18]crown-6 complex in toluene and esterification of the oxetanecarboxylic acid with diazomethane afforded the pure enantiomer *(3b)*

(a), R = (−)-$C_{10}H_{19}$; *(b)*, R = CH_3

with $[\alpha]_{546}^{20} = -15.13°$. In the same way, the diastereomeric mixture *(3a)* obtained on irradiation affords an enantiomeric mixture *(3b)* having a specific optical rotation of $[\alpha]_{546}^{20} = -8.05°$; in accord with the gas-chromatographically determined value this corresponds to an optical purity of 53%.

In an analogous way the irradiation of *(1a)* in the presence of 1,1-dimethoxyethene affords the diastereomeric oxetanecarboxylates *(4a)*[6] in 60% yield with an optical purity of 37% (GC and ^{1}H-NMR nalysis).

This surprisingly high asymmetric induction in an intermolecular photocycloaddition is unusual; for example, optical purities of up to only 17% are achieved in the thietane series[7].

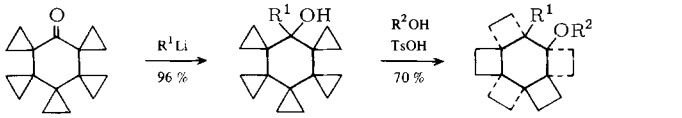
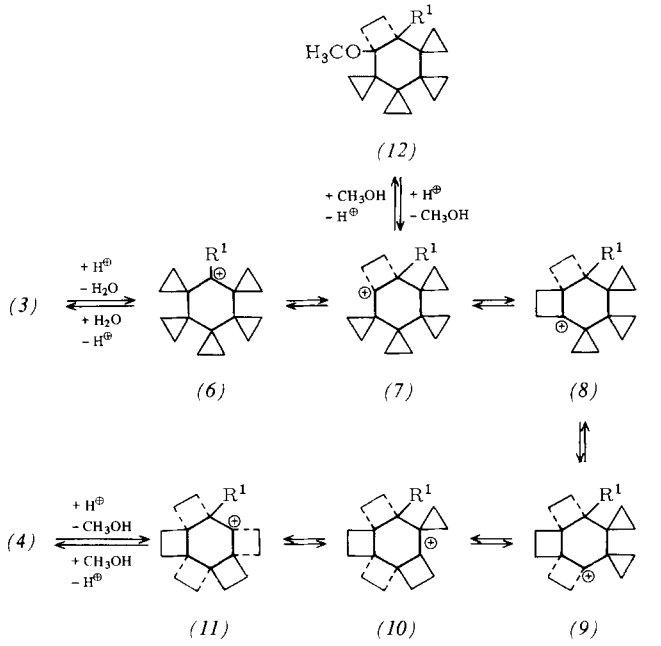
[**] Polyspiranes, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft. As Part 1 and 2: *L. Fitjer*, Angew. Chem. *88*, 803, 804 (1976); Angew. Chem. Int. Ed. Engl. *15*, 762, 763 (1976).



topology and can be shown to exhibit interesting chemical and physicochemical properties. A potentially useful technique for their synthesis is cascade-rearrangement[2], previously unexploited for the construction of repeating partial structures.

We report here on the initiation of a cascade of cyclopropylmethylcyclobutyl rearrangements in 16-methylpentaspiro[2.0.2.0.2.0.2.0.2.1]hexadecan-16-ol *(3)* as a possible key sequence for the synthesis of the [6.4]coronane *(1)*.



(1)

We obtained *(3)*[3] in 96% yield by reaction of pentaspiro[2.0.2.0.2.0.2.0.2.1]hexadecan-16-one *(2)*[4] with methyllithium in ether. On heating to 60 °C in methanolic solution with catalytic amounts of *p*-toluenesulfonic acid, *(3)* rearranges within 24—48 h *via* four gas-chromatographically detectable intermediates[5] into a preparative gas-chromatographically[5] separable solid to which we assign, on the basis of its mode of formation[6] and physical data[7], the structure of a 1-methoxy-2-methylhexacyclo[12.2.0.0^{2,5}.0^{5,8}.0^{8,11}.0^{11,14}]-hexadecane *(4)*. If the rearrangement is carried out in acetone/water (8:2), under otherwise the same conditions, the alcohol *(5)*[8] is obtained.

(2) *(3)*, R^1 = CH$_3$ *(4)*, R^1, R^2 = CH$_3$; *(5)*, R^1 = CH$_3$, R^2 = H

The formation of *(4)* and of *(5)* can be assumed to involve a five-fold cyclopropylmethyl-cyclobutyl rearrangement proceeding *via* the ionic intermediates *(6)*—*(11)*[6,9]. To confirm the postulated reaction course we interrupted the methanolysis of *(3)*, examined the unreacted *(3)* for accompanying rearrangement products, and isolated and characterized the first gas-chromatographically detectable intermediate product[5]. Since the composition of recovered *(3)* proved to be unchanged, and the first gas-chromatographically detectable intermediate was found to have the structure *(12)*[10], it can be assumed that the rearrangement *(3)*→*(4)* proceeds *via (7)* without previous addition of methanol to *(6)*. The remaining three intermediate products[5] could therefore be the methyl ethers of *(8)*, *(9)*, and *(10)*.

The above results would suggest that a more detailed examination of the utility of cascade rearrangement for the synthesis of [*m.n*]coronanes is certainly justified. Thus, by variation of R^1 the annelation of a further ring to *(11)* and hence a synthesis of the [6.4]coronane *(1)* ought to be possible, whereas using *m.n*-oriented fit, other [*m.n*]coronanes should be attainable from the corresponding polyspirane.

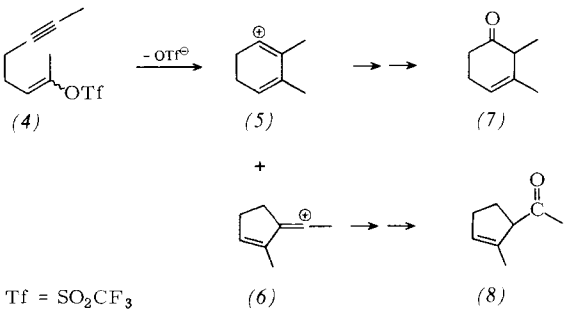
Formation of Phenyl Cations in the Solvolysis of a Dienynyl Trifluoromethanesulfonate[**]

By *Michael Hanack* and *Ulrich Michel*[*]

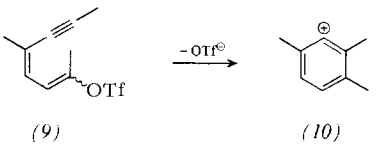
Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday



Phenyl cations *(3)* can not be generated by solvolysis of aryl esters even with use of the super-leaving groups triflate (trifluoromethanesulfonate) and nonaflate (nonafluorobutanesulfonate); in nucleophilic solvents, aryl triflates *(1)* and aryl nonaflates *(2)* react only with cleavage of the O—S bond[1].

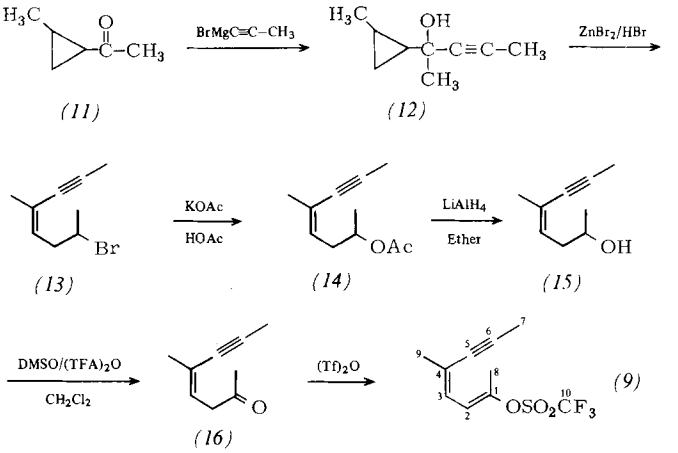
(1), $R_F = CF_3$
(2), $R_F = C_4F_9$ *(3)*

It has been shown theoretically that the phenyl cation is respectively 29 kcal/mol and 4 kcal/mol more stable than the methyl and the vinyl cation, but 11 kcal/mol and 18 kcal/mol less stable than the ethyl and the 1-methylvinyl cation[2]. An experimentally convincing demonstration of the formation of phenyl cations *(3)* has been achieved in the diazotization of aryldiazonium salts[3].



We report here on the first attempt to generate phenyl cations in a completely new way. As we have already found in earlier work, vinyl cations generated by solvolysis can react with participation of a triple bond. Thus the solvolysis of 1-methyl-1-hepten-5-ynyl triflate *(4)* in aqueous trifluoroethanol gave the ketones *(7)* and *(8)* by substitution of the cyclic vinyl cations *(5)* and *(6)*, respectively[4].

(4) *(5)* *(7)* *(6)* *(8)*



Tf = SO_2CF_3

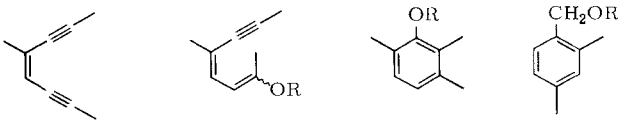
We tried to solvolyze a dienynyl triflate corresponding to *(4)* in order to check whether it cyclizes to aromatic compounds. If this should be the case, a phenyl cation could be postulated as intermediate.

(9) *(10)*

For the dienynyl triflate a *cis*-substituted $C^3{=}C^4$ double bond is essential. As dienyne derivative we chose 1,4-dimethyl-1,3-heptadien-5-ynyl triflate *(9)*, which is readily accessible in a comparatively easy way[5] (see Scheme 1).

(11) *(12)* *(13)* *(14)* *(15)* *(16)* *(9)*

Scheme 1. Synthesis of *(9)* [6]. All intermediates have been unequivocally characterized. DMSO: dimethyl sulfoxide; $(TFA)_2O$: trifluoroacetic anhydride; $(Tf)_2O$: trifluoromethanesulfonic anhydride.



The dienynyl triflate *(9)* was solvolyzed in solvents of various ionic strength and nucleophilicity; the composition of the solvolysis products was determined by capillary gas chromatography, by ^1H- and ^{13}C-NMR spectroscopy of the separated products, and by comparison with authentic samples (Table 1).

Table 1. Solvolysis products of *(9)* in various solvents (relative yields).

Solvent/Buffer	T [°C]	t	*(17)* [%]	*(18)*	[%]	*(19)*	[%]	*(20)*	[%]	Unknown [%]
Anhydrous trifluoroethanol/Na_2CO_3	110	2 d	39	*(18a)*	10	*(19a)*	9	*(20a)*	23	19
Acetone/water/Na_2CO_3	100	3 d	66	*(18b)*	2 [a]	*(19b)*	7	*(20b)*	11	9 [b]
Acetone/water/pyridine	100	3 d	79	*(18b)*	1 [a]	*(19b)*	2	*(20b)*	4	9 [b]
Anhydrous ethanol/Na_2CO_3	100	10 d	70			*(19c)*	1	*(20c)*	9	20

[a] Isolated as ketone *(16)*. [b] In addition 5% of *(15)* is formed.

The products listed in Table 1 are characteristic for the solvolysis of *(9)* with formation of a vinyl cation; this can react *via* elimination to give the diyne *(17)* or by substitution with the solvent to give the ether *(18a)* or *via* the enol *(18b)* to give the ketone *(16)*. The formation of the phenol *(19b)* or of the phenyl ethers *(19a)* and *(19c)* indicates participation of the triple bond during the solvolysis: the phenyl cation *(10)* is

(17) *(18)* *(19)* *(20)*

(a), R = CH_2CF_3; *(b)*, R = H; *(c)*, R = C_2H_5

Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

formed as intermediate; its substitution by solvent leads to *(19a)*, *(19b)*, or *(19c)*. The composition of the product reflects the typical solvent effects for a solvolysis reaction. In trifluoroethanol, a solvent of high ionic strength, the highest portions of cyclization products, in acetone/water and ethanol higher portions of elimination and substitution products are found.

The reaction path leading to formation of the benzyl derivatives *(20)* is still unclear, but there are all the indications of this reaction sequence also involving rearrangements and reactions with participation of the triple bond.

Spontaneous Rearrangement of a Carbene- to a Carbyne Complex: C,Cr Migration of a $Sn(C_6H_5)_3$ Group[1]

By *Ernst Otto Fischer, Helmut Fischer, Ulrich Schubert*, and *Richard B. A. Pardy*[*]

Dedicated to Professor Kurt Issleib on the occasion of his 60th birthday

We recently reported the synthesis of pentacarbonyl[diethylamino(triphenylstannyl)carbene]chromium(0) *(1)*, the first carbene complex in which a main group metal is bound to the carbene carbon[2], by reaction of pentacarbonyl(diethylaminocarbyne)chromium tetrafluoroborate with triphenylstannylpotassium.

We have now found that *(1)* rearranges spontaneously at room temperature, both in the solid state as well as in solution, with loss of CO to give *trans*-tetracarbonyl(diethylaminocarbyne)triphenylstannylchromium *(2)*.

(1) *(2)*

[*] Prof. Dr. E. O. Fischer, Dr. H. Fischer, Dr. U. Schubert, Dr. R. B. A. Pardy [**]
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] Royal Society fellow. Permanent address: Canol House, School Lane, Cutnall Green, Nr. Droitwich (England)

The yellow crystalline product *(2)*, which is stable under nitrogen at room temperature, is readily soluble in polar solvents and moderately soluble in apolar solvents. This new type of SnCr compound *(2)* was identified by elemental analysis, mass spectrometry, vibration spectroscopy, and X-ray structure analysis[3]. The IR spectrum of *(2)* shows four absorptions in the ν_{CO} region: 2045 m, 1982 s, 1963 vs, 1952 s cm^{-1} (in octane); thus, as in the crystal (cf. Fig. 1), there is also marked perturbation of the local C_{4v} symmetry of the metal carbonyl moiety in solution.

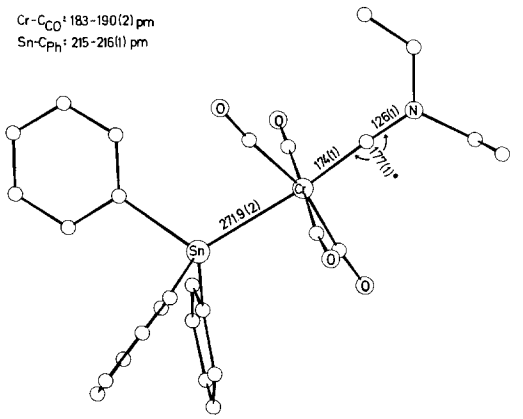

Fig. 1. Molecular structure of the carbyne complex *(2)* in the crystal.

The quantitative formation of *(2)* from *(1)* follows a first order rate law:

$$-d[(1)]/dt = k[(1)]$$

and the rate constants are almost independent of the polarity of the solvent, *e.g.*

$k = 0.85 \times 10^{-3}\ s^{-1}$ in *n*-octane ($\varepsilon_{20\,°C} = 1.95$)
$k = 1.00 \times 10^{-3}\ s^{-1}$ in nitromethane ($\varepsilon_{20\,°C} = 35.7$)

(each at 28.6 °C), thus ruling out a mechanism involving participation of ions.

Corresponding rearrangements have previously been observed in the case of carbene complexes of the type $(CO)_5CrC[N(C_2H_5)_2]X$ in solution, with X = Cl, Br and I, and in substance with X = Br[4], but not with X = F, CN, and NCS. The reaction now discovered by us, namely *(1)*→*(2)*, shows that presence of a lone pair on the migrating heteroatom is not necessary.

The finding that the bond between the carbene carbon atom and the halogen (X = Cl[5], Br[6]) or the tin atom[2] in the corresponding carbene complexes is longer than one would expect would seem to be directly connected with the feasibility of rearrangement to a carbyne complex.

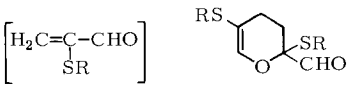
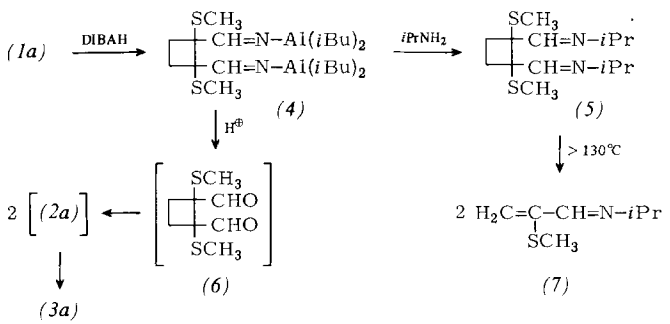
Influence of 1,2-Functionalization with —C≡N, —CH=NR, or —CH=O on the Stability of the Cyclobutane System



By *Karl-Dietrich Gundermann* and *Paul-Josef Hnida*[*]

Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday

1,2-Bis(alkylthio)- and 1,2-bis(arylthio)-1,2-cyclobutanedicarbonitriles *(1)* are readily formed by spontaneous dimerization of the corresponding acrylonitriles[1]. The dimerization is an equilibrium reaction; at 100 °C about 50% of the monomer is present[1b]. In order to check the influence of substituents on the stability of the cyclobutane system we have already attempted the synthesis of α-(alkylthio)acroleins *(2)* as starting substances for 1,2-dicarbaldehydes of type *(6)* corresponding to *(1)* on a previous occasion. All these attempts, however, led to the Diels-Alder dimers *(3)*[1a,2] instead of *(2)* [or *(6)*].



(1)

(2) *(3)*

The partial reduction of dinitriles *(1)* with diisobutylaluminum hydride (DIBAH) to *(4)* followed by hydrolysis ought to afford access to *(6)*, for reactions of this type have already been carried out successfully below 0 °C.

We have now found that reaction of *(1a)* with DIBAH in toluene at −70 °C leads to the aluminum compound *(4)*, which on careful treatment with isopropylamine affords the double Schiff base *(5)* in *ca.* 80% yield. Proof of the intact cyclobutane ring in *(5)* is provided by the AA'BB' signal of the —CH_2CH_2— group in the ^{1}H-NMR spectrum. *(5)* converts into the monomer *(7)* only above 130 °C, and apparently irreversibly.

(a), R = CH_3

On the other hand, acid hydrolysis of the product *(4)* obtained from *(1a)* and DIBAH leads, *inter alia*, to the dihydropyran derivative *(3a)* in *ca.* 30% yield. We conclude therefore that 1,2-bis(alkylthio)-1,2-cyclobutanecarbaldehydes of type *(6)* are apparently thermodynamically very unstable and readily form the "stable" dimers of type *(3)*—probably *via* the monomers *(2)*.

Organisch-chemisches Institut der Technischen Universität Clausthal
Leibnizstrasse 6, D-3392 Clausthal-Zellerfeld (Germany)

Experimental

Synthesis of *(5)*: A stirred solution of *cis,trans-(1a)*[3] (45.3 g) in toluene (1 l) under N_2 is treated within 45—60 min with 400 ml of a 20% solution of DIBAH in toluene. Stirring is continued for 2 h at −75 °C before adding 300 ml of anhydrous isopropylamine to the mixture. After a further 60 h at −75 °C 26 g of water is added dropwise and the temperature not allowed to exceed 20 °C. After removal of solvent *in vacuo* the residue is extracted with ether. Evaporation of the extract to dryness affords 77—81% *(5)*, m.p. 65 °C (from ethanol); IR (KBr): 1640 cm^{-1} (ν(C=N)); ^{1}H-NMR ($CDCl_3$): δ = 2.2 (mc, —CH_2CH_2—).

(3a) from *(1a)*: A 20% solution of DIBAH in toluene (90 ml) is added dropwise at −30 °C under N_2 to a stirred solution of *cis,trans-(1a)*[3] (10.2 g) in anhydrous toluene (250 ml). After 80 minutes' stirring, 400 ml of 5% sulfuric acid is added, the organic phase separated off, and the aqueous phase extracted several times with ether. The organic phase and the combined ether phases are washed with $NaHCO_3$ solution, with water, and then dried over sodium sulfate and fractionally distilled; yield *ca.* 3.0 g *(3a)*, b.p. 109 °C/0.6 torr; semicarbazone 149 °C (from ethyl acetate; IR (film): 1620 (ν(C=C)), 1730 cm^{-1} (ν(C=O)); ^{1}H-NMR ($CDCl_3$): δ = 6.54 (t, —CH—).

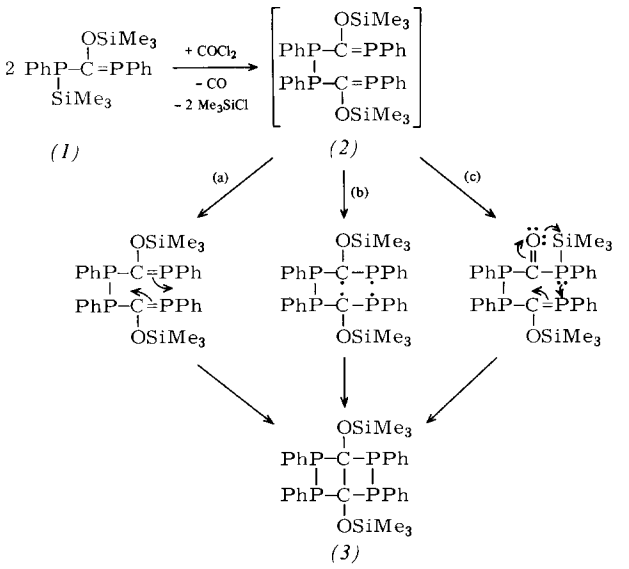
The First 2,3,5,6-Tetraphosphabicyclo[2.2.0]hexane[1]

By *Rolf Appel, Volker Barth, Mechthild Halstenberg, Gottfried Huttner*, and *Joachim von Seyerl*[*]



Dedicated to Professor Kurt Issleib on the occasion of his 60th birthday

We recently reported on the stepwise course of the reaction of phosgene with phenylbis(trimethylsilyl)phosphane in which the (phosphinomethylene)phosphane *(1)* and a secondary product of unknown structure but having the composition $[(PhP)_2(COSiMe_3)]_2$ are formed[1]. ^{31}P-NMR data[2] are not consistent with the assumption that *(1)* undergoes further reaction with phosgene with cleavage of a silyl group and P—P coupling to give *(2)*: Although the spectrum shows a characteristic fine structure for an AA'BB' spin system, the signal at δ = 164 for phosphorus of coordination 2 has disappeared.

By X-ray structure analysis[3] we have been able to identify this secondary product, which melts at 148—150 °C, as 1,4-bis(trimethylsiloxy)-2,3,5,6-tetraphenyl-2,3,5,6-tetraphosphabicyclo[2.2.0]hexane *(3)*. The non-equivalence of the AA' and BB' groups[2]—not apparent from formula *(3)*—is caused by strong twisting of the molecule: A molecular model or stereoscopic viewing of Figure 1 shows much more clearly than any two-dimensional representation of the molecule that the phosphorus atoms P1 and P1' have a different

Spectroscopic evidence for the intermediary existence of *(2)* is still lacking. The postulated reaction course—spontaneous intramolecular [2+2]-cycloaddition of *(2)* as pericyclic (a) free-radical (b) or multistep process (c)—is supported by isolation of an intermediate analogous to *(2)* in the reaction of phenylbis(trimethylsilyl)phosphane with phenyl isocyanide dichloride, an aza analog of phosgene[4] and by an independent synthesis of *(3)* from *(1)* and hexachloroethane.

In analogy to the formation of tetraorganyldiphosphanes from trimethylsilyl-substituted organylphosphanes and C_2Cl_6[5], it is assumed that the intermediate *(4)* reacts with *(1)* with P P-coupling.

The First 1,3,4,6-Tetraphospha-1,5-hexadiene, a Molecule with Fluxional Bonds (Identical Tetraphospha Cope Rearrangement) and Configurational Isomerism[1]

By *Rolf Appel, Volker Barth, Fritz Knoll*, and *Ingo Ruppert*[*]

Dedicated to Professor Kurt Issleib on the occasion of his 60th birthday

In continuation of our investigations on the reactions of silylphosphanes with halogen-carbon compounds we have now examined the reaction of isocyanide dihalides such as *(2)*, as aza analogs of phosgene, with phenylbis(trimethylsilyl)phosphane *(1)*. By replacing the oxygen by the imino function we had anticipated a stabilization and hence possible isolation of the postulated reactive intermediates *(3)* and *(5)*, which could not be detected in the reaction with phosgene[2].

As expected *(1)* reacts with *(2)* in *n*-pentane in the molar ratio 2:1 *via* double condensation and a 1,3 silyl shift to give the (phosphinomethylene)phosphane *(4)*, which could be

[*] Prof. Dr. R. Appel, Dipl.-Chem. V. Barth, Dr. F. Knoll, Dr. I. Ruppert Anorganisch-chemisches Institut der Universität Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (Germany)

identified by means of its distinctive AX-type ^{31}P-NMR spectrum; however, it has not yet been isolated in analytically pure form. On NMR investigation of the reaction in benzene an additional ^{31}P-signal appeared in the spectrum very close to the X-doublet of *(4)* at $\delta = 216$, which gradually disappeared again and which we assign to the intermediate *(3)*.

Further reaction with isocyanide dichloride *(2)* leads to elimination of phenyl isocyanide and precipitation of a yellow solid (m.p. 135 °C). Correct elemental analysis, cryoscopic molecular weight determination, and the sharp AA'XX'-^{31}P$\{^1$H$\}$ spectrum of *(5a)* at 30 °C shown in Figure 1—especially the PP coupling parameters and the characteristic downfield shift of the methylenephosphane (X) component (Table 1)—confirm the constitution of a tetraphosphahexadiene *(5)*.

Table 1. ^{31}P$\{^1$H$\}$-NMR data of the methylenephosphanes (Varian FT80A, 32.4 MHz, H_3PO_4 ext.).

(4) (C_6D_6): $\delta = -39.0$ [d, $^2J(P^xP^a) = 78.9$ Hz, P^a], 213.8 [d, $^2J(P^aP^x) = 78.9$ Hz, P^x]

(5a) (CD_2Cl_2, room temp.): $\delta = -12.3$ [P^a], 258.0 [P^x]; AA'XX' spectrum [7] with $^1J(P^aP^{a'}) = 112.5$, $^2J(P^aP^x) = 157.4$, $^3J(P^aP^{x'}) = 24.6$, $^5J(P^xP^{x'}) = 38.6$ Hz (notation: see scheme)

(5b) (CD_2Cl_2, -10 °C coalescence temp.): $\delta = 115.7$ (maximum of the exchange peaks); (CD_2Cl_2, -70 °C): $\delta = -3.2$ [P^a], 234.6 [P^x]; AA'XX' spectrum [7] with $^1J(P^aP^{a'}) = 150.9$, $^2J(P^aP^x) = 136.6$, $^3J(P^aP^{x'}) = 56.4$, $^5J(P^xP^{x'}) = 0.0$ Hz

Since analysis showed *(5)* to be homogeneous the additional exchange signal observed at room temperature must be assigned to a species *(5b)* having the same composition. Its individualization at -70 °C to a further AA'XX' multiplet pattern (Fig. 1) shows that *(5b)* is a diastereomeric tetraphosphahexadiene. Since its diphosphane (A)- and methylenephosphane (X)-signal groupings coalesce centrally and reversibly as a function of the recording temperature, we assume that *(5b)* experiences an identical rearrangement—independently of *(5a)*[3].

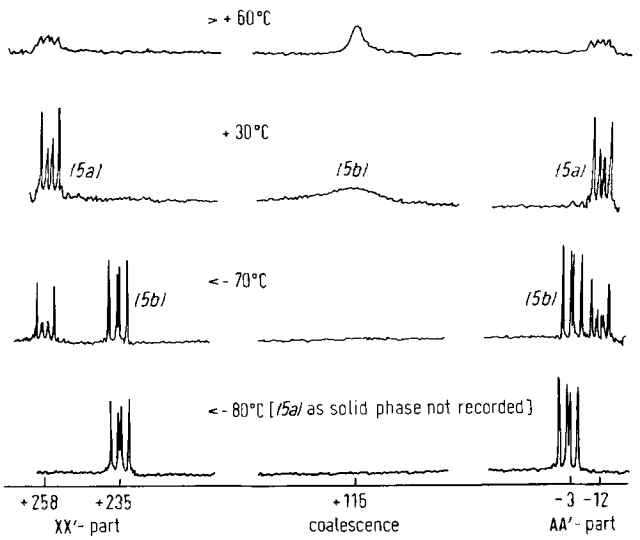

Fig. 1. Temperature dependent ^{31}P$\{^1$H$\}$-NMR spectrum of *(5)*; coupling parameters, see Table 1.

The equilibrium (d) would represent the first sigmatropic [3,3]-shift with P—P bond rupture, P—P linkage and migration of phosphorus-carbon p_π—p_π bonds; thus it would fully correspond to the degenerate Cope rearrangement in the carba-analogous 1,5-hexadiene system[4].

Diphosphanes with the substitution pattern $(XYP)_2$ are usually obtained as a 1:1 mixture of the *meso* form and racemate, which are distinguishable ^{31}P-NMR spectroscopically[5]. The oxidative coupling step *(4)*→*(5)* [eq. (c)] also leads to a statistically equimolar mixture of the diastereomers *(5a)* and *(5b)*. *(5a)* slowly crystallizes out below -80 °C (cf. Fig. 1) and can be separated by low-temperature filtration. Both the filtrate enriched in *(5b)*, and *(5a)* redissolved below -80 °C, rapidly equilibrate again above -70 °C to the racemate/*meso* form mixture [Equilibrium (e)]. Attempts with chiral shift reagents to identify *(5a)* as *meso* form and *(5b)* as racemate have proven unsuccessful. However, the rapid equilibration (d) of *(5b)* at room temperature, a temperature at which *(5a)* remains unchanged, would suggest—in analogy to the stereochemical requirements of the Cope rearrangement—a reaction starting from the conformation *(5b/5b')*, which is realizable only in the racemate (see scheme). With the same preferred *trans* location of the lone pairs the required proximity of the reactive P—C centers is not reached in the *meso* form. Consequently, this diastereomer only shows reversible line-broadening at a much higher temperature (Fig. 1, 60 °C); on raising the temperature further this is accompanied by an irreversible decomposition.

This finding would indicate a further more energy-demanding rearrangement process, *e.g.* following 180° rotation about the P—P axis in *(5a)*[6]. An unequivocal assignment of the diastereomers and simultaneous elucidation of the arrangement of the (*E,Z*)-substituents at the C—P bond is expected from an X-ray structure analysis of a crystal fraction which, according to low-temperature ^{31}P-NMR analysis, contains only the *(5a)*-form.

The marked analogy between the reaction of methylene*phosphanes* and corresponding alkene systems would suggest that the P—C bond does not have the known ylide character of methylene*phosphoranes* but in this connection is rather to be compared with the olefinic double bond.

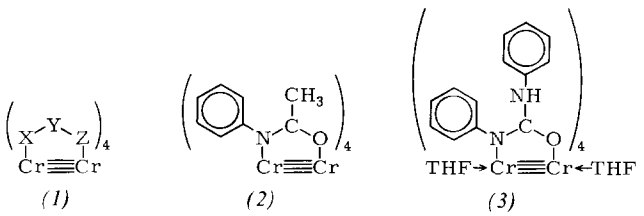
Tetracarbanilanilidodichromium(II): A Clue to the Understanding of the CrCr Quadruple Bond[**]



By *F. Albert Cotton, William H. Ilsley,* and *Wolfgang Kaim*[*]

Numerous complexes of the general type *(1)* have been prepared and investigated crystallographically since the

[*] Prof. Dr. F. A. Cotton, Dr. W. H. Ilsley, Dr. W. Kaim

structural characterization of a CrCr quadruple bond in $Cr_2(O_2CCH_3)_4(H_2O)_2$[1]. The results obtained so far allow a strict classification of the compounds *(1)* into two distinctly different groups: Complexes with four η^2-carboxylato ligands, $Cr_2(O_2CR)_4$, have Cr–Cr-bond lengths ranging from 2.283(2) Å to 2.541(1) Å[2]. The metal-metal distance is somewhat shorter in $[Cr_2(CO_3)_4(H_2O)_2]^{4-}$, *viz.* 2.214(1) Å[2c]. *All* compounds of this kind either contain strongly coordinated axial ligands, or they display a chain structure with short *inter*molecular Cr···O distances[2].—All the other complexes with the general structure *(1)* contain "supershort" (<1.90 Å) CrCr bonds; the bridge ligand type varies from arene[3] and heteroarene[4] to ylide[5] and carboxamide anions[6]. Molecules of this type do not exhibit any axial coordination.

(1) *(2)* *(3)*

The short Cr–Cr distance of 1.873(4) Å in tetraacetanilidodichromium *(2)*[6] has prompted the hypothesis, that the presence or absence of axial ligands *alone* might be responsible for the enormous variability of the CrCr bond length in Cr_2^{4+} complexes[6]. We have, therefore, increased our efforts to prepare and investigate crystallographically compounds with ligands similar to carboxylates.

We report here on the synthesis and X-ray structure analysis of tetracarbanilanilidodichromium(II), which is formed in the reaction of carbanilanilidolithium with dichromium tetracetate in tetrahydrofuran (THF). Crystals were obtained by diffusion (THF/*n*-hexane). Figure 1 shows the molecular structure of the $Cr_2[PhNC(NHPh)O]_4(THF)_2$ unit *(3)*[7].

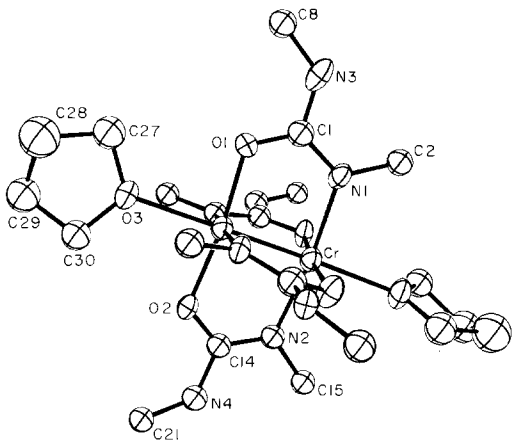

Fig. 1. Structure of $Cr_2[PhNC(NHPh)O]_4 \cdot 2THF$ *(3)* in the crystal. For clarity only the carbon of attachment of each phenyl group is shown.

The crucial difference between *(3)* and the otherwise very similar compound *(2)* lies in the influence of two relatively tightly bound THF molecules in the axial positions of *(3)*; the Cr···O'(THF) distance is 2.350(5) Å. This combination of coordinated solvent molecules increases the Cr–Cr-distance by 0.37 Å, from 1.873(4) Å in *(2)* to 2.246(2) Å in *(3)*.

Other important bond lengths and angles are: Cr–O 1.993(6), Cr–N 2.093(7) Å; Cr–Cr–O'(THF) 178.2(2), Cr–Cr–O 93.8(2), Cr–Cr–N 86.5(2)°. Comparison with *(2)*[6] indicates weaker bonding to the bridging ligands in *(3)*.

The enormous lengthening of the CrCr quadruple bond in *(3)* with respect to *(2)*, despite an essentially similar ligand type, shows that axial coordination is, (or, at least, can be) the major determining factor for the length (and strength) of the Cr–Cr bond. The somewhat shorter distance in *(3)* compared to the values for typical carboxylates ($d_{CrCr} \approx 2.35$ Å)[2] may be caused by the stronger basicity of the carboxanilide anion. Further investigations as well as theoretical studies[8] are necessary in order to distinguish the effects of axial and bridging ligands, and thus to understand the mechanisms of the variability of the chromium-chromium quadruple bond.

Metalated 2-Alkynyl- and 1,2-Alkadienyl 2-Tetrahydropyranyl Ethers: Versatile Building Blocks for Furan Syntheses[**]

By *Manfred Stähle* and *Manfred Schlosser*[*]

tert-Butyllithium metalates lithium 4-(2-tetrahydropyranyloxy)-2-butynolate *(1)* quantitatively to give the allenyllithium compound *(2)*. No side-reactions take place: neither the generally possible[1] hydrogen/metal exchange at the alcoholate group, nor the equally well known addition[2] of the organometallic compound to the triple bond is observed. The velocity and the uniform outcome of the reaction underlines once again the activating influence of an acetal group[3,4]. Methanol protonates *(2)* to afford the 4-(2-tetrahydropyranyloxy)-2,3-butadienolate (*(3)*: R = H); reaction with hexyl iodide or benzyl chloride yields the 2-alkylated derivatives (*(3)*: R = C_6H_{13}, $CH_2C_6H_5$). Further treatment with *tert*-butyllithium generates new allenyllithium compounds *(4)* which react with alkyl halides to give 4-alkylated 4-(2-tetrahydropyranyloxy)-2,3-butadienolates (*(5)*: R = C_6H_{13}; R′ = CH_3, $CH_2CH{=}CHCH_3$). The allenyl ethers *(3)* and *(5)* may be hydrolyzed with dilute acids and cyclized—presumably *via* a 2-(2-tetrapyranyloxy)-2,5-dihydrofuran *(6)* intermediate—to produce mono- and dialkylated furans (*(7a)*: R = C_6H_{13}, R′ = H, 67%; *(7b)*: R = $CH_2C_6H_5$, R′ = H, 39%;

(7c): $R = C_6H_{13}$, $R' = CH_3$, 55%; *(7d)*: $R = C_6H_{13}$, $R' = CH_2CH{=}CHCH_3$, 15%). If desired, the alcoholates *(3)* and *(5)* may be neutralized and the alcohols, though fairly labile, isolated. More advantageously, however, the entire multistep reaction sequence, is performed as a one-pot reaction, starting off with the preparation of *(1)* from 2-propynyl(2-tetrahydropyranyl) ether, butyllithium, and formaldehyde.

In the same way it was possible to convert the singly and doubly branched tetrahydropyranyloxybutynolates *(8)* [$R'' = C_6H_5$, $CH{=}C(CH_3)_2$, CH_3, C_3H_7, (Z)-$(CH_3){=}CHCH_3$] and *(9)* [$R' = CH_3$; $R'' = C_3H_7$, C_6H_{13}] into 2-mono-, and 2,3- and 2,5-di- as well as 2,3,5-trisubstituted furans *(10)*—*(13)*. The structure and purity of all the furans are confirmed by NMR spectra and elemental analysis[8].

We are aware of only one example related to this new synthetic access to furans: After metalation, 2-octynyl 2-tetrahydropyranyl ether reacts with benzaldehyde to yield a product mixture, which upon treatment with acid gives rise to some 3-pentyl-2-phenylfuran[5].

Structure of the Primary Adduct of a Phosphorus Ylide and Fluorenone

By *Hans Jürgen Bestmann, Kurt Roth, Eberhard Wilhelm, Reinhild Böhme*, and *Hans Burzlaff*[*]

From our investigations on the mechanism of the Wittig reaction[1] it follows that reaction of aldehydes *(1)* with phosphorus ylides *(2)* affords oxaphosphetanes *(3)* in which the substituents R^1 and R^2 on the four-membered ring are arranged in the *Z* position and, according to the rules on the entry and exit of nucleophiles in the mutual interconversion of tetra- and pentacoordinated phosphorus, the oxygen atom occupies an apical position[2]. Accordingly, decomposition into phosphane oxide and olefin requires a ligand rearrange-

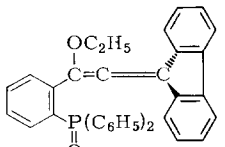
ment process in the trigonal-bipyramidal structure *(3)*, which brings the rupturing C—P bond into the apical position. We postulate that bond rupture occurs during or just after formation of *(4)*; a betaine *(5)* is formed.

The stereochemistry of the olefin being formed is determined by the electronic character of the residue R^2 on the original ylide and of the stationary ligands R^3. If R^2 is an electron donor and the ligands R^3 are phenyl groups a very rapid elimination from *(5)* of the triphenylphosphane oxide *(6)*, $R = C_6H_5$, takes place and *Z*-olefins *(9)* are obtained with high stereoselectivity. If R^2 is an electron acceptor the lifetime of *(5)* is increased. Rotation is possible, resulting in the thermodynamically more stable conformation *(7)*, from which the *E*-olefins *(8)* are formed with cleavage of *(6)*, $R = C_6H_5$. Substituents R^3 with donor character (*e.g.* alkyl or cycloalkyl groups) retard the phosphane oxide cleavage, and the probability of the conformational change *(5)*→*(7)* becomes greater. As a result, a sharp increase in *E*-olefin formation is observed on going from $R^3 = C_6H_5$ to R^3 = alkyl or cycloalkyl[1].



Reaction of the cyclic phosphaallene ylide *(10)*[3] with carbonyl compounds affords stable crystalline primary products, to which, on the basis of the mechanistic postulates discussed above, we assign a trigonal-bipyramidal structure *(3)*[3]. The X-ray structure analysis[4] of the adduct obtained from fluorenone and *(10)* now confirms this assignment.

(10)

(11)

(12)

The atoms bound directly to phosphorus in *(11)* form a distorted trigonal bipyramid (Fig. 1), in which the sum of the equatorial angles is 358.3°. P, O1, C1 and C2 lie in a plane at the corners of a distorted rhombus. The five-membered ring formed by the atoms P, C2, C3, C4, and C9 is likewise planar. The P—O bond, having a length of 183.5 pm, is markedly shorter than the corresponding bond in the adduct obtained from hexaphenylcarbodiphosphorane and hexafluoroacetone (201 pm)[5].

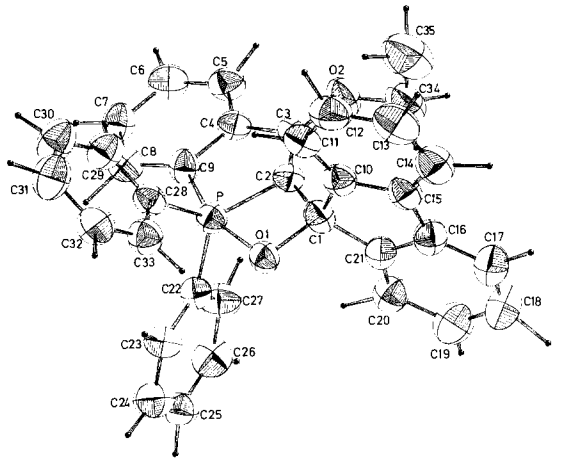


Fig. 1. ORTEP diagram of the molecular structure of *(11)* in the crystal.

Having now confirmed the structure of *(11)*, we regard the finding that *(11)* on the one hand is converted into the allene *(12)* and on the other splits off fluorenone only on heating above the melting point[3] as indirect proof for the ligand rearrangement process *(3)*→*(4)* in the course of the Wittig reaction; the rigidity of the molecule precludes such a rearrangement in the case of *(11)*.

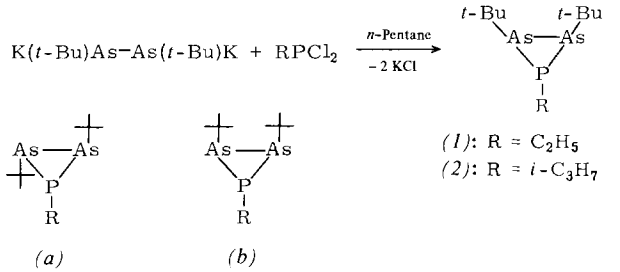
Phosphadiarsiranes[**]

By *Marianne Baudler* and *Dietrich Habermann*[*]

Dedicated to Professor Kurt Issleib on the occasion of his 60th birthday



Monocyclic three-membered ring compounds containing phosphorus are presently the subject of numerous studies in preparative phosphorus chemistry[1,2]. Cyclotriphosphanes $(RP)_3$[3], diphosphiranes $(RP)_2CR'_2$[4], diphosphasiliranes $(RP)_2SiR'_2$[5] and diphosphaboriranes $(RP)_2BNR'_2$[6] have already been synthesized and isolated. We now report on the first phosphadiarsiranes $(RAs)_2PR'$—thus demonstrating that three-membered heterocycles containing elements of the 4th period can also be stable enough for preparative isolation.

In the [2 + 1]-cyclocondensation of a 1,2-dialkali metal 1,2-diorganyldiarsenide with a dihaloorganylphosphane an oligomerization of the initially formed phosphadiarsirane to more stable larger ring systems was to be reckoned with. Such rearrangement reactions are favored by nucleophilic reaction partners, polar solvents and elevated reaction temperatures[3-6]. Yet metastable primary products can very often be kinetically stabilized by bulky substituents. With these points in mind 1,2-dipotassium 1,2-di-*tert*-butyldiarsenide was allowed to react with ethyl- and isopropyldichlorophosphane under mild conditions in a heterogeneous reaction.

The main products were found by ^{31}P-NMR spectroscopy to be the phosphadiarsiranes *(1)* and *(2)*, respectively. Both compounds were each present as a mixture of the diastereomers *(a)* and *(b)*, of which the isomer *(a)* with *trans*-oriented *tert*-butyl groups is the most stable. Some other compounds formed included the four-membered heterocycles $(t\text{-BuAs})_3PR$ [*(3)*: $R = C_2H_5$ and *(4)*: $R = i\text{-}C_3H_7$],

(t-BuAs)$_2$(PR)$_2$ [*(5)* and *(6)*], [(t-BuAs)(PR)]$_2$ [*(7)* and *(8)*], and t-BuAs(PR)$_3$ [*(9)* and *(10)*], respectively, in each of which the substituents of neighboring ring atoms are *trans* oriented (cf. Table 1). In addition small amounts of the diphosphaarsiranes t-BuAs(PR)$_2$[7] were detectable. In a later stage of the reaction increasing amounts of five- and six-membered ring compounds are also formed.

[a] All measurements in *n*-pentane; δ-values with negative sign for upfield shift.

Whereas the phosphadiarsirane *(1)* oligomerizes at a considerable rate even at −78 °C and cannot be isolated without decomposition, compound *(2)* is essentially thermally more stable owing to the effective shielding of the three-membered ring by the isopropyl group on the phosphorus. In this case the [2+1]-cyclocondensation can be carried out at 0 °C; the product *(2)* is obtainable as the pure isomer *(a)* by molecular distillation and low-temperature crystallization.

At room temperature *(2)* is a colorless, air-sensitive liquid which turns pale yellow on prolonged exposure to light. The composition of the compound is confirmed by elemental analysis (As, P, C, H) and its mass spectrum (field ionization, M^+: $m/e = 338$). An undecoupled ^{31}P-NMR spectrum shows an unresolved multiplet at $\delta = -81$ with a halfwidth of *ca.* 50 Hz, so no P—H bonds can be present. Strong ring-vibration bands are observed between 400 and 200 cm^{-1} in the IR and Raman spectra. The ^{1}H{^{31}P}-NMR spectrum confirms the assignment of the isomers.

Procedure

(2): A solution of freshly distilled dichloro(isopropyl)phosphane (2.56 g, 17.7 mmol, substoichiometric amount) in *n*-pentane (100 ml) is added dropwise within 5 h to a vigorously stirred suspension of 1,2-dipotassium 1,2-di-*tert*-butyldiarsenide[8] (10.7 g, 31 mmol) in pentane (100 ml) at 0 °C. Stirring is continued for a further 1 h; thereafter no more i-PrPCl$_2$ can be detected by ^{31}P-NMR spectroscopy, and *ca.* 40% of the phosphorus content is present as *(2)*. The precipitate is filtered off rapidly in the cold and washed twice with 20 ml of pentane. The combined filtrate and washings are evaporated down at 0 °C (oil-pump vacuum) until all solvent has been removed. The residue, an orange-yellow oil and a light yellow solid, is distilled at 10^{-4} torr over a sloping recovery bend (oil-bath preheated to 110 °C, receiver cooled with liquid nitrogen). The fraction distilling over up to a bath temperature of 140 °C is redistilled in the same way. On dissolution of the pale yellow, oily crude product (1.5 g) in *n*-pentane (1.5 ml) and cooling to −78 °C white crystals are obtained; these are recrystallized in the same way three times. Yield 0.8 g (13.4%) *(2)*; purity 99.8% (^{31}P-NMR).

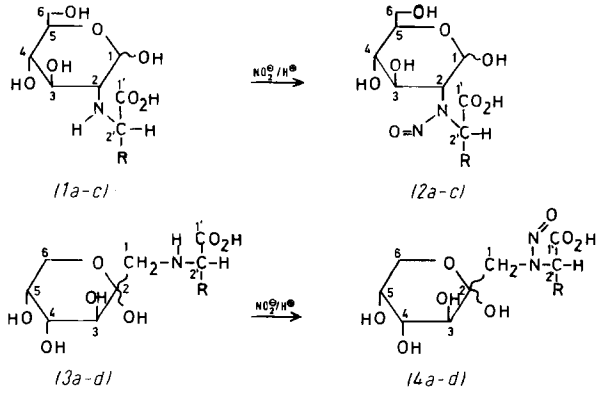
N-Nitroso Sugar Amino Acids[**]

By *Kurt Heyns, Siyka Röper, Harald Röper*, and *Bernd Meyer*[*]

Aldoses and ketoses react with amino acids to give sugar amino acids of type *(1)* and *(3)*, respectively; these are key substances of non-enzymating browning (Maillard reaction)[1].

We have now succeeded in preparing the *N*-nitroso glucose amino acids *(2a—c)* and *N*-nitroso fructose amino acids *(4a—d)* by reaction of the glucose amino acids *(1a—c)* and fructose amino acids *(3a—d)* with sodium nitrite (pH = 3, 0 °C) and in characterizing them (see Table 1).

The surprisingly easy and quantitative nitrosation of the substrates *(1)* and *(2)* poses several questions: what role does this reaction play on heating "natural" nitrite-containing Maillard systems, *e.g.* cured meat products? To what extent and under which conditions are *N*-nitroso sugar amino acids formed on heating such systems, and do these compounds exhibit mutagenic and/or carcinogenic action. Could the ingestion of *N*-nitroso compounds with food or their endogenic formation from sugar amino acids and nitrite in the stomach lead to cancer?



The *N*-nitroso derivative *(2a)*, like the parent compound *(1a)*, shows no mutagenic action in the Ames test; *(3b)* and *(4b)* are still under investigation[3].

N-nitrosation is very clearly recognizable in the ^{13}C-NMR spectrum. In contrast with the spectrum of *(1a)*, that of *(2a)* shows downfield shifts of $\Delta\delta = 9.4$ for C-2, ≈ 3.7 for C-3, 3.3 for C-1 and 1.5 for C-2′[2,4].

(1a-c) (2a-c) (3a-d) (4a-d)

spectrometric differentiation of *N*-nitroso fructose amino acids *(4)* from the *N*-nitroso glucose amino acids *(2)*.

General procedure

1 mmol of the D-glucose amino acids *(1a—c)*[7a,b] or D-fructose amino acids *(3a—d)*[7b,c] was dissolved in 5 ml water. The stirred solution was adjusted to pH = 3 with dilute HCl, cooled with ice, and treated with a solution of $NaNO_2$ (1.5 mmol) in H_2O (2 ml). Thin-layer chromatography after 6 min to 5 h showed that quantitative reaction to *(2a—c)* or *(4a—d)*, respectively, had taken place (Al foil, silica gel 60/F_{254} (Merck), solvent: $CHCl_3$/MeOH/conc. NH_4OH = 3/3/1 (v/v/v), detection of the substances by UV fluorescence,

Table 1. Selected data of the sugar amino acids of type *(1)* and *(3)* and of the *N*-nitroso-sugar amino acids of type *(2)* and *(4)* [2]. All products of type *(3)* and *(4)* gave correct elemental analyses.

[a] 270 MHz, *c* = 3—7% in D_2O, internal standard 0.5% acetone (δ = 2.09). [b] KBr pellet 1%. [c] The *syn*- and *anti*-forms are also detectable by NMR spectroscopy. [d] EI spectra of the trimethylsilyl derivatives. [e] The anomers were assigned on the basis of the chemical shift of H-4.

A large downfield shift of Δδ = 1.3—1.5 is observed for H-2 in the ^{1}H-NMR spectra of the *N*-nitroso-D-glucose amino acids *(2a—c)* compared with the spectra of *(1a—c)*. In the case of H-2′ the shift is somewhat smaller. Comparable circumstances are found in the case of the *N*-nitroso-D-fructose amino acids *(4a—d)* with Δδ ≈ 1.1 for H-1A and H-1B, and 0.6—0.8 for H-2′. The remaining protons of the products *(2a—c)* and *(4a—d)* show only slight shifts in comparison with those of the substrates.

As expected, in acidic media the *N*-nitroso derivatives anomerize more rapidly than the substrates, so that anomeric mixtures are present in all cases after nitrosation.

EI mass spectra[5] of the pentakis(trimethylsilyl) derivatives of the substrates and products have been recorded. The EI mass spectra of persilylated *(1a—c)* and *(3a—d)* show molecular ions with ≈2% and ions $M-15(CH_3)$ with ≈8% relative intensity. The EI mass spectra of the persilylated products *(2a—c)* show fragments in the upper mass region at $M-15(CH_3)$ and $M-30(NO)$; in the case of the persilylated products *(4a—d)* only the fragment at $M-15(CH_3)$ is found in this region (Table 1). Cleavage of $H_2CN(NO)CHRCOOSiMe_3$ radicals from the molecular ions leads to the appearance of characteristic sugar fragments in the spectra at *m/e* = 437 [35.6—17.9%][6]. This ion can be used for the mass Griess reagent[8] and color reaction with naphthoresorcinol solution. The products have R_f values about 0.1—0.2 greater than the substrates). The reaction solutions were evaporated to dryness *in vacuo* at 30 °C and extracted with anhydrous pyridine. After removal of pyridine the pure *N*-nitroso compounds are obtained as syrups (see Table 1).

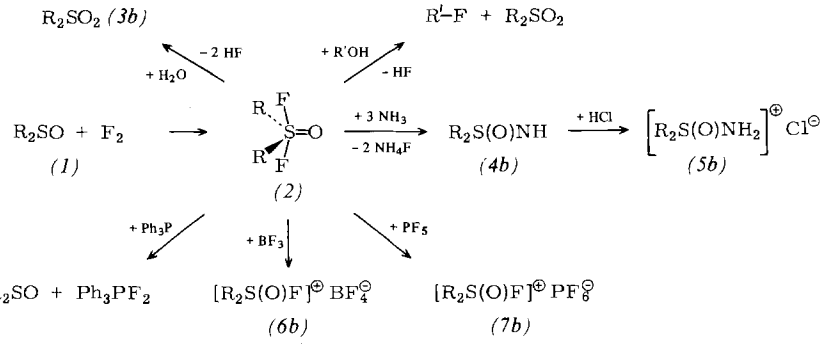
Diarylsulfur(VI) Oxide Difluoride by Direct Fluorination of Sulfoxides[**]

By *Ingo Ruppert*[*]

Dedicated to Professor Kurt Issleib on the occasion of his 60th birthday

All attempts to directly halogenate diorganyl sulfoxides have so far failed. Even on reaction with XeF_2 no diorganosulfur(VI) oxide fluorides could be trapped[1]. Fluorine, on the other hand, adds the diaryl sulfoxides *(1a, b)* smoothly under the gentle conditions of liquid phase fluorination (dilution of substrate and fluorine). The difluorides *(2a, b)* that are formed can be filtered off in high yields; their constitution is confirmed by elemental analysis and by mass[2] and NMR spectroscopic findings (Table 1).



Thus, for the first time we have ready access to such aryl derivatives of sulfur oxide fluoride, which cannot be obtained by arylation of SOF_4. The halogenation with fluorine has the advantage—apart from the favorable price of the reagent—that *(2a, b)* are formed without difficultly separable coupling products.

Competing CH-substitution or cleavage of the aryl moiety could be largely suppressed. The ^{19}F-NMR spectrum of the concentrated $CFCl_3$ filtrate, however, showed besides further *(2a)* also traces of the cleavage products $PhS(O)F$[3] and $PhS(O)F_3$; the latter cleavage product could be identified by its significant AB_2 coupling pattern[4] of chemically nonequivalent fluorine atoms, although comparable monoorgano-derivatives of SOF_4 are unknown.

Further investigations were carried out with *p*-fluoro-substituted *(2b)*, since incorporation of this fluorine probe facilitates monitoring of the reaction by the sensitive technique of ^{19}F-NMR spectroscopy with simultaneous recording of educt and product(s)[6].

The substitution behavior of the diarylsulfur oxide difluorides *(2)* is determined by the preferred formation of the sulfone coordination. Hydrolysis of *(2b)*, which is highly sensitive to moisture and can be handled only under dried protective gas, proceeds uniformly to the sulfone *(3b)*[7]. With alcohols, initial substitution is followed by elimination of the organyl group bound to the oxygen as alkyl fluoride. The driving force of this thia(VI)-analogous "Arbusov elimination" could be formation of the thermodynamically most favorable sulfone. Finally, ammonolysis leads to *(4b)*, the monoaza-analog of the sulfone. *(4b)* is hydrochlorinated to the analytically pure chloride *(5b)*.

Bonding comparable with that in the preferred sulfone arrangement should also be achievable by withdrawal of fluoride from *(2b)*. Indeed, reaction with strong fluoride-acceptors such as BF_3 or PF_5 affords the compounds *(6b)* and *(7b)*, respectively, which contain an oxo cation isoelectronic with the phosphinic fluorides and having pentavalent sulfur and a new fluoroorganic periphery. The $^{13}C\{^1H\}$-NMR spectrum

[**] Fluorinated Organoelements: Oxidative Liquid-Phase Direct Fluorination, Part 6. – Part 5: *I. Ruppert*, J. Fluorine Chem. 14, 81 (1979); part of Habilitationsschrift, Universität Bonn 1979.

of *(6b)* [and *(7b)*] shows besides the fluoroarene coupling an additional doublet splitting due to the fluorine atom attached to sulfur. This multiplicity, gradation of coupling constants comparable to the neutral compound, and, finally, the expected integration ratio in the ^{19}F-NMR spectrum confirm the salt-like structure of *(6b)* and *(7b)*.

In the reversal of its equation of formation, *(2a, b)* transfers both of its fluorine atoms to triphenylphosphane at room temperature. This reaction—hitherto only observed with SF_4[8a] and its covalent organo derivatives[8b]—is surprising for S^{VI} derivatives, insofar as the SF bond usually becomes stronger with increasing coordination by electronegative ligands and thus with increasing the partial charge of the sulfur atom.

Procedure

All operations must be carried out under strict exclusion of moisture.

Synthesis of *(2a)* and *(2b)*: A stream of fluorine diluted with helium (max. 20 ml F_2 to 100 ml He per min) is passed into a magnetically stirred solution of *(1)* (40 mmol) in anhydrous $CFCl_3$ (250 ml) (quartz flask with Teflon delivery tube and fitted with a frit with, −90 °C circulatory cooling). The gas mixture is additionally precooled by passage through a metal spiral in an EtOH-slush bath (−115 °C) and the reaction solution is kept at 0 °C for *(1a)* and at −78 °C for *(1b)*. The reaction is complete only after addition of a three- to fourfold excess of fluorine. For determining the end-point of the reaction, $^{13}C\{^1H\}$-NMR is recommended in the case of *(2a)* and ^{19}F-NMR in the case of *(2b)*. The suspension is filtered off cold and $CFCl_3$ is removed from the colorless residue *in vacuo* (mercury vapor jet pump); yield: 80—90% finely crystalline, analytically pure *(2a)* (m.p. 79 °C, dec.) or *(2b)* (m.p. 75 °C, dec.).

For ammonolysis and salt formation a stoichiometric amount of precondensed NH_3, NF_3, or PF_5 is added to a solution of freshly prepared *(2b)* (30 mmol) in CH_2Cl_2 (100 ml) in a vacuum system at −78 °C. The magnetically stirred reaction mixture is allowed to warm to room temperature overnight and the volatile components are then removed in a vacuum. The residue consists of *(4b)*, *(6b)*, or *(7b)* slightly contaminated with sulfone *(3b)*. *(4b)*, a light brownish oil, is taken up in ether and treated with HCl gas until precipitation is complete. Filtration affords colorless hydrochloride *(5b)* (73%, m.p. 179 °C, dec.), from which *(4b)* can be recovered again by addition of Et_3N.—Hydrolysis, alcoholysis[9], and defluorination[10] of *(2b)* were monitored ^{19}F-NMR spectroscopically.

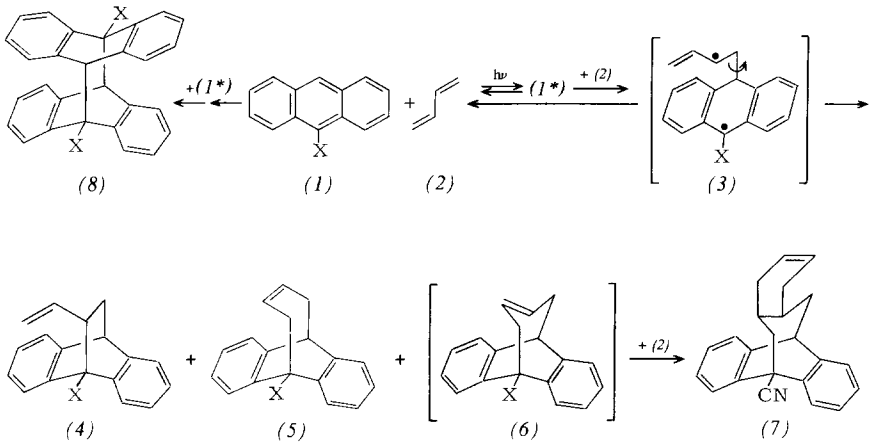
Polar [4+2]- and [4+4]-Photocycloadditions: Effects of Hybridization in Diradicals[**]

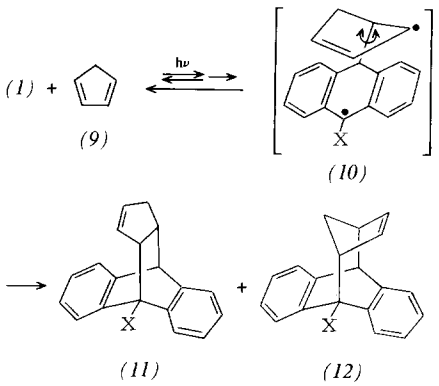
By *Gerd Kaupp* and *Heinz-Willi Grüter*[*]



Numerous orbital symmetry postulates (EHT-techniques) for "concerted reactions" had to be modified for polar reactions, using more sophisticated PMO- or CI-theories. Thus, it was "predicted" that photochemical Diels-Alder reactions between excited anthracene (anthracene substituted with acceptor groups) and acceptor- (donor-) dienophiles are "allowed" due to cross-over of orbital levels, while competing [4+4]-reactions are correspondingly "forbidden"[1]. The experimentally supported diradical mechanism operating in singlet reactions of this type[2] leads to different expectations. We report here on the suppression of photochemical [4+2]- and promotion of photochemical [4+4]-reactions by means of polar substituents, exactly as required by the diradical mechanism in the special cases under discussion.

Electronically excited anthracene *(1a*)* is trapped by 1,3-butadiene *(2)* (6 M) giving *(4a)* and *(5a)* in the ratio 20:1[3]. The ratio of [4+2]- to [4+4]-adducts is reversed, however, when electronically excited 9-anthracenecarbonitrile *(1b*)* ($\lambda = 310$—410 nm) reacts with *(2)* (3.2 M in benzene). One obtains *(4b)*, *(5b)* and *(6b)*→*(7)* in the ratio 1:3.2:13.3 [altogether 19%, together with 80% *(8b)*][4].

This striking difference is readily comprehensible upon considering molecular models of the diradical *(3)* (which is inferred by extrapolation), even though the extent of unproductive reverse reaction [*(3)*→*(1)*+*(2)*] cannot be predicted as yet: the formation of the six-membered ring [yielding *(4)*] requires considerable rehybridization at the benzhydrylic radical center of *(3)* out of planarity towards pyramidal geometry, in order to decrease the C—C-distance and to improve the overlap of electrons prior to the initiation of the bonding process. On the other hand the electron overlap is well suited for the formation of eight-membered rings [of *(5)* and *(6)*] (according to molecular models) even with the planar diradical *(3)*. However, the formation of *(5)* first requires an internal rotation within the allylic system [or else reaction of *s-cis-(2)* with *(1*)*] and for reasons of severe strain *(6)* will only be formed, when the planarity of the benzhydrylic radical center as in *(3b)* is stabilized by additional delocalization into the polar cyano group, since this effectively inhibits the competitive formation of *(4b)*. Therefore in the case of the apolar



[*] Univ.-Doz. Dr. G. Kaupp, H.-W. Grüter
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

system *(3a)* with less stabilization of the sp^2-geometry (more facile rehybridization) a higher proportion of Diels-Alder addition to *(4)* is to be expected than for the more polar *(3b)*, as is experimentally observed.

Similar effects may be used for control of cyclovinylogous photoadditions with *s-cis*-fixed 1,3-dienes. Thus, the photoreaction of anthracene *(1a)* in cyclopentadiene *(9)* at 0 °C yields the [4+2]- and [4+4]-adducts *(11a)* and *(12a)* in the

(a), X = H; *(b)*, X = CN; *(c)*, X = Cl

ratio 1:1.4[5]. Similarly 9-anthracenecarbonitrile *(1b)* and 9-chloroanthracene *(1c)* react with *(9)* after light absorption with fluorescence quenching (91.5% and 17.5% quenched; 5.0 M *(9)* in benzene) but without discernable exciplex fluorescence[6]. The [4+4]-adducts *(12b)* (79%)[4] and *(12c)* (40%)[4] are formed, but not the [4+2]-adducts *(11b,c)*. Again less geometrical change at the benzhydrylic radical center in *(10)* is required for the initiation of eight-membered ring formation (according to molecular models) than for the at least conceivable six-membered ring formation. Due to additional delocalization into the substituents the rehybridizations are more difficult and this also hinders the formation of rotamers which are well suited for closure to six-membered rings (methylene-H/*peri*-H interaction)[6].

The diradical intermediates *(3b)*, *(10b)*, and *(10c)* are favored sterically and electrostatically. Isomeric [4+2]-adducts, formally derived *via* primary attack of *(2)* or *(9)* on the substituted C-atom of *(1)*, are not found. In the photoreaction of 9-chloroanthracene *(1c)* (0 °C) with *(9)* thermolabile side-products (presumably due to attack on one of the outer rings) are formed, which, upon work-up, regenerate 4% of *(1c)*. Such side reactions are more prominent during photolysis of 9,10-dichloroanthracene dissolved in *(9)* (*ca.* 80% regeneration upon work-up). One obtains 14% of the [4+4]-adduct analogous to *(12)*)[4], but as expected no Diels-Alder adduct of type *(11)*.

The effects of polar substituents on the reactivity of 1,4-diradicals described here (and previously disregarded) promise further applications in preparative photochemistry.

Quantitative Trace Analysis of Thallium in Biological Material[**]

By *Christoph Achenbach, Rolf Ziskoven, Ferdinand Koehler, Ute Bahr*, and *Hans-Rolf Schulten*[*]

Regarding the pharmacokinetics of thallium we now have available the first results[1] obtained by the technique of field desorption mass spectrometry (FD-MS).

[**] Quantitative Field Desorption Mass Spectrometry, Part 18. This work was supported by the Deutsche Forschungsgemeinschaft and the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen. Part 17: *U. Bahr, H.-R. Schulten*, J. Labelled Compd. Radiopharm., in press.

[†] Author to whom correspondence should be addressed.

The recent discovery of high levels of thallium pollution in the environment has focused attention on the tetratogenicity (fetus malformation). For detailed investigations in this sector a method is required which enables the quantitative detection of thallium in extremely small tissue samples (embryos, placenta tissues *etc.*) thus permitting correlation of measured values with teratological findings.

FD-MS[2] enables direct detection and quantitative determination of metal cations in biological and environmental samples in the picogram range[3] without a separate charring step. The limit of detection with FD-MS is 10^{-15} g for cesium, 10^{-12} g for lithium and 10^{-11} g for thallium. For quantitative determinations by mass spectrometry, isotope dilution analysis using stable isotopes was chosen. The high specificity of FD-MS makes an involved and time-consuming sample preparation unnecessary, the tissues and cell components of the samples are merely homogenized and centrifuged. The time required for an analysis is only *ca.* 20 min; the amount of sample required is *ca.* 1 mg.

For the measurements a double focusing mass spectrometer (Varian MAT 731) with FD ion source and indirect emitter—heating with a tunable argon ion laser (Spectra Physics, Model 166)—was used. To compensate for statistical deviations in the flow of ions, the electric signals of the ions were accumulated *via* a multichannel analyzer (Tracor Northern NS-570A). On accumulation of electric signals over *ca.* 100 scans the accuracy of the results for pure salt solutions lies below 1%, for metals from complex matrixes between 5 and 10%.

For determination of the distribution of thallium with time in an organism we administered orally 160 mg of thallium per kg body weight to mice. After fixed periods of time the acutely poisoned mice were killed and the thallium concentrations in the heart, liver, kidney and brain were determined by FD-MS (Fig. 1). According to the results it would appear that the brain possesses an inbuilt barrier for thallium, which however breaks down in dependence of dosage after loss of excretory function of the kidney (see curves a and b in Fig. 1). In contrast, in the remaining organs a short-termed enrichment of thallium takes place, followed by a washing-out process. High concentrations are again observed in the kidney[4] only after *ca.* 12 h. After 24 h an increased concentration of about the same order of magnitude is found in all organs.

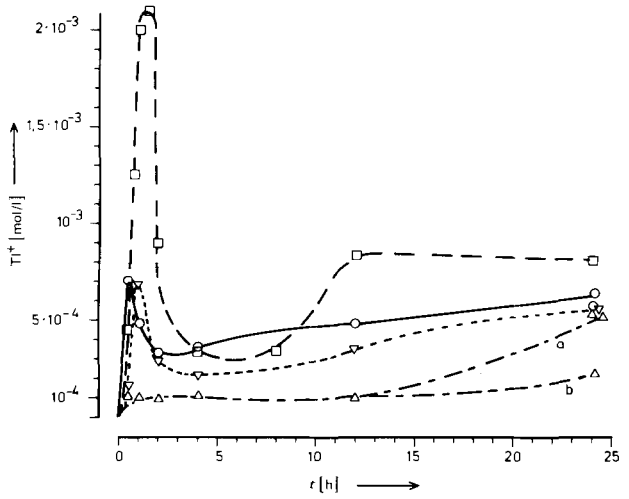

Fig. 1. Distribution of thallium with time in the heart ○, liver ▽, kidney □ and brain △ of mice after administration of 160 mg Tl per kg body weight. The enrichment and excretion processes are followed by a second, variable increase in thallium concentration. The brain takes up only small amounts of thallium; however, no excretion takes place. The curves a and b for the brain show the variable high increase in thallium concentration for thallium doses of 130 and 80 mg/kg, respectively.

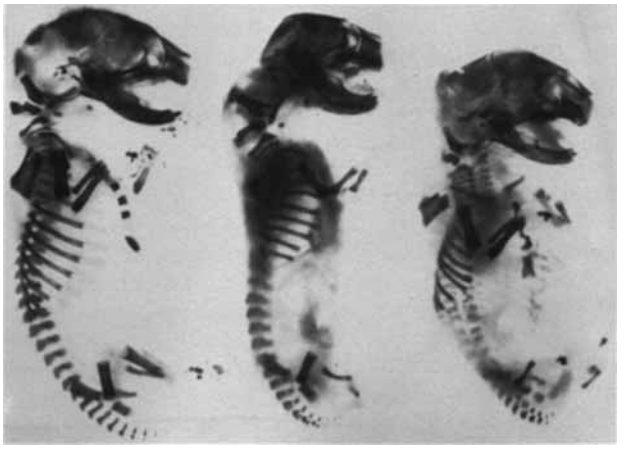

Fig. 2. Skeletons of mice embryos. Left: a normal embryo; center and right: damage after a single dose of 8 mg Tl/kg body weight to the mother animal.

For the teratological investigations pregnant mice were given doses of 8 mg Tl per kg body weight. At this dosage 50% of the embryos were found to have serious malformation of the skeleton (see Fig. 2). The teratogenic dose 50% was lower than the corresponding lethal dose 50% by a factor of approximately 40. As example, one mother proved to have 5.1×10^{-5} mol/l of thallium in the kidney, 1.5×10^{-6} mol/l in the brain, and 2.6×10^{-5} mol/l in the uterus together with the embryos. These values were found one hour after administration of the thallium. Furthermore, experiments with this line of test animals showed that even one thousandth part of the lethal dose 50% still gave 12.5% of fetal malformations. If this were transformed to humans it would mean that an oral dosage of *ca.* 10 microgram of thallium per kg body weight at the time of formation of the extremities and organs in the embryo would result in a significant enhancement of malformations.

Specialist Periodical Reports: General and Synthetic Methods, Vols. 1 and 2. Senior Reporter: *G. Pattenden.* The Chemical Society, London. Vol. 1: 1978, 445 pages, bound, £ 30.00, Vol. 2: 1979, 263 pages, bound, £ 26.00.

The first two volumes of a new series of "Specialist Periodical Reports" are now available. They are literature surveys for the years 1976 (Vol. 1) and 1977 (Vol. 2). The preparation and reactions of the main types of organic compounds are discussed, together with the use of novel reagents. The discussion is not limited to methods of wide and proven applicability, but also covers many reactions that are new and appear to have potential value in synthesis.

The present series differs from other similar series in that the methods are arranged by type of compound rather than by type of reaction. This makes the individual chapters more absorbing reading than works of more encyclopedic nature.

The first five chapters are concerned with hydrocarbons, aldehydes and ketones, carboxylic acids and their derivatives, alcohols, ethers, and halogen and nitrogen compounds. Although in the case of the hydrocarbons it is mainly novel reactions that are described, with the carbonyl compounds the emphasis is on their synthesis, plenty of space being devoted to butenolides, α-methylenebutyrolactones, and macrolides, where there has recently been much activity. A further chapter is concerned with the synthesis of oxygen, sulfur, and nitrogen heterocycles, beginning with oxiranes and going on to penicillins and cephalosporins. Similarly, new ring closure and annelation reactions for the preparation of carbocyclic compounds are presented, particularly with regard to their use in the synthesis of natural terpenoids.

Account is taken of the ever-increasing importance of organometallic compounds in synthesis, and there is a detailed description of transition-metal reagents which may be used catalytically or stoichiometrically; many examples are given to clarify the tremendous versatility obtainable by using main group elements in synthetic operations.

Unfortunately, the expositions on such important topics as synthesis planning and strategy are insufficient. Although the examples of the synthesis of naturally occurring materials are to some extent illustrative, the treatment of synthetic strategems is quite arbitrary. Retrosynthetic and synthon considerations are hardly mentioned, the concept of Umpolung has been misunderstood, and the treatment of methods for the production of optically active centers is too bald.

A suitable amplification of the topics handled is provided by the special chapter on phase transfer catalysis and complexing reagents. In addition, the reader interested in further study will find at the end of each volume a collection of review articles published in that year which deal with synthetic methods.

All in all, the first two volumes of the new series provide a thorough survey of the development of synthetic organic chemistry. They may be recommended to anyone interested in new synthetic reagents who wants to keep up to date with the range of synthetic methods available. However, the high price makes them appear more suitable for libraries than for a personal collection.

Herbert Siegel [NB 482 IE]

Highly Conducting One-Dimensional Solids. Edited by *J. T. Devreese, R. P. Evrard,* and *V. E. van Doren.* Plenum Press, New York 1979. xiii, 422 pages, bound, $ 51.00.

The second volume of the series "Physics of Solids and Liquids" contains seven papers by a total of ten internationally famous experts. The book is intended primarily for physicists who want to become acquainted with the physical peculiarities of one-dimensional metallic systems. The specific problems involved are presented in a short but very informative introduction *(A. J. Berlinsky)* that can also be understood by chemists. The following chapters on X-ray and neutron diffraction experiments *(R. Comès* and *G. Shirane),* "Charge Density Wave (CDW) phenomena" *(A. J. Heeger),* and the properties of "alloys" of various "organic" metals *(T. D. Schultz* and *R. A. Craven)* contain the fundamental experimental results obtained up to about 1977 on three selected one-dimensional metals (for the expert, these are TTF-TCNQ, TSeF-TCNQ, and KCP). Next come three theoretical sections *(L. J. Sham, V. J. Emery, H. Gutfreund,* and *W. A. Little).* The last two authors analyze the possible existence of exciton high-temperature superconductors. The final chapter *(J. Bardeen)* gives a critical comparison of the data in the previous sections and their interpretation. A brief survey of the possible future development of the field is appended.

The book gives a detailed and comprehensive presentation of the essential theoretical models and the special experimental methods used for the study of one-dimensional metals, on the basis of a few well-chosen examples. Nevertheless, the chemist will regret the absence of a brief summary of the materials that have been synthesized and clearly characterized up to the present.

To judge by the literature references, the printing of this book seems to have taken a very long time.

Heimo J. Keller [NB 483 IE]

Solid Electrolytes. General Principles, Characterization, Materials, Applications. Edited by *P. Hagenmuller* and *W. van Gool.* Academic Press, New York 1978. xvii, 549 pages, bound, $ 52.00.

The field of solid ionic conductors or solid electrolytes has rapidly developed and extended over recent years and the process is still continuing. The attempt of the present book to give a survey of the entire field is therefore welcome. The book contains 32 contributions from a large number of authors and is divided into three parts.

The first part deals with the theory of ionic conduction in solids, especially solids with very high conductivities, which are sometimes called "super ionic conductors" or "optimized ionic conductors". Both transport mechanisms and the experimental methods used to characterize solid ionic conductors are discussed. These include AC measurements and scattering experiments, but unfortunately the standard methods such as DC measurements, polarization measurements, and measurements with electrochemical potential probes have been omitted.

The second part contains most of the known solid ionic conductors, arranged by substance classes. These include sodium-ion-conducting β-aluminas, oxygen-ion conductors based on zirconium dioxide, fluorine-, copper- and silver-ion conductors, *etc.*

Finally, in the third part, the most important practical applications of solid electrolytes are discussed. These include high-temperature fuel cells, the sodium-sulfur cell as a high-energy accumulator, electrochemical measurement probes, and other systems. Reference is also made to solids with mixed ionic and electronic conduction, which are of importance as electrodes in galvanic cells.

This book will certainly be very useful for scientists working in the field of solid electrolytes, since not only does it per-

mit a rapid overview of the various parts of the subject but it also simplifies a more detailed study of specific problems by means of its extensive literature references.

Hans Rickert [NB 484 IE]

Chemical Kinetics and Transport. By *P. C. Jordan.* Plenum Press, New York 1979. xvi, 368 pages. Bound, $ 25.80.

In many open systems the interaction of chemical reaction and transport processes determines both the kinetics at steady state and the transient behavior. This applies not only to continuously operated reactors, all heterogeneous catalytic reactions, flames, and combustion systems but also to living cells and structures containing living cells. Yet, anyone buying this book in the expectation of learning something about the coupling of a chemical reaction and transport processes in such systems will be disappointed, since this subject is not discussed at all.

It is rather a theoretically oriented textbook of chemical kinetics in the usual sense, preceded by a 70-page introduction to the kinetic theory of gases and the theory of transport processes in electrolyte solutions. On further reading it is found, surprisingly enough, that there is no discussion of the coupling of a chemical reaction and macroscopic transport processes, even where it would be necessary, as in the section on heterogeneous catalysis. (The general statement that diffusion of the reactants to the catalyst is rate-determining only at very low pressures is certainly wrong.) The definition of the reaction rate used in the book applies only to closed, homogeneous systems at constant volume, and the treatment in general is limited to such systems.

The at first sight somewhat misleading title is justified by the last three chapters, which are essentially devoted to the theory of reaction rate constants, the emphasis being on aspects based on the kinetic theory of matter, *i. e.* on collisions. Gas reactions and the results of experiments with crossed molecular beams are in the foreground, but brief reference is also made to the relation between self-diffusion and the upper limits of the rates of bimolecular reactions in solutions. The comparison with transition state theory and the critical discussion of different theoretical concepts may be interesting and valuable to readers who are familiar with the subject.

It appears doubtful, however, whether this book is also suitable for students with only basic knowledge of chemical thermodynamics and statistical mechanics, as indicated in the preface. The present reviewer would not recommend it without reservations to this class of potential readers. Inaccurate statements and a somewhat carefree usage of definitions can be tolerated by the well-initiated reader but inaccurancy may be rather cumbersome if the subject matter is unfamiliar.

Nodal Nomenclature—General Principles

By Noël Lozac'h, Alan L. Goodson, and Warren H. Powell[*]

A new, comprehensive graph-based nomenclature system for chemical substances is proposed. Substances are named by using nodal nomenclature to name graphs derived from their structures by ignoring chemical details such as atom identities, bonding, charges, *etc.* After the fundamental graph is named, these chemical details are introduced by modifications and additions to the name of the graph to yield the name of the actual substance. Although development of nodal nomenclature originated with problems in naming some organic systems, it is not limited to organic substances. In this paper, only general principles for naming the graph are described; applications to specific substances will be discussed in future papers.

1. Preface

The work reported here originated as a suggestion by one of us (N. L.) during the 1973 meeting of the Commission on the Nomenclature of Organic Chemistry (CNOC) of the International Union of Pure and Applied Chemistry (IUPAC). It soon became apparent that this concept, conceived as a basis for naming a class of compounds known as "cyclophanes", had a very much wider applicability. In fact, its potential surpasses the confines of organic chemistry.

Independently, as part of a continuous review of nomenclature procedures, a study of ring nomenclature was started at Chemical Abstracts Service (CAS) in 1972 which developed into an effort to produce a general, graph-based nomenclature system.

When, at the 1975 meeting of CNOC, it became apparent that the CAS work and nodal nomenclature were developing along very similar lines, the evaluation and further development of nodal nomenclature became a joint effort.

Chemical nomenclature has developed in a rather random manner, paralleling the development of chemistry. Its principles were therefore not conceived from the beginning with a clear, overall plan, resulting in a mixture of nomenclature systems with overlapping rules, inconsistencies, and inadequate treatment for some types of compounds. An extensive set of organic nomenclature rules has been published[1–4], which is primarily a codification of the practices used by the chemical community insofar as these practices were determined to be sound.

The main objective of CNOC now is to improve this existing system of organic nomenclature. Accordingly, CNOC is engaged in revising its rules mainly through simplification, systematization, and extension, as necessary, and plans to publish these revised rules[5].

Nodal nomenclature will not be included in the proposed revised rules because to do so would not conform to the established CNOC policy of recommending the codified use of existing nomenclature practices. However, the potential of the nodal nomenclature system has been recognized and CNOC has therefore encouraged the publication of its basic principles and some guidelines for its use. This will enable nodal nomenclature to be used and evaluated by the chemi-

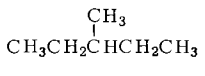
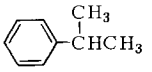
cal community where current nomenclature systems prove difficult, cumbersome, or inadequate. The experience gained will provide constructive criticism and guidance for further development. We do not regard nodal nomenclature as fully developed at this time and anticipate that some minor modifications may be necessary or desirable before it is considered by CNOC for assimilation into the IUPAC system of organic nomenclature.



We have taken considerable care to ensure that nodal nomenclature is compatible with existing nomenclature systems as well as with the proposed revised rules in order that nodal nomenclature will be as widely applicable as possible. Thus, some of the traditional practices of present nomenclature systems need not be abandoned.

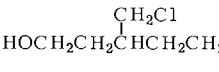
One of the most important features of nodal nomenclature is that this is the first time a comprehensive, computer-compatible system has been introduced to name structure graphs systematically, although numerous papers have been published dealing with structure graphs as an aid to describing ring systems. Furthermore, the resulting names are easily modified to describe actual chemical substances.



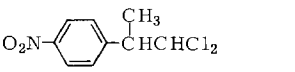
Complex examples with long systematic names are used at times in this paper to demonstrate the wide scope and facile application of nodal nomenclature, but it must be emphasized that nodal nomenclature has not been developed solely for naming unusual or complex structures; it is a system with completely general applicability. Structures which can be named easily by traditional nomenclature systems can be named just as easily by nodal nomenclature with attendant supplementary advantages.

2. Introduction

Development of nodal nomenclature was prompted by the recognition of various shortcomings in existing organic nomenclature systems. Most of these deficiencies are related in one way or another to the fact that even relatively simple structures, such as hydrocarbons, must be often described by substitutive principles, for example:

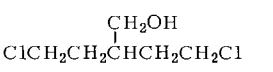


3-Methylpentane

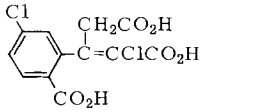


2-Phenylpropane
or
Isopropylbenzene

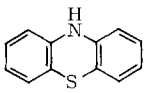
Consequences of using the substitutive principles of existing organic nomenclature systems include: (a) the names of simple structures, such as those illustrated above, are obscured and often completely lost when the structures are substituted by characteristic groups; (b) multiple occurrences of characteristic groups are often scattered throughout the name; and (c) unique locants are not available to denote each skeletal atom in the structure. These problems are illustrated in the following derivatives of the hydrocarbons shown above.



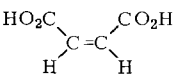
These problems are sometimes avoided in traditional organic nomenclature by use of a number of trivial names, *i.e.* simple names implying relatively large structural units, usually with complete unique numberings and often with implied stereochemistry. Such trivial names coexist with systematic names which are usually longer because they are derived from smaller structural units. The examples below illustrate this situation.



3-(Chloromethyl)-1,5-pentanediol



1,1-Dichloro-2-(4-nitrophenyl)propane
or
1-(2,2-Dichloro-1-methylethyl)-4-nitrobenzene



4-Chloro-2-(2-chloroethyl)-1-butanol

3-(2-Carboxy-5-chlorophenyl)-2-chloro-2-pentenedioic acid

Phenothiazine
or
10*H*-Dibenzo[*b*,*e*][1,4]thiazine

Maleic acid
or
cis-Butenedioic acid

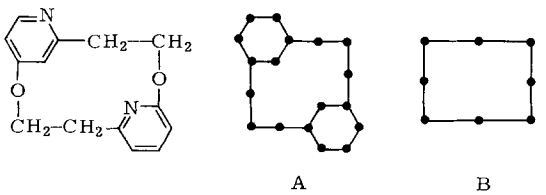
Tartaric acid
or
2,3-Dihydroxybutanedioic acid

Nodal nomenclature describes the graph of a compound and avoids the deficiencies noted above by providing a unique locant for each position in the structure (see Section 3). However, even though substitutive principles need not be used to describe the graph of a substance, as is the case in traditional systems, they may be used to indicate characteristic groups in names for specific compounds. This will be discussed in later papers.

3. General Concepts of Nodal Nomenclature

The basic logic of nodal nomenclature resides in the description of a structure in terms of its graph. The term "node"[6] is derived from the Latin "nodus" and has the meaning of a knot, bulge, or intersection of branches. It is applied to single skeletal units, *i.e.*, atoms, of a structure. It may also be applied to groups of atoms forming important structural units, such as a benzene ring in a cyclophane, an amino acid fragment in a polypeptide, or a mononuclear component of a polynuclear acid. Nodes representing such groups of atoms can be called "contraction nodes".

General nodal nomenclature, the subject of this paper, describes the numbering and arrangements of nodes of a graph. It does not specify the nature of the nodes. *Specific nodal nomenclature,* on the other hand, describes the nature or structure of the nodes, specifies the bonding between the nodes, *etc.* It will be discussed in subsequent publications.



Since the graph concept for naming and numbering[*] structures is most easily illustrated by use of graphs derived

[*] Here "numbering" means the assignment of locants to nodes or skeletal atoms (and of module seniority numbers to module seniority descriptors).

from organic structures, the rules of general nodal nomenclature are often illustrated in this paper by graphs derived from hydrocarbons and heterocycles. In addition, we use the suffix "-ane" (as "nodane") which denotes saturated structures in traditional organic nomenclature. However, this should not be taken to imply in any way that nodal nomenclature is not equally applicable to other types of compounds, such as coordination compounds. Furthermore, the examples and terminology of this paper should not conceal a fundamental difference between the concepts of classical organic nomenclature and those of nodal nomenclature. In classical organic nomenclature, the skeletal atoms are usually atoms of the common nonmetallic elements (such as carbon, nitrogen, and oxygen) and have defined ligancies based on classical valence considerations. On the other hand, in general nodal nomenclature, the ligancy of a node is not limited in any way and therefore a node can have a ligancy of any value, which becomes apparent only when the nature of the node is defined.

In contrast to classical organic nomenclature, nodal nomenclature provides a unique numerical locant for every node of a graph. This may also be useful in some specialized areas of traditional organic nomenclature, such as steroids and alkaloids, where trivial names may be preferred to systematic ones. Although proliferation of trivial names is not desirable, they are simpler than systematic organic names and often imply considerable stereochemical information. One rather serious problem with many trivial names is that the associated numbering is sometimes incomplete, often arbitrary, and may vary from structure to structure within the same class. Nodal nomenclature, on the other hand, provides a general numbering system that can be used with any trivial name or nomenclature system.

Before any specific compound can be named by nodal nomenclature, two decisions dealing with its structure need to be made. First, the parts of the structure that are to be excluded from the portion of the structure to which general nodal nomenclature is to be applied—and are therefore to be treated as substituents—must be determined. This choice is not necessary in the most general application of nodal nomenclature, but is peculiar to classical organic nomenclature. It is included here because, as noted above, we want to make general nodal nomenclature as compatible as possible with existing nomenclature systems (see Section 1). Secondly, the nature of the nodes that will be named by nodal nomenclature must be determined. General nodal nomenclature does not define the nature of the nodes; this is dependent on the type of compound and the circumstances in which it is reported. However, in order to name the graph by the principles of general nodal nomenclature, it is necessary to define the nature of the individual nodes. For example, the structure shown below can be named on the basis of graph A (in which each node is an atom) or of graph B (in which each pyridine ring has been "contracted" to a single node (contraction node) to simplify the graph, as has been proposed for naming cyclophanes)[7].

A B

Once the graph has been defined, general nodal nomenclature is used to describe the arrangement and numbering of the nodes, as detailed in this paper. Then, as will be discussed in subsequent papers, specific nodal nomenclature is used to describe the nodes, bonding, and substituents expressed as prefixes and/or suffixes.

Only after the nodes and bonds of the graph have been specified are the ligancies of the nodes satisfied by attaching hydrogen as needed if *substitutive nomenclature* is to be used. Thus, in general nodal nomenclature the graph of 3-methylpentane (see Section 2) would be named [5.1^3]hexanodane. In specific (substitutive) nodal nomenclature this parent hydrocarbon could be named, according to the rules of Section G[5], as [5.1^3]hexacarbane, or, more traditionally, as [5.1^3]hexane. The silicon analog could be named [5.1^3]hexasilane. Such parent hydrides can be substituted by characteristic groups as in classical organic nomenclature to yield names such as 5,6-dichloro[5.1^3]hexacarban-1-ol; according to current rules the compound has the name 5-chloro-3-(chloromethyl)-1-pentanol.

It is evident from the preceding discussion that, in comparison with classical organic nomenclature, nodal nomenclature has many advantages, including:

1. consistent treatment of chains and rings, and of assemblies of chains and rings;
2. systematic numbering of the atoms in complex structures, as commonly occur in natural products, such numberings being equally applicable to structures described by trivial or semisystematic names;
3. applicability to structures with nodes of high ligancy as, for example, occur in coordination compounds;
4. logical description of an assembly of subunits or modules of any type or degree of complexity, such as: (a) cyclic systems in ring assemblies, protophanes and cyclophanes; (b) amino acid fragments in polypeptides and proteins; (c) mononuclear components in polynuclear acids;
5. the nomenclature is suitable for computerization.

4. Glossary

For the usual terms of classical organic nomenclature, the definitions given in References [1–4] are followed. In addition, there are certain terms used in this and subsequent papers in this series which have a new or special meaning. These terms are defined as follows:

General Nodal Nomenclature: The description and numbering of the arrangement of nodes in a graph.

Assembly (of modules): A structure graph composed of more than one cyclic module or of at least one acyclic module and at least one cyclic module.

Contraction (of a module): The operation by which a module is reduced to a contraction node to simplify the descriptor and name a structure or to facilitate the numbering.

Contraction node: A group of nodes, that can be named as a unit in specific nodal nomenclature, which is contracted to a single node to facilitate the description of a complex system in general nodal nomenclature.

Descriptor: The numeric portion of a nodal name[8], enclosed in brackets, providing an unambiguous description of a graph.

Graph (Structure Graph): An arrangement of nodes and lines representing, respectively, the atoms or groups of atoms and bonds (or connectivities) forming a molecule.

Module: A single node or an entirely cyclic or acyclic subset of nodes that is treated as a separate entity during the numbering and naming of a graph assembly.

Module Seniority Descriptor A capital letter assigned to each module to designate its relative seniority in an assembly of modules.

Module Seniority Graph An arrangement of module seniority descriptors used for determining the order in which the various modules of an assembly are to be numbered.

Module Seniority Number Arabic numeral assigned to a module seniority descriptor in a module seniority graph.

Node[6]: The simplest unit of a graph, representing either a single atom or a group of atoms.

Principal Module: The senior module where numbering of the module seniority graph and unique numbering of the corresponding assembly begins.

Senior Module: The module, or one of the modules, of highest seniority in an assembly.

Specific Nodal Nomenclature: The description and numbering of a chemical structure, the specific nodal name being obtained by adding to the general nodal name a description of such details as the nature of the nodes, bonding, charges, *etc.*

Structure Graph (see *Graph*): Used principally to ensure that graphs related to chemical structures are not confused with other types of graph, *e.g.*, graphs related to reaction sequences.

5. Proposed Rules for General Nodal Nomenclature

Rule N-1—*Acyclic Graphs*

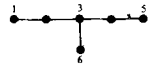
N-1.1. *An acyclic graph* is an unbranched chain of nodes or two or more unbranched chains of nodes connected to each other without formation of a cyclic structure. No matter how complex, it is never considered as a combination of separate structural parts[9].

N-1.2. The *main chain* in an acyclic graph is the longest unbranched chain of nodes and is numbered first, from one end to the other. When an acyclic graph has two or more equal unbranched chains of greatest length, the main chain is the one having the longest branches (see **Rule N-1.3**) attached to it. The main chain is numbered so that the lowest possible locants are given to these longest branches. If a choice remains, see **Rule N-1.6.**

N-1.3. *Branches* in an acyclic graph are unbranched chains of nodes attached to the main chain or to other, longer branches. Each is numbered from one end to the other, beginning always with the node attached to the part of the graph already numbered.

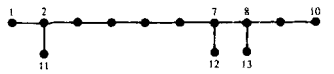
N-1.4. *Branches* in an acyclic graph are numbered successively in order of decreasing length. When two or more branches are of equal length, they are numbered in increasing order of the locants already assigned for the nodes of the chain(s) to which they are attached.

N-1.5. The *descriptor* of an acyclic graph consists of square brackets enclosing: (a) an Arabic numeral indicating the number of nodes in the main chain; (b) a period, followed by Arabic numerals denoting the number of nodes in each branch, cited in the order of their numbering (see **Rule N-1.4**); and (c) a superscript locant for each branch numeral denoting the node of the part of the graph already numbered to which the branch is attached[10].



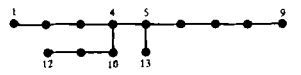
N-1.6. When two or more *alternative descriptors* for an acyclic graph can be derived, the correct descriptor is the one having the lowest superscript number at the first point of difference when these locants are compared term by term from the beginning of the descriptor[11].

N-1.7. The *name* of an acyclic graph consists of: (a) the descriptor derived as in **Rule N-1.5**; (b) a multiplying prefix, such as "di-", "tri-", "tetra-", *etc.*[12], denoting the total number of nodes; and (c) the ending "-nodane"[13].



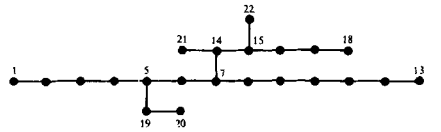
Examples[14]:

1. 



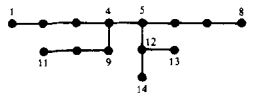
[6]Hexanodane

2. 



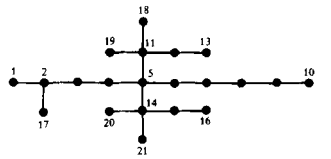
[5.1^3]Hexanodane

3. 



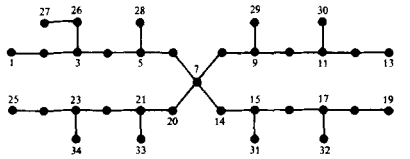
[10.1^{2}1^{7}1^8]Tridecanodane

4. 



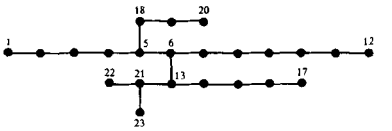
[9.3^{4}1^5]Tridecanodane

5. 



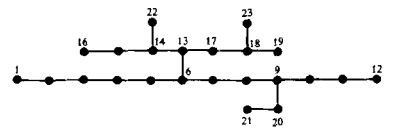
[13.5^{7}2^{5}1^{14}1^{15}]Docosanodane

6. 



[8.3^{4}2^{5}1^{12}]Tetradecanodane

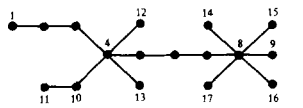
7. 



[10.3^{5}3^{5}1^{2}1^{11}1^{11}1^{14}1^{14}]Henicosanodane

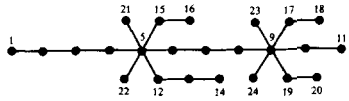
8. 

[13.6^{7}6^{7}2^{3}1^{5}1^{9}1^{11}1^{15}1^{17}1^{21}1^{23}]Tetratriacontanodane



9. 

[12.5^{6}3^{5}2^{13}1^{21}]Tricosanodane



10. 

[12.4^{6}3^{13}2^{9}1^{14}1^{18}]Tricosanodane

Note: The descriptor [12.4^{6}3^{13}2^{9}1^{15}1^{17}] is not correct because the locant series 6,13,9,*15*,17 is higher than 6,13,9,*14*,18 **(Rule N-1.6).**

11. 

[9.2^{4}1^{4}1^{4}1^{8}1^{8}1^{8}1^8]Heptadecanodane

12. 

[11.3^{5}2^{5}2^{9}2^{9}1^{5}1^{5}1^{9}1^9]Tetracosanodane

Rule N-2.—*Monocyclic Graphs*

N-2.1. Monocyclic graphs are *numbered* sequentially from any node in either direction until all nodes are numbered.

N-2.2. The *descriptor* of a monocyclic graph consists of square brackets enclosing a zero (indicating the presence of a ring) and an Arabic numeral denoting the number of nodes forming the ring.

N-2.3. The *name* of a monocyclic graph consists of: (a) the descriptive prefix "cyclo"; (b) a descriptor derived according to **Rule N-2.2**; (c) a multiplying prefix indicating the number of nodes in the ring[12,15]; and (d) the ending "-nodane"[13].

Example:

Cyclo[08]octanodane

Rule N-3.—*Polycyclic Graphs*[*]

N-3.1. A *polycyclic graph* consists of a monocyclic ring of nodes and one or more bridges, which are valence bonds or chains of nodes connecting nodes of the main ring and/or other bridges in the polycyclic system.

N-3.2. The *main ring* in a polycyclic graph is the monocyclic ring containing the greatest number of nodes. When two or more monocyclic rings have the same number of nodes, the main ring is chosen according to **Rule N-3.6.**

N-3.3. The *main bridge* in a polycyclic graph is the longest unbranched chain of nodes both ends of which are attached to the main ring[16]. When two or more chains are of equal length, the main bridge is chosen according to **Rule N-3.6.** Other bridges are called *secondary* bridges.

N-3.4. The *numbering* of a polycyclic graph begins at one of the nodes of the main ring to which the main bridge is attached (bridgehead) and proceeds in the direction that gives the lower locant to the other bridgehead. The main bridge is numbered sequentially after the main ring, beginning with the node of the main bridge connected to the node in the main ring having the locant 1. The secondary bridges are numbered successively in the same manner, beginning always with the longest bridge (or one of the longest bridges) connected to nodes of the graph previously numbered[17]. When there is a choice between two or more bridges of the same length, the first to be numbered is the one attached to

[*] In nodal nomenclature phanes can be treated as mono- or polycycles.

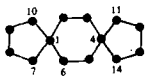
the node having the lowest locant in the part of the graph previously numbered. Each bridge is numbered beginning with the node of the bridge connected to the node of the part of the graph previously numbered having the lower locant.

N-3.5. The *descriptor* of a polycyclic graph consists of square brackets enclosing: (a) a zero indicating the presence of a ring followed by an Arabic numeral indicating the number of nodes in the main ring (see **Rule N-2.2**); (b) a period followed by Arabic numerals denoting the number of nodes in each bridge, cited in the order of their numbering (see **Rule N-3.4**); and (c) a pair of superscript locants for each bridge numeral, separated by a comma and cited in increasing numerical order, denoting the nodes in the part of the polycyclic graph already numbered to which each bridge is attached[18].

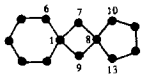
N-3.6. When two or more *alternative descriptors* for a polycyclic graph can be derived because there is a choice for the main ring, main bridge, starting point and/or direction of numbering, Arabic numerals, in each descriptor, denoting the lengths of the bridges *and* the positions of the bridges in the graph are compared term by term in the order they appear (see **Rule N-3.5**). The correct descriptor is the one with the preferred Arabic numeral at the first difference: if the first difference corresponds to a bridge length, the preferred numeral is higher; if the first difference appears in a superscript numeral (locant), the preferred numeral is lower[19].

N-3.7. The *name* of a polycyclic graph consists of: (a) a descriptive prefix, such as "bicyclo-", "tricyclo-", *etc.*, indicating the number of rings in the ring system[20]; (b) the descriptor derived according to **Rules N-3.5** and **N-3.6**; (c) a multiplying prefix[12] indicating the total number of nodes; and (d) the ending "-nodane"[13].

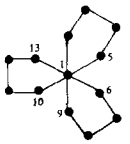
Examples[21]:



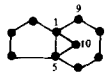
1.  Bicyclo[06.$2^{1,4}$]octanodane



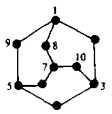
2.  Bicyclo[05.$4^{1,1}$]nonanodane



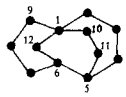
3.  Bicyclo[07.$1^{1,4}$]octanodane



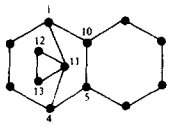
Note: The descriptor [07.$1^{1,5}$] is not correct because, for the main bridge, the locant series 1,*5* is higher then 1,*4* **(Rule N-3.4).**



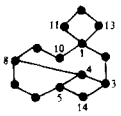
4.  Tricyclo[08.$1^{1,4}1^{5,8}$]decanodane



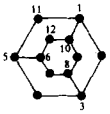
5.  Tricyclo[06.$4^{1,1}4^{4,4}$]tetradecanodane



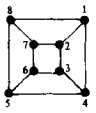
6.  Tricyclo[06.$3^{1,1}4^{8,8}$]tridecanodane



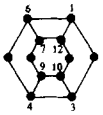
7.  Tricyclo[05.$4^{1,1}4^{1,1}$]tridecanodane



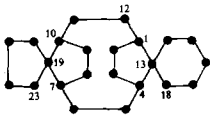
8.  Tricyclo[09.$1^{1,5}0^{1,5}$]decanodane
*[4.3.1]Propellane



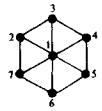
9.  Tricyclo[08.$1^{1,5}1^{3,7}$]decanodane
*Adamantane



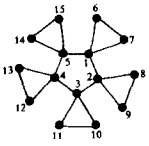
10.  Tricyclo[09.$2^{1,5}1^{1,6}$]dodecanodane



11.  Tetracyclo[010.$1^{1,4}2^{11,11}0^{5,10}$]-tridecanodane



12.  Tetracyclo[010.$3^{1,1}1^{3,5}0^{4,8}$]-tetradecanodane

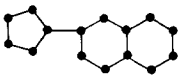


13.  Tetracyclo[010.$1^{1,5}1^{6,10}0^{3,8}$]-dodecanodane
*Iceane

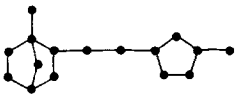
14.  Pentacyclo[08.$0^{1,4}0^{2,7}0^{3,6}0^{5,8}$]-octanodane
*Cubane

15.  Pentacyclo[012.$0^{1,6}0^{3,10}0^{4,9}0^{7,12}$]-dodecanodane
*Tetraasterane

16.  Pentacyclo[012.$1^{1,4}5^{13,13}1^{7,10}4^{19,19}$]-tricosanodane



17.  Hexacyclo[07.$0^{1,3}0^{1,4}0^{1,5}0^{1,6}0^{2,7}$]-heptanodane



18.  Hexacyclo[05.$2^{1,1}2^{2,2}2^{3,3}2^{4,4}2^{5,5}$]-pentadecanodane
*[5]Rotane

Rule N-4.—*Assemblies of Cyclic and Acyclic Graphs*

N-4.1. A structure graph is called an *assembly* if it is composed of more than one cyclic module or of at least one acyclic module and at least one cyclic module[9].

Examples:

1. 

2. 

N-4.11. An *acyclic module* is a single node or a branched or unbranched chain of nodes in an assembly.

N-4.12. A *cyclic module* is the graph of a ring or ring system in the conventional meaning of these terms[1]. Assemblies of directly-connected, identical cyclic modules, such as the structure graph of terphenyl, are not considered as one module; each component is considered as a separate cyclic module.

N-4.2. An *assembly descriptor* consists of square brackets enclosing: (a) in parentheses, the nodal descriptor of the principal module (which is the senior module (determined by **Rule N-4.3**), or one of the senior modules, chosen according to **Rules N-5.34** and **N-5.4**); (b) in parentheses, the nodal descriptors of the remaining modules, cited in order of numbering according to **Rules N-5.3** and **N-5.4**[22]; and (c) numerical locants, separated by colons, indicating the nodes through which each pair of modules is linked, each locant set linking the appropriate pair of module descriptors.

Example: [(06)1:7(4)10:11(05)]

N-4.21. The *descriptor* of each module in an assembly is identical with the descriptor of the corresponding isolated graph except that the enclosing square brackets are replaced by parentheses. Accordingly, this descriptor retains its original numbering, *i.e.*, the numbering that would be used to describe it if it were an isolated graph.

Example: [(06.$1^{1,4}$)2:10(4.1^{2})]

N-4.22. The *locant set* separating each pair of module descriptors in an assembly descriptor is derived from the definitive sequential numbering for the whole assembly as given in **Rule N-5.** Each locant set is written as follows: (a) the locant of the node, in the part of the graph previously numbered, through which the following module is attached; (b) a colon; and (c) the locant of the node, in the following module, through which that module is attached to the part of the graph previously numbered.

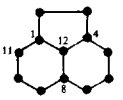
Example: [(06.$1^{1,4}$)2:10(4.1^{2})]

N-4.23. In an *unbranched assembly* with a *terminal* principal module, the first locant of any locant set refers to the immediately preceding module. Each locant is higher than the immediately preceding locant in the descriptor.

Example: [(06)1:7(06)10:13(06)16:19(06)]

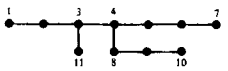
Note: The locant series 1,7,10,13,16,19 increases steadily.

N-4.24. In an *unbranched assembly* with a *nonterminal* principal module and in a *branched assembly,* the first locant of at least one locant set refers to a module cited in the descriptor earlier than the immediately preceding module. This locant is lower than the immediately preceding locant in the descriptor.



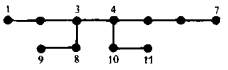
Examples:

1. [(06)1:7(05)4:12(05)]
   Note: In this descriptor of an assembly with a nonterminal principal module, the locant series 1,7,4,12 does not increase steadily and the locant 4, being lower than 7, refers to the first module cited in the descriptor, and not to the second module.
2. [(06)1:7(06)9:13(06)11:19(06)]
   Note: In this descriptor of a branched assembly, the locant series 1,7,9,13,11,19 does not increase steadily and the locant 11, being lower than 13, refers to the second module in the descriptor, and not to the third module.



N-4.3. *Seniority of modules* in an assembly is determined by the following criteria, which are applied successively until a decision is reached[19]:

a) Largest number of nodes.
b) Cyclic module preferred to acyclic module.
c) Largest number of rings or branches (side chains).
d) Largest main ring or longest chain.
e) Longest bridge or branch (side chain).
f) Lowest locants for attachment of bridges or branches (side chains).



Examples (in order of decreasing seniority: the criterion deciding the seniority of an example over the one following is noted in each case):

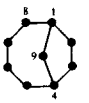
1.  Tricyclo[011.$1^{1,4}0^{8,12}$]dodecanodane

(senior to the following module, according to criterion a)

2.  [7.$3^{4}1^{3}$]Undecanodane

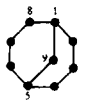
(senior to the following module, according to criterion e)

3.  [7.$2^{3}2^{4}$]Undecanodane



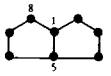
(senior to the following module, according to criterion a)

4.  Tricyclo[07.$2^{1,4}0^{5,7}$]nonanodane



(senior to the following module, according to criterion e)

5.  Tricyclo[07.$1^{1,3}1^{4,7}$]nonanodane



(senior to the following module, according to criterion c)

6.  Bicyclo[08.$1^{1,4}$]nonanodane

(senior to the following module, according to criterion f)

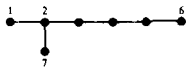
7.  Bicyclo[08.1^{1,5}]nonanodane

(senior to the following module, according to criterion a)

8.  Bicyclo[08.0^{1,5}]octanodane

(senior to the following module, according to criterion d)

9.  Bicyclo[07.1^{1,3}]octanodane

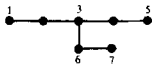


(senior to the following module, according to criterion b)

10.  [8]Octanodane

(senior to the following module, according to criterion a)

11.  [5.1^{2}1^3]Heptanodane



(senior to the following module, according to criterion c)

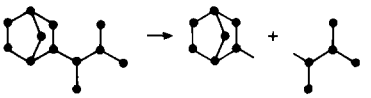
12.  [6.1^2]Heptanodane

(senior to the following module, according to criterion f)

13.  [6.1^3]Heptanodane

(senior to the following module, according to criterion d)

14.  [5.2^3]Heptanodane



N-4.4. The *name* of an assembly consists of: (a) a descriptive prefix (such as "cyclo", "bicyclo", *etc.*) indicating the total number of rings in the assembly; (b) the assembly descriptor (see **Rule N-4.2**); (c) a multiplying prefix[12] indicating the total number of nodes in the assembly; and (d) the ending "-nodane"[13].

Example: Bicyclo[(06)1:7(05)4:13(3)]tetradecanodane

Rule N-5.—*Definitive Numbering of Assemblies*

N-5.1. The *definitive numbering* of an assembly defines the correct assembly descriptor. This numbering begins with the principal module (see **Rule N-4.2**) for which the original numbering is retained. The other modules are renumbered sequentially, beginning with a module adjoining the principal module and proceeding, where necessary, as described in **Rules N-5.3** and **N-5.4**. Each module is renumbered by adding to each of its original locants a number equal to the total number of nodes in the assembly that have already been assigned definitive locants. When there is a choice for the origin and/or the direction of numbering in a module, the correct numbering is the one giving the lowest locants to the nodes of attachment of the module to other modules in the assembly.

Example:

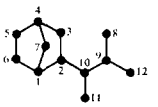
A B

This assembly consists of two modules, A and B. The procedure for numbering this assembly is:

a) Module A, the senior module of the assembly (see **Rule N-4.3a)**, is numbered and the descriptor generated according to **Rule N-3**.

 [06.1^{1,4}]

Since this module is the principal module of the assembly (see **Rule N-4.2**), it retains this numbering in the final numbering of the assembly. However, in this module there are two possible origins for numbering, each with two possible directions. Hence, in the assembly, the module is numbered so that the locant for the node of the attachment to the next module is as low as possible, *i.e.*, 2 (not 3, 5 or 6).



b) Module B is numbered and the descriptor generated according to **Rule N-1**.

 [4.1^2]

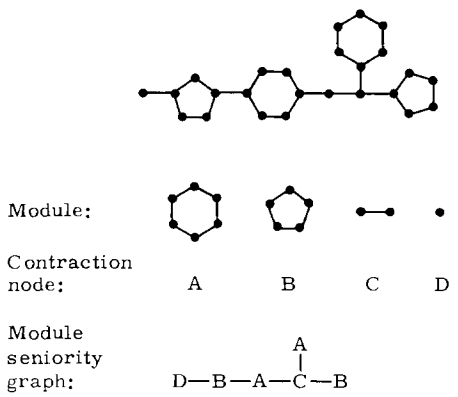
c) Module B is renumbered by adding 7 (the total number of nodes in module A) to each original locant.

d) The modules are recombined with their new numberings, where needed, and named according to **Rule N-4.4.**

Bicyclo[(06.1^{1,4})2 : 10(4.1^2)]dodecanodane

N-5.11. All assemblies in which the principal module terminates a *single linear chain of modules* are numbered and named by extension of the procedure described in **Rule N-5.1.**

Example:



Bicyclo[(06)1 : 7(4)10 : 11(05)]pentadecanodane

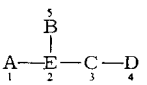
N-5.12. In assemblies in which the principal module is attached to *a single, branched chain of modules or to two or more linear or branched chains of modules* and in which two or more definitive numberings are possible, the correct numbering is chosen on the basis of the order of *module seniority numbers* assigned to the *module seniority descriptors* of the *module seniority graph* (see **Rules N-5.2** and **N-5.3**). When this is not definitive, the correct numbering is chosen by comparing the descriptors derived from the various possible numberings (see **Rule N-5.4**).

N-5.2. The *module seniority graph* of an assembly is a representation of the component modules of the assembly in terms of their relative seniorities. Each component module is represented in the module seniority graph by a capital letter, *i.e.* a module seniority descriptor, signifying its relative seniority and its position in the assembly. The most senior module(s) is (are) denoted by A, the next most senior by B *etc.*

Example:

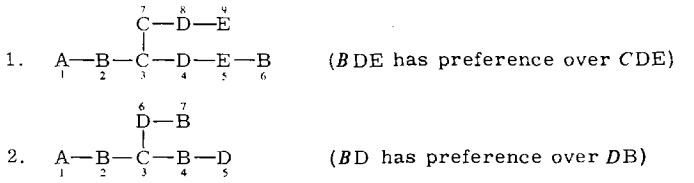
N-5.3. *Numbering of the module seniority graph, i.e.* assignment of the module seniority numbers, which determines the order of assignment of the definitive sequential numbering of the assembly (see **Rule N-5.1**), begins with the principal module (see **Rule N-4.2**) and proceeds, in order of decreasing seniority as defined in **Rule N-5.33**, through each chain of contraction nodes attached to the principal module[23].

N-5.31. *Module seniority numbers* are assigned to each chain of contraction nodes attached to the principal module of the seniority graph.



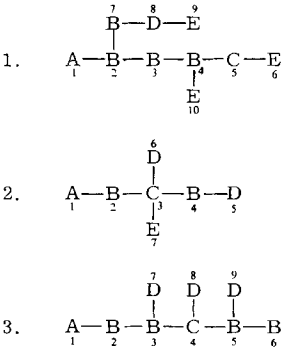
N-5.311. An *unbranched chain* of contraction nodes is numbered sequentially after the principal module whose seniority number is 1, according to **Rule N-5.1.**

Example:



N-5.312. In a branched module seniority graph, the *longest unbranched chain* of module seniority descriptors (the main chain) is numbered first according to **Rule N-5.311**, followed by the branches attached to the main chain, in order of decreasing seniority as given in **Rule N-5.313**, where necessary.

Example:



N-5.313. When, in a branched module seniority graph, two or more chains are of equal length, seniority numbers are first assigned to the unbranched chain in which the most senior contraction node is encountered at the first difference, the module seniority descriptors being compared term by term in order of seniority as defined in **Rule N-4.3**, regardless of their positions in the chain, and then in order of their position in the chain.

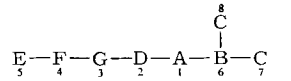
Examples:

N-5.314. *Branches* to the main chain of contraction nodes are numbered according to the following criteria which are applied successively as far as necessary in order to achieve a definitive numbering: (a) in order of decreasing length; (b) in order of seniority of the module seniority descriptors as defined in **Rule N-5.313**; (c) in order of the increasing numerical value of the seniority number for the contraction node to which the branch is attached in the part of the chain already numbered.

Examples:

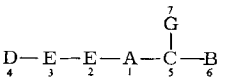
N-5.315. *Branched branches* of contraction nodes are numbered by following the procedures given in **Rules N-5.312** and **N-5.313.**

N-5.32. When two or more chains of contraction nodes are attached to the principal module, *module seniority numbers* are assigned to each chain in its entirety, as described in **Rule N-5.31**, before proceeding to the next.



Example:

N-5.33. *Module seniority numbers* are assigned to two or more chains of contraction nodes attached to the principal module in order of seniority according to the following criteria, considered successively until a definitive numbering is obtained:



a) Largest number of contraction nodes in the entire chain.

Example:

b) Longest unbranched chain of contraction nodes.

Example:

c) The most senior contraction node encountered at the first difference, the module seniority descriptors being compared term by term in order of seniority as defined in **Rule N-4.3**, regardless of their positions in each chain.
Example:

D—B—A—C—B (BC *not* BD)
5 4 1 2 3

d) The most senior contraction node having the lowest seniority number
Example:

B—C—A—B—C *not* B—C—A—B—C
5 4 1 2 3 3 2 1 4 5

(*BC not CB*, because 2 is lower than 3)

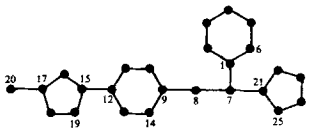
N-5.34. When a module seniority graph contains two or more modules of highest seniority, *i. e.* with module seniority descriptor = A, the *principal module* is that senior module to which is attached the most senior chain of contraction nodes, as determined by the criteria described in **Rule N-5.33.**
Examples:

a) A—A—B *not* A—A—B
1 2 3 2 1 3
(see Rule N-5.33a)

b) A—A—A (A at 4) *not* A—A—A (A at 4)
1 2 3 3 1 2
(see Rule N-533a)

c) C—B—A—A—B—C—D (D at 8) *not* C—B—A—A—B—C—D (D at 5)
7 6 1 2 3 4 5 4 3 2 1 6 7 8
(see Rule N-5.33b)

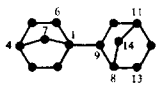
d) D—A—B—A—C *not* D—A—B—A—C
5 1 2 3 4 4 3 2 1 5
(ABA*C*, *not* ABA*D*, see Rule N-5.33c)



e) C—A—D—B—B—A—C *not* C—A—D—B—B—A—C
6 5 4 3 2 1 7 7 1 2 3 4 5 6
(*B*B, *not* *D*B, see Rule N-5.33d)

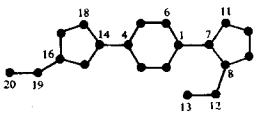
N-5.35. When the *numbering of the module seniority graph* is defined unambiguously by **Rules N-5.31** through **N-5.34,** an assembly is numbered by the procedure of **Rule N-5.1** applied to the modules in order of increasing numerical value of their seniority numbers.

Example (see the assembly illustrating **Rule N-5.2** above):



Module seniority graph: D—B—A—C—B (A at 1)
5 4 3 2 6

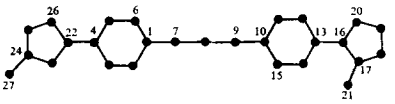
Module Seniority Number	Contraction Node Seniority	Number of Nodes	Module Locants	Assembly Locants
1	A	6	1—6	1—6
2	C	2	1—2	7—8
3	A	6	1—6	9—14
4	B	5	1—5	15—19
5	D	1	1	20
6	B	5	1—5	21—25



Tetracyclo[(06)1 : 7(2)8 : 9(06)12 : 15(05)17 : 20(1)-7 : 21(05)]pentacosanodane

N-5.4. When a *definitive order for numbering* the modules of an assembly cannot be determined by sole application of the principles of the module seniority graph **(Rules N-5.2** and **N-5.3)**[22], the correct order corresponds to the assembly descriptor that has the lowest locants defining the attachments of the modules. The set of lowest locants is the locant series having the lowest locant at the first point of difference when two or more series are compared term by term in order of appearance in each assembly descriptor.
Examples:

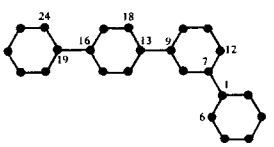
1. 



Tetracyclo[(06.1^{1,4})1 : 9(06.1^{1,4})]-tetradecanodane

Note: The descriptor [(06.1^{1,4})2:8(06.1^{1,4})] is not correct because the locant series for the module attachments *2,8* is higher than *1,9*.

2. 



Tricyclo[(06)1 : 7(05)8 : 12(2)4 : 14(05)16 : 19(2)]icosanodane

Note: The descriptor [(06)1:7(05)9:12(2)4:14(05)15:19(2)] for this assembly, whose seniority graph is C-B-*A*-B-C, is not correct because the locant series 1,7,*9*,12,4,14,15,19 is higher than 1,7,*8*,12,4,14,16,19.

3. 

Tetracyclo[(06)1 : 7(3)9 : 10(06)13 : 16-(05)17 : 21(1)4 : 22(05)24 : 27(1)]heptacosanodane

Note: The descriptor [(06)1:7(3)9:10(06)13:16(05)18:21(1)4:22(05)23:27(1)] for this assembly, whose seniority graph is D-B-*A*-C-*A*-B-D, is not correct because the locant series 1,7,9,10,13,16,*18*,21,4,22,23,27 is higher than 1,7,9,10,13,16,*17*,21,4,22,24,27.

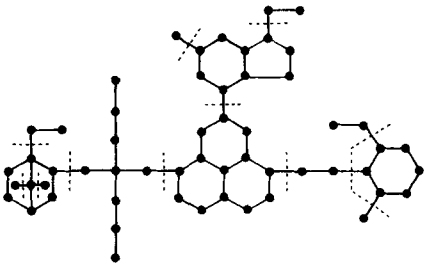
4. 

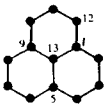
Tetracyclo[(06)1 : 7(06)9 : 13(06)16 : 19(06)]tetracosanodane

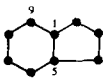
Note: The descriptor [(06)1:7(06)10:13(06)15:19(06)] is not correct because the locant series 1,7,*10*,13,15,19 is higher than 1,7,*9*,13,16,19.

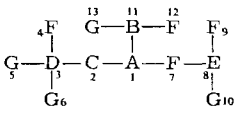
6. A Procedure for Deriving the Correct Numbering and Name of an Assembly

The concept of the module seniority graph (see **Rules N-5.2** and **N-5.3**) enables even very complex assemblies to be numbered and named with ease. We now illustrate a procedure that has worked well for us in numbering and naming assemblies. We have deliberately chosen a very complex assembly because it illustrates well the use of the module seniority graph, even though most assemblies normally encountered in chemical substances are much simpler.









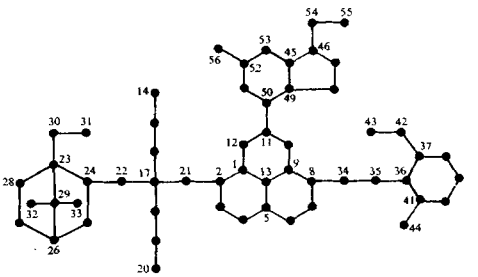


Fig. 1. Separation of an assembly into its modules.

Module Structure	Number of Nodes	Module Descriptor	Module Seniority	Module Seniority Number	Assembly Locants
	13	[012.1^{1,5}0^{9,13}]	A	1	1—13
	9	[7.1^{4}1^{4}]	C	2	14—22
	9	[09.0^{1,5}]	B	11	45—53
	7	[06.1^{1,4}]	D	3	23—29
	6	[06]	E	8	36—41
	2	[2]	F	4	30—31
	2	[2]	F	7	34—35
	2	[2]	F	9	42—43
	2	[2]	F	12	54—55
	1	[1]	G	5	32
	1	[1]	G	6	33
	1	[1]	G	10	44
	1	[1]	G	13	56

Module seniority graph:

Octacyclo[(012.1^{1,5}0^{9,13})2 : 21(7.1^{4}1^{4})22 : 24(06.1^{1,4})23 : 30-(2)29 : 32(1)29 : 33(1)8 : 34(2)35 : 36(06)37 : 42(2)41 : 44-(1)11 : 50(09.0^{1,5})46 : 54(2)52 : 56(1)]hexapentacontanodane

Fig. 2. Illustrative procedure for derivation of correct numbering and name of an assembly.

An assembly, such as the one shown on p. 897, is numbered and named in the following stepwise manner: (1) the assembly is separated into its modules as indicated in Figure 1; (2) the modules are sorted in order of decreasing number of nodes; (3) each module is numbered according to **Rule N-1, N-2,** or **N-3**; (4) the descriptor is derived for each module; (5) seniority is assigned to each module according to **Rule N-4.3;** (6) the seniority graph is drawn and the module seniority numbers assigned according to **Rules N-5.2** and **N-5.3**; (7) assembly locants are assigned by renumbering each module according to **Rules N-5.1** and **N-5.3**, or **N-5.4;** (8) the assembly locants are added to the structure of the assembly; (9) the assembly name is generated (see **Rule N-4.4**); and (10) the name is checked against the structure. This procedure is illustrated in Figure 2.

Nodal names are easily checked against the structure for accuracy. In the absence of the structure, nodal names provide a wealth of information about the structure. As in von Baeyer nomenclature, the descriptor portion of a nodal name contains all the information necessary to derive the structure; all the rest of the name, while essentially superfluous, provides a check on the descriptor and is also of value for listing in an alphabetical index.

Preliminary inspection of a nodal name provides much useful information that aids checking the name and in visualizing the structure. For example, inspection of the name [7.1^{4}1^4]nonanodane indicates: (1) the structure is acyclic since there is no "cyclo" term at the beginning of the name and no zero immediately precedes the first numeral of the descriptor; (2) the main chain consists of seven nodes and there are two one-atom branches attached to the fourth node; and (3) the total number of nodes is nine, obtained by summing the nonsuperscript numerals, which is confirmed by the term "nona" following the descriptor.

Similarly, inspection of the name bicyclo[06.1^{1,4}]heptanodane indicates: (1) the structure is cyclic because of the term "cyclo" before the descriptor and the zero immediately preceding the first numeral of the descriptor; (2) the structure consists of two rings, since there are two terms in the descriptor and the term "bi" precedes cyclo; and (3) the total number of nodes in the structure is seven, obtained by summing the nonsuperscript numerals of the descriptor, which is confirmed by the term "hepta" following the descriptor.

Such inspection is especially useful when checking the name of a complex assembly such as the one generated above (Fig. 2). From the assembly descriptor, we can see that there are eight rings in all, obtained by adding the number of nonsuperscript numerals in the module descriptors that begin with a zero (*i.e.*, 3+2+1+2); thus the numerical prefix "octa" to the term cyclo should be found in front of the assembly descriptor. By adding the values of all the nonsuperscript numbers, the total number of nodes in the structure is found to be 56 (*i.e.*, 12+1+7+1+1+6+1+2+1+1+2+6+2+1+9+2+1); this should correspond to the numerical prefix "hexapentaconta" which is found following the descriptor.

7. Deriving the Structure of an Assembly from its Name

Inspection of the assembly descriptor is also extremely valuable when deriving the structure of a complex assembly from its name. By using the following name,

Octacyclo[(012.1^{1,5}0^{9,13})2:21(7.1^{4}1^4)22:24(06.1^{1,4})23:30(2)29:32(1)29:33(1)8:34(2)35:36(06)37:42(2)41:44(1)11:50(09.0^{1,5})46:54(2)52:56(1)]hexapentacontanodane,

derived for the complex assembly given in Section 6, we can learn the following information by inspection of the descriptor: (1) the structure is an assembly of thirteen modules since

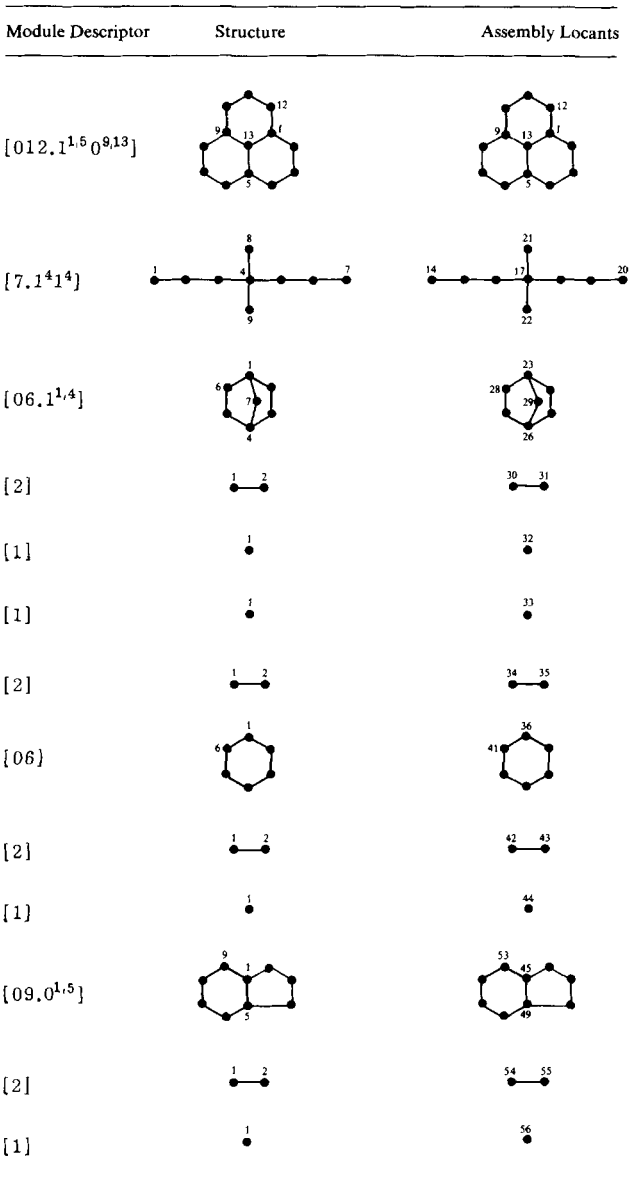

Fig. 3. Illustrative procedure for derivation of the structure of an assembly from its name.

there are thirteen descriptors, each enclosed in parentheses, in the total assembly descriptor defined by the square brackets; (2) four of the modules are cyclic since four module descriptors have a "zero" preceding the first numeral in the descriptor; (3) the assembly has a total of eight rings since the four modules defining cyclic structures have a total of eight terms and the prefix "octa" precedes cyclo in the name; (4) the assembly has nine acyclic modules, one of which is branched; and (5) the total assembly has 56 nodes, deter-

mined by summing all nonsuperscript numbers within the parentheses and confirmed by the numerical prefix "hexapentaconta" following the assembly descriptor.

The structure of this assembly may be derived from the name as follows: (1) each of the thirteen modules is drawn and numbered, according to its descriptor, in order of appearance in the name; (2) the assembly numbering is assigned to each module by adding to each locant the total number of preceding locants; (3) the modules are assembled in accordance with the locant sets for each pair of modules in the assembly descriptor; (4) the structure (see Fig. 2) is checked against the name as outlined above.

This procedure is summarized in Figure 3.

8. Conclusion

We have presented a comprehensive system for numbering and naming graphs of chemical compounds. The system can easily be adapted to naming chemical compounds and it avoids a number of shortcomings apparent in existing nomenclature systems. Not only does this system result in uniformity and a new approach for organic nomenclature, but it also provides new approaches for the nomenclature of complex coordination, inorganic, and biochemical systems. Future publications will delineate the application of this general system to specific types of compounds.

[6] The term "node" has been used for multivalent centers by *M. Gordon* and *W. B. Temple* in *A. T. Balaban:* Chemical Applications of Graph Theory, Academic Press, London, 1976, p. 312. This term was introduced by *J. J. Sylvester*, Am. J. Math. *1*, 64 (1878) as follows: "The conception of hydrocarbon graphs as 'trees with nodes, branches and terminals' ... [is] exclusively my own and [was] used by me in my communications with Professor Crum Brown on the subject and stated by me in a letter to Professor Cayley who has adopted [it] as the basis of his own isomerical researches". It should be noted that it is convenient in nodal nomenclature for the term "node" to include terminals, (*i.e.*, "univalent" centers) and for the term "graph" to be conceptually distinct from chemical structures with specified nodes and bonds.

[7] *K. Hirayama*, Tetrahedron Lett. *1972*, 2109—2112; *Th. Kauffmann*, Tetrahedron *28*, 5183 (1972).

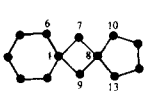
[8] As in the extended von Baeyer nomenclature system, the descriptor is sufficient, by itself, for the derivation of the structure in the nodal system.

[9] In contrast to classical organic nomenclature, all acyclic nodes not interrupted by cyclic nodes are treated together as one unit.

[10] The sum of the numbers denoting the lengths of the chains is equal to the total number of nodes and, since the locants for the attachment of chains are indicated by the superscript numbers, the descriptor itself is sufficient for deriving the structure. The same is true in the extended von Baeyer system currently in use.

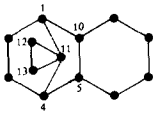
[11] Since the lengths of the branches are cited in the order of their numbering, *i.e.*, in order of decreasing length, the only difference occurs in the superscript locants (cf. **Rule N-3.4**).

[12] The multiplying prefixes are the same as given by **Rule A-2.5** in [1] and Table III, p. 142, in [2], except that the prefix "mono" is not used and—in accordance with the most recent recommendation of CNOC (see [24])—the prefix for twenty is spelled "icosa" rather than "eicosa".



[13] As indicated in Section 3, for convenience only, we are illustrating the principles of nodal nomenclature mainly with graphs derived from organic structures, and we are using the general ending "-ane" of classical hydrocarbon nomenclature. However, this is not meant to imply that nodal nomenclature is designed only for use in substitutive nomenclature. Because the ending "-nodane" could convey the concept of a fully hydrogenated parent system in substitutive nomenclature, the selection of another ending derived from the same root "nod" is under consideration for use in the most general applications of nodal nomenclature.

[14] To facilitate the comparison between nodal nomenclature and traditional organic nomenclature, most of these examples correspond to the acyclic hydrocarbons given in Section A in [1].



[15] In nodal names for monocyclic graphs, the prefix "cyclo" and the "zero" are mutually redundant, as are the Arabic numbers and the multiplying prefix. They are retained, however, in order to distinguish monocyclic modules from unbranched acyclic modules in assembly descriptors. Without the zero denoting the presence of a ring, a name such as "cyclo[(5)1:6(4)]nonanodane" is ambiguous: it could represent either "cyclo[(05)1:6(4)]nonanodane" or "cyclo[(5)1:6(04)]nonanodane".

[16] Thus, two rings joined only by a single common (spiro) atom do not, together, constitute a main ring, but form a main ring and a bridge.

[17] Occasionally, as shown in the examples below, a longer bridge is present, but cannot be numbered until after a shorter bridge has been numbered.

Tricyclo[06.$3^{1,1}4^{8,8}$]-tridecanodane

Tetracyclo[010.$1^{1,4}2^{11,11}0^{5,10}$]-tridecanodane

[18] The total number of terms in the descriptor of a polycyclic graph is the same as the number of rings and the sum of the nonsuperscript numerals is equal to the number of nodes in the total graph.

[19] Seniority order for polycyclic modules (**Rule N-4.3**) does not follow the method of selection for polycyclic descriptors (**Rule N-3.6**). Selection of the descriptor for polycyclic graphs follows the method used for numbering the structure. At each step, the numbering continues by the longest possible bridge attached to nodes with the lowest locants in the part of the graph previously numbered. As a consequence, all numerals representing either bridge lengths or locants are successively compared in their order of appearance in the descriptor, preference being given to the descriptor where, at the first difference, either the longest bridge or the lowest locant occurs. On the other hand, for selecting the senior module of an assembly, it seems to be more consistent with usual practice to compare first the bridge lengths and then, only if a choice remains, superscript locants. It should be noted that, in many cases, either method of selection will lead to the same result. Comments on this decision will be welcome.

[20] The number of rings in a polycyclic system is equal to the minimum number of scissions needed to convert the system into an acyclic structure (see **Rule A-32.12** in [1]).

[21] For some of these examples, the trivial or semisystematic name of the corresponding hydrocarbon is given and marked by an asterisk.

[22] Symmetry of the module seniority graph often precludes the determination of the correct order for numbering of the modules attached to the principal module, or the choice of the principal module from two or more modules of the same highest seniority.

[23] Selection rules for numbering the module seniority graph (**Rule N-5.3**) differ from those applied to acyclic graphs (**Rule N-1**) because module seniority graphs deal with constituent units (modules) which may greatly differ in structural complexity. Accordingly, rules for the module seniority graph take into consideration the nature of the contraction nodes, while, according to **Rule N-1**, the nature of the nodes does not affect the numbering of the graph.

Developments in Arylnitrene Chemistry: Syntheses and Mechanisms

New synthetic methods (31)

By B. Iddon, O. Meth-Cohn, E. F. V. Scriven, H. Suschitzky, and P. T. Gallagher[*]

Aryl- and heteroaryl-nitrenes can take part in intra- and intermolecular reactions in both of their possible electronic states (triplet and singlet). In this review we have endeavored to highlight recent synthetic uses of these reactive intermediates as well as draw attention to avenues open to further exploration in this field. Singlet arylnitrenes will interact with suitable *ortho*-positioned substituents to give a variety of fused azoles, some in excellent yield. In suitable solvents and in presence of amines and alcohols, phenylnitrenes undergo ring expansion to azepines which can also occur in nitrenes of certain fused bicyclic aromatics (naphthalene, quinoline, isoquinoline, benzo[*b*]thiophene). The latter nitrenes may also give rise to *o*-diamines which are useful starters for further heterocyclic synthesis. Triplet arylnitrenes (usually regarded as having only a nuisance effect in synthetic work) may also be utilized in practicable heterocyclic syntheses within a suitable molecular framework. Decomposition of aryl azides in a mixture of an organic and polyphosphoric acid leads to fused oxazoles. The mechanism is discussed for all the reactions considered.

1. Introduction

The study of nitrenes and nitrenoid intermediates has if anything been intensified over the last 10—15 years as is evident from the stream of publications, a recent monograph[1], and reviews[2] on the subject. It is not intended to duplicate any of the existing surveys or to present a comprehensive article on the whole field. Our aim is to deal concisely with the recent observations in the field of aryl- and hetarylnitrenes, to a large extent made in our own laboratories, and draw especial attention to the less recognized synthetic possibilities of these reactive intermediates in solution. Their chemistry in the gas phase is outside our domain and this fruitful field has been recently reviewed[2h].

Arylnitrenes are uncharged, electron-deficient, reactive intermediates possessing a sextet of electrons in their outer shell. Two of these electrons are located in a formal carbon-nitrogen single bond, two in a lone pair orbital, and the remainder may be arranged in either a spin paired configuration in a non-bonded orbital giving rise to an electrophilic

(1) Aryl–N̈ Aryl–N̈: *(2)*

singlet nitrene *(1)* or alternatively orthogonally and unpaired giving the biradical triplet nitrene *(2)*.

Arylnitrenes have been shown to have a triplet ground state by *Smolinsky et al.*[3] who recorded the low temperature ESR spectra of several triplet nitrenes.

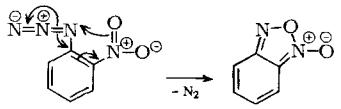
2. Generation of Arylnitrenes



Many methods have been described that give rise either to distinct arylnitrenes or to nitrene-like intermediates (nitrenoid used here in its generic sense). The latter type is equally useful for synthetic purposes and its participation is usually diagnosed from indirect evidence, such as the formation of typical nitrene products. We shall, however, only list those preparations that have at least some synthetic merit. The best approach is usually the thermal or photodecomposition of aryl azides in solution.

2.1. Thermolysis of Aryl Azides

Thermal decomposition of an aromatic azide *(3)* produces initially a singlet nitrene *(1)* because of spin conservation. Pyrolysis temperatures are usually in the range of 100—180 °C. With *ortho*-substituents, *e.g.* nitro-, phenylazo-, and carbonyl groups, the rate of decomposition is usually accelerated and the temperature of pyrolysis often lowered. *Dyall*[4] has proposed that the neighboring group participates in a pericyclic process [*(4)*→*(5)*] with little nitrene character developing, which in some cases leads to a heterocyclic ring such as furoxan.

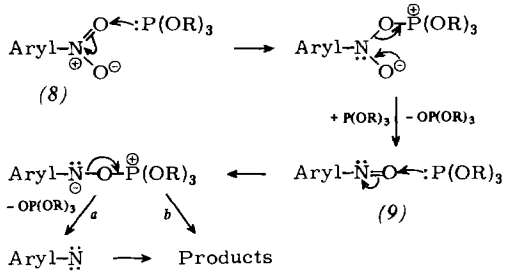
An extreme example of anchimeric assistance is the explosive formation of 3-phenyl-2,1-benzisothiazole *(7)* at room temperature from *o*-azidothiobenzophenone *(6)*[5] as shown.

(6) *(7)*

2.2. Photolysis of Aryl Azides

Reiser and *Marley*[6] have shown that the primary step in the photolytic decomposition of aryl azides is light absorption by the aromatic nucleus. This is followed by vibrational transmission of the absorbed energy to the azido moiety which decomposes to give a nitrene. Once excitation of the azido-group has occurred, four pathways[2g] are available for its decomposition either to singlet or to the less favorable triplet nitrene (Scheme 1).



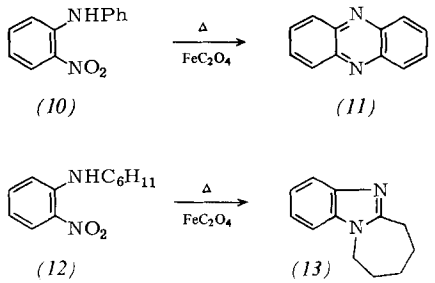
Scheme 1. Photolysis of arylnitrenes. ISC = intersystem crossing.

That the pathways *a* and *b* are followed was demonstrated by *Reiser* and *Leyshon*[7] who detected 12—13% of triplet nitrene when photolyzing phenyl azide. Sensitization can vary the ratio of products obtained from photolyses[8]. Singlet sensitized photolyses are believed to involve an electron transfer process, whereas triplet sensitization involves initial light absorption by the sensitizing agent which then sensitizes the azide directly to the triplet spin state. A marked effect on changing the sensitizing agent was observed by *Swenton*[9] who found that photolysis of 2-azidobiphenyl gave carbazole *(17) via* the nitrene *(31)* (71%) (see Section 3.1.1) whilst in the presence of acetophenone (a triplet sensitizer) the azobiphenyl (43%) was formed at the expense of the carbazole (8%). Conversely, photolysis in the presence of the triplet quencher piperylene reduced the formation of azo compound (4%) and stepped up the yield of carbazole (89%).

By the judicious use of sensitizers and solvents it is possible to form nitrenes in either the triplet or singlet states by photolysis[10–13], which is a useful way of controlling the nature of the product by way of the spin state.

2.3. Deoxygenation of Arylnitro- and Arylnitroso Compounds

Arylnitrenes are possible intermediates in the deoxygenation of arylnitro- *(8)* and arylnitroso compound *(9)* using tervalent phosphorus reagents *e.g.* R_3P or $(RO)_3P$. The evidence is based largely on the similarity of the nature and ratio of products in deoxygenation reactions to those found in the photolysis of aryl azides[14–18]. The position is, however, by no means resolved and a nitrene as well as a non-nitrene pathway can be envisaged (Scheme 2).



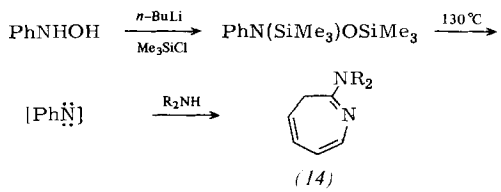
(8) *(9)*

Scheme 2. Deoxygenation *via* nitrenes (pathway *a*) and *via* the non-nitrene route (pathway *b*).

Thus, in the deoxygenation of 2-nitrosobiphenyl a charged intermediate involving both reactants was postulated to explain the kinetic data obtained[19] and further support for a non-nitrene pathway has been adduced from labeling experiments by *Brooke et al.*[20].

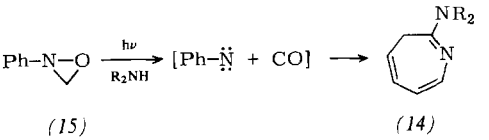
Arylnitroso compounds *(9)* deoxygenate rapidly at room temperature with tervalent phosphorus reagents but arylnitro compounds require usually prolonged reflux in solvents such as chlorobenzene or cumene.

Deoxygenation of nitro compounds has also been effected with ferrous oxalate. Thus, *o*-nitrodiphenylamine *(10)* was made to cyclize to give phenazine *(11)*[21], and *N*-cyclohexyl-*o*-nitroaniline *(12)* yielded a benzimidazole *(13)* by a non-nitrene route[22].



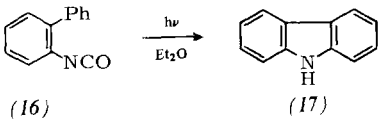
(10) *(11)*

(12) *(13)*



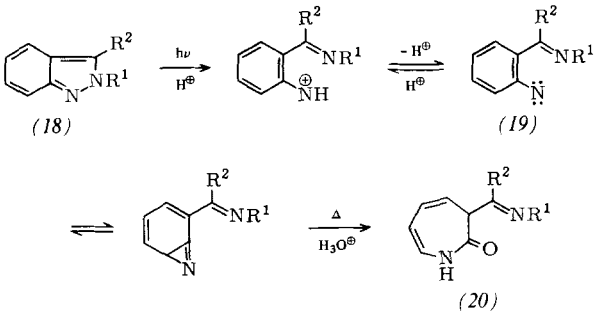
2.4. Miscellaneous Methods

A recently reported synthesis of 2-dialkylamino-3*H*-azepine *(14)* by thermal elimination of hexamethyldisiloxane from *N,O*-disilylated *N*-phenylhydroxylamine[23] gives the highest yield (95%) so far reported for an arylnitrene ring expansion to an azepine in presence of an amine. The scope of this method is undoubtedly restricted in view of the unavailability of arylhydroxylamines.



(14)

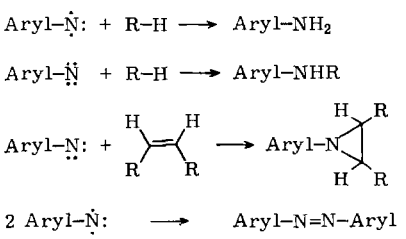
An arylnitrene intermediate is postulated in the photolysis of oxaziridines *(15)*[24] because azepines of type *(14)* are formed in the presence of amines. Also, irradiation of isocyanates such as *(16)* is reported[25] to yield occasionally carba-



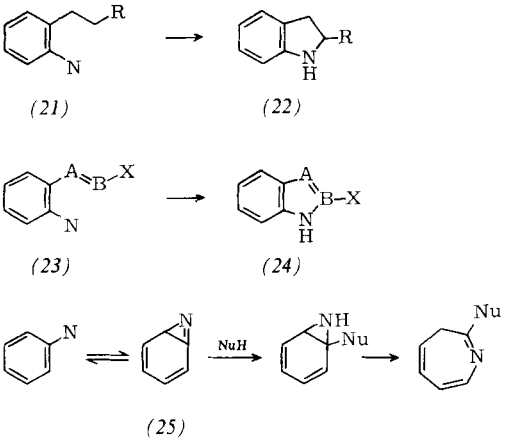
(15) (14)

zoles such as *(17)* which could be derived from an intermediate arylnitrene.

(16) (17)



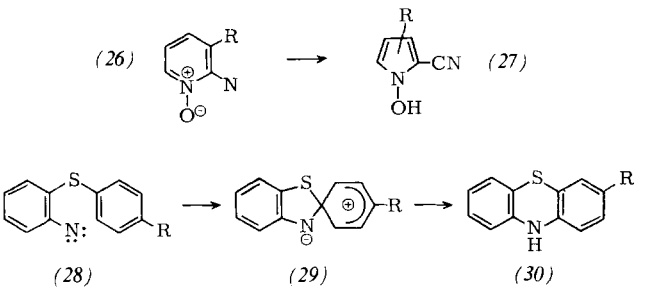
Finally, a recent synthesis of azepinones *(20)* from 2-substituted indazoles *(18)* was postulated[26] to proceed *via* an *ortho*-substituted arylnitrene *(19)* as shown.



(18) (19) (20)

3. Reactions of Arylnitrenes

Reactions of nitrenes can be discussed under various headings, for instance (a) "intermolecular" and (b) "intramolecular". The former is exemplified by abstraction of hydrogen from the solvent to give an amine, insertion into a single bond (usually C—H), or addition to a multiple bond (rare for arylnitrenes) or a formal dimerization to an azo compound.

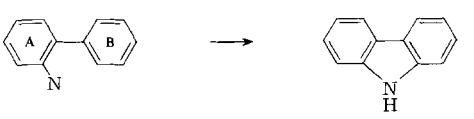


"Intramolecular" reactions [type (b)] involve cyclization onto an *ortho*-substituent or a saturated [*(21)*→*(22)*] or unsaturated side-chain [*(23)*→*(24)*] giving rise preferentially to five-membered nitrogen heterocycles. This behavior constitutes one of the most important synthetic applications of arylnitrenes because of its scope. Alternatively, an arylnitrene can interact with its own ring to give an azirine such as *(25)* which in the presence of a suitable nucleophile (NuH) ring-expands to an azepine or sometimes ring-opens in polycyclic nitrenes to an *ortho*-substituted amine. We shall show that these reactions are also of considerable synthetic utility.

(21) (22) (23) (24) (25)

Other less common observations are that certain nitrenes, *e.g.* those derived from 2-azidopyridine 1-oxides[27] ring-contract leading to 1-hydroxy-2-pyrrolecarbonitriles [*(26)*→*(27)*] or that aryl 2-(arylthio)arylnitrenes *(28)* undergo rearrangement to phenothiazines *(30)*[2f,28] (nitrenes with other bridges often reacting in an analogous way, cf. *(46)*).

(26) (27) (28) (29) (30)



An alternative to the above classification of nitrene reactions is to consider the chemistry of the singlet and the triplet species separately, both of which can partake in inter- and intra-molecular reactions. We shall present our discussion substantially on this basis, which we feel will best illustrate the synthetic versatility of arylnitrenes.

3.1. Singlet Nitrene Reactions

Singlet arylnitrenes are sluggish electrophiles on the nitrene scale of reactivity and only with strongly electron-withdrawing groups present does the full spectrum of reactions observed with the aliphatic ethoxycarbonylnitrene show up. However, some general reactions are now of wide application and importance.

3.1.1. Intramolecular Cyclization Yielding Five-Membered Rings

The archetype of this reaction is the well-known synthesis of carbazole *(17)*[1]. This reaction is unique in the arylnitrene field, in that high yields of products are obtained irrespective of the nature or position of substituents (except that nitro- or cyano groups *ortho* to the nitrene-precursor group divert the

(31) (17)

reaction to give products of non-nitrene pathways). Furthermore, ring B of the biphenyl may be replaced successfully by electron-rich (*e.g.* thienyl, furyl, or mesoionic) or electron-poor (*e.g.* pyridyl, benzothiazolyl, or benzimidazolyl) rings or even by alkene (—CH=CHR) or Schiff base (—CH=NR) moieties to give the corresponding heterocycles. A wide range of ring-systems (*e.g.* thienyl, benzo[*b*]thienyl, or pyridyl) have replaced ring A with equal facility. Some typical examples are shown in Table 1, the majority of the reactions proceeding in high yield. Other examples will be found in the literature[40–44].

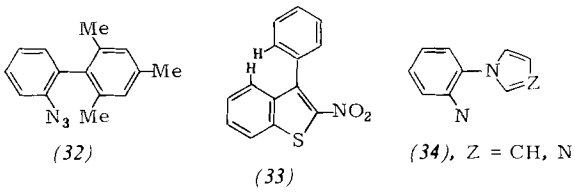


Table 1. Some recent analogues of the carbazole reaction. The site of nitrene attack is shown in bold print.

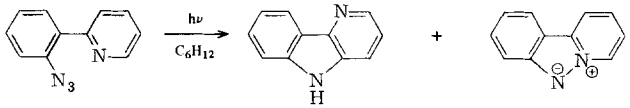
		X, Z	[1, 30]	(Benzo)-thienoindole
		X, Z	[40]	Benzo-thienopyrrole
		X, Z	[30]	Benzo-thienoindole

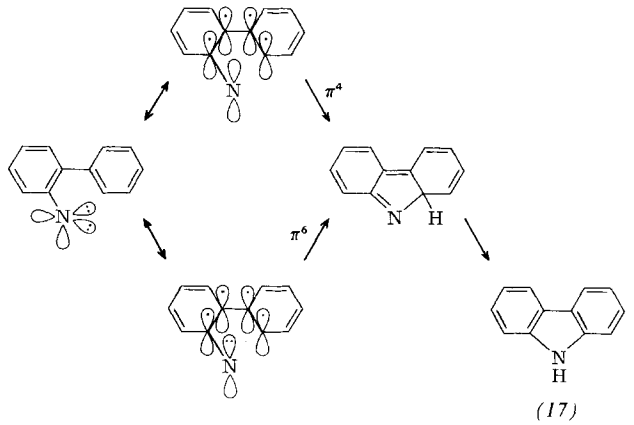


[a] X: thermolysis of azide, Y: photolysis of azide, Z: deoxygenation of nitro compound.

Very few limitations have been observed for this reaction. These include (i) steric limitations such as in the biphenyl *(32)*[29] and the *peri*-interaction effect in *(33)*[30]; (ii) the presence of a "bridgehead" nitrogen in ring B [*e.g. (34)*][29b]; and (iii) the action of added nucleophiles (*e.g.* diethylamine) which may divert some of the nitrene to yield an azepine.

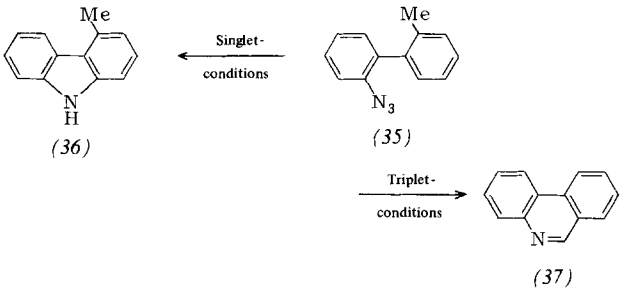
(32) *(33)* *(34)*, Z = CH, N

As well as the above factors, the course of the reaction is dependent upon (i) the reaction temperature (for both thermal *and* photolytic methods)[31,29b]; (ii) the solvent (particularly in the case of photolyses); and (iii) the wavelength of the light used[32]. Thus, the highest temperature commensurate with product stability has been recommended for thermal decomposition of azides[31] (2-azidobiphenyl gave 100% yield of carbazole *(17)* at 360 °C in liquid paraffin solution[29b]). On the other hand, it is often advantageous to photolyze azides at ≈ 107 °C (below their thermal decomposition temperature) to optimize yields[31]. Two types of solvent effects have been noted; the "heavy atom" effect during both thermal and photochemical routes causes a small increase in triplet-derived products (*e.g.* the amine or azo compound corresponding to the azide) at the expense of carbazole[29b]; more dramatically, triplet photosensitization using ketones such as acetophenone totally alters the reaction pathway (see Section 3.2.1). Little has been reported on the influence of the wavelength of the light used during photolyses but a good example of this unexplained phenomenon is shown in Scheme 3, where the usually noted preference for attack at a ring nitrogen is diminished at shorter wavelength[32].



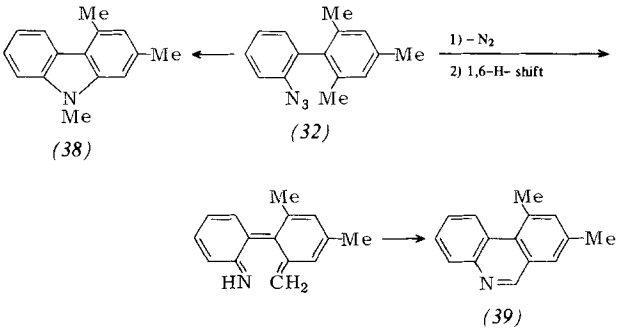
λ = 254nm	36%	61%
λ = 350nm	15%	80%

Scheme 3. Influence of wavelength in photolysis.



Despite much early evidence in support of a triplet-nitrene pathway to carbazoles (including matrix isolation[45] and flash photolysis studies[46]), it is now clear that this reaction is characteristic of a singlet nitrene[47,29b]. The above data speak strongly for a concerted (π^4 or π^6 depending upon whether an empty or full orbital of the singlet nitrene is utilized[*]) low-energy route, capable of accommodating substituent effects by choice of the appropriate nitrene orbital, but being very sensitive to steric effects (which limit ring coplanarity) and to "bridgehead" heteroatoms (which interfere with the concertedness of the process by requiring higher-energy dipolar transition states and intermediates). *Sundberg*[47c] has elegantly demonstrated that the lifetime of the

[*] *Wentrup* [48] has recently also drawn attention to the importance of this dual role of singlet carbenes and nitrenes in his vapor-phase work, and he underlines the consequent electrophilic or nucleophilic property of the nitrene that this duality implies.



(17)

species supposed to be the triplet nitrene noted above, does not conform to the time-scale of the carbazole-forming reaction, and that the competitive conversion into an azepine in the presence of added amines[47] speaks for the singlet nitrene. We have also noted a choice of pathways for 2-azido-2'-methylbiphenyl *(35)* when singlet and triplet nitrene-forming conditions are chosen leading to carbazole *(36)* or phenanthridine *(37)* respectively (Table 2), again supporting

(36) (35) (37)

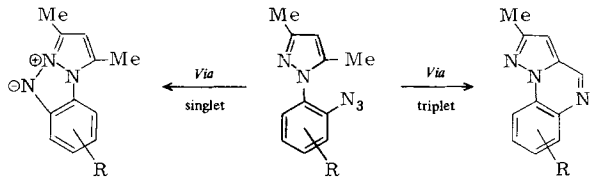
[a] "Heavy atom effect". [b] Triplet photosensitizer.



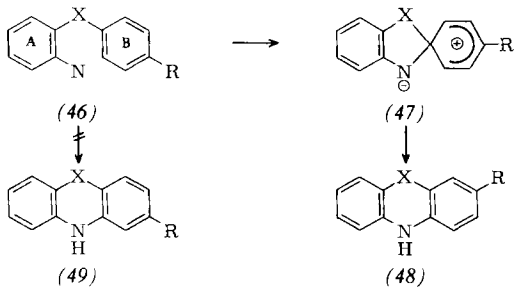
the contention that the triplet nitrene does not lead efficiently to carbazole[29b,31]. A similar competitive study of the products derived from thermal decomposition of the azide *(32)* at various temperatures was also revealing. At temperatures high enough to facilitate coplanarity of the two phenyl rings, formation of the carbazole *(38)* did not increase beyond 8% but an alternative singlet-nitrene mediated, concerted pathway to the phenanthridine *(39)* was observed instead, as indicated by the diminution of the typical triplet products (the 2-aminobiphenyl *(32)*, NH_2 in place of N_3) with increase in yield of the phenanthridine as the temperature of reaction was raised[31].

Examination of Table 2 demonstrates that the site of ring-closure may be carbon or nitrogen, and that the latter site, being nucleophilic, is preferred where a choice exists. Despite much effort, almost no successful attack at sulfur (either intra- or inter-molecular) by an arylnitrene has been noted. The more electrophilic sulfonylnitrenes have been long known to yield sulfoximides, for example in dimethyl sulfoxide[49a], as does pentafluorophenylnitrene[49b]. However, as well as those cases recorded in Table 2 no trace of attack at sulfur was noted in the three azides *(40)*, *(41)*, and *(42)* under a wide variety of conditions[29b,31,50].

(40) (41) (42)

Apart from the carbazole-type reaction, which clearly involves a very low activation energy for ring-closure, nitrene cyclizations are often sensitive to substituent effects. Thus, the pyrazole *(43)* which has a choice of both singlet or triplet cyclization routes, yields solely the singlet product *(44)* when electron-withdrawing substituents (Cl, CF_3, NO_2) are *meta* to the azide group. When similar *para* substituents (Cl, Br, CF_3) are present the ylide *(44)* (57—70%)[38] is the main product.

(44) (43) (45)



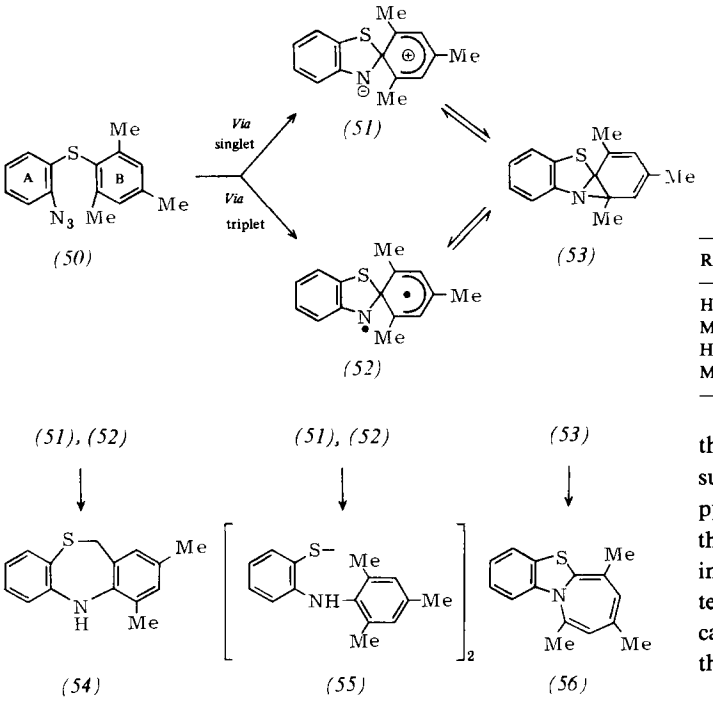
However, when electron-releasing groups conjugate with the nitrene (OMe, NMe_2), and thus reduce its electrophilicity, no singlet product is isolated, the pyrazoloquinoxaline *(45)* being formed by radical coupling[38].

3.1.2. Intramolecular Cyclization Yielding Six-Membered Rings

One of the peculiarities of nitrene cyclizations is their propensity to prefer five-membered rather than six-membered ring formation. Indeed, many reactions included in this chapter occur initially by formation of a five-membered ring followed by rearrangement.

A typical reaction of this type is depicted *(46)*→*(48)*. Reaction involving initial formation of a dipolar spirodiene *(47)* from a nitrene *(46)* results in a phenothiazine *(48)* by a Smiles-type rearrangement which has been studied extensively by *Cadogan et al.*[28,51,21]. The substituent acts as a la-

bel for indicating the nature of the rearrangement since the expected product would be *(49)*. The variations of the bridge X are also indicated.



X = S, O, NAc, CH_2, CO, SO_2

(46)-(48), X = S ≡ *(28)-(30)*

This reaction is unique for nitrenes because conditions that favor formation of singlet or triplet nitrenes can give rise to the same products, the variation in the ratio of the products being delicately dependent on the reaction temperature and solvent as demonstrated for the azide *(50)* (Table 3).

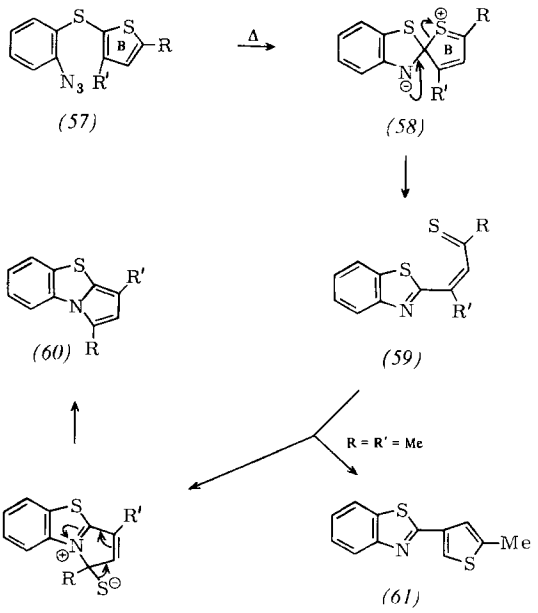


Table 3. Dependence of product ratio upon conditions of reaction of the azide *(50)*.

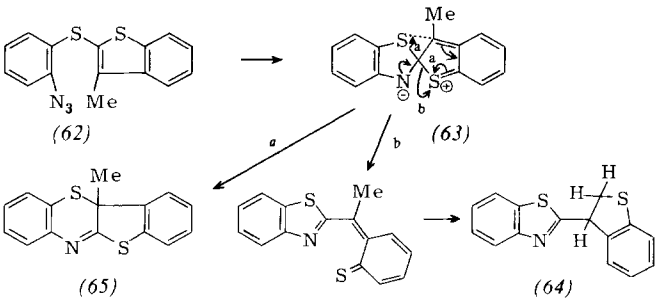
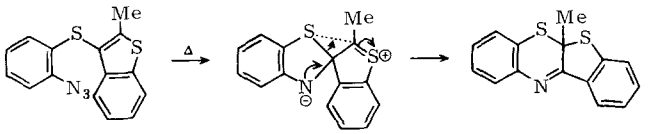
Conditions	*(54)* [%]	*(55)* [%]	*(56)* [%]	Ref.
Δ/Decalin/180 °C	45	33	0	[51c]
Δ/PhBr/154 °C	50	17	6	[52]
hν/PhAc/20 °C	Trace	28	20	[52]
hν/PhAc/107 °C	14	45	20	[53]



We rationalize these results by the equilibria shown and further underline this delicate balance by noting that introduction of a chloro substituent *para* to the azido group (which we find increases efficiency of both singlet and triplet reactions) gives the corresponding disulfide of type *(55)* (51%) and azepinobenzothiazole of type *(56)* (48%) on photolysis in acetophenone at 20 °C. The phenothiazine reaction itself *[(46)→(48)]* is also more efficiently brought about by photolysis in a hot (107 °C) acetophenone solution. Thus, 2-azido-4'-methyldiphenyl sulfide gives double the yield of the phenothiazine (69%)[53] compared to the thermal[51c] route[*].

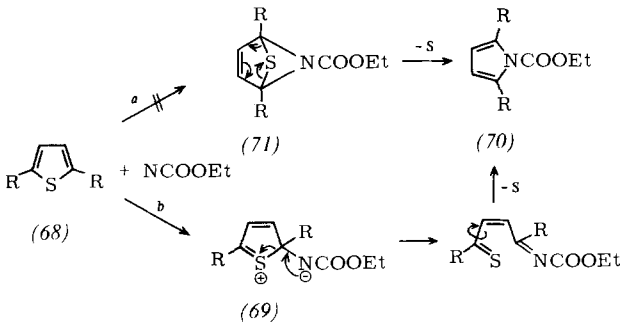
An interesting variant of the phenothiazine reaction derives from replacing the B ring in *(46)* by a heterocycle. When this ring has a heteroatom α to the site of nitrene attack [*e.g.* as in *(57)*] the *spiro* intermediate *(58)* becomes an ortho-ester analogue and is thus prone to fission of ring B [*e.g.* to *(59)*] rather than rearrangement. In the case of the

R	R'	*(60)*, [%]
H	H	23
Me	H	19
H	Me	65
Me	Me	74



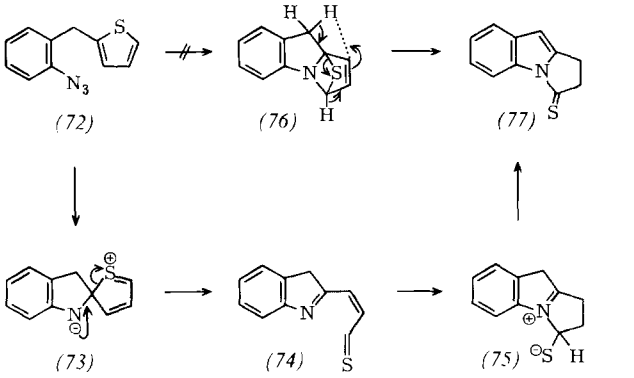
thiophenes *(57)* a highly reactive intermediate *(59)*[**] is presumably formed which cyclizes to the hitherto unreported pyrrolobenzothiazole *(60)*, but which may also give a little 2-thienylbenzothiazole *(61)* when R' = Me[54]. The corresponding benzothiophene *(62)* yields a spirodiene *(63)* in which the tendency for rearomatization of the ring B is a major factor, causing formation of both a benzothiazole *(64)* and a benzothiazine *(65)* derivative in about equal amounts[55].

[*] It is, however, possible that a different mechanism may operate in hot acetophenone solution.



[**] Despite much effort, we have not yet been able to trap these intermediates.

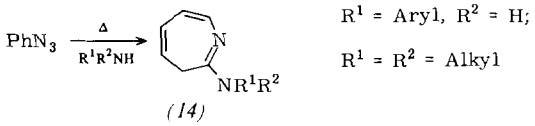
The 2-azidophenyl benzothienyl sulfide *(66)* isomeric to *(62)*, not surprisingly, gives an almost quantitative yield of the benzothiazine *(67)* with no ring-fission products since the ortho-ester-like spiro intermediate of type *(63)* cannot form in this case[55].



(66) *(67)*

The tendency of nitrenes to react as an electrophile as evidenced by the intermediate spiro system (see above) encourages us to reinterpret certain reported reactions such as the action of ethoxycarbonylnitrene on thiophenes *(68)* as an electrophilic attack at position 2 of the thiophene ring in *(69)* followed by a ring-opening/ring-closure process (path *b*) leading to the pyrrole *(70)* rather than the unprecedented 1,4-addition *via (71)* previously suggested[56].

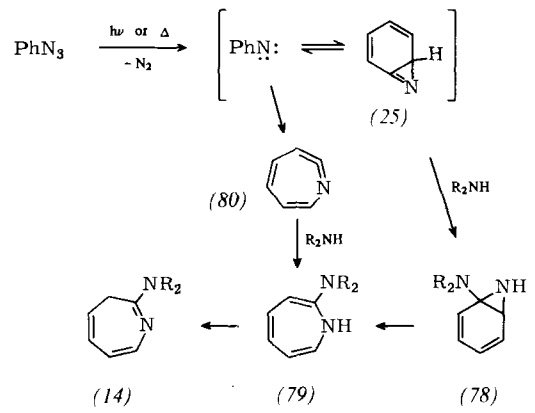
(68) *(69)* *(71)* *(70)*



(72) *(76)* *(77)* *(73)* *(74)* *(75)*

An analogous interpretation which involves the intermediates *(73)*, *(74)*, and *(75)* rather than *(76)* as suggested[57] appears to us also more plausible for explaining the product *(77)* derived from 2-azidobenzylthiophene *(72)*.

3.1.3. The Singlet-Nitrene⇌Benzazirine Pathway



In 1912 *Wolff* thermolyzed phenyl azide in aniline and isolated from the reaction product a crystalline base in small yield which he called "dibenzamil"[58]. The structure of dibenzamil remained uncertain for nearly fifty years (although an incorrect structure found its way into a textbook[59]) until *Huisgen* assigned to it an azepine structure and rationalized the mechanism of its formation[60]. The 3*H*-azepine was confirmed by NMR[61] and photolysis of phenyl azide in aliphatic amines was also shown to lead to ring expansion[3] (Scheme 4).

(14)

Scheme 4. Ring expansion of phenyl azide to azepines.

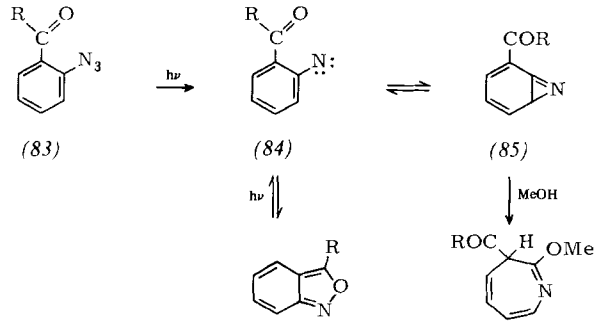
The accepted mechanism of this ring expansion is considered to involve unimolecular loss of nitrogen[60,61] leading to the formation of the equilibrium mixture singlet nitrene ⇌ benzazirine *(25)*. The benzazirine undergoes nucleophilic attack in the presence of an amine to give an aziridine *(78)* which yields ultimately a 3*H*-azepine *(14)* *via* a 1*H*-azepine intermediate *(79)*[62a].

(25) *(80)* *(14)* *(79)* *(78)*

An alternative mechanism to the benzazirine pathway was put forward recently[62b]. It was observed that irradiation of phenyl azide in an argon matrix at 8 K gave a new photoproduct to which the structure of 1-aza-1,2,4,6-cycloheptatetraene *(80)* was assigned on the basis of infrared data. It was suggested that *(80)* could feasibly react with nucleophiles such as R_2NH to give a 3*H*-azepine *(14)*. It remains, however, to be seen whether this alternative singlet nitrene route is relevant for reactions at room temperature and applies to the interpretation of other photoproducts such as *o*-diamines and azepines derived from fused bicyclic arylnitrenes (see below).

The success of the azepine reaction was found to be dependent upon the substituents in the benzene ring. For instance, thermolysis of *p*-anisyl azide[63] and *p*-nitrophenyl azide[60] in aniline gives no detectable azepines. Recently it has been found that irradiation of phenyl azide in triethylamine also yields the azepine *(14)*, R = Et[65].

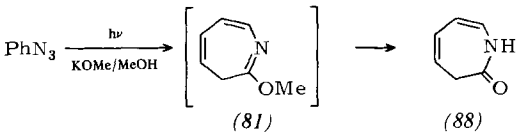
The use of oxygen and sulfur nucleophiles has not proved as rewarding as that of amines in promoting ring expansion to azepines. Photolysis of phenyl azide in methanol[64] or in hydrogen sulfide/diethyl ether[61] has been reported to give a very modest yield of the azepines *(81)* and *(82)*, respectively.



Very much better yields of azepines are obtained when aryl azides of type *(83)* bearing an *o*-carbonyl substituent are photolyzed in methanol (or other alcohols)[66]. This effect

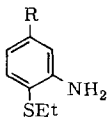
may be attributable to coordination of the singlet nitrene by the carbonyl group, suppressing intersystem crossing to trip-

(81) (82)



let nitrene and consequently promoting attack by the weak nucleophile methanol [(85)→(86)]. It is noteworthy that anthranils (87) also yield azepines on photolysis in methanol[67].

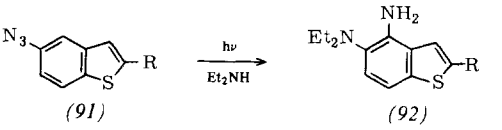
(83) (84) (85) (87) (86)



R = OMe, OPh, NHPh, NH_2 40-80%

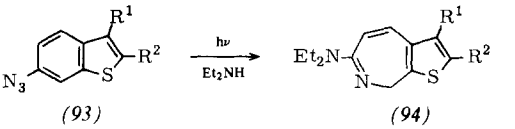
Increase in the strength of the nucleophile provides another method of raising the yield of azepine. For instance, *Rigaudy et al.*[68a] reported that photolysis of 2-naphthyl azide and 2-anthryl azide in the presence of concentrated potassium methoxide in methanol gives the corresponding azepines. We found that photolysis of phenyl azide under these conditions affords 1*H*-azepin-2(3*H*)-one (88) (32%), presumably *via* 2-methoxy-3*H*-azepine (82), which undergoes hydrolysis during work-up[68b]. Carrying out the above procedure in the presence of a small amount of [18]crown-6 ether raises the yield of (88) to 48%[68b].

(81) (88)



Photolysis of phenyl and *p*-tolyl azide in ethanethiol does not give azepines; instead the anilines (89) and (90) are the major products[69]. Thermolysis of phenyl azide in benzenethiol was found to give *o*-aminodiphenyl sulfide. The formation of this product was attributed to aromatic substitution of phenylthio radicals[70]. *Sundberg* and co-workers have deox-

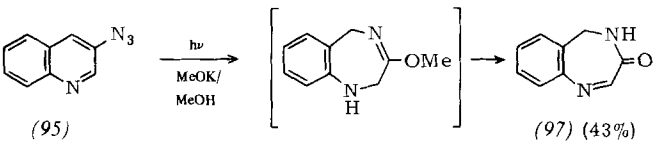
(89), R = H
(90), R = Me



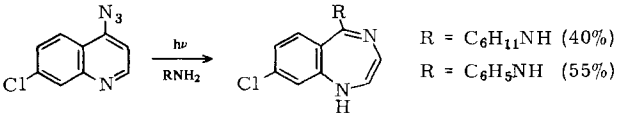
ygenated nitrosobenzene in methanol and obtained substituted anilines rather than azepines, by a route which was considered to involve nucleophilic attack on a phosphorus intermediate[64,71].

The potential synthetic application of the above ring expansion reactions (Scheme 4) to the synthesis of benzazepines from aromatic bicycles was appreciated early by *Huisgen*. On thermolysis of naphthyl azides in aniline only naphthylamines and tars[60b] were produced, which is typical of involvement of a triplet nitrene. More recently a series of bicyclic aromatic azides has been decomposed successfully in our laboratories to give bicyclic azepines. While photolysis of 5-azidobenzo[*b*]thiophenes (91) in diethylamine using a high pressure mercury lamp with a pyrex filter, gave *o*-diamines

(91) (92)



R = H (24%); R = CO_2Et (43%)



(93) (94)

$R^1 = R^2$ = Br (22%); R^1 = H, R^2 = CO_2Me (34%)

(92) in fair yield but no ring expansion[72] similar treatment of 6-azidobenzo[*b*]thiophene (93) led to the ring-expansion product thienoazepine (94). This represented the first example of a bicyclic aromatic azide undergoing ring enlargement to give a novel heterocyclic system; some derivatives of (94) showed biological activity[73]. Irradiation of the 4- and the 7-azidobenzo[*b*]thiophene under similar conditions merely gave the corresponding amines, presumably *via* the triplet nitrene[72,74]. We also obtained the 1,4-benzodiazepines (97) and (98), (99), and (100) by photolysis of 3-quinolyl azide (95) and 7-chloro-4-quinolyl azide (96) in the presence of methoxide ions or amines[75]. Recently[76] 1,3,5-triazepines were obtained by photolysis of various azidouracils which are, however, vinylic rather than heteroaromatic azides.

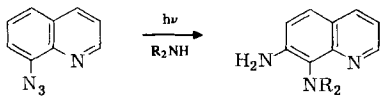
(99) (50%) (100) (20%)



A variety of bicyclic aromatic azides has been photolyzed in diethylamine and other secondary amines to give the appropriate *o*-diamines in most cases and an azepine in a few: 1- and 2-naphthyl azide[77,78a], 3-, 4-, 5-, 6-, 7-, and 8-quino-

lyl azide[77,79] (2-quinolyl azide forms a stable tetrazole), 4-, 5-, 6-, and 7-indolyl azides[80], 4-, 5-, 6-, and 7-azidobenzo[*b*]thiophenes[72–74] and 6-azidobenzothiazole[74] (giving 7-amino-6-diethylaminobenzothiazole in 33% yield) are among them.

A few guidelines arising from the above results may be more helpful to gauge the synthetic scope and limitation of the reaction involving bicyclic arylnitrenes with secondary amines than giving a comprehensive list of the products and yields obtained so far.

"β-Azido compounds" ("β" referring to the benzene ring) generally yield *o*-diamines in fair to excellent yields. With "α-azido compounds" *o*-diamines are not usually formed, but instead low yields of the corresponding amines and tars are produced. An exception is 8-quinolyl azide *(101)* (an α-azide) which gives high yields of *o*-diamines with most common secondary aliphatic amines (Table 4). It appears to hold that the larger the attacking secondary amine the lower the yield of *o*-diamines, probably due to steric hindrance. Carrying out these photolyses with a small amount of TMEDA (tetramethylethylenediamine) results in an increased yield of *o*-diamines (Table 4)[79].

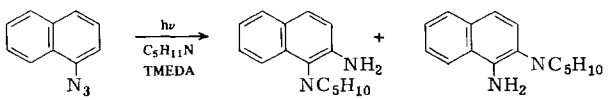


Table 4. Photolysis of 8-quinolyl azide *(101)* in secondary amines.

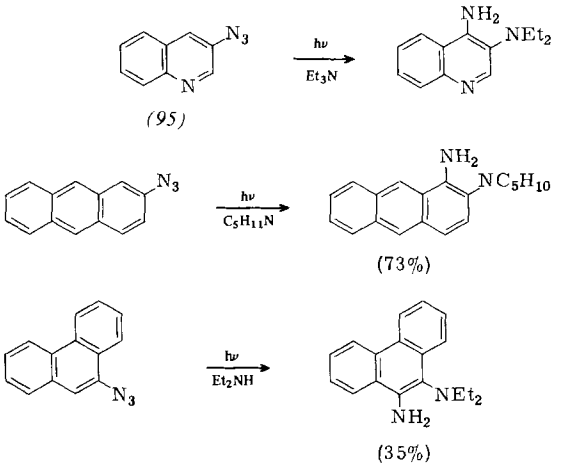
(101)



R_2NH	Yield [%]
Diethylamine	86
Pyrrolidine	36
Piperidine	47
Piperidine + Tetramethylethylenediamine (TMEDA)	60

Photolysis of 1-naphthyl azide *(102)* in secondary amines leads to a small yield of 1-naphthylamine, azonaphthalene, and tars; however, in piperidine with TMEDA as a co-solvent the nature of the products unexpectedly changes to a mixture of isomeric *o*-diamines *(103)* and *(104)*[77]. The size of the amine does not affect the yield of *o*-diamines from 2-naphthyl azide photolysis, probably because attack occurs at a β-position[81]. Triethylamine and dioxane have been found to be as efficient as TMEDA in promoting these reactions. Triethylamine can itself behave as the nucleophile in some cases, as with 3-quinolyl azide *(95)*[79]. Some tricyclic aromatic azides, such as 2-anthryl azide and 9-phenanthryl azide can also be converted into the respective *o*-diamines on irradiation in the presence of secondary amines[78b].

(102) *(103)* (50%) *(104)* (25%)

Unexpectedly, bicyclic α-aryl azides can be made to give azepines on decomposition in primary aliphatic amines. Thus, photolysis of 8-quinolyl azide *(101)* in cyclohexylamine was found to give mainly ring-expansion to an azepine *(108a)* rather than just the expected *o*-diamine *(109a)* (cf. Table 4)[82]. The yields of azepine and diamine can be optimized by varying the ratio of primary amine to TMEDA used as solvent. Several other α-azidobicyclic arenes also undergo this reaction, but β-azidobicyclics have so far only been found to give *o*-diamines (Table 5).

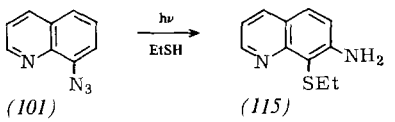
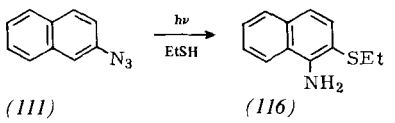
As previously mentioned, *Rigaudy* and co-workers[68a] have found that irradiation of 2-naphthyl azide *(111)* in 3 M KOMe/MeOH/dioxane gives either a high yield of methoxyazepine *(112)* or *o*-methoxyamine *(113)*, respectively. Recently, we found that various α-azidobicyclics also undergo this reaction in high yield; for instance, 8-quinolyl azide *(101)* yields the methoxypyridoazepine *(114)*[83].



(112) (111) (113)



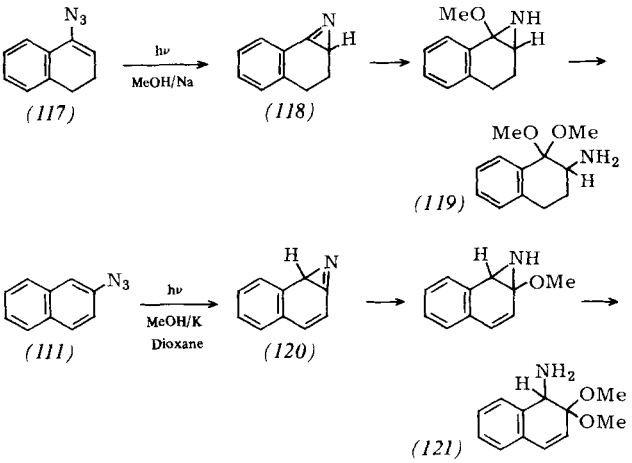
(101) (114)

Little work has been done on the decomposition of bicyclic aromatic azides in alkanethiols. In the few cases studied, ring expansion has not been observed but *o*-amino thioethers *(115)* and *(116)* were formed from *(101)* and *(111)* in the the presence of ethanethiol.

(101) (115)

(111) (116)

Certain principles summarized below are emerging from the above results which should be borne in mind in any synthesis utilizing arylnitrenes.

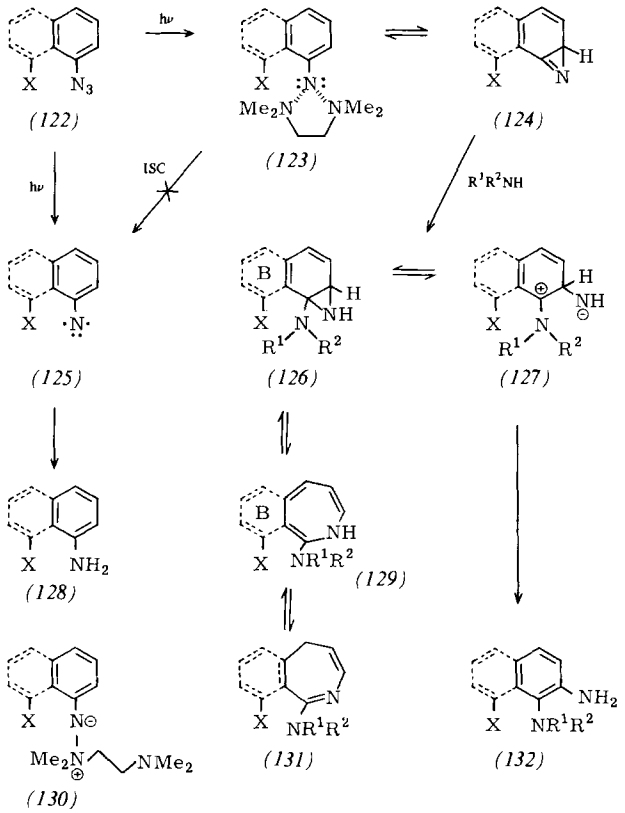


Factors that influence the overall yield of singlet nitrene derived products: These devolve mainly upon stabilizing the singlet nitrene which is believed to be in equilibrium with a benzazirine [such as *(25)*] to prevent intersystem crossing to triplet nitrene. This may be done in three ways: (a) carrying out nitrene reactions in co-solvents with lone pairs, *e.g.* TMEDA[77], dioxane[68], THF[84], triethylamine[79], and dichloromethane. (b) Intramolecular stabilization by an *ortho*-substituent, *e.g.* CO_2Et[66,67]. (c) Intrinsic stabilization by substituents *e.g.* electron-withdrawing groups in the second ring appear to lead to an increase in yields of products attributed to azirine intermediates[73,74].

Azepine versus o-diamine formation: Azepines are thought to be the products of kinetic control and so any stabilizing features they possess should promote their formation. In all the azepines prepared so far from bicyclic compounds by ring expansion of arylnitrenes the following points were observed: (a) the annelated aromatic ring always undergoes rearomatization; (b) the saturated C-atom (or N-atom) in the azepine always appears next to the ring junction; (c) considering azides of naphthalene and heteronaphthalenes: an amidine unit is incorporated into the azepine if possible. α-Azides with *primary* amines give azepines and *o*-diamines and yields may be optimized using a co-solvent (cf. Table 5)[82]. α-Azides with *secondary* amines give the corresponding parent amine. β-Azides give *o*-diamines with *primary* and *secondary* amines. α- and β-Azides give azepines or *o*-methoxyamines with methoxide/methanol/dioxane depending upon reaction conditions[68a]; considering azides of indene and heteroindenes: the products from these reactions cannot be as clearly delineated because of lack of examples. Generally, α-azides give the corresponding parent amine with secondary amines (*i.e.* the triplet product) while β-azides give mainly *o*-diamines with *secondary* amines and frequently a small yield of azepine. The behavior towards primary amines is being investigated.

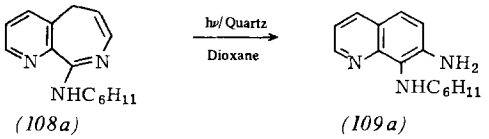
Some mechanistic aspects relating to the photolysis of bicyclic aryl azides in nucleophilic solvents leading to the formation of bicyclic azepines and/or *o*-diamines are appropriately considered as an extension of the above guidelines.

Both products, azepines and *o*-diamines originate initially from addition of the nucleophile to the azirine intermediate which has so far defied isolation. However, indirect evidence goes some way to support its involvement.



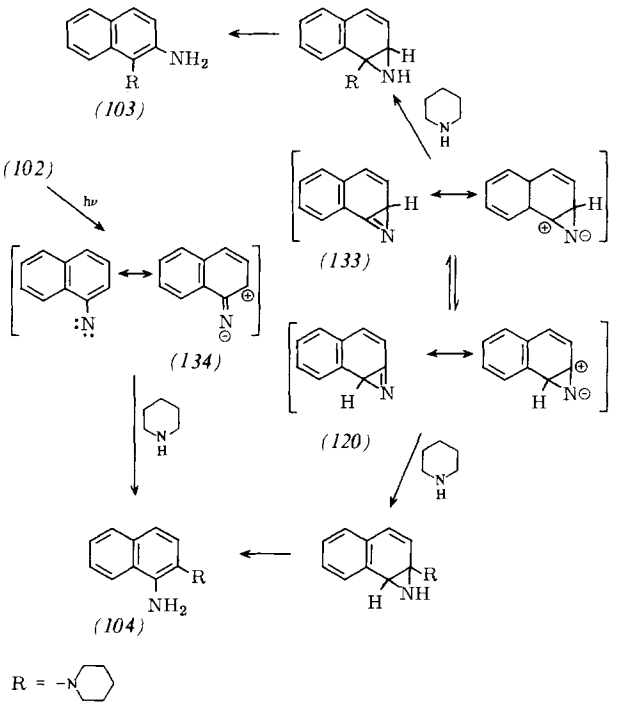
Abramovitch was the first to suggest a singlet nitrene ⇌ azirine equilibrium[2b]. *Hassner*[85] decomposed a vinyl azide *(117)* in methanol, a type of azide which is known to give azirine *(118)* and obtained an aminoketal *(119)*. Similarly, an aminoketal *(121)* was also obtained[68a] from the decomposition of the aromatic 2-naphthyl azide *(111)* in the presence of methoxide/methanol which not unreasonably points to a close analogy between the two pathways.

(117) (118) (119)



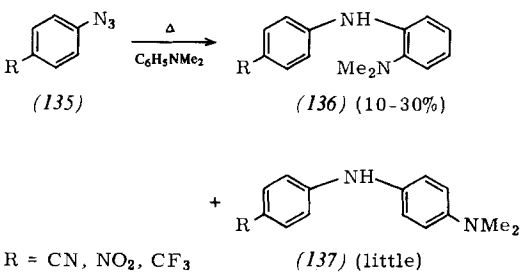
(111) (120) (121)

Moreover, on the basis of an azirine intermediate, formation of azepine and diamine may be rationalized by considering Scheme 5. Irradiation of the azide *(122)* in a primary or secondary amine with TMEDA as co-solvent gives the singlet nitrene which coordinates with co-solvent as shown *(123)*[12] or forms an ylide *(130)*[11]. This suppresses unwanted intersystem crossing to triplet nitrene, thus promoting benzazirine formation *(124)* which in turn is then available for nucleophilic attack. The formation of a small amount of triplet nitrene *(125)* presumably directly from the azide cannot easily be prevented. Nucleophilic attack on *(124)* by an amine leads to the equilibrium *(126)*⇌*(127)* the position of which depends on the nature of R^2 [R^2 = alkyl, favors *(127)* while R^2 = H favors *(126)*]. The zwitterion *(127)*, R^2 = alkyl, readily aromatizes to give the diamine *(132)*, the product of thermodynamic control. The aziridine *(126)*, R^2 = H, may slowly equilibrate to *(127)* with subsequent rearomatization or it can ring-expand to the 1*H*-azepine *(129)*. Several factors affect the position of the equilibrium *(127)*⇌*(126)*⇌*(129)*. In fused bicyclic aromatic systems loss of aromaticity in ring B during the rearrangement militates against ring expansion whilst relief of unfavorable *peri*-interaction between NR^1R^2



Scheme 5. Photochemical reactions of bicyclic α-azidoarenes. ISC = intersystem crossing. *(132)* is a product of thermodynamic control, and *(131)* of kinetic control. R^1 = alkyl, R^2 = H or alkyl, X = H or lone pair on a heteroatom.

and X should promote ring expansion of *(126)* to *(129)*. The matter is further complicated because 1*H*-azepines such as *(129)* rapidly interconvert to more stable 4*H*-azepines such as *(131)* usually by 1,5 hydrogen shifts. Therefore, any stabilizing features in a potential azepine product (*e.g.* aromatic ring B, incorporation of an amidine unit or an sp^3 C-atom adjacent to the ring junction) will favor its formation. That *(129)*⇌*(131)* is indeed an equilibrium was confirmed when the azepine *(108a)* was irradiated (using a medium pressure mercury lamp, quartz cell) in dioxane to give a quantitative yield of *o*-diamine *(109a)*[79].

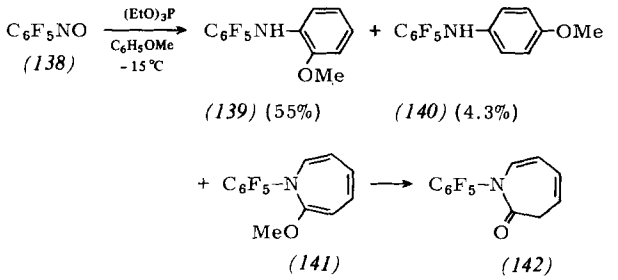


(108a) *(109a)*

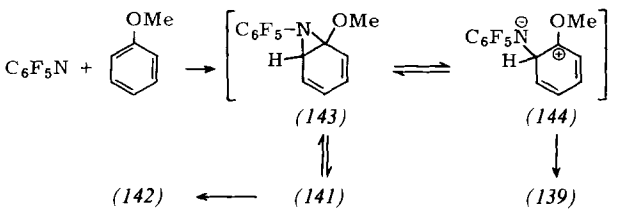
Photolysis of 1-naphthyl azide *(102)* in piperidine/TMEDA gives a mixture of isomeric *o*-diamines as previously described[77] [*(103)* and *(104)*; 50 and 25%]. The mechanism is still under investigation but could be rationalized by an interconversion between two benzazirines *(133)* and *(120)*. Other explanations are, however, possible: the unprecedented interconversion of azirines can be avoided by postulating competitive attack by piperidine at the 2-position on a canonical form *(134)* of the nitrene to give *(104)*[86].

3.1.4. Intermolecular Reactions

Few *inter*molecular reactions of singlet phenylnitrene itself or its derivatives were known up to 1969, apart from the observation that arylnitrenes could be intercepted by carbon monoxide at high pressure to give isocyanates[87]. *Abramovitch*[88] reasoned that if the singlet arylnitrene could be made more electrophilic and longer lived (for example by an electron-withdrawing substituent) attack on a suitable solvent should occur. Indeed, thermolysis of such *para*-substituted aryl azides *(135)* in a solvent activated towards electrophilic attack gave diarylamines *(136)* and *(137)* as predicted[88]. The mechanism of this reaction was further probed by generating



(135) *(136)* (10-30%)



R = CN, NO_2, CF_3 *(137)* (little)

perfluorophenylnitrene in the presence of anisole by deoxygenation of nitrosoperfluorobenzene *(138)*[89]. A mixture of diarylamines *(139)* and *(140)* was found as expected and also the azepinone *(142)* resulting from a ring expansion to a methoxyazepine *(141)* and hydrolysis during work-up. The formation of the inter- and intra-molecular types of product may be rationalized by considering the factors influencing the equilibrium *(143)*⇌*(144)*. Substituents that can stabilize positive charges (*e.g.* methoxy) clearly shift this equilibrium in favor of *(144)* and thereby promote rearomatization to give *(139)*, the product of thermodynamic control. As the ring expansion step *(143)*⇌*(141)* is reversible, substituents that

stabilize *(141)* (*e.g.* strongly electron-withdrawing groups on N-1)[90] favor this ring enlargement. Reaction conditions (and work-up conditions) clearly should be kept as mild as possible to obtain the azepines *(141)* or *(142)* which are the products of kinetic control.

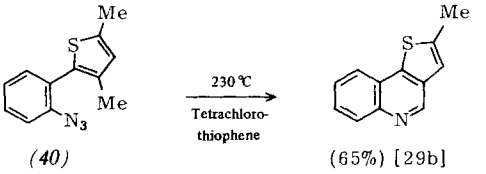
(143) *(144)* *(142)* *(141)* *(139)*

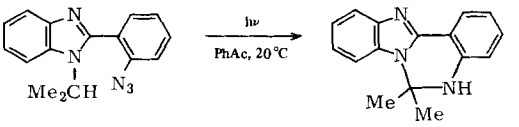
3.2. Triplet Nitrene Reactions

The synthetic utility of triplet arylnitrenes is generally underrated owing to their dominant tendency to yield either an amine (usually the parent of the nitrene precursor) by hydrogen abstraction or an azo compound by apparent dimerization. This latter reaction is in fact little understood and it often competes efficiently with easy intramolecular alternatives. The synthetic usefulness of the triplet species has recently been demonstrated in both intra- and inter-molecular pathways and its value can be heightened by the appropriate choice of substrates and methods of generating this intermediate.

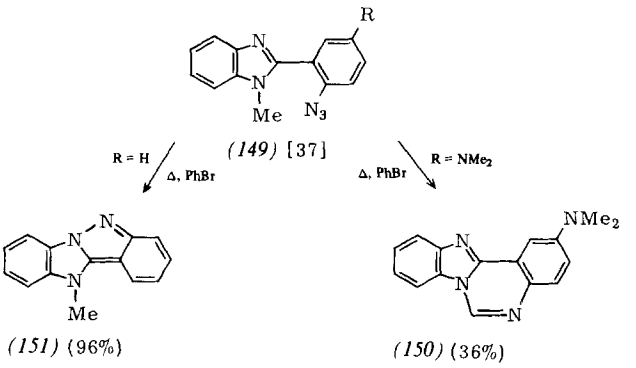


3.2.1. Intramolecular Triplet Arylnitrene Reactions

Probably the most versatile and useful cyclization involving a triplet arylnitrene is hydrogen abstraction from a nearby alkyl group followed by spin inversion and cyclization



(145) *(146)* *(147)*



[*(145)*→*(146)*→*(147)*]. Since decomposition of an azide usually generates a singlet nitrene which decays to the triplet species relatively slowly compared with many competitive singlet reactions, special methods are needed to optimize the triplet reactivity. These include triplet photosensitization, use of "heavy atom" solvents to accelerate the intersystem crossing, and substituents which deactivate the singlet species by conjugation with the nitrene. Each of these methods has its limitations, but when no competitive singlet pathway exists, the thermal method is the best synthetic approach. Some recent examples are the reactions of the azides *(40)*, *(148)*,

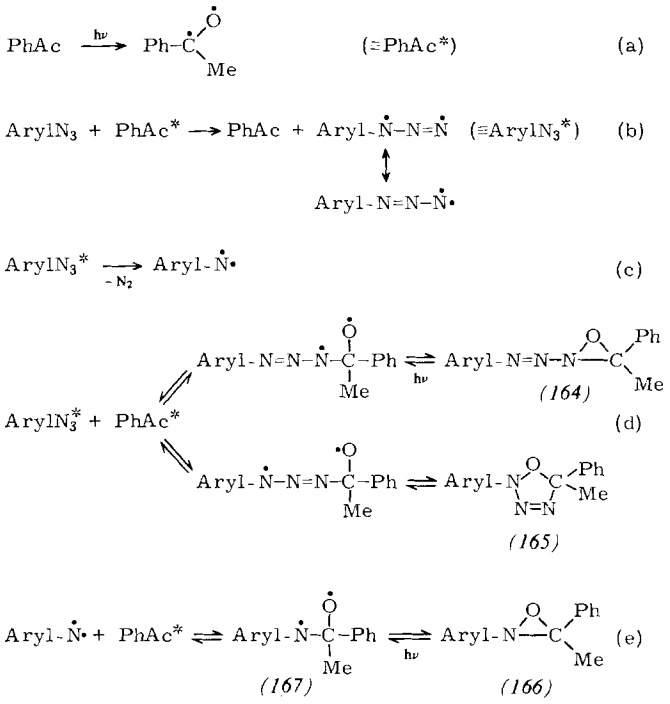
		hν, PhAc, 98 °C		42

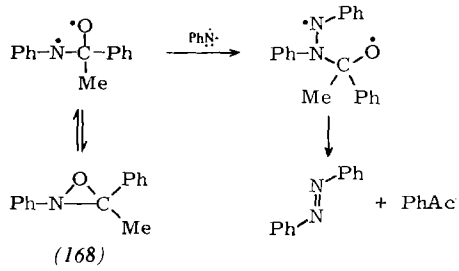
(149), (152), (153), (156), (157), and *(160)* (see also Table 6)[29b, 37, 50].

The use of solvents without aliphatic protons is advantageous for triplet cyclizations and yields are often considerably improved by use of high temperatures and short reaction times. Thus boiling bromobenzene, trichlorobenzene, or tetrachlorothiophene are very suitable solvents. Lower temperatures favor azo-compound formation, apparently an energetically easier alternative to H-abstraction. The dimethylamino-group is especially effective in causing deactivation of a singlet nitrene by mesomerically satisfying its "electrophilic thirst" [*(163)*].



(163)

Thus 2-(2-azidophenyl)-1-methylbenzimidazole *(149)* R = H, gives no triplet cyclization product *(150)*, H in place of NMe_2, at all on thermolysis but 96% of the singlet-derived benzimidazoloindazole *(151)*[37]. However, introduction of dimethylamino group *para* to the azide group [*(149)*, R = NMe_2] results in a complete reversal, thermolysis giving only triplet nitrene-derived products, *e.g. (150)*. It also illustrates the efficiency of photosensitization (especially with acetophenone) for bringing about selective triplet cyclizations, further exemplified by reactions of *(148), (152), (153), (156), (157),* and *(160)*. As observed earlier, it is often advantageous to conduct such sensitized photolyses at elevated temperature but low enough as not to cause thermolysis of the azide, but only to energize the triplet nitrene and, thereby, avoid azo-compound formation. In our experience the photo-generated triplet nitrene is a relatively low energy species. A bonus of this thermal excitation is that the time for photolysis is substantially reduced. However, this method occasionally leads to interesting side reactions. Thus, the secondary role of triplet acetophenone as a dehydrogenating agent is highly effective for the synthesis of the annelated benzimidazoles *(154)* and *(155)*, perhaps because the preferred *cis* geometry of the dihydro intermediate allows two hydrogen atoms to be abstracted simultaneously.



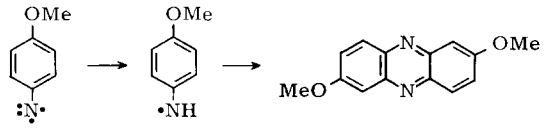
An unusual alternative to cyclization open to an appropriate *o*-azidophenyl derivative is the concerted abstraction of two vicinal hydrogen atoms from a paraffinic side-chain as in the reaction *(160)* → *(161)*.

Another more deep-seated change in reactivity is sometimes noted in sensitized photolyses which, we believe, are best explained as reactions of the triplet *azide* or of a triplet nitrene-triplet ketone derived molecule. We would include in this category: (a) the unexpected ease of azo-compound formation often at the expense of ready intramolecular alternatives[29b, 31, 91]; (b) the co-production of apparently singlet-derived products during triplet photosensitized reactions[29b]; and (c) the occasional formation of unexpected by-products, sometimes containing two or more[*] of the azide nitrogen atoms. These reactions may be seen to derive from a new family of longer-lived reactive intermediates visualized as the oxaziridines [see *(164)* and *(166)*] or oxatriazole *(165)* which may behave as masked singlet or triplet azides or nitrenes as shown in Scheme 6.

Scheme 6. Reactions of triplet nitrenes. * indicates a triplet state.

The oxaziridine *(168)* possibly derived as indicated in eq. (e) which is a known photo-source of triplet nitrene products[24], may behave as a "template" for azo-compound formation, the triplet nitrene having been scavenged by the steady state concentration of triplet acetophenone. Formation of azo compound could also be envisaged as occurring from the intermediates *(164)* and *(165)* in an analogous manner.

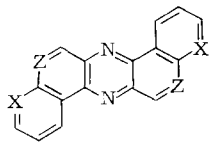
(168)



We believe that the unexplained origin of azo compounds from arylnitrenes (or their precursors) could be related to the above ideas. Thus formation of a "long-lived triplet nitrene complex" [cf. *(167)*] with reaction solvents or even vessel walls could form a template upon which further attack by a triplet nitrene would give the azo compound. Such complexes could involve a π-cloud of an aromatic solvent, for example. We hope that these tentative ideas may stimulate discussion of the little understood problem of azo-compound formation observed in nitrene decompositions.

3.2.2. Intermolecular Triplet Arylnitrene Reactions

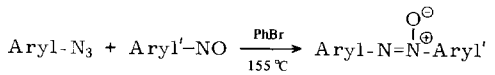
Formation of phenazines: Walker and *Waters*[92] observed the formation of 2,7-dimethoxyphenazine *(171)* on thermoly-



[*] A footnote in an early paper [92] on the photolysis of phenyl azide reported the slow formation of benzotriazole, though we have not been able to corroborate this.

sis of *p*-methoxyphenyl azide in cumene in trace yield. The result can be interpreted as a dimerization of the appropriate radicals *(170)* derived from a triplet nitrene *(169)* by hydrogen abstraction. While no other monocyclic arylnitrenes have been reported so far to give phenazines we have found certain fused bicyclic azides to give small yields of phenazines on thermolysis in bromobenzene, which is known to promote singlet → triplet intersystem crossing[93]. Thus, thermolysis of 1- and 2-naphthyl azide gives a dibenzophenazine *(172)* and other triplet products such as the corresponding

(169) *(170)* *(171)*



amines and azo compounds[78]. Similarly, thermolysis of the 3- or 5-quinolyl azide gives the corresponding phenazines[79] *(173)* and *(174)* apart from the expected azo- and amino compounds. As these yields were not optimized and polycyclic phenazines would only be available through multistep and cumbersome syntheses the scope of this method deserves further study.

(172), Z = X = CH
(173), Z = N, X = CH
(174), Z = CH, X = N

Formation of unsymmetrical diarylazoxy compounds: Practicable yields of azoxy compounds *(175)* can be realized when aryl azides with electron donating substituents especially in the *para*-position (Me, MeO) or naphthyl azides are thermolyzed in the presence of *p*-nitroso-*N,N*-dimethylaniline (Table 7)[94a]. Only one of the two possible azoxy compounds is formed and the method is thus unambiguous with regard to the position of the oxygen. The mechanism obviously involves a triplet nitrene which is intercepted by a nitrosoarene, a well-known spin-trap for radicals[95]. This promising approach to mixed azoxy compounds which resulted from a chance observation[96] is open to improvement and widening of the scope.

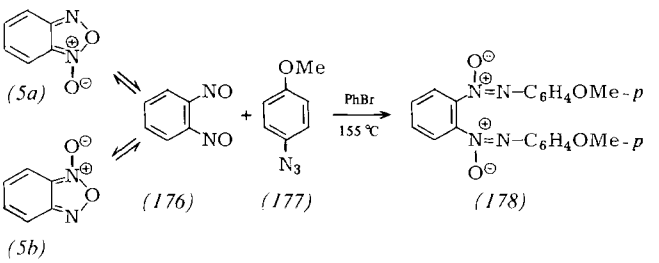


Table 7. Synthesis of unsymmetrical diarylazoxy compounds *(175)*.

(175)

Aryl	Aryl′	Yield [%]

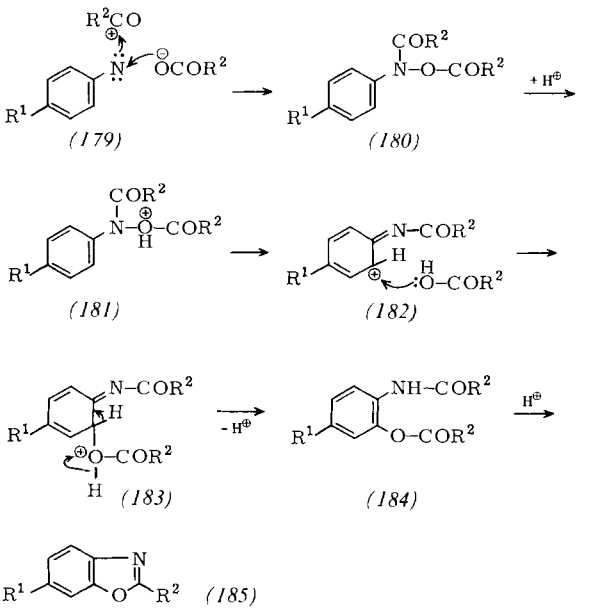
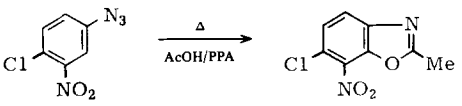
β-$C_{10}H_7$	*p*-$Me_2NC_6H_4$	93



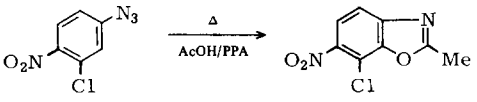
The trapping of nitroso compounds with arylnitrenes was used to demonstrate the tautomerism between benzofuroxan and *o*-dinitrosobenzene *(5)*⇌*(176)*[94b]. On heating *p*-anisyl azide *(177)* in bromobenzene (a triplet promoter) in the presence of benzofuroxan *(5)* the *o*-bis(azoxy) compound *(178)* was one of the products (40%). Its significance as a chemical proof for the existence of the equilibrium between *(5)* and *(176)* is plain.

(5a) *(5b)* *(176)* *(177)* *(178)*

4. Acid-Catalyzed Decompositions of Aryl Azides—Formation of Benzoxazoles



Derivatives of phenyl azide substituted by electron-withdrawing groups and with the *para*-position blocked yield 2,6-disubstituted benzoxazoles *(185)* when heated in a mixture of carboxylic acid and polyphosphoric acid (PPA). For example, in mixtures of polyphosphoric acid and acetic, propionic, or benzoic acid, *p*-nitrophenyl azides give 2-methyl- (83% yield), 2-ethyl- (75%), and 2-phenyl-6-nitrobenzoxazole (70%), respectively[97] [*(185)*, $R^1 = NO_2$, R^2 = Me, Et, Ph].

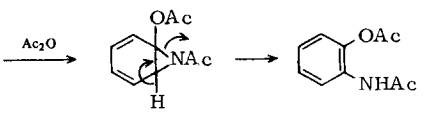


(179) *(180)* *(181)* *(182)* *(183)* *(184)* *(185)*

A rational mechanism for these reactions is shown. It is proposed that the initially generated singlet arylnitrene *(179)* inserts into the anhydride of the carboxylic acid (although a triplet insertion is also possible)[98] to give the corresponding *N,O*-diacylphenylhydroxylamine *(180)*. This is followed by transfer of the acyloxy moiety to the *ortho*-position. The nucleophilic nature of the attack [*(182)*→*(183)*] is supported by the necessary presence of an electron-withdrawing group in the *para*-position of phenyl azides, but also by the fact that 4-chloro-3-nitro *(186)* and 3-chloro-4-nitro-phenyl azide *(188)*

gave mainly the oxazoles *(187)* and *(189)* respectively, *i.e.* the acyloxy group moved to the most electron depleted point of the ring[97]. The function of the polyphosphoric acid is probably threefold: (i) to promote formation of the carboxylic acid anhydride; (ii) to promote a Bamberger-type rearrangement of the *N,O*-diacylphenylhydroxylamine *(180)*; and (iii) to cyclize the key *N,O*-diacylated *o*-aminophenol intermediates *(184)*. In some cases these species can be isolated and cyclized under more vigorous conditions.

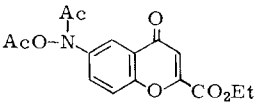
(186) *(187)*



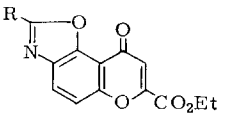
(188) *(189)*

In a mixture of acetic and polyphosphoric acids, phenyl azide itself gives *p*-acetamidophenyl acetate (75% yield) by a Bamberger-type rearrangement of the intermediate *N,O*-diacylphenylhydroxylamine *(180)*, $R^1 = H$, $R^2 = Me$, whilst compounds substituted by electron-donating groups (Me, MeO) in the *para*-position yield the corresponding amine and tars[97].

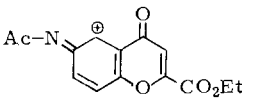
Thermal decomposition of phenyl azide and several of its simple derivatives (*o*-Me, *p*-Me, *o*-Cl, *p*-Br) in acetic anhydride alone yields the corresponding *N,O*-diacetylated *o*-aminophenol *(184)*[98] while photolysis in acetic acid affords *o*-acetamidophenol[49a]. Under these conditions *ortho*-disubstituted products are formed even when the *para*-position is free. At first these reactions were thought to involve a Claisen-type rearrangement[98] but we now favor addition of acetic anhydride to an intermediate azirine [*(25)*→*(190)*] followed by ring-opening and rearrangement to give *(191)*[99] which is more in keeping with the accepted mechanism of azide decompositions in the presence of nucleophiles.



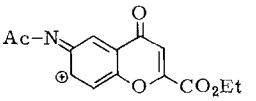
(25)



(190) *(191)*

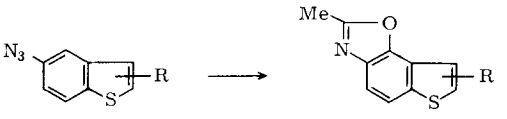


The possibility that aryl azides react in mixtures of polyphosphoric acid and a carboxylic acid by an *intra*molecular process of the Claisen type appears unlikely since the chromone derivative *(192)* analogous to *(180)* synthesized independently gave a mixture of two oxazoles *(193)* and *(194)* when heated in a mixture of polyphosphoric and propionic acids[100]. This result can be rationalized by competitive attack of the added propionic acid and migration of the acyl group in the cation *(195)*.

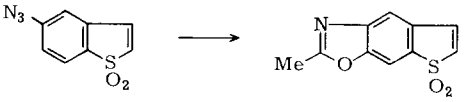


(192)

(193), R = Me
(194), R = Et

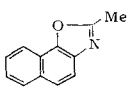


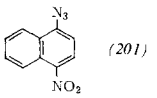
(195)

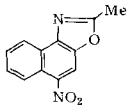


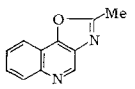
(196)

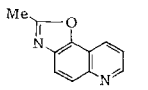
The formation of the angular [*(193)* and *(194)*] rather than linear products can be attributed to the greater stability of intermediate *(195)* as against *(196)*[100]. Only in *(195)* is the aromaticity of the γ-pyrone system preserved. Likewise, 5-azidobenzo[*b*]thiophenes *(197)* gives the angular products *(198)*[101]. By contrast, however, the sulfone *(199)* yields the linear product *(200)*[101]. In this case the thiophene ring is no longer aromatic and steric hindrance proves decisive.

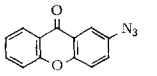


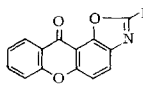


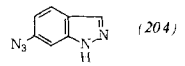


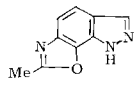


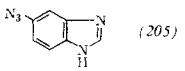


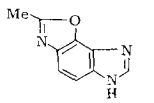


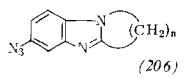


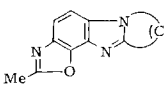












(197) *(198)*

(199) *(200)* (38%)

In view of the synthetic utility of this reaction its scope is illustrated in Table 8 (for other examples see references[73,74,101]). The advantage of the method lies clearly in the fact that it obviates the necessity for an *o*-aminophenol as starting material, as in the conventional synthesis of benzoxazoles. This is particularly valuable in the case of polynuclear aromatics [cf. Table 8, *e.g.* quinolines *(90)*, xanthones *(203)*] where the preparation of the required *o*-aminophenol would be cumbersome in the extreme. The scope of this reaction should be further investigated in other polycyclic aromatic systems when novel fused oxazoles could be produced. Moreover, as described above [*(179)*→*(185)*] *o*-aminophenols of fused polycyclics could also be prepared by this method as starting materials for novel azoles, azines, azepines, and possibly large rings by suitable cyclization procedures. These aminophenols are, of course, also obtainable by alkaline hydrolysis of the corresponding oxazoles.

Table 8. Synthesis of oxazoles by thermolysis of aryl azides in acetic acid/polyphosphoric acid.

Azide	Product	Yield [%]	Ref.
 *(111)*		5 [a]	[102]
 *(201)*		25	[97]
 *(95)*		50 [b]	[97]
 *(202)*		70 [b]	[102]
 *(203)*		92 [b]	[102]
 *(204)*		60	[102]
 *(205)*		60	[97]
 *(206)*		30–81 [c]	[103]

[a] A 35% yield of the intermediate *N,O*-diacetylated 2-amino-1-naphthol was isolated also which could be cyclized by heating in a solvent or by sublimation. [b] An *o*-acetamidohydroxy compound was first isolated which cyclized on further heating. [c] Yield depending on the nature of the alicyclic ring.

5. Conclusion

A strong inducement for continuing research into arylnitrenes lies in their application as photoresists in the solid state industry and in their versatility for photoaffinity labeling by irradiation of aryl azides in the presence of appropriate acceptors.

There exists, moreover, a wide scope for further exploration on the basis of the known synthetic uses of arylnitrenes. For instance, the successful diamine formation, ring expansion, and oxazole conversion elaborated by us in bicyclic systems could obviously be extended into the field of tricycles which play a prominent role in neuropharmacology as antipsychotics and antidepressants[104]. This work may lead to novel azepino and oxazolo tricycles of potential biological activity. Germane to this topic is the further exploration of the phenothiazine reaction [*(46)*→*(48)*] which by replacing ring B in *(46)* may feasibly produce novel tricyclic systems.

While the ring expansion and diamine formation of bicyclic, fused arylnitrenes are well established, prediction as to which product will be formed or as to the ratio of the two products in advance of experimental trial is far from certain. Much basic work remains to be done and preliminary results[105] indicate that the nature of the products can be influenced by introducing appropriate substituents into the nitrene ring[27c].

The synthetic value of diamine formation would be considerably enhanced if instead of the type of diamine represented by *(92)* one could produce the corresponding free *o*-diamines (NH_2 in place of Et_2N). Attempts at using ammonia as a nucleophile for this purpose have failed. Such diamines would serve as versatile starting materials for a wide range of rather inaccessible heterocyclic systems. Obvious innovations by analogy with sulfur nucleophiles [such as *(89)* and *(115)*] would be the study of carbon and phosphorus nucleophiles as well as the use of bidentate reagents. The potential of the latter has already been demonstrated for the vinylic azidouracil in presence of certain amino esters[84].

An imaginative and novel synthetic use of arylnitrenes has recently been described for the preparation of pentacoordinate spirophosphoranes[106]; this method is wide open to further elaboration.

Biochemical interest in arylnitrenes has so far not been prominent. Yet in view of a striking analogy between the chemical behavior of arene oxides[107] and aromatic azirines, *e.g. (124)*, there may also be a parallel in their respective metabolism. That arylnitrenes and their numerous precursors could well be involved in carcinogenesis was in fact suggested some time ago[108].

There are a number of purely mechanistic problems in the arylnitrene field which need further clarification. Paramount amongst them is the role of the recently observed photointermediate 1-aza-1,2,4,6-cycloheptatetraene *(80)* which challenges the accepted mechanism *via* benzoazirine *(25)*. Similar matrix studies are being carried out on bi- and polycyclic arylnitrenes to establish "whether the tetraene intermediate is generally observable".

The novice to arylnitrene chemistry should be encouraged to know that aryl azides may be safely decomposed and handled in solvents and sufficiently purified for all purposes by chromatography or recrystallization. Unless heated dry to their decomposition point they are not explosive. It is hoped that the practical aspects described in this review will stimulate new ideas leading to fruitful experimentation.

We are indebted to our co-workers cited in the references for their enthusiasm and untiring collaboration. Our own laboratory work was generously sponsored by the Science Research Council, Glaxo-Allenburys Limited, I.C.I. Pharmaceuticals Limited, Smith Kline and French Laboratories (Philadelphia), Nicholas Laboratories Limited, and Pfizer Central Research (Kent).

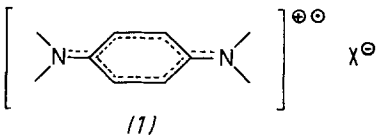
Capto-dative Substituent Effects in Syntheses with Radicals and Radicophiles[**]

New synthetic methods (32)



By Heinz Günter Viehe, Robert Merényi, Lucien Stella, and Zdenek Janousek[*]

Dedicated to the double anniversary: 100 years Wurster's salts and 50 years Paneth's radical reactions with metal mirrors

The 100 years old Wurster's salts have long been recognized as compounds with radical cations. Their unusual stabilization derives partly from *capto-dative (cd)* substitution. This principle is now discussed as one factor of radical stabilization and it is applied to simple methine derivatives. *cd*-Substitution has synthetically useful applications: *cd*-substituents on a carbon atom allow its selective dehydrodimerization. Olefins with geminal and thus cross-conjugated *cd*-substituents are "radicophilic" and permit twofold carbon radical addition. *cd*-Substituted olefins are useful antioxidants, polymerization inhibitors and are promising agents in the control of biological radical reactions. Generally, many reactions of *cd*-substituted molecules appear to involve radicals.

1. Introduction

In 1879, Wurster's salts *(1)* were discovered[1] but their radical nature was recognized only about half a century later[2].

(1)

Wurster's salts: 1879

In 1929, the surprising stability of *(1)* as isolable salts with radical cation structure was contrasted with the unstable methyl and phenyl radicals when *Paneth* published his famous mirror experiments[3]. Thus, when tetramethyllead was decomposed thermally in a glass tube it produced ethane, and lead as a deposit. This lead mirror could be dissolved as tetramethyllead when exposed to a stream of methyl radicals generated by thermolysis from other organometallic compounds such as trimethylbismuth (Fig. 1).

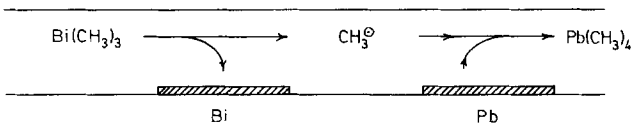


Fig. 1. *Paneth*'s methyl radicals dissolving lead mirrors: 1929.

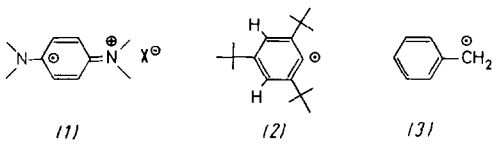
With these historical events of organic and particularly of radical chemistry in mind, it now appears appropriate to report on a general principle in radical chemistry which partly explains the stability of Wurster's salts: the *capto-dative (cd) substituent effect*[4].

In the past, organic free radicals have been divided into two classes: 1) The long-lived radicals which are stabilized by resonance, and for which, as for Wurster's salts *(1)*, one can formulate several mesomeric forms with the lone electron in different positions. 2) The short-lived radicals like methyl or phenyl which do not enjoy such stabilization and for which only one mesomeric form is possible.



Later, the notion of stabilization was dissociated from that of persistence[5]. The persistence of a radical $R^{\odot}$ refers to its

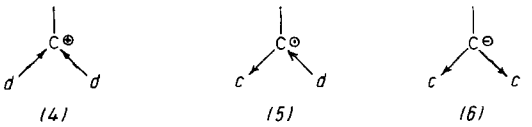
[**] Capto-dative Substitution Effects, Part 5.—Part 4: [67].

 © *Verlag Chemie, GmbH, 6940 Weinheim, 1979* *0570-0833/79/1212-0917 $ 02.50/0*

lifetime under specified experimental conditions[5], while the stabilization has been defined[6] in terms of dissociation energies of the R—H bond. Thus, a persistent radical is not necessarily stabilized, *e.g.* the 2,4,6-tri-*tert*-butylphenyl radical *(2)*, while a stabilized radical can often be transient, such as the benzyl radical *(3)*.



(1) *(2)* *(3)*

(1): Salt with persistent stabilized radical cation
(2): Persistent destabilized radical
(3): Short-lived (transient) stabilized radical

Another definition[7] of radical stabilization is based on equilibrium constants derived from polarographic redox potentials in reversible systems. Spin density delocalization also reflects the thermodynamic stabilization of radicals[8].

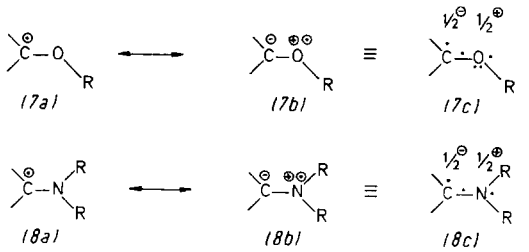
The capto-dative *(cd)* substituent effect[4] derives from a logical extension of the principles governing the stabilization of cations and anions: whereas carbocations *(4)* are stabilized by electron donor-substituents, and carbanions *(6)* by electron acceptor-groups, electroneutral radicals *(5)*—formally situated between *(4)* and *(6)*—enjoy particular stabilization when they are substituted simultaneously by a donor and an acceptor group.

(4) *(5)* *(6)*

c = electron acceptor group *("capto")*
d = electron donor group *("dative")*

The *cd*-substitution concept further leads to the notion of *radicophilicity* as a complement to nucleophilicity and electrophilicity. Moreover, this concept represents a practical tool for organic chemistry and biochemistry. Its application enables, *e.g.*, the design of new radical inhibitors, antioxidants and spin-traps. *cd*-Substituent effects can also be useful in polymer chemistry and organic synthesis and appear in many chemical processes where radical reactions are involved. In biochemistry, the *cd*-systems are omnipresent, since they occur, for example, in amino-acids, sugars, and vitamins C and E. In biology and medicine *cd*-substituent effects are linked to photosynthesis, the radioprotection of organisms and to enzymatic dehydrogenation. They appear to play an important role in controlling mutagens[9] and in the processes of ageing.

2. Radical Stabilization by Capto-dative *(cd)* Substitution

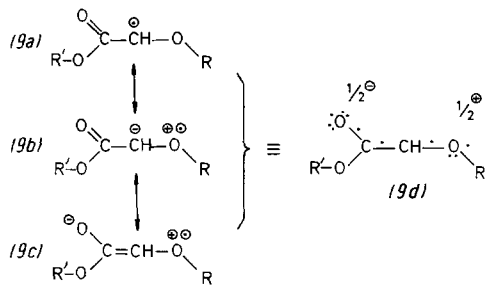


It is well known that free radicals are stabilized by both electron acceptor groups *(c)* and by electron donor groups *(d)*.

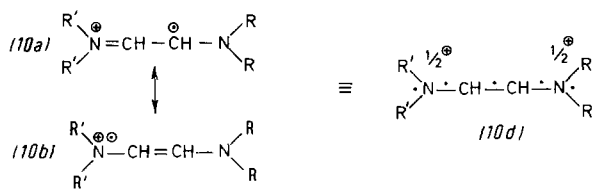
c = —CN, —CO—R, —COOR, —CR=$\overset{\oplus}{N}$R$_2$, —NO$_2$, *etc.*
d = —OR, —NR$_2$, —SR, —SeR, —O$^{\ominus}$, *etc.*

Kinetic studies indicate that substituents such as —CN stabilize an adjacent radical to a large extent[10]. Substituents with heteroatoms of the first Period such as —OR have a smaller stabilizing effect[11,12,13], those with heteroatoms of the second Period such as —SR display an intermediate effect[11,12].

Although the data for stabilization energies are derived principally from kinetic experiments, they reflect the substituent effects for the stability of the radical. Bond dissociation energies[14] reveal the same trend. The oxidation of ethers or amines gives an example of selective radical formation in the α-position to the heteroatom [see *(7)* and *(8)*].



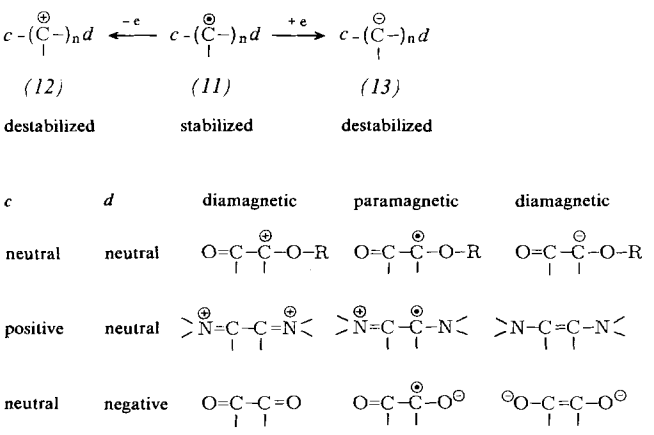
This selectivity can be explained by electronic assistance of the donor group which stabilizes adjacent radicals by resonance, but charge separation in the resonance forms *(7b)* and *(8b)* leads to an increase in energy because it is opposed to the relative electronegativies. The Linnett structures *(7c)* and *(8c)*[15] lead to the same conclusion: spin-delocalization imparts double quartet electron configuration to all atoms, but the polarization is unfavorable.



(7a) *(7b)* *(7c)*

(8a) *(8b)* *(8c)*

If these radicals are further substituted by an electron acceptor group, and hence are *cd*-substituted, then the resonance becomes greatly enhanced since the negative charge is delocalized over the electron-acceptor group. Hereby the radicals such as *(9)* and *(10)* with *cd*-substitution derived from alkoxyacetic esters or from 1,2-diaminoethylenes enjoy particular dipolar resonance stabilization and the "right" polarization.

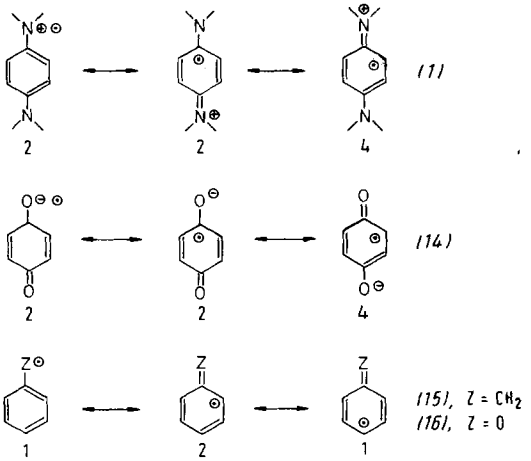


(9a) *(9b)* *(9c)* *(9d)*

(10a) *(10b)* *(10d)*

More generally, the substitution by neutral or charged acceptor *c* and donor *d* groups in *(11)* leads to *cd*-stabilization if *n* is an odd number. Conversely, the diamagnetic species *(12)* and *(13)* obtained from *(11)* by one-electron release or

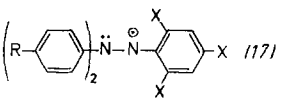
uptake, respectively, are destabilized by the opposite polarization effect of the two substituents (Scheme 1).



Scheme 1. Stabilization and destabilization by *cd*-substitution.

On the other hand, the species *(11)* in which n is an even number are stable diamagnetic compounds such as amides, esters, *etc.* The groups *c* and *d* act in a synergetic way. Only radicals *(11)*, $n=1$, are dealt with in this article.

Many examples of vinylogous radical ions, like Wurster's salts *(1)* and their oxa-analogues, the semiquinones *(14)*, can be found in a recent review[7].



In radical ions of the type *(1)* and *(14)* the *cd*-effect is enhanced by delocalization in the π system of the aromatic ring. Such delocalization is more profound than that in benzyl *(15)* or phenoxyl *(16)* radicals where only alternate carbon atoms are involved. In *(1)* and *(14)*, however, the delocalization effectively takes place over all the six carbon atoms of the benzene ring and thus leads to much greater stabilization (Scheme 2).

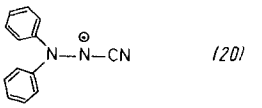
Scheme 2. Stabilization of radicals and radical ions by delocalization. The number of resonance structures for different positions of the unpaired electron is given under the formulas.

3. Historical Development

After *Gomberg*'s discovery[16] of triphenylmethyl as the first stabilized free radical great efforts were made to determine the factors governing the stability of radicals. For triphenylhydrazyl radicals *(17)* *Goldschmidt* observed an increase in stabilization with increasing strength of the acceptor group X ($\sim c$)[17].

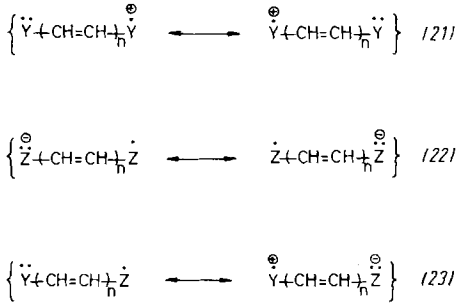
It should be noted that the stable diphenylpicrylhydrazyl radical (DPPH) *(17)*, R = H, X = NO_2, can be considered as a *cd*-substituted aminyl radical.

Walter tried to interpret the influence of different groups R on the properties of *(17)* and related radicals[18].—The radical nature of Wurster's salts *(1)* was already recognized by *Weitz* in 1925 (cf. [19]).



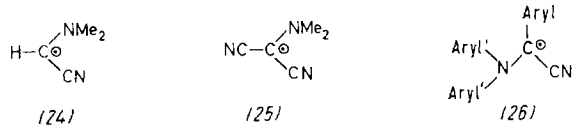
It appears that the first theoretical formulation of the stabilizing effect of a donor and an acceptor substituent, when applied to conjugated alternate odd numbered hydrocarbon radicals, was made by *Dewar* in 1952[20].

Linnett formulated the double quartet rule which explains the stability of radicals and radical ions such as nitrogen monoxide and the nitroxides, semiquinones and Wurster's salts[15].



Based on the analogy between merocyanines *(19)* and radicals of the type *(18)*, *Katritzky* developed the principle of merostabilization[21].

Balaban introduced the term push-pull stabilization for nitrogen-centered radicals, like *(20)*[22].

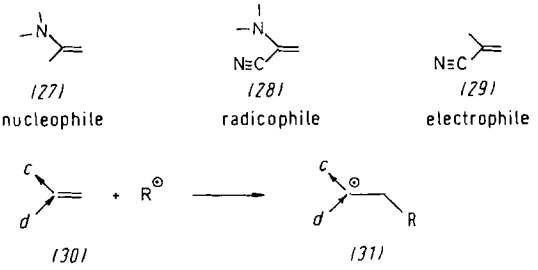


Hünig (cf. [7]) studied the one-electron redox systems which involve a semiquinone (SEM) between the reduced (RED) and oxidized (OX) form. The semiquinones *(21)*, *(22)* and *(23)* correspond to radicals which are stabilized by *c,d*-substitution.

The thermodynamic stabilization is expressed by the equilibrium constant K.

$$K=[\mathrm{SEM}]^2/[\mathrm{RED}][\mathrm{OX}]$$

De Vries[23] detected the radicals *(24)* and *(25)* and *Aurich*[24]



(24) (25) (26)

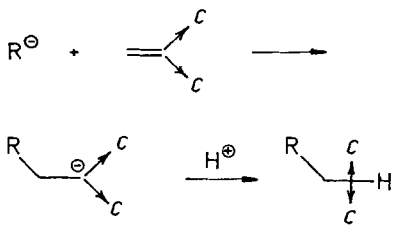
generated those of type *(26)*; both authors recognized the stabilizing effects discussed by *Katritzky* and *Balaban*.

4. Radicophilicity of Olefins as a Consequence of *cd*-Substitution

Since electron-rich olefins such as enamines *(27)* are nucleophilic and electron-poor ones like acrylonitrile *(29)* are electrophilic, the α-cyano-substituted enamines *(28)* and all *cd*-substituted olefins *(30)* can be considered as radicophilic [4]. The stabilized *cd*-substituted radicals *(31)* formed in the addition step do not undergo typical reactions such as polymerization or hydrogen abstraction but rather they trap another radical $R^{\ominus}$ or dimerize.

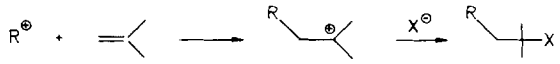
(27) nucleophile (28) radicophile (29) electrophile

(30) (31)



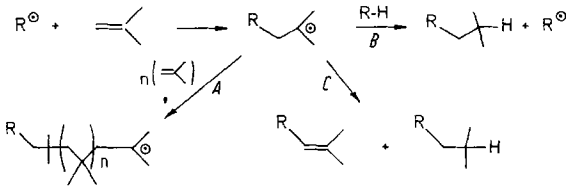
Although this definition of radicophilicity corresponds mainly to the thermodynamic stabilization of the radical adduct *(31)* by capto-dative substitution[4], it is not excluded that the kinetic aspects of addition, which depend primarily on steric and polar factors, may also be favorably influenced by *cd*-substitution[25] (cf. Section 12).

Because of cross conjugation of the *cd*-substituents, the π orbital of the double bond in *(30)* must have a marked degree of dissymetry. "One-electron conjugation" in the adduct *(31)* replaces the original cross conjugation in the *cd*-olefin *(30)*.

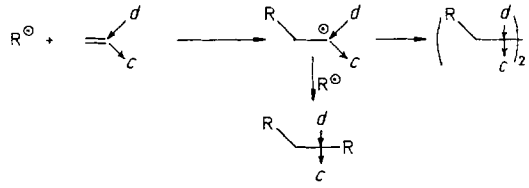


Moreover, radicophilic olefins, because of opposite substituent polarization, should trap any radicals regardless of their polarity.

This concept of radicophilicity is in many ways useful for syntheses. Most obvious is the possibility of twofold carbon radical addition to *cd*-substituted olefins. This is practically impossible for ionic reactions except for polymerization and cycloadditions.



Nucleophilic addition of carbanions (and $H^{\oplus}$) to electrophilic double bonds leads only to C and H addition:



Similarly, electrophilic addition of carbenium ions (and $X^{\ominus}$) to olefins results in both C and X addition:

The adducts of radicals to simple olefins such as propene or isobutene are not sufficiently stabilized or are too polar to be able to couple with themselves or with other radicals. Usual reactions are polymerization (Route A), H-abstraction as chain reaction (Route B) as well as disproportionation and chain termination.

In contrast to simple olefins, a radicophilic olefin can undergo twofold radical addition; the usual chain reactions do not take place.

Variation of the nature of both the groups *c* and *d* should make it possible to establish a scale of radicophilicity of different *cd*-substituted olefins and even a scale of stabilizing effects on radicals. The experimental approach is equally attractive for the organic chemist because of its potential in syntheses.

5. *c,d*-Substituent Effects and Orbital Correlation

5.1. *cd*-Substituent Effects on Radicals

The effect of α-substituents on the stability of radicals has been rationalized in terms of one-electron molecular orbital theory[26]. Interaction of a radical with either an electron-acceptor group (c = –C≡N, –CO–R, –CO_2R *etc.*) or an electron donor group (d = –OR, –NR_2, –SR *etc.*) leads to stabilization (Fig. 2).

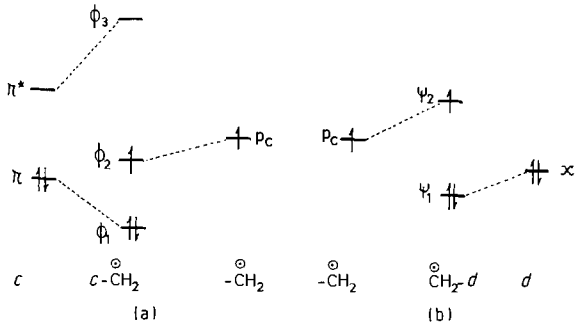


Fig. 2. Orbital interactions involved in the stabilization of a radical by a) an unsaturated group *c*, and b) by a group *d* with an heteroatom of the first or second period.

If we consider a radical $H\overset{\oplus}{C}cd$[27] whose substituents have opposite effects and can interact with the singly occupied atomic orbital p_C we can construct the correlation diagram for $H\overset{\oplus}{C}cd$ by the successive combination of $-\overset{\oplus}{C}H_2$ with *c* and *d*. Considering first the union with *c* (see Fig. 2) and next the union of $H_2\overset{\oplus}{C}c$ with *d* (Fig. 3), the interaction between the two filled orbitals Φ_1 and χ will be antibonding while that between the filled orbital χ and the singly occupied one of $H_2\overset{\oplus}{C}c$ (Φ_2) will be bonding.

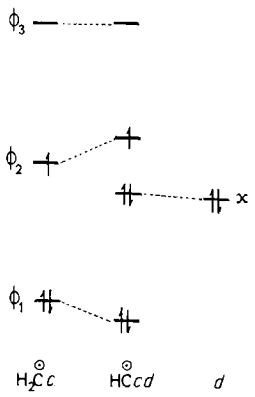

Fig. 3. Orbital interactions involved in the stabilization of a radical by an unsaturated group *c* and a group *d* with an heteroatom.

The net result will depend on the relative magnitudes of these two apparently conflicting effects. The magnitude of the interaction between χ and the two MOs Φ_1 and Φ_2 will then be determined by the orbital coefficients of the carbon atom adjacent to *d*. These in turn will depend on the extent of the coupling between the *c* orbitals π and π^* and the singly occupied atomic orbital p_C.

Comparing for example an allyl radical with a cyanomethyl radical (Fig. 4), it is well known[28] that for the latter there are two main consequences arising from the additional electron-acceptor effect of the nitrogen atom:

1) The energy levels of all the MOs in the cyanomethyl radical are lowered and so the C≡N triple bond affords a stabilization energy greater than that of a C=C double bond. In addition, the SOMO bearing the unpaired electron is lower in energy than in the allyl radical.

2) The orbital coefficients in the bonding MO Φ_1 increase strongly towards the nitrogen atom, and inversely decrease in the nonbonding MO Φ_2[29].

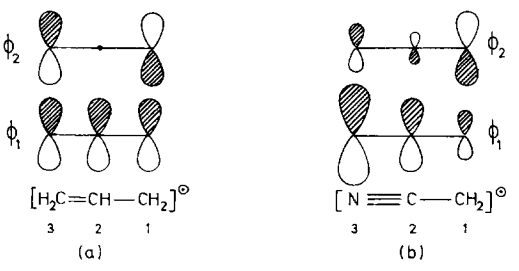

Fig. 4. Orbital coefficients in MOs Φ_1 and Φ_2 of a) the allyl radical and b) the cyanomethyl radical.

This implies that the unpaired electron will be strongly localized on carbon 1, where the orbital coefficient is high[30]. Under these conditions the net interaction resulting from the next union with the heteroatom in the donor substituent *d* will be more bonding because only the singly occupied MO will interact effectively with the orbital of the heteroatom. In addition, the singly occupied orbital Φ_2 of the cyanomethyl radical is lower in energy than $A\overset{\oplus}{O}p_C$ of methyl. Consequently in the construction of $NC{-}\overset{\oplus}{C}H{-}d$ the net stabilizing effect of *d* will be higher than it would be on methyl itself. Under these conditions one substituent augments the effect of the other.

As mentioned above, it should be emphasized that the first theoretical hint of such an effect was already given in 1952[20] (see Section 3).

5.2. *cd*-Substituent Effects in Olefins

The *cd*-substituent effect on frontier orbitals π and π^* of an olefin is now considered. In agreement with qualitative notions of substituent effects on orbital energies[31], electron donating substituents *d* raise both frontier orbital energies, but the HOMO more than the LUMO, and electron accepting substituents *c* lower both frontier orbital energies, in this case the LUMO more than the HOMO (Fig. 5).

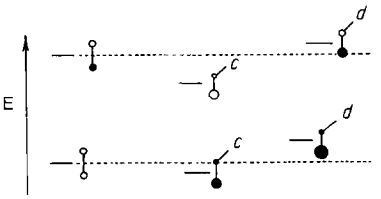

Fig. 5. Frontier orbital energies and coefficients for olefins with electron acceptor (*c*= C—N, CO R, *etc.*) and electron donor (*d*= OR, NR_2, *etc.*) substituents.

Thus geminal *cd*-substitution on olefins reduces the frontier orbital separation.

In general, radicals which have a low-energy SOMO show electrophilic properties and react more easily with nucleophilic olefins which have a high energy HOMO. On the other hand, radicals which have a high energy SOMO show nucleophilic properties and react more easily with electrophilic olefins which have a low energy LUMO[26].

Reducing the frontier orbital separation in *cd* olefins $cdC^1{=}C^2H_2$ makes them radicophilic by drawing the SOMO of the radical near to both the LUMO and the HOMO of the olefin. The relative magnitudes of the coefficients can also be deduced from qualitative considerations[31]. Electron donor groups increase the remote coefficient in the HOMO and the nearby coefficients in the LUMO. Electron acceptor groups have exactly the opposite effect from that of donor groups if they interact only inductively (*e.g.* $-CF_3$), but since most of the substituents of this type are also conjugating, the magnitude of the remote coefficients in the LUMO is strengthened, while the difference in the HOMO coefficient values is diminished or reversed. Consequently, the combined action of

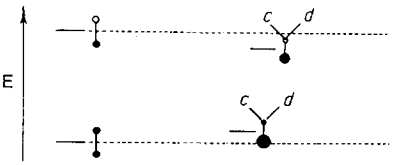

Fig. 6. Frontier orbital energies and coefficients for radicophilic olefins compared with those of ethylene.

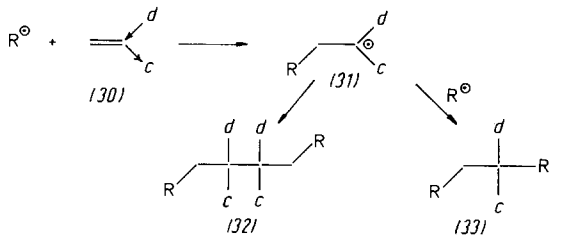
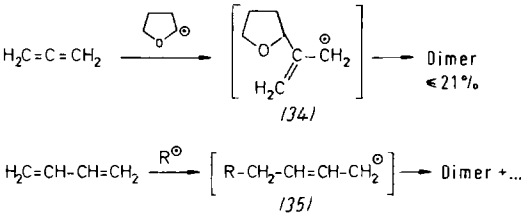


donor and acceptor groups on olefins must lead to an increase of the remote coefficient in both the LUMO and the HOMO (Fig. 6).

In this way it becomes evident that radical addition to the unsubstituted carbon of a *cd* olefin is thus favored by both polar and steric factors.

6. Syntheses by Radical Addition to Radicophilic Olefins

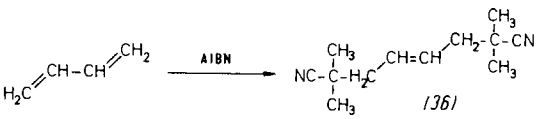
6.1. General Remarks



As already explained, geminal *cd*-substituted olefins *(30)* are excellent radical traps over a wide temperature range (see Section 4); the adducts *(32)* and *(33)* can be isolated in good yields. The *meso* and DL forms of the "adduct-dimer" *(32)* are obtained.

(30) *(31)* *(32)* *(33)*

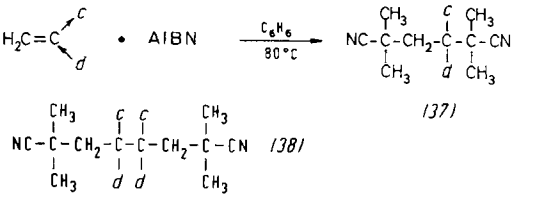
Additive radical dimerizations from monoolefins other than those bearing *cd*-substituents are practically unknown. 1,1-Diphenylethylene behaves as a radicophile towards isobutyronitrile (IBN) radicals giving the bisadduct *(39)* (see Section 6.2).



Allene[33] and 1,3-butadiene[34] may occasionally lead to adduct-dimers *via* the corresponding resonance stabilized allyl radicals *(34)* and *(35)*. Butadiene also forms oligomers.

(34) *(35)*

6.2. Addition of Isobutyronitrile (IBN) Radicals

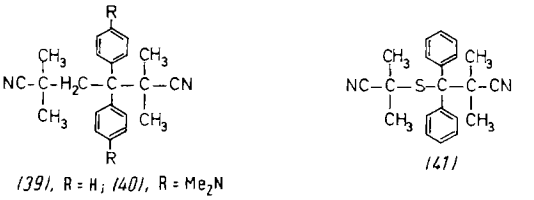


IBN radicals conveniently generated thermally or photochemically from azodiisobutyronitrile (AIBN) are used as initiators of polymerization and as very mild hydrogen abstractors *e.g.* from thiols[35] and trialkyltin hydrides[36]. Homolytic substitutions with IBN radicals are very uncommon[37] and so is their addition to multiple C—C bonds. Thus, 4-vinylcyclohexene reacts with IBN$^{\odot}$ to give a mixture containing addition, substitution and adduct-dimer products in low yield[38]. According to a patent[39] butadiene affords the bisadduct *(36)* in satisfactory yield.

(36)

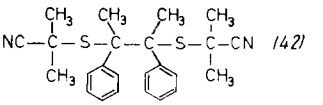
On the other hand, the radicophilic olefins *(30)* react with AIBN at 80 °C in benzene to form either bisadducts *(37)* or adduct-dimers *(38)*[32], which can be isolated in moderate to very good yields (see Table 1).

Table 1. Formation of bisadducts *(37)* from radicophiles *(30)* and IBN$^{\odot}$.



(37) *(38)*

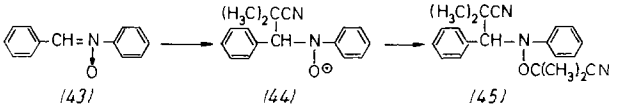
c	*d*	*(37)* Yield [%]	*c*	*d*	*(37)* Yield [%]
CN	*t*BuS	88	CN	Morpholino	68
CO_2Me	*t*BuS	76	CN	Me_2N	38
CO_2Me	MeS	35	CO_2Me	Et_2N	37
CO_2Me	MeO	49	CN	Me_3SiO	33 [40] [a]
$CONMe_2$	Me_2N	40	CN	MeS	18 [b]



[a] See also *(49)*. [b] Alongside 51% *(38)*, for clarity shown as *meso*-form [cf. *(47a)*].

It should be noted that the bulky IBN$^{\odot}$ adds only to *cd*-olefins bearing a free methylene group.

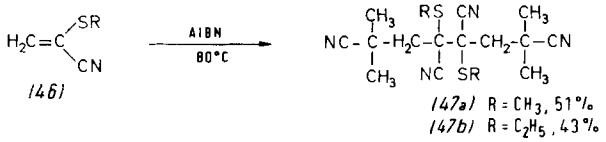
1,1-Diphenyl- and 1,1-bis(*p*-dimethylaminophenyl)ethylenes behave also as good radicophiles giving 55% and 65% yields, respectively, of bisadducts *(39)* and *(40)*[32,41].



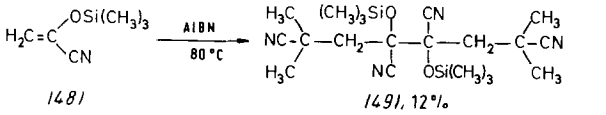
(39), R = H; *(40)*, R = Me_2N *(41)*

(42)

Radicophiles do not have to be olefins. The radicophiles thiobenzophenone and thioacetophenone react exclusively to give the bisadduct *(41)* and the adduct-dimer *(42)*, respectively[42].



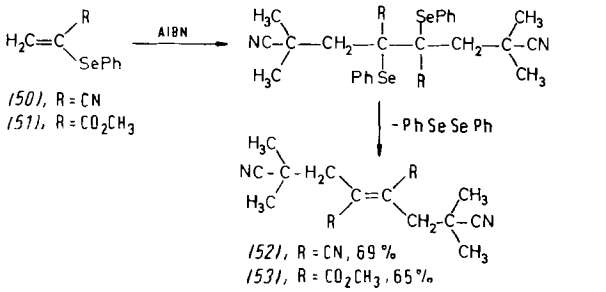
Nitrones *(43)*, the well known spin traps, are necessarily radicophilic and consequently they add to IBN$^{\odot}$ in stoichiometric amounts[43] leading to the bisadduct *(45)* *via* the nitroxide *(44)*. CIDNP signals could be observed during this addition[44].



(43) *(44)* *(45)*

Galvinoxyl, which is known as a highly efficient radical scavenger, traps IBN$^{\odot}$ in 63% yield[45]. Radicophilic olefins of type *(46)* and *(48)* afford, besides the bisadduct, the ad-

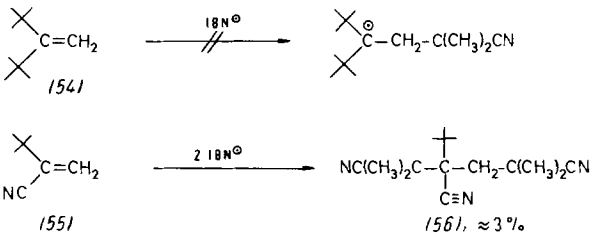
duct-dimers *(47)* and *(49)* as a mixture of DL and *meso* forms[32,40].



146 → *147a* R = CH_3, 51%; *147b* R = C_2H_5, 43%

148 → *149*, 12%

Yet another feature is encountered with α-(phenylseleno)acrylonitrile *(50)* and the ester *(51)*. The adduct-dimers spontaneously lose diphenyl diselenide to afford olefins *(52)* and *(53)*[32].

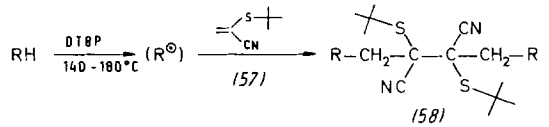


150, R = CN
151, R = CO_2CH_3

152, R = CN, 69%
153, R = CO_2CH_3, 65%

IBN$^{\odot}$ adds only to olefins bearing *cd*-substituents or aryl substituents. Accordingly, electron-rich olefins, namely enamines, vinyl ethers, ketene acetals (O,O-, N,S- and N,O-acetals) fail to react altogether under the above conditions. Electron-poor vinyl compounds, *e.g.* acrylonitrile, acryl esters and methylene malonates lead only to oligo- and polymerization[32]. The latter reaction, however, is prevented by the presence of radicophilic olefins, which demonstrates their usefulness as inhibitors of polymerization and of radical processes in general.

IBN$^{\odot}$ does not react with the olefin *(54)*, and reaction with α-*tert*-butylacrylonitrile *(55)* leads to only very low yields of the bisadduct *(56)*[32]. This indicates that it is the thermodynamic stability of the adduct rather than its persistency which is responsible for radicophilicity.



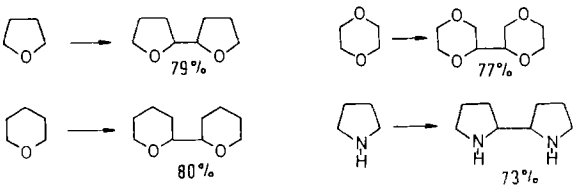
154

155 → *156*, ≈3%

6.3. Addition of Other Radicals to Radicophilic Olefins

The little reactive and highly selective IBN$^{\odot}$ adds preparatively only to radicophilic olefins. These compounds could be anticipated to smoothly add both electrophilic and nucleophilic radicals. This has been borne out in practice, although most of the work was done with α-(*tert*-butylthio)acrylonitrile *(57)* and the radicals were generated thermally by oxidation with di-*tert*-butyl peroxide (DTBP)[46]. Unlike with IBN$^{\odot}$ these additions lead in the majority of cases to adduct-dimers *(58)* which are particularly attractive for synthetic organic chemistry as new valuable highly functionalized intermediates (see Table 2).

Table 2. Radical addition to α-(*tert*-butylthio)acrylonitrile *(57)* [46].



157 → *158*

RH	$R^{\odot}$	*(58)*, Yield [%]

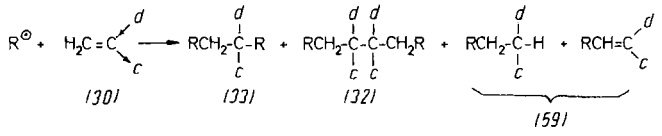
[18]Crown-6	$[C_{12}H_{23}O_6]^{\odot}$	51 [a]

[a] Together with disproportionation products.

In the absence of a radicophile, radical dimers are obtained in very good yields[59], *e.g.*



Pyrrolidine adducts of type *(58)* could not be obtained.

The behavior of the *N*-methylanilinomethyl radical towards a number of different radicophilic olefins has been studied in some detail[46]. The results show clearly the influence of substituents on the fate of the intermediate radical. Thus α-aminoacrylonitrile and diphenylethylene[47] adducts tend to undergo exclusively disproportionation. It is puzzling that replacement of the cyano group by an ester group in α-(alkylthio)acrylic derivatives leads to the formation of bisadducts with only a trace of adduct-dimers (Table 3).

Electrochemically generated methyl radicals from the Kolbe reaction could be trapped by α-(*tert*-butylthio)acrylonitrile *(57)* to give a low yield of the adduct-dimer *(60)*[48] which can also be obtained in better yield from the thermal decomposition of DTBP dissolved in *(57)*[49].—The main

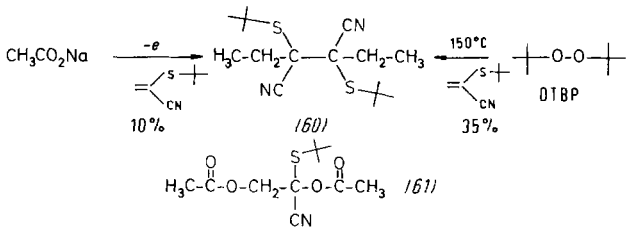


Table 3. Addition of *N*-methylanilinomethyl radicals to radicophilic olefins *(30)*. $R^{\odot} = PhNMe\overset{\odot}{C}H_2$.

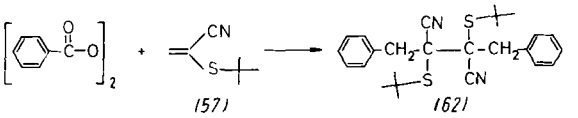
(30) *(33)* *(32)* *(59)*



c	d	Yield [%] (33)	(32)	(59)

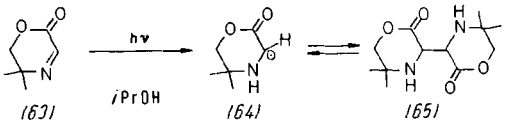
Ph	Ph	—	—	50

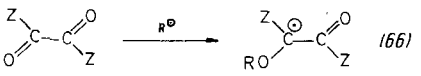
product (60%) of the electrochemical reaction is the diacetate *(61)*[48].



(60) *(61)*

The phenyl radical from the thermal decomposition of dibenzoyl peroxide could also be trapped with α-(*tert*-butylthio)acrylonitrile *(57)* to give the adduct-dimer *(62)*[50].

(57) *(62)*



The terminal CH_2 group in radicophilic olefins can be replaced by heteroatoms *e.g.* O, S, and N(R). Thus, when 1,4-oxazin-2-one *(63)* is irradiated in isopropanol as solvent it undergoes reductive dimerization[51] to *(65)*, apparently *via* the *cd*-substituted radical *(64)*.

(63) *(64)* *(65)*

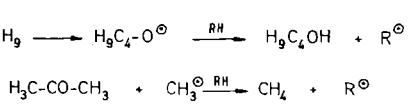
The dimer *(65)* exists in equilibrium with the radical *(64)*; the enthalpy of dissociation in ethanol (11 kcal/mol) is about the same as in the case of the triphenylmethyl dimer[52]. The central C—C bond in *(65)* is unusually long (1.591 Å)[53]. This lengthening and the extremely easy dissociation were attributed to steric strain only, which does not seem to be justified in this case.

The trapping of radicals by α-diketones and 1,2 and 1,4 quinones leads also to *cd*-substituted radicals *(66)*[54,55].

(66)

The 4-pyridine carbonitrile adducts *(67)* of silyl, germyl and stannyl radicals have recently been investigated[56].

(67)

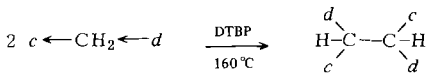


Pyridinyl radicals and their importance in biology have been extensively reviewed[57].

7. Dehydrodimerization of Compounds with *cd*-Substituted Methylene or Methine Groups

Numerous examples of dehydrodimerization, also known as "oxidative dimerization" or "oxidative coupling" reactions have been reported in the literature[58].

$$R' + R^{\odot}H \rightarrow R'H + R^{\odot} \qquad 2R^{\odot} \rightarrow R{-}R$$

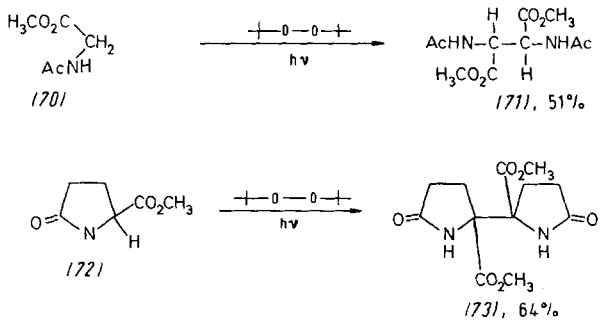


As expected, the hydrogen atom is abstracted mostly, but not necessarily, from a carbon in the α-position to a heteroatom, a cyano or an ester group. Di-*tert*-butyl peroxide (DTBP) has an advantage over other oxidizing species since it forms first very efficient, electrophilic *tert*-butoxy radicals which may further decompose to acetone and (nucleophilic) methyl radicals. The methyl radicals can abstract hydrogen atoms very well, even in the cases where *tert*-butoxy radicals fail, *e.g.* from malonic esters. It is possible to determine which path is operative by measuring the acetone/*tert*-butyl alcohol ratio.

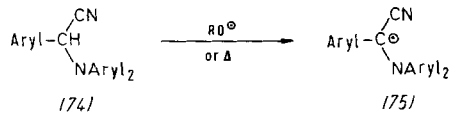
In this review we are concerned only with substrates bearing *cd*-substituents on methylene or methine groups. The available evidence clearly shows that such sites are attacked preferentially and can therefore be considered as "proradical".

This principle is illustrated by the examples given in Table 4[59].

Table 4. Reactions of proradical methylene derivatives *(68)* with di-*tert*-butyl peroxide (DTBP).

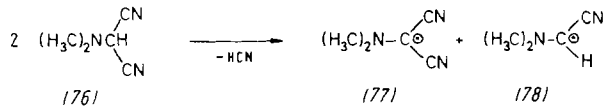


(68) *(69)*

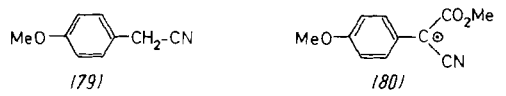


c	d	(69), Yield [%]
CO_2Me	MeO	91
CO_2Me	Me_2N	25
CO_2Me	$MeCO_2$	83
CN	MeO	51
CN	Me_2N	52
$CONMe_2$	Me_2N	31

Even in cases where the yields are low, owing to side reactions, only products arising from attack at the *cd*-substituted site could be isolated.



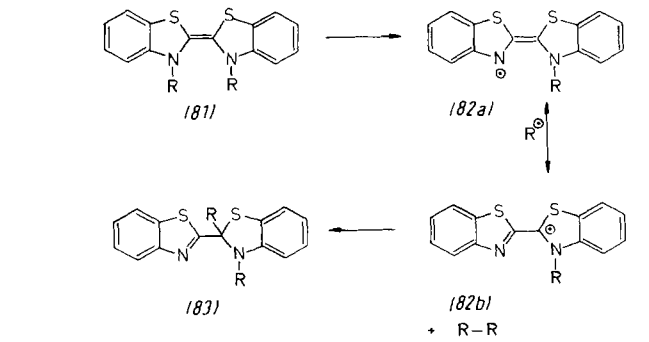
Photochemically generated *tert*-butoxy radicals effected the dimerization of methyl *N*-acetylglycinate *(70)* to *(71)* and of methyl pyroglutamate *(72)* to *(73)*, respectively[60].



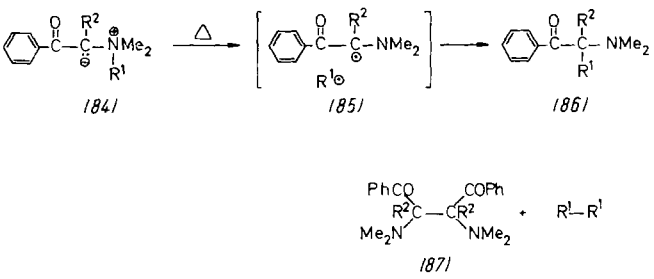
α-Aminobenzyl cyanides *(74)* undergo a very easy hydrogen abstraction with alkoxy and aminyl radicals in benzene; the persistent radicals *(75)* are formed[24] [cf. *(26)*].

Dimethylaminomalononitrile *(76)* decomposes at room temperature to give the persistent radical *(77)*, radical *(78)* and HCN. The abstracting species here is thought to be dimethylamino(cyano)carbene[23].

In another study[61], the relative rates of hydrogen abstraction from substituted phenylacetonitriles by the trichloromethyl radical were measured. This work revealed that *p*-methoxyphenylacetonitrile *(79)*, which can be regarded as *cd*-substituted phenylogous methoxyacetonitrile, reacts three times faster than phenylacetonitrile.



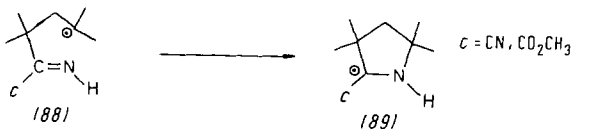
An ESR study disclosed an enhanced spin delocalization in *(80)* owing to the presence of a *p*-methoxy group[21].



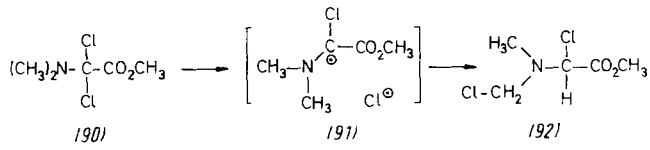
8. Rearrangements Involving *cd*-Substituted Radicals

An increasing number of rearrangements previously thought to be concerted or ionic are now recognized as being of a radical or diradical nature. These rearrangements may proceed with unexpected ease when the radicals involved possess the stabilization imparted by *cd*-substitution.

Thus, the benzothiazoles *(81)*, R = benzyl, are unstable and undergo a [1,3] benzyl shift to give the rearranged product *(83)*. A careful investigation[62] has revealed that the first step involves a dissociation to *(82)* and $R^{\odot}$ followed by recombination to *(83)*. The *cd*-substitution in *(82b)* is obvious.

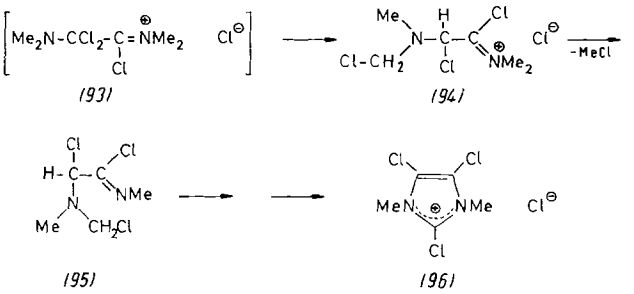


Considerable efforts have been made to establish the mechanism of the Stevens rearrangement and related [1,2] anionic rearrangements[63,64]. The conclusion that such processes proceed *via* radical pair pathways is based on CIDNP results. The isolation of escape products such as *(87)* formed from radical pair intermediates, strong dependence upon solvent viscosity and temperature effects support this mechanism.



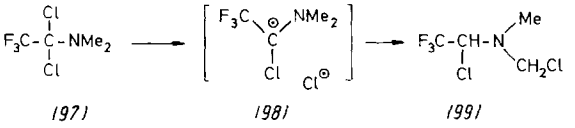
The high degree of stereoselectivity[64] in rearrangements of *(84)* when R^1 is a chiral group seemed at first to be inconsistent with a radical pair process but such stereoselective recombination of radical pairs is now widely accepted. It is a consequence of the limited translational movement required within the radical pair before they recombine to the [1,2] coupling product. More racemization occurs in the competitive [1,3] coupling mode.

An unusual ring-closure of radicals *(88)*, observed recently[65], leads to the more stable *cd*-substituted radicals *(89)*.



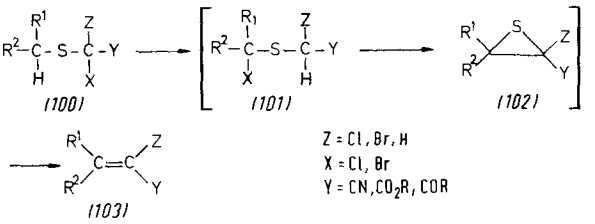
Chlorine attached to a carbon bearing *cd*-substituents as in *(90)* undergoes a peculiar [1,3] migration to the *N*-methyl group[66]:

This reaction might also conceivably proceed through a radical pair *(91)*.



The intermediate *(93)*, which resembles *(90)* and is itself unstable even at low temperatures, apparently rearranges in the same fashion to give *(94)*, which then undergoes loss of

methyl chloride and finally forms the imidazolium chloride *(96) via (95)*[67].



(93) *(94)* *(95)* *(96)*

The covalent amide chloride *(97)* can be isolated, but it rearranges to *(99)* when heated above 100 °C[68].

(97) *(98)* *(99)*

Even more elevated temperatures are necessary for α-haloalkyl sulfides *(100)* bearing various electron acceptor groups. During the flash-pyrolysis, secondary reactions become predominant with accompanying loss of HX and sulfur to give olefins *(103)*[69].

(100) *(101)* *(102)* *(103)*

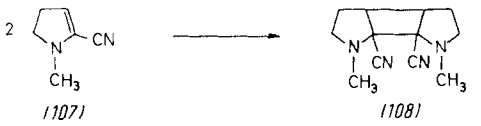
9. Cycloadditions

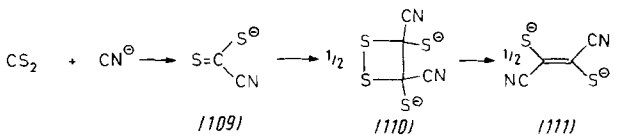
An understanding of the mechanism of cycloaddition reactions has been one of the most challenging problems in modern organic chemistry. Of particular interest is the question whether cycloadditions, retrocycloadditions and related rearrangements are fully concerted, involve a considerable degree of charge separation in the transition state or involve spin-paired diradicals[70]. Polar intermediates can be readily discounted if there is little change in the rate of reaction in different solvents or if the presence of either electron-donating or withdrawing groups leads to an increase in rate. It is much more difficult to distinguish between a concerted process and one in which a spin-paired diradical is formed. In many cases the solvent and substituent effects found, as well as negative values of $\Delta S^{\neq}$, are consistent with either process[71]. Recent studies[72] discuss the possibility of a "concerted-diradical" mechanism for 1,3 dipolar cycloadditions and it was suggested that a more appropriate term for "1,3-dipolar" compounds would be "zwitterionic diradical hybrid"[72].

No matter how important diradical intermediates may be, it is obvious that cycloadditions (or their reversal) would be more likely to develop radical pairs if the compounds carried *cd*-substituents.



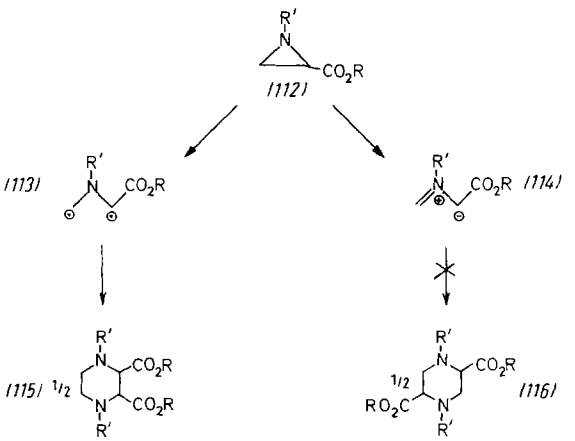
One pertinent example[73] is the spontaneous and reversible dimerization of α-(arylthio)acrylonitriles *(104)* to cyclobutane derivatives *(106)*.

(104) *(105)* *(106)*



The analogous dimerization of acrylonitrile also involves a radical process because it leads to a head-to-head-dimer[74], but it proceeds at much higher temperatures and the yields are low.

A further example is the dimerization of the α-cyano-substituted enamine *(107)*[75].

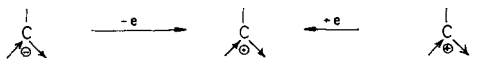


(107) *(108)*

Cyanodithioformate salts *(109)* readily dimerize to fumaronitriles *(111)*[76]. This reaction might also be envisaged as proceeding *via* a 1,4-diradical to give a dithietane *(110)* followed by loss of sulfur.

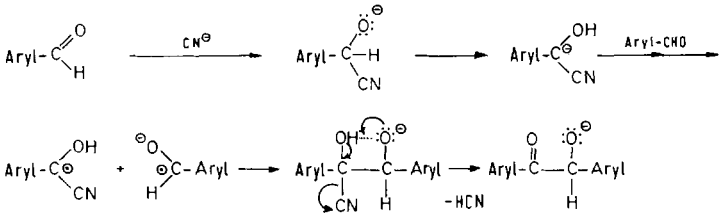
(109) *(110)* *(111)*

Yet another interesting example[77] is the thermal dimerization of the aziridine ester *(112)* leading to a "head-to-head" adduct *(115)*. The dipolar intermediate *(114)* should lead to the other geometric isomer *(116)* but the observed regiospecific formation of *(115)* is consistent with assumption of the existence of diradical *(113)*.



(112) *(113)* *(114)* *(115)* *(116)*

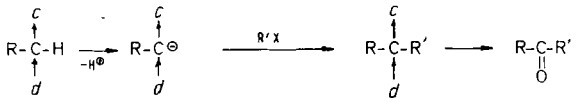
10. Radical Formation by One Electron Transfer Processes Involving *cd*-Substituted Anions and Cations

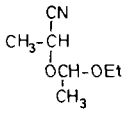


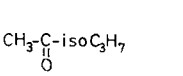
Contrary to radicals, anions are destabilized by *cd*-substitution when the donor groups are amino or alkoxy groups;

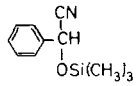
cations are destabilized by poor donors such as alkylthio groups in the presence of electron-acceptor groups.

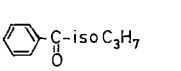
Consequently these very reactive ions should be prone to one-electron transfer reactions:



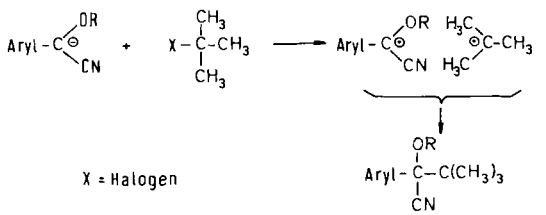






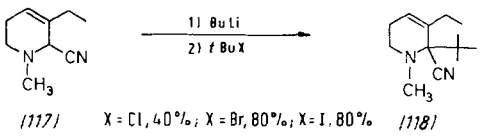


This scheme should enable many classical reactions and certain mechanistic puzzles to be more readily understood. The well known benzoin condensation[78], for example, and its recent extension to vinylogous benzoins[79] are known to pass through *cd*-substituted anions. The high reactivity of these carbanions might be suggestive of one-electron transfer followed by radical coupling.



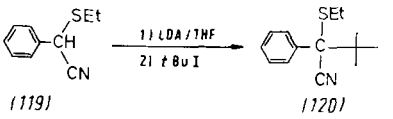
This interpretation is supported by the high nucleophilicity of α-cyano-α-alkoxy substituted anions, even towards tertiary halides[80] (Table 5).

Table 5. Formation of ketones *via cd*-substituted anions.



Substrate	Electrophile	Product	Yield [%]	Ref.
	iso C_3H_7-I		80	[81]
			84	[81]
	iso C_3H_7-I		95	[82]
	t Bu-I		85	[82]

One-electron transfer followed by radical coupling could explain this puzzling but highly useful ditertiary carbon-carbon bond formation.

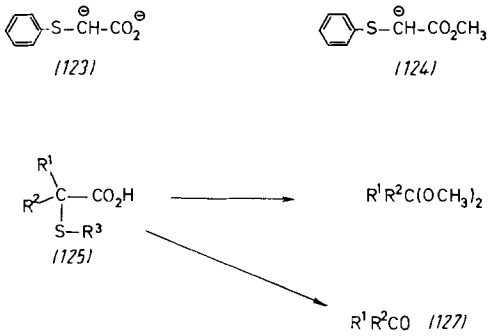


It should be kept in mind that these reactions do not always proceed through radical pairs and there is compelling evidence that strongly polar transition states may develop in some cases[83].

Anions derived from α-aminonitriles[84] or α-aminoesters[85] have also been used successfully as synthetic equivalents to nucleophilic acyl anions, even in cases where dithiane anions[86] do not work[87]. The classical S_N2 mechanism does not suffice to explain some recent results, as for example in the reaction of *(117)*[88].

(117) X = Cl, 40%; X = Br, 80%; X = I, 80% *(118)*

α-Alkylthionitrile anions *(119)*, which have already been used in substitution reactions with alkyl halides[89,90], can also be alkylated in high yield with *tert*-butyl iodide[91] (LDA = lithium diisopropylamide).

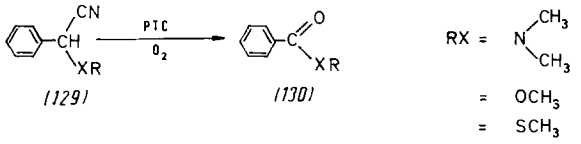


(119) *(120)*

Ethyl 2-lithio-1,3-dithiane-2-carboxylate *(121)*, *Schlessinger's* reagent[92], reacts stereoselectively *via* 1,4-addition with α,β-unsaturated ketones, whereas 2-lithio-1,3-dithiane requires the presence of a copper salt[93]. The alkylation of *(122)* has been described as being very easy and yields are very high even with isopropyl iodide (91%)[94].

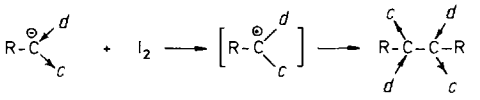
(121) *(122)*

The dianions *(123)* of (phenylthio)acetic acid and the monoanion *(124)* have been reported to react very smoothly with alkyl halides and carbonyl compounds[95]. The resulting α-(alkylthio)carboxylic acids *(125)* can be transformed into ketals *(126)* using the procedure of *Trost*[96], which involves an oxidative decarboxylation. An alternative method involves electrolysis under very mild conditions; the ketones *(127)* corresponding to *(126)* are obtained[97].



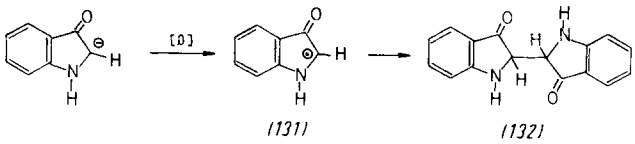
The dianion of phenoxyacetic acid *(128)* also reacts with remarkable ease with alkyl halides and ketones[98].

Furthermore, besides substitution reactions which proceed *via* radical anion intermediates[99], there are only a few well-authenticated examples of S_N2 displacements at a tertiary carbon atom[100].



Since the tendency towards reduction of alkyl halides[101] decreases in the order C—I > C—Br > C—Cl, electron transfer reactions from *cd*-anions to alkyl halides must follow the same trend.

The high probability of one-electron-transfer from *cd*-anions is also supported by their great ease of oxidation. Thus α-(dimethylamino)-, α-methoxy- and α-(methylthio)benzyl cyanides *(129)* mostly lead quantitatively *via* phase transfer catalysis (PTC) to the amides, esters and thioesters *(130)*, respectively, under conditions which do not affect phenylacetonitrile[102].



The well known dimerization of carbanions by iodine proceeds either through radicals formed *via* one-electron-transfer or through iodides which couple with the carbanion present in an S_N reaction[103]. The latter path is less probable in the case of *cd*-substituted carbanions and one-electron-transfer is a more realistic alternative (see Table 6).

Table 6. Dimerization of carbanions with iodine.

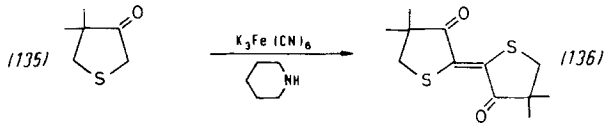
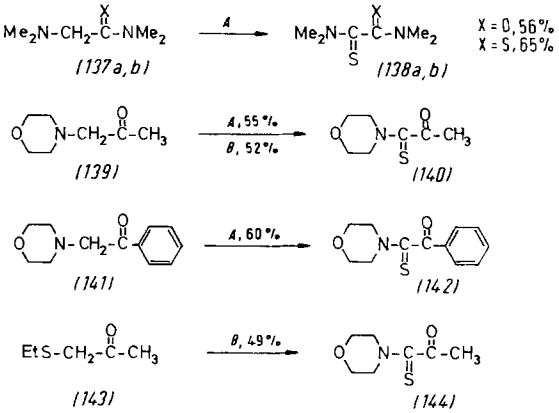
S*i*Pr	*i*PrS	S*i*Pr	50	[104]



The conversion of indoxyl into indigo by the action of oxygen in basic solution proceeds *via* indoxyl radicals *(131)* followed by coupling to give leucoindigo *(132)*[105].

The oxidation of the piperazinedione *(133)* to *(134)* takes place with exceptional ease at the *cd*-substituted methine position[106].

The dihydrothiophen-3(2H)-ones *(135)* can be oxidized directly to thioindigo-like compounds *(136)*[107].



Other oxidizing agents like halogens and sulfur are also very good reaction partners for *cd*-substituted methylene compounds. Photochemical bromination proceeds very smoothly and yields are very good[91], except when *d* is an amino group (see Table 7).

Table 7. Photochemical bromination of *cd*-substituted methylene compounds.

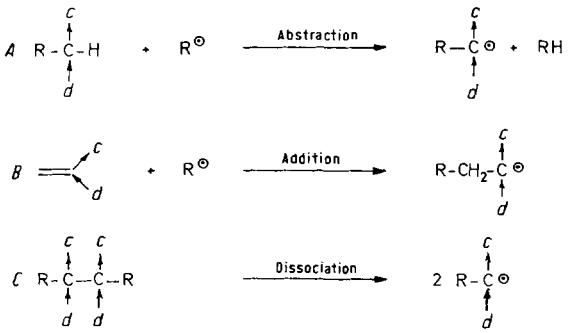
CO_2Me	MeO	91
CN	MeO	87
CN	MeS	94
CO_2Et	EtS	95
COMe	EtS	92

A number of *cd*-substituted methylene groups have been sulfurated using sulfur in DMF at 150 °C (conditions *A*) or at



Scheme 3. Reaction of *cd*-substituted methylene compounds with sulfur. *A*, *B* see text.

room temperature with sulfur, DMF and morpholine (Route *B*). The results are summarized in Scheme 3[108].

11. *cd*-Substituted Radicals in ESR Spectroscopy

Three routes have been used for the generation of *cd*-substituted radicals in an ESR cavity:

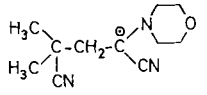
Thus formed, many *cd*-substituted radicals can be detected by ESR at unusually high temperatures. If $d = NR_2$ or SR, the signal disappears on cooling and reappears reversibly upon heating. ESR data of radicals generated by method *B* are presented in Table 8.

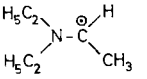
Table 8. ESR data of *cd*-substituted radicals *(145)* in chlorobenzene at 130 °C [4, 109].

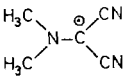
	c	*d*	a_N CN	a_N NR_2	β	a_H γ	δ
(145a)	CO_2CH_3	OCH_3	—	—	9.82	2.65	1.19
(145b)	CN	Morpholino	2.94	7.9	10.12	7.12	—
(145c)	CN	$N(CH_3)_2$	3.0	8.0	7.4	6.2	—
(145d)	CN	SCH_3	2.75	—	9.14	3.68	—
(145e)	CO_2CH_3	SCH_3	—	—	7.9	4.1	0.9

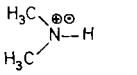
If we compare the hyperfine coupling constants on nitrogen atoms of the amino group and of the cyano group in radicals *(145)* with those observed for α-cyano or α-amino radicals (Table 9), it is clear that:

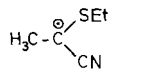
a) Introduction of a donor (morpholino) group on the radical already substituted by a cyano group [*(146)*→*(145b)*], decreases the spin density on the cyano nitrogen atom.





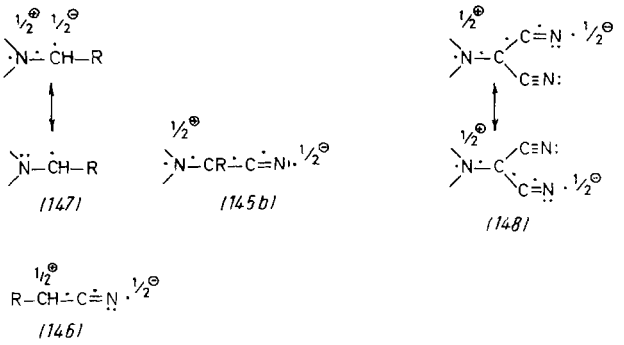






b) Introduction of an acceptor (cyano) group on the radical already substituted by an amino group [*(147)*→*(145b)*] increases the spin density on the amino nitrogen.

c) Introduction of a second cyano group [*(145b)*→*(148)*] on the *cd*-radical again increases the spin density on the amino group nitrogen atom.



The same trend is observed for *cd*-systems with an alkylthio substituent as donor group (Table 9).

Linnett structures are in agreement with these facts: the stabilization by electron sharing gives an unfavorable polarization in the radical *(147)* and a favorable one in *(146)*. Thus, considering the *cd*-substituted radical *(145b)*, the gain in spin delocalization is more important relative to *(147)* than to *(146)*.

Table 9. ESR data of radicals with α-cyano-, α-amino and α-alkylthio substituents.

	$R^{\odot}$	a_N^{CN}	$a_N^{NR_2}$	$a_H^{SCH_2}$	Ref.
(145b)		2.94	7.9		[4, 109]
(146)		3.41			[110]
(147)		—	5.2		[111]
(148)		1.99	10.25		[23]
(149)		—	19.28		[112]
(150)				1.6	[113]
(151)		2.6		2.0	[114]

The double-quartet of electrons is realized for each atom in *(145b)*, and the molecule is polarized in the favorable direction. This occurs even more so in radical *(148)*.

According to their radicophilic nature, *cd*-substituted olefins can trap radicals more or less independent of their polarization. Thus, for all of the various types of radicals listed in Table 10, α-(alkylthio)acrylonitriles act as very powerful scavengers[114].

Table 10. ESR data of radical-adducts in chlorobenzene at 130 °C [114].

	$R^{\odot}$	$a_\beta^{CH_2}$	a_N^{CN}
(153a)	$(nBu)_3\overset{\oplus}{Sn}$	8.5	2.5
(153b)	$(CH_3)_2\overset{\oplus}{C}$ OH	8.5	2.6
(153c)	$CH_3S^{\odot}$	8.3	2.5
(153d)	$(CH_3)_2\overset{\oplus}{C}$ CN	8.3	2.5
(153e)	$Cl_3C^{\odot}$	7.5	2.5

The use of α-(*tert*-butylthio)acrylonitrile *(152)* in spin trapping studies of transient radicals, where the unpaired electron is located on a non-zero spin nucleus such as phosphorus[114], is complementary to the trapping with nitroso compounds and nitrones in that ^{31}P-couplings can be studied up to 170 °C (Table 11).

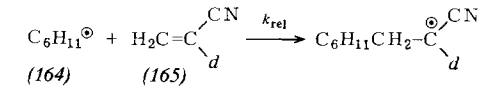
Table 11. ESR data of adducts *(154)* from substituted phosphorus radicals and α-(*tert*-butylthio)acrylonitrile *(152)* [114].

(152) *(154)*

	$L_nP^{\odot}$	a_P	a_{H^1}	a_{H^2}	a_N
(154a)	$Et_2\overset{\odot}{P}O$	39.0	10.0	10.0	2.6
(154b)	$Ph_2\overset{\odot}{P}O$	41.0	10.0	9.2	2.6
(154c)	$EtO(Ph)\overset{\odot}{P}O$	46.8	9.7	9.5	2.6
(154d)	$(EtO)_2\overset{\odot}{P}O$	51.5	10.0	10.0	2.6
(154e)	$(Me_3SiO)_2\overset{\odot}{P}O$	57.2	9.2	9.2	2.6
(154f)		63.0	10.0	9.5	2.6
(154g)		75.0	8.7	8.7	2.6

Another aspect of ESR studies of *cd*-substituted radicals concerns the effect of substituents upon the structure[115].

Both the cyano and the alkylthio groups have been shown to induce a planar configuration at a radical center[116,117]. Accordingly, a radical substituted by both these groups should be planar, since electron delocalization gives the C—CN and C—SR bonds some double bond character. This conclusion is supported by the experimental value of $a_{^{13}C}$ for radical *(153d)* and its temperature dependence:



$a_{^{13}C} = [(25.76 \pm 0.02) + (8.0 \pm 0.8) \times 10^{-3} t]$ Gauss ($t = °C$)[114].

The decrease in the spin density at the radical center is a qualitative indication of the radical stabilizing effect of the substituents. The α-CH_3 coupling constants of the radical $CH_3-\overset{\odot}{C}H-X$ are proportional to the spin density on the central carbon atom (*Fischer*'s approach[118]). However, to compare spin densities in a quantitative way, planar configurations of the radical centers are required. This is certainly the case for *cd*-substituted radicals; thus, the decrease in spin density on the radical center, caused by the combined action of an acceptor and a donor substituent, can be deduced from the ESR parameters (Table 12).

The negative difference between the observed and calculated ρ values, for the planar radical *(151)* seems to reflect a certain trend in the mutual interaction of the acceptor and donor groups. This qualitative approach is in good agreement with an enhanced radical stabilization by the *cd*-effect. In contrast, $(\rho_{obs.} - \rho_{calc.})$ is positive for the bis(thioethyl)-substituted radical *(163)*. As far as the known *cd*-substituted ethyl radicals *(159)* to *(162)* are concerned, this difference is negative. Nevertheless, the latter values should be regarded with caution since a planar configuration of these radicals has not been proven.

12. Rates of Addition of Radicals to *cd*-Substituted Alkenes

Alkyl radicals behave like nucleophiles in addition reactions with alkenes. This polar effect has been confirmed by positive ρ^+-values in reactions with styrene derivatives[123]. On insertion of electron-donor groups *d* into electron-deficient alkenes with acceptor groups *c* the rate of reaction depends on the opposing influences of the *d*-substituents on the radical stability and the polar effect. In fact, *Giese et al.*[25,124] found that the strong electron-donor *d* = morpholino hardly changes the reaction rate in additions of cyclohexyl radicals *(164)* to acrylonitriles *(165)*, although unsubstituted enamines react very slowly with alkyl radicals. Thio and seleno groups increase the rate of addition (cf. Table 13).

(164) *(165)*

Table 12. p-Orbital spin density at the center of the radical $R^{\odot}$.

	$R^{\odot}$	$a_{\beta}^{CH_3}$ [Gauss]	$\rho_{obs.}$ [a]	$\rho_{calc.}$ [b]	$(\rho_{obs.} - \rho_{calc.})$	Ref.

[a] Mean error ±5%; for determination cf. [123].

13. Outlook

The *cd*-substituent effect represents a challenge for theoretical chemistry, in particular for quantitative molecular orbital considerations and for *ab-initio* calculations. Spectroscopic studies are necessary to determine the structures and configurations of *cd*-substituted radicals and to measure their life-times and monomer-dimer equilibrium constants.

The concept of *cd*-substitution sets new goals and reveals new possibilities for organic synthesis especially in the fields of cycloadditions, nucleophilic and electrophilic substitutions, and selective reductive or oxidative transformations *via* radicals.

These applications reach far beyond the field of chemistry into everyday life, for example in the design of new inhibitors of polymerization and oxidation. In medicine and generally in biology, there appears a possibility of controlling the ageing of cells. The anticipated control of mutagenicity based upon the concept of radicophilicity has been proven in the Ames Test.

Radicals, afterall, pervade the whole of life: in photosynthesis, growth and ageing. Hence, the synthesis of radicals and control of radical processes represents an exciting research problem both for the present and for the future.

For helpful discussions we thank our colleagues: A. T. Balaban, Sir D. H. R. Barton, J. I. G. Cadogan, R. A. Firestone, B. Giese, R. Huisgen, S. Hünig, K. U. Ingold, A. R. Katritzky, G. Leroy, H. Naarmann, Nguyen-Trong-Anh, Ch. Rüchardt, G. Smets, J. M. Surzur, Lord J. M. Tedder, P. Tordo and J. C. Walton. For their particular assistance we thank our coworkers: T. G. C. Bird, F. Hervens-Gorissen, B. Le Clef, M. Demolder-Marin and L. Vertommen. We gratefully acknowledge generous support from the Institut pour l'Encouragement de la Recherche Scientifique dans l'Industrie et l'Agriculture (IRSIA), BASF A.G. Ludwigshafen, and the Fonds de la Recherche Fondamentale et Collective.

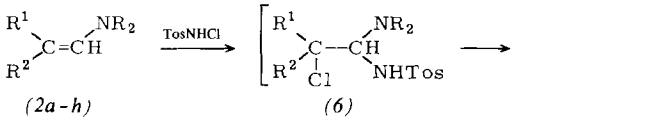
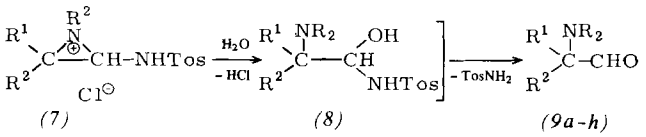
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

α-Aminoaldehydes from Enamines and Chloramine-T[**]

By *Ingolf Dyong* and *Quan Lam-Chi*[*]



In the search for new synthetic routes to antibiotic sugars with >N–C–R-branching we started from the idea that regioorientation in the vicinal *cis*-hydroxyamination of olefins with OsO_4/Chloramine-T trihydrate[1,2] [reactive species: *(3)*[1]] can be steered by electronic substituent effects[3]. Thus, 1,3-dipolar cycloaddition of *(3)* to β-C branched olefins having an electron donor on the α-C atom [vinyl ethers *(1)* or enamines *(2)*] should lead to α-amino derivatives of type *(4)*, and after cleavage of alcohol or amine to α-(*N*-tosylamino)aldehydes *(5)*, respectively.



(1), X = OR
(2), X = NR_2

(4) *(5)*

Vinyl ethers *(1)* react, as expected, to give compounds *(5)*. This reaction also takes place with the trihydrate of *N*-chloro-*p*-toluenesulfonamide (Chloramine-T)[4] in absence of OsO_4. Under these conditions, however, the enamines *(2a–h)* afford almost quantitatively (crude products) the *N,N*-dialkylated α-aminoaldehydes *(9a–h)* (Table 1).

(2a–h) *(6)*

(7) *(8)* *(9a–h)*

Table 1. Physical data of the α-aminoaldehydes *(9a–h)*. In the mass spectra the ions with $m/e = M^+ - CHO$ always appear as base fragment. All compounds *(9)* gave correct elemental analyses.

	R^1	R^2	NR_2	Yield [%]	M.p. [°C] B.p. [°C/Torr]	^{1}H-NMR [δ_{CHO}]
(9a)	$-(CH_2)_5-$		Piperidino	70	30	9.32 [a]
(9b)	$-(CH_2)_5-$		$N(CH_3)_2$	50	42/0.1	9.34 [a]
(9c)	CH_3	CH_3	Piperidino	77	40/0.1	9.36 [a]
(9d)	CH_3	CH_3	Morpholino	64	69/4	9.31 [b]
(9e)	C_2H_5	C_2H_5	Piperidino	74	81/3	9.38 [b]
(9f)	C_2H_5	C_2H_5	Pyrrolidino	72	77/5	9.60 [a]
(9g)	C_6H_5	CH_3	$N(CH_3)_2$	83	62/0.01	9.33 [b]
(9h)	C_6H_5	CH_3	Piperidino	84	110/0.01	9.30 [b]

[a] 100 MHz in $CDCl_3$; [b] 60 MHz in $CDCl_3$.

To our knowledge the hitherto best entry to α-aminoaldehydes *(9)* was by reaction of the corresponding α-haloaldehydes proceeding *via* β-haloiminium salts[5,6] to the aziridinium ions, which react with alcohol/triethylamine to give acetals of *(9)*[5] or with bases to give *(9)*[7].

The initial step of the reaction *(2)*→*(9)* is most likely an electrophilic halogenation of the enamines *(2)* by *N*-chloro-*p*-toluenesulfonamide[8]. In the resulting aminals *(6)* the dialkylated nitrogen is the better nucleophile, so that reaction proceeds *via* aziridinium salts of type *(7)* giving *N*-tosylated "*N,O*-semiacetals" *(8)*, which lose tosylamide with formation of the α-dialkylaminoaldehydes *(9a–h)*.

The rearrangement *(6)*→*(8)* proceeds intramolecularly, since only *(9)* is formed, even in the presence of competing amines.

Since the reaction of ketones with *N*-alkylated lithioaminomethylphosphonates leads directly to enamines of α-branched aldehydes[9] and since hexopyranoside-*n*-uloses ($n = 2$–4) are readily accessible the reaction *(2)*→*(9)* with enamines of *C*-formyl branched hexopyranosides could lead to carbohydrates with >N–C–R-branching.

General procedure

A mixture of *(2)* (0.04 mol) and Chloramine-T·$3H_2O$ (0.05 mol) in CH_2Cl_2 (140 ml) is stirred for 3.5–20 h at room temperature (chromatographic monitoring). The filtrate is washed twice with 200 ml 4% NaOCl and once with 200 ml semi-saturated NaCl solution, dried and evaporated down. The residue is distilled under reduced pressure.

Structure of the Dicyanophosphide Ion in a Crown-Ether Sodium Salt[**]

By *William S. Sheldrick, Jürgen Kroner, Franz Zwaschka,* and *Alfred Schmidpeter*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

The dicyanophosphide ion $P(CN)_2^-$ is formed on reduction of phosphorus tricyanide, *e.g.* with [18]crown-6-sodium cation surrounded by a crown ether and situated at a crystallographic inversion center (0.5, 0, 0.5 and 0, 0.5, 0.5, respectively), which takes up two further ligands in the *trans* position, namely two *O*-coordinated tetrahydrofuran molecules or two *N*-coordinated dicyanophosphide ions (Fig. 1)[3]. The latter randomly populate two different sites with occupation factors of 0.42 and 0.58(1), respectively (Fig. 1, *(2)* bottom view). In *(1)*, as in *(2)*, the ligand atoms surround the Na^+ ion in an almost (squat, cf. bond lengths, Fig. 1) hexagonal

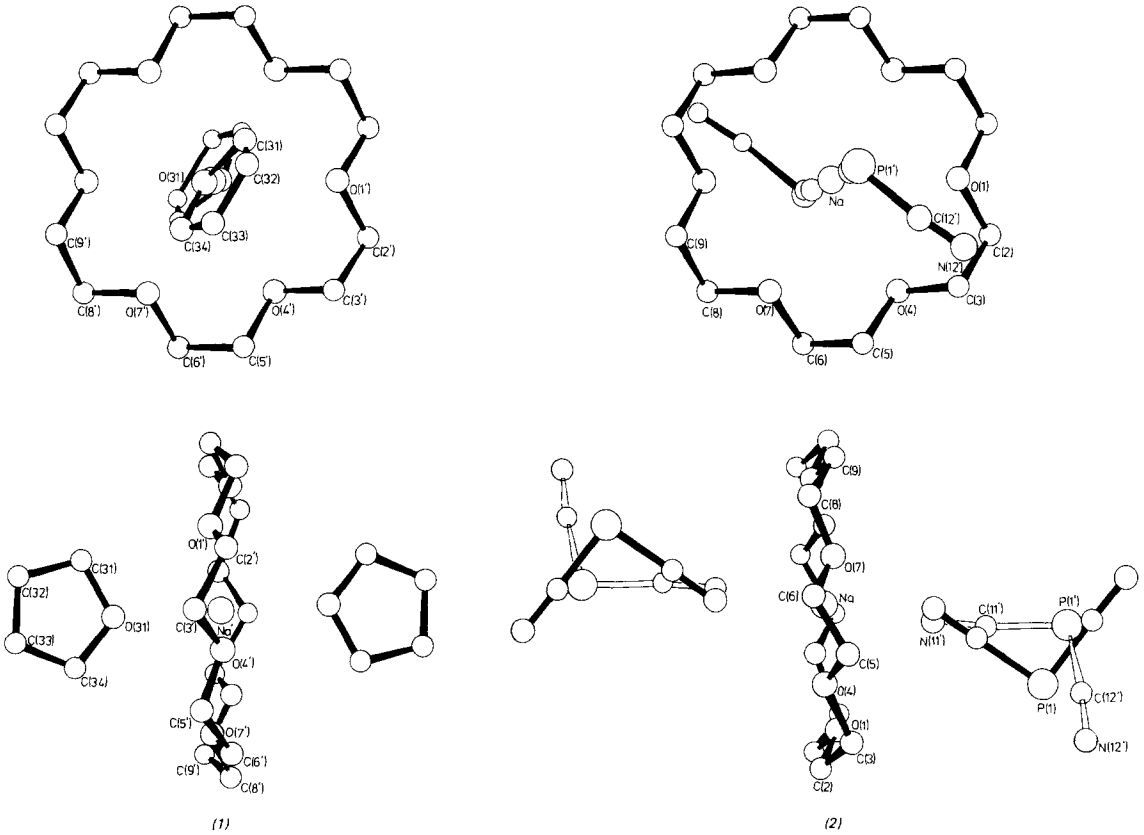

Fig. 1. View of the $\{[18]crown\text{-}6\text{-}Na(tetrahydrofuran)_2^+\}^-$ *(1)* and the $\{[18]crown\text{-}6\text{-}Na[P(CN)_2^-]_2\}^+$-unit *(2)* perpendicular (top) and parallel (bottom) to the crown-ether plane.

Bond lengths [pm]					Apex-(Na or Na')-equator angles [°]			
		Na	N(11)	244(2)				
Na' O(31)	236.4(7)	Na	N(11')	248(2)		O(31)	N(11)	N(11')
Na' O(1')	271.2(5)	Na	O(1)	277.5(2)	O(1 or 1')	88.8(2)	81.9(4)	75.0(5)
Na' O(4')	273.9(5)	Na	O(4)	277.9(6)	O(4 or 4')	92.3(2)	87.5(4)	89.6(5)
Na' O(7')	279.1(4)	Na	O(7)	273.2(7)	O(7 or 7')	83.3(2)	84.9(4)	94.0(6)

diethyl phosphite in tetrahydrofuran[1]. $NaP(CN)_2$ crystallizes with the crown ether and tetrahydrofuran in the molar ratio 1:1:1. The X-ray structure analysis[2] shows that comparable positively *(1)* and negatively *(2)* charged units are present in the crystal. They are each formed from a sodium bipyramidal arrangement. As a result of the alternating deviations of the crown ether oxygen from the mean NaO_6 plane (O(1') −16.3, O(4') 16.2, O(7') −16.1; O(1) −17.2, O(4) 17.0, O(7) −17.4) it is clearly distorted into a scalenohedron, and in *(2)* additionally so by the inclination of the NP axis.

The optimization of all bonding parameters by the STO-3G method[4] predicts a planar molecular skeleton for the $P(CN)_2^-$ ion with the bond lengths and angles shown in Figure 2a. The PCN moieties are bent slightly outwards[5]. The calculated net densities show that the anionic charge is distributed completely over the two cyanide residues while the phosphorus remains free. The high population on N corresponds to the (charge-controlled) *N*-coordination of $P(CN)_2^-$ to Na^+ in the structure described here[6, 7].

The calculated structure is largely confirmed by the X-ray structure analysis (cf. Fig. 2b). However, the values mea-

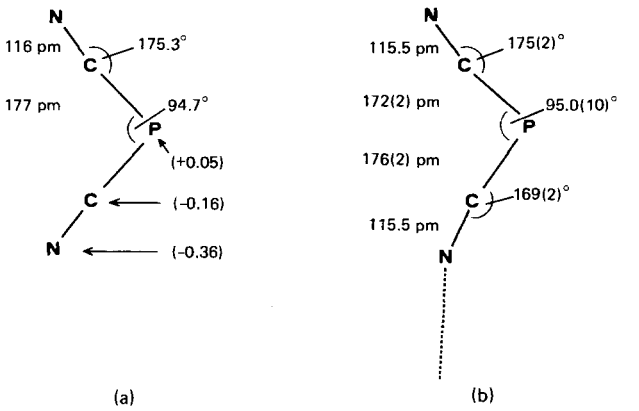

Fig. 2. Bond lengths and angles (and net charge densities) in the cyanophosphide ion: a) calculated [STO-3G], b) from the structure determination (mean values according to the given refinement model [2]).

sured for the $P(CN)_2^-$ ion are subject to larger standard deviations than normal owing to its disorder. In particular the bond lengths P(1)—C(11) [P(1′)—C(11′)] and Na—N(11) [Na—N(11′)] and the angles P(1)—C(11)—N(11) [P(1′)—C(11′)—N(11′)] should be treated with reservation owing to the overlapping of the disordered atoms C(11) and C(11′) and N(11) and N(11′) (for refinement conditions see [2]). Remarkably, the $P(CN)_2^-$ parameters deviate very little from those of $P(CN)_3$ (PC 178, CN 115 pm; CPC 93, PCN 172°)[8]. Only the PC bonds appear somewhat shorter—also compared with the calculated values—and the CPC angle of 95(1)° is not—as would be expected for a phosphide—narrower, but wider than in $P(CN)_3$. Both these findings are consistent with an increased charge delocalization in the cyanide residue. The PCN angles correspond to the calculated value, but they are not coplanar.

Five-coordinate Tervalent Phosphorus in the Tricyanobromo- and -iodophosphate(III) Ion[**]

By *William S. Sheldrick, Franz Zwaschka,* and *Alfred Schmidpeter*[*]

Dedicated to Professor Kurt Issleib on the occasion of his 60th birthday

High-coordination polyhedra are naturally attained more easily for a high oxidation state of an element than for a lower one. In a recent classification of phosphorus compounds[1], of all the reasonable phosphorus coordination possibilities

for P^{III}—in contrast to P^V—only the first two are shown. The third one should be present in the recently prepared cyanohalophosphates(III)[2]. The structure determination of two prototypes, the crown ether alkali metal salts $NaP(CN)_3Br$ and $NaP(CN)_3I$, now surprisingly shows an even higher phosphorus coordination owing to a dimerization of the anion. They provide the first examples of pseudo-(ψ-)octahedral phosphate(III) species[3].

The two compounds crystallize isomorphously in the space group Cmca with four units of the dimer in the elementary cell[4]. The cation shows crystallographic C_h-, the anion C_{2h}-symmetry. The Na^+ cation is eightfold oxygen-coordinated by the [18]crown-6 and perpendicular to its ring by two tetrahydrofuran molecules (as in the case of crown ether complexed $NaP(CN)_2$[5]); one of the tetrahydrofuran ligands is disordered with respect to a plane of symmetry.

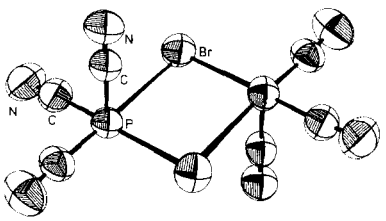

Fig. 1. Structure of the anion $[P_2(CN)_6Br_2]^{2-}$ in the crystal.

The phosphorus coordination in the anion (Fig. 1) can be described as an octahedron, formed by three facial cyano groups, two halogen atoms X, and the lone pair of electrons. Two of these ψ-octahedra are linked by a common X_2-edge with the apical cyano groups in the *trans*-position. The only other examples of edge-linked ψ-octahedra were found in

$Bi_2Cl_8^{2-}$[6] and as structural unit in the $SbS_{\frac{2}{2}}^{-}$-layer[7]. Here again the apical ligands are *trans* to each other[8].

As expected from electron pair repulsion the phosphorus atom lies below the basal plane of the pyramid (Fig. 1). The basal PCN groups are bent in such a way that their N atoms too are below this plane. The apical PCN group on the other hand is linear and leans somewhat towards the linking edge. Whereas in ψ-octahedra the apical bond is normally shorter than the equatorial ones, the PC-distances here do not differ significantly. In accordance with its synthesis the $P_2(CN)_6X_2^{2-}$ ion can be regarded as two $P(CN)_3$ molecules linked by a halide double bridge. Actually the geometries of the $P(CN)_3$ units therein, for X = Br as well as for X = I, deviate only slightly from free $P(CN)_3$ itself (Table 1). Thus the

Table 1. Bond lengths [pm] and angles [°] of the anion in $[C_{12}H_{24}O_6Na(OC_4H_8)_2]_2[P_2(CN)_6X_2]$ and of $P(CN)_3$ (average values) for comparison [9], deviations [pm] of P and of N from the basal C_2X_2-plane (opposite to the apex direction).

N		7.6	10.7	

CPC-angles shrink by only about 1°. On average the PC bonds lengthen by 4 pm and the CN bonds shorten by 3 pm, indicating a weaker bond between P and CN. The distances from P to X are considerably longer than for every known PX bond, being approximately the average of the single bond length in PX_3 (X = Br: 222, X = I: 243 pm) and the sum of the van-der-Waals radii (X = Br: 385, X = I: 405 pm). The coordination number 5, unexpected high for P^{III}, is thus apparently a result of the small reorganization necessary, rather than of strong PX bonds (the ψ-octahedral structure of the dimer with ideal PCP angles of 90° should be more favorable than the ψ-trigonal-bipyramidal one of the monomer with two ideal angles of 90° and one of 120°).

For the solid $P(CN)_3X$ salts we find $\delta^{31}P = -177$ (X = Br) and -168 (X = I); in solution these shifts are almost the same, indicating the dimeric anion to be preserved in solution.

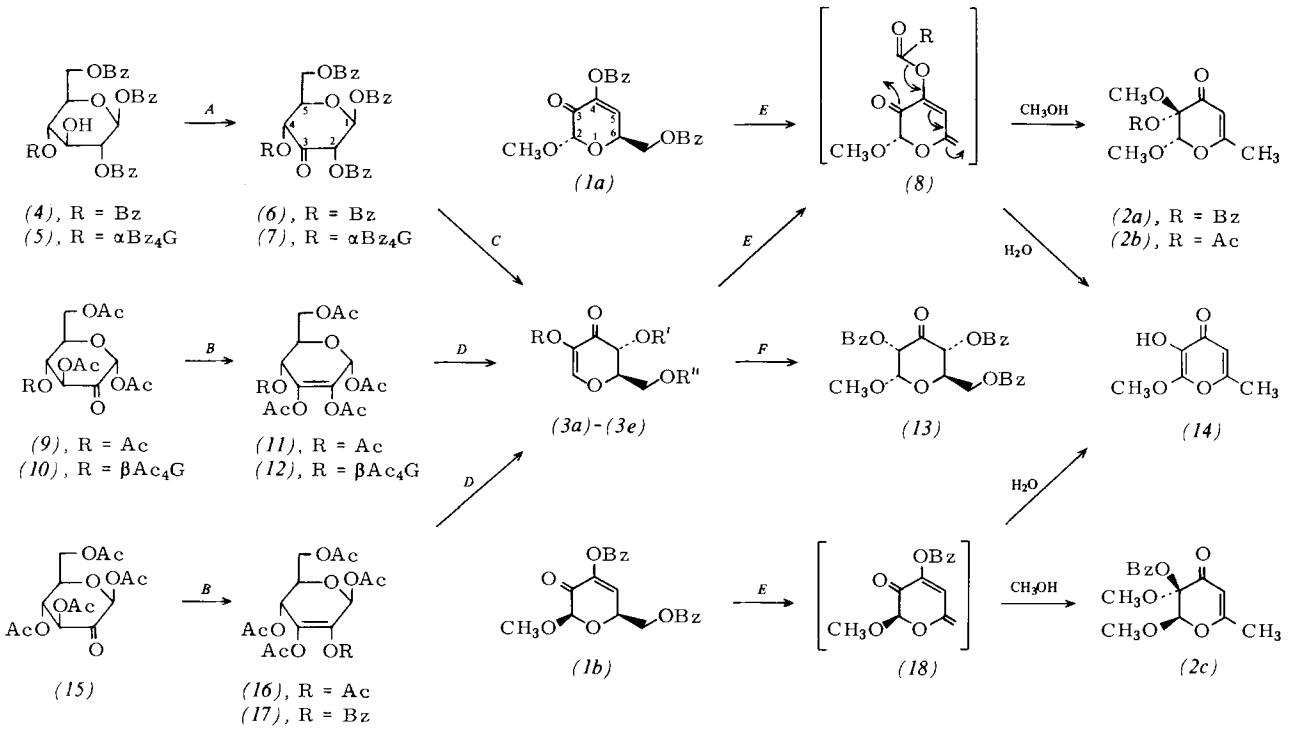
Novel, Highly Stereoselective Rearrangements of Chiral Dihydropyranones[1]

By *Frieder W. Lichtenthaler, Shigeru Nishiyama,* and *Pan Jarglis*[*]

Dihydropyranones *(1)*[2] are important chiral synthons[3] since the enolone grouping is flanked on each side by chiral centers. A similar synthetic potential attends enediolones *(3)* which hitherto have only been obtained sporadically and in multistep syntheses[4]. We here wish to report on new, facile procedures for the preparation of *(3)* and on the very ready rearrangements of type *(1)*→*(2)* and *(3)*→*(2)*, the latter being remarkable in so far as it comprises a highly stereoselective chirality transfer from one side of the ring to the other.

(1) *(2)* *(3)*

R = Acyl, R' = Alkyl



Pyranoid enediolones *(3)* are not only accessible from peracylated hexos-3-uloses by an expectedly[3] facile elimination

of the anomeric substituent, but also from the corresponding hexos-2-uloses *via* a 2→3 shift of the carbonyl group prior to elimination. Thus, the preparatively most convenient method of synthesis is determined by the accessibility of the educt. For instance, the tribenzoyl compound *(3a)* (Scheme 1, Table 1) may be prepared in high yield from tetrabenzoylhexosulose *(6)* by brief heating with $NaHCO_3$ in moist benzene or from the tetrabenzoyl-glucose *(4)* by reaction with dimethyl sulfoxide (DMSO)/acetic anhydride or DMSO/trifluoroacetic anhydride (cf. Table 1). Correspondingly, maltose can be converted into the disaccharide enediolone *(3b)* in 67% yield by benzoylation to the heptabenzoate *(5)*[6] and subsequent reaction with DMSO/acetic anhydride. *O*-Acetylated enediolones such as *(3c)*, *(3d)*, and *(3e)* are most conveniently prepared from the readily accessible[2e,3] peracetylhexos-2-uloses *(9)*, *(10)*, and *(15)* by cautious acylation[8] to the corresponding 2,3-dehydrosugars *(11)*, *(12)*, *(16)*, and *(17)*, and treatment with $AlCl_3$ or $SnCl_4$ in chloroform. The latter step proceeds *via* the 1-chloride and subsequent removal of the elements of acetyl chloride. Alternatively, the enedioldiacetate → enediolone conversion may also be achieved by treatment with HBr/acetic acid (to the 1-bromide) and subsequent treatment with pyridine.

On BF_3 catalysis, enediolones *(3)* add methanol at the anomeric carbon preferentially from the α-side, *e.g.* *(3a)*→*(13)*. Mildly basic conditions, however, such as methanol/potassium carbonate in DMSO, initiate more profound transformations with the elaboration of 5-methyldihydropyranones, as illustrated by the conversions *(3a)*→*(2a)*, *(3d)*→*(2a)*, and *(3c)*→*(2b)*, which proceed with high stereoselectivity[9]. On the other hand, analogously feasible conversions of enolones of type *(1)* are practically stereospecific: *(1b)* yields the 2*R*,3*R*-dihydropyranone *(2c)* in high yield (quantitative conversion, 77% isolated), whilst the anomeric α-enolone *(1a)* is as readily transformed into the 2*S*,3*S* enantiomer *(2a)*.

Structural assignments for dihydropyranones *(2a)* and *(2c)* are based on UV [$\lambda_{max}^{CH_3OH}$ = 233 (11000) and 267 nm (8500)] and ^{1}H-NMR data [δ = 2.06 (C–CH_3), 3.38 and 3.51 ($2OCH_3$), 5.40 (s, 1 anomeric H), 6.18 (s, 1 olefinic H). That the compounds are enantiomers is deduced from identical IR and NMR data and the same magnitude yet opposite sign of their rotations and CD data [*(2a)*: Δε = −1.7 (229 nm), +6.3 (260), +0.6 (290), +2.0 (319)], from which the configuration at the tertiary carbon may also be deduced[10].

The conversion *(1)*→*(2)* is obviously initiated by a known[2b,c] 5,6-elimination of benzoic acid to give the dienolones *(8)* and *(18)*, followed by protonation of the exocyclic double bond and benzoyl migration, and is concluded by addition of the nucleophile ($CH_3O^{\ominus}$), which is stereocontrolled by the anomeric substituent. The elaboration of the γ-pyrone system in the form of methoxyallomaltol *(14)* on replacement of methanol with water is in accord with this view. The conversion *(3)*→*(2)* proceeds *via* analogous intermediates; the 3,2-enolone system *(1)* is primarily formed by preferential α-addition of the alcohol [*e.g.* *(3a)*→*(13)*], *O*-2→*O*-3-acyl migration to the hexosid-2-ulose, and β-elimination of HO-Acyl. This course is substantiated by the observation that peracylated hexosid-3-uloses as readily yield dihydropyranones *(2)* under these conditions [*e.g.* *(13)*→*(2a)*], whereas the 4-*O*-glycosylated enediolones *(3b)* and *(3e)*, lacking a displaceable substituent at C-4, do not undergo these reactions.

These highly stereoselective rearrangements, practically stereospecific in the case of enolones *(1)*, considerably widen the scope of application of pyranoid sugar enolones as chiral synthons, particular with respect to the synthesis of uscharine-type cardiac glycosides and spectinomycin antibiotics.

[8] Excess pyridine causes partial 3,4-elimination to the 3,2-enolone *(1a)*, Ac instead of Bz and CH_3; pyridine/acetic anhydride converts *(9)* quantitatively into di-*O*-acetylkojic acid.

[9] The *(3a)*-derived *(2a)* contains 8—10% of the β-enantiomer *(2c)* as evidenced by its rotation (+236° in $CHCl_3$ *versus* +263° for a product obtained from *(1a)*). The step determining the stereoselectivity of the conversions *(3a)*→*(2a)* and *(3c)*→*(2b)*, in fact, is the addition of methanol at the anomeric carbon, which preferentially (*ca.* 10:1) occurs from the α-side. The α- [*e.g. (13)*] and β-hexosid-3-uloses formed *e.g.* from *(3a)* subsequently yield the respective enediolones *(2a)* and *(2c)* in practically stereospecific reactions.

[10] *Note added in Proof* (Nov. 15, 1979): The structure and configuration of the dihydropyranones *(2)* have meanwhile been corroborated by an x-ray structure analysis of *(2c)*: *H. J. Lindner*, unpublished.

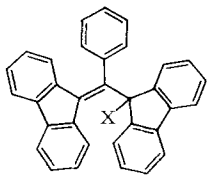
Model System for the Electrochemical Reduction of the Carbon-Halogen Bond[**]

By *Andreas Merz* and *Robert Tomahogh*[*]

Palle Iversen in memoriam

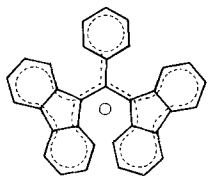
Radicals and carbanions are discussed as intermediates in the reductive electrochemical cleavage of the carbon-halogen bond:

$$\left.\begin{array}{l} R{-}X + e \rightarrow X^{\ominus} + R^{\odot} \\ R^{\odot} \quad + e \rightarrow R^{\ominus} \end{array}\right\} \text{ products} \qquad \begin{array}{l}(a)\\(b)\end{array}$$



In many cases, however, it is still unclear from which intermediate the products are actually derived; moreover, radicals could be detected neither directly nor by spin-trap methods[1].

We report here on cyclic-voltammetric and coulometric investigations of the model systems 9-fluoro- and 9-chloro-9-[α-(9-fluorenylidene)benzyl]fluorenes *(1a)* and *(1b)*[2], respectively, in which both the carbanion *(2a)*[3a] and the radical *(2b)*[3b] are stable.



[*] Priv.-Doz. Dr. A. Merz, R. Tomahogh
Institut für Chemie der Universität
Universitätsstr. 31, D-8400 Regensburg (Germany)

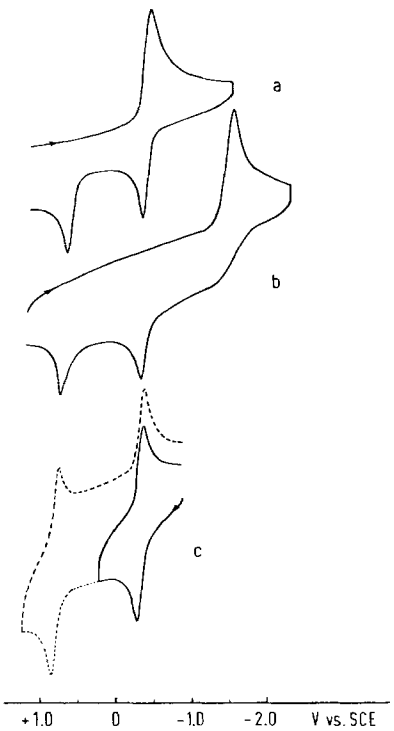
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Figure 1 shows the cyclic voltammograms of *(1a)* (curve b) and *(1b)* (curve a) obtained in anhydrous acetonitrile/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$ (TBAP) with glassy carbon electrodes[4]. The

(1a), X = F
(1b), X = Cl
(1c), X = Br
(3), X = OH
(4), X = H

(2a), O = ⊖
(2b), O = ⊙
(2c), O = ⊕

half-peak potentials (two electron waves) $E_{p/2}$ are −1.35 V for *(1a)* and −0.30 V for *(1b)*. The anodic branch of the voltammogram shows the same maxima for both compounds, those corresponding to the oxidation of the carbanion *(2a)* to the radical *(2b)* and of *(2b)* to the cation *(2c)*.



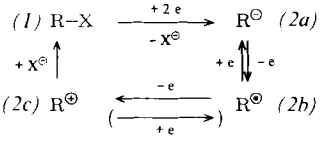


Fig. 1. Cyclic voltammogram in anhydrous acetonitrile/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$ at a carbon disk electrode; 200 mV/s. Curve a: *(1b)*; curve b: *(1a)*; curve c: carbanion *(2a)* after coulometric generation from the radical *(2b)*. The unbroken curve is also obtained directly after coulometric reduction of *(1a)* or *(1b)*. Concentrations *ca.* 5×10^{-4} M.

This interpretation is confirmed by coulometric reduction of *(1a)* and *(1b)* at −1.4 V and −0.4, respectively, which in each case leads with uptake of 2 F/mol to the deep-blue solution of the carbanion *(2a)*. Whereas in the electrolysis of *(1a)* the blue color of the carbanion is stable from the beginning, in the electrolysis of *(1b)* the blue schlieren from the cathode fade with formation of the yellow solution of the radical *(2b)*; the color of *(2a)* persists only after uptake of 1 F/mol. Thus *(2a)* is able to reduce the chloro compound *(1b)*, but not the

fluoro compound *(1a)*, in a homogeneous electron transfer reaction:

$$\underset{(1b)}{R{-}X} + \underset{(2a)}{R^{\ominus}} \rightarrow \underset{(2b)}{2R^{\ominus}} + Cl^{\ominus} \qquad (c)$$

The carbanion *(2a)* can be oxidized coulometrically at 0.0 V (1 F/mol) reversibly to the radical *(2b)* ($E^0 = -0.31$ V). In a further one-electron oxidation at +0.95 V, *(2b)* is transformed into the cation *(2c)*. The latter reaction appears irreversible in the voltammogram; this can be attributed to a rapid back reaction of *(2c)* with the halide ion to give the starting halides *(1a)* and *(1b)*, respectively, whose cyclic voltammograms are observed again after completion of the coulometric cycle (Scheme 1).

Scheme 1

This cycle can be passed through several times without any notable loss in electroactivity. These constitute the first examples of the chemically reversible electroreduction of organic halogen compounds, even though the pathways of the forward and reverse reactions are different[5].

Starting from the isolated radical *(2b)*, in halide-free solution, also the oxidation *(2b)*→*(2c)* is electrochemically reversible, but only on the cyclic voltammetry time scale. Coulometrically generated red *(2c)* reacts with a half-life of a few minutes in an intramolecular Friedel-Crafts reaction[6].

Our results can be discussed in terms of a model for the mechanistic variants of the electroreduction of the carbon-halogen bond: The radical can form at the cathode [eq. (a)][7] only if the reduction potential of the halogen compound is more positive than the redox potential of the radical/carbanion pair [eq. (b)]. This seemingly trivial picture is extended by the electrochemical reduction of the chloro compound *(1b)*, the first well documented example of the "father-son" or "Oedipus" mechanism already postulated by *Elving*[8]. This combination [eq. (a)+(b)+(c)] is possible then, if the redox potential of the radical/carbanion system lies *between* the (unknown) *thermodynamically* and the observed *kinetically* controlled reduction potential of the halogen compound [eq. (a)]. Only in this case the carbanion exclusively formed at the electrodes will be able to reduce the starting compound. As we have found, *(1b)* ($E_{p/2} = -0.30$ V) can be reduced to the radical *(2b)* in homogeneous solution even by ferrocene ($E^0 = +0.42$ V *vs.* SCE, in CH_3CN/TBAP). This proves that the thermodynamic reduction potential is at least 0.7 V more positive than the irreversible half-peak potential at glassy carbon.

The controversy surrounding the mechanism of the electroreduction of the benzyl and allyl halides—carbanion[1c] *vs.* radical mechanism[1d]—is readily settled by this approach, since in the mechanism under discussion both carbanions as well as radicals occur as intermediates, either of which, depending upon the conditions, may be product-determining. Demonstration of such a reaction behavior is afforded by the facile indirect electroreduction of these halides with chromium(II) salts, which proceeds exclusively *via* radical dimerization[9].

Direct Removal of Functional Groups by Catalytic Hydrogenolysis[**]

By *Wilhelm F. Maier, Peter Grubmüller, Irina Thies, Peter M. Stein, M. Anthony McKervey*, and *Paul von Ragué Schleyer*[*]

The removal of functional groups from organic molecules to yield the parent hydrocarbon often requires multistep procedures; yields may be poor particularly if the functional group is tertiary. For example, the replacement of carboxylic acid, ester, amide, nitrile, ether, alcohol, or amine functions by hydrogen is usually accomplished by indirect methods[2].

Following the discovery that a variety of alkyladamantanes can be dealkylated cleanly and efficiently by gas phase hydrogenolyses on nickel[1,3], we have investigated the gas phase hydrogenolytic removal of functional groups containing heteroatoms. Examples are listed in Table 1 and the course of reaction is apparent from Figure 1. We stress that these reactions are quite general and are not restricted to polycycloalkyl systems such as adamantane.

The experimental procedure involved a flow system in which each substrate was vaporized in a stream of hydrogen at atmospheric pressure (flow rate 20—25 ml/min) and passed through a horizontal catalyst bed consisting of 30% nickel on alumina. Products were collected in a cold trap in high yield and purity[1,2]. The optimum hydrogenolysis temperatures (Table 1) reflect differences in volatility and polarity of the substrates and their rate of passage through the catalyst bed. The results listed in Table 1 show that a wide range of heteroatomic functional groups can be replaced by hydrogen in excellent yields. Previously, synthetically useful catalytic hydrogenolyses were limited largely to carbon-halogen bonds[4] and protecting groups such as benzyl[4]. The direct defunctionalization of unactivated acids and alcohols is feasible

(2c)	CH_3	OH	150	*(5)*	99
(5)			235	*(4)*	99

only in special cases, whereas the direct defunctionalization of esters and ethers appears to be unknown, at least as a synthetically useful procedure. The reductive hydrogenolyses of a nitrile group to a methyl group has been observed in solution with a platinum catalyst[5]. However, the present gas-phase method using nickel allows product control by temperature variation; either 1-methyladamantane *(3)* or adamantane *(4)* can be obtained from 1-adamantanecarbonitrile *(1i)*. Similarly, the sterically crowded hydroxyl group in 2-methyl-2-adamantanol *(2c)* can be removed cleanly at 150 °C; at 235 °C the resulting 2-methyladamantane *(5)* is demethylated to give adamantane.

Particularly noteworthy is the quantitative conversion of 1-(trimethylsiloxy)adamantane (I, $X=OSiMe_3$) into adamantane at only 150 °C. The conversion of adamantanone *(3a)* into adamantane using the gas-phase hydrogenolytic procedure is superior to conventional solution methods[6]. Interesting differences in behavior are observed with closely related systems. Thus 1-adamantanemethanol *(1e)* suffers hydrogenolysis with loss of the carbon and oxygen atoms of the CH_2OH group whereas 1-bromomethyladamantane *(1k)* is converted into 1-methyladamantane *(3)* exclusively. Although hydrogenolysis of halogen-containing substrates leads efficiently to hydrocarbon, the catalyst is deactivated in the process and is no longer effective in dealkylation of methyladamantane. Such deactivation is not observed with oxygen containing functional groups. These observations may be relevant to the mechanism of catalytic defunctionalization.

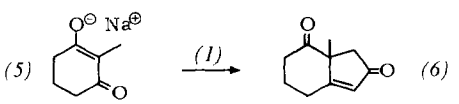
(Bromoacetylmethylene)triphenylphosphorane—A Novel Cyclopentannelating Agent

By *Hans-Josef Altenbach*[*]

Application of the principle of Robinson annelation for the preparation of cyclohexenones to the synthesis of cyclopentenones requires suitable electrophilic C_3 synthons. Since 1-haloacetones undergo smooth alkylation only in exceptional cases a series of electrophilic acetonyl systems has been developed in recent years[1], in which the ketone function is latent. In most cases, however, drastic conditions are necessary for liberation of the ketone. A potential alternative agent for the cyclopentannelation is the already known (bromoacetylmethylene)triphenylphosphorane *(1)*[2].



This easily accessible, stabilized ylide has a readily substitutable bromine atom[2b], while the keto group should not react even with hard nucleophiles such as enolates. Moreover, in the intermediate *(3)*, formed by alkylation of an enolate *(2)*, the ylide function should also cause cyclization by intramolecular Wittig reaction[3].

(a), $R^1 = CH_3$, $R^2 = H$, $R^3 = CO_2CH_2CH_3$, $M = Na$

In fact, *(1)* fulfills this expectation: Reaction with the sodium salt of ethyl acetoacetate *(2a)* in ethanol (3 h, 0 °C; 14 h reflux) affords the cyclopentenone *(4a)*[4], which after aqueous workup is isolated by distillation (b.p. 70—72 °C/0.4 torr; yield 39%). The anion of *(5)* prepared by reaction of 2-methyl-1,3-cyclohexanedione with sodium hydride likewise reacts with *(1)* in dimethylformamide (3 h, 0 °C, 16 h, 80 °C), to give the annelated product *(6)*[5] directly (m.p. 74—75 °C; yield 31%).

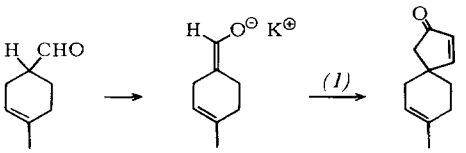
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/1212-0940 $ 02.50/0

This example demonstrates the advantage of ring closure by Wittig reaction: under the usual conditions 2-acetonyl-1,3-cyclohexanedione does not cyclize to *(6)* but undergoes fragmentation[5].



Cyclopentannelation with (bromoacetylmethylene)triphenylphosphorane *(1)* is not restricted to stabilized enolates. Reaction of the anion *(7a)*, generated by treatment of cyclohexanone with lithium diisopropylamide in tetrahydrofuran, with one equivalent of *(1)* at −20 °C affords, after 2 hours' stirring at 0 °C, 14 hours' boiling under reflux, and aqueous workup with pentane, the annelated cyclopentenone *(8a)*[6] (b.p. 50—52 °C/0.02 torr; yield 29%).

(a), R^1 = H, R^2 = H
(b), R^1 = H, R^2 = CH_3
(c), R^1 = CH_3, R^2 = H

(1) is sufficiently reactive towards the enolates *(7b)* (generated by reaction of 2-methyl-1-cyclohexenyl acetate with methyllithium[7]) and *(7c)* (obtained by reaction of 2-methylcyclohexanone with lithium diisopropylamide in tetrahydrofuran[7]) to form regioselectively *(8b)*[8] (yield 25%) and *(8c)*[2f] (yield 22%; mixture of diastereomers), respectively.

The method is also applicable to potassium enolates of aldehydes. If the aldehyde *(9)*[9] is deprotonated with potassium hydride in tetrahydrofuran[10] and the enolate is allowed to react with *(1)*, the spirocyclic compound *(10)*[11] can be isolated (b.p. 54—56 °C/0.1 torr; yield 14%).

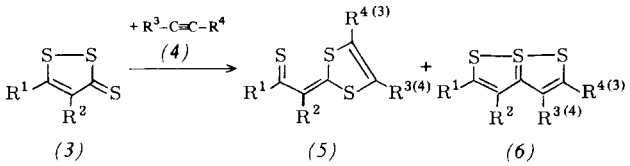
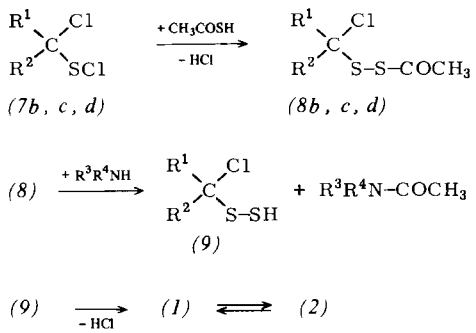
Dithiiranes and Thiosulfines as Reactive Intermediates[**]



By *Alexander Senning*[*]

Little has hitherto been reported about the dithiiranes *(1)* and the isomeric thiosulfines *(2)*. The molecular geometry of the hypothetical dithiirane *(1a)* has, however, been calcu-

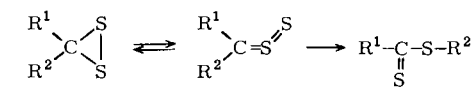


(a), $R^1 = R^2 = H$; *(b)*, $R^1 = R^2 = Cl$;
(c), $R^1 = C_6H_5S$, $R^2 = 4\text{-}CH_3C_6H_4SO_2$; *(d)*, $R^1 = R^2 = C_6H_5CO$

lated[1]. The formation of adducts *(6)*, together with *(5)*, on reaction of 1,2-dithiol-3-thiones *(3)* with alkynes *(4)*[2] can, in our opinion, be readily explained in terms of a preceding

(3) *(5)* *(6)*

rearrangement of *(3)* into *(2)*. Finally, in the mass spectra of some sulfur compounds, fragments occur which derive from *(1)* and/or *(2)*, *e.g. (1a)/(2a)* and *(1b)/(2b)*[3].

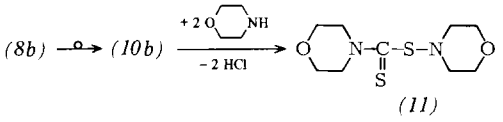


(7b, c, d) *(8b, c, d)*

(9)

We have developed a "wet" synthetic route starting from *(7)*, which conveniently leads *via (8)* (see Table 1) to the unstable α-chloroalkyldisulfanes *(9)* as precursors of *(1)* and/or *(2)*.

The intermediate *(1b)/(2b)* obtained from *(8b)*[4] and morpholine cannot be trapped with either alkynes or strained alkenes (*e.g.* norbornadiene) by cycloaddition, but rearranges



(1b, c) *(2b, c)* *(10b, c)*

to the dithioester *(10b)*, which on reaction with morpholine gives the stable product *(11)*[5]. Reaction of *(8c)* with morpholine analogously leads *via (10c)* to the stable products *(12)*[6] and *(13)*.

(11)

This novel rearrangement is analogous to the rearrangement of oxiranes into aldehydes or ketones[7] and to the hypothetical rearrangement of dioxiranes into esters (cf. [8]).

(12) (13)

The intermediate *(8d)* does not rearrange to *(10d)*. The end-product is formed immediately by addition of morpholine to *(2d)*.

(14)

Table 1. New compounds of type *(7)* and *(8)*.

Product	Yield [%]	M.p. [°C]
(7d) [a]	≥53	oil
(8c) [b]	74	85—87 (ethanol)
(8d) [b]	53 [c]	107—108 (ethanol)

[a] From $(C_6H_5CO)_2CH$ S S $CH(COC_6H_5)_2$, m.p. 162—166 °C [9]. [b] Synthesized by analogy with [4]. [c] Based on the disulfide [9].

Procedure

A solution of morpholine (0.6 mol) in ether or benzene (50 ml) is added dropwise to a stirred solution of *(8)* (0.1 mol) in 100 ml of the same solvent at such a rate that the temperature does not increase noticeably. The reaction mixture is extracted three times with water and the organic phase is dried over $CaCl_2$ and evaporated to dryness in a rotary evaporator. The crude product crystallizing on trituration in ether is recrystallized from ethanol [*(8b)*→*(11)*[5], yield 22%; *(8c)*→*(12)*[6], yield 60%; *(8d)*→*(14)*, m.p. 121—122 °C, yield 25%].

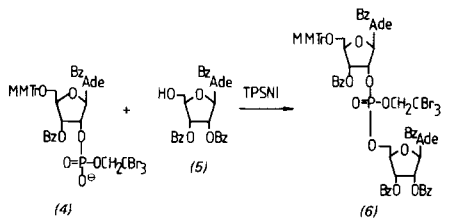
Directed Synthesis of the Trimeric Isoadenylate A2′p5′A2′p5′A

By *Joachim Engels* and *Ute Krahmer*[*]

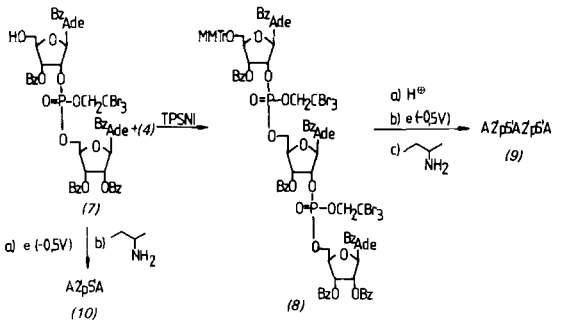


A trimeric oligoadenylate with the "unnatural" linkage 2′-5′ has been isolated from interferon-treated cells[1]. This so-called isoadenylate A2′p5′A2′p5′A inhibits protein biosynthesis in sub-nanomolar concentrations and promises to give new impetus to virus therapy[2].

We report here on a novel directed synthesis of A2′p5′A2′p5′A *(9)* according to the triester method, which enables preparation of the compound on the gram scale. Reaction of the readily accessible N^6-benzoyladenosine *(1)*[3] with orthobenzoic triethyl ester[4] (CCl_3COOH in dioxane) and hydrolysis of the resulting orthoester with 4% aqueous acetic acid afforded dibenzoyladenosine *(2a)* (m.p. 194 °C).

(1) (2a), R=H (2b), R=MMTr (3)

Subsequent reaction of *(2a)* with monomethoxytrityl chloride (MMTrCl) in pyridine at room temperature led to the 5′-substituted derivative *(2b)* in 96% yield, which on phosphorylation with (tribromoethyl)phosphoric dichloride in the presence of triazole and *N*-propylimidazole, followed by 3-hydroxypropionitrile, gave, after chromatography on silica gel ($CHCl_3$/MeOH 25:1), the fully protected nucleoside 2′-phosphate *(3)* in 82% yield. The triester *(3)* could be quantitatively converted with NEt_3 in pyridine/H_2O (1:2:1) into the diester *(4)*, which was condensed with tribenzoyladenosine *(5)* (m.p. 185 °C) and TPSNI (triisopropylbenzenesulfonylnitroimidazolide)[5] to give the dinucleoside phosphate *(6)* in 90% yield.



(4) (5) (6)

For proof of the structure, *(6)* was converted with BF_3/MeOH in CH_2Cl_2 into *(7)* (91% yield) and reduced electrochemically (Hg cathode, CH_3CN, $+Bu_4NBF_4$, lutidine)[6]. After extraction of the supporting electrolyte with $CHCl_3$ the aqueous phase was freeze-dried and debenzoylated with *sec*-butylamine in MeOH to A2′p5′A *(10)* (90% yield). The identity of *(10)* with authentic A2′p5′A (Serva) was confirmed chromatographically on PEI-cellulose (NH_4HCO_3) and by liquid chromatography (Polygosil 60-10 $N(CH_3)_2$ from Macherey-Nagel with 0.03 M NH_4HCOO (pH = 6.2) and 3% CH_3CN). According to the liquid chromatogram, less than 2% A3′p5′A is formed.

The dinucleoside phosphate *(7)* was converted with the diester *(4)* and TPSNI into the completely protected trimer *(8)* in 84% yield. For conversion into the native trimeric isoadenylate *(9)* the triester *(8)* was first detritylated (BF_3/MeOH in CH_2Cl_2) and then electrolyzed (Hg cathode, CH_3CN, $LiClO_4$, lutidine)[6]. The diester recovered by ex-

traction with $CHCl_3$ was debenzoylated with *sec*-butylamine in MeOH. Purification [DEAE-cellulose column (0.1—0.3 M NEt_3HCO_3) and RP 8 (H_2O)] afforded crystalline *(9)* as the triethylammonium salt in 70% yield. The ^{1}H-NMR spectrum [D_2O, adenine-H: 7.76, 7.90, 7.95, 7.97, 8.08, 8.17; H1' (doublet): 5.82, 5.92, 6.17] and chromatogram [PEI-cellulose (NH_4HCO_3)] are consistent with the data in the literature[7]. As expected *(9)* is cleaved enzymatically by phosphodiesterase from snake venom but not by phosphodiesterase from spleen[8].

Detection of Heavy Metal Ions by ESR Spectroscopy[**]

By *Hartmut B. Stegmann, Martin Schnabel,* and *Klaus Scheffler*[*]

The high sensitivity and the pronounced selectivity of ESR spectroscopy have prompted us to examine the potential of this method for the detection of heavy metal ions. The proposed technique requires ligands which form complexes with cations and can subsequently be transformed into paramagnetic systems. Moreover, both the complex and the free ligand should be insoluble in water in order to permit two-phase reactions. These requirements are satisfied, for example, by 3,6-di-*tert*-butyl-2-(2-hydroxybenzylidenamino)hydroquinone *(1)*[1].

The ligand *(1)* reacts in pyridine with $Pb^{2\oplus}$, $Zn^{2\oplus}$, or $Cd^{2\oplus}$ to form chelates which are oxidized to paramagnetic complexes by atmospheric oxygen, silver oxide, or lead dioxide. Some experimental values are listed in Table 1.

The spectra of two paramagnetic species can be observed simultaneously in the *(1)*/$Et_2Tl^{\oplus}$ system[2]. The complex *(5)* shows the metal splitting given while the other signal consists merely of a doublet due to a proton. We assign this signal to

(1)

Table 1. ESR data of the heavy metal complexes formed from *(1)* and various cations in pyridine at room temperature.

Complex	Cation	a_H [G]	a_{Metal} [G]	ΔH [G]	g
(2)	$Pb^{2\oplus}$	3.95	7.3	0.45	1.9993
(3)	$Zn^{2\oplus}$	4.00	—	0.45	2.0046
(4)	$Cd^{2\oplus}$	3.90	^{111}Cd 3.95 [a] ^{113}Cd 4.13 [a]	0.35	2.0044
(5) [b]	$Et_2Tl^{\oplus}$	3.25	11.75	0.60	2.0035
(6)	"free"	2.35	—	0.35	2.0048

[a] Determined by spectral simulation. [b] Diethylthallium hydroxide was provided by *U. Bergler*.

the free ligand *(6)*. Its proton coupling constant is considerably smaller and thus reveals the failure of complex formation to take place.

As a result of the different g factors and metal splitting it is possible to detect several ions simultaneously. Figure 1 shows the hyperfine structure observed on reaction of *(1)* with $Cd^{2\oplus}$ and $Pb^{2\oplus}$ ions in pyridine. The lines marked × correspond to the chelate *(4)*, whereas the unmarked lines are assigned to the chelate *(2)*.

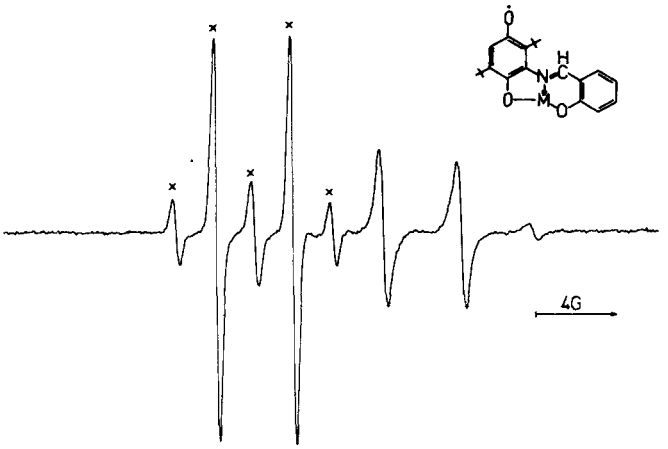

Fig. 1. ESR spectra of the $Cd^{2\oplus}$ chelate *(4)* (×) and the $Pb^{2\oplus}$ chelate *(2)* in pyridine at room temperature.

The above cations can also be detected if they are present in aqueous phase. The aqueous solution is shaken with a benzene solution of the ligand *(1)* in the presence of 10% of pyridine. After separation, the organic phase is dried over sodium sulfate and transferred directly to the ESR sample tube. Some lead dioxide may be added as oxidizing agent. The ESR parameters of the resulting complex agree with the values listed in Table 1. Working in this way with a 10^{-6} molar solution of zinc acetate and a 10^{-2} mol/l concentration of the ligand *(1)* in the organic phase the signal of *(3)* can be recognized without difficulty with a signal to noise ratio of 15:1. This sensitivity can be increased by two orders of magnitude on computerized spectral accumulation.

Structure and Reactions of Methylenesulfur Tetrafluoride[**]

By *Hans Bock, James E. Boggs, Gert Kleemann, Dieter Lentz, Heinz Oberhammer, Eva Maria Peters, Konrad Seppelt, Arndt Simon,* and *Bahman Solouki*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

$H_2C{=}SF_4$ is easily prepared by reaction of $SF_5{-}CH_2Br$ and n-C_4H_9Li at $-110\,^{\circ}C$[1]. This methylene compound is thermally more stable than all known phosphorus and sulfur ylides and metal carbene complexes. In the gaseous state at 10^{-2} torr, it is stable up to 650 °C. The vibrational spectra[2] and the ^1H-, ^{13}C-, and ^{19}F-NMR spectra[1] are in agreement with an ylidic double bond.

The resonance formula with the double bond, however, is much more important than in other ylides: the spectroscopic bond order is 1.8[2]; the charge on the carbon atom is −0.6, as calculated by *ab initio* methods[3].

These findings are supported by the photoelectron spectrum (Fig. 1). This shows a single band at 10.65 eV which is assigned to π_{CS} ionization. Compared with phosphorus ylides, which have first ionization potentials below 7 eV[4], in $H_2C{=}SF_4$ the energy difference to the radical cationic state is increased by the fluorine substitution.

Formal addition of (excited[4b]) CH_2 to the F_4S sulfur electron pair (cf. Fig. 1) generates the π_{CS}- and σ_{CS} bonds[4]; the radical cationic states of the type n_F and σ_{SF} remain nearly unchanged[5].

The IR, Raman, NMR, or PE spectra do not readily indicate the orientation of the methylene group or its possible axial ⇌ equatorial interchange, *e.g.* by pseudorotation of the trigonal bipyramidal F_4SC skeleton. The NMR data, however, indicated that the probably planar H_2C group must be oriented either axially (a) or equatorially (e).

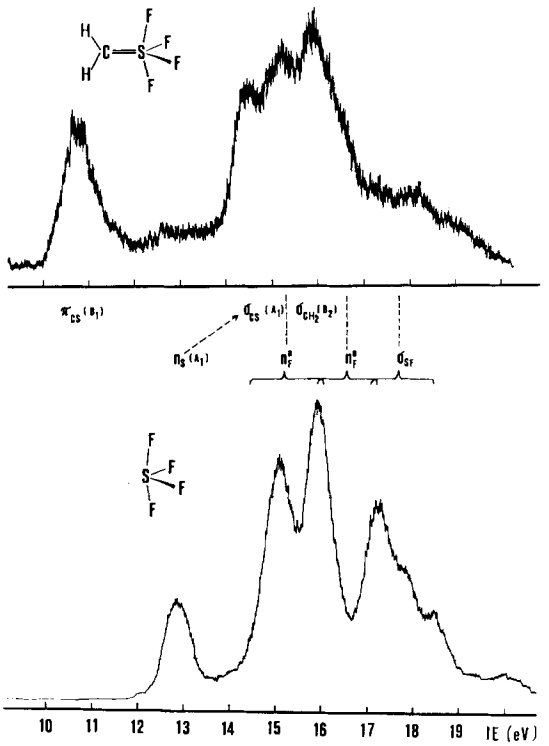

Fig. 1. He(I) PE spectrum of $H_2C{=}SF_4$ with qualitative assignment by comparison with SF_4.

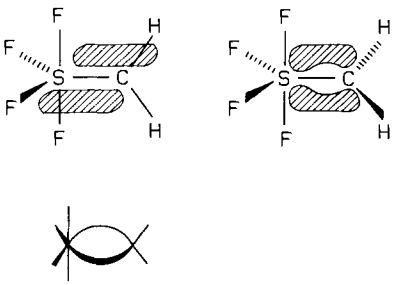

Fig. 2. Structural possibilities of $H_2C{=}SF_4$. According to the valence shell electron pair repulsion model the observed "axial" position of the protons is preferred. Qualitatively the observed structure (left) may be rationalized by linking a tetrahedron with an octahedron through two bent bonds.

Low temperature crystal structure analysis[6], electron diffraction[8], and an *ab initio* calculation (Table 1) all resulted in a trigonal bipyramidal structure similar to that of SF_4, but with a much smaller equatorial angle FSF. The methylene group is oriented in the plane of the axial fluorine atoms. This can be explained by the valence shell electron pair repulsion model: Only in this configuration can the π_{CS} electron density easily be accommodated, and the equatorial

Table 1. Structural data of $H_2C{=}SF_4$.

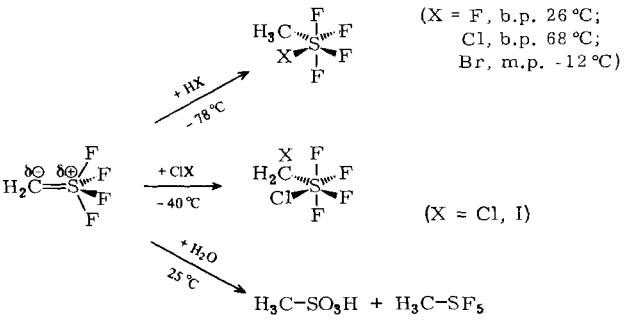
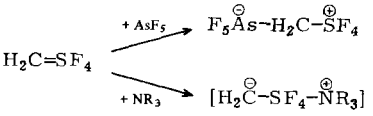
fluorine atoms are brought closer together (see Fig. 2). The distance between the axial fluorine atoms and the hydrogen atoms is only 240 pm; however, no evidence of H...F bridges is apparent from the spectroscopic data.



The SCF geometrical optimization shows that the isomer with an equatorially oriented CH_2 group is unstable, and that a high torsional barrier exists, with an estimated value of 77 kcal/mol[3].

In spite of its thermal stability, $H_2C{=}SF_4$ is very reactive. Reactions with halogens or photolysis yield SF_4.



Free carbene has not yet been detected as an intermediate in these reactions (however irradiation of diluted diazomethane also yields large amounts of ethylene[8]).

With polar reagents, addition to the C=S bond occurs.

The addition products are hydrolytically stable liquids having an octahedral *cis*-configuration. The polarity of the C=S bond is indicated by two further reactions: Lewis acids interact with the carbon atom, while Lewis bases attack the sulfur atom:

The trimethylamine adduct is unstable at room temperature. The AsF_5 adduct, however, is stable enough to be characterized by the usual analytical and spectroscopic methods.

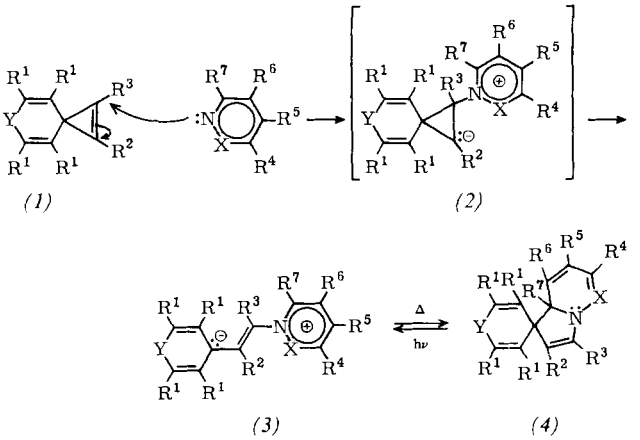
1,8a-Dihydroindolizines as Components of Novel Photochromic Systems

By *G. Hauck* and *H. Dürr*[*]



Photochromic systems are currently attracting a great deal of interest. The light-induced formation of colored products can be utilized in silver-free photography (*inter alia* "microimaging systems"), in the production of light-filtering tinted glasses or in data display systems (*e.g.* in computers)[1]. Of topical interest is the potential use of reversible photochromic substances as solar energy storage systems[2]. We describe here a novel photochromic system based on 1,8a-dihydroindolizines (Scheme 1, type A) whose photochromism arises from bond heterolysis[1]. The essential difference between A and the photochromic spiropyrans or rhodamine derivatives[3] (type B) is apparent from Scheme 1.

Scheme 1. Comparison of the photochromic systems of type A (1,8-dihydroindolizines) and type B (spiropyrans or rhodamine derivatives). X = electron donor, Y = electron acceptor.

In case B the electron acceptor Y can only be a heteroatom, whereas in A it can also be a substituted C-atom.

For the synthesis of the photochromic 1,8a-dihydroindolizines *(4)* we allowed cyclopropenes *(1)*[4] to react with *N*-heterocycles in ethereal solution at room temperature. As a rule quantitative yields of colorless to yellow[5] 1:1 adducts were formed, which, on the basis of ^{1}H-NMR, IR, UV and mass spectroscopic data, were assigned the structure 1,8-dihydroindolizines *(4)* (Table 1)[6], a class of compound hitherto rarely taken into consideration because of alleged instability[7]. The synthesis of *(4)* proceeded *via* the intermediate *(2)* and the deep-colored zwitterionic intermediate *(3)*. Only in very few cases (see Table 1) could *(3)* be isolated since it spontaneously reacts further to give *(4)*. The betaine *(3)* was decolorized on addition of acid, a reaction which is reversible with bases.

As demonstrated by the examples *(3g,f)*→*(4g,f)* the cyclization is regiospecific. However, the alternative possibility of

ring closure can be brought about if a position is blocked by benzoannelation. This has been proven by the synthesis of the benzo derivative *(4i)* methylated on C-8a. The thermal back reaction *(3)*→*(4)* is of first order, with rate constant k depending on the polarity of the solvent medium and on the resonance and inductive effects of the substituents.

The destabilization of the positive charge by annelated benzene rings is especially effective in *(3)*. But also lack of stabilization of the carbanion by removal of an electron acceptor substituent leads to a drastic reduction in the rate constant k. The longwave absorption maxima of *(3)* show a remarkably strong hypsochromism, thus indicating that an intramolecular charge-transfer—as is observed in the case of the vinylogous pyridinium cyclopentadienylides[8]—is responsible for the color of the betaine *(3)*. The activation parameters of the thermal cyclization *(3a)*→*(4a)* in benzene are: $\Delta G^{\ddagger} = 6.3$ kcal/mol, $E_A = 15.9$ kcal/mol, $\Delta S^{\ddagger} = -32$ cal K^{-1} mol^{-1} (determined UV spectroscopically). The 1,2,3,8a-tetrahydroindolizines accessible by hydrogenation of *(4)* are also photochromic[9], even if to a lesser degree than *(4)*.

Procedure

Synthesis of *(4c)*: 0.52 g (4.80 mmol) of 4-methoxypyridine is added with stirring at room temperature and in the absence of light to a suspension of dimethyl spiro[cyclopropene-1,9′-fluorene]-2,3-dicarboxylate (1.47 g, 4.80 mmol) in anhydrous diethyl ether (40 ml). After 24 h some of the solvent is removed and, on cooling the solution, bright yellow crystals begin to separate out. These are filtered off and washed with pre-cooled ether; yield 1.74 g. IR: 1740 and 1700 (C=O) cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 3.10$ (s, 3H, OCH_3), 3.27, 4.00 (s, each 3H, CO_2CH_3), 3.35 (mc, 8-H), 5.08 (dd, $J_{6,5} = 8$ Hz, 6-H), 5.63 (s, 8a-H), 6.49 (d, $J_{5,6} = 8$ Hz, 5-H), 7.3—7.9 (8 aromatic-H); MS: $m/e = 415$ (M^+), 356 ($M^+ - CO_2CH_3$).

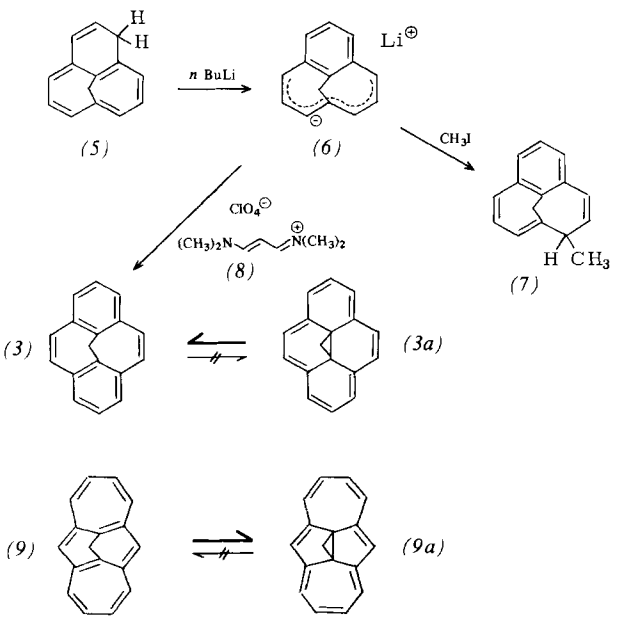
8,16-Methano[2.2]metacyclophane-1,9-diene. A Valence Isomer of 10b,10c-Methano-*cis*-10b,10c-dihydropyrene[**]

By *Kazuhiro Nakasuji, Masanori Katada*, and *Ichiro Murata*[*]

Although much attention has recently been focused on *trans*-10b,10c-dihydropyrenes and their photoisomerization to the corresponding metacyclophane valence isomers[2], little is known about *cis*-10b,10c-dihydropyrene/metacyclophane isomers. The only previous examples known are the bridged and/or highly substituted derivatives *(1)*[3a], *(2)*[3b], and *(4)*[3c]. We now report the preparation of the methano-bridged [2.2]metacyclophane-1,9-diene *(3)*, a valence isomer of 10b,10c-methano-*cis*-10b,10c-dihydropyrene *(3a)*.

(1), X = O
(2), X = NR
(3), X = CH_2



(4)

10,11-Homophenalene *(5)* readily undergoes proton abstraction with *n*-butyllithium to give anion *(6)* which upon reaction with methyl iodide gives the methylated hydrocarbon *(7)*[1]. Thus, it could be expected that *(5)* would undergo six-membered ring annelation in analogy to the formation of pyrene from phenalene as reported by *Jutz*[4]. This was found to be the case. Treatment of a tetrahydrofuran solution of *(5)* with 1.5 eq. of *n*-butyllithium in the presence of hexamethylphosphoramide gives a deep green solution of the anion *(6)*. On treatment with dimethyl(3-dimethylaminopropenyli-

dene)ammonium perchlorate *(8)*[5] at −55 °C for 0.5 h this solution yields an intermediate fulvene which was not isolated. In order to effect cyclization of the fulvene to *(3)*, the solvent is replaced by quinoline and the solution is heated at 170 °C for 12 h. After the usual work-up the crude product is purified by column chromatography over alumina with hexane. The desired compound *(3)* was obtained as colorless needles, m.p. 140 °C (sealed capillary), in 35% yield[6]. Its structural assignment is supported by its NMR spectrum [singlets at $\delta = 2.53$ (2H) and 7.29 (4H); AB_2 pattern at $\delta = 6.83$ (A part) and 7.30 (B part) with $J_{AB} = 8.7$ Hz]. The UV absorption spectrum of *(3)* is very similar to those of *(1)*[3a] and *(2)*[3b] [λ_{max} (cyclohexane) = 223 nm ($\varepsilon = 28\,800$), 236 (27 400), 246 (28 200), 305 (14 700)]. In the mass spectrum of *(3)* [$m/e = 216$ (M^+, 100%), 215 ($M^+ - H$, 75%)] a peak due to loss of the bridged methano group, though very weak, was also observed [$m/e = 202$ ($M^+ - CH_2$, 3%)]. These spectral findings indicate that, of the two valence isomers *(3)* and *(3a)*, only the metacyclophane structure *(3)* exists at room temperature.

In contrast to our compound *(3)*, an isomeric hydrocarbon synthesized recently by *Vogel*, exists solely as cyclopropanediylidene[14]annulene with a 14π periphery *(9a)* rather than in a cyclophane structure *(9)*[7].

Heating of *(3)* in a quartz tube (500 °C/4 torr/0.5 h) gives 1-methylpyrene *(10)* as colorless plates of m.p. 66–68 °C in quantitative yield[8] (identified by comparison with an authentic sample[4,9]). In contrast, pyrolysis of *(4)* gives the corresponding hexasubstituted pyrene by loss of the methano bridge[3c]. Attempts to effect a photoisomerization of *(3)* to *(3a)* have been unsuccessful. However, irradiation of a cyclohexane solution of *(3)* (6-W low-pressure Hg lamp, N_2, 2 h) led to quantitative conversion of the cyclophane into a single product which was identified as 4,5-cyclopropano-4,5-dihydropyrene *(11)*[10] by spectroscopic comparison with authentic material.

Thus the metacyclophane derivative *(3)* does not rearrange to the dihydropyrene derivative *(3a)* at room temperature. However, the thermal and photochemical isomerizations of *(3)* are most reasonably explained by postulating *(3a)* as an intermediate.

Synthesis and Reactions of Diazoacetyl Chloride—Detection of Diazoketene

By *Hans Jürgen Bestmann* and *Fouad M. Soliman*[*]

The reaction of diazomethane *(2)* with acyl chlorides to give diazoketones has long been known as a standard reaction[1]. Surprisingly, however, no report has yet appeared concerning the reaction of phosgene *(1)* with *(2)*.

On reacting phosgene *(1)* with diazomethane *(2)* in a molar ratio of 1:2 we were able to isolate the hitherto unknown compound diazoacetyl chloride *(3)* (94%) alongside chloroacetyl chloride *(4)* (2%) and 1,3-dichloroacetone *(6)* (4%). Reaction of *(3)* with liberated HCl gives *(4)*, which in turn reacts with *(2)* to afford 1-chloro-3-diazoacetone *(5)* from which *(6)* is formed with HCl.

On reaction of *(1)* and *(2)* in a molar ratio of 1:4 both *(6)* and the diazoketone *(5)* are obtained. The same reaction in the presence of triethylamine (1:4:1) gives only *(5)*.

Compound *(3)* is a yellow liquid which boils at 15 °C/0.5 torr and decomposes only slowly below 0 °C; IR: 2120 (CH—N_2), 1720 cm^{-1} (CO); MS: $m/e = 104/106$ (M^+), 76/78 ($M^+ - N_2$), 69 ($M^+ - Cl$), 68 ($M^+ - HCl$), *etc.* The last-named fragment suggests formation of diazoketene *(10)* in the gas phase. The ^{1}H-NMR spectrum of *(3)* (in CCl_4) is dependent on temperature[2]; at room temperature it shows two signals at $\delta = 5.2$ and 5.5. The coalescence temperature is 33 °C.

Compound *(3)* is an excellent diazoacetylation reagent. Addition of a tertiary base to a solution of *(3)* and *(7)* (X = R—O, R—S, R—NH) in aprotic solvents (molar ratio 1:1:1) leads to a diazoacetic ester derivative *(8)* in high yield; the hydrochloride precipitates. Table 1 shows some examples.

[a] Purified by chromatography since *(8c)* decomposes on distillation.

(9). We cannot yet say for certain whether the long-sought diazoketene *(10)*[3] is involved as intermediate.

We were able to generate and identify the diazoketene *(10)* in the following way: an ethereal solution of diazabicyclooctane was added dropwise to a boiling solution of *(3)* in ether from which the solvent distilled colorless at a bath temperature of 40 °C. The distillate immediately turned pale yellow. It was collected with ethanol in a receiver. After evaporation of the ether from the distillate the IR spectrum of the residue showed the typical band of diazoacetic ester *(8)*, X = OC_2H_5, at 2100 cm^{-1}. Addition of HBr to the distillate liberates nitrogen, and the bromoacetic ester *(11)* (yield 4%) can be unequivocally identified by gas chromatography. The diazoacetic ester *(8)*, X = OC_2H_5, formed in the receiver cannot have arisen from distilled *(3)* and ethanol since any HCl liberated in this reaction would transform the diazoacetic ester into chloroacetic ester.

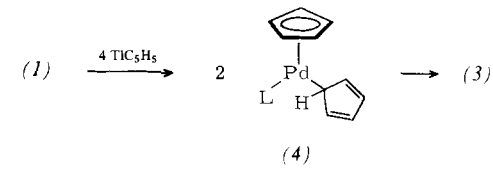
Synthesis and Structural Dynamics of Bis(cyclopentadienyl)phosphanepalladium Complexes[1]



By *Helmut Werner* and *Hans-Jürgen Kraus*[*]

Dedicated to Professor André S. Dreiding on the occasion of his 60th birthday

Palladocene $Pd(C_5H_5)_2$ has so far not been reported in the literature[2]. Recently, however, we were able to synthesize the dinuclear sandwich complex *(3)*, L = $P(iPr)_3$, *via* the *in situ* intermediate *(2)*[3]:

On attempting to isolate *(2)* we observed that *(3)* is also formed directly from *(1)* and cyclopentadienylthallium. This "one-pot synthesis" of the dinuclear complex should proceed *via (4)* as intermediate, which then reacts—probably *via* a $C_5H_5Pd(L)$ radical—to give *(3)*:

We have now been able to isolate compounds of type *(4)* and to demonstrate that they have a fluxional structure, at least in solution.

Reaction of *(1)* [L = PMe_3, $P(iPr)_3$, PPh_3] with TlC_5H_5 (molar ratio ≈ 1:4.4) in benzene at room temperature leads within a few minutes to a dark-green solution from which, after removal of solvent and extraction with pentane, green crystals of *(4)* are obtained (yield 60—85%). These are only slightly air-sensitive and can be stored almost indefinitely at −20 °C. They react at 25 °C in toluene slowly to give *(3)*; for L = PMe_3, the reaction to $(\mu\text{-}C_5H_5)_2Pd_2(PMe_3)_2$ is complete after about nine days. Reaction of *(4)* and $CHCl_3$ affords the compounds $(\eta^5\text{-}C_5H_5)Pd(L)Cl$[4].

The composition of the complexes *(4a)* [L = PMe_3], *(4b)* [L = $P(iPr)_3$] and *(4c)* [L = PPh_3] is confirmed by elemental analysis and mass spectra. The mass spectra (70 eV; inlet temperature 60—120 °C) show the molecular ion with relatively high intensity and consistently PdL^+ as the most intense fragment. The room-temperature ^{1}H-NMR spectra show a *single* sharp signal for the 10 protons of the two cyclopentadienyl ligands. On cooling, this signal broadens to a flat hump (*e.g.* at −23 °C in the case of *(4b)*). At −47 °C *two* signals of different width but *equal intensity* appear in the C_5H_5 region in the case of *(4b)* (see Fig. 1). On further cooling the signal at δ = 5.04 becomes increasingly sharper and at −80 °C a PH-coupling of 1.6 Hz can be observed; the signal at δ = 6.20, on the other hand, becomes broader below −50 °C and coalesces at *ca.* −80 °C. From the chemical shift the former signal can be unequivocally assigned to the $\eta^5\text{-}C_5H_5$ protons and the latter to the $\eta^1\text{-}C_5H_5$ protons.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/1212-0948 $ 02.50/0

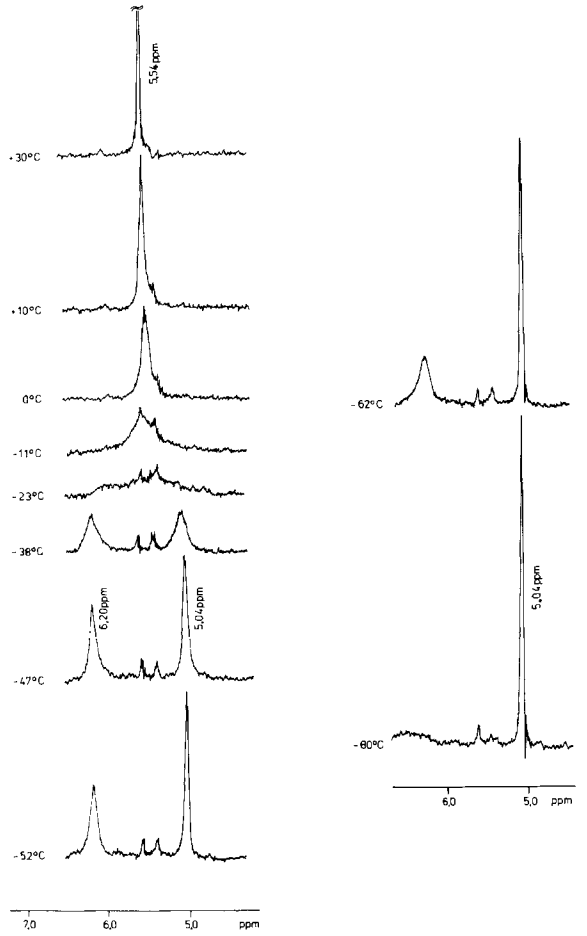

Fig. 1. ^{1}H-NMR spectra of (π-Cp)Pd(σ-Cp)P(iPr)$_3$ *(4b)*.

We conclude from the changes in the NMR spectra that *two dynamic processes take place simultaneously* at higher temperatures (above about $-25\,^\circ$C in the case of *(4b)*): that with the higher activation energy is a π/σ-(η^5/η^1) exchange of the two differently bound cyclopentadienyl ligands; that with the lower activation energy, which for the phosphanes employed can be frozen-in only below $-80\,^\circ$C, is a metallotropic rearrangement of the cyclopentadiene derivative C_5H_5X, *i.e.* a migration of the group $X = Pd(PR_3)(\eta^5\text{-}C_5H_5)$ around the ring. The rate, both of the ring exchange as well as of the metallotropic rearrangement, depends upon the size of the phosphane ligand. Hence, for example, the coalescence temperature for the process with the higher activation energy decreases along the series $PR_3 = P(i\text{Pr})_3$ (*ca.* $-25\,^\circ$C) > PPh_3 (*ca.* $-30\,^\circ$C) > PMe_3 (*ca.* $-65\,^\circ$C).

The ^{13}C-NMR spectrum of *(4b)* confirms the above discussed dynamics for this molecule. At $+35\,^\circ$C (in [D$_8$]toluene) a sharp signal is observed in the region of the ring C-atoms at $\delta = 106.31$, which on cooling to $-30\,^\circ$C splits into two signals of different width. At $-80\,^\circ$C the signal at higher field ($\delta = 100.63$) becomes a sharp doublet with $J_{PC} = 6.6$ Hz, while that at lower field ($\delta \approx 110.4$ at $-35\,^\circ$C) disappears into the background.

To our knowledge, in addition to *(4a)—(4c)* there are two further compounds having the composition $(C_5H_5)_2Mo(NO)(S_2CNR_2)$ [R = Me, *n*Bu][5] which contain one η^5- and one η^1-C_5H_5 ligand and in which π/σ ring exchange (besides a metallotropic rearrangement) takes place[6]. *Cotton* assumes that the ring exchange in these complexes is made possible by the transition of one of the ligands NO or S_2CNR_2 from a 3-electron donor into a 1-electron donor[7]. The η^1-C_5H_5 ligand could then undergo stronger interaction with the metal involving an η^4-C_5H_5 coordination in an intermediate of the exchange. Such a mechanism is out of the question in the case of the ring exchange in *(4a)—(4c)*. We assume that during the transition from (η^5-C_5H_5)(η^1-C_5H_5')PdL to (η^1-C_5H_5)(η^5-C_5H_5')PdL an intermediate is formed in which *both* rings are η^3-bonded. The number of the electrons in the valence shell of the palladium would thus remain unchanged *vis-a-vis* in *(4a)—(4c)*.

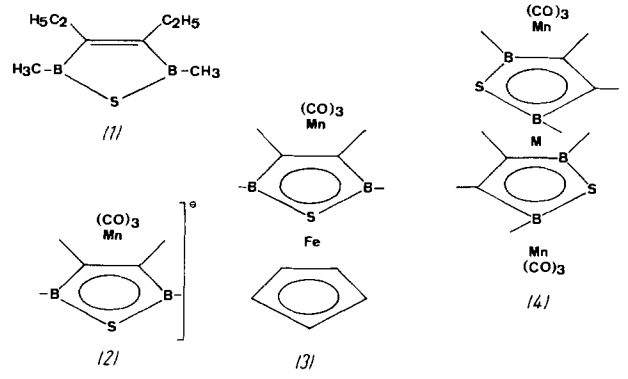
New Pathways to Trinuclear Complexes—Structure of the Tetra-decker Sandwich Complex Bis(η-thiadiborolenecobalt-μ,η-thiadiborolene)iron[1]

By *Walter Siebert, Wilfried Rothermel, Christian Böhle, Carl Krüger,* and *David J. Brauer*[*]



Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

Triple-decker sandwich complexes are prepared by reacting dinuclear metal carbonyl compounds with Lewis-acidic boron heterocycles[2] as well as by the nearly quantitative "stacking" of sandwich compounds[3] with fragments of metal complexes [(C_5H_5)M, ($CO)_3$M']. Several preparative routes to tetra-decker complexes are conceivable, of which the thermolysis of the triple-decker salt [(C_6H_6)Fe·*(1)*·Mn($CO)_3$]$^{\oplus}$$AlCl_4^{\ominus}$ giving low yields of centrosymmetric *(4)*, M = Fe, was the first to be reported[1]. Earlier attempts[4] to prepare *(4)* from the tricarbonylmanganese-η-thiadiborolene anion *(2)* and $FeCl_2$ failed since the anion *(2)* cannot be obtained from $(CO)_5$MnNa and *(1)*. We now report the cleavage of triple-decker compounds with cyclopentadienide and conversion of the anionic mononuclear complexes thus formed into trinuclear complexes.

The reaction of *(3)*[1] with $C_5H_5^{\ominus}$ gives ferrocene and *(2)*. Combination of the latter with MCl_2 affords the tetra-decker complexes *(4)* (M = Fe, Co, and Ni) in 23, 45, and 2% yields, respectively. The ^{1}H-NMR spectrum of the iron complex *(4)* contains broad, weakly structured signals indicating the presence of conformational isomers. The ESR spectrum of the 43

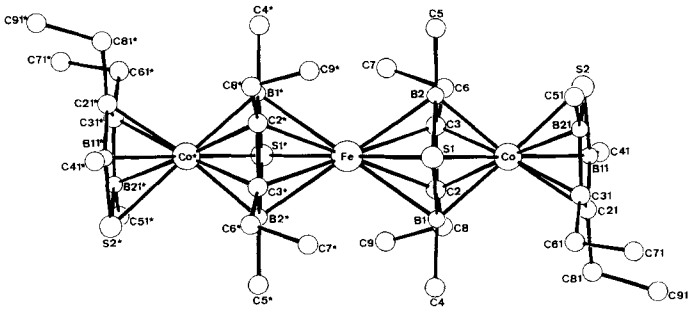
(1) (2) (3) (4)

valence-electron, paramagnetic cobalt complex *(4)* contains 8 lines [$\langle g\rangle = 2.099$, $\bar{a}(^{59}Co) = 39.7(2)$ G] caused by $I = 7/2$ of ^{59}Co. The black complexes *(4)* (M = Fe, Co, Ni) give analogous MS fragmentation patterns and the IR absorptions $\nu(CO) = 2022$ (s), 1957 (s), 1946 (s) cm^{-1} (in C_2Cl_4).



On attempting to replace the thiadiborolenecobalt fragment in the triple-decker sandwich complex *(6)* by $(CO)_3Mn$, the complex *(4)*, M = Co, was unexpectedly formed in 9% yield. Apparently [*(1)*·Co·*(1)*·$Mn(CO)_3$], which is isoelectronic with the 30 valence-electron complex [*(1)*·Co·*(1)*·$Co(CO)_2$][5], is stacked by excess $[Mn_2(CO)_{10}]$ to give tetra-decker *(4)*, M = Co.

(5) (6) (7)

Like *(3)*, compound *(6)* is split by $C_5H_5^{\ominus}$ into [(C_5H_5)Co·*(1)*] and the anion *(5)*, which was isolated as the tetraphenylphosphonium salt (yield 96%) [$\delta^1H = 7.2$—8.0 (M, 20), 1.85 (M, 8), 0.86 (T, 12), 0.22 (S, 12) (in CH_2Cl_2); $\delta^{11}B = 24.7$ (in CH_2Cl_2)]. *(5)* reacts with $FeCl_2$ to give the black tetra-decker sandwich complex *(7)* in 29% yield. The ^{1}H-NMR spectrum of this 42 valence-electron complex is similar to that of *(4)*, M = Fe, with overlapping signals [$\delta = 2.2$ (M, 6), 1.09 (S, 6), 1.04 (T, 12), 0.99 (T, 12), 0.96 (S, 6)] indicating different conformers in solution. On the basis of analytical and mass spectroscopic evidence we proposed a tetra-decker sandwich structure for *(7)*[6a]. This structure has been confirmed by an X-ray structure analysis[7] (Fig. 1).

The Fe···Co distance [3.5370(4) Å] is longer than the corresponding Fe···Mn separation [3.400(7) Å] in *(4)*. As in the latter complex, the Fe atom is located at an inversion center with the μ-rings mutually *trans*. The η-ligands are nearly parallel to the μ-rings and are rotated axially through 102.2°. Comparison of the distances between the best planes of the μ-ligands (D) and the bonded metal atoms in *(4)* and *(7)* reveals a lengthening of about 0.16 Å for Mn/Co [Mn—D *(4)* 1.757 Å; Co—D *(7)* 1.601 Å] but a 0.3 Å shortening for Fe—D [Fe—D *(4)* 1.631 Å; Fe—D *(7)* 1.934 Å]. In agreement with previous investigations of triple-decker complexes[8], we observe in *(7)* a Co-η-D distance [1.691 Å]

which is 0.090 Å longer than the Co-μ-D length. Following the cluster rules, *(7)* may be described by two *nido* and two *closo*-structures with a total of $2\times16+2\times16=64$ skeleton electrons as opposed to 42 valence electrons in the π^6/d^6 description. Further tetra-decker sandwiches have recently been reported[6].

Experimental

A mixture of *(6)* (0.66 g, 1.07 mmol) and C_5H_5Na (0.14 g, 1.60 mmol) in THF (50 ml) was stirred for 20 h. After addition of excess $FeCl_2$, stirring was continued for a further 20 h and the mixture then filtered. After evaporation of the filtrate, ferrocene and [(C_5H_5)Co·*(1)*] were removed from the residue by sublimation. The remainder was treated repeatedly with 30 ml portions of toluene from which black rods of *(7)* crystallize on cooling (0.13 g, 29%); m.p. 210—212 °C (decomp.).

cludes an intramolecular 1,2 hydride shift[1]. However, only *(1)* has hitherto been detected as a stable cation in a superacid medium and in the gas phase[2]; all attempts to isolate *(2)* or to identify it by spectroscopy failed[1e,3].

(1) *(2)*

(3) *(4)*

(5a), $R^1 = R^2 = H$
(5b), $R^1 = R^2 = D$
(5c), $R^1 = H$, $R^2 = D$

We have generated the $[M-Br]^+$ ions from 1- and 2-bromoadamantane *(3)* and *(4)*, respectively, by dissociative ionization in the gas phase and recorded their collision activation (CA) spectra[4]. In spite of certain common features, the CA spectra of the $[M-Br]^+$ ions of *(3)* and *(4)* differ to such a degree (for example, see the section between $m/e=65$ and $m/e=81$ shown in Fig. 1[5]) that we have to assign the ions *different* structures (fingerprint criterion).

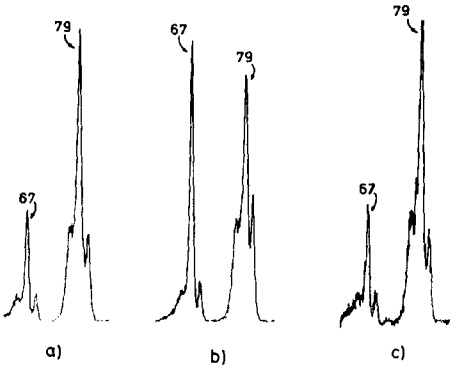

Fig. 1. Section from the CA spectra of the ions $C_{10}H_{15}^+$: a) from *(3)*, $[M-Br]^+$; b) from *(4)*, $[M-Br]^+$; c) from *(5a)*, $[M-H]^+$; the numbers are the m/e values of the collision-induced fragments.

Exothermic isomerization of the $C_{10}H_{15}^+$ ions before or during elimination of Br$^\cdot$ can be ruled out since the kinetic energy liberated on unimolecular decomposition of *(3)* and *(4)*, *i.e.* $T^{1/2}$, and also the line shape of the transition signals[6], are identical: for $[(3)]^{+\cdot} \rightarrow [M-Br]^+$ we obtain $T^{1/2}=0.25$ kcal mol^{-1} and for the decomposition of $[(4)]^{+\cdot}$ a value of $T^{1/2}=0.26$ kcal mol^{-1}.

Since the decomposition of *(3)* can certainly be regarded as a simple dissociation to form the stable 1-adamantyl cation *(1)*, we deduce from the CA and T results that bromine is eliminated from the radical cation of *(4)* in a mechanistically analogous reaction (*i.e.* without rearrangement or σ-neighboring group participation), thus giving the long-sought 2-adamantyl cation *(2)*.

Remarkably, the CA spectrum of the $[M-H]^+$ ion of adamantane *(5a)* and that of *(1)* are identical. This means that either the tertiary C–H bond dissociates specifically or the cation subsequently isomerizes to *(1)* following nonspecific H elimination. The latter alternative can be ruled out because deuterium is exclusively eliminated from the tetradeuterated adamantane *(5b)*. The trideuterated species *(5c)* loses both H$^\cdot$ and D$^\cdot$; after correcting for the statistical probability of H/D elimination the experimental data afford a kinetic isotope effect of $k_H/k_D=1.9$.

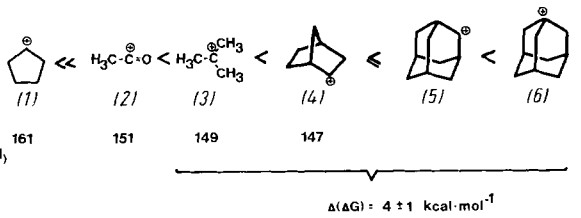
Ion Cyclotron Resonance Studies on *tert*-Butyl, 2-Norbornyl, and 1- and 2-Adamantyl Cations[**]

By *Raymond Houriet* and *Helmut Schwarz*[*]

The relative stability of carbocations $R^\oplus$ in the gas phase can be determined by ion cyclotron resonance (ICR) spectroscopy[1]; in this technique the direction of anion transfers and the position of the equilibrium are established [eq. (a), X = F, Br]. The heterolytic bond dissociation energy $D(R^\oplus - X^\ominus)$, which can be regarded as a measure of the relative stability of $R^\oplus$[2,3] and is defined by eq. (b), can be calculated from the equilibrium constant of reaction (a)[3].



$$R'^\oplus + R''X \rightleftarrows R'X + R''^\oplus \quad (a)$$

$$RX \rightarrow R^\oplus + X^\ominus; \quad \Delta H_r = D(R^\oplus - X^\ominus) \quad (b)$$

We have examined the bromide transfer between the cations *(1)*—*(6)* (Fig. 1[4]) and obtained the stability sequence given in Scheme 1 from the position of the equilibria. These agree both quantitatively and qualitatively with the sequence given by *Beauchamp et al.*[3b] in the case of *(1)*—*(4)*, while qualitative agreement was found for *(6)*. However, we found

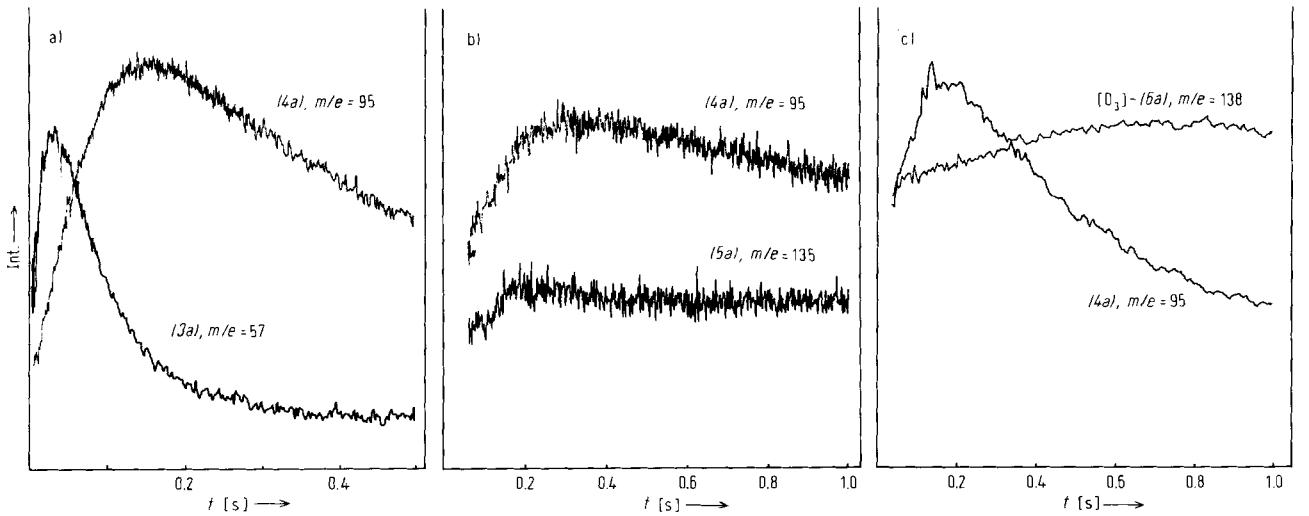
Scheme 1. Stability sequence of cations *(1)* to *(6)*; $D(R^{\oplus}\ X^{\ominus})$ values taken from [3b].

that the $\Delta(\Delta G)$ values for the pair *(3)/(6)*, and hence also the differences in the bond dissociation energies, to be ≤ 4 kcal mol^{-1}[5]. This means that, with regard to its stability, *(6)* must be regarded as a normal tertiary carbocation[7], and not, as frequently assumed, as a highly stabilized carbocation.



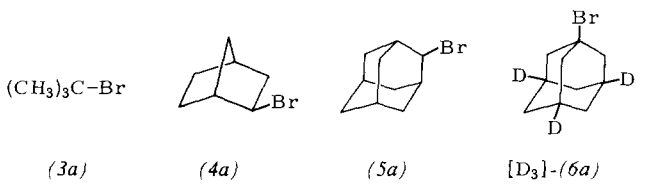


Fig. 1. Ion intensities as function of time in binary mixtures of a) *exo*-2-norbornyl bromide *(4a)* (2.3×10^{-6} torr) and *tert*-butyl bromide *(3a)* (8×10^{-6} torr), b) *(4a)* and 2-adamantyl bromide *(5a)* (1:1 mixture, total pressure: 5.5×10^{-6} torr), and c) *(4a)* and $[D_3]$-*(6a)* (1:1 mixture, total pressure: 7.2×10^{-6} torr).

The situation is completely different in the 2-adamantyl cation *(5)*, which has recently been detected for the first time as

(3a) *(4a)* *(5a)* $[D_3]$-*(6a)*

a stable ion in the gas phase[8]. The stability difference of *ca.* 16 kcal mol^{-1}[2] to be expected for classical *sec/tert* cations is not present; *(5)* and *(6)* differ by 4 kcal mol^{-1} at most. The analogy with the controversial[9] system 2-norbornyl/2-methyl-2-norbornyl cation cannot be overlooked.

[4] In order to ensure internal consistency, a total of eleven pairs was examined (some under double resonance conditions). $Br^{\ominus}$ transfer for the pairs *(3)/(4)*, *(4)/(5)*, and *(4)/(6)* are reproduced in Fig. 1. In cases of equal mass, as with *(5)/(6)*, deuterated compounds were used.—The ICR spectrometer built at the ETH Lausanne and used for the measurements contains a Varian V 7300 magnet; the experiments were performed in a flat four-section cell under trapped ion conditions [*T. B. McMahon, J. L. Beauchamp*, Rev. Sci. Instrum. *43*, 509 (1972)]. The dissociative ionization of the bromides was accomplished by a 2.5-ms pulse of 20-eV electrons. All compounds were introduced *via* a dual inlet system.
[5] The data reported in [3a] yield a difference of 10 kcal mol^{-1} for *(3)/(6)*. However, it is emphasized in that publication that the value for *(6)* is attended by considerable uncertainty. On using data from the literature, our measurements yield the enthalpy of formation of *(6)* as $\Delta H^{\circ}_{f(6)} = 159 \pm 3$ kcal mol^{-1}. This value is in excellent agreement with the results obtained by other methods, *e.g.* 160.7 [6a] or 160 kcal mol^{-1} [6b].

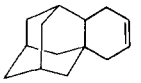
Adamantene in the Gas Phase[**]



By *Helmut Schwarz, Manfred T. Reetz, Wilhelm F. Maier, Chrysostomos Wesdemiotis, Ioannis Chatziiosifidis,* and *Marita Schilling*[*]

Adamantene *(1)* occupies a special place among the bridgehead olefins[1]. So far, however, the intermediacy of *(1)* has only been established indirectly by trapping experiments [such as cycloaddition to give *(2)*][2]. If the reaction is

(1)

(2)

carried out in the condensed phase, contradictory results are is obtained with regard to the existence and properties of *(1)*[2].

We now wish to report a simple experiment in which adamantene *(1)* is generated directly as the neutral molecule under high vacuum conditions ($p \approx 10^{-6}$ torr) by an unequivocal decomposition of radical cations.

On ionization of 2-(1-adamantyl)cyclohexanone *(3)*[3] or the ketones *(4)* and *(5)* by electron impact (15 eV, 70 eV) the radical cations decompose *inter alia via* a McLafferty rearrangement[4] (Scheme 1). Peak shape analysis of the fragmentations of metastable ions (lifetime $t \approx 10^{-5}$ s; minimum excess energy in $M^{+\cdot}$) shows that (i) the peak profiles for the three fragmentation processes are identical (Gaussian form) and (ii) the translational energy T liberated on unimolecular decomposition is practically equal to within the limits of experimental error ($T^{1/2}$ values in Scheme 1).

Scheme 1. Olefin elimination from *(3)*—*(5)* ($T^{1/2}$ values in kcal mol^{-1}).

In view of the fact that (i) the T data are a very sensitive probe for the analysis of reaction mechanisms and can vary by up to four powers of ten depending upon the particular reaction type[5] and (ii) the reaction profile can also be influenced by the reaction type[5,6], it must be concluded from the experimental results that the fragmentations of *(3)*—*(5)* proceed *via* a single mechanism. According to the collision activation spectra[7] only the enol form *(6)* need be considered for the ionized fragment[8]. Since the neutral molecules C_4H_8 and C_6H_{10} [from *(4)* and *(5)*], respectively are undoubtedly olefins[4] and no deuterium is transferred from *(3b)* it must be concluded that the $C_{10}H_{14}$ fragment from *(3a)* or $C_{10}H_{11}D_3$ from *(3b)* has the structure of adamantene *(1)*. A hypothetical exothermic isomerization of the incipient neutral molecule should lead to peak broadening and hence to greater T values on decomposition of *(3)*. However, there is no experimental evidence for such a reaction. Two further points warrant mention: (i) formation of adamantene is not limited to cyclohexanone derivatives. T data and peak profile analysis suggest that *(1)* is also formed by unimolecular decomposition of the 2-(1-adamantyl)-derivatives of cyclopentanone and cyclooctanone. (ii) The generation of adamantene expectedly requires considerable energy. Whereas the intensities for *(6)* (15 eV) are 76 and 87%, respectively, for *(4)* and *(5)*, much lower values are found with the adamantyl derivatives ($\approx 2.5\%$)[9].

Synthesis of a Platinum Complex with a Derivative of Monomeric Metathiophosphoric Acid as η^2-Ligand[**]

By *Otto J. Scherer* and *Herbert Jungmann*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

Metathiophosphoric acid derivatives of type *(1)* can be isolated as monomeric double ylides[1] which prove to be extremely reactive[2]. Thus they should also be capable of σ- and/or π-coordination to transition metals. On reaction of $(Ph_3P)_2Pt(C_2H_4)$ with the amino(imino)thiophosphorane *(1)* we have now succeeded for the first time in preparing a complex containing such a species as π-bonded (side-on) ligand.

R = $C(CH_3)_3$, R' = $Si(CH_3)_3$

Compound *(2)* forms yellow crystals[3] which are moderately soluble in benzene, toluene, and ether, and readily soluble in CH_2Cl_2 and $CHCl_3$[4].

Unlike the free ligand[1] (sp^2 hybridization at the P atom) the complexed ligand *(1)* (sp^3 hybridization at the P atom)

exhibits dynamic behavior. Temperature-dependent ^1H- and ^{13}C-NMR spectra (Table 1) suggest the presence of form *(b)* having a pentacoordinated Si atom in solution at low temperature[5].

The equivalence of the two $(CH_3)_3C$ groups observed at room temperature (Table 1) is due to an intramolecular 1,3-shift of the $(CH_3)_3Si$ group. The ^{31}P-NMR data (Table 1)—they reflect the expected differences in the PP coupling constants for the *cis* and the *trans* arrangement of the P atoms[6]—show that the amino(imino)thiophosphorane ligand in *(2)* fails to undergo NMR-spectroscopically measurable rotation about an imaginary Pt/P=S bond axis at 20 °C. Crystal structure analysis[7] confirms structure *(a)*.

Procedure

A solution of $(Ph_3P)_2Pt(C_2H_4)$ (960 mg, 1.28 mmol) in anhydrous benzene (7 ml) is added dropwise within 5 min to a stirred, ice-cooled solution of *(1)*[1] (360 mg, 1.29 mmol) in anhydrous benzene (3 ml). After *ca.* 15 min at room temperature, the solution is concentrated in an oil-pump vacuum and the product allowed to crystallize in a refrigerator. The crystals are washed twice with a little cold benzene and dried in an oil-pump vacuum for 30 min at room temperature: yield 1.04 g (70%) *(2)*·$2C_6H_6$. Recrystallization once again from benzene and drying for 16 h in an oil-pump vacuum affords 650 mg (47%) of *(2)*·$1C_6H_6$. On washing these crystals twice in pentane and drying for several hours, benzene-free *(2)*, m.p. 147—149 °C (dec.), is obtained.

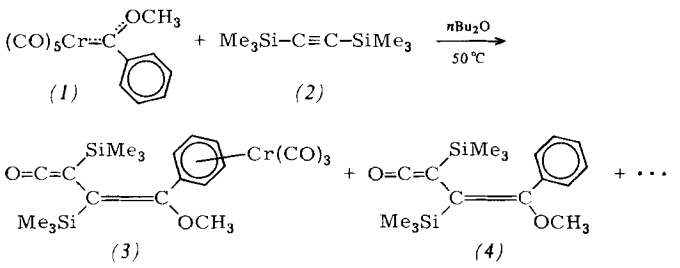
Preparation of Stable Vinylketenes by Metal Complex-Induced Olefination and Carbonylation of Alkynes[**]

By *Karl Heinz Dötz*[*]

Vinylketenes have been postulated as intermediates in the electrocyclic ring cleavage of cyclobutenones[1]. However, they have so far resisted all attempts at isolation and detailed characterization[2]. Our studies on the reactions of carbonyl-carbene complexes with alkynes[3] have now opened a new entry to vinylketenes which are stable and can be handled under normal conditions.



Pentacarbonyl[methoxy(phenyl)carbene]chromium *(1)* reacts with bis(trimethylsilyl)acetylene *(2)* on warming in dibutyl ether to give tricarbonyl[4-methoxy-4-phenyl-2,3-bis(trimethylsilyl)-1,3-butadienone]chromium *(3)*; in addition the metal-free vinylketene derivative *(4)* can also be isolated.

In their IR spectra[4a] the products show ν(C=O) absorptions at 2089 [alongside ν(Cr—C=O): 1980, 1917] for *(3)*

[**] Vinylketenes, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft.

and 2090 cm^{-1} for *(4)* while the ^{13}C-NMR spectrum[4b] exhibits signals at $\delta = 180.4$ and 18.3 for *(3)* and at 183.1 and 18.0

(1) *(2)*

(3) *(4)*

for *(4)*, which are to be assigned to the ketene carbon atoms C^1 and C^2[5]. As shown by the X-ray analysis[6] of a single crystal of *(3)* grown from a solution in ether/pentane (1:10) the vinylketene has a *s-trans* conformation and (with respect to the olefinic C=C bond) a *Z* configuration. Furthermore, as is already apparent from the IR and the ^{13}C-NMR spectrum for the dissolved state, a significant conjugation can be ruled out also in the crystal on the basis of the interatomic distances within the diene structural unit and the almost orthogonal arrangement of the olefin and the ketene function.

Hitherto, vinylketenes could only be stabilized by coordination of the diene moiety to transition metals, which considerably modifies their properties[7]. The characteristic steps leading to the formation of the novel compounds *(3)* and *(4)* may be insertion of the alkyne into the metal-carbene bond, giving a *Z*-styryl-carbene complex[8], and carbonylation of the new carbene atom. This vinylketene synthesis formally amounts to head-to-tail addition of a carbene and a carbonyl ligand to the alkyne.

Procedure

A solution of *(1)* (2.53 g, 8.12 mmol) in di-*n*-butyl ether (20 ml) is warmed to 50 °C in an N_2 atmosphere with compound *(2)* (1.90 ml, 8.95 mmol) for 2 h. After removal of the solvent the residue is taken up in dichloromethane/pentane (1:1, 6 ml) and chromatographed on silica gel (Merck, act. 2—3). Non-coordinated vinylketene *(4)* can be eluted in front of the main red zone and isolated as an orange oil which solidifies at −30 °C. There follows the complex *(3)* which precipitates as red crystals from ether/pentane (1:10). Yields: 1.92 g (52%) of *(3)*, m.p. 85 °C; 0.51 g (20%) of *(4)*.

The Homologous Series of Cyclic Polysilanes from $(Me_2Si)_5$ to $(Me_2Si)_{35}$[**]

By *Lawrence F. Brough, Koichi Matsumura*, and *Robert West*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

Because they show unusual properties resulting from electron delocalization[1], the cyclopolysilanes are of interest as model compounds for electronic effects in elemental silicon[6]. Variously substituted four-, five-, six-, and seven-membered silane rings are known[7], and $(Me_2Si)_8$ and $(Me_2Si)_9$ were recently isolated from the reaction of Me_2SiCl_2 with lithium metal[8]. We now report a modification of the synthesis of cyclopolysilanes from Me_2SiCl_2 and Na/K alloy, which apparently produces *all of the permethylcyclosilanes* $(Me_2Si)_n$ *from* $n = 5$ *through* $n = 35$.

The usual synthesis of $(Me_2Si)_n$ from Me_2SiCl_2 and Na/K in tetrahydrofuran (THF) yields mostly $(Me_2Si)_6$, along with about 10% $(Me_2Si)_5$ and 2% $(Me_2Si)_7$[9]. Medium and large-ring cyclosilanes are obtained only if the Me_2SiCl_2 is added *slowly* to Na/K in refluxing THF. In a typical experiment 1200 ml of dry THF and 185 ml (4.7 mol) of Na/K alloy were stirred at reflux in a 5-l flask equipped with a high capacity condenser and 244 ml (2.0 mol) of $(CH_3)_2SiCl_2$ was added dropwise over a period of 10 h. The mixture was cooled slightly, 1200 ml of hexane was added, and the excess alloy was gradually destroyed by the cautious dropwise addition of approximately 100 ml of water. Another 1000 ml of water was then added, after which the organic phase was separated, filtered to remove polymer, and washed with aqueous NaCl. The solvent was removed by distillation giving a crystalline precipitate. A combination of recrystallization from ethanol/THF (7:1) and fractional sublimation served to remove most of the $(Me_2Si)_5$ and $(Me_2Si)_6$ from the product mixture. The residual solids, now enriched in medium and large rings, could be separated by high pressure liquid chromatography (HPLC) as shown in Figure 1.

The compounds were identified as $(Me_2Si)_n$ oligomers by mass spectrometry. Peak matches were obtained at high resolution for $n = 8$ through 19 and for $n = 24$, all with deviations less than 3.5 ppm. The compounds appear to be pure as obtained by HPLC, in that only sharp singlets are observed in the ^1H-NMR spectra (Table 1). The cyclosilane structure is assigned to the higher fractions through $n = 35$ on the basis of the HPLC results.

Table 1. Yields and ^1H-NMR absorptions for permethylcyclosilanes, $(Me_2Si)_n$.

n	Yield [%] [a]	δ	*n*	Yield [%] [a]	δ
5	17.0	0.135	13	0.19	0.192
6	52.1	0.132	14	0.21	0.200
7	2.6	0.128	15	0.22	0.197
8	1.3	0.144	16	0.19	0.196
9	0.76	0.163	17	0.14	0.196
10	0.16	0.188	18	0.09	0.197

[**] Cyclic Polysilanes, Part 14. This work was supported by the U. S. Air Force of Scientific Research, Grant AF-AFOSR-78-3570.—Part 13: [3].

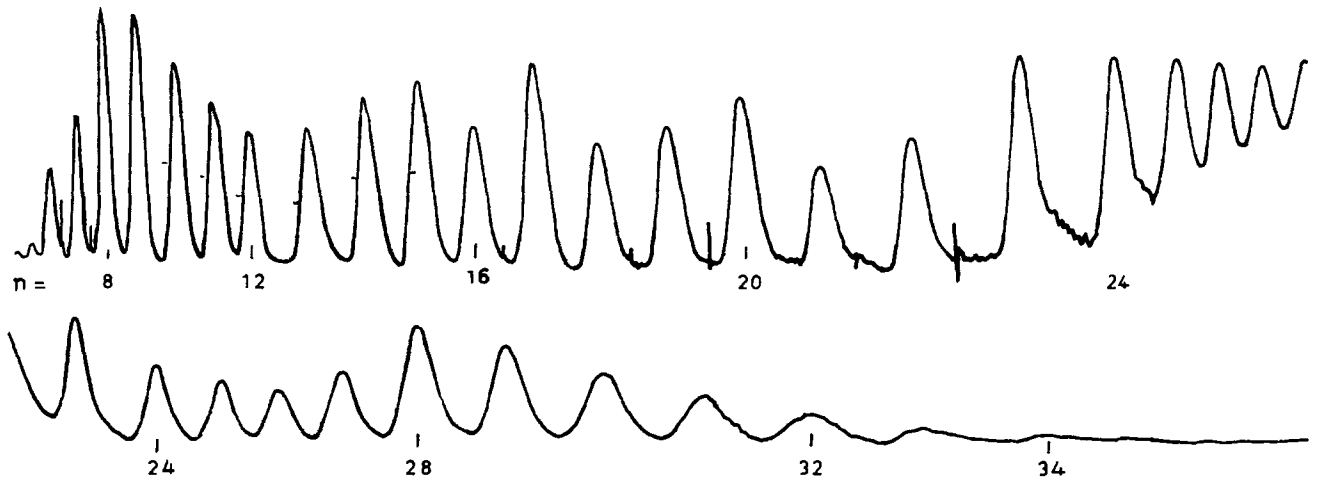

Fig. 1. High pressure liquid chromatogram of permethylcyclosilanes, $(Me_2Si)_n$ (methanol/THF on a Whatman M9 column containing Partisil-10 ODS).

Estimated yields are given in Table 1. As expected on statistical grounds, yields decrease with increasing ring size from $n=6$ to 10 and above $n=16$. However from $n=10$ to $n=16$ the yield of each compound is approximately equal. Apparently these cyclosilanes exhibit a medium-ring effect of the type known in cycloalkane chemistry, in which the increased entropy requirement for closure as ring size increases is balanced by decreased steric repulsion. Except for the cycloalkanes the 31 permethylcyclosilanes may form the longest homologous series of cyclic compounds known to chemistry.

One-Pot Syntheses of α-Ferrocenylalkylamines[**]

By *Rudolf Herrmann* and *Ivar Ugi*[*]

The use of 1-ferrocenyl-2-methylpropylamine *(4b)* permits asymmetric peptide syntheses with high overall yields and unlimited stereoselectivity[1]; however, this reagent was previously accessible only with difficulty[2].

[*] Prof. Dr. I. Ugi, Dipl.-Chem. R. Herrmann
Organisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

$$\underset{(1)}{FcH} + \underset{(2)}{R^1R^2C{=}O} + \underset{(3)}{HNR^3R^4} \rightarrow \underset{(4)}{Fc{-}CR^1R^2{-}NR^3R^4} + H_2O \qquad (a)$$

Fc = Ferrocenyl; *(a)*, $R^1=R^2=H$, $R^3=R^4=Me$; *(b)*, $R^1=H$, $R^2=i$Pr, $R^3=R^4=H$; *(c)*, $R^1=H$, $R^2=i$Pr, $R^3=R^4=Me$

The synthesis of α-ferrocenylalkylamines *(4)* by α-aminoalkylation according to eq. (a) would seem an obvious course of action since *(4a)* can be obtained from ferrocene *(1)* and iminium ions [formally from *(2)* + *(3)*][3]. However, we were unable to obtain *(4b)* and *(4c)* by reaction of *(1)* with the iminium ions formed from isobutyraldehyde and ammonia or dimethylamine.

Since α-ferrocenylalkylcarbenium salts *(5)* are stabilized by the ferrocene substituent[4] we examined whether eq. (b) might be a practical proposition.

$$(1) + (2) \xrightarrow{HX} \underset{\underset{(5)}{\oplus}}{Fc{=}CR^1R^2}\ X^{\ominus} \xrightarrow[-HX]{HNR^3R^4\ (3)} (4) \qquad (b)$$

Condensations of ferrocene *(1)* with carbonyl compounds *(2)* to give macromolecular and "oligomeric", and in some cases also "monomeric", compounds have already been described[5]. These reactions probably proceed *via* carbenium ions as in *(5)*. We recently reported the reaction of ferrocene and isobutyraldehyde in trifluoroacetic acid to form the α-ferrocenylisobutylcarbenium ion[6].

We have now discovered that one-pot syntheses of compounds of type *(4)* according to eq. (b) proceed particularly favorably on working in the trichloroacetic acid/fluorosulfuric acid system and when the reaction mixture is introduced into a solution of the amine *(3)*. Some examples are shown in Table 1.

Procedure

Synthesis of *(4)*: Compounds *(1)* (1.86 g, 10 mmol) and *(2)* (20 mmol) are dissolved with stirring in a mixture of trichloroacetic acid (10.0 g) and acetic acid (1.5 ml) at −10 °C under N_2. After addition of fluorosulfuric acid (1.5 ml) the mixture is allowed to react for 20 to 40 min at −10 to 0 °C. The reaction mixture is diluted with dichloromethane (10 ml) and added with vigorous stirring at −78 °C to a mixture

α,β-Unsaturated Carbonyl Compounds with Sterically Protected Carbonyl Groups—Enforced a³ *versus* a¹ Reactivity

By *Dieter Seebach* and *Rita Locher*[*]

The ambident character of enones and of acrylic, crotonic, and cinnamic acid derivatives is an age-old synthetic problem; generally, organolithium compounds prefer the 1,2-addition[1a] and Gilman reagents the Michael addition[1b]. Grignard compounds are not selective. Steric hindrance of the carbonyl group shifts the reactivity into the β-position[1c].

[*] Prof. Dr. D. Seebach, Dipl.-Chem. R. Locher
Laboratorium für Organische Chemie der
Eidgenössischen Technischen Hochschule
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)

Compounds of type *(3)* and *(4)* with readily cleavable steric protecting groups[2] which do not cancel the effect of the CO group should only undergo addition at the C=C double bond.

Aldol condensation of 1,1,1-triphenylacetone *(1)*[3a], which—as expected—is smoothly deprotonated by butyllithium in tetrahydrofuran (THF), with acetaldehyde and benzaldehyde afforded the enones *(3a)* and *(3b)*, respectively. The amides *(4a)* to *(4c)* were obtained by acylation of the base *(2)*[2c] with acid chlorides (see Table 1).

Indeed, the enones *(3)* and amides *(4)* are extraordinarily reactive a^3 reagents: between -80 and $-40\,^{\circ}C$ (in THF) methyl-, *n*-butyl-, phenyl- and 1,3-dithian-2-yllithium add in high yields to give, respectively, the saturated carbonyl compounds *(5)* and *(6)*. Even with *tert*-butyllithium an adduct [*(5c)*] could be isolated (see Table 1). No alcohols resulting from carbonyl addition (a^1 reactivity) could be detected; surprisingly, deprotonation of *(3a)* in the γ-position, which would lead to a dienolate, takes place at most as a side reaction.

Table 1. Yields and physical data of the products of type *(3)*—*(6)* after purification by chromatography on silica gel and/or recrystallization. Reactions: *(1)*→*(3)*; *(2)*→*(4)*; *(3)*→*(5)*; *(4)*→*(6)* (if not otherwise indicated).

Product	R^1	R^2	Yield [%]	M.p. [°C] B.p. [°C/torr]
(3a)	CH_3		82	177
(3b)	C_6H_5		54	153—154
(4a)	H		47 [a]	69
(4b)	CH_3		83 [a]	76—77
(4c)	C_6H_5		45 [a]	118
(5aa)	CH_3	CH_3	89	81
(5ab)	CH_3	*n*-C_4H_9	90	oil [b]
(5ac)	CH_3	*t*-C_4H_9	22	102—103
(5ad) ≡ *(5ba)*	CH_3	C_6H_5	78	120—121
(5ae)	CH_3	1,3-dithian-2-yl	59	112—113
(5ba) ≡ *(5ad)*	C_6H_5	CH_3	62	120—121
(5bb)	C_6H_5	*n*-C_4H_9	78	102—103
(5bc)	C_6H_5	1,3-dithian-2-yl	77	161
(5c) [c]	H	C_6H_{13}	57	91
(6aa)	H	CH_3	36 [d]	$55/10^{-3}$
(6ab)	H	*n*-C_4H_9	80	oil [b]
(6ba)	CH_3	*n*-C_4H_9	67	oil [b]
(6ca)	C_6H_5	CH_3	87	oil [b]
(6cb)	C_6H_5	*n*-C_4H_9	81	oil [b]
(6d) [e]	H	C_6H_{13}	98	$80/10^{-2}$
R_b $COCH_3$ [f]			82 [a]	49

[a] Based on the acid chloride on reaction with *(2)* in the molar ratio 1:2 [2c]. [b] After chromatography on silica gel with hexane/ethyl acetate [in the case of amides *(6)*] or dichloromethane/hexane [in the case of ketone *(5ab)*]. [c] From *(1)* and 1-iodoheptane. [d] Together with 52% of the "dimeric methylation product" *(6)*, R^1 = H, R^2 = $CH(COR_b)(C_2H_5)$ in the α-position, m.p. 120—121 °C. [e] From R_b $COCH_3$ and 1-iodoheptane. [f] From *(2)* and acetyl chloride.

For cleavage of *(5)* we exploited the suitability of the trityl anion as a leaving group[4], and for the cleavage of *(6)* the retro-*Mannich* reaction of the group R_b[2c]. Thus, cleavage of the trityl ketones *(5c)*[3b] and *(5bb)* using a procedure recommended for carboxylic acid derivatives, which are difficult to hydrolyze[3c], afforded triphenylmethane (>96%) and the acids *(7)*, X = OH [nonanoic (82%) and 3-phenylheptanoic acid (81%), respectively]. On reaction with ethanolic hydrochloric acid, the amide *(6d)*[3d] is cleaved to give a mixture of nonanoic acid (10%) and its ethyl ester (62%)[3e]. All new compounds were identified spectroscopically and by elemental analyses; their melting points and yields are listed in Table 1.

The experiments described here show that Michael acceptors of the type *(3)* and *(4)* can be useful reagents for the synthesis of acid derivatives *(7)*: the adducts *(5)*, which can also be obtained with Grignard reagents, are beautifully crystalline and can be readily isolated. The carbonyl group is protected against nucleophilic attack, but can, if necessary, be converted into carboxylic acid functions.

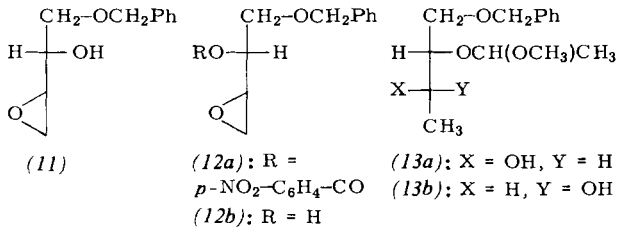
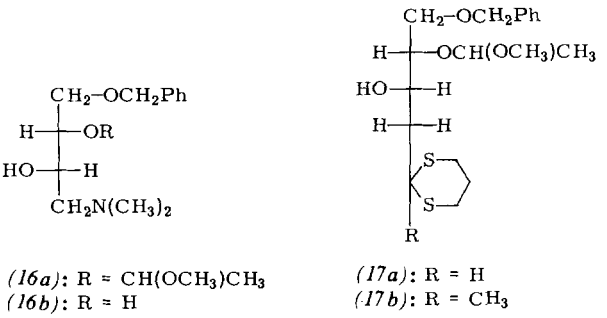
Chiral Reagents from Tartaric Acid—1-Benzyloxy-3,4-epoxy-2-butanol, a Versatile Intermediate for the Synthesis of Enantiomers

By *Ernst Hungerbühler, Dieter Seebach,* and *Daniel Wasmuth*[*]

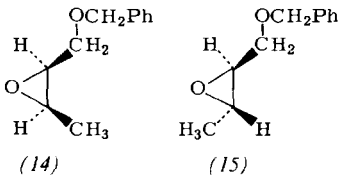


Tartaric acid, *both enantiomeric forms* of which are readily accessible, has already proven its value as precursor for chiral reagents in natural product synthesis. The number of possible target molecules would increase enormously if the structural changes indicated in *(1)*—*(10)* for natural (*R,R*)-tartaric acid could be effected. All the transformations



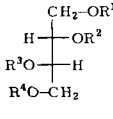
should be capable of being carried out in high yields and with large quantities. *All the structures (1)—(10) with reversed chirality* would then also be preparable from unnatural tartaric acid.

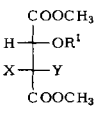
[*] Prof. Dr. D. Seebach, Dipl.-Chem. E. Hungerbühler, Dipl. sc. nat. D. Wasmuth
Laboratorium für Organische Chemie der
Eidgenössischen Technischen Hochschule
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)

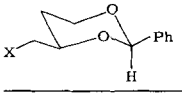


We describe here the synthesis of the key compound *(11)*, *via* which structures of the type *(1)*—*(8)* are accessible, as well as a productive route from natural tartaric acid to unnatural malic acid [cf. *(9)*] and from this to a 1,3-butanediol derivative [see *(10)*]. The individual steps with conditions and yields are given in Table 1. The *epoxyalcohol (11)* [cf. *(1)*] is a distillable liquid (b.p. 130 °C/0.01 torr) and can be stored in the refrigerator; the total yield from tartrate is 45%, while the intermediate products (Table 1) are either distillable or can—like the tosylates—be used further without purification. Inversion at C-2 of *(11)* [cf. *(2)*] can be achieved by the method of *Mitsunobu* [azocarboxylate/triphenylphosphane/RCOOH[1], →*(12a)*], whereby the *erythro*-isomer *(12b)* is accessible. Protection of the OH group of *(11)* by reaction with methyl vinyl ether and opening of the epoxide ring with $LiHB(C_2H_5)_3$ [tetrahydrofuran (THF), −40 to 20 °C, 3 h, then H_2O_2/NaOH] leads to the *triol derivative (13a)* [79% from *(11)*] whose epimer *(13b)* is prepared *via* the benzoate according to the method of *Mitsunobu* [46% from *(11)*]. Tosylation of the free hydroxy group in the two diastereomers *(13a)* and *(13b)*, cleavage of the methoxyethyl protecting group and γ-elimination with KOH/CH_3OH affords the *cis/trans* isomeric *epoxides (14)* and *(15)* [yield from *(13)* 69 and 76%, respectively]. In *(13)*—*(15)* the structural changes to *(3)* and *(4)* are effected. The oxiranes *(14)* and *(15)* are precursors for *branching* [see *(5)* and *(6)*]; they are attacked regioselectively at the methylated C atom by nucleophiles[2].—Opening of the methoxyethyl derivative of *(11)* with dimethylamine or 2-lithio-1,3-dithianes affords the benzyloxyaminodiol *(16b)* [62% from *(11)*][3] and the *chain-lengthened* [cf. *(7)*, *(8)*] compounds *(17)*, respectively. *(17b)* [78% from *(11)*] is a ketotriol containing three different types of protecting groups and a free functional group; it derives from a 4,6-dideoxyhexose, whose derivatives occur as glycons of macrolide antibiotics[4]. *(17a)* [82% from *(11)*] is a derivative of 2-deoxy-L-lyxose; correspondingly, from the mirror image of *(12b)* a thioacetal of 2-deoxy-L-ribose would be formed.

(11) *(12a)*: R = *p*-NO_2–C_6H_4–CO *(12b)*: R = H *(13a)*: X = OH, Y = H *(13b)*: X = H, Y = OH







(16a): R = $CH(OCH_3)CH_3$ *(16b)*: R = H *(17a)*: R = H *(17b)*: R = CH_3

	X=H [f]		

[a] Separation of the dibenzylated product by bulb-to-bulb distillation (b.p. 145 °C/0.005 torr). [b] Before workup, excess TosCl must be hydrolyzed by dropwise addition of water. [c] The hydrolysis must be carried out in homogeneous solution, otherwise it forms very difficultly hydrolyzable cyclic acetaldehyde acetals. [d] Distillation of *(11)* from the crude product without decomposition is possible only if it does not contain tosylates (^{1}H-NMR monitoring). If necessary, tosylates are removed chromatographically (silica gel, ether). [e] The correlation of tartaric acid with malic acid was first described by *Freudenberg* in 1922 [6]. For the conversion [7] of malic acid methyl ester into 1-bromo-3,4-epoxybutane and its use in the synthesis of vermiculin, see [8]. [f] For the use of the respective diols in the synthesis of pyrenophorin see [8, 9].

A few characteristic data of the compounds *(11)*, *(12)*, and *(14)—(17)* are collected in Table 2. Apart from the diastereomerism caused by the methoxyethyl protecting group in *(13)*, *(16a)*, and *(17)*, the compounds are, according to the ^{1}H- and ^{13}C-NMR spectra, diastereomerically pure and thus in the present case also enantiomerically pure; we have prepared *(11)* and *(14)* in both enantiomeric forms.

Table 2. Characteristic physical data of the compounds *(11)*, *(12)*, *(14)—(17)* obtained from (*R,R*)-tartaric acids. ^{1}H-NMR, ^{13}C-NMR, IR, and MS data are consistent with the given structures.

(17b)		4.52 (s, CH_2Ph), 3.3 and 3.28 (each 1 s, OCH_3 (diastereomeric ratio 1:1)), 3.15 (d, $J=4$) and 3.06 (d, $J=5$, OH [a]), 1.65 (s, 3 6-H)

[a] Exchangeable with D_2O. [b] 360-MHz ^{1}H-NMR spectra in $CDCl_3$ and in C_6D_6 were also recorded.

Through the reagents described here the *enantiomeric* tartaric acids[5] have become a versatile source of chirality. In contrast to the carbohydrates generally employed so far (see references cited in [8]) inexpensive tartaric acid has only two types (C_2 axis!) of functional groups, whose number can be readily doubled [see *(1)*, *(2)*]; moreover, a C_4 unit can be incorporated with less effort into a greater number of target molecules than a C_6 building block.

The μ_3-($\eta^3C\eta^2O$) Bridge—A Novel Mode of Coordination in the Structural Chemistry of Carbonylmetal Compounds[1]

By *Wolfgang A. Herrmann, Manfred L. Ziegler, Klaus Weidenhammer*, and *Helmut Biersack*[*]

Hock and *Mills'* first encounter with the phenomenon of "semibridging" carbonyl ligands in 1961, which was later interpreted by *Cotton*[2,3], provided yet another challenge to carbonylmetal chemistry. Apart from the "classical" coordination modes *(1)*, *(2a)*, *(3a)* previously reported exclusively, it has recently also proved possible to detect the quasi-bridging CO ligands *(2b)*[3,4] and *(3b)*[5] in which the π-system of the carbonyl unit engages in bonding interaction with a further metal center. Precisely these chemically reversible complexation types [*e.g. (2b)→(1)*] are nowadays assigned a key function in carbonylation processes proceeding on surfaces and possibly also in homogeneously catalyzed systems[6]. The mode of coordination also has a decisive influence on the kinetics of CO substitution[7] and the molecular dynamics of carbonyl clusters[3].

During our experiments on the photochemistry of tetracarbonyl(η^5-cyclopentadienyl)niobium *(4)*, now accessible on a large scale by a new synthesis[1], we not only produced the first carbonylniobium cluster compound *(5)* but also detected the hitherto unknown structural type *(3c)*, in which the terminal CO ligand is coordinated *via* both its orthogonal π systems to two further metal centers and thus constitutes a novel variant of the classical bonding type *(1)*.

In contrast to the photolysis of the half-sandwich (η^5-C_5H_5)$V(CO)_4$, which affords the dinuclear species (η^5-$C_5H_5)_2V_2(CO)_5$[8], the action of sunlight on *n*-hexane solutions of the homologous niobium compound *(4)* leads directly (with CO elimination) to a crystalline, nonsublimable product *(5)*, which is air-stable for a short period of time and does not decompose thermally below 100 °C. Compound *(5)* was identified as a trinuclear cluster (η^5-$C_5H_5)_3Nb_3(CO)_7$ by complete elemental analysis and its FD mass spectrum ($m/e = 670$; from acetone).

$$3(\eta^5\text{-}C_5H_5)Nb(CO)_4 \xrightarrow{h\nu} (\eta^5\text{-}C_5H_5)_3Nb_3(CO)_7 + 5\,CO\uparrow$$
(4) *(5)*

Since the ^{1}H- and the ^{13}C-NMR as well as the IR data[9] did not permit unequivocal structural assignment, we have car-

[*] Prof. Dr. W. A. Herrmann, H. Biersack

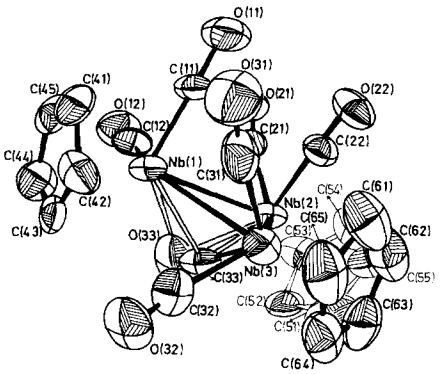
ried out an X-ray structure analysis (Fig. 1)[10], which shows the geometry of *(5)* to have the following characteristics (cf. Table 1):

1) The principal structural feature is an almost equilateral Nb_3 triangle which arises by aggregation of the photochemically generated $(\eta^5\text{-}C_5H_5)Nb(CO)_x$ fragments ($x=2$, 3). The symmetrically π-bonded cyclopentadienyl rings are tipped towards the quasi-bridging group C(33)—O(33) relative to the triangular cluster plane. The six exclusively terminal CO ligands are expectedly coordinated in linear fashion.



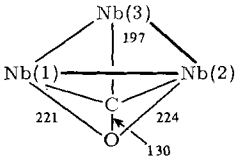


Fig. 1. ORTEP drawing of $(\eta^5\text{-}C_5H_5)_3Nb_3(CO)_7$ *(5)*. The ellipsoids of thermal vibration correspond to 50% probability.

2) The structural outfit of the seventh CO group is surprising: although terminally bonded to the metal center Nb(3), thus representing an almost linear carbonyl-metal function [Nb(3)—C(33)—O(33): 170°], its contact with the two metal atoms Nb(1) and Nb(2) is so close that a true bonding interaction is present beyond any doubt! The corresponding distances Nb(1)—O(33), Nb(2)—O(33), Nb(1)—C(33), and Nb(2)—C(33) are admittedly 24—30 pm greater than the Nb(3)—C(33) contact of 197 pm, responsible for terminal coordination, but only slightly greater than the sum of the covalent *Pauling* radii. Hitherto, M···CO distances of 230—250 pm have been found in "semi-bridging" systems of type *(2b)* and *(3b)* (M = V, Mo, Rh, *etc.*), whereas the M—CO distances range in the order of 190 pm[3-5, 7].

Table 1. Selected structural parameters of *(5)*.

Bond lengths [pm]			Angles [°]			
Nb(1)	Nb(2)	304.4(2)	Nb(1)	Nb(2)	Nb(3)	64.43(5)
Nb(1)	Nb(3)	332.0(2)	Nb(2)	Nb(1)	Nb(3)	59.79(5)
Nb(2)	Nb(3)	318.1(2)	Nb(1)	Nb(3)	Nb(2)	55.79(4)
Nb(1)	C(11)	203.6(19)	Nb(1)	C(33)	Nb(2)	85.04(48)
Nb(2)	C(22)	205.6(15)	Nb(1)	O(33)	Nb(2)	86.32(31)
Nb(3)	C(32)	211.7(23)	Nb(3)	C(33)	O(33)	169.6(1.1)
Nb(3)	C(33)	196.6(12)				
Nb(1)	C(33)	227.8(14)				
Nb(2)	C(33)	222.6(18)				
Nb(1)	O(33)	221.2(10)				
Nb(2)	O(33)	223.8(10)				
C(11)	O(11)	116.9(23)				
C(22)	O(22)	114.2(20)				
C(32)	O(32)	108.2(29)				
C(33)	O(33)	130.3(14)				

3) As a consequence of this additional twofold bridging function, the C(33)—O(33) distance (130 pm) exceeds the distances in the other CO groups by 13—22 pm. This is associated with a drastic lowering of the carbonyl bond order: in the solid-state IR spectrum a sharp, extremely long-wave shifted band at 1330 cm^{-1} is demonstrated by ^{13}CO and $C^{18}O$ labeling (30 and 10% enrichment, respectively) to belong to the corresponding CO frequency. In keeping with the requirements of the synergic mechanism of bonding of CO ligands, the Nb(3)—C(33) bond length is significantly shorter than the "normal" niobium-carbonyl distances.

This unusual molecular structure becomes understandable on considering the electronic requirements of the $(\eta^5\text{-}C_5H_5)Nb(CO)_x$ units ($x=2$, 3) including the metal-metal bonds: while Nb(3) has an 18-electron configuration and therefore has no need of any further coordination, the two $(\eta^5\text{-}C_5H_5)Nb(CO)_2$ fragments [Nb(1) and Nb(2)] are coordinatively unsaturated. This situation can be alleviated by the sterically available Nb(3)—CO group which, as a twofold donating bridge, helps to saturate these electron-deficient centers. In this function we see the molecular origin of ligand bridging in *(5)*. The finding that the angles Nb(1)—C(33)—Nb(2) and Nb(1)—O(33)—Nb(2) are close to 90° is no accident, and suggests that the CO ligand interacts to equal extents with Nb(1) and Nb(2) *via* its two orthogonal systems, thus formally acting as 6-electron donor.

Procedure[11]:

A solution of *(4)*[1] (2.70 g, 10 mmol) in *n*-hexane (250 ml) is exposed to sunlight (coolants CH_3OH; HAAKE KT 33) for 15 to 80 h, depending upon the light intensity, in a thermostatable Schlenk tube (DURAN; Hg relief valve). Slow evolution of CO is accompanied by precipitation of dark black lustrous needles, which occasionally have to be removed from the wall of the vessel. (Photolysis in conventional immersion well apparatus with a Hg lamp—*e.g.* Original Hanau TQ 150—failed to give crystalline products.) The crystals are washed several times with *n*-hexane and dried *in vacuo*. Yield 1.45—1.83 g (65—82%). Dec. $>$*ca.* 100 °C with partial formation of *(4)*. Moderately soluble in diethyl ether, readily soluble in dichloromethane and tetrahydrofuran (brown, air-sensitive solutions).

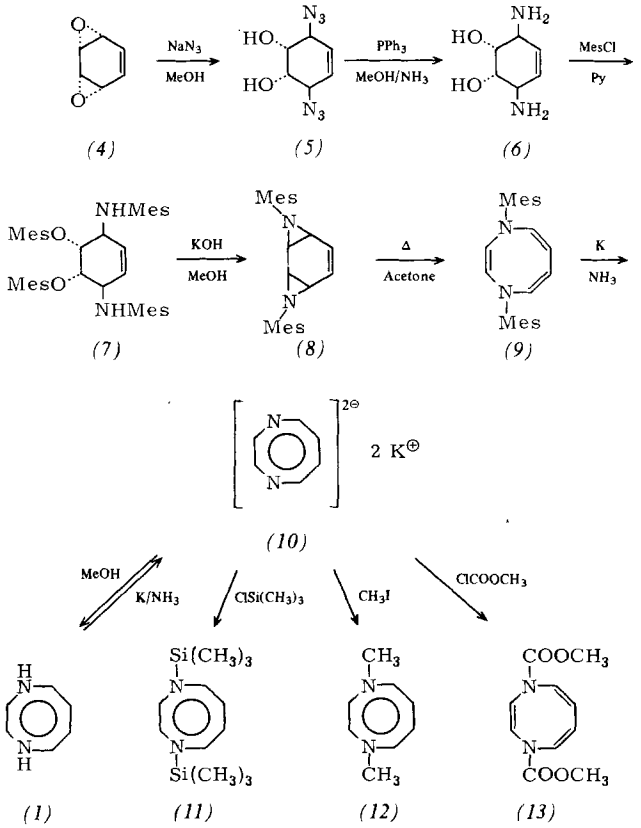
1,4-Dihydro-1,4-diazocine and *N,N'*-Disubstitution Products—A Rational Synthesis

By *Hans-Josef Altenbach, Hartmut Stegelmeier, Monika Wilhelm, Burkhard Voss, Johann Lex,* and *Emanuel Vogel*[*]

1,4-Dihydro-1,4-diazocine *(1)* and the 1,4-diheterocins *(2)* and *(3)*—eight-membered heterocycles isoelectronic with the cyclooctatetraene dianion—have recently attracted both theoretical[1] and practical interest as potential 10π-aromatic species. A straightforward entry to *(1)*—*(3)* and derivatives consists in the intramolecular retro-Diels-Alder reaction of *syn*-benzene diimines[2], *syn*-benzene dioxides[3], and *syn*-benzene bisepisulfides[4]. Indeed, it proved possible in this way to prepare the 1,4-dioxocin *(2)* (an olefinic compound[3a,b]) and some *N,N'*-derivatives of *(1)*, including the dimethylated compound *(12)* formulated as an aromatic molecule[2].



This communication describes a rational synthesis of the parent compound *(1)*, its dipotassium salt *(10)*, and some of

(1) *(2)* *(3)*

its *N,N'*-derivatives with the bismethanesulfonate *(8)* of *syn*-benzene diimine serving as intermediate[5].

On reaction with sodium azide in methanol in the presence of magnesium chloride, *syn*-benzene dioxide *(4)*[3b,c] undergoes the expected regioselective opening of the two oxirane rings to form the diazide *(5)* [m.p. 59—60 °C (ether/pentane), yield 79%][6]. Transformation of *(5)* into *(6)*, which was unsuccessful when attempted with the usual reducing agents, was effected by triphenylphosphane in ammoniacal methanol/pyridine[7]. Compound *(6)* which was only sparingly soluble in organic solvents was converted as the crude product into tetrakismethanesulfonate *(7)* by treatment with methanesulfonyl chloride in pyridine. After isolation of *(7)* by chromatography on silica gel (acetone) [m.p. 218—219 °C, dec. (methanol), yield 40% referred to *(5)*] it reacts with 5% methanolic potassium hydroxide *via* twofold aziridine ring closure to give *(8)* [m.p. 157 °C (dichloromethane/ether), yield 83%] which rearranges completely to the valence isomeric bismethanesulfonate *(9)* [m.p. 157 °C (dichloromethane), yield 94%] on heating in acetone (2 h). Reaction of *(9)* with potassium in liquid ammonia proceeds *via* reductive elimination of the mesyl groups to give a poorly soluble salt-like product, shown by its NMR spectra to be the dipotassium salt *(10)* of *(1)*[8]. Treatment of *(10)* with methanol gives a 74% yield [based on *(9)*] of the parent compound *(1)* [which regenerates *(10)* with potassium in liquid ammonia], while its reaction with electrophiles such as chlorotrimethylsilane, methyl iodide, and methyl chloroformate also smoothly affords the corresponding *N,N'*-disubstituted 1,4-dihydro-1,4-diazocines [*(11)*, m.p. 113 °C (pentane), yield 70%; *(12)*[2], colorless liquid, molecular distillation at 60 °C/1 torr, yield 75%; *(13)*[2], m.p. 80 °C (ethanol), yield 73%].

Compound *(1)* is very sensitive to oxygen in solution and is best purified by sublimation (60 °C/1 torr); colorless crystals, m.p. 196—198 °C (in evacuated capillary; heating in the presence of air leads to decomposition over a wide temperature range). Interestingly, *(1)* undergoes neither acid- nor alkali-catalyzed prototropic shift, although transformation of an enamine into an imine structure is normally accompanied by a gain in energy (10—14 kcal/mol); this finding, which is suggestive of a relationship between *(1)* and pyrrole and azonine[9], can be regarded as chemical evidence for a 10π aromatic compound.

The ^{1}H- and ^{13}C-NMR spectra of *(1)* and its derivatives (cf. Table 1) reveal the following points of value for elucidation of the problem of aromaticity: Compounds *(1)*, *(11)*, *(12)*, in which the lone pairs of the N atoms can delocalize into the ring, exhibit ^{13}C resonances at relatively high field strength for all ring carbon atoms, in keeping with such a charge transfer. In parallel herewith, comparatively large and nearly equal vicinal coupling constants J_{56} and J_{67} are observed for *(1)*, *(11)*, and *(12)*, indicating that not only the β-effect of the heteroatoms is operative[3a,b] but that there is also some equalization of the bond orders in the diene moiety. Moreover, the resonance signals of the ring protons are to be regarded as diamagnetically shifted, as already established by *Prinzbach et al.*[2] in the case of *(12)* [comparison with 1,4,7-trimethyl-1*H*-4,7-dihydro-1,4,7-triazonine and the [*b*]benzo derivative of *(12)*].

These results can readily be reconciled with each other by assuming cyclic 10π-electron delocalization in *(1)*, *(11)*, and

(9)	6.44	6.76	5.90	9.82	7.06	−0.75	0.47	107.3	121.1	111.2
(13)	6.12	6.34	5.96	8.96	4.75	−1.26	0.34	113.1	127.1	117.5

[a] We are indebted to Dr. *H. Schmickler* for the exact spectral analysis. [b] Assignment from the non-^{1}H-decoupled spectra. [c] No evidence has so far been obtained for the existence of *syn*-benzene diimine in equilibrium with *(1)*.

(12)—but not in the electron-acceptor substituted derivatives *(9)* and *(13)*. By analogy with the situation in the azonines[9], it appears justifiable to classify the 1,4-dihydro-1,4-diazocines as aromatic or olefinic species, depending upon the nature of the substituents on nitrogen.

Such a distinction is also suggested by the observation that the UV spectra of *(1)* [(acetonitrile) $\lambda_{max}=262$ nm ($\varepsilon=9000$)], *(11)*, and *(12)* resemble that of the cyclooctatetraene dianion, whereas those of *(9)* and *(13)* are more like that of 1,3,6-cyclooctatriene.

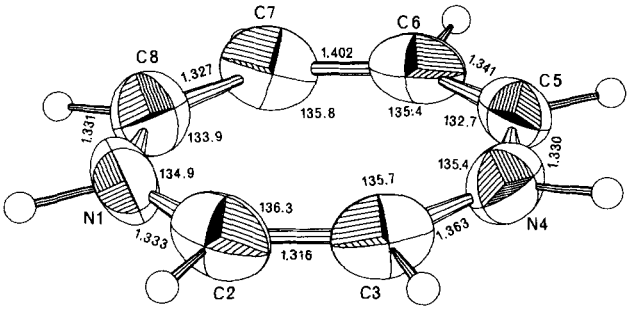

Fig. 1. Structure of 1,4-dihydro-1,4-diazocine *(1)* in the crystal. The bond lengths [Å] and angles [°] refer to one of the four independent molecules in the asymmetric unit. The corresponding values for the other three molecules do not deviate significantly.

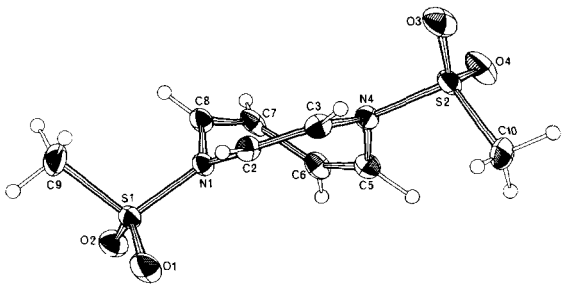

Fig. 2. Structure of *N,N'*-bis(methanesulfonyl)-1,4-dihydro-1,4-diazocine *(9)* in the crystal. Bond lengths and angles: N1 C2 1.426, C2 C3 1.323, C3 N4 1.418, N4 C5 1.429, C5 C6 1.327, C6 C7 1.436, C7 C8 1.316, C8 N1 1.453 Å; N1 C2 C3 128.4, C2 C3 N4 128.4, C3 N4 C5 123.2, N4 C5 C6 123.3, C5 C6 C7 124.8, C6 C7 C8 127.4, C7 C8 N1 123.2, C8 N1 C2 123.3°.

The conclusions drawn from chemical and spectroscopic properties concerning the π-electron configuration of the 1,4-dihydro-1,4-diazocines receive support from X-ray structure analyses performed by *J. Lex* on *(1)* (Fig. 1), *(9)* (Fig. 2), and *(11)*[10]. In agreement with their postulated aromatic character, compounds *(1)* and *(11)*[11] possess a planar ring skeleton—maximum deviation of atoms from the mean ring plane 0.02 Å—while compound *(9)*, being regarded as an olefin, has a twisted conformation [mean value of the ring bond angles is 135° for *(1)* and *(11)* and 125° for *(9)*]. On going from *(9)* to *(1)* and *(11)* there is a noticeable tendency for equalization of the bond lengths in the 1,4-dihydro-1,4-diazocine system[12]; however, this trend is not so pronounced as expected from the flattening of the ring.

Vogel, ibid. 84*, 985 (1972) and *11*, 937 (1972), respectively; c) *E. Vogel, H.-J. Altenbach, E. Schmidbauer, ibid. 85*, 862 (1973) and *12*, 838 (1973), respectively; d) concerning a naturally occurring *syn*-benzene dioxide/1,4-dioxocin system, see *D. B. Borders, J. E. Lancaster*, J. Org. Chem. *39*, 435 (1974).

[4] *E. Vogel, E. Schmidbauer, H.-J. Altenbach*, Angew. Chem. *86*, 818 (1974); Angew. Chem. Int. Ed. Engl. *13*, 736 (1974).—The first synthesis of a simple 1,4-dithiocin, the 6-acetoxy derivative, proceeded *via* an eight-membered ring precursor. The compound is not planar and does not possess aromatic character: *H. J. Eggelte, F. Bickelhaupt*, Tetrahedron *33*, 2151 (1977); *H. J. Eggelte, F. Bickelhaupt, B. O. Loopstra, ibid. 34*, 3631 (1978).

[5] An independent synthesis of *(1)* has been developed by *M. Breuninger, B. Gallenkamp, K.-H. Müller, H. Fritz, H. Prinzbach, J. J. Daly, P. Schönholzer*, Angew. Chem. *91*, 1030 (1979); Angew. Chem. Int. Ed. Engl. *18*, 970 (1979).

[6] *(5)* is also accessible from *(15a)* [3b, c] by reaction with sodium azide in 2-methoxyethanol at 100 °C and saponification of the resulting acetate with methanolic potassium hydroxide (yield 79%). This additional route to *(5)* considerably enhances the value of the synthesis of *(1)* and its *N,N'*-disubstitution products because both the stereoisomers *(14a)* and *(14b)* arising on NBS-bromination of 1,2-epoxy-4-cyclohexene can now be utilized:

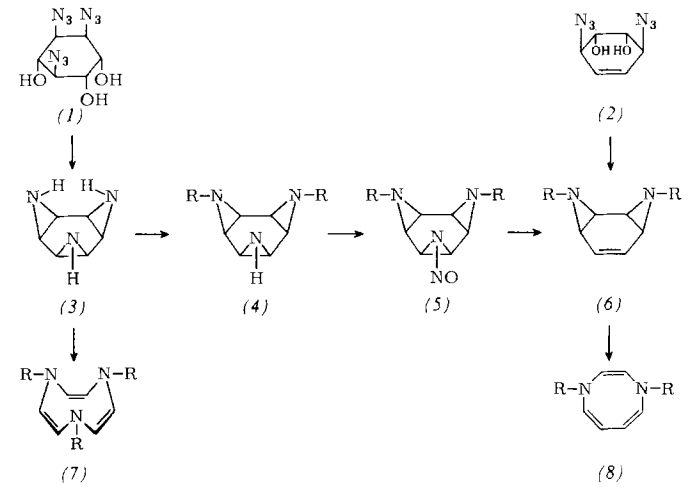
Transformation of *(5)* into *(1)* (*via syn*-benzene diimine) by reaction with phosphanes [*Y. Ittah, Y. Sasson, I. Shahak, S. Tsaroom, J. Blum*, J. Org. Chem. *43*, 4271 (1978)] is possible, but we found it to be an unpractical method.

[7] *L. Horner, A. Gross*, Justus Liebigs Ann. Chem. *591*, 117 (1955); *W. S. Mungall, G. L. Greene, G. A. Heavner, R. L. Letsinger*, J. Org. Chem. *40*, 1659 (1975).

[8] ^{1}H-NMR [$(CD_3)_2SO$]: $\delta = 6.16$ (s, H-2,3), 6.70 and 5.34 (AA'XX'-system with $J_{56} = 9.29$, $J_{67} = 10.70$, $J_{57} = 0.47$, $J_{58} = 0.29$ Hz, H-5,8 and H-6,7); ^{13}C-NMR [$(CD_3)_2SO$]: $\delta = 99.8$ (C-2,3), 112.0 (C-5,8) and 90.3 (C-6,7). The relatively slight differences between these data and those of the parent compound *(1)* suggest that most of the negative charge is located on the two nitrogen atoms in *(10)*.

[9] *A. G. Anastassiou*, Top. Nonbenzenoid Aromat. Chem. *1*, 1 (1973); *A. V. Kemp-Jones, S. Masamune, ibid. 1*, 121 (1973).

[10] Crystal data of *(1)*: triclinic, space group $P\bar{1}$, $a = 6.965(2)$, $b = 12.124(2)$, $c = 15.076(6)$ Å, $\alpha = 85.77(2)$, $\beta = 103.33(3)$, $\gamma = 106.65(2)°$, $Z = 8$, $\rho_{exp} = 1.19$, $\rho_{calc} = 1.21$ g/cm^3; Nonius CAD4, 2133 reflections with $I > 2\sigma(I)$, $R = 0.047$.—*(11)*: monoclinic, space group $P2_1/n$, $a = 6.711(2)$, $b = 23.565(5)$, $c = 9.888(1)$ Å, $\beta = 100.92(3)°$, $Z = 4$, $\rho_{exp} = 1.07$, $\rho_{calc} = 1.092$ g/cm^3; Nonius CAD4, 2086 reflections with $I > 2\sigma(I)$, $R = 0.053$.—*(9)*: monoclinic, space group $P2_1/c$, $a = 9.449(2)$, $b = 5.618(1)$, $c = 21.562(3)$ Å, $\beta = 98.25(1)°$, $Z = 4$, $\rho_{exp} = 1.55$, $\rho_{calc} = 1.55$ g/cm^3; Nonius CAD4, 1772 reflections with $I > 2\sigma(I)$, $R = 0.050$.



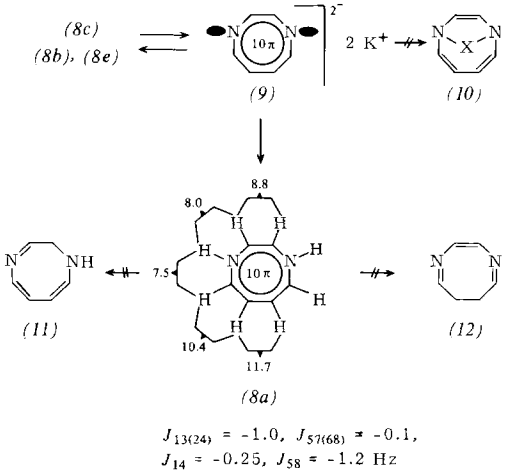
[11] It follows from the presence of a delocalized 10π electron system in *(11)* that the SiN bond has only weak $d_\pi p_\pi$ character, by analogy with the situation in trimethylsilylpyrrole [*J. Nagy, P. Hencsei, E. Gergö*, Z. Anorg. Allg. Chem. *367*, 293 (1969)].

[12] Cf. the largely equalized CC bond lengths in pyrrole [*A. Gossauer*: Die Chemie der Pyrrole. Springer-Verlag, Berlin 1974, p. 7].

1,4-Dihydro-1,4-diazocine; *N*-Substitution and Structure ("Aromaticity")[**]

By *Manfred Breuninger, Bernd Gallenkamp, Klaus-Helmut Müller, Hans Fritz, Horst Prinzbach, John J. Daly*, and *Peter Schönholzer*[*]

We have already reported on the synthesis of the *cis*-"benzene triimine" *(3)* from the *chiro*-triazidocyclohexanetriol *(1)*[1a] and the synthesis of *N,N'*-disubstituted *cis*-"benzene diimines" *(6)* from *(3)* as well as on the cycloreversion reactions to the 1*H*-4,7-dihydro-1,4,7-triazonines *(7)* and 1,4-dihydro-1,4-diazocines *(8)*[1b], respectively. It was established that the nature of the *N*-substituents (R) determines the geometry and electron density distribution ("aromaticity") in the ring skeleton of *(8)*: the dimethyl compound *(8f)* is planar/diatropic, the amides *(8b)* and *(8c)* are twisted/non-diatropic. As mentioned in a previous communication[1b] this relationship between substitution and molecular structure, which for larger azaannulenes is typical[1b,2] yet seldom so pronounced, was corroborated by synthesis of the parent compound *(8a)*, its dianion *(9)* and other derivatives[3].



Unsubstituted *(6a)* and *(8a)* were not accessible *via* the route primarily intended for the isolation of the labile diimines *(6)* (E_a for the most stable derivative *(6b)* 23.2 ± 0.5 kcal/mol) and outlined in the formula scheme. On attempting a selective mononitrosation of the triimine *(3)*—stabilized by H-bridges[4]—(to *(5a)*) we obtained practically only benzene (*e.g.* from *(5g)*).

(8a) was therefore prepared by alcoholysis of the bisurethane *(6c)* (methanol/sodium methoxide) or preferably *via* the dianion *(9)* (potassium *tert*-butylate, $-60\,°C$)[5]. The dipotassium salt *(9)*, which is obtained in almost quantitative yield, rapidly decomposes on exposure to air but can be stored in an inert atmosphere and is soluble *e.g.* in anhydrous [D_6]-dimethyl sulfoxide, giving a deep-brown solution. The ^{1}H-NMR spectrum resembles that of the derivatives *(8b)—(8f)* except that the two multiplets for 5(8)- and 6(7)-H ($\delta = 6.72$, 5.33) show no fine splitting; the coupling constants ($J_{56(78)} \simeq 14$, $J_{57(68)} \simeq 0.1$, $J_{58} \simeq 1.5$, $J_{67} \simeq 9$ Hz) are therefore only approximated values. Treatment of a solution of *(9)* in tetrahydrofuran at $-60\,°C$ with an excess of water, toluenesulfonic anhydride or dimethylcarbamoyl chloride leads quantitatively to *(8a)*, *(8b)* and *(8e)*, respectively. On the other hand, attempted *N,N'*-bridging (phosgene, thiophosgene, sulfinyl chloride, sulfonyl chloride) to *(10)* or oxidation (I_2) of *(9)* to 1,4-diazocine has so far failed.

(8a), which is isolable as colorless crystals, is very sensitive to air only in solution; when heated above $150\,°C$ it decomposes without melting and turns brown, but it can be sublimed at *ca.* $60\,°C/2$ torr. As in the case of *(8f)* the molecular ion [$m/e = 108$ (44%)] is rather stable and preferentially fragments to the pyridinium ion [$m/e = 80$ (100%)].

The electronic spectrum [λ_{max} (CH_3CN) = 282 (sh, $\varepsilon = 24560$), 263 (6550), 254 (sh, 5920)] is similar to that of the cyclooctatetraene dianion[6] as regards the position, intensity and structure of the longest wavelength absorption bands.

$J_{13(24)} = -1.0$, $J_{57(68)} = -0.1$, $J_{14} = -0.25$, $J_{58} = -1.2$ Hz

(8a) is stable towards base (*e.g.* aqueous NaOH, sodium methoxide/methanol) and acid (dil. formic acid, silica gel). After treatment with acid or base, there are besides *(8a)* no (TLC, ^{1}H-NMR; <3%) tautomeric imines *(11)* or "diimines"

(12) present; as shown by MS and ^{1}H-NMR analysis two hydrogen atoms (N–H) in *(8a)* are exchanged in deuterated solvents (D_2O, CH_3OD).

The additional data obtained from *(8a)*, *(8d)*, *(8e)* and *(9)* are consistent with those found for *(8b)*, *(8c)* and *(8f)*[1b]. In particular, the trend in the quotients $J_{67}/J_{56(78)}$ and $J_{57(68)}/J_{56(78)}$ and the $\delta(^1H)$ and $\delta(^{13}C)$ values—compared with those of the analogously substituted pyrroles or 1*H*-4,7-dihydrotriazonines *(7)*—emphasize the difference between planar/diatropic [*(8a)*, *(8e)*, *(8f)*] and twisted/non-diatropic [*(8b)*—*(8d)*][7]. How subtle the balance between these alternatives is, follows from the fact that the attenuation of the $N^1(N^4)CO$ resonance in *(8e)* by the $N(CH_3)_2$ groups—in concert with the steric hindrance of coplanarity—facilitates the inner-cyclic availability of the N-electron pairs to such an extent that even this "amide" is planar and diatropic. An estimation of the "aromaticity" is facilitated, *inter alia*, by the finding that no tautomers are detectable in equilibrium with *(8a)*; thus a stabilization energy of *ca.* 20 kcal/mol is plausible. The first results on the stability of charge-transfer complexes (1,3,5-trinitrobenzene/*(8f)* isolated) or diene reactivity ([4+2]-adducts of *(8c)* and *(8d)* with *N*-phenyltriazoline-dione isolated) as characteristic chemical criteria are available.

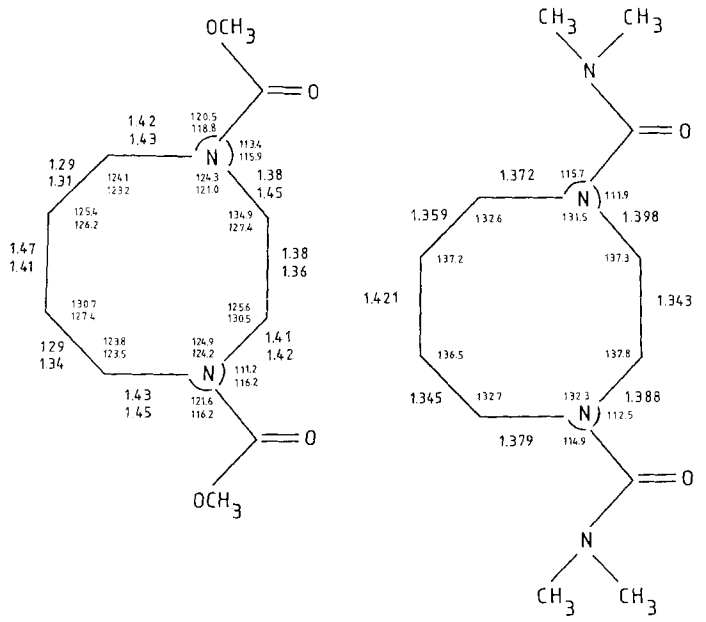

Fig. 1. X-ray structure data (bond lengths and angles) of (8c) and (8e).

X-ray structure analyses (Fig. 1)[8] confirm the spectroscopic investigations: In the crystal *(8c)* has a twisted conformation (approaching C_2) with distinct alternance of bond lengths (cf. azepines[9a]) and an average bond angle of 125.4° (128.0°) in the eight-membered ring. On the other hand, *(8a)* and *(8c)* are practically planar (mean deviation from the ideal plane 0.014(2) and 0.052 Å, resp.); the bond lengths are more equalized (cf. pyrrole[9b]), the mean bond angle is 135.0 and 134.9°, respectively. Thus, the theoretical prediction[10] that a 10π-electron delocalization is most unlikely in *(8a)* is not consistent with experimental findings. Compared to the analogous dithia skeleton[11], *(8a)* might have the advantage that planarization requires less energy.

SUBJECT INDEX

FP = Full paper (review article) SC = Short communication
G.E. = Reference to Volume *91* (1979) of the German Edition of Angewandte Chemie
References are given for Review Articles and Short Communications only.

ABIETOSPIRAN, the triterpene from the bark of the white fir (Abies alba) (SC) 698 [G.E. 751]
Absolute conformation, Circular dichroism and ~: application of qualitative MO theory to chiroptical phenomena (FP) 363 [G.E. 380]
Acetophenone enol, Acidity in aqueous solution (SC) 617 [G.E. 652]
Acetylene, Redox addition/elimination processes of cluster-bound ligands: oxidative elimination of CO from $Co_3(CO)_9C$—OH and reductive addition of ~ to $Co_3(CO)_9H$ (SC) 619 [G.E. 657]
Acetylene bond, Chemistry of functional groups. Chemistry of the carbon-carbon triple bond (Book Review) 639
Acetylenedicarboxylate, Di-tert-butyl ~ and its cyclotrimerization (SC) 149 [G.E. 157]
Acetylenes, Synthesis of allenes from electrophilic ~ via novel allenemanganese complexes (SC) 688 [G.E. 736]
Acidity of acetophenone enol in aqueous solution (SC) 617 [G.E. 652]
Activation analysis—its present state of development and its importance as an analytical tool (FP) 123 [G.E. 132]
C-Acylation under virtually neutral conditions (SC) 72 [G.E. 76]
Acyl halides, Flash vacuum thermolysis of doubly unsaturated ~ to give phenols (SC) 170 [G.E. 163]
Acyl ortho esters, Directed synthesis (SC) 309 [G.E. 337]
Adamantene in the gas phase (SC) 952 [G.E. 1019]
α-Adamantyl carbonyl compounds, General synthesis of potentially antiviral ~ (SC) 72 [G.E. 78]
2-Adamantyl cation, Stable ~ in the gas phase (SC) 950 [G.E. 1017]
Ion cyclotron resonance studies on tert-butyl, 2-norbornyl, and 1-adamantyl cation and ~ (SC) 951 [G.E. 1018]
Adenylates, Directed synthesis of the trimeric isoadenylate A2′p5′A2′p5′A (SC) 942 [G.E. 1007]
Adiabatic photoreactions of organic molecules (FP) 572 [G.E. 597]
β-Alanine, Cyclooligocondensation of amino acids: macrocyclic amides of ~ (SC) 74 [G.E. 79]
Aldehydes, Catalytic conversion of ~ into higher α-siloxy-~ by hydrosilane and carbon monoxide (SC) 393 [G.E. 421]
Fragmentation of γ-hydroxyammonium compounds to unsaturated ~ by flash thermolysis (SC) 541 [G.E. 576]
Stereoselective synthesis of Z-α,β-unsaturated ~ (SC) 687 [G.E. 748]
α-Amino-~ from enamines and chloramine-T (SC) 933 [G.E. 997]
Alkali metal anions, Compounds (FP) 587 [G.E. 613]
Alkali metals, Steric course of the reduction of ketoacetal esters with ~ in liquid ammonia (SC) 637 [G.E. 673]
Alkaloids, Thermodynamically controlled stereoselective synthesis of geissoschizine (SC) 862 [G.E. 921]
Alkanes, Thermal pericyclic reaction between alkynes and ~ (SC) 71 [G.E. 75]
Alkenediazonium salts, A new chapter of classical organic chemistry (FP) 259 [G.E. 279]
Alkenes, Reversal of the selectivity principle in free-radical additions to ~ (SC) 154 [G.E. 167]
Alkoxylipids, Synthesis and biosynthesis (FP) 493 [G.E. 550]
Alkylammonium ions, Long-chain ~ as phase transfer reagents for the synthesis of mixed-ligand complexes of the platinum metals (SC) 151 [G.E. 160]
Alkylation, Catalytic ~ of benzene with CO and H_2: a homogeneously catalyzed Fischer-Tropsch synthesis (SC) 77 [G.E. 83]
Asymmetric synthesis of ant alarm pheromones—α-~ of acyclic ketones with almost complete asymmetric induction (SC) 397 [G.E. 425]
Regioselective ~ of 1,4,5-trihydroxy-9,10-anthraquinone with formaldehyde and glyoxylic acid (SC) 621 [G.E. 658]
2-Alkylcyclohexanones, Asymmetric synthesis of ~ on solid phases (SC) 221 [G.E. 255]
Alkyne metathesis, Cyclobutadiene-metal complexes as potential intermediates in ~: flash vacuum pyrolysis of substituted η^4-cyclobutadiene-η^5-cyclopentadienylcobalt complexes (SC) 409 [G.E. 439]
Alkynes, Thermal pericyclic reaction between ~ and alkanes (SC) 71 [G.E. 75]
Preparation of stable vinylketenes by metal complex-induced olefination and carbonylation of ~ (SC) 954 [G.E. 1021]
Allenes, Synthesis from electrophilic acetylenes via novel allenemanganese complexes (SC) 688 [G.E. 736]
Allyl bromides, Ring-opening of 5-(bromomethyl)-2-isoxazolines to β,γ-enoximes—a new principle for the γ-substitution of ~ by α-functionalized alkyl groups (SC) 78 [G.E. 91]
Allylurea, A metalated ~ with sterically protected carbonyl group as novel d^3-reagent (SC) 399 [G.E. 427]
Amide chlorides, Synthesis and intramolecular 1,3 Cl,H disproportionation of ethyl 2,2-dichloro-2-(dimethylamino)acetate (SC) 615 [G.E. 650]
Amides, Extreme liquid chromatographic separation effects in the case of diastereomeric ~ containing polar substituents (SC) 62 [G.E. 64]
Preparative scale directed resolution of enantiomeric amines via liquid chromatography of diastereomeric 4-hydroxybutyr-~ (SC) 65 [G.E. 66]
Amines, Preparative scale directed resolution of enantiomeric ~ via liquid chromatography of diastereomeric 4-hydroxybutyramides (SC) 65 [G.E. 66]
^{23}Na-NMR study of the competition of biogenic ~ with sodium ion for binding to lasalocid (X-537 A) (SC) 153 [G.E. 166]
Tellurium catalyzed reactions of ~ with carbon monoxide (SC) 547 [G.E. 582]
Reactions of carbonyl selenide with ~ and amino alcohols to produce ureas and carbamates (SC) 692 [G.E. 760]
Amino acid esters, Economic synthesis of activated N-tert-butyloxycarbonyl-~ (Z) (SC) 307 [G.E. 326]
Amino acids, Cyclooligocondensation of ~: macrocyclic amides of β-alanine (SC) 74 [G.E. 79]
New synthesis from halogenated carboxylic esters (SC) 474 [G.E. 504]
Thermal generation of pteridines and flavines from amino acid mixtures (SC) 478 [G.E. 510]
Enantioselective synthesis of α-methyl-α-aminocarboxylic acids by alkylation of the lactim ether of cyclo-(L-Ala-L-Ala) (SC) 863 [G.E. 922]
N-Nitroso sugar ~ (SC) 878 [G.E. 940]
Amino alcohols, Reactions of carbonyl selenide with amines and ~ to produce ureas and carbamates (SC) 692 [G.E. 760]
α-Aminoaldehydes from enamines and chloramine-T (SC) 933 [G.E. 997]
Aminobicyclo[4.1.0]heptanes, The morpholino group as stereoindicator in ~ (SC) 798 [G.E. 860]
Aminoethynylation, β-Stannylated ynamines as ~ reagents (SC) 405 [G.E. 432]
Aminophosphanes, Synthesis, resolution, and characterization of an aminophosphane rotamer pair (SC) 679 [G.E. 741]
Aminyl oxides, Enantioselective oxidation by a chiral acylaminyl oxide (SC) 864 [G.E. 923]
Ammonium ions, Long-chain alkyl-~ as phase transfer reagents for the synthesis of mixed-ligand complexes of the platinum metals (SC) 151 [G.E. 160]
Analytical methods, Activation analysis—its present state of development and its importance as an analytical tool (FP) 123 [G.E. 132]
Liquid column chromatography with chemical derivatizations after separation (FP) 180 [G.E. 192]
Applications of SEPIL to the solid state defect chemistry of fluorites and ultra-trace inorganic analysis (FP) 738 [G.E. 765]
Anchimeric assistance, Anchimerically accelerated bond homolysis (FP) 173 [G.E. 185]
Anions, Compounds of alkali metal ~ (FP) 587 [G.E. 613]
Dianion and tetraanion of octalene (SC) 229 [G.E. 251]
Annulenes, Aza[18]-~ (SC) 312 [G.E. 332]
Annulenoannulenes (FP) 202 [G.E. 215]
Ant alarm pheromones, Asymmetric synthesis of ~—α-Alkylation of acyclic ketones with almost complete asymmetric induction (SC) 397 [G.E. 425]
syn-Anthracene 4a,10:9,9a-dioxide (SC) 413 [G.E. 443]
Anthraquinone, Mono- and bis(η^3-allylnickel) derivatives of 1,8-dihydroxy-~ and of some 1,3,5-triketones (SC) 681 [G.E. 742]
Antibiotic, Sequences of the membrane-modifying peptide ~ trichotoxin A-40 (SC) 476 [G.E. 508]
Antigenic determinant, Chemical synthesis of human blood group B ~: type 2 tetrasaccharide (SC) 464 [G.E. 501]
Antimonate, Tris(trichlorophosphoranediylamino)carbenium hexachloro-~, $[C(NPCl_3)_3]^+SbCl_6^-$ (SC) 693 [G.E. 735]
D-Arabinofuranosyl-7-deazapurine, Preferred β-glycoside formation by phase transfer catalysis in the synthesis of ~ nucleosides (SC) 536 [G.E. 570]
Areno-analogy, From the principle of ~ to heterocyclopolyaromatic compounds (FP) 1 [G.E. 1]
Arsanediylphosphorane, Stabilization (SC) 233 [G.E. 244]
Arsanes, Mesityl(diphenylmethylene)arsane (SC) 395 [G.E. 423]
Novel polycyclic phosphanes and ~: $P_{11}(SiMe_3)_3$ and $As_7(SiMe_3)_3$ (SC) 679 [G.E. 755]
Arsenic compounds, Phosphadiarsiranes (SC) 877 [G.E. 939]
Arylnitrene chemistry, Developments in ~ syntheses and mechanisms (FP) 900 [G.E. 965]

Asymmetric epoxidation of simple olefins with an optically active molybdenum(VI) peroxo complex (SC) 485 [G.E. 511]
Asymmetric induction, Unusually high ~ in the photochemical formation of oxetane (SC) 868 [G.E. 926]
Asymmetric synthesis, ~ of 2-alkylcyclohexanones on solid phases (SC) 221 [G.E. 255]
~ of ant alarm pheromones—α-Alkylation of acyclic ketones with almost complete asymmetric induction (SC) 397 [G.E. 425]
Atmosphere, Rates of reactive removal of anthropogenic emissions (FP) 663 [G.E. 707]
Aza[18]annulenes (SC) 312 [G.E. 332]
Aza-arenes, New synthetic reactions based on the onium salts of ~ (FP) 707 [G.E. 798]
Azacyclopentadienylium salts, Stable ~ and diazacyclopentadienylium salts (SC) 156 [G.E. 170]
Azoalkanes, Polycyclic ~ via dipolar cycloaddition of 4-phenyl-1,2,4-triazoline-3,5-dione with strained bicyclic olefins (SC) 468 [G.E. 512]
Azoalkenes, [3+2]-Cycloadditions of ~ to enamines—"criss-cross" cycloadditions to ~ (SC) 695 [G.E. 756]
[4+2]-Cycloadditions of ~ to azodicarbonyl compounds. A novel facile route to the 1,2,3,4-tetrazine system (SC) 696 [G.e. 757]
Azodicarbonyl compounds, [4+2]-Cycloadditions of azoalenes to ~. A novel facile route to the 1,2,3,4-tetrazine system (SC) 696 [G.E. 757]
Azo esters, Competition in the three-component system triphenylphosphane/azo ester/3-hydroxy-carboxylic acid: OH- versus COOH-activation (SC) 622 [G.E. 654]
Azulene, Surprising transformation of ~ by cycloaddition with 1-(diethylamino)propyne (SC) 161 [G.E. 173]
Synthesis of 5,5'-biazulenyl (SC) 214 [G.E. 227]

BACTERIA, Permeability of the outer membrane of ~ (FP) 337 [G.E. 394]
Bee venom, Synthesis of the mast cell degranulating (MCD) peptide from ~ (SC) 147 [G.E. 156]
Benzaldehyde, Synthesis and X-ray structure analysis of a Mo complex with η^2-coordinated ~; transformation of a CO ligand by double α-addition (SC) 861 [G.E. 920]
Benzene, Catalytic alkylation of ~ with CO and H_2: a homogenously catalyzed Fischer-Tropsch synthesis (SC) 77 [G.E. 83]
Tricyclo[4.2.2.$1^{2,5}$]undeca-3,7,9-triene, the [4+4]cycloadduct of ~ and cyclopentadiene. Reaction sequence of its retro-cleavage (SC) 224 [G.E. 254]
Benzene derivatives, Regiospecific synthesis of disubstituted ~ (SC) 402 [G.E. 430]
Benzenehexacarboxylate, Di-tert-butyl acetylenedicarboxylate and its cyclotrimerization (SC) 149 [G.E. 157]
Benzenetricarboxylate, Di-tert-butyl acetylenedicarboxylate and its cyclotrimerization (SC) 149 [G.E. 157]
1,2,3-Benzoxadiazole, Existence of ~ in the gas phase (SC) 692 [G.E. 737]
Benzyl ether, Oxidative removal of the ~ protecting group by homogeneous electron transfer (SC) 801 [G.E. 850]
Benzyl(triethyl)ammonium permanganate, Detonation (SC) 786 [G.E. 852]
Stability (SC) 787 [G.E. 852]
5,5'-Biazulenyl, Synthesis (SC) 214 [G.E. 227]
Bicyclo[n.1.0]alkanes, Morpholino group as stereoindicator in aminobicyclo[4.1.0]heptanes (SC) 798 [G.E. 860]
Morpholino(succinimido)-~ from enaminosulfonium salts (SC) 800 [G.E. 861]
Bicyclo[1.1.0]butane, Bonding in ~ derivatives (SC) 694 [G.E. 750]
Bicyclo[4.2.1]non-1(8)-ene, Metal complexes of Bredt olefins: synthesis and structure of ~-bis(triphenylphosphane)platinum(0) 685 [G.E. 746]
Bicyclo[2.2.2]octa-5,7-diene-2-carboxylic acid, and 7-methylenebicyclo[2.2.2]octa-2,5-diene (SC) 470 [G.E. 500]
Bicyclo[2.2.0]pent-2-ene, Thermal "walk" rearrangement in the ~ system (SC) 674 [G.E. 738]
Bilane, Enzymatic formation of uroporphyrinogen I and III from a substituted ~ (SC) 778 [G.E. 838]
Biochemistry—The chemical reactions of the living cell (Book Review) 335
Biogenic amines, ^{23}Na-NMR study of the competition of ~ with sodium ion for binding to lasalocid (X-537 A) (SC) 153 [G.E. 166]
Bis(bicyclo[1.1.0]butane), An expeditious synthesis of heptalene from naphthalene via a ~ intermediate (SC) 546 [G.E. 581]
Bis(chlorophenylphosphoranediyl)methane (SC) 169 [G.E. 177]
Blood group B, Chemical synthesis of human ~ antigenic determinant: type 2 tetrasaccharide (SC) 464 [G.E. 501]
Blood plasma, ω-Formyl- and 4-oxocarboxylic acids in ~ (SC) 305 [G.E. 328]
Boc-Amino acid esters, Economic synthesis of activated ~ (SC) 307 [G.E. 326]
Bond delocalization, 1H-1,2,3λ^2-diazaphospholes—~ in λ^2-phospholes (SC) 413 [G.E. 442]
Bond energy, Existence and ~ of the cesium auride molecule (SC) 629 [G.E. 664]
Bonding, Structure and ~ in cyclic sulfur-nitrogen compounds (FP) 91 [G.E. 112]
~ properties of cyclopropane and their chemical consequences (FP) 809 [G.E. 867]
Bond length, Discovery of an exceptionally long unbridged carbon-carbon bond (SC) 406 [G.E. 434]
Bond switch with participation of π-bonded S^{IV} in thiathiophthene-analogous systems (SC) 166 [G.E. 176]
Boron compounds, Chemistry of the $H_3B(CH_3)_2P$ group: unusual properties of some simple reference compounds (SC) 781 [G.E. 847]
Synthesis and crystal structure of a salt containing the anion $[H_3B(CH_3)_2P{-}CH{-}P(CH_3)_2BH_3]^-$; precursors and related compounds (SC) 782 [G.E. 848]
Borylamines, Bis(dichloroboryl)silylamines and tris(dichloroboryl)amine (SC) 326 [G.E. 357]
Breathing crown ethers, Crown ethers with fluctuating ring size ("~") (SC) 311 [G.E. 331]
Bredt olefins, Metal complexes of ~: synthesis and structure of bicyclo[4.2.1]non-1(8)-enebis(triphenylphosphane)platinum(0) (SC) 685 [G.E. 746]
μ_3-(η^3Cη^2O) bridge—a novel mode of coordination in the structure in the structural chemistry of carbonylmetal compounds (SC) 960 [G.E. 1026]
Bridging mode, New ~ of carbon disulfide in a dinuclear cobalt(I) complex (SC) 673 [G.E. 739]
(Bromoacetylmethylene)triphenylphosphorane—a novel cyclopentannelating agent (SC) 940 [G.E. 1005]
Bromolithiocarbenoids, Direct ^{13}C-NMR spectroscopic observation of cyclopropylidene ~ (SC) 784 [G.E. 844]
3-Bromo-3-methyl-2-trimethylsiloxy-1-butene—A new cycloaddition reagent (SC) 163 [G.E. 178]
Bromotrimethylsilane, Ring-opening of lactones and cyclic carbonates with ~ or iodotrimethylsilane (SC) 689 [G.E. 749]
Bullvalene, Crown ethers with fluctuating ring size ("breathing crown ethers") (SC) 311 [G.E. 331]
Butadiene, Ligand concentration-control in the system nickel(0)/triphenylphosphane/~ (SC) 400 [G.E. 428]
N-tert-Butyloxycarbonyl amino acid esters, Economic synthesis of activated ~ (SC) 307 [G.E. 326]
CADMIUM compounds, Bis(trimethylsilyl)-zinc and -cadmium (SC) 60 [G.E. 62]
Cancerostatic activity, Titanocene dichloride—the first metallocene with ~ (SC) 477 [G.E. 509]
Capto-dative substituent effects in syntheses with radicals and radicophiles (FP) 917 [G.E. 982]
Carbamates, Reactions of carbonyl selenide with amines and amino alcohols to produce ureas and ~ (SC) 692 [G.E. 760]
Carbamoyl chlorides, α,β-Unsaturated isocyanates by thermolysis of N-(1-alkenyl)-N-alkyl-~ (SC) 319 [G.E. 334]
Carbamoyllithium, Carbonylation of lithium dialkylamides to give ~-s (SC) 83 [G.E. 73]
Carbene-carbene rearrangements of cis- and trans-2-(1,3-butadienyl)cyclopropylidene (SC) 396 [G.E. 424]
Carbene complexes, Spontaneous rearrangement of a carbene- to a carbyne complex: C,Cr migration of a $Sn(C_6H_5)_3$ group (SC) 871 [G.E. 929]
Carbene reactions, (Diazomethyl)cyclopropenes—synthesis, isomerization, and ~ (SC) 531 [G.E. 566]
Carbenes, Iminocarbene/ketenimine rearrangement (SC) 320 [G.E. 337]
Carbenoids, Direct ^{13}C-NMR spectroscopic observation of cyclopropylidene bromolithio-~ (SC) 784 [G.E. 844]
Carbido carbon, A metalloporphyrin containing carbyne-like ~: 5,10,15,20-tetraphenylporphyrinato[bis(μ-carbidotricarbonylrhenium)]tin(IV) (SC) 83 [G.E. 85]
Carbocations, Ion cyclotron resonance studies on tert-butyl, 2-norbornyl, and 1- and 2-adamantyl cations (SC) 951 [G.E. 1018]
Carbodiphosphoranes, Problem of the structure of ~, R_3PCPR_3: new aspects (SC) 408 [G.E. 437]
Carbohydrates, Chemical synthesis of human blood group B antigenic determinant: type 2 tetrasaccharide (SC) 464 [G.E. 501]
Facile, highly selective synthesis of α- and β-disaccharides from 1-O-metalated D-ribofuranoses (SC) 466 [G.E. 497]
Carbonates, Ring-opening of lactones and cyclic ~ with bromo- or iodotrimethylsilane (SC) 689 [G.E. 749]
Carbon-carbon bond, Discovery of an exceptionally long unbridged ~ (SC) 406 [G.E. 434]
Carbon disulfide, New bridging mode of ~ in a dinuclear cobalt(I) complex (SC) 673 [G.E. 739]
Carbon-halogen bond, Model system for the electrochemical reduction of the ~ (SC) 938 [G.E. 1002]
Carbon monoxide, Catalytic reactions with hydrosilane and ~ (FP) 837 [G.E. 896]
Catalytic alkylation of benzene with ~ and H_2: a homogeneously catalyzed Fischer-Tropsch synthesis (SC) 77 [G.E. 83]
Catalytic conversion of aldehydes into higher α-siloxy aldehydes by hydrosilane and ~ (SC) 393 [G.E. 421]
Tellurium catalyzed reactions of amines with ~ (SC) 547 [G.E. 582]
Carbonylation, ~ of lithium dialkylamides to give carbamoyllithiums (SC) 83 [G.E. 73]
~ of lithium monoalkylamides to give N-lithio(alkyl)formamides (SC) 85 [G.E. 72]
Carbonyl compounds, Facile regeneration from 1,3-dithiane 1-oxides via 1-ethoxy-1,3-dithianium salts (SC) 165 [G.E. 179]
α,β-Unsaturated ~ with sterically protected carbonyl groups—enforced a^3 versus a^1 reactivity (SC) 957 [G.E. 1024]
Carbonyl group, Metalated allylurea with sterically protected ~ as novel d^3-reagent (SC) 399 [G.E. 427]
Carbonylmetal compounds, The μ_3-(η^3Cη^2O) bridge—a novel mode of coordination in the structural chemistry of ~ (SC) 960 [G.E. 1026]

Carbonyl selenide, New synthesis (SC) 691 [G.E. 760]
Reactions with amines and amino alcohols to produce ureas and carbamates (SC) 692 [G.E. 760]
Carboxylic acids, Preparative scale directed resolution of enantiomeric ~ and lactones via liquid chromatography and neighboring-group assisted hydrolysis of diastereomeric amides (SC) 63 [G.E. 65]
Carbyne complexes, Complex-stabilized hydroxy(p-tolyl)acetylene by reaction of trans-chlorotetracarbonyl(tolylcarbyne)-tungsten with acetylacetone (SC) 327 [G.E. 345]
Spontaneous rearrangement of a carbene- to a carbyne complex: C,Cr migration of a $Sn(C_6H_5)_3$ group (SC) 871 [G.E. 929]
Catalysis, Triphase ~ (FP) 421 [G.E. 464]
Catalytic reactions with hydrosilane and carbon monoxide (FP) 837 [G.E. 896]
Koordinationschemische Katalyse organischer Reaktionen (Book Review) 171
Organometallic mechanisms and catalysis (Book Review) 804
Catalysts, Complexes with chiral alkylcyclopentadienyl ligands for homogeneous catalytic asymmetric hydrogenation of 2-phenyl-1-butene (SC) 779 [G.E. 842]
Cations, Chemistry of isolated ~ (FP) 451 [G.E. 484]
Cesium auride, Existence and bond energy of the ~ molecule (SC) 629 [G.E. 664]
Chemical technology, Kirk-Othmer: Encyclopedia of ~ (Book Review) 237, 491, 704
Chirality, $(-)_{579}$-Bis[(S)-(+)-O,O'(1,1'-binaphthyl-2,2'-diyl)dithiophosphato]nickel-(II)—The first dithiophosphato complex to have axial ~ (SC) 415 [G.E. 448]
Chiral reagents from tartaric acid—1-benzyloxy-3,4-epoxy-2-butanol, a versatile intermediate for the synthesis of enantiomers (SC) 958 [G.E. 1025]
Chiroptical phenomena, Circular dichroism and absolute conformation: application of qualitative MO theory to ~ (FP) 363 [G.E. 380]
Chloramine-T, α-Aminoaldehydes from enamines and ~ (SC) 933 [G.E. 997]
Chlorine-hydrogen exchange, Synthesis and intramolecular 1,3 Cl,H disproportionation of ethyl 2,2-dichloro-2-(dimethylamino)acetate (SC) 615 [G.E. 650]
Intramolecular Cl,H disproportionation of an oxamide chloride. An entry to imidazole derivatives (SC) 616 [G.E. 651]
Chromatography, Liquid column ~ with chemical derivatizations after separation (FP) 180 [G.E. 192]
Extreme liquid chromatographic separation effects in the case of diastereomeric amides containing polar substituents (SC) 62 [G.E. 64]
Preparative scale directed resolution of enantiomeric carboxylic acids and lactones via liquid ~ and neighboring-group assisted hydrolysis of diastereomeric amides (SC) 63 [G.E. 65]
Preparative scale directed resolution of enantiomeric amines via liquid ~ of diastereomeric 4-hydroxybutyramides (SC) 65 [G.E. 66]
Chromium catalyst, Homogeneously catalyzed dimerization of isoprene to 2,7-dimethyl-2,trans-4,6-octatriene at chromium (SC) 324 [G.E. 344]
Chromium complexes, η^5-Cyclopentadienylchromium complexes with thiocarbonyl and nitrosyl ligands (SC) 631 [G.E. 662]
Chromium compounds, [(triphos)Co(μ-P_3)$Cr_2(CO)_{10}$]: A trinuclear heterometal complex containing cyclo-triphosphorus as μ_3-ligand (SC) 81 [G.E. 93]
Stabilization of an arsanediylphosphorane (SC) 233 [G.E. 244]
Spontaneous rearrangement of a carbene- to a carbyne complex: C,Cr migration of a $Sn(C_6H_5)_3$ group (SC) 871 [G.E. 929]
Tetracarbanilanilidodichromium(II): A clue to the understanding of the CrCr quadruple bond (SC) 874 [G.E. 937]
Cinnamic acid, Asymmetric hydrogenation of (Z)-α-(acetylamino)-~ by a Rh/norphos catalyst (SC) 620 [G.E. 655]
Circular dichroism and absolute conformation: application of qualitative MO theory to chiroptical phenomena (FP) 363 [G.E. 380]
Clusters, Synthesis and structure of the nido-cluster $(CH_3)_5C_5Sn^+$ (SC) 59 [G.E. 81]
Reversible opening of a trinuclear heterometal cluster (SC) 76 [G.E. 82]
$FeCoMoWS(AsMe_2)Cp_2(CO)_7$: The first cluster to contain four different metal atoms (SC) 531 [G.E. 566]
Coal, Liquid fuels from ~ (Book Review) 87
Cobalt complexes, Stepwise addition of a Lewis acid and a Lewis base to a metal-metal bond (SC) 158 [G.E. 172]
Cyclobutadiene-metal complexes as potential intermediates in alkyne metathesis: flash vacuum pyrolysis of substituted η^4-cyclobutadiene-η^5-cyclopentadienylcobalt complexes (SC) 409 [G.E. 439]
$(C_5H_5)_3Co_3(CS)(S)$; the first complex to have a μ_3-thiocarbonyl bridge (SC) 627 [G.E. 663]
New bridging mode of carbon disulfide in a dinuclear cobalt(I) complex (SC) 673 [G.E. 739]
Experiments on the HOMO-LUMO nature of metal-metal bonds (SC) 690 [G.E. 751]
New pathways to trinuclear complexes—structure of the tetradecker sandwich complex bis(η-thiadiborolencobalt-μ,η-thiadiborolene)iron (SC) 949 [G.E. 1014]
Cobalt compounds, Coordination number 3 in Co^{II}: $Na_{10}[Co_4O_9]$, an oligooxocobaltate(II) (SC) 61 [G.E. 71]
Six-coordinate hydrogen: structure of $[(Ph_3P)_2N]^+[HCo_6(CO)_{15}]^-$ by single-crystal neutron diffraction analysis (SC) 80 [G.E. 86]
[(triphos)Co(μ-P_3)$Cr_2(CO)_{10}$]: A trinuclear heterometal complex containing cyclo-triphosphorus as μ_3-ligand (SC) 81 [G.E. 93]
Stable coordination compounds of "thiazyl fluoride": structure of $[Co(NSF)_6]^{2+}$ in the crystal (SC) 231 [G.E. 253]
$FeCoMoWS(AsMe_2)Cp_2(CO)_7$: The first cluster to contain four different metal atoms (SC) 531 [G.E. 566]
Co^{II} with coordination number 3: $Na_4[CoO_3]$—the first oxocobaltate(II) with an island structure (SC) 542 [G.E. 577]
Cobalt(I)phthalocyanine vitamin B_{12s}-model: selectivity in reactions with electrophiles (SC) 794 [G.E. 841]
Collision spectroscopy (Book Review) 171
Colloid chemistry, Principles of colloid and surface chemistry (Book Review) 86
Column chromatography, Liquid ~ with chemical derivatizations after separation (FP) 180 [G.E. 192]
Complexation, Multidentate acyclic neutral ligands and their ~ (FP) 753 [G.E. 813]
Complexation equilibria, Atlas of metal-ligand equilibria in aqueous solutions (Book Review) 236
Computers in chemistry, New applications of ~ (FP) 111 [G.E. 99]
Conformation, Circular dichroism and absolute ~: application of qualitative MO theory to chiroptical phenomena (FP) 363 [G.E. 380]
Boat ~ of cyclo-[L-Pro_2-D-Pro] 538 [G.E. 573]
Conformational analysis, ~ by photoelectron spectroscopy (FP) 826 [G.E. 885]
Stereochemie und Konformationsanalyse (Book Review) 419
Coordination, The μ_3-(η^3Cη^2O) bridge—a novel mode of ~ in the structural chemistry of carbonylmetal compounds (SC) 960 [G.E. 1026]
Cope rearrangement, Synthesis of cis-2-vinylcyclopropyl ketones: a new synthesis of 4-cycloheptenones (SC) 791 [G.E. 857]
The first 1,3,4,6-tetraphospha-1,5-hexadiene, a molecule with fluxional bonds (identical tetraphospha ~) and configurational isomerism (SC) 873 [G.E. 936]
Copper complexes, [{Cu_3WS_3Cl}/$(PPh_3)_3O$], directed synthesis of a compound containing different metal atoms in a cubane-like skeleton (SC) 628 [G.E. 656]
Coronates, Complexes of γ-cyclodextrin with crown ethers, cryptands, ~, and cryptates (SC) 623 [G.E. 676]
Criss-cross cycloaddition, Formal ~ of sulfur trioxide to cyanogen (SC) 223 [G.E. 243]
[3+2]-Cycloadditions of azoalkenes to enamines—~ to azoalkenes (SC) 695 [G.E. 756]
Crown ethers, "Multi-loop ~" with multiple selectivity (SC) 219 [G.E. 230]
Spherical wrapping of a linear polyether around a cation—1,20-bis(8-quinolyloxy)-3,6,9,12,15,18-hexaoxaeicosane·RbI (SC) 226 [G.E. 234]
~ with fluctuating ring size ("breathing ~") (SC) 311 [G.E. 331]
Complex of γ-cyclodextrin with ~, cryptands, coronates, and cryptates (SC) 623 [G.E. 676]
Structure of the dicyanophosphide ion in a crown-ether sodium salt (SC) 934 [G.E. 998]
Crown ether surfactants, Complexes of nitrogen-containing ~ with stable silver atoms (SC) 630 [G.E. 669]
Cryptands, Spherical wrapping of a linear polyether around a cation—1,20-bis(8-quinolyloxy)-3,6,9,12,15,18-hexaoxaeicosane·RbI (SC) 226 [G.E. 234]
Complexes of γ-cyclodextrin with crown ethers, ~, coronates, and cryptates (SC) 623 [G.E. 676]
Cryptates, Complexes of γ-cyclodextrin with crown ethers, cryptands, coronates, and ~ (SC) 623 [G.E. 676]
Cubane, [{Cu_3WS_3Cl}/$(PPh_3)_3O$], directed synthesis of a compound containing different metal atoms in a ~-like skelton (SC) 628 [G.E. 656]
Cyanides, Krypton and xenon inclusion compounds of complex metal ~ (SC) 486 [G.E. 517]
Cyanogen, Formal criss-cross cycloaddition of sulfur trioxide to ~ (SC) 223 [G.E. 243]
Cyanohalophosphates(III)—Hypervalent anions containing λ^5-phosphorus(III) (SC) 411 [G.E. 441]
Cyclization, Mechanistic aspects of the palladium catalyzed ~ of 5-methylenecyclooctene (SC) 867 [G.E. 925]
Cycloaddition, Synchronous mechanism of the 1,1-~ of nitrile ylides to C=C double bonds (SC) 167 [G.E. 168]
Formal criss-cross ~ of sulfur trioxide to cyanogen (SC) 223 [G.E. 243]
~-s of α-diazo carbonyl compounds to enamines (SC) 330 [G.E. 346]
[2+4]-~-s with di-tert-butyl acetylenedicarboxylate (SC) 483 [G.E. 517]
[2+2]-~ of a vinyl cation (SC) 614 [G.E. 649]
[3+2]-~-s of azoalkenes to enamines—"criss-cross" ~-s to azoalkenes (SC) 695 [G.E. 756]
[4+2]-~-s of azoalkenes to azodicarbonyl compounds. A novel facile route to the 1,2,3,4-tetrazine system (SC) 696 [G.E. 757]
Cycloaddition reagent, 3-Bromo-3-methyl-2-trimethylsiloxy-1-butene—a new ~ (SC) 163 [G.E. 178]
Cyclobutadiene, Electrophilic behavior of tri-tert-butyl-~ (SC) 308 [G.E. 327]
~-metal complexes as potential intermediates in alkyne metathesis: flash vacuum pyrolysis of substituted η^4-~-η^5-cyclopentadienylcobalt complexes (SC) 409 [G.E. 439]

Cyclobutane, Multiple cyclopropylmethyl-cyclobutyl rearrangements in a pentaspirohexadecanol (SC) 868 [G.E. 927]
Influence of 1,2-functionalization with —C≡N, —CH=NR, or —CH=O on the stability of the ~ system (SC) 872 [G.E. 930]
γ-Cyclodextrin, Complexes with crown ethers, cryptands, coronates, and cryptates (SC) 623 [G.E. 676]
Cyclodiaza-λ^6-thianes—syntheses and structures (SC) 235 [G.E. 231]
4-Cycloheptenones, Synthesis of cis-2-vinylcyclopropyl ketones; a new synthesis of ~ (SC) 791 [G.E. 857]
2,4-Cyclohexadienones, Spectroscopic identification of polymethyl-substituted ~ (SC) 556 [G.E. 584]
Question of π^*,n- and π^*,π selective photochemistry of 2,4-cyclohexadienones (SC) 557 [G.E. 585]
Cyclohexanones, Asymmetric synthesis of 2-alkyl-~ on solid phases (SC) 221 [G.E. 255]
Cyclooctatetraene, Chemistry of ~ and its derivatives (Book Review) 236
Cyclooctene, Mechanistic aspects of the palladium-catalyzed cyclization of 5-methylene-~ (SC) 867 [G.E. 925]
Cyclooligocondensation of amino acids: macrocyclic amides of β-alanine (SC) 74 [G.E. 79]
Cyclopentacyclononene, Facile ring enlargement of azulene to give the ~ system by dipolar cycloaddition (SC) 162 [G.E. 175]
Cyclopentadiene, Tricyclo[4.2.2.1^{2,5}]undeca-3,7,9-triene: the [4+4]cycloadduct of benzene and ~. Reaction sequence of its retrocleavage (SC) 224 [G.E. 254]
Intermolecular exchange of substituents via ions (ion pairs) in cyclopentadienyl- and cyclononatetraenyl-trimethylstannane (SC) 218 [G.E. 228]
Cyclopentannelating agent, (Bromoacetylmethylene)triphenylphosphorane—a novel ~ (SC) 940 [G.E. 1005]
Cyclopeptides, Boat conformation of cyclo-[L-Pro$_2$-D-Pro] 538 [G.E. 573]
Cyclophane, [2.2.2.2](1,2,3,4)-~ (SC) 329 [G.E. 336]
Cyclopropane, Bonding properties of ~ and their chemical consequences (FP) 809 [G.E. 867]
Cyclopropanediazonium ions, Stereochemistry of nucleophilic substitution at ~ (SC) 228 [G.E. 240]
Cyclopropenes, Vinyl ketenimines by nucleophilic ring cleavage of ~ with tert-butyl isocyanide (SC) 67 [G.E. 62]
Cyclopropenylium ions, Structure and formation of triorganylphosphonio-~ (SC) 472 [G.E. 505]
Cyclopropenylium salt, Synthesis of a donor-substituted tris(cyclopropenylio)-~ (SC) 473 [G.E. 506]
Cyclopropylalkadienes, Facile synthesis (SC) 231 [G.E. 239]
Cyclopropylidene, Carbene-carbene rearrangements of cis- and trans-2-(1,3-butadienyl)-~ (SC) 396 [G.E. 424]
Cyclopropylmethyl-cyclobutyl rearrangements, Multiple ~ in a pentaspirohexadecanol (SC) 868 [G.E. 927]
Cycloreversions, 1,3-Dipolar ~ (FP) 721 [G.E. 781]
Tricyclo[4.2.2.1^{2,5}]undeca-3,7,9-triene, the [4+4]-cycloadduct of benzene and cyclopentadiene. Reaction sequence of its retrocleavage (SC) 224 [G.E. 254]
cyclo-Triphosphorus ligand, [(triphos)Co(μ-P$_3$)Cr$_2$(CO)$_{10}$]: A trinuclear heterometal complex containing cyclo-triphosphorus as μ_3-ligand (SC) 81 [G.E. 93]
Cyclotristannatellurane, 2,2,4,4,6,6-Hexamethyl-~, a Sn$_3$Te$_3$-ring with C$_2$-symmetry (SC) 677 [G.E. 740]

DEFECT chemistry, Applications of SEPIL to the solid state ~ of fluorites and ultra-trace inorganic analysis (FP) 738 [G.E. 765]
Degradation kinetics, Effects of long-chain branches on the ~ of polymers (SC) 321 [G.E. 341]
Dehydrating agents, Competition in the three-component system triphenylphosphane/azo ester/3-hydroxy-carboxylic acid: OH- versus COOH-activation (SC) 622 [G.E. 654]
Deprotection, Oxidative removal of the benzyl ether protecting group by homogeneous electron transfer (SC) 801 [G.E. 850]
Selective ~ of primary and secondary hydroxy functions by homogeneous electron transfer (SC) 802 [G.E. 851]
Desorption, Kinetics of sorption, ~, and diffusion in zeolites (FP) 266 [G.E. 309]
Deuteration, Selective ~ of enamines with deuterated formic acids (SC) 320 [G.E. 341]
Dianion and tetraanion of octalene (SC) 229 [G.E. 251]
Diastereomers, Extreme liquid chromatographic separation effects in the case of diastereomeric amides containing polar substituents (SC) 62 [G.E. 64]
Preparative scale directed resolution of enantiomeric carboxylic acids and lactones via liquid chromatography and neighboring-group assisted hydrolysis of diastereomeric amides (SC) 63 [G.E. 65]
Preparative scale directed resolution of enantiomeric amines via liquid chromatography of diastereomeric 4-hydroxybutyramides (SC) 65 [G.E. 66]
1H-1,2,3σ^2-Diazaphospholes—bond delocalization in σ^2-phospholes (SC) 413 [G.E. 442]
Diazoacetyl chloride, Synthesis and reactions—detection of diazoketene (SC) 947 [G.E. 1012]
α-Diazo carbonyl compounds, Cycloadditions to enamines (SC) 330 [G.E. 346]
1,4-Diazocine, 1,4-Dihydro-~ and N,N′-disubstitution products—a rational synthesis (SC) 962 [G.E. 1028]
1,4-Dihydro-~; N-substitution and structure ("aromaticity") (SC) 964 [G.E. 1030]
Diazo compounds, Cycloadditions of α-diazo carbonyl compounds to enamines (SC) 330 [G.E. 346]
Chemistry of functional groups. The chemistry of diazonium and diazo groups (Book Review) 804
Diazoketene, Synthesis and reactions of diazoacetyl chloride—detection of ~ (SC) 947 [G.E. 1012]
(Diazomethyl)cyclopropenes—synthesis, isomerization, and carbene reactions (SC) 531 [G.E. 566]
Diazonium ions, Chemistry of functional groups. The chemistry of diazonium and diazo groups (Book Review) 804
Diazonium salts, Alkene-~: a new chapter of classical organic chemistry (FP) 259 [G.E. 279]
Thermolysis of arenediazonium pentacarbonylcyano-6A-metalates in various media: a route to novel α-functionalized isocyanides (SC) 75 [G.E. 80]
α,α-Dichloroamines, Synthesis and intramolecular 1,3 Cl,H disproportionation of ethyl 2,2-dichloro-2-(dimethylamino)acetate (SC) 615 [G.E. 650]
Dicyanophosphide ion, Structure of the ~ in a crown-ether sodium salt (SC) 934 [G.E. 998]
Dicyclobuta[b,e]pyridine, 1,2,4,5-Tetrahydro-~ (SC) 411 [G.E. 440]
Dienynyl trifluoromethanesulfonate, Formation of phenyl cations in the solvolysis of a ~ (SC) 870 [G.E. 928]
1-(Diethylamino)propyne, Surprising transformation of azulene by cycloaddition with ~ (SC) 161 [G.E. 173]
Diffusion, Kinetics of sorption, desorption, and ~ in zeolites (FP) 266 [G.E. 309]
1,4-Dihydro-1,4-diazocine, ~ and N,N′-disubstitution products—a rational synthesis (SC) 962 [G.E. 1028]
~; N-substitution and structure ("aromaticity") (SC) 964 [G.E. 1030]
1,2-Dihydro-4,6-dimethyl-2-thioxo-3-pyridinecarbonitrile, Ester and lactone formation with the reagent ~ (SC) 308 [G.E. 330]
1,8a-Dihydroindolizines as components of novel photochromic systems (SC) 945 [G.E. 1010]
1,4-Dihydronicotinic acid, Synthesis of ~ derivatives by photochemical cycloaddition (SC) 540 [G.E. 575]
Dihydropyranones, Novel highly stereoselective rearrangements of chiral ~ (SC) 936 [G.E. 1001]
Dihydropyrene, 8,16-Methano[2.2]metacyclophane-1,9-diene. A valence isomer of 10b,10c-methano-cis-10b,10c-~ (SC) 946 [G.E. 1011]
Dihydropyridines, Metalation of pyrans and ~: when is an 8π-system cost effective? (SC) 489 [G.E. 515]
1,8-Dihydroxyanthraquinone, Mono- and bis(η^3-allylnickel) derivatives of ~ and of some 1,3,5-triketones (SC) 681 [G.E. 742]
α,α′-Dihydroxy ketones, Lactide contraction—a method for the synthesis of ~ from α-hydroxy carboxylic acids (SC) 310 [G.E. 329]
1,2-Dioxetanes, A 3-imino-1,2-dioxetane via singlet oxygenation of a ketenimine (SC) 788 [G.E. 855]
Diradical hybridization, Polar [4+2]- and [4+4]-photocycloadditions: effects of hybridization in diradicals (SC) 881 [G.E. 943]
Diradicals, First spectroscopic detection of ~ in photocycloreversions (SC) 215 [G.E. 232]
Disaccharides, Facile, high selective synthesis of α- and β-~ from 1-O-metalated D-ribofuranoses (SC) 466 [G.E. 497]
Disulfide bridges, Fully active insulin by selective formation of the ~ between a synthetic A-chain and natural B-chain (SC) 536 [G.E. 571]
η-Disulfido complexes, Generation of the triangulo-group Mo^V-η-S$_2$ in the "condensation" of [Mo^{VI}O$_2$S$_2$]$^{2-}$ to [Mo$^V_2$O$_2$S$_2$(S$_2$)$_2$]$^{2-}$ (SC) 530 [G.E. 565]
1,3-Di-tert-butylcyclooctatetraene (SC) 544 [G.E. 578]
1,3-Dithiane 1-oxides, Facile regeneration of carbonyl compounds from ~ via 1-ethoxy-1,3-dithianium salts (SC) 165 [G.E. 179]
1,3-Dithianium salts, Facile regeneration of carbonyl compounds from 1,3-dithiane 1-oxides via 1-ethoxy-~ (SC) 165 [G.E. 179]
Dithiiranes and thiosulfines as reactive intermediates (SC) 941 [G.E. 1006]
Dithiocarboxylato-metal complexes, CS$_2$- and CS$_3$-bridged transition metal complexes—directed synthesis of metallo-~ (SC) 626 [G.E. 661]
Dithionite formation, The double salt Na$_2$S$_2$O$_5$·NaOOCH as intermediate in sodium ~ by reduction of SO$_2$ with sodium formate (SC) 313 [G.E. 333]
Dithiophosphato complex, (−)$_{579}$-Bis[(S)-(+)-O,O′(1,1′-binaphthyl-2,2′-diyl)dithiophosphato]nickel(II)—The first ~ to have axial chirality (SC) 415 [G.E. 448]
Donor-acceptor approach to molecular interactions (Book Review) 560
Double bond, Synchronous mechanism of the 1,1-cycloaddition of nitrile ylides to C=C ~-s (SC) 167 [G.E. 168]
Mesityl(diphenylmethylene)arsane (SC) 395 [G.E. 423]

ELECTROCHEMISTRY, Selective electrochemical removal of protecting groups in nucleotide synthesis (SC) 148 [G.E. 155]
Model system for the electrochemical reduction of the carbon-halogen bond (SC) 938 [G.E. 1002]

Transient techniques in ~ (Book Review) 334
Electrolytes, Solid ~. General principles, characterization, materials, applications (Book Review) 884
Electronic effects, Separation of steric and ~ in the reaction enthalpies of association of phosphorus ligands (SC) 401 [G.E. 429]
Electronic structure of μ-methylenetransition metal complexes (SC) 554 [G.E. 591]
Electron transfer, Oxidative removal of the benzyl ether protecting group by homogeneous ~ (SC) 801 [G.E. 850]
Selective deprotection of primary and secondary hydroxy functions by homogeneous ~ (SC) 802 [G.E. 802]
(S)-Elenolide, Use of biogenetic key compounds for the biomimetic synthesis of natural products. ~ from secologanin (SC) 539 [G.E. 574]
Emissions, Rates of reactive removal of anthropogenic ~ in the atmosphere (FP) 663 [G.E. 707]
Enamines, Selective deuteration of ~ with deuterated formic acids (SC) 320 [G.E. 341]
Cycloadditions of α-diazo carbonyl compounds to ~ (SC) 330 [G.E. 346]
[3+2]-Cycloadditions of azoalkenes to ~—"criss-cross" cycloadditions to azoalkenes (SC) 695 [G.E. 756]
α-Aminoaldehydes from ~ and chloramine-T (SC) 933 [G.E. 997]
Enaminosulfonium salts, Morpholino(succinimido)bicyclo[n.1.0]alkanes from ~ (SC) 800 [G.E. 861]
Enantiomers, Preparative scale directed resolution of enantiomeric carboxylic acids and lactones via liquid chromatography and neighboring-group assisted hydrolysis of diastereomeric amides (SC) 63 [G.E. 65]
Preparative scale directed resolution of enantiomeric amines via liquid chromatography of diastereomeric 4-hydroxybutyramides (SC) 65 [G.E. 66]
Enantioselective oxidation by a chiral acylaminyl oxide (SC) 864 [G.E. 923]
Enantioselective synthesis of α-methyl-α-aminocarboxylic acids by alkylation of the lactim ether of cyclo-(L-Ala-L-Ala) (SC) 863 [G.E. 922]
Encyclopedia of chemical technology: Kirk-Othmer (Book Review) 237, 491, 704
Ene reactions, Intermolecular ~ in a high-pressure/high-temperature flow apparatus (SC) 70 [G.E. 74]
Thermal pericyclic reaction between alkynes and alkanes (SC) 71 [G.E. 75]
Energy storage, Criteria for the efficiency, stability, and capacity of abiotic photochemical solar ~ systems (FP) 652 [G.E. 696]
Enols, Acidity of acetophenone enol in aqueous solution (SC) 617 [G.E. 652]
β,γ-Enoximes, Ring-opening of 5-(bromomethyl)-2-isoxazolines to ~—a new principle for the γ-substitution of allyl bromides by α-functionalized alkyl groups (SC) 78 [G.E. 91]
Epoxidation, Asymmetric ~ of simple olefins with an optically active molybdenum(VI) peroxo complex (SC) 485 [G.E. 511]
ESR spectroscopy, Detection of heavy metal ions by ~ (SC) 943 [G.E. 1007]
Ester formation and lactone formation with the reagent 1,2-dihydro-4,6-dimethyl-2-thioxo-3-pyridinecarbonitrile (SC) 308 [G.E. 330]
Ethylene, Nickel(0)-induced synthesis of ethyllithium from lithium, hydrogen, and ~ (SC) 488 [G.E. 521]
Ethylenehydridometal complex, An example of the equilibrium ~ ⇌ ethylmetal complex (SC) 157 [G.E. 171]
Ethylmetal complex, An example of the equilibrium ethylene-hydridometal ⇌ ~ complex (SC) 157 [G.E. 171]
Explosion, Detonation of benzyl(triethyl)ammonium permanganate (SC) 786 [G.E. 852]
Stability of benzyl(triethyl)ammonium permanganate (SC) 787 [G.E. 852]

FERROCENE, Phase transfer catalyzed synthesis of ~ derivatives (SC) 792 [G.E. 858]
α-Ferrocenylalkylamines, One-pot syntheses ~ (SC) 956 [G.E. 1023]
Fischer-Tropsch synthesis, Catalytic alkylation of benzene with CO and H_2: A homogeneously catalyzed Fischer-Tropsch synthesis (SC) 77 [G.E. 83]
Flash thermolysis, Fragmentation of γ-hydroxyammonium compounds to unsaturated aldehydes by ~ (SC) 541 [G.E. 576]
Flash vacuum thermolysis of doubly unsaturated acyl halides to give phenols (SC) 170 [G.E. 163]
Flavines, Thermal generation of pteridines and ~ from amino acid mixtures (SC) 478 [G.E. 510]
Fluctuating ring size, Crown ethers with ~ ("breathing crown ethers") (SC) 311 [G.E. 331]
Fluorenone, Structure of the primary adduct of a phosphorus ylide and ~ (SC) 876 [G.E. 945]
Fluorides, Structural chemistry of ~ and oxide fluorides of nonmetals (FP) 186 [G.E. 199]
Fluorination, Diarylsulfur(VI) oxide difluoride by direct ~ of sulfoxides (SC) 880 [G.E. 941]
Fluorine compounds, Stable coordination compounds of "thiazyl fluoride": structure of $[Co(NSF)_6]^{2+}$ in the crystal (SC) 231 [G.E. 253]
Structure and reactions of methylenesulfur tetrafluoride (SC) 944 [G.E. 1008]
Fluorites, Applications of SEPIL to the solid state defect chemistry of ~ and ultra-trace inorganic analysis (FP) 738 [G.E. 765]
Fluorotellurates, $Xe(OTeF_5)_6$, a deep-colored noble gas compound, and $O{=}Xe(OTeF_5)_4$—the existence of $Kr(OTeF_5)_2$ (SC) 66 [G.E. 62]
Fluxional bonds, First 1,3,4,6-tetraphospha-1,5-hexadiene, a molecule with ~ (identical tetraphospha Cope rearrangement) and configurational isomerism (SC) 873 [G.E. 936]
Formaldehyde, Regioselective alkylation of 1,4,5-trihydroxy-9,10-anthraquinone with ~ and glyoxylic acid (SC) 621 [G.E. 658]
Formamides, Carbonylation of lithium monoalkylamides to give N-lithio(alkyl)formamides (SC) 85 [G.E. 72]
Formic acids, Selective deuteration of enamines with deuterated ~ (SC) 320 [G.E. 341]
Formic anhydride, (SC) 614 [G.E. 649]
ω-Formyl-carboxylic acids, ω-Formyl- and 4-oxocarboxylic acids in blood plasma (SC) 305 [G.E. 328]
Fragmentation, A fragmentational approach to macrolides: (5-E, 8-Z)-6-methyl-5,8-undecadien-11-olide (SC) 634 [G.E. 670]
Free-radical additions, Reversal of the selectivity principle in ~ to alkenes (SC) 154 [G.E. 167]
Fuels, Liquid ~ from coal (Book Review) 87
Functional groups, Direct removal of ~ by catalytic hydrogenolysis (SC) 939 [G.E. 1004]
Furan, Metalated 2-alkynyl- and 1,2-alkadienyl 2-tetrahydropyranyl ethers: versatile building blocks for ~ syntheses (SC) 875 [G.E. 938]

GAMMA rays, The ~ of the radionuclides (Book Review) 703
Gas chromatography with glass capillary columns (Book Review) 237
Geissoschizine, Thermodynamically controlled stereoselective synthesis (SC) 862 [G.E. 921]
Gels, Spatial structure formation in protein ~ (FP) 599 [G.E. 634]
Germanium phthalocyanines, trans-Bis(1-alkynyl)-4B-metal ~ (SC) 322 [G.E. 343]
Glycals, Novel ~ as synthons for saccharide syntheses (SC) 222 [G.E. 242]
β-Glycosides, Preferred β-glycoside formation by phase transfer catalysis in the synthesis of D-arabinofuranosyl-7-deazapurine nucleosides (SC) 536 [G.E. 570]
Gold compounds, Existence and bond energy of the cesium auride molecule (SC) 629 [G.E. 664]
Graphs, Nodal nomenclature—general principles (FP) 887 [G.E. 951]

HALF-SANDWICH complexes, η^5-Cyclopentadienyl(trinitrosyl)vanadium hexafluorophosphate, $[CpV(NO)_3]PF_6$ (SC) 220 [G.E. 241]
Halogenated carboxylic esters, New synthesis of amino acids from ~ (SC) 474 [G.E. 504]
Halogen compounds, Model system for the electrochemical reduction of the carbon-halogen bond (SC) 938 [G.E. 1002]
Heavy metal ions, Detection by ESR spectroscopy (SC) 943 [G.E. 1007]
Heptalene, An expeditious synthesis of ~ from naphthalene via a bis(bicyclo-[1.1.0]butane) intermediate (SC) 546 [G.E. 581]
Heptalenebis(tricarbonyliron) (SC) 545 [G.E. 579]
2,4,6-Heptanetrithionediate, Bis(η^3-allylnickel) 2,4,6-heptanetrithionediate (SC) 683 [G.E. 744]
Heteroaromatic compounds, From the principle of areno-analogy to heterocyclopolyaromatic compounds (FP) 1 [G.E. 1]
Heterocyclopolyaromatic compounds, From the principle of areno-analogy to ~ (FP) 1 [G.E. 1]
Heterometal cluster, Reversible opening of a trinuclear ~ (SC) 76 [G.E. 82]
Hexachloroantimonate, Tris(trichlorophosphoranediylamino)carbenium ~, $[C(NPCl_3)_3]^+SbCl_6^-$ (SC) 693 [G.E. 735]
High-pressure liquid chromatography, Liquid column chromatography with chemical derivatizations after separation (FP) 180 [G.E. 192]
Hindered rotation at the triple bond (SC) 159 [G.E. 163]
Homoallyl alcohols, Diastereoselective synthesis of β-methyl ~ (SC) 306 [G.E. 329]
Homolysis, Anchimerically accelerated bond ~ (FP) 173 [G.E. 185]
σ-Homotropilidenes, endo-Hydroxytrioxatris-~ (SC) 611 [G.E. 646]
Hormones, Molecular structure of Phe^2-TRH, an analogue of thyrotropin-releasing hormone (SC) 225 [G.E. 243]
Hydrido complex, New cationic binuclear tri-~ containing one four- and one five-coordinate platinum atom (SC) 155 [G.E. 169]
An example of the equilibrium ethylenehydridometal ⇌ ethylmetal complex (SC) 157 [G.E. 171]
Hydrocarbons, Oxidation of ~ with benzyl(triethyl)ammonium permanganate (SC) 68 [G.E. 77]
Regio- and stereospecific hydroxylation of alicyclic ~ with substituted perbenzoic acids (SC) 407 [G.E. 438]
Hydrogen, Six-coordinate ~: structure of $[(Ph_3P)_2N]^+[HCo_6(CO)_{15}]^-$ by single-crystal neutron diffraction analysis (SC) 80 [G.E. 86]
Colloidal redox catalysts for evolution of oxygen and for light-induced evolution of ~ from water (SC) 624 [G.E. 659]
Cyclic cleavage of water into ~ and O_2 by visible light with coupled redox catalysts (SC) 701 [G.E. 759]
Hydrogenation, Asymmetric ~ of (Z)-α-(acetylamino)cinnamic acid by a Rh/norphos catalyst (SC) 620 [G.E. 655]
Complexes with chiral alkylcyclopentadienyl ligands for homogeneous catalytic asymmetric ~ of 2-phenyl-1-butene (SC) 779 [G.E. 842]

Hydrogen-chlorine exchange, Synthesis and intramolecular 1,3 Cl,H disproportionation of ethyl 2,2-dichloro-2-(dimethylamino)acetate (SC) 615 [G.E. 650]
Intramolecular Cl,H disproportionation of an oxamide chloride. An entry to imidazole derivatives (SC) 616 [G.E. 651]
Hydrogen formation, Catalysis of ~ from an organic radical in aqueous solution by colloidal silver (SC) 418 [G.E. 449]
Hydrogenolysis, Direct removal of functional groups by catalytic ~ (SC) 939 [G.E. 1004]
Hydrosilane, Catalytic conversion of aldehydes into higher α-siloxy aldehydes by ~ and carbon monoxide (SC) 393 [G.E. 421]
Catalytic reactions with ~ and carbon monoxide (FP) 837 [G.E. 896]
α-Hydroxy carboxylic acids, Lactide contraction—a method for the synthesis of α,α'-dihydroxy ketones from ~ (SC) 310 [G.E. 329]
Hydroxylamido ligand, Synthesis of a hydroxylamido(2−)-O,N-(nitrosyl)molybdenum complex (SC) 549 [G.E. 583]
γ-Hydroxyammonium compounds, Fragmentation to unsaturated aldehydes by flash thermolysis (SC) 541 [G.E. 576]
Hydroxy carboxylic acids, Competition in the three-component system triphenylphosphane/azo ester/β-~: OH- versus COOH-activation (SC) 622 [G.E. 654]
Hydroxy functions, Selective deprotection of primary and secondary ~ by homogeneous electron transfer (SC) 802 [G.E. 851]
Hydroxylamine, Reactions of molybdate(VI) with ~ and N-methyl-~ (SC) 548 [G.E. 582]
Hydroxylation, Regio- and stereospecific ~ of alicyclic hydrocarbons with substituted perbenzoic acids (SC) 407 [G.E. 438]
endo-Hydroxytrioxatris-σ-homotropilidenes (SC) 611 [G.E. 646]

IMIDAZOLE derivatives, Intramolecular Cl,H disproportionation of an oxamide chloride. An entry to ~ (SC) 616 [G.E. 651]
Imides, Homogeneous catalytic vinylation of cyclic ~ and lactams for the synthesis of N-vinyl monomers (SC) 533 [G.E. 568]
Iminocarbene/ketenimine rearrangement (SC) 320 [G.E. 337]
3-Imino-1,2-dioxetane via singlet oxygenation of a ketenimine (SC) 788 [G.E. 855]
Imino-sulfur compounds, Cyclodiaza-λ⁶-thianes—syntheses and structures (SC) 235 [G.E. 231]
Inclusion compounds, Krypton and xenon ~ of complex metal cyanides (SC) 486 [G.E. 517]
Indolizines, 1,8a-Dihydro-~ as components of novel photochromic systems (SC) 945 [G.E. 1010]
Infrared spectroscopy, Infrared and Raman spectroscopy (Book Review) 237
Infrared and Raman spectra of inorganic and coordination compounds (Book Review) 639
Insect pheromones, Isopropyl carboxylates—a new class of ~ (SC) 796 [G.E. 843]
Insulin, Fully active ~ by selective formation of the disulfide bridges between a synthetic A-chain and natural B-chain (SC) 536 [G.E. 571]
Interdiffusion, Thin films—~ and reactions (Book Review) 560
Interfacial phenomena, Surfactants and ~ (Book Review) 419
Intermolecular interactions: from diatomics to biopolymers (Book Review) 418
Inversion, Internal rotation and ~. An introduction to large amplitude motions in molecules (Book Review) 419
Iodine azide, Chemistry of ~ (FP) 507 [G.E. 527]
Iodine compounds, Synthesis and properties of tetrabutylammonium octaiododirhenate(III), $[(n\text{-}C_4H_9)_4N]_2[Re_2I_8]$ (SC) 150 [G.E. 159]
Iodotrimethylsilane, Hexamethyldisilane/iodine: convenient in situ generation of ~ (SC) 612 [G.E. 648]
Ring-opening of lactones and cyclic carbonates with bromomethylsilane or ~ (SC) 689 [G.E. 749]
Ion cyclotron resonance studies on tert-butyl, 2-norbornyl, and 1- and 2-adamantyl cations (SC) 951 [G.E. 1018]
Ion pairs, Intermolecular exchange of substituents via ions (~) in cyclopentadienyl- and cyclononatetraenyl-trimethylstannane (SC) 218 [G.E. 228]
Iron complexes, Simple route to Li- or Zn-metalated η^5-cyclopentadienyliron-olefin complexes (SC) 549 [G.E. 590]
Tetrakis(ethylene)irondilithium and bis(η^4-1,5-cyclooctadiene)irondilithium (SC) 550 [G.E. 590]
Experiments on the HOMO-LUMO nature of metal-metal bonds (SC) 690 [G.E. 751]
New pathways to trinuclear complexes—structure of the tetradecker sandwich complex bis(η-thiadiborolenecobalt-μ,η-thiadiborolene)iron (SC) 949 [G.E. 1014]
Iron compounds, $FeCoMoWS(AsMe_2)Cp_2(CO)_7$: The first cluster to contain four different metal atoms (SC) 531 [G.E. 566]
Synthesis of metallacycles with reactive metal-carbon σ bonds (SC) 535 [G.E. 569]
Heptalenebis(tricarbonyliron) (SC) 545 [G.E. 579]
Island structure, Co^{II} with coordination number 3: $Na_4[CoO_3]$—the first oxocobaltate(II) with an ~ (SC) 542 [G.E. 577]
Isoadenylate, Directed synthesis of the trimeric ~ A2'p5'A2'p5'A (SC) 942 [G.E. 1007]
Isopropyl carboxylates, A new class of insect pheromones (SC) 796 [G.E. 843]
Isobacteriochlorin, Synthetic approach to the ~ macrocycle (SC) 675 [G.E. 752]
Isocyanates, α,β-Unsaturated ~ by thermolysis of N-(1-alkenyl)-N-alkylcarbamoyl chlorides (SC) 319 [G.E. 334]
Isocyanides, Vinyl ketenimines by nucleophilic ring cleavage of cyclopropenes with tert-butyl isocyanide (SC) 67 [G.E. 62]
Thermolysis of arenediazonium pentacarbonylcyano-6A-metalates in various media: a route to novel α-functionalized ~ (SC) 75 [G.E. 80]
Isoprene dimerization, Homogeneously catalyzed ~ to 2,7-dimethyl-2,trans-4,6-octatriene at chromium (SC) 324 [G.E. 344]
2-Isoxazolines, Ring-opening of 5-(bromomethyl)-~ to β,γ-enoximes—a new principle for the γ-substitution of allyl bromides by α-functionalized alkyl groups (SC) 78 [G.E. 91]

KEKULÉ, August ~—The architect of chemistry. Commemorating the 150th anniversary of his birth (FP) 641 [G.E. 685]
Kekulene, Molecular structure and spectroscopic properties of ~ (SC) 699 [G.E. 733]
Ketenes, Preparation of stable vinyl-~ by metal complex-induced olefination and carbonylation of alkynes (SC) 954 [G.E. 1021]
Ketenimine, Vinyl-~-s by nucleophilic ring cleavage of cyclopropenes with tert-butyl isocyanide (SC) 67 [G.E. 62]
Iminocarbene/~ rearrangement (SC) 320 [G.E. 337]
3-Imino-1,2-dioxetane via singlet oxygenation of a ~ (SC) 788 [G.E. 855]
Ketoacetal esters, Steric course of the reduction of ~ with alkali metals in liquid ammonia (SC) 637 [G.E. 673]
Ketones, Lactide contraction—a method for the synthesis of α,α'-dihydroxy ~ from α-hydroxy carboxylic acids (SC) 310 [G.E. 329]
Asymmetric synthesis of ant alarm pheromones—α-alkylation of acyclic ~ with almost complete asymmetric induction (SC) 397 [G.E. 425]
Key building blocks of natural product biosynthesis and their significance in chemistry and medicine (FP) 429 [G.E. 453]
Kinetics, Principles of chemical ~ (Book Review) 559
Chemical ~ and transport (Book Review) 885
Krypton and xenon inclusion compounds of complex metal cyanides (SC) 486 [G.E. 517]
Krypton compounds, $Xe(OTeF_5)_6$, a deep-colored noble gas compound, and $O{=}Xe(OTeF_5)_4$—the existence of $Kr(OTeF_5)_2$ (SC) 66 [G.E. 68]

LACTAMS, Homogeneous catalytic vinylation of cyclic imides and ~ for the synthesis of N-vinyl monomers (SC) 533 [G.E. 568]
Thermodynamically controlled stereoselective synthesis of geissoschizine (SC) 862 [G.E. 921]
Lactide contraction—a method for the synthesis of α,α'-dihydroxy ketones from α-hydroxy carboxylic acids (SC) 310 [G.E. 329]
Lactim ether, Enantioselective synthesis of α-methyl-α-aminocarboxylic acids by alkylation of the ~ of cyclo-(L-Ala-L-Ala) (SC) 863 [G.E. 922]
Lactone formation, Ester formation and ~ with the reagent 1,2-dihydro-4,6-dimethyl-2-thioxo-3-pyridinecarbonitrile (SC) 308 [G.E. 330]
Lactones, Preparative scale directed resolution of enantiomeric carboxylic acids and ~ via liquid chromatography and neighboring-group assisted hydrolysis of diastereomeric amides (SC) 63 [G.E. 65]
Ring-opening of ~ and cyclic carbonates with bromo- or iodotrimethylsilane (SC) 689 [G.E. 749]
Stereospecific synthesis of γ-~ by dyotropic Wagner-Meerwein rearrangement (SC) 793 [G.E. 840]
Lasalocid, ^{23}Na-NMR study of the competition of biogenic amines with sodium ion for binding to ~ (X-527 A) (SC) 153 [G.E. 166]
Laser chemistry, Megawatt infrared ~ (Book Review) 639
Lewis acid, Stepwise addition of a ~ and a Lewis base to a metal-metal bond (SC) 158 [G.E. 172]
Lewis base, Stepwise addition of a Lewis acid and a ~ to a metal-metal bond (SC) 158 [G.E. 172]
Ligand concentration-control in the system nickel(0)/triphenylphosphane/butadiene (SC) 400 [G.E. 428]
Ligands, Multidentate acyclic neutral ~ and their complexation (FP) 753 [G.E. 813]
Linear free-energy relationships, Empirical parameters of solvent polarity as ~ (FP) 98 [G.E. 119]
Lipids, Synthesis and biosynthesis of alkoxy-~ (FP) 493 [G.E. 550]
Liquid chromatography, Liquid column chromatography with chemical derivatizations after separation (FP) 180 [G.E. 192]
Liquids, Model of simple ~ (FP) 350 [G.E. 408]
α-Lithioacetic acid esters, Reaction with succinic anhydrides (SC) 632 [G.E. 656]
Lithiocarbenoids, Direct ^{13}C-NMR spectroscopic observation of cyclopropylidene bromo-~ (SC) 784 [G.E. 844]
Lithium, Nickel(0)-induced synthesis of ethyl-~ from ~, hydrogen, and ethylene (SC) 488 [G.E. 521]
Lithium compounds, Tetrakis(ethylene)irondilithium and Bis(η^4-1,5-cyclooctadiene)irondilithium (SC) 550 [G.E. 590]
^{13}C-NMR spectra of tribromomethyllithium and 1,1-dibromoethyllithium (SC) 785 [G.E. 845]
Lithium dialkylamides, Carbonylation to give carbamoyllithiums (SC) 83 [G.E. 73]
Lithium monoalkylamides, Carbonylation to give N-lithio(alkyl)formamides (SC) 85 [G.E. 72]

Lithium-nickel polynuclear complex, New ~: $Ni(C_{12}H_{17}NiLi)_2(THF)_4$ (SC) 487 [G.E. 520]

MACROLIDES, Fragmentational approach to ~: (5-E, 8-Z)-6-methyl-5,8-undecadien-11-olide (SC) 634 [G.E. 670]
Fragmentational approach to ~: (5-E, 9-E)-6-methyl-5,9-undecadien-11-olide (SC) 636 [G.E. 672]
Maleic anhydride, Radical complexes of palladium and platinum with bisphosphane derivatives of ~ (SC) 677 [G.E. 754]
Manganese compounds, Manganese-containing heterocycles having a λ^4-thia-λ^5-phosphanorbornadiene skeleton (SC) 534 [G.E. 568]
Synthesis of metallacycles with reactive metal-carbon σ bonds (SC) 535 [G.E. 569]
Synthesis and crystal structure of a chiral complex containing a non-linear heterotrimetal chain: $PtMn_2(\mu_2\text{-}PPh_2)_2(CO)_9$ (SC) 797 [G.E. 859]
Mass spectrometry, Chemistry of isolated cations (FP) 451 [G.E. 484]
Mast cell degranulating peptide, Synthesis of ~ from bee venom (SC) 147 [G.E. 156]
MCD Peptide, Synthesis of ~ from bee venom (SC) 147 [G.E. 156]
Medical laboratory, Methodische Fortschritte im medizinischen Laboratorium (Book Review) 86
Membrane, Permeability of the outer ~ of bacteria (FP) 337 [G.E. 394]
Mesityl(diphenylmethylene)arsane (SC) 395 [G.E. 423]
Metal anions, Compounds of alkali ~ (FP) 587 [G.E. 613]
Metalation of pyrans and dihydropyridines: when is an 8π-system cost effective? (SC) 489 [G.E. 515]
Metal clusters, Reversible opening of a trinuclear hetero-~ (SC) 76 [G.E. 82]
Metallacycles, Synthesis of ~ with reactive metal-carbon σ bonds (SC) 535 [G.E. 569]
Metalloporphyrin containing carbyne-like carbido carbon: 5,10,15,20-Tetraphenylporphyrinato [bis(μ-carbidotricarbonylrhenium)]tin(IV) (SC) 83 [G.E. 85]
Metal-metal bond, Stepwise addition of a Lewis acid and a Lewis base to a ~ (SC) 158 [G.E. 172]
Novel titanium halides containing ~-s: Ti_7Cl_{16} and Ti_7Br_{16} (SC) 325 [G.E. 343]
An easily prepared, air-stable compound with a triple (MoMo) ~ (SC) 462 [G.E. 496]
Experiments on the HOMO-LUMO nature of ~-s (SC) 690 [G.E. 751]
Metathiophosphoric acid, Synthesis of a platinum complex with a derivative of monomeric ~ as η^2-ligand (SC) 953 [G.E. 1020]
8,16-Methano[2.2]metacyclophane-1,9-diene. A valence isomer of 10b,10c-methano-cis-10b,10c-dihydropyrene (SC) 946 [G.E. 1011]
Methionine, Enantioselective synthesis of the hydroxy-analogues of D- and L-~ (SC) 797 [G.E. 858]
7-Methylenebicyclo[2.2.2]octa-2,5-diene, Bicyclo[2.2.2]octa-5,7-diene-2-carboxylic acid and ~ (SC) 470 [G.E. 500]
5-Methylenecycloоctene, Mechanistic aspects of the palladium catalyzed cyclization of ~ (SC) 867 [G.E. 925]
Methylenesulfur tetrafluoride, Structure and reactions (SC) 944 [G.E. 1008]
μ-Methylene transition metal complexes, Electronic structure (SC) 554 [G.E. 591]
β-Methyl homoallyl alcohols, Diastereoselective synthesis (SC) 306 [G.E. 329]
Molecular interactions, The donor-acceptor approach to ~ (Book Review) 560
Molybdate, Reactions of ~-(VI) with hydroxylamine and N-methylhydroxylamine (SC) 548 [G.E. 582]
Molybdenum compounds, S_2^{2-} as simultaneous end-on and side-on bonded ligand in the novel transition-metal complex $[Mo_4(NO)_4S_{13}]^{4-}$ (SC) 168 [G.E. 158]
Oxidative addition to a quadruple bond. The complete X-ray structure of $[Mo_2Cl_8H]^{3-}$ (SC) 332 [G.E. 356]
An easily prepared, air-stable compound with a triple metal-to-metal (MoMo) bond (SC) 462 [G.E. 496]
Generation of the triangulo-group Mo^V-η-S_2 in the "condensation" of $[Mo^{VI}O_2S_2]^{2-}$ to $[Mo_2^{V}O_2S_2(S_2)_2]^{2-}$ (SC) 530 [G.E. 565]
$FeCoMoWS(AsMe_2)Cp_2(CO)_7$: The first cluster to contain four different metal atoms (SC) 531 [G.E. 566]
Synthesis of a hydroxylamido(2-)-O,N-(nitrosyl)molybdenum complex (SC) 549 [G.E. 583]
Synthesis and X-ray structure analysis of a Mo complex with η^2-coordinated benzaldehyde; transformation of a CO ligand by double α-addition (SC) 861 [G.E. 920]
Molybdenum(VI) peroxo complex, Asymmetric epoxidation of simple olefins with an optically active ~ (SC) 485 [G.E. 511]
Monolayer assemblies, Photochemical reactions of surfactant molecules in condensed ~—environment control and modification of reactivity (FP) 440 [G.E. 472]
Morpholino group as stereoindicator in aminobicyclo[4.1.0]heptanes (SC) 798 [G.E. 860]
Morpholino(succinimido)bicyclo[n.1.0]-alkanes from enaminosulfonium salts (SC) 800 [G.E. 861]
MO theory, Circular dichroism and absolute conformation: application of qualitative ~ to chiroptical phenomena (FP) 363 [G.E. 380]

NAPHTHALENE, An expeditious synthesis of heptalene from ~ via a bis(bicyclo-[1.1.0]butane) intermediate (SC) 546 [G.E. 581]
Naphthalene oxides, New entry to ~ (SC) 304 [G.E. 325]
Natural products, Key building blocks of natural product biosynthesis and their significance in chemistry and medicine (FP) 429 [G.E. 453]
Neurohypophysial hormones, Neurophysins: molecular and cellular aspects (FP) 846 [G.E. 905]
Neurophysins: molecular and cellular aspects (FP) 846 [G.E. 905]
Nickel catalysts, Ligand concentration-control in the system nickel(0)/triphenylphosphane/butadiene (SC) 400 [G.E. 428]
Nickel complexes, $(-)_{579}$-Bis[(S)-(+)-O,O'(1,1'-binaphthyl-2,2'-diyl)dithiophosphato]nickel(II)—The first dithiophosphato complex to have axial chirality (SC) 415 [G.E. 448]
Tetrahedro-tetraphosphorus as monodentate ligand in a nickel(0) complex (SC) 469 [G.E. 510]
Mono- and bis(η^3-allylnickel) derivatives of 1,8-dihydroxyanthraquinone and of some 1,3,5-triketones (SC) 681 [G.E. 742]
Bis(η^3-allylnickel) 2,4,6-heptanetrithionediate (SC) 683 [G.E. 744]
Nickel-olefin complexes, New lithium-nickel polynuclear complex: $Ni(C_{12}H_{17}NiLi)_2(THF)_4$ (SC) 487 [G.E. 520]
Nickel(0)-induced synthesis of ethyllithium from lithium, hydrogen, and ethylene (SC) 488 [G.E. 521]
Nitrenes, Developments in arylnitrene chemistry: syntheses and mechanisms (FP) 900 [G.E. 965]
Nitrile ylides, Synchronous mechanism of the 1,1-cycloaddition of ~ to C=C double bonds (SC) 167 [G.E. 168]
Nitrogen complexes, Photochemical behavior of ~: photoluminescence of trans-$(N_2)_2W(diphos)_2$ and trans-$(CO)_2W(diphos)_2$ (SC) 328 [G.E. 335]
Nitrogen compounds, Structure and bonding in cyclic sulfur-nitrogen compounds (FP) 101 [G.E. 112]
SN ring with di-, tri-, and tetra-coordinated sulfur atoms by nucleophilic substitution (SC) 415 [G.E. 444]
$S_5N_6(CH_2)_4$—the first spirocyclic 1'λ^6-thiacyclopentane derivative of a sulfur-nitrogen compound (SC) 780 [G.E. 846]
Nitrogen-sulfur compounds, Cyclodiaza-λ^6-thianes—syntheses and structures (SC) 235 [G.E. 231]
Nitrogen-sulfur-fluorine compound, Stable coordination compounds of "thiazyl fluoride": structure of $[Co(NSF)_6]^{2+}$ in the crystal (SC) 231 [G.E. 253]
Nitrogen ylides, Synthesis of a Zeise salt derivative with a phosphorus-nitrogen ylide as chelate ligand (SC) 234 [G.E. 238]
Nitrosylated metal cations, η^5-Cyclopentadienyl(trinitrosyl)vanadium hexafluorophosphate, $[CpV(NO)_3]PF_6$ (SC) 220 [G.E. 241]
Nitrosyl ligands, η^5-Cyclopentadienylchromium complexes with thiocarbonyl ligands and ~ (SC) 631 [G.E. 662]
Nitroxides, Enantioselective oxidation by a chiral acylaminyl oxide (SC) 864 [G.E. 923]
NMR spectroscopy, Direct ^{13}C-NMR spectroscopic observation of cyclopropylidene bromolithiocarbenoids (SC) 784 [G.E. 844]
^{13}C-NMR spectra of tribromomethyllithium and 1,1-dibromoethyllithium (SC) 785 [G.E. 845]
Nodal nomenclature—general principles (FP) 887 [G.E. 951]
Nomenclature, Nodal ~—general principles (FP) 887 [G.E. 951]
Nucleophilic substitution, Stereochemistry of ~ at cyclopropanediazonium ions (SC) 228 [G.E. 240]
Nucleosides, Preferred β-glycoside formation by phase transfer catalysis in the synthesis of D-arabinofuranosyl-7-deazapurine ~ (SC) 536 [G.E. 570]
Nucleotide synthesis, Selective electrochemical removal of protecting groups in ~ (SC) 148 [G.E. 155]

OCTAIODODIRHENATE(III), Synthesis and properties of tetrabutylammonium ~, $[(n\text{-}C_4H_9)_4N]_2[Re_2I_8]$ (SC) 150 [G.E. 159]
Octalene, Dianion and tetraanion of ~ (SC) 229 [G.E. 251]
Octatriene, Homogeneously catalyzed dimerization of isoprene to 2,7-dimethyl-2,trans-4,6-~ at chromium (SC) 324 [G.E. 344]
Olefination, Preparation of stable vinylketenes by metal complex-induced ~ and carbonylation of alkynes (SC) 954 [G.E. 1021]
Olefins, Polycyclic azoalkanes via dipolar cycloaddition of 4-phenyl-1,2,4-triazoline-3,5-dione with strained bicyclic ~ (SC) 468 [G.E. 512]
Asymmetric epoxidation of simple ~ with an optically active molybdenum(VI) peroxo complex (SC) 485 [G.E. 511]
Metal complexes of Bredt ~: synthesis and structure of bicyclo[4.2.1]non-1(8)-ene-bis(triphenylphosphane)platinum(0) (SC) 685 [G.E. 746]
Cyclic systems by palladium-catalyzed oxidation of di-~ (SC) 866 [G.E. 924]
One-dimensional conductors, Highly conducting one-dimensional solids (Book Review) 884
Onium salts, New synthetic reactions based on the ~ of aza-arenes (FP) 707 [G.E. 798]
Optical materials, Plastics as ~ (FP) 49 [G.E. 52]
Orbital symmetry, A basis for ~ rules (FP) 377 [G.E. 363]
Organometallic chemistry, Organometallic mechanisms and catalysis (Book Review) 804
Orthocarbonic acid, Planar tetracoordinate silicon (SC) 553 [G.E. 588]
Ortho esters, Directed synthesis of acyl ~ (SC) 309 [G.E. 337]

Orthonitrate, Crystal structure of Na_3NO_4 (SC) 698 [G.E. 762]
Orthosilicic acid, Structure and reactivity of the orthocarbonic and ~ esters of pyrocatechol (SC) 551 [G.E. 587]
Planar tetracoordinate silicon (SC) 533 [G.E. 588]
Oxamide chloride, Intramolecular Cl,H disproportionation of an ~. An entry to imidazole derivatives (SC) 616 [G.E. 651]
Oxetanes, Unusually high asymmetric induction in photochemical formation (SC) 868 [G.E. 926]
Oxidation, ~ of hydrocarbons with benzyl(triethyl)ammonium permanganate (SC) 68 [G.E. 77]
~ of ethers with benzyl(triethyl)ammonium permanganate (SC) 69 [G.E. 78]
Cyclic systems by palladium-catalyzed ~ of diolefins (SC) 866 [G.E. 924]
Oxidative addition to a quadruple bond. The complete X-ray structure of $[Mo_2Cl_8H]^{3-}$ (SC) 332 [G.E. 356]
Oxidative elimination, Redox addition/elimination processes of cluster-bound ligands: ~ of CO from $Co_3(CO)_9C$—OH and reductive addition of acetylene to $Co_3(CO)_9H$ (SC) 619 [G.E. 657]
Oxide fluorides, Structural chemistry of fluorides and ~ of nonmetals (FP) 186 [G.E. 199]
4-Oxocarboxylic acids, ω-Formylcarboxylic acids and ~ in blood plasma (SC) 305 [G.E. 328]
Oxocobaltate(II), Co^{II} with coordination number 3: $Na_4[CoO_3]$—the first ~ with an island structure (SC) 542 [G.E. 577]
Oxygen, Cyclic cleavage of water into H_2 and ~ by visible light with coupled redox catalysts (SC) 701 [G.E. 759]
Oxygenation, A 3-imino-1,2-dioxetane via singlet ~ of a ketenimine (SC) 788 [G.E. 855]
Ozonation in organic chemistry (Book Review) 492

PALLADIUM complexes, Structural isomers of ~ of type $C_5H_5Pd(2\text{-}RC_3H_4)L$—A case of simultaneous π/σ and σ/π rearrangement of two organic ligands (SC) 416 [G.E. 447]
Radical complexes of palladium and platinum with bisphosphane derivatives of maleic anhydride (SC) 677 [G.E. 754]
ortho-Palladated complex of 2,5-diphenyl-1,6,6aλ⁴-trithiapentalene (SC) 684 [G.E. 745]
Cyclic systems by palladium-catalyzed oxidation of diolefins (SC) 866 [G.E. 924]
Mechanistic aspects of the palladium catalyzed cyclization of 5-methylenecyclooctene (SC) 867 [G.E. 925]
Synthesis and structural dynamics of bis(cyclopentadienyl)phosphane-~ (SC) 948 [G.E. 1013]
Pentaspirohexadecanol, Multiple cyclopropylmethyl-cyclobutyl rearrangements in a ~ (SC) 868 [G.E. 927]
Peptide antibiotics, Sequences of membrane-modifying peptide antibiotic trichotoxin A-40 (SC) 476 [G.E. 508]
Peptide protecting groups, Solubilizing acid-labile ~ (SC) 686 [G.E. 747]
Peptides, Boat conformation of cyclo-[L-Pro_2-D-Pro] (SC) 538 [G.E. 573]
Peptide synthesis, Synthesis of the mast cell degranulating (MCD) peptide from bee venom (SC) 147 [G.E. 156]
Synthesis of thymosin α_1, a polypeptide of the thymus (SC) 394 [G.E. 422]
Perbenzoic acids, Regio- and stereospecific hydroxylation of alicyclic hydrocarbons with substituted ~ (SC) 407 [G.E. 438]
Permanganate, Oxidation of hydrocarbons with benzyl(triethyl)ammonium ~ (SC) 68 [G.E. 77]
Oxidation of ethers with benzyl(triethyl)-ammonium ~ (SC) 69 [G.E. 78]
Detonation of benzyl(triethyl)ammonium ~ (SC) 786 [G.E. 852]
Stability of benzyl(triethyl)ammonium ~ (SC) 787 [G.E. 852]
Permeability of the outer membrane of bacteria (FP) 337 [G.E. 394]
pH values, pH-Wert-Berechnungen (Book Review) 703
Pharmaceutical chemistry, Einführung in die Pharmazeutische Chemie (Book Review) 334
Phase transfer catalysis, Preferred β-glycoside formation by ~ in the synthesis of D-arabinofuranosyl-7-deazapurine nucleosides (SC) 536 [G.E. 570]
Phase transfer catalyzed synthesis of ferrocene derivatives (SC) 792 [G.E. 858]
~ in organic chemistry (Book Review) 559
Phase transfer reagents, Long-chain alkylammonium ions as ~ for the synthesis of mixed-ligand complexes of the platinum metals (SC) 151 [G.E. 160]
Phenols, Flash vacuum thermolysis of doubly unsaturated acyl halides to give ~ (SC) 170 [G.E. 163]
Phenyl cations, Formation in the solvolysis of a dienynyl trifluoromethane sulfonate (SC) 870 [G.E. 928]
Pheromones, Asymmetric synthesis of ant alarm ~—α-alkylation of acyclic ketones with almost complete asymmetric induction (SC) 397 [G.E. 425]
Phosgene, Stepwise reaction of phenylbis(trimethylsilyl)phosphane with ~—isolation of a (phosphinomethylene)phosphane (SC) 469 [G.E. 497]
Phosphane, Ligand concentration-control in the system nickel(0)/triphenyl-~/butadiene (SC) 400 [G.E. 428]
Competition in the three-component system triphenyl-~/azo ester/3-hydroxy-carboxylic acid: OH- versus COOH-activation (SC) 622 [G.E. 654]
Synthesis, resolutions, and characterization of an amino-~ rotamer pair (SC) 679 [G.E. 741]
Novel polycyclic ~-s and arsanes: $P_{11}(SiMe_3)_3$ and $As_7(SiMe_3)_3$ (SC) 679 [G.E. 755]
Phosphanepalladium complexes, Synthesis and structural dynamics of bis(cyclopentadienyl)-~ (SC) 948 [G.E. 1013]
λ²-Phospholes, 1H-1,2,3λ²-diazophospholes—bond delocalization in ~ (SC) 413 [G.E. 442]
Phosphorane, Stabilization of an arsanediyl-~ (SC) 233 [G.E. 244]
(Bromoacetylmethylene)triphenyl-~—a novel cyclopentannelating agent (SC) 940 [G.E. 1005]
Phosphoranediylamino compounds, Tris(trichlorophosphoranediylamino)carbenium hexachloroantimonate, $[C(NPCl_3)_3]^+SbCl_6^-$ (SC) 693 [G.E. 735]
Phosphorus compounds, [(Triphos)Co(μ-P_3)$Cr_2(CO)_{10}$]: A trinuclear heterometal complex containing cyclo-triphosphorus as μ_3-ligand (SC) 81 [G.E. 93]
Bis(chlorophenylphosphoranediyl)methane (SC) 169 [G.E. 177]
Problem of the structure of carbodiphosphoranes, R_3PCPR_3: new aspects (SC) 408 [G.E. 437]
Cyanohalophosphates(III)-hypervalent anions containing λ⁵-phosphorus(III) (SC) 411 [G.E. 441]
Structure and formation of triorganylphosphoniocyclopropenylium ions (SC) 472 [G.E. 505]
Methylidynetris(dimethylphosphane) (SC) 484 [G.E. 518]
Radical complexes of palladium and platinum with bisphosphane derivatives of maleic anhydride (SC) 677 [G.E. 754]
Experiments on the HOMO-LUMO nature of metal-metal bonds (SC) 690 [G.E. 751]
Chemistry of the $H_3B(CH_3)_2P$ group: unusual properties of some simple reference compounds (SC) 781 [G.E. 847]
Synthesis and crystal structure of a salt containing the anion $[H_3B(CH_3)_2P{\cdots}CH{\cdots}P(CH_3)_2BH_3]^-$; precursors and related compounds (SC) 782 [G.E. 848]
The first 2,3,5,6-tetraphosphabicyclo[2.2.0]hexane (SC) 872 [G.E. 935]
First 1,3,4,6-tetraphospha-1,5-hexadiene, a molecule with fluxional bonds (identical tetraphospha Cope rearrangement) and configurational isomerism (SC) 873 [G.E. 936]
Five-coordinate tervalent phosphorus in the tricyanobromo- and -iodophosphate(III) ion (SC) 935 [G.E. 1000]
Phosphorus ligands, Separation of steric and electronic effects in the reaction enthalpies of association of phosphorus ligands (SC) 401 [G.E. 429]
Phosphorus-nitrogen ylide, Synthesis of a Zeise salt derivative with a ~ as chelate ligand (SC) 234 [G.E. 238]
Phosphorus ylide, A ~ with symmetrical resonance-stabilized sp^2-carbanion (SC) 484 [G.E. 519]
Structure of the primary adduct of a ~ and fluorenone (SC) 876 [G.E. 945]
Photochemical cycloaddition, Synthesis of 1,4-dihydronicotinic acid derivatives by ~ (SC) 540 [G.E. 575]
Photochemical reactions of surfactant molecules in condensed monolayer assemblies—environment control and modification of reactivity (FP) 440 [G.E. 472]
Photochemistry, Criteria for the efficiency, stability, and capacity of abiotic photochemical solar energy storage systems (FP) 652 [G.E. 696]
Characterization of short-lived photoproducts by pulse Raman spectroscopy (SC) 323 [G.E. 348]
Question of π*, n- and π*, π selective ~ of 2,4-cyclohexadienones (SC) 557 [G.E. 585]
Colloid redox catalysts for evolution of oxygen and for light-induced evolution of hydrogen from water (SC) 624 [G.E. 659]
Unusually high asymmetric induction in the photochemical formation of oxetane (SC) 868 [G.E. 926]
Photochromic systems, 1,8a-Dihydroindolizines as components of novel ~ (SC) 945 [G.E. 1010]
Photocycloadditions, Polar [4+2]- and [4+4]-~: effects of hybridization in diradicals (SC) 881 [G.E. 943]
Photocycloreversions, First spectroscopic detection of diradicals in ~ (SC) 215 [G.E. 232]
Photoelectron spectroscopy, Conformational analysis by ~ (FP) 826 [G.E. 885]
Photoluminescence, Photochemical behavior of N_2-complexes: ~ of trans-$(N_2)_2W(diphos)_2$ and trans-$(CO)_2W(diphos)_2$ (SC) 328 [G.E. 335]
Photoreactions, Adiabatic ~ of organic molecules (FP) 572 [G.E. 597]
Phthalocyanine, trans-Bis(1-alkynyl)-4B-metal ~-s (SC) 322 [G.E. 343]
Cobalt(I)-~ as vitamin B_{12s}-model: selectivity in reactions with electrophiles (SC) 794 [G.E. 841]
Plasmalogens, Synthesis and biosynthesis of alkoxylipids (FP) 493 [G.E. 550]
Plastics as optical materials (FP) 49 [G.E. 52]
Platinum complexes, Long-chain alkylammonium ions as phase transfer reagents for the synthesis of mixed-ligand complexes of the platinum metals (SC) 151 [G.E. 160]
New cationic binuclear trihydrido complex containing one four- and one five-coordinate platinum atom (SC) 155 [G.E. 169]
CS_2- and CS_3-bridged transition metal complexes—directed synthesis of metallodithiocarboxylato-metal complexes (SC) 626 [G.E. 661]
Radical complexes of palladium and platinum with bisphosphane derivatives of maleic anhydride (SC) 677 [G.E. 754]
Metal complexes of Bredt olefins: synthesis and structure of bicyclo[4.2.1]non-1(8)-enebis(triphenylphosphane)platinum(0) (SC) 685 [G.E. 746]

Synthesis and crystal structure of a chiral complex containing a non-linear heterotrimetal chain: $PtMn_2(\mu_2\text{-}PPh_2)_2(CO)_8$ (SC) 797 [G.E. 859]
Synthesis of a platinum complex with a derivative of monomeric metathiophosphoric acid as η^2-ligand (SC) 953 [G.E. 1020]
Polarity, Empirical parameters of solvent ~ as linear free-energy relationships (FP) 98 [G.E. 119]
Polyblends, Polymer alloys—their structure, morphology, and properties (FP) 273 [G.E. 286]
Polyethers, Multidentate acyclic neutral ligands and their complexation (FP) 753 [G.E. 813]
Spherical wrapping of a linear polyether around a cation—1,20-Bis(8-quinolyloxy)-3,6,9,12,15,18-hexaoxaeicosane·RbI (SC) 226 [G.E. 234]
S-shaped binuclear cation complex of a linear polyether: 1,5-Bis 2-[5-(2-nitrophenoxy)-3-oxapentyloxy]phenoxy-3-oxapentane · 2 KSCN (SC) 227 [G.E. 237]
Polymer alloys—their structure, morphology, and properties (FP) 273 [G.E. 286]
Polymer analysis, Hummel/Scholl: Atlas of polymer and plastics analysis (Book Review) 702
Polymers, Effects of long-chain branches on the degradation kinetics of ~ (SC) 321 [G.E. 341]
Inorganic ~ (Book Review) 559
Polysilanes, Homologous series of cyclic ~ from $(Me_2Si)_5$ to $(Me_2Si)_{35}$ (SC) 955 [G.E. 1022]
Potassium complexes, S-shaped binuclear cation complex of a linear polyether: 1,5-Bis-2-[5-(2-nitrophenoxy)-3-oxapentyloxy]phenoxy-3-oxapentane·2 KSCN (SC) 227 [G.E. 237]
Proline, Boat conformation of cyclo-[L-Pro_2-D-Pro] 538 [G.E. 573]
Propyne, Surprising transformation of azulene by cycloaddition with 1-(diethylamino)-~ (SC) 161 [G.E. 173]
Protecting groups, Selective electrochemical removal of ~ in nucleotide synthesis (SC) 148 [G.E. 155]
Solubilizing acid-labile peptide ~ (SC) 686 [G.E. 747]
Oxidative removal of the benzyl ether protecting group by homogeneous electron transfer (SC) 801 [G.E. 850]
Selective deprotection of primary and secondary hydroxy functions by homogeneous electron transfer (SC) 802 [G.E. 851]
Protein gels, Spatial structure formation in ~ (FP) 599 [G.E. 634]
Pteridines, Thermal generation of ~ and flavines from amino acid mixtures (SC) 478 [G.E. 510]
Pulse Raman spectroscopy, Characterization of short-lived photoproducts by ~ (SC) 323 [G.E. 348]
Pyrans, Metalation of ~ and dihydropyridines: when is an 8π-system cost effective? (SC) 489 [G.E. 515]
Pyridine-3-carbonitrile, Ester and lactone formation with the reagent 1,2-dihydro-4,6-dimethyl-2-thioxo-~ (SC) 308 [G.E. 330]
Pyridines, Regiospecific nucleophilic attack at the γ-position of 1-(2,6-dimethyl-4-oxo-1,4-dihydro-1-pyridyl)pyridinium compounds; novel synthesis of 4-substituted ~ (SC) 792 [G.E. 856]
Pyrocatechol, Structure and reactivity of the orthocarbonic and orthosilicic acid esters of ~ (SC) 551 [G.E. 587]
Planar tetracoordinate silicon (SC) 553 [G.E. 588]

QUADRUPLE bond, Oxidative addition to a ~. Complete X-ray structure of $[Mo_2Cl_8H]^{3-}$ (SC) 332 [G.E. 356]
Tetracarbanilanilidodichromium(II): A clue to the understanding of the CrCr ~ (SC) 874 [G.E. 937]
Quinazoline, N^2-(Trichlorovinyl)amidines—new 1,3-biselectrophilic reagents (SC) 333 [G.E. 355]

RADICAL complexes of palladium and platinum with bisphosphane derivatives of maleic anhydride (SC) 677 [G.E. 754]
Radical reactions, Anchimerically accelerated bond homolysis (FP) 173 [G.E. 185]
Radicals, Capto-dative substituent effects in syntheses with ~ and radicophiles (FP) 917 [G.E. 982]
Reversal of the selectivity principle in free-radical additions to alkenes (SC) 154 [G.E. 167]
First spectroscopic detection of di-~ in photocycloreversions (SC) 215 [G.E. 232]
Catalysis of hydrogen formation from an organic radical in aqueous solution by colloidal silver (SC) 418 [G.E. 449]
Enantioselective oxidation by a chiral acylaminyl oxide (SC) 864 [G.E. 923]
Polar [4+2]- and [4+4]-photocycloadditions: effects of hybridization in di-~ (SC) 881 [G.E. 943]
Radicophiles, Capto-dative substituent effects in syntheses with radicals and ~ (FP) 917 [G.E. 982]
Radionuclides, The gamma rays of the ~ (Book Review) 703
Raman spectroscopy, Characterization of short-lived photoproducts by pulse ~ (SC) 323 [G.E. 348]
Infrared and ~ (Book Review) 237
Infrared and Raman spectra of inorganic and coordination compounds (Book Review) 639
Reaction enthalpies, Separation of steric and electronic effects in the ~ of association of phosphorus ligands (SC) 401 [G.E. 429]
Reaction rates, A basis for orbital symmetry rules (FP) 377 [G.E. 363]
Reactivity Umpolung, Methods of ~ (FP) 239 [G.E. 259]
d^3-Reagent, Metalated allylurea with sterically protected carbonyl group as novel ~ (SC) 399 [G.E. 427]
Rearrangements, Stereochemistry of [2,3]sigmatropic ~ (FP) 563 [G.E. 625]
Thermal "walk"-~ in the bicyclo[2.1.0]pent-2-ene system (SC) 674 [G.E. 738]
Multiple cyclopropylmethyl-cyclobutyl ~ in a pentaspirohexadecanol (SC) 868 [G.E. 927]
Spontaneous rearrangement of a carbene-to a carbyne complex: C,Cr migration of a $Sn(C_6H_5)_3$ group (SC) 871 [G.E. 929]
Novel highly stereoselective ~ of chiral dihydropyranones (SC) 936 [G.E. 1001]
Redox addition/elimination processes of cluster-bond ligands: oxidative elimination of CO from $Co_3(CO)_9C$—OH and reductive addition of acetylene to $Co_3(CO)_9H$ (SC) 619 [G.E. 657]
Redox catalysts, Colloid ~ for evolution of oxygen and for light-induced evolution of hydrogen from water (SC) 624 [G.E. 659]
Cyclic cleavage of water into H_2 and O_2 by visible light with coupled ~ (SC) 701 [G.E. 759]
Reduction, Steric course of the ~ of ketoacetal esters with alkali metals in liquid ammonia (SC) 637 [G.E. 673]
Model system for the electrochemical ~ of the carbon-halogen bond (SC) 938 [G.E. 1002]
Reductive addition, Redox addition/elimination processes of cluster-bond ligands: oxidative elimination of CO from $Co_3(CO)_9C$—OH and ~ of acetylene to $Co_3(CO)_9H$ (SC) 619 [G.E. 657]
Regioselective alkylation of 1,4,5-trihydroxy-9,10-anthraquinone with formaldehyde and glyoxylic acid (SC) 621 [G.E. 658]
Regiospecific synthesis of disubstituted benzene derivatives (SC) 402 [G.E. 430]
Relaxation, Fundamentals of chemical ~ (Book Review) 171
Transient techniques in electrochemistry (Book Review) 334
Rhenium compounds, A metalloporphyrin containing carbyne-like carbido carbon: 5,10,15,20-Tetraphenylporphyrinato [bis(μ-carbidotricarbonylrhenium)]tin(IV) (SC) 83 [G.E. 85]
Synthesis and properties of tetrabutylammonium octaiododirhenate(III), $[(n\text{-}C_4H_9)_4N]_2[Re_2I_8]$ (SC) 150 [G.E. 159]
Synthesis of metallacycles with reactive metal-carbon σ bonds (SC) 535 [G.E. 569]
Rhodium complexes, Asymmetric hydrogenation of (Z)-α-(acetylamino)cinnamic acid by a Rh/norphos catalyst (SC) 620 [G.E. 655]
D-Ribofuranoses, Facile, highly selective synthesis of α- and β-disaccharides from 1-O-metalated ~ (SC) 466 [G.E. 497]
Ring enlargement, Facile ~ of azulene to give the cyclopentacyclononene system by dipolar cycloaddition (SC) 162 [G.E. 175]
Ring-opening, ~ of 5-(bromomethyl)-2-isoxazolines to β,γ-enoximes—a new principle for the γ-substitution of allyl bromides by α-functionalized alkyl groups (SC) 78 [G.E. 91]
~ of lactones and cyclic carbonates with bromo- or iodotrimethylsilane (SC) 689 [G.E. 749]
Rotamers, Synthesis, resolution, and characterization of an aminophosphane rotamer pair (SC) 679 [G.E. 741]
Rotation, Hindered ~ at the triple bond (SC) 159 [G.E. 163]
Internal ~ and inversion. An introduction to large amplitude motions in molecules (Book Review) 419
Rubidium compounds, Spherical wrapping of a linear polyether around a cation—1,20-Bis(8-quinolyloxy)-3,6,9,12,15,18-hexaoxaeicosane·RbI (SC) 226 [G.E. 234]

SACCHARIDE syntheses, Novel glycals as synthons for ~ (SC) 222 [G.E. 242]
Safety, Verordnung über gefährliche Arbeitsstoffe (Book Review) 236
Secologanin, Use of biogenetic key compounds for the biomimetic synthesis of natural products. (S)-Elenolide from ~ (SC) 539 [G.E. 574]
Selectivity, "Multi-loop crown ethers" with multiple ~ (SC) 219 [G.E. 230]
Selectivity principle, Reversal of ~ in free-radical additions to alkenes (SC) 154 [G.E. 167]
Selenium compounds, New synthesis of carbonyl selenide (SC) 691 [G.E. 760]
Reactions of carbonyl selenide with amines and aminoalcohols to produce ureas and carbamates (SC) 692 [G.E. 760]
Thiocarbonyl-metal complexes from CSSe (SC) 865 [G.E. 930]
Separation effects, Extreme liquid chromatographic ~ in the case of diastereomeric amide containing polar substituents (SC) 62 [G.E. 64]
SEPIL, Applications to the solid state defect chemistry of fluorites and ultra-trace inorganic analysis (FP) 738 [G.E. 765]
Silabenzene, 1,4-Di-tert-butyl-~: generation and trapping reactions (SC) 789 [G.E. 863]
Silane, Hexamethyldi-~/iodine: convenient in situ generation of iodotrimethyl-~ (SC) 612 [G.E. 648]
Homologous series of cyclic poly-~-s from $(Me_2Si)_5$ to $Me_2Si)_{35}$ (SC) 955 [G.E. 1022]
Silicate, $Ag_{10}Si_4O_{13}$—the first tetra-~ (SC) 464 [G.E. 500]
Silicon carbide, Chemical vapor deposition of ~ and silicon nitride—chemistry's contribution to modern silicon ceramics (FP) 295 [G.E. 316]
Silicon ceramics, Chemical vapor deposition of silicon carbide and silicon nitride—chemistry's contribution to modern ~ (FP) 295 [G.E. 316]

Silicon compounds, Catalytic reactions with hydrosilane and carbon monoxide (FP) 837 [G.E. 896]
Novel polycyclic phosphanes and arsanes: $P_{11}(SiMe_3)_3$ and $As_7(SiMe_3)_3$ (SC) 679 [G.E. 755]
Ring-opening of lactones and cyclic carbonates with bromo- or iodotrimethylsilane (SC) 689 [G.E. 749]
Silicon nitride, Chemical vapor deposition of silicon carbide and ~—chemistry's contribution to modern silicon ceramics (FP) 295 [G.E. 316]
Silicon phthalocyanines, trans-Bis(1-alkynyl)-4B-metal phthalocyanines (SC) 322 [G.E. 343]
α-Siloxy aldehydes, Catalytic conversion of aldehydes into higher ~ by hydrosilane and carbon monoxide (SC) 393 [G.E. 421]
Silver, Catalysis of hydrogen formation from an organic radical in aqueous solution by colloidal ~ (SC) 418 [G.E. 449]
Silver atoms, Complexes of nitrogen-containing crown ether surfactants with stable ~ (SC) 630 [G.E. 669]
Silver fir, Abietospiran, the triterpene from the bark of the ~ (Abies alba) (SC) 698 [G.E. 751]
Silylamines, Bis(dichloroboryl)-~ and tris(dichloroboryl)amine (SC) 326 [G.E. 357]
Singlet oxygen, reactions with organic compounds and polymers (Book Review) 335
Sodium, ^{23}Na-NMR study of the competition of biogenic amines with ~ ion for binding to lasalocid (X-537 A) (SC) 153 [G.E. 166]
Sodium dithionite, The double salt $Na_2S_2O_5 \cdot NaOOCH$ as intermediate in the formation of ~ by reduction of SO_2 with sodium formate (SC) 313 [G.E. 333]
Sodium orthonitrate, Crystal structure (SC) 698 [G.E. 762]
Solar energy, Criteria for the efficiency, stability, and capacity of abiotic photochemical ~ storage systems (FP) 652 [G.E. 696]
Solid state chemistry, Applications of SEPIL to the solid state defect chemistry of fluorites and ultra-trace inorganic analysis (FP) 738 [G.E. 765]
Solvent polarity, Empirical parameters of ~ as linear free-energy relationships (FP) 98 [G.E. 119]
Solvents, Ureas as ~ for chemical investigations (FP) 503 [G.E. 560]
Solvent effects in organic chemistry (Book Review) 803
Sorption, Kinetics of ~, desorption, and diffusion in zeolites (FP) 266 [G.E. 309]
Spectroscopy, Collision ~ (Book Review) 171
The spectrum in chemistry (Book Review) 560
7-Stannanorbornane, The first stable derivative of ~ and its thermolysis (SC) 543 [G.E. 577]
Stereochemistry, ~ of [2,3]sigmatropic rearrangements (FP) 563 [G.E. 625]
~ of nucleophilic substitution at cyclopropanediazonium ions (SC) 228 [G.E. 240]
Stereochemie und Konformationsanalyse (Book Review) 419
Stereoselective synthesis of Z-α,β-unsaturated aldehydes (SC) 687 [G.E. 748]
Steric effects, Separation of electronic and ~ in the reaction enthalpies of association of phosphorus ligands (SC) 401 [G.E. 429]
Structure reports (Book Review) 87
Substituent effects, Capto-dative ~ in syntheses with radicals and radicophiles (FP) 917 [G.E. 982]
Succinic anhydrides, Reaction of α-lithioacetic acid esters with ~ (SC) 632 [G.E. 656]
(Succinimido)bicyclo[n.1.0]alkanes, Morpholino-~ from enaminosulfonium salts (SC) 800 [G.E. 861]
Sugar amino acids, N-Nitroso-~ (SC) 878 [G.E. 940]
Sulfone pyrolysis as a synthetic method (FP) 515 [G.E. 534]
Sulfoxides, Diarylsulfur(VI) oxide difluoride by direct fluorination of ~ (SC) 880 [G.E. 941]
Sulfur, Detection of large-ring ~ molecules in liquid ~: simple preparation of S_{12}, α-S_{18}, and S_{20} from S_8 (SC) 152 [G.E. 165]
Sulfur compounds, Facile regeneration of carbonyl compounds from 1,3-dithiane 1-oxides via 1-ethoxy-1,3-dithianium salts (SC) 165 [G.E. 179]
Bond switch with participation of π-bonded S^{IV} in thiathiophthene-analogous systems (SC) 166 [G.E. 176]
S_2^{2-} as simultaneous end-on and side-on bonded ligand in the novel transition-metal complex $[Mo_4(NO)_4S_{13}]^{4-}$ (SC) 168 [G.E. 158]
Elemental sulfur/alkali metal hydroxide/dimethyl sulfoxide—a new "reagent" for preparing organic ~ (SC) 217 [G.E. 228]
Cyclodiaza-λ^6-thianes—syntheses and structures (SC) 235 [G.E. 231]
CS_2- and CS_3-bridged transition metal complexes—directed synthesis of metallodithiocarboxylato-metal complexes (SC) 626 [G.E. 661]
$(C_5H_5)_3Co_3(CS)(S)$; the first complex to have a μ_3-thiocarbonyl bridge (SC) 627 [G.E. 663]
Structure and reactions of methylene-sulfur tetrafluoride (SC) 944 [G.E. 1008]
Sulfur dioxide, Double salt $Na_2S_2O_5 \cdot NaOOCH$ as intermediate in the formation of sodium dithionite by reduction of ~ with sodium formate (SC) 313 [G.E. 333]
Sulfur-fluorine compounds, Stable coordination compounds of "thiazyl fluoride": structure of $[Co(NSF)_6]^{2+}$ in the crystal (SC) 231 [G.E. 253]
Sulfur-nitrogen compounds, Structure and bonding in cyclic ~-s (FP) 91 [G.E. 112]
$S_5N_6(CH_2)_4$—the first spirocyclic $1'\lambda^6$-thiacyclopentane derivative of a ~ (SC) 780 [G.E. 846]
SN ring with di-, tri-, and tetra-coordinated sulfur atoms by nucleophilic substitution (SC) 415 [G.E. 444]
Sulfur(VI) oxide difluoride, Diaryl-~ by direct fluorination of sulfoxides (SC) 880 [G.E. 941]
Sulfur trioxide, Formal criss-cross cycloaddition of ~ to cyanogen (SC) 223 [G.E. 243]
Surfactants, Photochemical reactions of surfactant molecules in condensed monolayer assemblies—environment control and modification of reactivity (FP) 440 [G.E. 472]
~ and interfacial phenomena (Book Review) 419
Synthetic methods, Triphase catalysis (FP) 421 [G.E. 464]
Pyrolysis of sulfones as a synthetic method (FP) 515 [G.E. 534]
New synthetic reactions based on the onium salts of aza-arenes (FP) 707 [G.E. 798]
Catalytic reactions with hydrosilane and carbon monoxide (FP) 837 [G.E. 896]
Specialist periodical reports: general and ~ (Book Review) 884
Symmetry, A basis for orbital ~ rules (FP) 377 [G.E. 363]
TARTARIC acid, Chiral reagents from ~—1-benzyloxy-3,4-epoxy-2-butanol, a versatile intermediate for the synthesis of enantiomers (SC) 958 [G.E. 1025]
Technical chemistry, Ullmanns Enzyklopädie der technischen Chemie (Book Review) 88, 491
Tellurates $Xe(OTeF_5)_6$, a deep-colored noble gas compound, and $O{=}Xe(OTeF_5)_4$—the existence of $Kr(OTeF_5)_2$ (SC) 66 [G.E. 68]
Tellurium catalyzed reactions of amines with carbon monoxide (SC) 547 [G.E. 582]
Tellurium compounds, 2,2,4,4,6,6-Hexamethylcyclotristannatellurane, a Sn_3Te_3-ring with C_2-symmetry (SC) 677 [G.E. 740]
Tetraanion, Dianion and ~ of octalene (SC) 229 [G.E. 251]
1,2,4,5-Tetrahydrodicyclobuta[b,e]pyridine (SC) 411 [G.E. 440]
2-Tetrahydropyranyl ethers, Metalated 2-alkynyl- and 1,2-alkadienyl: ~ versatile building blocks for furan syntheses (SC) 875 [G.E. 938]
2,3,5,6-Tetraphosphabicyclo[2.2.0]hexane, The first ~ (SC) 872 [G.E. 935]
1,3,4,6-Tetraphospha-1,5-hexadiene, The first ~, a molecule with fluxional bonds (identical tetraphospha Cope rearrangement) and configurational isomerism (SC) 873 [G.E. 936]
Tetrasilicate, $Ag_{10}Si_4O_{13}$—the first ~ (SC) 464 [G.E. 500]
Tetrathiosquarate dianion, Transition metal complexes with the ~ as bridging bischelate ligand (SC) 463 [G.E. 499]
1,2,3,4-Tetrazine, [4+2]-Cycloadditions of azoalkanes to azodicarbonyl compounds. A novel facile route to the ~ system (SC) 696 [G.E. 757]
Thallium, Quantitative trace analysis in biological material (SC) 882 [G.E. 944]
Thermolysis, Flash vacuum ~ of doubly unsaturated acyl halides to give phenols (SC) 170 [G.E. 163]
$1'\lambda^6$-Thiacyclopentane, $S_5N_6(CH_2)_4$—the first spirocyclic ~ derivative of a sulfur-nitrogen compound (SC) 780 [G.E. 846]
Thiadiborolene, New pathways to trinuclear complexes—structure of the tetradecker complex bis(η-~-cobalt-μ,η-~)iron (SC) 949 [G.E. 1014]
λ^4-Thia-λ^5-phosphanorbornadiene, Manganese-containing heterocycles having a ~ skeleton (SC) 534 [G.E. 568]
Thiathiophthene, Bond switch with participation of π-bonded S^{IV} in ~-analogous systems (SC) 166 [G.E. 176]
Thiazyl fluoride, Stable coordination compounds of "~": structure of $[Co(NSF)_6]^{2+}$ in the crystal (SC) 231 [G.E. 253]
Thieno[3,4-d][1,3]dioxol-2-one 5,5-dioxide, Economic synthesis of activated N-tert-butyloxycarbonyl amino acid esters (SC) 307 [G.E. 326]
Thin films—interdiffusion and reactions (Book Review) 560
Thiocarbonyl bridge, $(C_5H_5)_3Co_3(CS)(S)$; the first complex to have a μ_3-~ (SC) 627 [G.E. 663]
Thiocarbonyl ligands, η^5-Cyclopentadienylchromium complexes with ~ and nitrosyl ligands (SC) 631 [G.E. 662]
Thiocarbonyl-metal complexes from CSSe (SC) 865 [G.E. 930]
Thiosulfines, Dithiiranes and ~ as reactive intermediates (SC) 941 [G.E. 1006]
Thymosin, Synthesis of ~ α_1, a polypeptide of the thymus (SC) 394 [G.E. 422]
Thyrotropin-releasing hormone, Molecular structure of Phe^2-THR, an analogue of ~ (SC) 225 [G.E. 243]
Tin compounds, Synthesis and structure of the nido-cluster $(CH_3)_5C_5Sn^+$ (SC) 59 [G.E. 81]
A metalloporphyrin containing carbyne-like carbido carbon: 5,10,15,20-tetraphenylporphyrinato [bis(μ-carbidotricarbonylrhenium)]tin(IV) (SC) 83 [G.E. 85]
Intermolecular exchange of substituents via ions (ion pairs) in cyclopentadienyl- and cyclononatetraenyl-trimethylstannane (SC) 218 [G.E. 228]
β-Stannylated ynamines as aminoethynylation reagents (SC) 405 [G.E. 432]
2,2,4,4,6,6-Hexamethylcyclotristannatellurane, a Sn_3Te_3-ring with C_2-symmetry (SC) 677 [G.E. 740]
Spontaneous rearrangement of a carbene-to a carbyne complex: C,Cr migration of a $Sn(C_6H_5)_3$ group (SC) 871 [G.E. 929]
Tin phthalocyanines, trans-Bis(1-alkynyl)-4B-metal phthalocyanines (SC) 322 [G.E. 343]

Titanium compounds, Complexes with chiral alkylcyclopentadienyl ligands for homogeneous catalytic asymmetric hydrogenation of 2-phenyl-1-butene (SC) 779 [G.E. 842]
Titanium halides, Novel ~ containing metal-metal bonds: Ti_7Cl_{16} and Ti_7Br_{16} (SC) 325 [G.E. 343]
Titanocene, 1,1'-Trimethylenebis(η^5-3-tert-butylcyclopentadienyl)titanium(IV) dichloride, a chiral ansa-~ derivative (SC) 777 [G.E. 837]
Titanocene dichloride—the first metallocene with cancerostatic acitivity (SC) 477 [G.E. 509]
Titration, From classical end points to modern differential and dynamic analysis (FP) 20 [G.E. 20]
Trace analysis, Applications of SEPIL to the solid state defect chemistry of fluorites and ultra-trace inorganic analysis (FP) 738 [G.E. 765]
Quantitative ~ of thallium in biological material (SC) 882 [G.E. 944]
Transform techniques in chemistry (Book Review) 420
Transition metal complexes with the tetrathiosquarate dianion as bridging bischelate ligand (SC) 463 [G.E. 499]
Transport processes, Chemical kinetics and transport (Book Review) 885
Triazine, N^2-(Trichlorovinyl)amidines—new 1,3-biselectrophilic reagents (SC) 333 [G.E. 355]
Triazole, N^2-(Trichlorovinyl)amidines—new 1,3-biselectrophilic reagents (SC) 333 [G.E. 355]
1,2,4-Triazoline-3,5-dione, Polycyclic azoalkanes via dipolar cycloaddition of 4-phenyl-~ with strained bicyclic olefins (SC) 468 [G.E. 512]
Tri-tert-butylcyclobutadiene, Electrophilic behavior (SC) 308 [G.E. 327]
N^2-(Trichlorovinyl)amidines—new 1,3-biselectrophilic reagents (SC) 333 [G.E. 355]
Trichotoxin A-40, Sequences of the membrane-modifying peptide antibiotic ~ (SC) 476 [G.E. 508]
Tricyclo[4.2.2.$1^{2,5}$]undeca-3,7,9-triene, the [4+4]cycloadduct of benzene and cyclopentadiene. Reaction sequence of its retrocleavage (SC) 224 [G.E. 254]
1,3,5-Triketones, Mono- and bis(η^3-allylnickel) derivatives of 1,8-dihydroxyanthraquinone and of some ~ (SC) 681 [G.E. 742]
Trinuclear complexes, New pathways to ~—structure of the tetradecker sandwich complex bis(η-thiadiborolenecobalt-μ,η-thiadiborolene)iron (SC) 949 [G.E. 1014]
Trioxatris-σ-homotropilidenes, endo-Hydroxy-~ (SC) 611 [G.E. 646]
Triphase catalysis (FP) 421 [G.E. 464]
Triple bond, Hindered rotation at the ~ (SC) 159 [G.E. 163]
An easily prepared, air-stable compound with a metal-to-metal (MoMo) ~ (SC) 462 [G.E. 496]
Chemistry of functional groups. Chemistry of the carbon-carbon ~ (Book Review) 639
Triterpene, Abietospiran, the ~ from the bark of the white fir (Abies alba) (SC) 698 [G.E. 751]
1,6,6aλ^4-Trithiapentalene, An ortho-palladated complex of 2,5-diphenyl-~ (SC) 684 [G.E. 745]
Tungsten compounds, Complex-stabilized hydroxy(p-tolyl)acetylene by reaction of trans-chlorotetracarbonyl(tolylcarbyne)-tungsten with acetylacetone (SC) 327 [G.E. 345]
Photochemical behavior of N_2-complexes: photoluminescence of trans-$(N_2)_2W(diphos)_2$ and trans-$(CO)_2W(diphos)_2$ (SC) 328 [G.E. 335]
Unsymmetrical binuclear complexes of tungsten with three OR bridges, η^3-$C_7H_7(CO)_2W(OR)_3W(CO)_2$-$\eta^4$-$C_7H_8$ (SC) 404 [G.E. 432]
$FeCoMoWS(AsMe_2)Cp_2(CO)_7$: The first cluster to contain four different metal atoms (SC) 531 [G.E. 566]
$[\{Cu_3WS_3Cl\}(PPh_3)_3O]$, directed synthesis of a compound containing different metal atoms in a cubane-like skeleton (SC) 628 [G.E. 656]

ULLMANNS Encyklopädie der technischen Chemie (Book Review) 88, 491
Umpolung, Methods of reactivity ~ (FP) 239 [G.E. 259]
5,8-Undecadien-11-olide, Fragmentational approach to macrolides: (5-E, 8-Z)-6-methyl-~ (SC) 634 [G.E. 670]
5,9-Undecadien-11-olide, Fragmentational approach to macrolides: (5-E,9-E)-6-methyl-~ (SC) 636 [G.E. 672]
Ureas, ~ as solvents for chemical investigations (FP) 503 [G.E. 560]
Reactions of carbonyl selenide with amines and aminoalcohols to produce ~ and carbamates (SC) 692 [G.E. 760]
Uroporphyrinogen, Enzymatic formation of ~ I and III from a substituted bilane (SC) 778 [G.E. 838]

VACUUM thermolysis, Flash ~ of doubly unsaturated acyl halides to give phenols (SC) 170 [G.E. 163]
Vanadium complexes, η^5-Cyclopentadienyl(trinitrosyl)vanadium hexafluorophosphate, $[CpV(NO)_3]PF_6$ (SC) 220 [G.E. 241]
Vapor deposition, Chemical ~ of silicon carbide and silicon nitride—chemistry's contribution to modern silicon ceramics (FP) 295 [G.E. 316]
Vinylation, Homogeneous catalytic ~ of cyclic imides and lactams for the synthesis of N-vinyl monomers (SC) 533 [G.E. 568]
Vinyl cation, [2+2]-Cycloaddition (SC) 614 [G.E. 649]
cis-2-Vinylcyclopropyl ketone, Synthesis of ~: a new synthesis of 4-cycloheptenones (SC) 791 [G.E. 857]
Vinylketenes, Preparation of stable ~ by metal complex-induced olefination and carbonylation of alkynes (SC) 954 [G.E. 1021]
Vinylketenimines by nucleophilic ring cleavage of cyclopropenes with tert-butyl isocyanide (SC) 67 [G.E. 62]
N-Vinyl monomers, Homogeneous catalytic vinylation of cyclic imides and lactams for the synthesis of ~ (SC) 533 [G.E. 568]
Vitamin B_{12}, Cobalt(I)-phthalocyanine as vitamin B_{12s}-model: selectivity in reactions with electrophiles (SC) 794 [G.E. 841]

WAGNER-Meerwein rearrangement, Stereospecific synthesis of γ-lactones by dyotropic ~ (SC) 793 [G.E. 840]
Walk rearrangement, Thermal ~ in the bicyclo[2.1.0]pent-2-ene system (SC) 674 [G.E. 738]
Water, Colloidal redox catalysts for evolution of oxygen and for light-induced evolution of hydrogen from ~ (SC) 624 [G.E. 659]
Cyclic cleavage of ~ into H_2 and O_2 by visible light with coupled redox catalysts (SC) 701 [G.E. 759]
White fir, Abietospiran, the triterpene from the bark of the ~ (Abies alba) (SC) 698 [G.E. 751]
Wittig reaction, New evidence for zwitterionic intermediates in the ~ (SC) 633 [G.E. 675]

XENON compounds, $Xe(OTeF_5)_6$, a deep-colored noble gas compound, and $O{=}Xe(OTeF_5)_4$—the existence of $Kr(OTeF_5)_2$ (SC) 66 [G.E. 68]
Krypton and xenon inclusion compounds of complex metal cyanides (SC) 486 [G.E. 517]

YLIDES, Synchronous mechanism of the 1,1-cycloaddition of nitrile ~ to C=C double bonds (SC) 167 [G.E. 168]
Synthesis of a Zeise salt derivative with a phosphorus-nitrogen ylide as chelate ligand (SC) 234 [G.E. 238]
Phosphorus ylide with symmetrical resonance-stabilized sp^2-carbanion (SC) 484 [G.E. 519]
Ynamines, β-Stannylated ~ as aminoethynylation reagents (SC) 405 [G.E. 432]

ZEISE salt, Synthesis of a ~ derivative with a phosphorus-nitrogen ylide as chelate ligand (SC) 234 [G.E. 238]
Zeolites, Kinetics of sorption, desorption, and diffusion in ~ (FP) 266 [G.E. 309]
Zinc compounds, Bis(trimethylsilyl)zinc and -cadmium (SC) 60 [G.E. 62]
