Figure 12 shows that U_σ is independent of temperature for all substances which are not highly polar up to about $T/T_c < 0.9$. *Einstein*[17] erroneously concluded from this that the molecular heat at the surface is zero. Correctly stated, the difference between the molecular heats of the surface and of the interior of the liquid is zero. It follows from this that the loss of intermolecular degrees of freedom is compensated at the surface by translation.

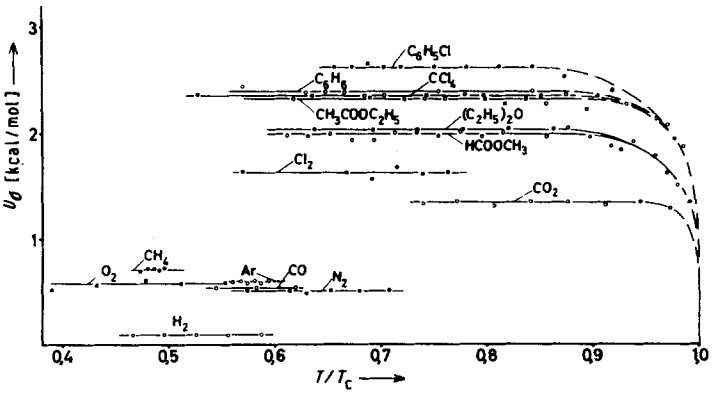

Fig. 12. The surface energy U_σ is T-constant for all nonpolar or weakly polar liquids up to about $T/T_c < 0.9$.

In earlier publications[15], the following relation, with an error of $\partial V^{2/3}/\partial T$

$$U'_\sigma = N_A^{1/3} V^{2/3}\left[\sigma - T\frac{\partial \sigma}{\partial T}\right]$$

was frequently used, and the good temperature constancy of U_σ was therefore overlooked.

If the coordination number at the surface is denoted by Z, then according to our model of a liquid one should expect:

$$U_\sigma = f(Z-X)\frac{3}{4}RT_c \tag{25}$$

Figure 13 confirms the good proportionality of U_σ and T_c over a very wide range of critical temperatures. In the case of substances with very low values of T_c the understandable deviation, amounting to $E_0/3$, again makes an appearance.

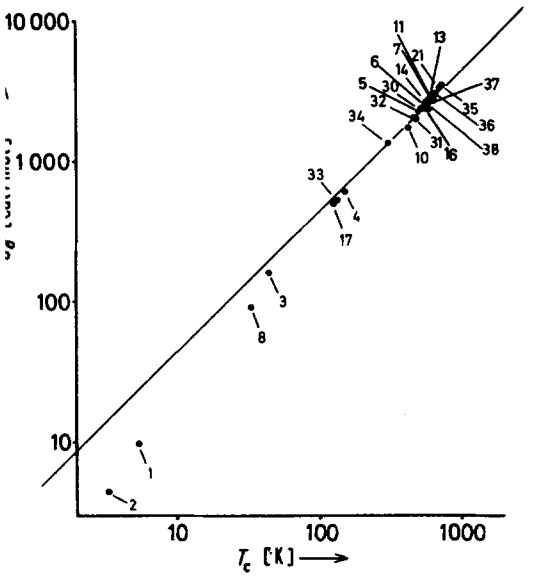

Fig. 13. The surface energy U_σ for $T/T_c < 0.9$ is proportional to T_c. 1, ^{4}He; 2, ^{3}He; 3, Ne; 4, Ar; 5, *n*-hexane; 6, benzene; 7, toluene; 8, H_2; 10, Cl_2; 11, *o*-xylene; 12, *m*-xylene; 13, *p*-xylene; 14, cyclohexane; 16, CCl_4; 17, N_2; 21, aniline; 30, ethyl acetate; 31, methyl formate; 32, diethyl ether, 33, CO; 34, CO_2; 35, *N,N*-dimethylaniline.

For most substances we obtain $fZ = 2.85$ from $4U_\sigma/3RT_c$[5]. In the case of closest spherical packing, we would have $X = 9$ and $Z - X = 3$. We can therefore estimate unknown surface tensions on the basis of the hole model:

$$\sigma_M = U_\sigma + T\frac{\partial\sigma_M}{\partial T} = 2.85\frac{3}{4}R(T_c - T) \tag{26}$$

and therefore σ as well from Eq. (23). In this way it is also possible to derive the empirical Eötvös rule, which gave a value fluctuating around 2.1 in place of $f(Z-X)\times 3/4 = 2.85\times 3/4 = 2.14$. Deviations from this rule can again be explained in terms of the packing density $(Z-X)$. In the case of substances with hydrogen bonds a maximum appears for $U_\sigma = f(T)$, which can be explained quantitatively by the orientation defect model[2, 18, 19].

6.2. The Temperature Dependence of U_σ for $T/T_c > 0.9$

According to the hole model, a temperature dependence of U_σ should be expected for $T/T_c > 0.85$ because of the factor $(1-2x_F)$. This term describes the experimentally found decrease in U_σ with rising temperature, but only approximately—it is too large. The influence of temperature can be better represented by a factor $(1-4x_F)$ in Eq. (25). The reasons for this are possibly a higher concentration of hole defects on the surface or a higher concentration of vapor in the neighborhood of the boundary layer.

6.3. *Stefan*'s Law

The so-called *Stefan*'s law was erroneously taken to mean that the expected ratio $L_V/U_\sigma = 2$ is valid. Values of 3 to 4 actually found for this quotient at room temperature have been explained incorrectly[15, 20].

According to Eqs. (9) and (25), the Stefan quotient is a function of temperature[5]:

$$\frac{L_V}{U_\sigma} = \frac{Z\left(\frac{3}{2}T_c - T\right)(1-2x_F)}{(Z-X)\frac{3}{2}T_c(1-4x_F)} \tag{27}$$

It is precisely this T function (27) and its limiting value

$$\lim_{T\to 0}\frac{L_V}{U_\sigma} = \frac{Z}{Z-X} = 4$$

which have been obtained experimentally.

7. Calculation of Enthalpy

To a second approximation it is also possible to attempt a calculation of the enthalpies H_v and H_l for the vapor and liquid under saturation conditions. This is easily possible on the basis of considerations that have already been discussed. A higher accuracy is achieved if it is borne in mind that the translational degrees of freedom are absent in the liquid state. We obtain astonishingly good agreement with formulas (28) and (29).

$$H_v = \frac{fZ}{2}\cdot\frac{3}{2}RT_c(1-x_F) + \frac{fZ}{2}RTx_F + \int_0^T C_V\,dT - \frac{3}{2}RTx_l + PV_v \tag{28}$$

The individual summands in Eq. (28) have the following significance:

1a: evaporation against potential energy at $T = 0$ K;
1b: summand 1a times x_F is absent in the real gas;
2: heat content of intermolecular degrees of freedom;
3: heat content of intramolecular degrees of freedom plus translation;
4: fall in the translational degrees of freedom due to association;
5: pressure-volume correction of the internal energy.

$$H_l = \frac{fZ}{2}\cdot\frac{3}{2}RT_cx_F + \frac{fZ}{2}RT(1-x_F) + \int_0^T C_V\,dT - \frac{3}{2}RT(1-x_F) + PV_l \tag{29}$$

The significance of the summands is analogous to the case of Eq. (28). In the fourth term the translational energy $3RT/2$ contained in the third term is deducted. At low values of

T, the first and the third summands are the largest for H_v, and the second summand for H_l. Eqs. (28) and (29), together with the straight lines of $L_V(1-2x_F)$ extrapolated to 0 K, give a sensitive delimitation of the range of error of fZ. It is possible to calculate directly all three quantities H_v, H_l, and L_V with one value of fZ.

In this way we obtain the heat of evaporation $L_V(T=0\,K)=1850$ cal/mol for argon with $fZ=8.18$, in good agreement with the value of 1840 cal/mol extrapolated by *Born* from the vapor pressure[22]. For carbon monoxide, with $fZ=9.525$, the heat of evaporation was found to be $L_V(T=0\,K)=1900$ cal/mol.

Figures 14 and 15 shows that Eqs. (28) and (29) describe well the results obtained by experiment[21]. As a rule, Eq. (29) gives somewhat low values for substances with low critical temperatures T_c such as argon and carbon monoxide. This can be corrected by the assumption that a translational degree of freedom is retained in liquid Ar and CO—an additional movement of aggregates taking place in phase appears plausible. In this case, the four summands in Eq. (29) must be replaced by the term $-2/2\times RT(1-x_F)$ and analogously in Eq. (28) by the term $-2/2\times RTx_F$.

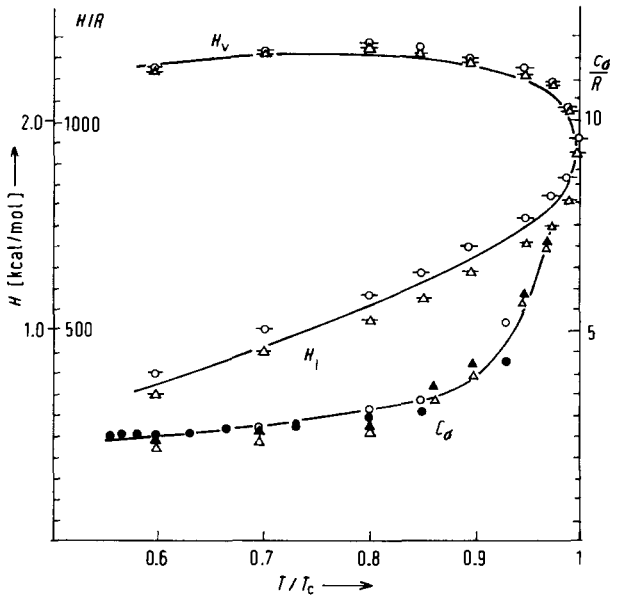

Fig. 14. Top: Enthalpies for saturation vapor H_v and saturated liquid H_l of argon; continuous curve: experimental values [21]; △, calculated according to Eqs. (28), (29), ○, calculated according to Eqs. (28), (29) with one "translational degree of freedom." Bottom: molar heats for saturated liquids; experimental [23]; ○, C_σ/R; ●, C_P/R; ▲, calculated according to Eq. (30); △, calculated according to Eq. (30) with one "translational degree of freedom".

Such effects already approach the limits of error of the model, which can be refined further by taking into account the zero-point energy, P, V corrections, *etc.* The correction introduced here for translation in the liquid becomes particularly appreciable in the case of the noble gases and substances with low molecular heats and without vibrational excitation. The necessity for this correction can also be seen from Eq. (9) for L_V. In the case of argon the straight line $L_V/(1-2x_F)$ intercepts the abscissa at somewhat higher values than 1.5 T/T_c since, because of the correction in Eq. (9), a factor of $T(Z/2(f)-$

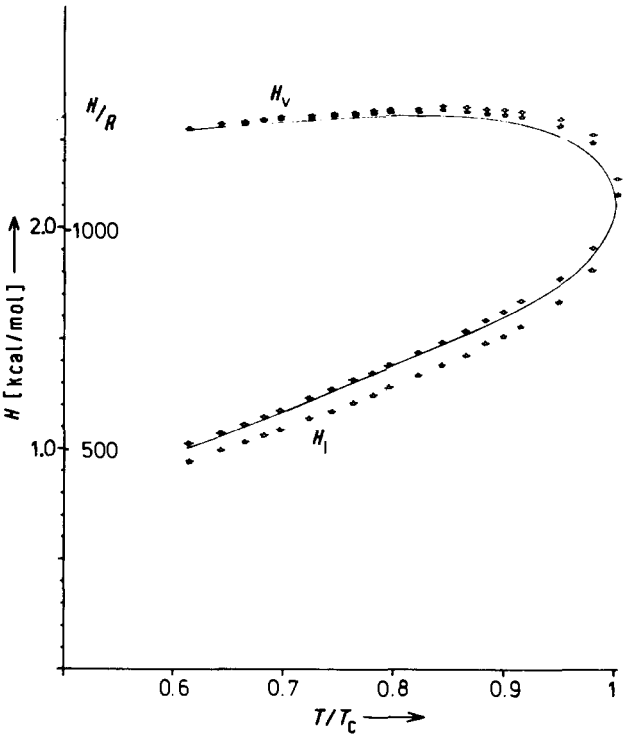

Fig. 15. H_v and H_l for carbon monoxide; continuous curve, experimental values [21]; △, calculated according to Eq. (28); ○, according to (29).

$^3/_2)R$ would be required [compare $L_V=H_v-H_l$ according to eq. (28), (29)].

8. Calculation of the Intermolecular Component of the Molecular Heat in the Condensed State

The molar heat C_σ on the saturation line for the internal energy U in the liquid state is expressed by means of Eq. (30):

$$C_\sigma=\frac{dx_F}{dT}R\left[\frac{fZ}{2}\frac{3}{2}T_c-\left(\frac{fZ}{2}-\frac{3}{2}\right)T\right]+$$
$$+R\left(\frac{fZ}{2}-\frac{3}{2}\right)(1-x_F)+C_{V,id} \quad (30)$$

where $C_{V,id}$ is the molar heat of the molecular degrees of freedom for the ideal gas. The translation has been corrected by the summand $R3(1-x_F)/2$ for the liquid. The factor after dx_F/dT corresponds to the straight line $L_V/(1-2x_F)$, see Section 5.

Figure 14 shows the values of C_σ/R calculated for argon by means of Eq. (30) and the experimental values given by *Rowlinson*[23]. In this case too we obtain better agreement between experiment and theory when we permit a "translational degree of freedom" in liquid argon. Values of dx_F/dT were taken from Figure 2.

In order to test the validity of formula (30) also for more complicated molecules with temperature-dependent molar heats of their ideal gas state, we have ourselves measured the molar heat of benzene along the saturation line in a *Calvet* adiabatic high-temperature calorimeter. The results are shown in Figure 16. In this case the agreement of experimental and calculated ($fZ=13.5$) values is again satisfactory.

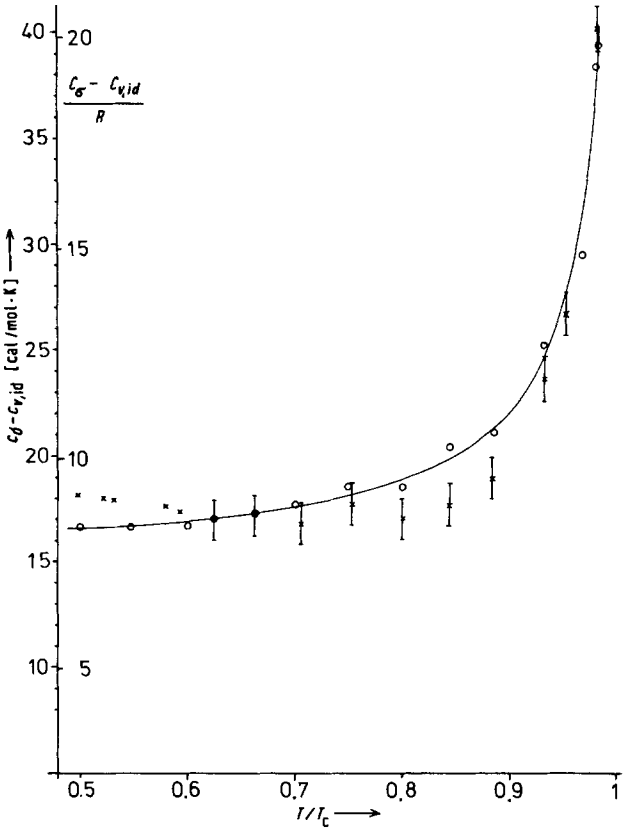

Fig. 16. Intermolecular component of the molar heat of liquid benzene under saturation conditions. Experimental: ×, according to *Rowlinson* [23]; *, own measurements. ○, calculated according to Eq. (30).

Deviations at low values of T/T_c may be due, *inter alia*, to some degree of displacement of the 20 vibrational frequencies, used for calculating $C_{V,id}$ by *Zeise*[24,25], by intermolecular forces, leading to a slight change in the oscillatory component of the molar heat. A correction for such second-order effects oversteps the accuracy of our approximate model. Originally we had hardly expected that the model, first tested on the heat of evaporation, could ever be applied to enthalpies and their differential quotients C_σ. These astonishing results could delude us into believing that the hole model is more than a mere empirical contrivance.

9. A One-Dimensional Lennard-Jones Model

The hole model described in the preceding sections is more informative than would have been expected on the basis of the simple assumptions. Why is this possible with a temperature-independent and therefore a distance-dependent pair potential? In the model, a T function is used with x_F only at high temperatures. According to *Lennard-Jones* the interaction potential varies with the intermolecular distance r in the following manner:

$$E_{pot} = 4\,\varepsilon_0 \left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6} \right] \tag{31}$$

$E(\sigma)=0$; ε_0 is the potential minimum at $r=1.22\,\sigma$ (here σ denotes not the surface tension but a definite distance)

To answer the question, let us consider a one-dimensional Lennard-Jones model with three particles on a straight line; we determine the sum of the Lennard-Jones potentials of two particles at a distance of $2r_0$ on a third particle lying between them at a distance of r from the midpoint of the line joining them; r_0 and r are measured in reduced and general units as multiples of σ. The parameters in the results of the calculation which are shown in Figure 17, are the

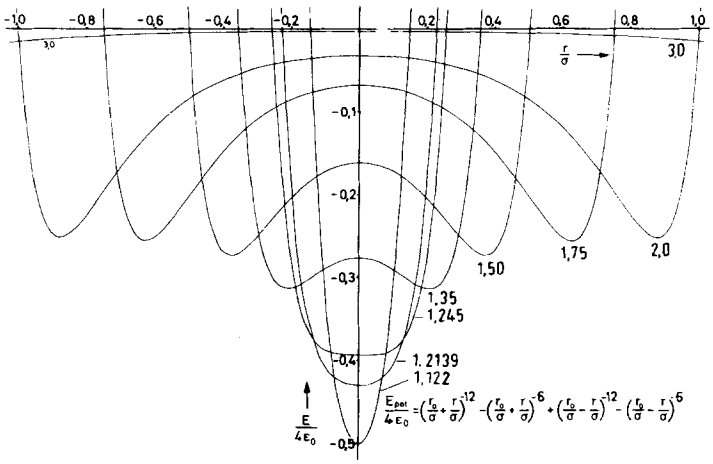

Fig. 17. One-dimensional Lennard-Jones model. Potential of the interaction of two outer particles with another particle between them on the line joining them. Parameters: distance r_0/σ of the outer particles from the center. Abscissa: Position of the middle particle in r/σ.

distances r_0/σ, the distances of the two outer particles from the center. The ordinate is the sum of the energies of interaction on the third particle in units of $4\,\varepsilon_0$. The most important results are summarized in Table 1.

Table 1. Minima of Figure 17 (see text).

r_0/σ	Corresponds in the case of CCl_4 to	Potential minimum	Minimum distance of outer particles
1.122	$T=0$ K	$-2\,\varepsilon_0$	$1.122\,\sigma$
1.2139	$T_m=0.445\,T_c$	$-1.72\,\varepsilon_0$	$1.122\,\sigma$
1.245		$-1.57\,\varepsilon_0$ (very flat)	1.2 to $1.245\,\sigma$
above 1.245		2 minima	
1.26	$T_b=0.63\,T_c$		
1.35	$T=0.83\,T_c$	$-1.25\,\varepsilon_0$	$1.14\,\sigma$
1.5	$T=0.97\,T_c$	$-1.088\,\varepsilon_0$	$1.13\,\sigma$
1.75	$T=T_c$	$-1.022\,\varepsilon_0$	$1.122\,\sigma$
1.8	$T>T_c$	$-1.016\,\varepsilon_0$	$1.122\,\sigma$
2	$T>T_c$	$-1.007\,\varepsilon_0$	$1.122\,\sigma$

Column 2 of Table 1 gives the temperatures for CCl_4 at which the mean separations calculated from the densities and the assumption $Z=12$ would correspond to the values of column 1. In the hole model the distances would be smaller: about $1.4\,\sigma$ for T_c and about $1.32\,\sigma$ for $T=0.83\,T_c$.

Table 1 is interpreted as follows. From about the boiling point T_b, above which the proportion of defects in the hole model becomes greater than 1%, two minima occur in the one-dimensional Lennard-Jones model. The distance of these minima to an outer particle corresponds, to within a few parts per thousand, to the distance for the minimum of the pair potential between two particles. This result explains the observation that in X-ray scattering diagrams the maximum for the nearest neighbors is practically independent of temperature and their distance is only slightly greater than the distance in the crystal. The position of that for second-nearest neighbors

from the X-ray data are T-dependent in agreement with the second minimum of Figure 17. The depth of the potential minimum is between the value ε_0 of the interaction with a nearest neighbor and the value $2\varepsilon_0$ for the interaction with two neighbors. The quotient of these energies corresponds to the number of hole defects. Consequently, the decrease of Z and T found by X-ray scattering becomes understandable. The depth of the potential minimum can be interpreted as if at a distance of 1.122σ a fraction of two molecules were to act instead of one neighbor. Since the hole model is independent of whether holes the size of complete molecules or several fractions of "molecular holes" are present, the two descriptions are equivalent. The potential depth at 1.12σ is naturally T-independent and for $Z=1$ it is always ε_0. The one-dimensional model of three "Lennard-Jones particles" would give a higher content of hole defects than our model. A two-dimensional model of six first nearest neighbors around a central molecule gives the following potential minima in reduced units (the corresponding distances r_0/σ are given in brackets): 1 (1.122); 0.859 (1.214); 0.78 (1.245); 0.585 (1.35) and 0.5 (1.42).

With increasing values of T/T_c the activation energy for migration between the two minima in Figure 17 would increase, but so would the mean thermal energy available for this purpose. Such migration is also in agreement with the unsymmetrical broadening of the pair distribution function in the direction of greater distances than the maximum of nearest neighbors. In addition, a relationship analogous to Eq. (7) applies[23]:

$$\varepsilon_0 = (1.25 \text{ to } 1.4)\, RT_c$$

According to *Rowlinson*[26], for polyatomic molecules the deviations from the central force field can be taken into account by a correction factor in the Lennard-Jones potential. The correction leads to a deeper potential minimum. It appears highly likely that the slight increase in fZ with molecular size in our hole model is caused by this circumstance. By means of this correction factor we can account for the influence of the effect on the thermal properties. The slight increase in quantities such as ρ_0/ρ_c, *etc.*, can probably be ascribed to the same cause.

Like chemical binding forces[27], the Lennard-Jones potential, with an attraction component proportional to $1/r^6$ and a repulsion component proportional to $1/r^{12}$, can also be ascribed to the superposition of the Coulomb potentials from point charges. *London*[28] interpreted his quantum-mechanically calculated dispersion forces on the assumption that in intermolecular interaction the symmetries resulting in the statistical mean are not decisive, but that even a single argon atom "senses" the approach of a second one as the action of point charges. Just as the Morse potential of the homopolar H_2 bond can be completely understood physically in terms of interactions between two dipoles[27], the dispersion forces can be explained by means of a quadrupole model. In Figure 18 the Coulomb interaction of two quadrupoles—as a model for He atoms—is compared with the Lennard-Jones potential. The inclination of the quadrupole with respect to the line joining the nuclei is derived from orientational quantization in the field of the second atom.

As can be seen from Figure 18, the mathematical course of the Lennard-Jones potential can be satisfactorily reproduced

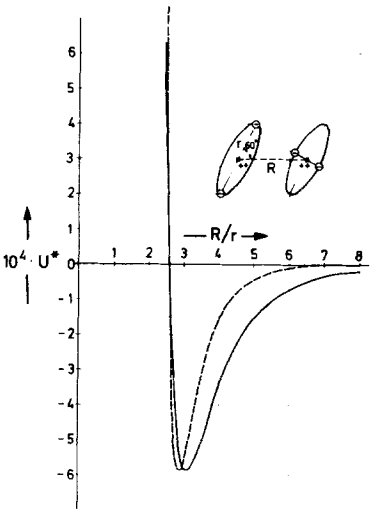

Fig. 18. – – – – –, Lennard-Jones potential; ————, Coulomb potential of two quadrupoles as a model for He-He interaction.

by a simple model of this kind. This supports *London*'s simple interpretation of the dispersion forces[28].

10. Melting Point

10.1. Cooperative Interpretation

A sharp melting point T_m can be explained only by cooperative mechanisms[29,30]. This means that the energy U_F required to generate a defect must depend on the defect concentration, *i.e.* on the degree of order $(1-x_F)$. The simplest case would be a linear relationship

$$U_F = U_{0F} + U_{1F}(1-x_F) \tag{32}$$

Bresler[29] has shown that with this equation and the formalism of statistical thermodynamics it is possible to obtain the T function for $(1-x_F)$ given in Figure 19. Under equilibrium

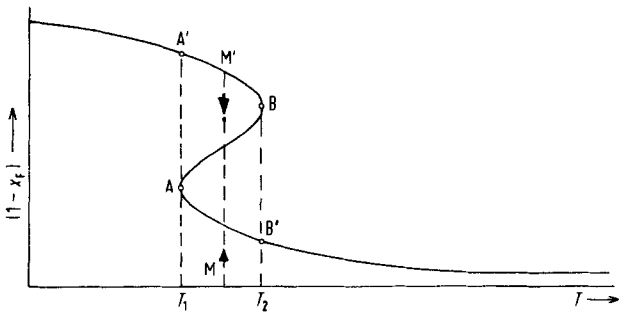

Fig. 19. Model for a sharp melting point in the defect model. The linear dependence of the defect production energy on the degree of order $(1-x_F)$ causes a jump-like change [29] in the degree of ordering at MM'.

conditions, therefore, $(1-x_F)$ would change in jump-like fashion at a temperature MM'. This would be the simplest explanation for a sharp melting point.

Our hole model with an interaction energy

$$E_{pot} = fZ\frac{R}{2}\frac{3}{2}T_c(1-x_F) \tag{33}$$

satisfies and specifies the idea of cooperative mechanisms. Where a defect is present at random the interaction energy is lower because of the smaller coordination number $Z(1-x_F)$. The probability of the occurrence of a second defect on further supply of heat energy is therefore shown by Eq. (33) to be higher in the neighborhood of a defect than in ordered defect-free regions.

10.2. Geometric Interpretation

According to an empirical rule due to *Lorenz*[31], the volume in the melt at T_m is:

$$V_m(T_m) = 1.2\, V_0(T=0\,K) \tag{34}$$

For a densest packing of spheres with $Z=12$, the separation of the (111) molecular planes should become greater by a factor $\Delta h = 1.061$[5] as the distance between the spheres increases as a consequence of the increase in vibration volume with T, so that the spheres of one (111) plane can slide over the gaps between the spheres in a neighboring plane without geometric hindrance[5] (see Fig. 7: direction of motion perpendicular to the plane of the drawing). This would correspond, in analogy with the Lorenz rule, to an increase in volume to $V=(\Delta h)^3\ V_0 = 1.194\ V_0$.

The 20 % increase in volume is due to equal extents—about 10 % each—to the sudden increase in volume at T_m and to the thermal expansion on going from T_0 to T_m.

In order to permit the (111) planes to slide freely over the neighboring planes in all directions (see Fig. 7: movement from left to right), an increase in the distance corresponding to an increase in volume to $V=1.84\ V_0$ is necessary[5]. In the hole model for most substances with $T_c > 200$ K: $3.7 < \rho_0/\rho_c < 4$. This corresponds at T_c with $x_F = 50$ % to $1.92 < V_{c,id}/V_0 < 2$.

10.3. In the Hole Model

The enthalpy rises more slowly in solids than H_1 in liquids. We can explain this by assuming that the intermolecular degrees of freedom are not completely excited in the solid state or that they are partly coupled by phase relationships[32] (lattice vibrations). Consequently, their number in the second summand of Eq. (29) should be put at less than $Z/2$. This idea can be illustrated directly under a microscope in the crystallization of monodisperse latices[33] with particle diameters of about 1 μm. The Brownian motion of individual latex particles becomes unrecognizable when they are superposed on an energetically favorable gap (Kossel step) of an aggregation.

In this model the heat of fusion essentially causes an increase in the number of independent intermolecular degrees of freedom (of the order of 50 % of Z). This also counters the objection that small aggregates with a crystal-like structure should melt below T_m according to *Gibbs-Thomson*. The region of ordering of the liquid differs from the solid not least by the fact that there are no phase relationships between its units, *i.e.* no lattice vibration.

10.4. In the One-Dimensional Lennard-Jones Model

The one-dimensional Lennard-Jones model discussed in Section 9 has the remarkable property that at a separation of the outer particles of $r_0 = 1.2444\,\sigma$, at which their two pair potentials intersect precisely at the point of inflection, a very flat minimum occurs with almost equal potentials for a certain range of distances (see Fig. 17). Above these distances the potential then splits into two minima. The range of distances of the deep flat potential minimum corresponds to a volume change of about 10 %.

11. Application to More Complicated Problems

11.1. The Supercritical Region

The hole model also permits semiquantitative answers to complicated questions. Thus, just above the critical point a reduction in the defect concentration is to be expected. In the range $T_c < T < 1.1\ T_c$ in the X-ray scattering for $V < V_c$ liquid-like maxima of the radial distribution curve are observed, which disappear at $V > V_c$[34]. Correspondingly, in the same range of T pronounced anomalies of the enthalpy and of the isotherms appear for $V < V_c$. *Eucken* pointed out the remarkable behavior of the molar heat in this temperature range[35]. Along the saturation line below T_c the molar heat has a ridge-sharp maximum in the P, T diagram, which clearly extends as an extrapolation of the saturation line to $1.1\ T_c$. In the same way as the melt can be described as the remainder of a disturbed crystal structure, the supercritical region $T_c < T < 1.1\ T_c$ for $V < V_c$ can be regarded as the residue of a disturbed liquid structure[36]. Because $(\partial P/\partial V)_{T_c} = 0$ or $(\partial V/\partial P)_{T_c} = \infty$, high density gradients may arise in the gravity field, which explains the pronounced tendency toward convection up to $1.1\ T_c$[36, 37].

11.2. Adsorption and Separation Processes

The estimation of the pair potential of intermolecular forces from RT_c is useful for the estimation of many material properties. Starting from the quantum-mechanical approximation that dispersion forces in mixtures depend on the geometric mean of the pair potentials of the components[28], properties of binary mixed systems can be derived from $R\sqrt{T_{c1}\,T_{c2}}$ or according to Eq. (7) from $R\sqrt{C_1 C_2}$ (see, for example, Table 2).

Table 2. Experimental dissociation energies of diatomic species in comparison with model data.

	ΔH [cal/mol] [38]	C_1	C_2	$R\sqrt{C_1 C_2}$ [cal/mol]
Hg_2	1600 ± 400	880	880	1760
HgKr	800	880	184	804
HgAr	600	880	130	670

Correspondingly, the heat of adsorption $\Delta H_{ad} \approx ZR/\sqrt{T_{c,A}\,T_{c,a}}$ is proportional both to the root of the critical temperature $T_{c,A}$ of the adsorbent and also to $T_{c,a}$ of the adsorbate, while, as already mentioned, when T_c is unknown it is instead possible to use T_b or, with lower accuracy, T_m (with a proportionality factor) in order to obtain an estimate. With the same adsorbent A, the magnitude $\Delta H_{ad}/\sqrt{T_{c,a}}$ or an equivalent quotient of T_b should be constant for various adsorbates a. Some examples of this are known:

1) Adsorption of gases on charcoal ($\Delta H_{ad}/R\sqrt{T_b}$) according to *Eucken*[39]: H_2 (275), N_2 (257), CO (265), CH_4 (260), C_2H_4 (260), C_2H_2 (290), CO_2 (287), NH_3 (287), CH_3OCH_3 (285) (cf. [40]).
2) Adsorption of gases on silica gel ($\Delta H_{ad}/R\sqrt{T_c}$) according to *Cremer* and *Prior*[41]: C_2H_4 (185), CO_2 (185), C_2H_2 (195), CH_2CHCl (191).

In some cases a proportionality between ΔH_{ad} and $T_{c,a}$, but not $\sqrt{T_{c,a}}$, has been reported[42–44]. This obviously relates to a multilayer adsorption, for which the interaction of the adsorbed molecules with one another is decisive[45].

Summarizing, it can thence be seen that in the case of a separation by adsorption, as for example in chromatography, the retention time may be expected to be proportional to $T_{c,a}$ or $T_{b,a}$ if highly polar substances and, in particular, those forming H-bonds are excluded. This fact came to light already in the pioneer investigations on gas chromatography by *Peters* and *Weil*[46] and by *Cremer* and *Müller*[47], in which the sequence of the retention times of a mixture of gases[47] $N_2 < C_2H_4 < C_2H_2$. This can be correlated with the sequence of the Sutherland constants N_2 (127) < C_2H_4 (283) < C_2H_2 (309).

Similar relationships are established with the results[48,49] of column chromatography, where the adsorbability generally agrees with the sequence of the melting points (T_m in °C), *e.g.*: 1,8-diphenyloctatetraene (225) > 1,6-diphenylhexatriene (194) > 1,4-diphenylbutadiene (152) > stilbene (124) > biphenyl (70). Since T_c and T_b increase approximately as the square root of the molecular weight (highly polar substances representing an exception), the adsorbability, and therefore the separation effect too, show a tendency to increase with molecular weight[50] or, in homologous series, with chain length[51,52].

When the adsorbents are changed[49], their adsorption capacity for the same adsorbate generally falls with their melting point, *e.g.*: Al_2O_3 (T_m = 2040 °C) > CrO_3 (1990) > ZnS (1900) > CaF_2 (1360) > $CaCO_3$ (1339).

Because of the high critical temperature and the high intermolecular energy of the adsorbents, the condition $L_V < L_p < \Delta H_{ad}$ is always satisfied, which explains the better separation effect of adsorption processes as compared with simple distillation (see Table 3).

Table 3. Comparison of the separation effect of distillation and adsorption on wood charcoal.

	L_P [cal/mol]	ΔH_{ad} [cal/mol]	$e^{-L_P(H_2)/RT}/e^{-L_P(N_2)/RT}$	$e^{-\Delta H_{ad}(H_2)/RT}/e^{-\Delta H_{ad}(N_2)/RT}$
H_2	220	2500	0.69 : 0.11 = 6.3	0.15 : 0.006 = 25
N_2	1330	4400		

11.3. Spectroscopy

The ordering principle of intermolecular effects based on the critical temperature applies for the most diverse material properties. Thus, the IR frequency shift $\Delta\nu$ observed by *Barnes et al.*[53] for HCl by the low-temperature matrix technique can be arranged according to the T_c values of the matrices used; $\Delta\nu$ is a measure of the interaction[54]. Similarly, the $\Delta\nu$ of the UV bands of benzene in various solvents[55] can be correlated with the T_c of the solvent. The solubility of gases in 2,2,4-trimethylpentane, investigated by *Wilhelm* and *Battino*[56], can also be explained in a simple manner on the basis of the T_c values of the gases. In all these applications, however, substances with extensive hydrogen bonding are excluded[2,3]. These will be described in a subsequent paper. Liquid metals must also be discussed separately.

At the end of the twenties, H. Mark and H. Meyer were the first to found a research team for the "molecular engineering" mentioned in the introduction, at the Ludwigshafen plant of IG Farben—later BASF AG. After the war, its reconstruction was entrusted to me by W. Reppe. This gave the initial impetus to the present study, and for this opportunity I am indebted to the research directors of BASF.

I am also grateful to the Deutsche Forschungsgemeinschaft for supporting further investigations, to W. Ditter for discussion contributions, and to M. Kuballa and G. Schietke for molar heat measurements.

Circular Dichroism and Absolute Conformation: Application of Qualitative MO Theory to Chiroptical Phenomena[1]

By Günther Snatzke[*]

Although chiroptical methods have been used in chemistry for some 150 years, and the basic theory was developed by *Rosenfeld* 50 years ago, their success in determining absolute conformation rests mainly on empirical rules. Some of these can be proved theoretically; however, in the case of more complex molecules this is not yet always possible. In what follows, an attempt is made to bridge the wide gap between theory and empiricism: "qualitative MO-theory", which has already been successfully used to explain reaction mechanisms, the shape of molecules, or photoelectron spectra, can also be applied to circular dichroism (CD). In general we shall have to be content with a reasonable interpretation of the experimentally determined sign correlation, but even this will be of great value since it can yield general relations between the geometry of molecules and the sign of CD. Such relations become particularly important when only a few examples of a given chromophore are known. If first and second sphere of a molecule are achiral then sector rules can be put forward, and in other cases helicity or chirality rules.

1. Chiroptical Phenomena

Circular dichroism (CD) is nowadays the most frequently used chiroptical method [others involve *e.g.* measurement of optical rotation or optical rotatory dispersion, ellipticity, Raman-CID ("Raman Circular Intensity Differential"), CD in emission bands] and is defined as the difference of the molar decadic absorption coefficients $\Delta\varepsilon \equiv \varepsilon_L - \varepsilon_R$ for left and right circularly polarized light[2]. CD can therefore be observed only within absorption bands. These are mostly due to electron excitations in the VIS- or UV region of the spectrum, but the occurrence of CD within vibrational bands has also been experimentally proved[3]. In an unordered phase (*e.g.* solution, vapor), CD (a "Cotton effect") appears only when the respective molecules are chiral, *i.e.* if they are not congruent with their mirror image. However, this statement is not reversible:

[*] Prof. Dr. G. Snatzke

Postfach 102148, D-4630 Bochum 1 (Germany)

© *Verlag Chemie, GmbH, 6940 Weinheim, 1979* *0570-0833/79/0505-0363 $ 02.50/0*

although each molecule of a racemate is chiral, compensation precludes measurement of optical activity.

It is now our aim to correlate the *substance property CD* with the *geometric property chirality* (absolute conformation[*]) of the pertinent molecules.

2. Transition Moments in Electronic and CD Spectra

Light is well known to be electromagnetic radiation, whose electric field vector $\mathfrak{E}$ at each point oscillates at the frequency ν as a cosine function. "Allowed" (mostly $\varepsilon \geq 10^4$) excitation of a molecule by light is possible only if 1) the energy difference between the excited and the ground state is $E_a - E_g = \Delta E = h\nu$, and 2) the transition of the electron from the initial into the final orbital is associated with a charge migration, which leads to an electric dipole (transition moment $\vec{\mu}$)[4]. This is most readily established qualitatively by group theory: the direct product of the irreducible representations of the two orbitals engaged in the excitation must contain one component of the translation (T_x, T_y, T_z)[5]. A quantitative answer requires extensive calculations[6]; however, the following estimation will frequently suffice: The better the overlap between the respective orbitals, the larger will be ε. The following simple "recipe" yields both[7]: initial and final orbital are formally multiplied together; this procedure generally yields a multipole (*e.g.* a quadrupole Q). If the centers of gravity of positive and negative charge form a dipole then this excitation is electrically allowed and the line connecting the centers of gravity of the two charges yields the direction of the charge translation during excitation, *i.e.* the direction in which the excitation is "polarized". Examples of this formalism will be given in what follows.

The intensity of light absorption within a band can be described by the integrated absorption

$$\int_{\lambda_1}^{\lambda_2} \frac{\varepsilon(\lambda)}{\lambda} \mathrm{d}\lambda$$

better than by ε_{max}; it is essentially the area of the band[4]. If this experimentally accessible value is multiplied by

$$\frac{3hc \times 10^3 \ln 10}{8\pi^3 N_L} = 0.918 \times 10^{-38}$$

the "dipole strength" D is obtained, which according to theory is equal to the square of the electric transition moment $\vec{\mu}$

$$D = \mu^2 = \frac{3hc \times 10^3 \ln 10}{8\pi^3 N_L} \int_{\lambda_1}^{\lambda_2} \frac{\varepsilon(\lambda)}{\lambda} \mathrm{d}\lambda \qquad (1)$$

This equation (1) relates the measurable substance property "area of band" with the theoretically calculable molecular property "transition moment".

[*] The term "absolute conformation" is used here by analogy with "absolute configuration": The conformation of a molecule is known if we know the magnitudes and relative signs of all torsion angles. If we also know which one is positive, and which one is negative, we have then determined the "absolute conformation".

CD can only occur within an absorption band if the electron excitation is associated not only with a charge translation $(\vec{\mu})$ but also with a charge rotation; the electron thus formally has to be excited along a helical path[6, 8]. Each rotation of electric charge around an axis is equivalent to a circular current, which according to *Biot-Savart* creates a magnetic field proportional to the area enclosed by the path of the point charge; this magnetic field can in our case be described by a magnetic transition moment $\vec{m}$[9]. Once again both methods mentioned for $\vec{\mu}$, *viz.* group theory and formal orbital multiplication, yield the approximate magnitude and direction of $\vec{m}$ during an excitation.

The integral circular dichroic absorption is a better quantitative measure for CD than $\Delta\varepsilon_{max}$

$$\int_{\lambda_1}^{\lambda_2} \frac{\Delta\varepsilon(\lambda)}{\lambda} \mathrm{d}\lambda$$

i.e. essentially the area under the CD curve; multiplication of this experimentally accessible value by

$$\frac{3hc \times 10^3 \ln 10}{32\pi^3 N_L} = 0.229 \times 10^{-38}$$

(for theoretical reasons this factor is only one fourth of the factor for D), one obtains the "rotational strength" R, which also can be obtained by calculation[10]:

$$R = \mu m \cos(\vec{\mu}, \vec{m}) = \frac{3hc \times 10^3 \ln 10}{32\pi^3 N_L} \int_{\lambda_1}^{\lambda_2} \frac{\Delta\varepsilon(\lambda)}{\lambda} \mathrm{d}\lambda \qquad (2)$$

The occurrence of CD thus not only requires that the transition be associated with an electric $(\vec{\mu})$ and a magnetic $(\vec{m})$ moment but also precludes orthogonality of these moments; $\vec{\mu}$ and $\vec{m}$ must have components in the same direction. If the angle between $\vec{\mu}$ and $\vec{m}$ is acute (extreme case: parallel arrangement), eq. (2) shows the CD to be positive; if the angle is obtuse (extreme case: antiparallel arrangement) then the CD is negative. We thus obtain the sign of the CD provided we can determine the mutual relative orientation of $\vec{m}$ and $\vec{\mu}$ for a transition.

3. Classification of Chromophores; g Values

Absorptions which are not associated with a transition moment $\vec{\mu}$ should not be observable in spite of meeting the condition $\Delta E = h\nu$. That they can still occur (albeit with relatively small ε) is attributable mainly to modification of the symmetry of the chromophore by non-totally-symmetric vibrations, the forbidden transition then "stealing" intensity from an allowed transition[4]. The order of magnitude of $\vec{\mu}$ for an electric dipole allowed transition is one Debye ($\mu_D = 10^{-18}$ cgs units), and that of $\vec{m}$ for a magnetically allowed transition is one Bohr magneton ($\mu_B = 0.927 \times 10^{-20}$ cgs units); $\vec{m}$ can also be "stolen" from other transitions *via* vibrations if necessary. As shown by group theory, $\vec{\mu}$ and $\vec{m}$ can have components in the same direction only in the case of chiral chromophores; to a zero approximation CD can therefore only occur in

such cases. *Moscowitz*[11] therefore divides chiral molecules into two classes, *viz.* those which contain an inherently chiral chromophore (class I) and those whose chromophore is locally achiral but is perturbed by its chiral surroundings (class II).

W. Kuhn has introduced the wavelength-dependent g value[12] for the characterization of optically active compounds by means of the definition

$$g = \frac{\Delta\varepsilon(\lambda)}{\varepsilon(\lambda)} = 2\frac{\varepsilon_L - \varepsilon_R}{\varepsilon_L + \varepsilon_R} \tag{3a}$$

(the conventionally measured ε value is an average value $\varepsilon = (\varepsilon_L + \varepsilon_R)/2$), or as a number characterizing the whole band[10]:

$$g^I = 4R/D \tag{3b}$$

From (1) and (2) it follows that

$$g^I = 4\mu m \cos(\vec{\mu},\vec{m})/\mu^2$$

and is therefore of the order of magnitude $g^I \approx m/\mu$; for allowed bands of substances, whose molecules belong to *Moscowitz*'s class I, the g^I value is therefore approximately

$$1\,\mu_B/1\,\mu_D \approx 10^{-2}$$

For molecules of class II $g^I < 10^{-2}$ (mostly $\approx 10^{-4}$) for a given transition if it is electrically allowed but magnetically forbidden; however, the value is $> 10^{-2}$ (mostly between 5×10^{-3} and 10^{-1}) if the transition is magnetically allowed and electrically forbidden. The magnitude of the g value is therefore a good means of identifying the type of a transition[8].

From the practical point of view, it proved convenient to further subdivide class II[13]. To this end the molecule is divided into spheres; the chromophore itself forms the first sphere, and any ring possibly incorporating the chromophore forms the second one. Groups or rings connected with this make up the third sphere, *etc.* Accordingly, molecules with a chiral first sphere belong to *Moscowitz*'s class I. It turned out for practically every chromophore that the chiral sphere nearest to the chromophore mainly determines the sign and magnitude of the Cotton effect. A few apparent exceptions[14] can be explained if the chirality of the chiral sphere nearest to the chromophore is quite small while that of the following one is very large.

If we know the exact geometry of a molecule, as well as the chromophore and electron excitation responsible for a band, then the electric and the magnetic transition moment can be calculated, and thus also the CD. However, such calculations involve enormous expenditure and their results depend on the chosen approximation (sometimes this even applies to the sign!). Of the many relevant publications only a few may be cited here[15-26]. In many cases, however, general predictions about CD can also be obtained with the aid of simple MO arguments, an approach adopted *e.g.* with great success in interpreting photoelectron spectra[27]. This "elementary" procedure depends upon which chiral sphere is nearest to the chromophore, and uses the formal multiplication method mentioned in Section 2 for determining $\vec{\mu}$ and $\vec{m}$. When using this procedure it must be born in mind that the signs of the phases within each lobe of an MO (*e.g.* $\Psi_1 = \pi$ or $\Psi_2 = \pi^*$ of an olefin, Fig. 1) have no physical meaning; only their relative distribution is important. They are therefore not indicated by + or −, but by hatching or non-hatching. The meaning of the product $\Psi_1 \otimes \Psi_2$ (only real MOs are considered) within the common region of space (orbitals actually extend to infinity, but the value of Ψ decreases rapidly with the distance from the nucleus) is that of an electron density (or electron probability) function; where $\Psi_1 \otimes \Psi_2$ is positive the charge is negative, and *vice versa*[7]. This determines the direction of the transition moment $\vec{\mu}$ (from the positive to the negative pole), which of course still depends on the arbitrary initial choice of the relative phase signs in Ψ_1 and Ψ_2. The signs of the charges acquire significance only after correlation with the direction of $\vec{m}$.

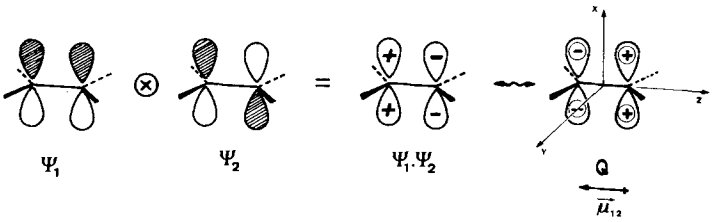

Fig. 1. Determination of the transition moments for a $\pi_x \rightarrow \pi_x^*$ transition. The two p-AOs which make up the MOs occupy practically the same space; overlap is optimal. The electron density distribution created by this transition is described [4, 7] by the product function $\Psi_1 \otimes \Psi_2$; it is obtained by formal multiplication of the orbital functions. A negative charge corresponds to a positive electron density and a deficit of electrons (during the excitation), and a positive charge to a negative one. $\Psi_i \otimes \Psi_2$ therefore describes a quadrupole Q (right), whose signs oppose those of $\Psi_1 \otimes \Psi_2$. In the quadrupole drawn the two partial dipoles add up to a dipole $\vec{\mu}_{12}$ along the z axis, whose direction depends on the (arbitrary) choice of the phase signs within the lobes of the orbitals, and which has no physical significance (energy transfer from the photon to the molecule is possible if the electric field vector $\mathfrak{E}$ points in the $(+z)$- or in the $(-z)$ direction). No charge rotation results, however ($\vec{m} = 0$).

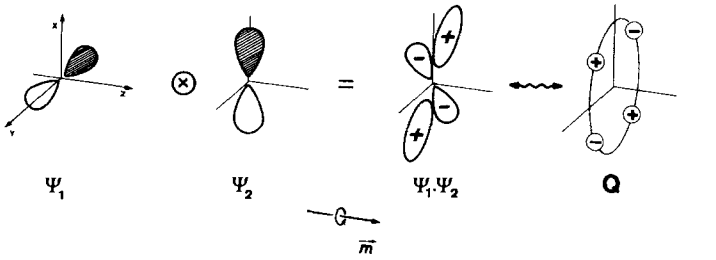

Fig. 2. Determination of the transition moments for a $p_y \rightarrow p_x^*$ transition. The overlap is much smaller than for the case shown in Fig. 1. The quadrupole Q obtained in analogous manner does not correspond to a dipole, since the two partial dipoles compensate each other for symmetry reasons; therefore $\vec{\mu}_{12} = 0$. On the other hand, electron charge is rotated during this excitation; the "right-hand rule" indicates the direction of the associated magnetic transition moment $\vec{m}$, which, however, again depends on the (arbitrary) choice of the signs of the orbital lobes.

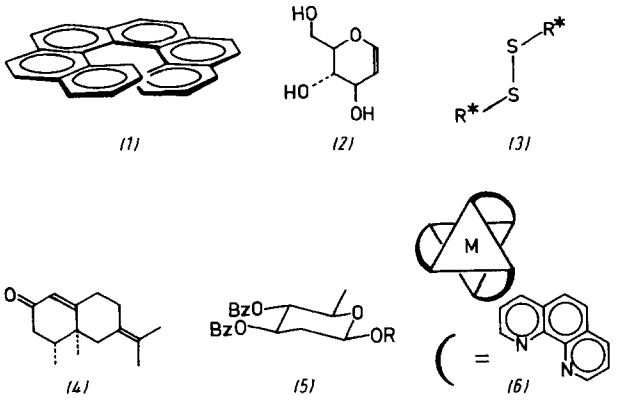

The magnetic transition moment $\vec{m}$ is generally associated with the appearance of an electrical quadrupole Q, and Figure 2 shows the relation between the two for the case $\Psi_1 = p_y$ and $\Psi_2 = p_x$. The orbital lobes of Ψ_1 are rotated through the smaller angle in such a way relative to those of Ψ_2 that like phase signs become superimposed, and this determines the direction of $\vec{m}$ according to the right-hand rule[*] (Fig. 2). Formal multiplication yields four regions of alternating signs for the product $\Psi_1 \otimes \Psi_2$ separated by nodal planes; the signs

[*] This rule states: If the 2nd through 5th finger of the right fist follow the movement of the orbital lobes then the thumb points in the direction of $\vec{m}$.

of the four "poles" of this quadrupole Q (essentially of its (x,y) component) again follow by sign inversion (Fig. 2, right). Thus if the sign pattern of Q is known, then the direction of $\vec{m}$ follows from Figure 2 provided it is known which of the two orbitals Ψ_1 and Ψ_2 is the initial orbital and which is the final one.

4. The Chiral First Sphere

Typical examples are hexahelicene *(1)*, glycals like *(2)*, chiral disulfides *(3)*, noncoplanar conjugated enones *(4)*, chiral dibenzoates *(5)*, or octahedral complexes with three bidentate ligands *(6)*. Two types may be recognized: those in which the σ skeleton of the chromophore, and therefore also at least one of the two MOs involved in the excitation, may be chiral [*(1)–(4)*], and those in which two or more achiral chromophores are in a chiral mutual arrangement and so

(1) *(2)* *(3)* *(4)* *(5)* *(6)*

close together that, according to the exciton theory[8, 28–31], the excitation cannot be localized in one individual chromophore [*(5)*, *(6)*, but also polymers with periodically ordered structure such as the α- or β form of proteins; base-stacked forms of nucleic acids]. In the case of C_2-symmetry of the whole chromophore, the signs of the CD can be determined by a general rule given by *Hug* and *Wagnière*[32]. This is possible even for such complex chromophores as *(1)*; however, it requires an exact identification of the transitions for the many bands in the spectrum. An "elementary" treatment seems not very reasonable for *(1)*.

In glycals such as glucal *(2)*, the enol ether system has to be regarded as the chromophore, and is isoelectronic with the allyl anion. On incorporation into a dihydropyran ring, this chromophore cannot be arranged in a single plane, and crystal structure analysis of several such compounds shows that the deviation from coplanarity is either equally distributed over the C=C and the C—O bond, or that the latter is "softer" and its twist is therefore larger than that of the former[33, 34]. Figure 3a shows the HOMO and LUMO of the allyl anion. In comparison, the symmetry is somewhat perturbed for an enol ether and for π^0 a small electron density appears also on the central atom [C(1) of *(2)*][35]; however, the MO picture is only insignificantly changed. For example, if we assume a negative torsion angle $\omega_{C(5)-O-C(1)-C(2)}$ in *(2)* as drawn in Figure 3b then formal multiplication of Ψ_g with Ψ_a gives a picture of the kind shown in Figure

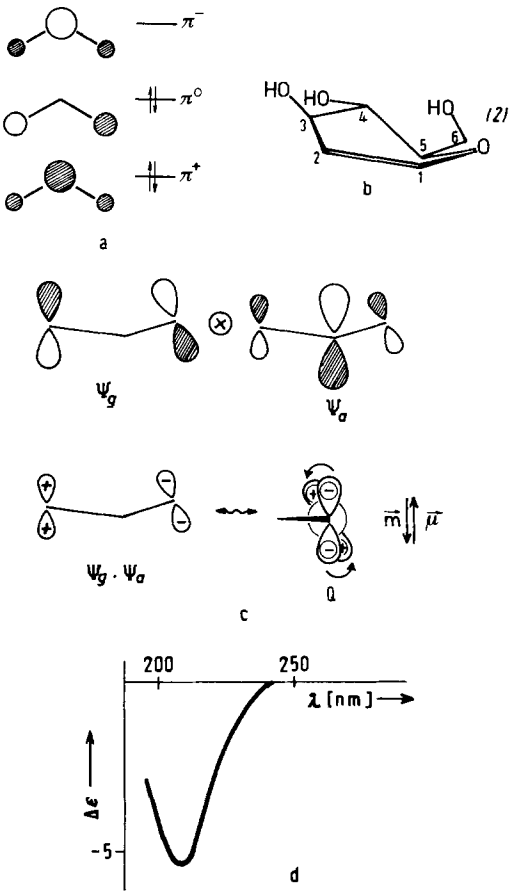

Fig. 3. The inherently chiral enol ether chromophore. a) The three MOs of the isoelectronic allyl anion; b) favored conformation of D-glucal *(2)*; c) chirality of the initial ($\Psi_g = \pi^0$) and final MO ($\Psi_a = \pi^-$), product of the two, and resulting quadrupole Q. The charge translation ($\vec{\mu}$) is in this case associated with a charge rotation ($\vec{m}$); the two partial dipoles are not parallel as in Fig. 1, but oblique to each other. The arrangement describes a left-handed screw; $\vec{m}$ and $\vec{\mu}$ are thus antiparallel and the CD is therefore negative. d) CD of D-glucal in acetonitrile.—Any other choice of the phase signs of the MOs must, of course, also lead to a left-handed screw for this transition.

3c: the centers of gravity of the positive charges lie on a line which is oblique to the line connecting the centers of gravity of the negative charges. If, in the course of excitation, electron charge is translated, say, from the oxygen towards C(2), then according to Figure 3c a concomitant charge rotation around the connecting line O—C(2) occurs. According to the right-hand rule $\vec{m}$ is therefore antiparallel to $\vec{\mu}$ ("the excitation takes place along a left-handed screw"), and the CD for this band should be negative, as has indeed been found for several D-glycals around 195—210 nm[36].

This example also demonstrates another point: the measured CD of a glycal reveals the sign of the torsional angle $\omega_{C(5)-O-C(1)-C(2)}$; the *absolute conformation* of the enol ether moiety is therefore derivable. In order to infer from this the *absolute configuration* we have first to correlate configuration and conformation. This can be done, *e.g.* by conformational analysis, discussion of NMR spectra, or resorting to X-ray diffraction analysis. In our example of glucal *(2)* the absolute conformation of the ring is determined from the negative CD (Fig. 4). A simple conformational analysis, which is in agreement with the X-ray analysis of similar products[34], shows that the absolute conformation found is compatible only with the D-configuration of glucal. *The absolute configura-*

tion can thus be determined from the CD only indirectly, not directly.

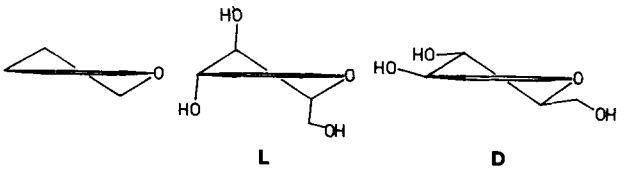

Fig. 4. Left: conformation of the helical dihydropyran ring of a glycal, as derived from the CD (cf. Fig. 3). Center and right: stereoformulae for L- and D-glucal with this conformation of the ring. It is the energetically least favored one for the L-form (all substituents axial), the most favored one for the D-form (all substituents equatorial).

For disulfides such as *(3)* the preferred conformation[37] is that in which the torsional angle around the S—S bond is approximately 90°. In order to understand their CD we have first to discuss the thioethers. The HOMO is shown by several calculations[22] to be the n_x orbital (Fig. 5); in the

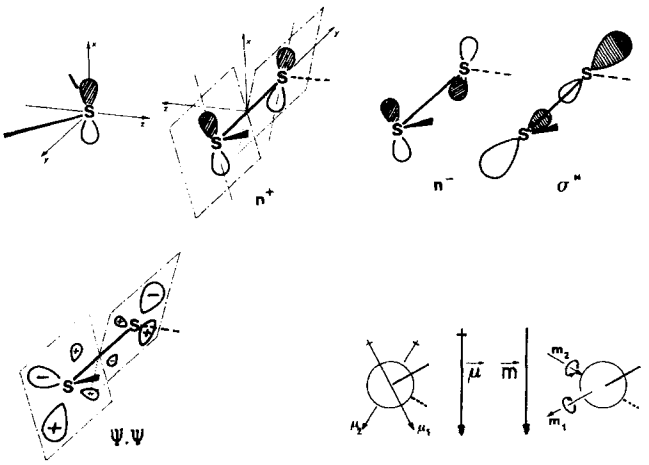

Fig. 5. The chiral disulfide chromophore. Top, HOMO of a thioether chromophore [22]; center, its two possible combinations n^+ and n^-, and LUMO of the disulfide [16]. A chiral conformation with positive torsion angle (<90°) was chosen. n^- contains (perpendicular to the S—S bond) one nodal plane more than n^+ and therefore has a higher energy than n^+. Bottom left, formal MO multiplication ($n^- \otimes \sigma^*$). An octupole is obtained, which consists of two quadrupoles. Because of the (albeit slight) overlap of the (mainly) p_x-AO on one S atom with the p_y-AO on the other S atom the "inner" poles are smaller than the "outer" ones; the partial dipoles no longer compensate each other (as was the case in Fig. 2). Bottom right, resulting direction of the electric and magnetic transition moments on S-1 and S-2, and their respective sum moments $\vec{\mu}$ and $\vec{m}$. These are parallel to each other, and a positive torsion angle (<90°) of the C—S—S—C chromophore therefore leads to a positive CD for the absorption band at longest wavelengths. Another choice of the phase signs of the involved MOs might change the direction of the individual transition moments, but not the mutual orientation of the sum moments; they always remain parallel for the chosen absolute conformation.

case of disulfides, these respective orbitals on the two S atoms have to be combined because of mutual overlap, and for a torsion angle $\omega_{C-S-S-C} < 90°$ the n^+-MO is energetically favored over n^-, which has one nodal plane perpendicular to the S—S bond; the latter is therefore the HOMO for the disulfide chromophore[16]. The LUMO is σ^* of the S—S group. Formal multiplication of HOMO and LUMO yields an octupole (Fig. 5), whose charges are, however, "outside" larger than "inside"; in spite of partial compensation there thus arises an electric transition moment $\vec{\mu}$, which points in the $(-x)$ direction if the signs of HOMO and LUMO are chosen in the given manner. Furthermore, on each of the two S atoms electronic charge is rotated around the bond leading to the next C atom, and the directions of the corresponding local magnetic transition moments $\vec{m}_1$ and $\vec{m}_2$ follow from the right-hand rule; their sum vector $\vec{m}$ is arranged parallel to $\vec{\mu}$. For a positive torsional angle $\omega_{C-S-S-C} < 90°$ a positive CD is thus predicted for the band at longest wavelengths[16], as is also found experimentally[38]. The next band, corresponding to the $n^+ \rightarrow \sigma^*$ transition, then shows a negative Cotton effect for the same absolute conformation of the C—S—S—C chromophore, as can be derived analogously. If the torsion angle is larger than 90°, then $\vec{\mu}$ and $\vec{m}$ for the band at longest wavelengths (now formally $n^+ \rightarrow \sigma^*$) are arranged in the manner just derived for the second transition, and the sign of the CD must therefore be negative. This has also been confirmed experimentally[39].

For $\omega_{C-S-S-C} = 90°$ the orbital energies of n^+ and n^- are equal; the orbitals are degenerate and the two CD bands of opposite sign compensate each other. The inherent chiral CD contribution is thus zero in spite of the chiral arrangement of the C—S—S—C moiety; of course, a weak CD from approximations of higher order still remains. Improved calculations do not change this picture in principle; the degeneracy may

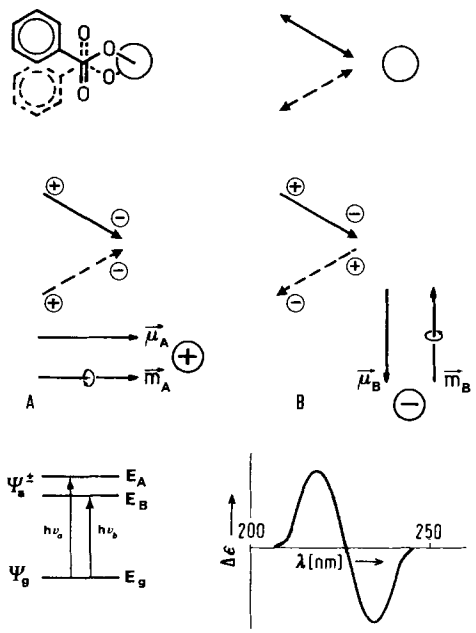

Fig. 6. Coupled oscillators: The chiral dibenzoate chromophore. Top left, preferred conformation of the benzoate groups of a 1,2-glycol dibenzoate [42]. The chosen absolute conformation is characterized by a negative torsion angle. Top right, relative orientation of the strong electric transition moments (CT transition) of the two benzoate chromophores. Center, the two possible combinations (A and B) of the mutually inclined transition moments. A, the total electric transition moment is oriented along the C_2 axis of the dibenzoate chromophore; the charge rotation created by the combined action of the two partial moments corresponds to a right-handed helix. $\vec{\mu}_A$ and $\vec{m}_A$ are therefore parallel, and the corresponding CD is positive. (The charge rotation can be recognized very simply by envisaging the total $\vec{\mu}$ as the axis of a cylinder, and the two individual $\vec{\mu}$ as tangents to this same cylinder.) B, the electric total transition moment is perpendicular to $\vec{\mu}_A$ (and lies in the plane of the figure), the magnetic transition moment $\vec{m}_B$, obtained as for A, is oriented antiparallel to $\vec{\mu}_B$, and the CD of the corresponding band is therefore negative. Bottom, relative energies of the two excited states: for A the two poles of same signs are closest to each other, and the overall interaction is therefore repulsive. For B the total interaction is attractive, and the energy of the combination A is therefore higher than of the combination B; accordingly, λ_A is smaller than λ_B. The resulting "CD couplet" is negative; its branch at longer wavelengths is negative, and that at shorter wavelengths positive. In analogous manner, a positive couplet is obtained for an absolute conformation with positive torsion angle [30, 40].

just appear at angles $\omega_{C-S-S-C}$ somewhat larger or smaller than 90°, depending *e.g.* on the bond angle Θ_{C-S-S}[16].

Dibenzoates likewise contain an inherently chiral chromophore[30,40]. Benzoates have a very intense absorption band around 230 nm, corresponding to a "charge-transfer transition" ("conjugation band" between benzene ring and COOR moiety), whose $\vec{\mu}$ is thus very large. The direction of $\vec{\mu}$ is only insignificantly inclined to the bond between the benzene ring and the C of the ester moiety (approximately 6.5° in the plane of the whole system), and thus lies approximately parallel to the C—O bond of the alcohol moiety[41], if the preferred conformation[42] of the benzoate group is assumed (see Fig. 6). For a dibenzoate of a 1,2-cyclohexanediol the torsional angle between these bonds is either about 60° (e-e, e-a, a-e) or somewhat smaller than 180° (a-a); the first three arrangements are therefore chiral, and the latter is approximately achiral. According to the exciton theory[23,29], in the case of chromophores which are closely adjacent to each other (they need not be identical as in our example) the site of excitation—first or second chromophore—cannot be localized (this would violate *Heisenberg*'s uncertainty principle).

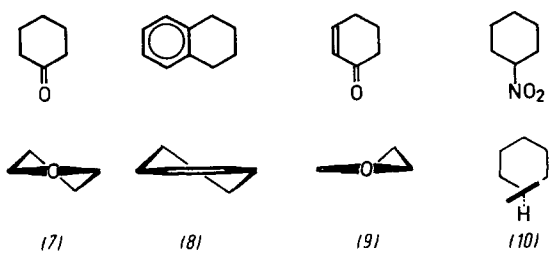
If we designate the "local" orbitals in the ground state as Φ_{ig} ($i=1, 2$), and those in the corresponding excited state as Φ_{ia}, then of course only a single ground state exists for the whole molecule ($\Psi_g=\Phi_{1g}\cdot\Phi_{2g}$), whereas the excited state is degenerate, because it can result on excitation within chromophore 1 ($\Phi_{1a}\cdot\Phi_{2g}$) or within chromophore 2 ($\Phi_{1g}\cdot\Phi_{2a}$). As always in such cases, these two states interact, leading to a splitting of energy levels ($N^{\pm}$ are normalizing factors; (4) is valid for two like chromophores):

$$\Psi_a^{\pm}=N^{\pm}(\Phi_{1a}\cdot\Phi_{2g}\pm\Phi_{1g}\cdot\Phi_{2a}) \qquad (4)$$

As easily proved by calculation, $\vec{\mu}$ for the two transitions $\Psi_g\rightarrow\Psi_a^+$ and $\Psi_g\rightarrow\Psi_a^-$ is given by the sum of the two "local" transition moments for $\Phi_{1g}\rightarrow\Phi_{1a}$ and $\Phi_{2g}\rightarrow\Phi_{2a}$; each of the two possible relative phase relations (A and B in Fig. 6) must be chosen once. Coupling of the two moments $\vec{\mu}$ leads then to parallel (A) and antiparallel (B) arrangement of $\vec{\mu}$ and $\vec{m}$, and the sign of the CD is immediately derived therefrom (in the present case: $\Delta\varepsilon$(A) positive, $\Delta\varepsilon$(B) negative). Because $h\nu_i=E_{ia}-E_g$ ($E_{ia}=E^+$ or E^-) the position of the bands is solely determined by the energy in the excited state.

However, the relative magnitudes of E_A and E_B cannot always be estimated so easily as in the example of dibenzoates. Figure 6 shows that the most important interaction (*viz.* that between the "poles" separated by the shortest distance) is repulsive for combination A and attractive for B if the torsion angle $\omega_{O-C-C-O}$ is negative. A therefore has higher energy, and B lower energy, $h\nu_A>h\nu_B$, or $\lambda_A<\lambda_B$. The negative Cotton effect (B) is therefore at longer wavelength, and the (equally large) positive one (A) at shorter wavelengths; for this absolute conformation a "negative couplet"[28,43] arises. This result is in agreement with experiment. However, the two benzoate groups need not be linked to adjacent C atoms in order to apply the method of "coupled oscillators" (also called[30,40] the "exciton chirality method"). Although this method is very valuable for the determination of absolute conformation, it must nevertheless be confined to those cases in which both transition moments are large, the position of the individual transition moments is well known, and the "geometric factor"[28] (relative energy difference between A- and B coupling) can be derived unequivocally from the geometry of the molecule.

5. The Achiral First Sphere



In order for CD to occur in a given electron transition of molecules in which the first sphere is achiral, one has to "steal" from some other transition the missing transition moment lying in the direction of the present one. This second transition can be in the same chromophore ("intrachromophoric"), or in another one ("interchromophoric", *e.g.* a $\sigma\rightarrow\sigma^*$ transition within a C—C or C—H bond). Perturbation theory of first or second order then describes how the two transition moments are to be mixed. In the case of "static coupling" it is assumed that this mixing of MO states of different symmetry, which should be forbidden, can be brought about by the chiral positive residual field of the nuclei not fully shielded by their electrons[6,28]. In case of "dynamic coupling" this mixing is effected by induced multipoles (dipoles, quadrupoles, octupoles, ...) in other chirally arranged bonds of the molecule as a result of the electronic rearrangement which takes place in the chromophore on excitation[6,28].

In both cases the expression for the rotational strength R contains several terms, some of which describe a possible exciton interaction if the transition in question is associated with a strong electric transition moment. Others are of the form of products $\mu\cdot m\cdot\cos(\vec{\mu},\vec{m})$ ("optical factor"[28]), which have to be multiplied by a "geometric factor". The energies of the orbitals involved contribute to this geometric factor, as does the exchange energy between them, which, of course, must also depend on the geometry of the molecule. This will be explained in more detail in Section 8 taking the $n\rightarrow\pi^*$ band of oxo compounds as example.

The fact that groups or bonds close to the chromophore cause the most effective perturbation justifies the special significance of the chiral second sphere. Nevertheless, groups which are more distant may still provide an exceedingly large contribution to the CD, if a fully antiperiplanar (zig-zag shaped and coplanar) through-bond connection exists between them and the chromophore[44].

6. The Chiral Second Sphere

Figure 7 illustrates a few examples[2] [*(7)—(10)*] of chirality of the second sphere. Experience shows that in such cases

(7) *(8)* *(9)* *(10)*

Fig. 7. Examples for a chirality of the second sphere [2a]. All absolute conformations depicted give rise to a positive CD for the specified transitions: $n\rightarrow\pi^*$ band of a cyclohexanone *(7)* in twist form; B_{2u} band of a tetralin *(8)*; $n\rightarrow\pi^*$ band of a conjugated cyclohexenone *(9)* with coplanar arrangement of C=O and C=C; $n\rightarrow\pi^*$ band of an axial nitrocyclohexane *(10)*.

the contribution of the third (fourth, ...) sphere generally influences only the magnitude of the CD to a slight extent, but does not affect its sign. For a new chromophore it therefore suffices to examine the correlation between the CD sign and the absolute conformation of the ring for a few selected examples. A line of contiguous bonds within the second sphere is, by the way, not essential; the importance of the second sphere is mainly to fix the torsional angle around the bond between the chromophore and the next chirally arranged bond. (The mechanism of this chiral perturbation will be discussed in Section 7.)

7. The Chiral Third Sphere

Now chromophore and "skeleton" are locally achiral; only on suitable substitution (often with achiral groups) does the whole molecule become chiral (*e.g.* chirally substituted cyclohexanone in chair form). An algebraic treatment of this case has been published by *Ruch*[45] and two general solutions have been given for the chirality functions (and thus also for the rotational strength). For our purpose only the second one is important. According to this, each chirality function (χ) can be built up as a sum of simpler ones (ω), which are valid for chiral molecules of the same type in which the maximum number of identical ligands is present. This maximum number is called the "chirality order o". The number of atoms in general positions which are connected by the symmetry elements of the skeleton (*i.e.* which belong to the same "transitivity area") is *n*.

The difference $(n-o)$ can only be 1, 2, or 3, and the chirality functions for these three cases are

$$\chi_1 = \sum\omega(i); \quad \chi_2 = \sum\omega(i,j); \quad \chi_3 = \sum\omega(i,j,k)$$

The indices i, j, and k refer to symmetry equivalent ligand sites in the skeleton. The functions $\omega(i)$ thus depend only on the substituent at a single ligand site, $\omega(i,j)$ on two, and $\omega(i,j,k)$ on three substituents. Figure 8 demonstrates the

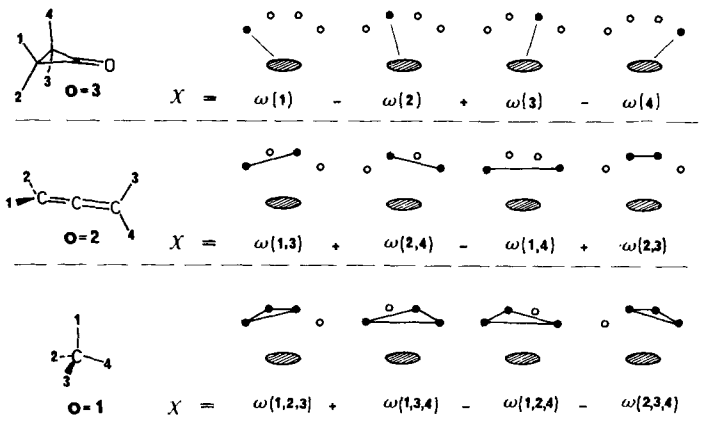


Fig. 8. Chirality functions χ for three molecules each having four ligands per transitivity area. The chirality functions ω refer to the corresponding chiral molecules with the maximal number of like ligands. The hatched area represents the chromophore, the four circles the ligands. Filled circles belong to those ligand sites which appear in the chirality functions ω. Top, carbonyl chromophore (*e.g.* in cyclopropanone), local C_{2v} symmetry, chirality order o = 3. Center, allene chromophore, local D_{2d} symmetry, chirality order o = 2. Bottom, asymmetric C atom as chromophore, local T_d symmetry, chirality order o = 1.

determination of o for three examples with $n=4$: for an asymmetric C atom as chromophore not even two ligands may be identical, and the chirality order is therefore o = 1; for allenes o = 2, and for cyclopropanones even three ligands may be identical and a chiral molecule is still obtained: o = 3. The chirality functions χ are also given in Figure 8, as well as their graphic interpretation. Only in the case of $(n-o)=1$ may specific increments appear for individual substituents; these are the functions $\omega(i)$ themselves, whereas in the other examples several terms $\omega(i,j)$ or $\omega(i,j,k)$ will change their values on replacement of one substituent by a new one. We may therefore expect a general sector rule to be valid only for the case $(n-o)=1$; in the other cases we can at best look for "special" sector rules, which are applicable, however, only when we keep one or two of the remaining substituents constant.

Having convinced ourselves, according to *Ruch*[45], that a sector rule may be valid at all for the chromophore in question then the simplest ("symmetry-determined") one can be found according to *Schellman*[46] by making the mirror planes of the chromophore into nodal planes of the sector rule (a nodal plane separates two adjacent sectors, within which the contributions to the CD have opposite signs for substituents arranged symmetrically with respect to each other; ligands lying within a nodal plane, make no contribution to the CD). We accordingly expect a "planarity rule" for an ester, a quadrant rule for a ketone, an octant rule for an olefin, a rule with 24 sectors for a benzene derivative, *etc.* To these nodal planes, however, must still be added "orbital-determined" nodal surfaces; these are nodal surfaces for the orbitals involved in the excitation, and they may be curved or even closed (finite) surfaces. These MO-determined nodal surfaces may of course be different for different transitions within one and the same chromophore. Their number can also depend on the type of approximation one is using. For example, the symmetry-determined quadrant rule for the 300 nm band of a ketone has to be extended to an octant rule to account for that nodal surface of the π^* orbital which cuts the C=O bond perpendicularly; if the n-orbital is also delocalized, then even more nodal surfaces have to be introduced[2,15]. The determination of the sign within different sectors will be described in what follows for the carbonyl and the benzene chromophore. Depending on the approximation used, intra- or interchromophoric terms may proponderate; the signs may therefore not always be predicted unequivocally.

8. The n→π* Band of Saturated Carbonyl Compounds

The n→π* transition in the carbonyl chromophore is correlated, according to Figure 2 (n-orbital = $p_{O,y}$; π^*-orbital = $N(p_{O,x}-p_{C,x})$, with a magnetic transition moment $\vec{m}$ in the direction of the C=O bond; a μ_z has to be "stolen" from another transition. In the intrachromophoric case, this can be, *e.g.*, the π→π* transition (*z*-allowed according to Fig. 1), a Rydberg transition[47], or a σ→σ* transition from the C=O bond; in condensed phase the π→π* transition is the most probable one. In formaldehyde itself there is no a_2-type normal vibration[5,47] which could lead to intensity stealing from such a *z*-allowed transition; however, the chiral

environment of the chromophore may lead to mixing of orbitals or states because of the lowering of the overall symmetry. Some time ago *Wagnière*[48] compared different mechanisms of such mixing; first-order perturbation theory leads to a quadrant rule, and only on incorporation of suitable d-orbitals or more prominent delocalization does the experimentally found octant rule[49] result.

For an electrically forbidden transition, the exciton terms mentioned in Section 5 may be dropped in the approximative formula for the rotational strength, and there remain the following four terms (first-order perturbation theory)[6, 15, 23, 28]:

$$R = T_1 + T_2 + T_3 + T_4 =$$

$$= \frac{2}{h} \frac{\nu_{0,k} \cdot V_{0,a(1);0,k(2)}}{\nu_{0,k}^2 - \nu_{0,a}^2} \cdot \mu_{0,k}(2) \cdot m_{0,a}(1) \cdot \cos(\vec{\mu},\vec{m})$$

$$+ \frac{1}{h} \frac{V_{a,b(1);0,0(2)}}{\nu_{0,b} - \nu_{0,a}} \cdot \mu_{0,b}(1) \cdot m_{0,a}(1) \cdot \cos(\vec{\mu},\vec{m}) \qquad (5)$$

$$+ \frac{1}{h} \frac{V_{0,b(1);0,0(2)}}{\nu_{0,b}} \cdot \mu_{a,b}(1) \cdot m_{0,a}(1) \cdot \cos(\vec{\mu},\vec{m})$$

$$+ \frac{1}{h} \frac{V_{0,a(1);0,0(2)}}{\nu_{0,a}} \cdot |(\vec{\mu}_{a,a}(1) - \vec{\mu}_{0,0}(1))| \cdot m_{0,a}(1) \cdot \cos(\Delta\vec{\mu},\vec{m})$$

In these formulae the subscript 0 refers to the ground state, a to the n→π* state of the carbonyl, b to another excited state in the same chromophore, and k to an excited state in the "perturbing chromophore" (*e.g.* a C—C bond arranged chirally with respect to the C=O group). The meaning of the interaction energy V is illustrated graphically in Figure 9, $m_{0,a}$ (1) is z-allowed, and its order of magnitude is the Bohr magneton μ_B.

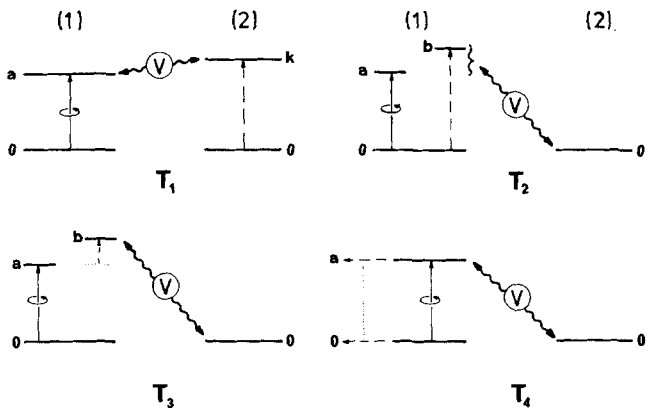

Fig. 9. Illustration of interaction energies V resulting from first-order perturbation calculations for the four terms T_1 to T_4 of eq. (5) [23]. (1) and (2) refer to two different chromophores in the same molecule (*e.g.* 1: C=O group, 2: C—C bond), 0 is the (common) ground state of the molecule; a and b characterize excited states of chromophore 1, and k an excited state of chromophore 2.

In the first term we need an electric transition moment in the z-direction from another chromophore; that may be a σ→σ* transition within a C—X bond. For the second term we have to obtain a μ_z from the carbonyl chromophore itself, and the energetically nearest excited (not Rydberg) state is the π→π* state. The third term may be neglected, as for this a transition from the first into another still higher excited state of a_2 symmetry is required; because of the denominator $\nu_{0,b}$, which is then quite large, the geometric factor will become relatively small. The fourth term contains a contribution from the difference of the permanent dipole moments for the first excited ($\vec{\mu}_{aa}$) and the ground-state ($\vec{\mu}_{00}$) of the carbonyl chromophore; this term is also of a lower order of magnitude than the first or the second.

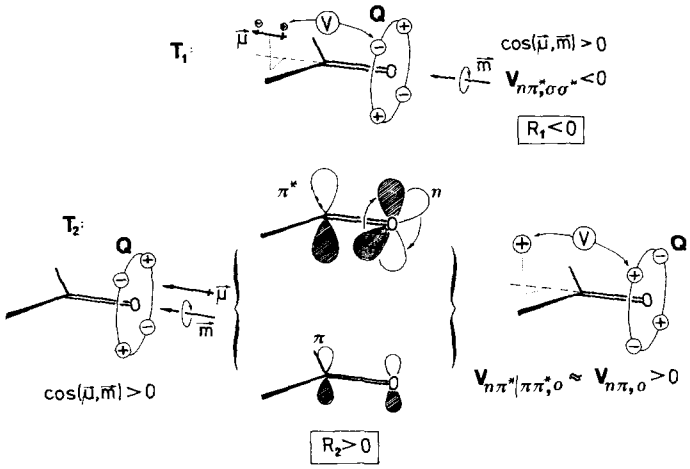

Fig. 10. Determination of the signs of the terms T_1 and T_2 in equation (5). Top, T_1. The transition 0→a of the carbonyl chromophore 1 is associated with a magnetic moment $\vec{m}$, and the transition 0→k in a C—C bond (chromophore 2) with an electric moment $\vec{\mu}$. For a C—C bond in the upper left back octant the direction of $\vec{\mu}$ was chosen arbitrarily such that it is parallel to that of $\vec{m}$ (also chosen arbitrarily). The "optical factor", $\cos(\vec{\mu},\vec{m})$ is therefore positive. The overall interaction of Q with $\vec{\mu}$ is attractive (for the correlation between Q and $\vec{m}$, cf. Fig. 2), the interaction potential V ("geometric factor") is negative, and the product of the two [$\cos(\vec{\mu},\vec{m})$ and V] is also negative. This "interchromophoric" interaction leads to a negative contribution to the CD, contradicting the experimentally found octant rule. Any other choice of the direction of the two transition moments gives the same result. Bottom, T_2. $\vec{m}$ is associated with the n→π* transition of the carbonyl chromophore; $\vec{\mu}$ is taken from the π→π* transition of the same chromophore ("intrachromophoric" interaction). Again both are chosen parallel to each other, and the optical factor is therefore positive. For instance, if we hatch the left lobe of the n orbital on oxygen, then the relative phase signs for π and π* result as given at the bottom (center; cf. also Fig. 1 and 2). According to theory, V is proportional to the energy between the perturbing partial charge and the quadrupole obtained by multiplication of the n- and π orbital (not π*!). The overall interaction of Q (bottom right) with a positive charge is repulsive, and V is therefore positive. $\cos(\vec{\mu},\vec{m}) \times V$ is also positive; a positive charge in the upper left back octant therefore gives a positive contribution to the CD. T_1 describes an octant rule, and T_2 a quadrant rule. The signs of the contributions to the CD also depend upon the sign of the perturbing charge.

The signs of the terms T_1 and T_2 are derived in Figure 10; if the positive residual charges of the nuclei which are not completely screened by their electrons[6, 15] are chosen as the chiral perturbation of the skeleton then a quadrant rule with the correct sign is obtained from T_2. The term T_1 does indeed yield an octant rule, but with the wrong signs. Clearly, the second term T_2 is the leading one. The experimentally established octant rule would also be obtained by admixture of 3d orbitals[15a]; however, their energy might differ too much[50]. Recent calculations which also account for delocalization of the n orbitals lead to the correct octant rule without any need for contributions from such d orbitals[15b-e].

Second-order perturbation theory[4, 7, 51, 52] also yields an octant rule with the right signs (Fig. 11). According to the general rules for interaction of orbitals we can undertake this mixing step by step. First of all, the mixing can be supposed to be caused by the energetically closest chiral orbital, a σ-MO from the C—C bond next to the chromophore (chiral second sphere!). As its energy is lower than that of π and n, we

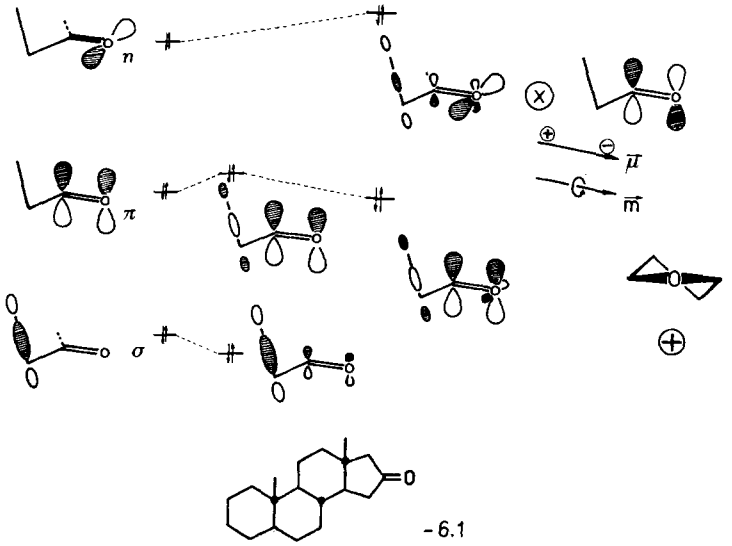

Fig. 11. Second order perturbation for ketones with chiral second sphere (mixing of MOs). The admixture (forbidden for symmetry reasons in formaldehyde) of π character to the n orbital of the carbonyl can be caused by a neighboring, chirally arranged σ bond. As the energy of a C—H bond is lower than of a C—C bond, σ_{C-C} governs the interaction. Its phase signs have again been chosen arbitrarily (top center). Instead of "localized" orbitals the suitable combination of "canonical" p_x- and p_y-AOs could also have been used. Since n- and π-MO have higher energies than the σ-MO, the latter is admixed to the first one in such a way that the energetically unfavored combination is obtained for the slightly modified MOs n″ and π″. The overlap between the σ-MO and the n- as well as the admixed π-MO is therefore negative, and this is the way the relative phase signs for the orbitals have been drawn. Whatever phase signs are chosen for the π*-MO, according to Fig. 1 and 2 a parallel arrangement of the two transition moments will always result, and a positive CD will therefore arise for the given absolute conformation of the chiral moiety C—C—C=O. In a twist form of a cycloalkanone this same arrangement appears twice, whence the mentioned rule could be derived. The CD of a 16-oxo steroid, with absolute conformation of ring D enantiomeric to this one, is accordingly strongly negative (−6.1) [2].

have for this purpose always to use the energetically less favored combination with σ. If we choose for the σ orbital the phase signs as given in Figure 11, then the unfavored combination for the admixture of the π- with the n orbital will have a nodal plane perpendicular to the C_α—C(=O) bond; the unfavored combination with the n-MO itself is that with negative overlap. As shown by Figure 11, the σ orbital of the chiral C—C bond thus induces the relative signs for the n- and the admixed π orbital lobes. Whichever phase signs we choose for π*, the product $n'' \otimes \pi^*$ in each case leads to a small $\vec{\mu}$, which is parallel to $\vec{m}$; the CD of the absolute conformation given in Figure 11 (CD of the second sphere) is therefore positive. This is the CD sign which has been found experimentally for (7) (Fig. 7)[2, 53]; the conformation of ring D of a 16-oxo steroid is the mirror image. This perturbation mechanism leads to a kind of octant rule, although the exact position of the third "orbital-determined" nodal surface cannot be derived from this simple picture. For a coplanar arrangement ($\omega = 180°$ in Fig. 11) the interaction for both possible choices of the phase signs of the admixed π orbital is of course identical, and there is no preferred orbital lobe sign. A similar situation arises for the n orbital at $\omega \approx 90°$. In the range $120° < \omega < 150°$ (deviation from coplanarity approximately 30—60°) the perturbation may be expected to reach a maximum, and this explains the particularly large Δε values for twist forms[53] of cycloalkanones. More exact calculations[54] give the same result.

The farther away the perturbing chiral bond is from the chromophore, the smaller will be its influence. An exception is seen, however, in the fully antiperiplanar train of bonds between perturbing group and chromophore[44], mentioned in Section 5; the influence of β-situated axial substituents of a cyclohexanone upon the CD, which is contrary to the general octant rule, can also be explained in this way (Figure 12). This bond comes very close to the n- and its admixed π orbital, and thus induces the relative phase signs in the manner considered above. Once again, it does not matter how the phase signs for the π* orbital are chosen: product formation leads for the given geometry to an antiparallel arrangement of $\vec{\mu}$ and $\vec{m}$; the CD is thus negative and hence in agreement with the experimental values[55] found for such groups.

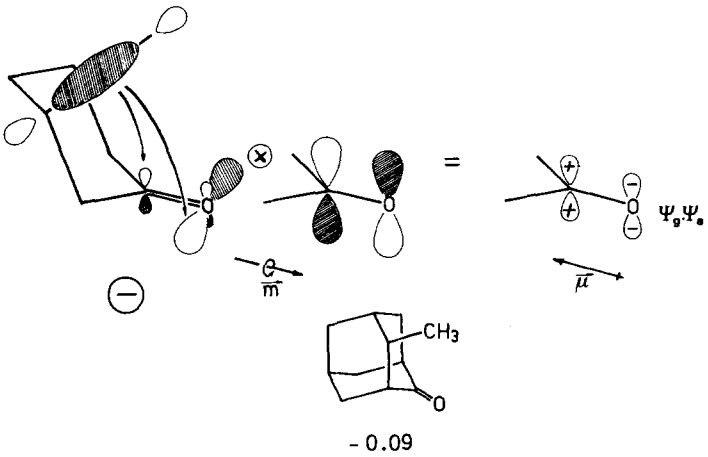

Fig. 12. The antioctant contribution of a β-axial substituent on a cyclohexanone [55]. The corresponding σ bond is very close to the MOs of the carbonyl chromophore; the relative phase signs—and therefore the relative directions of $\vec{m}$ and $\vec{\mu}$—are obtained analogously to Fig. 11. The two transition moments are antiparallel to each other for the absolute configuration chosen; the contribution to the CD is therefore negative. "Axial" 4-methyl-2-adamantanone is cited as an example. That the methyl group does not appear in a front octant follows from more detailed calculations, according to which the third nodal surface exhibits a concave curvature towards the oxygen [15e].

Perturbations through space can come from "poles" (*e.g.* the positive residual charges of nuclei not completely screened by their electrons; "one-electron theory"), or from dipoles induced in other bonds by electron excitation in the chromophore ("polarizability theory"), or from transition dipoles in such bonds, which can supply the missing electric transition moment. If we wish to apply *Coulomb*'s law we cannot, of course, investigate the interaction between a charge and an orbital lobe, but again only that between a charge and dipoles or quadrupoles. For this we have to know the relative energies of the excited states which can interact with each other. This is particularly easy for the 300 nm band of a saturated ketone as this corresponds to the excitation from the ground state into the lowest excited singlet state S_1 ($n\pi^*$). Whatever state S_i we use for the production of a μ_z, it must always have higher energy than S_1; that one of the two new states which differs only slightly from S_1 is the energetically favored one, S^+ (Fig. 13). This gives the recipe for the induction of the charge signs as a result of Coulomb interaction: we have to use the attractive and not the repulsive combination of the charges.

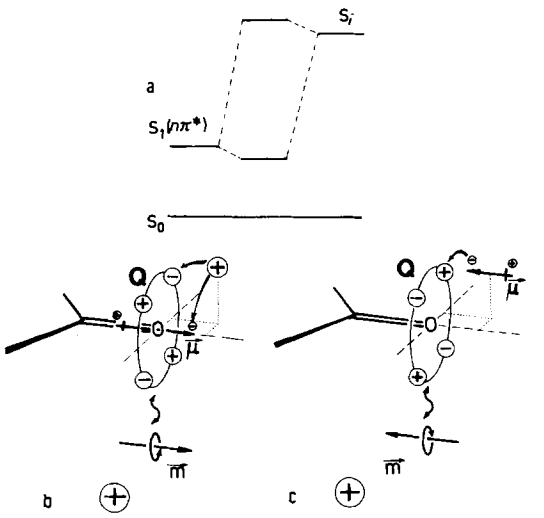

Fig. 13. Second-order perturbation theory for ketones with chiral third sphere (mixing of excited states). The chiral environment intra- or extra-chromophorically admixes an excited state S_i (always of higher energy), which is associated with an electric transition moment $\vec{\mu}$ along the same coordinate, with the first excited singlet state S_1 ($n\pi^*$), which is associated with a magnetic transition moment. a) The slightly modified first excited singlet state is here the energetically favored combination of S_1 and S_i; the interaction of a perturbing group must therefore be of the same sign for S_1 as for S_i (for instance, the energetically favored combination is used on both occasions). b) the ($\pi\pi^*$) state can supply the missing $\vec{\mu}$, which lies along the C=O bond, intrachromophorically. If a (*e.g.* positive) charge is present in the upper right front octant, and we choose the energetically favored combination between transition dipole and -quadrupole, then we obtain the signs for the individual poles as given in the Figure. According to Fig. 2 this corresponds to a parallel arrangement of $\vec{\mu}$ and $\vec{m}$; the CD is positive. Thus the correct sign for an octant rule is obtained. In this derivation a change of the sign of the charge does not lead to inversion of the sign of the contributions [which is in agreement with the experiment [75]] and one could just as well have used one pole of a dipole (induced by the excitation) instead of one isolated charge. c) The missing $\vec{\mu}$ could, *e.g.*, also be taken interchromophorically from a ($\sigma\rightarrow\sigma^*$) state of a C—C bond. Again the energetically favored combination between this transition dipole and the transition quadrupole has to be considered, from which a parallel orientation of $\vec{\mu}$ and $\vec{m}$ results according to Fig. 2, *i.e.* a positive contribution to the CD. Hence this contribution also yields an octant rule with correct signs.

If $\vec{\mu}$ is "stolen" intrachromophorically by admixture of the ($\pi\pi^*$) state, then μ_z and m_z are collinear; the parallel and the antiparallel arrangement have the same energy. The more favored interaction then always has to refer to one of the residual charges mentioned, or to a (possibly induced) dipole: for instance, if there is a positive pole present in the upper right front octant (Fig. 13b) not too close to the z axis, then it determines the sign pattern in the quadrupole Q and in the dipole $\vec{\mu}$ according to *Coulomb*'s law in such a way that the poles at the smallest distance from the perturbing pole must be negative. Figure 2 then reveals a parallel arrangement of $\vec{\mu}$ and $\vec{m}$; the CD is positive. An octant rule results once again, and its signs are those found experimentally. If the n orbital is delocalized, then additional (smaller) quadrupoles are also formed around the C of the C=O group, around the two C_α atoms, *etc.*, creating additional "enclaves" of opposite sign in a few restricted regions. Such "enclaves" have indeed been proposed by *Bouman* and *Lightner*[15e] on the basis of improved CNDO/S calculations.

Interchromophoric interaction can also be utilized to produce a $\vec{\mu}$; this latter should then come from a $\sigma\rightarrow\sigma^*$ excitation within a C—C bond near to the chromophore. If this transition dipole lies, *e.g.*, parallel to the $(-z)$ axis in the upper right front octant (Fig. 13c), then according to Figure 13a that charge pattern within the quadrupole Q must be favored which (in combination with the facts of Figure 2) leads to parallel arrangement of $\vec{\mu}$ and $\vec{m}$; again the correct sign for an octant rule is predicted. In this case, however, the interaction energy also depends to some extent on the orientation of the dipole and not only on the coordinates of its center. Improved calculations give more complex pictures for such interactions[15c].

This simple approximation procedure for finding a new sector rule (including the corresponding signs) can in general readily be applied, if one considers those transitions which are magnetically allowed but electrically forbidden (*e.g.* $n\rightarrow\sigma^*$ transitions of episulfides and thioethers[56], $n^-\rightarrow\pi^*$ transitions of pyrazines[57]). A general recipe can be formulated in the following way[56] (cf. Figure 14): if a band is caused by a

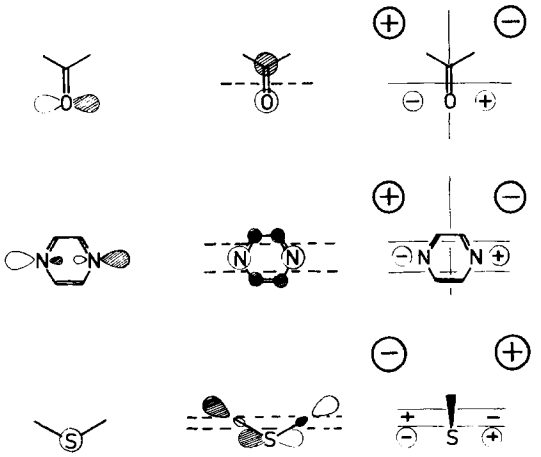

Fig. 14. Generalized rule for the CD in the case of $p_x\rightarrow p_y$ transitions. Top, $n\rightarrow\pi^*$ transition of a carbonyl compound; center, $n^-\rightarrow\pi_4^*$ transition of a pyrazine; bottom, $n\rightarrow\sigma^*$ transition of a thioether. Left, initial orbital; center, final orbital; right, generalized sector rule. The signs of the contribution in the proximity of the initial orbital are constant; on going towards the back sectors, each crossing of a nodal surface inverts the sign. The signs of contributions in the back sectors found experimentally are drawn larger. Notice that the plane of the C—S—C chromophore has to be placed perpendicular to the plane of the paper for setting up the rule.

transition which (at least to a large extent if LCAO-MOs are used) can be characterized by $p_y\rightarrow p_x$ (coordinate system as in Fig. 2), then the sign pattern in the proximity of the initial orbital in the four front sectors ($z>0$) is dissignate[58], *e.g.* as given in Figure 14. The signs in the other sectors are found by reversal for each crossing of a nodal surface. Figure 14 shows this for the octant rule of saturated ketones, for the rule mentioned for the $n^-\rightarrow\pi^*$ transition of pyrazines, and for the rule of the 240 nm band of thioethers. If the n orbital is delocalized further, *e.g.* by considering the p orbitals of corresponding symmetry at the C atom of the carbonyl group as well as at both C_α atoms, then according to this recipe an additional nodal surface perpendicular to the carbonyl plane is obtained, as has been described by *Pao* and *Santry*[15b] as the result of a more sophisticated calculation.

9. The $n\rightarrow\pi^*$ Band of Conjugated Carbonyl Compounds

The $n\rightarrow\pi^*$ band of conjugated carbonyl compounds appears approximately between 330 and 350 nm, since the HOMO

and the LUMO approach each other as a result of interaction between the π systems of C=O and C=C[4]. Figure 15 shows

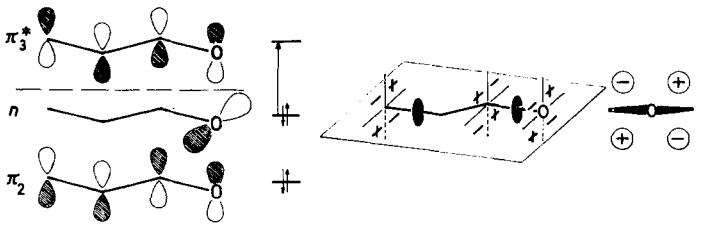

Fig. 15. Conjugated enone with coplanar arrangement of the C=C—C=O chromophore. The signs obtained according to Fig. 13 for the contributions to the CD of a ligand in a front octant, where the MOs for a saturated and a conjugated ketone are similar, are shown in the middle drawing. The signs of the contributions change on each crossing of a nodal surface; this will happen twice on proceeding to sectors lying farther back, as the final orbital π_3^* has two nodal surfaces. In the back sectors the sign pattern given on the right will therefore result [59, 60].

the symmetry properties of the two highest filled orbitals (π_2 and n) and that of the LUMO. While π^* of the saturated ketone has only one nodal plane, π_3^* of a conjugated ketone contains two nodal surfaces, and according to the generalized rule[56] the sign pattern has to change twice on going from the oxygen in the $(-z)$ direction. Thus a rule is obtained for the back octants which opposes the rule for saturated ketones. This has been proved experimentally[59] and is also obtained by a more sophisticated calculation[60].

However, this rule can only be applied when the enone moiety is completely or nearly coplanar. If it is more severely twisted around the central bond, as very often happens on incorporation into a ring system, then we are dealing with a chiral first sphere, for which only the final and not the initial orbital is chiral. The simple multiplication procedure is therefore inapplicable (at least as long as the n orbital is not extensively delocalized). On the other hand, the method of admixing of π character with the n orbital, as used for saturated ketones, gives the correct result if we make the obvious assumption that the chiral part of π_2 is the most effective perturber and will therefore determine the phase signs of the n orbital (Fig. 16). Formal multiplication by

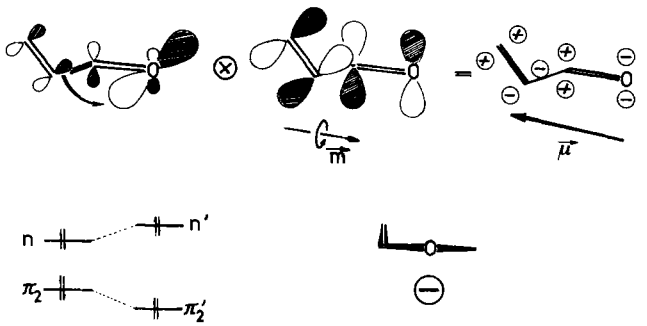

Fig. 16. The CD within the n→π* band of non-coplanar conjugated enones. The missing electric transition moment for the magnetically allowed n→π* transition can again be obtained by admixture of some π_2 character to the n orbital. As π_2 is itself chiral and lies energetically lower than the n-MO, the energetically unfavored combination of phase signs has to be used for n' (as in Fig. 11); participation of σ-MOs is no longer necessary. If one deliberately chooses the signs for π_2 as shown on the left, the phase signs for the n-orbital will follow. Whatever signs are used for the final orbital π_3^*, $\vec{m}$ and $\vec{\mu}$ will always be arranged (nearly) antiparallel to each other when the absolute conformation corresponds to that in the figure. The experimentally well-supported rule which follows from this is given on the bottom right [13].

the LUMO (the choice of signs within the orbital lobes around the oxygen is again arbitrary) yields an antiparallel arrangement of $\vec{\mu}$ and $\vec{m}$ according to Figure 16 for absolute conformation of the nonplanar enone system shown; the CD is thus predicted to be negative, and this is also found experimentally[13].

A completely analogous approach for ketones having a three-membered ring (cyclopropane or oxirane) "conjugated" with the carbonyl and in a chiral arrangement again gives the correct results[61] if the Walsh orbitals of the three-membered ring are used (Fig. 17).

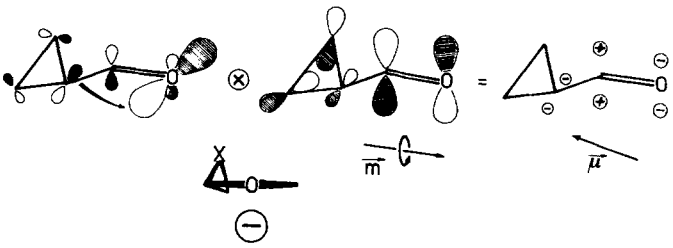

Fig. 17. The CD of the n→π* band for a chirally arranged three-membered ring (cyclopropane or oxirane ring) in "conjugation" with the C=O group. As in Fig. 16 the p-AO from π_2 at C_α determines the phases of the n orbital; this is accomplished here by the same p-AO from the Walsh orbital of the three-membered ring. For the given absolute conformation, an (approximately) antiparallel orientation of $\vec{m}$ and $\vec{\mu}$ results. The rule obtained, which again complies with experience [61], is illustrated below.

10. CD of Benzene Derivatives

The three known absorption bands of benzene around 260 (α-), 200 (p-), and 185 nm (β band) are generally[4] ascribed to π→π* transitions from the degenerate HOMOs into the likewise degenerate LUMOs, and belong in the D_{6h} point group of benzene to the representations B_{2u}, B_{1u}, and E_{1u}, respectively. An E_{2g} assignment has also been proposed for the p band[62]. *Allen* and *Schnepp*[63] have shown by comparison of the UV- and CD spectra of 1-methylindan (vapor state) that these three bands are accompanied by two additional band systems around 217 and 195 nm, for which E_{1g}- and E_{2g} symmetry have been proposed. Solution spectra sometimes also show these additional bands but in most cases they are rather indistinct. In the following, only the CD within the α band is discussed in detail.

11. CD of the α Band of Benzene

In the case of benzene, the transition into the B_{2u} state is forbidden electrically as well as magnetically. Only if additional molecular vibrations which lower the D_{6h} symmetry are excited in the electronically excited state will a small transition moment appear. The α band of benzene therefore shows a very pronounced vibronic fine structure; the 0-0 transition does not appear. The D_{6h} symmetry of the π system can, however, also be perturbed by substitution. Conjugation with π- or p electrons, as well as hyperconjugation with σ bonds, therefore also creates a small electric transition moment, and hence the UV spectrum of toluene is found to contain one fine structure series, which commences at the 0-0 transition, and at least one other one corresponding to that of benzene. For both series of chirally substituted benzene

derivatives, the pertinent magnetic transition moments have to be "stolen"; the signs of the corresponding Cotton effects therefore do not have to be identical. This further complicates the CD spectra within the α band. Moreover, "hot" bands may also appear; these are bands for which one normal vibration is already excited in the electronic ground state. Yet another rule may be valid here. We therefore suggest that the position of the 0-0 transition be calculated first (*e.g.* by using suitable estimates[64,75]) and this partial CD band consulted only for stereochemical correlation.

For chirally monosubstituted benzene derivatives and for tetrahydronaphthalenes and isoquinolines we have published[66] empirical sector rules for the α- and p bands. Although the skeleton of a monosubstituted benzene belongs to the C_{2v} point group, it is general practice to characterize the MOs and the transitions by the corresponding irreducible representations of benzene itself (D_{6h} symmetry). Such a monosubstitution confers upon the transition into the B_{2u} state (α band) a small electric moment in the plane of the ring perpendicular to the Ph—R bond: a small magnetic moment arises perpendicular to the plane of the ring[64,65]. According to *Allen* and *Schnepp*[63] a state of E_{1g} symmetry is energetically adjacent to the B_{2u} state, and is associated with a magnetic transition moment in the plane of the ring[5], as is necessary for the occurrence of CD. The α band can therefore intrachromophorically gain the $\vec{\mu}$ from the B_{2u} and the $\vec{m}$ from the E_{1g} state. Such an E_{1g} state corresponds to a $\pi\rightarrow\sigma^*$ (or $\sigma\rightarrow\pi^*$) transition; however, the double degeneracy of initial and final orbital render prediction of the sign of the Cotton effects very difficult in the case of a chiral second sphere (similar to that shown in Figure 11 for ketones). The experimentally found sector rule for contributions of a chiral third sphere, which is supported by theoretical calculations[17a], can, however, again be readily explained (Fig. 18). A (*e.g.* positive) "residual charge" will—in similar manner to that discussed for ketones (cf. Fig. 13)—again mix the two transition moments (*i.e.* $\vec{\mu}$ and that component of $\vec{m}$ which is parallel or antiparallel to it), thus determining the relative sign patterns for the dipole and the quadrupole. The experimentally found sign, and therefore the direction of $\vec{m}$, for the CD of the α band is obtained only on excitation from the π- into the σ* orbital[63]. Since, however, the weight of interchromophoric contributions to the same CD is unknown, the treatment shown in Figure 18 should be understood only as a suggestion to make this CD plausible; during recent years we have therefore focused our attention on changes arising in the CD on additional achiral substitution of the benzene ring[67]. According to *Platt*[64], the magnitude of the electric transition moments induced in benzene by substitution can be described quantitatively by "q-values", which are tabulated for numerous ligands[64,65]. In the case of multiple substitution, individual moments still have to be added vectorially even if these substituents are achiral, such as OH, OCH_3, alkyl, which are very often present in natural products. This substitution can drastically change the direction of the overall moment, so that sign inversion may also be observed for the CD bands in homochirally analogous series. For instance, the CD is negative within the α band of estradiol and of its 3-*O*-methyl ether but positive for the corresponding acetate.

We have tried[67] several different empirical formulae in order to correlate the induced magnetic transition moment

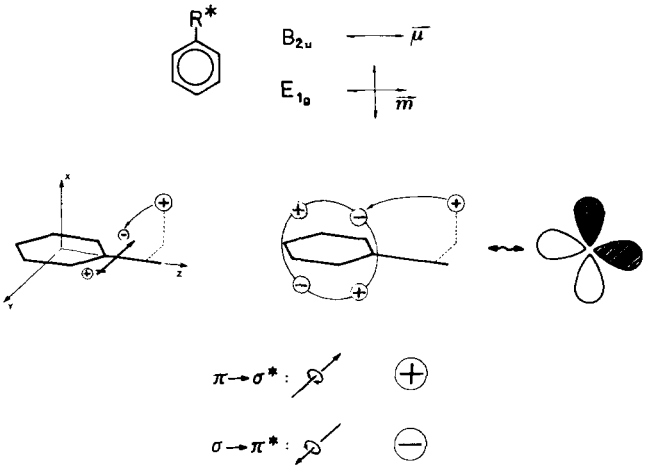

Fig. 18. CD of the α band of benzene derivatives with a chiral substituent (intrachromophoric mechanism). Top, introduction of a group R* yields a (weak) electric transition moment in the given direction for the B_{2u} band. The energetically closest [63] state has E_{1g} symmetry; with this is associated a magnetic transition moment in the plane of the ring. Center, relative signs of $\vec{\mu}$ and the transition quadrupole. This transition quadrupole corresponds to a sign pattern of the orbital lobes as given on the right. For a $\pi\rightarrow\sigma^*$ transition $\vec{m}$ and $\vec{\mu}$ are parallel, and the CD is positive; for a $\sigma\rightarrow\pi^*$ transition $\vec{m}$ and $\vec{\mu}$ would be antiparallel, and the CD negative. The positive CD found for the given absolute conformation corresponds to a preferred contribution of the $\pi\rightarrow\sigma^*$ transition to the E_{1g} state.

$\vec{m}$ [which must be coplanar with the present electric transition moment $\vec{\mu}$] with the molecular structure, and to this end we have synthesized a great number of model compounds. Occasional sign inversion is found experimentally if benzene derivatives already containing a chiral substituent are further substituted by an achiral group in a *p*-, *m*-, or *o* position. This change of sign depends on the type (and therefore, on the q value) of both groups, and on their relative position. In Table 1 these "sign patterns" are given for three series.

Table 1. Sign of the CD within the α band of mono- and disubstituted benzene derivatives R*—Ph' with one chiral substituent. Ph' stands for phenyl and toluyl. Top, α-D-glucosides; center, bornanyl derivatives; bottom, isoborneol derivatives.

	R*	R* CH_3	R* CH_3	R* CH_3
HO, HO, HO, HO, O, OPh'	+	+	+	+
Ph'	+	−	+	−
OH, Ph'	+	−	+	+

The results can be described by a simple model, which leads to the following formulae:

$$R_p = R^* \left[1 + (1-\gamma)\frac{q}{q^*} - \gamma\left(\frac{q}{q^*}\right)^2\right]$$

$$R_m = R^* \left[1 - \frac{1+\beta}{2}\frac{q}{q^*} + \beta\left(\frac{q}{q^*}\right)^2\right] \qquad (6)$$

$$R_o = R^* \left[1 - \frac{1-\alpha}{2}\frac{q}{q^*} - \alpha\left(\frac{q}{q^*}\right)^2\right]$$

R^*: rotational strength of the chirally monosubstituted benzene; R_p, R_m, and R_o: rotational strengths of the products with additional achiral substituent in *p*-, *m*-, or *o* positions; q* and q: the q values for the chiral and achiral groups, respectively. The parameters α, β, and γ which characterize the *o*-, *m*- and *p* substituent, obey the restriction $0 \leq \gamma \leq \beta \leq \alpha \leq 1$. With the exception of a few *o*-substituted derivatives, whose conformation has most probably changed, all known CD data can be described correctly by using a value of about 0.7 for all these parameters. From the identical (positive) signs reported for L-phenylalanine and L-tyrosine we formerly[66] concluded that the above-mentioned parameters approach their lower limiting value on separation of the chirality center from the benzene ring by one CH_2 group. We found, however, that the CD of L-phenylalanine is negative in organic solvents; these amino acids therefore behave like our analogous model compounds[67].

Equations (6) thus do not describe the CD directly, but only the influence of additional achiral substituents (sign inversion or not). Similar influences were also found for tetralins and tetrahydroisoquinolines[66, 67]. However, a recent publication[68] presents a calculation which seems to indicate no influence of additional (achiral) substituents for such compounds. In this paper, the orientation of the coordinate system was kept constant in spite of different substitution by having the *z* axis coincide with the C_2 axis of the non-aromatic ring regardless of the substitution type; this can only lead to the cited result! *Sagiv*[69] gives a description of the CD

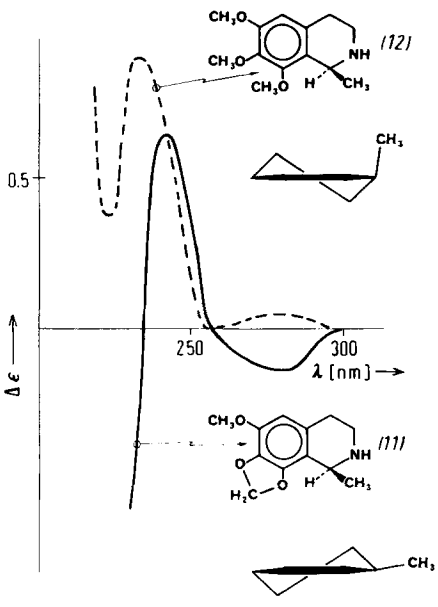

Fig. 19. The CD above 220 nm of (−)-anhalonine *(11)* and (+)-*O*-methylanhalonidine *(12)* of same absolute configuration. The projections given under the formulae are valid for the crystalline state as well for solution, and are performed along the C_2 axis of the ring system (from the benzene ring towards the piperideine ring).

of benzene derivatives resembling our own treatment, in which the additional substitution of the chromophore by achiral groups also plays an important rôle.

An inherent weakness of these rules for the Cotton effects of chirally monosubstituted benzene derivatives lies in the fact that the preferred conformation of the chiral side chain is not always known; for tetralins and tetrahydroisoquinolines the situation is very often much simpler, although—as in all other cases—the CD can give only the absolute conformation and not the absolute configuration. Figure 19 strikingly illustrates this fact: (−)-anhalonine *(11)* and (+)-*O*-methylanhalonidine *(12)* have the same absolute configuration but opposite rotations at the NaD line and also Cotton effects of opposite signs within the bands at longest wavelengths[70]. The reason becomes clear from X-ray data[70]: the methyl group is arranged quasi-equatorially in *(11)* but quasi-axially in *(12)*; *(11)* and *(12)* therefore have opposite ring helicities in spite of their identical absolute configuration. This conformational difference must also persist in solution, as proved by CD.

12. Future Prospects

As a rule, the empirical correlations between absolute conformation and Cotton effect gained by comparison of a great number of CD spectra can now be understood relatively well—with the aid of sophisticated calculations in favorable cases, and frequently already on the basis of simple qualitative MO considerations—even though the sign cannot always be predicted unequivocally. Nevertheless, combination of empirical rules and theoretical interpretation can reveal—if only *post festum*—valuable general regularities, from which one at least can derive the limits of applicability and even explain occasional exceptions. The qualitative MO consideration applied here will continue to be of value in the near future because *ab initio* calculations are much too expensive—especially for more complicated molecules—and all semi-empirical methods make several assumptions and use approximations. Although such semi-empirical methods do yield numbers and not only qualitative results, one can generally only rely on trends and not on these absolute values. This qualitative treatment can also be refined without difficulty, *e.g.* by incorporation of configurational interaction[76].

Apart from "classical" CD measurements in the range from about 180 to 800 nm, other methods have been developed in recent years whose general applicability cannot yet be foreseen. Thus the range of measurement was extended to below 140 nm[63, 71] and into the IR[3], and CD recorded in emission[72] and CID in Raman scattering[73]. Furthermore, chiral guest molecules in appropriate nematic mesophases can cause a transition to cholesteric phases of preferred helicity[74], and the chiroptical data of the host phase in the IR permit conclusions to be drawn about the absolute configuration of the guest molecules. In this case, it is not the chiral environment of a chromophore which is investigated, but rather the conformation of the whole molecule. Both this method and CID ("circular intensity differential") may perhaps in the future yield valuable results supplementing classical chiroptical methods for the determination of absolute configuration.

I would like to thank my many enthusiastic co-workers at Bonn and Bochum, as well as many colleagues in Germany and abroad for the synthesis of model compounds, supply of valuable samples, and many fruitful discussions, Mr. E. Kirmayr and Ing. U. Wagner for careful measurements, as well as the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for generous financial support.

A Basis for Orbital Symmetry Rules

By Horia Metiu, John Ross, and George M. Whitesides[*]

The influence of molecular symmetry on reaction rates is examined with an approach in which reactions are viewed as electronic transitions between states of reactants and products (described, in turn, by quasiadiabatic potential surfaces). The molecular Hamiltonian is used to derive selection rules for these transitions. The *complete* Hamiltonian has no useful symmetry. Neglect of non-Born-Oppenheimer and spin-orbit terms (and of other angular momentum coupling terms) leads to an approximate Hamiltonian and to selection rules which form the basis for the Woodward-Hoffmann rules. This approach provides an alternative to the adiabatic potential surfaces, reaction coordinates, and transition state theory used in more familiar discussions of the Woodward-Hoffmann rules. Further, it provides a particularly clear method for discussing violations of these symmetry rules, and for differentiating concerted and nonconcerted reactions.

1. Introduction

The prediction of chemical reaction rates and rate constants is a difficult endeavor. Formal theories of reaction rates[1] are just beginning to be used successfully[2] (at times with great computational expense) for the simplest three-atom exchange reactions and are not presently applicable to more complex problems. The difficulty in analyzing the motion of many-atom systems can, however, be reduced substantially by considerations of symmetry. In molecular quantum mechanics, the classification of electron states of atoms and molecules according to symmetry is fundamental to the construction of correlation diagrams and optical selection rules. By considering symmetry, these rules can be constructed and applied without calculating details of the motion of the electrons and nuclei. Similarly, "symmetry rules" such as those proposed by *Wigner* and *Witmer*[3], *Shuler*[4], and *Woodward* and *Hoffmann*[5], and discussed by many other authors[6], have greatly clarified certain types of problems in kinetics, without requiring elaborate calculation. The Woodward-Hoffmann (W-H) rules for the prediction of relative rates of concerted reactions are based on considerations of the symmetry of the electronic wavefunctions of the chemical reactants and products. These wave functions seldom figure *explicitly* in applications of the W-H rules: because electronic wavefunctions calculated in the Hückel LCAO-MO approximation[7] reflect molecular symmetry in easily predictable ways, a knowledge of the molecular symmetry of the substance(s) of interest, and of the symmetry properties of the Hückel wavefunctions derived previously for these or related materials, normally is sufficient for an application of the W-H rules.

The Hückel wavefunctions, on which the application of the W-H rules usually depends, are calculated with an approximate Hamiltonian: any influence of nuclear motion on the electronic wavefunction is neglected (the Born-Oppenheimer approximation); angular momentum terms (molecular, electronic spin-orbit, and nuclear and electronic spin) are ignored; and electron-electron interactions are incorporated semi-empirically. The enormous predictive success of the W-H rules indicates that the neglected terms are normally unimportant for the success of *qualitative* arguments based on orbital symmetry. *Nonetheless, the complete molecular Hamiltonian does not have the symmetry required to provide a rigorous basis for the W-H rules*, and a more complete calculation, including Born-Oppenheimer terms and consideration of angular momentum may, in principle, lead to predictions different from those of the W-H rules.

The purpose of this article is to discuss a number of aspects of symmetry rules in chemical kinetics, particularly the W-H rules. We present a theoretical framework with which we:
- derive symmetry rules and their limits of applicability
- provide operational definitions of the concepts of concerted and nonconcerted reactions
- derive extensions of present symmetry rules.

The utility of our analysis is tested for various applications. Further, we show that symmetry rules for reactions can be obtained as *selection rules* analogous to those used in optical spectroscopy.

Our interest is in the influence of symmetry on reaction rates and in the assumptions underlying the symmetry rules, not in the detailed calculation of rates for specific reactions. Recent work on photodissociation of polyatomic molecules[8] and dynamics of simple rearrangement reactions[2b] indicates, however, that the types of methods discussed here can be used to provide quantitative estimates of rates.

Our treatment of reaction rates clarifies the relationship between the relatively high symmetries assumed in applying these rules and the much lower symmetry actually characteristic of the complete molecular Hamiltonian. Two other worthwhile features emerge from this development. First, it is possible to derive relatively compact expressions which give the reaction rates in terms of the complete Hamiltonian (including nuclear and non-Born-Oppenheimer terms) and appropriate wave functions of reactants and products. This expression can be separated into a part having the symmetry assumed in the W-H rules (that is, the symmetry of the nuclear framework), and other parts that do not have this symmetry. The experimental observation that many reactions obey the W-H rules then makes it possible to identify terms in this rate expression that are normally *not* important in determining reaction rates. Thus, the observation that certain features of reaction rates are adequately described by terms having symmetries characteristic of only a part of the complete molecular Hamiltonian permits an estimation of the relative importance of the remaining parts in determining reaction rates. Second, by identifying explicitly the terms in the Hamiltonian that do not have the symmetry of the molecular framework, it is possible to suggest areas and circumstances in which the W-H rules might be expected to fail. Our discussion proceeds in four stages:

First, we describe the distinction between "adiabatic" and "quasiadiabatic" potential surfaces[*], and indicate the advantages of the latter in discussing the role of symmetry in the reaction rates. Briefly, *adiabatic* potential surfaces are those which organic chemists commonly use in discussing kinetics (Fig. 1). A continuous surface connects reactants and products, and the lowest energy path between the two is called the "reaction coordinate". The "activated complex" or "transition state" is considered as a discrete species at the position of highest energy along that path. A complete adiabatic surface is generated with a single electronic Hamiltonian: reactants, products, and intermediates are represented by eigenfunctions of this Hamiltonian calculated for different sets of nuclear coordinates. A reaction is the result of the motion of nuclei; since the adiabatic surface is continuous, reactants and products belong to the same electronic state. In the present work, a distinct *quasiadiabatic* potential surface is required for reactants and products; each is calculated using a procedure specifically designed to *eliminate* all of the interactions which provide the driving force for reaction. The wave functions used to represent these artificially non-reacting species are *not* eigenfunctions of the Hamiltonian for the complete system. A reaction is considered as an electronic transition between the quasiadiabatic surface (state) of the reactants and the quasiadiabatic surface of the product. The transition state may be viewed as the nuclear configuration at or near the crossing of these two surfaces. Although the quasiadiabatic picture of a reaction is not the one customarily used in physical organic chemistry, *Evans*[9] proposed and made innovative use of quasiadiabatic energy surfaces, as early as 1938, for a discussion of the electronic theory of reactions.

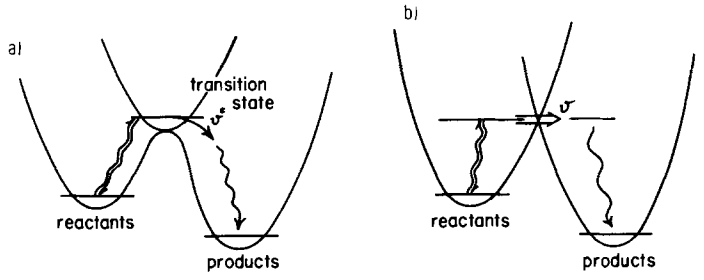

Fig. 1. A reaction in an adiabatic model (a) is represented by a smooth progression of nuclear positions within a *single* electronic state. All interactions present in the real physical system are, in principle, included in this representation. The highest energy species in this progression is called the transition state or activated complex, and, within the usual activated complex theory, is assumed to be in thermodynamic equilibrium with the ground state of the reactants. Its decomposition to products is the result of molecular motion along a vibrational coordinate having a negative force constant. A reaction in a quasiadiabatic model (b) is treated as a transition between electronic states of distinct species—"reactants" and "products".

[*] In this context, adiabatic and quasiadiabatic should be considered as arbitrary labels, with no obvious connection to the word adiabatic as used in classical thermodynamics.

Second, we state and develop an equation that describes the rate of a concerted reaction in terms of the quasiadiabatic wave functions for reactants and products, and the Hamiltonian of the reacting system. This equation permits the rate to be expressed in terms of contributions from several well-defined, although not necessarily easily calculated, quantities: overlap integrals of electronic wave functions; overlap integrals of nuclear wave functions; nuclear geometry at the intersection of the two quasiadiabatic potential surfaces; non-Born-Oppenheimer terms; and spin-orbit terms. Those terms which must be negligible for the reaction to follow orbital symmetry rules of the W-H type are easily identified.

Third, we study various contributions to the rate expression for reactions which are forbidden according to electronic symmetry rules of the W-H type. Examination of the vibronic and spin-orbit contributions to the rate shows that these also follow symmetry rules. These rules differ significantly from the W-H rules, however, and are neither generally nor easily applicable. These discussions are illustrated with the example of the closure of butadiene to cyclobutene.

Fourth, we discuss the concepts of concerted and nonconcerted reactions, and present useful (operational) definitions.

Our analysis emphasizes that many organic reactions classified according to the simplest electronic symmetry rules (W-H) as allowed or forbidden can in fact be categorized according to varying degrees of reactivity, and that reactions forbidden by these simplest rules may at times proceed at significant rates. Several representative reactions are classified in terms of "orders of forbiddenness". Identification of those terms in the complete rate equation that are not taken into account in the W-H treatment makes it possible to suggest reaction types in which violations of orbital symmetry rules might be expected.

2. Adiabatic and Quasiadiabatic Potential Surfaces

Most discussions of reaction kinetics based on transition state theory presuppose a single, continuous, potential surface connecting reactants and products. The points on this surface are calculated by assuming the nuclei to be stationary (the Born-Oppenheimer approximation) and solving the Schrödinger equation (1) to obtain electronic energies and wavefunctions for selected nuclear positions,

$$H_e(r, R_0)\Phi_i(r, R_0) = E_i(R_0)\Phi_i(r, R_0) \quad (1)$$

Here, H_e is the electronic Hamiltonian, r are the electronic coordinates, R_0 are the (fixed) nuclear coordinates, $\Phi_i(r, R_0)$ is the eigenfunction which describes a particular (i-th) electronic state (say the ground state, for thermal reactions) at the chosen values of R_0, and $E_i(R_0)$ is the associated electronic energy[*]. By varying the coordinates R_0 to correspond to the forming and breaking of bonds hypothesized for the reaction, we trace out a reaction coordinate. Many approximations have been introduced to make this procedure practical in the Hückel approximation; in particular, a limited number of atomic orbitals are used as the basis set, and two-electron terms and certain integrals are neglected.

For example, for the exchange of a hydrogen atom between dihydrogen and a hydrogen atom

$$H_A - H_B + H_C \rightarrow H_A + H_B - H_C$$

one can calculate the changes in energy accompanying the transfer of H_B from H_A to H_C by assuming a linear arrangement of three nuclei, choosing one distance, and minimizing the total energy of the system by varying the second distance. The results of such a calculation are summarized in Figure 2a. It is, of course, not generally useful to consider potential energies varying with a single distance for any purpose but schematic illustration; we shall do so here since a qualitative representation is all that is required. Surfaces generated in this way by the solution of Eq. (1) for the particular chosen system are called *adiabatic*. We emphasize that since a single Hamiltonian is used to calculate the energies and wavefunctions of nuclear configurations corresponding to what we call the reactants, products, and intermediates between the two, and since the resulting surface is continuous, all of these species are normally in the same electronic state: that is, they have the same electronic wave function.

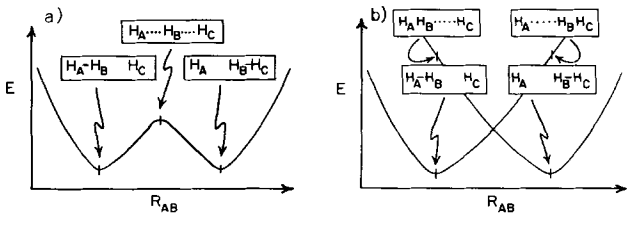

Fig. 2. Schematic adiabatic (a) and quasiadiabatic (b) potential surfaces for H_A—$H_B + H_C \rightarrow H_A + H_B$—$H_C$. For all curves, the distance between H_A and H_C, R_{AC}, is fixed, and R_{AB} is varied. In the left-hand curve for the quasiadiabatic surfaces, no interaction is allowed between H_B and H_C at any value of R_{AB}; for the right-hand curve, no interaction between H_A and H_B is allowed.

[*] Of course, this term also contains the Coulomb energy of the nuclear skeleton at rest.

Alternative theoretical methods for studying reaction rates are available, although they are not commonly used in physical-organic chemistry. The one employed throughout this paper involves calculations of two distinct potential surfaces, one for reactants and one for products. Reaction is considered to result from a transition between them. The procedure used to construct these so-called *quasiadiabatic* potential surfaces (and the corresponding electronic states) is based on calculating energies and wavefunctions for systems in which certain interactions actually present and crucial for the reaction to occur are intentionally omitted. This procedure is thus not based on finding electronic eigenfunctions for the chosen reacting system, and is thus very different in spirit from that used for adiabatic surfaces[10]. Typically, for the reaction of H_A—H_B with H_C, the calculation of a quasiadiabatic surface for the three-atom system that forms the reactants determines the energy of that configuration with explicit *exclusion* of bonding between H_C and H_A—H_B. The calculation of the quasiadiabatic surface of the products, that is the calculation for $H_A + H_B$—H_C, is done with explicit *exclusion* of bonding between H_A and H_B—H_C. The results of these calculations can be represented schematically by two intersecting potential energy curves (Fig. 2). The electronic quasiadiabatic wave functions are not eigenfunctions of the Hamiltonian of the complete system, because this Hamiltonian includes *all* the interactions present in the system. The quasiadiabatic wave functions explicitly exclude all *bonding* interactions between products and reactants.

Both adiabatic and quasiadiabatic representations have attractive features for describing chemical reactions. The former is more readily appreciated physically, and seems conceptually simple. Construction of an adiabatic energy surface involves assuming a position for the nuclei and then calculating the total electronic energy of the system at this position. This calculation is repeated for any nuclear positions that are considered relevant to the problem being considered. The resulting adiabatic energy surface thus (in principle) provides the correct energy of the system as a function of the nuclear positions. The continuous rearrangement of the nuclei from reactant to product configurations traces a path on this surface. The lowest energy path from reactants to products is frequently called the "reaction coordinate". The transition state is just the point of highest energy along this coordinate. In the activated complex theory, which is formulated with the adiabatic energy surface, the rate is determined by the curvature of the surface (that is, by the force constants) at the saddle point corresponding to the transition state. Adiabatic potential surfaces have the appeal of being "physically measurable", in the sense that they give the correct energy for the best approximation to this energy that can be calculated (with the particular procedure used) for any assumed set of nuclear positions. They have, however, a deficiency as the basis for discussing the influence of symmetry.

The reason for this will become clear as we proceed. At this point we only note that once the adiabatic energy surface is calculated the electronic wave function is eliminated from the problem. If we want to compute the rate of reaction numerically we have to solve the mechanical equations of motion (classical or quantum) with the adiabatic energy surface serving as potential energy. For instance, in Figure 3 we give a simple one-dimensional representation of this point,

where we show the adiabatic energy surface along the lowest path from reactants to products (usually called reaction coordinate). The total energy of the system is a constant and hence a straight line. The difference between the two lines is the kinetic energy of the nuclei, which changes as the reaction proceeds. The potential energy allows us to compute the forces exerted on the moving (reacting) nuclei, at any given nuclear configuration. Nowhere is the electronic symmetry of reactants and products obviously present in this type of treatment.

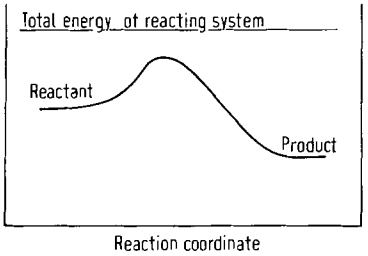

Fig. 3. Typical reaction coordinate. The level of the total energy of the reacting system, which is constant, is indicated by the horizontal line.

In the quasiadiabatic scheme the situation is conspicuously different. The reaction is considered to be a transition from the potential surface (*i. e.* the electronic state) of the reactants to the potential surface (*i. e.* the electronic state) of the products. We emphasize that the adiabatic and quasiadiabatic ways of describing reactions are equivalent and the choice of one of them depends on the problem to be solved. For a discussion of electronic symmetry it is more convenient to use a representation that displays the electronic degrees of freedom. The reader will discover, as he proceeds, that the language of the symmetry rules is that of the quasiadiabatic representation.

The quasiadiabatic potential surfaces do not necessarily give the correct energies, because the bonding interactions that are responsible for conversion of reactants to products are explicitly omitted in their calculation. For nuclear configurations which can be identified clearly as "products" or "reactants", quasiadiabatic potential surfaces give energies very close to those of adiabatic surfaces; for intermediate configurations, however, the two types or surfaces are very different. Although the idea of a reaction as a transition between two electronic states seems qualitatively more complex than that of a smooth progression along a reaction coordinate, the quasiadiabatic approach offers a great advantage for discussions of the influence of symmetry on rate. The reaction is considered as an electronic transition from a state of the reactant to a state of the product, and it is possible to calculate the rate using an expression of the form of Eq. (2)[6g].

$$k_{\text{reactant}\rightarrow\text{product}} \sim \langle\psi^{\text{product}}|\text{Operator}|\psi^{\text{reactant}}\rangle^2 \qquad (2)$$

$$\text{Intensity} = k_{\text{ground}\rightarrow\text{excited}} \sim \langle\psi^{\text{excited}}|O_{\text{dipole}}|\psi^{\text{ground}}\rangle^2 \qquad (3)$$

Once the symmetry of the appropriate operator and that of the wave functions ψ^{product} and ψ^{reactant} have been identified, then it is easily possible to establish whether the rate must be small *on the basis of symmetry* (it may, of course, be small, for reasons unrelated to symmetry). This type of procedure has abundant precedent in the development of optical selection rules (that is, in procedures for estimating the rules of spectroscopic transitions), where expressions of the same form are used [Eq. (3)]. The ability to classify reaction rates in terms of symmetries is of obvious pertinence to the W-H rules. This approach is also very convenient in dealing with "unusual" contributions to the kinetics, such as the dynamic effects arising from non-Born-Oppenheimer terms or spin-orbit coupling, which may cause violations of the W-H symmetry rules, much in the way in which they cause violations of the selection rules in spectroscopy. Such terms are not presently included in transition state theory.

To illustrate the construction of adiabatic and quasiadiabatic surfaces in an example directly relevant to pericyclic reactions, we consider the closure of butadiene to cyclobutene. For a qualitative discussion of an adiabatic potential energy surface for this transformation we consider only the interconversions of molecular orbitals formed from four atomic orbitals. Hückel-level calculation of the adiabatic potential surface would proceed with the solution of the secular determinant in the usual way for various nuclear coordinates corresponding to butadiene, cyclobutene, and plausible geometries intermediate between these extremes

$$\left|\begin{array}{cccc} \alpha_1-E & \beta_{12} & 0 & \beta_{14} \\ & \alpha_2-E & \beta_{23} & 0 \\ & & \alpha_3-E & \beta_{34} \\ & & & \alpha_4-E \end{array}\right| \begin{array}{l}\text{adiabatic} \\ = 0\end{array}$$

Changes in the magnitudes of the resonance ($\beta_{ij}=\langle i|H|j\rangle$) and Coulomb ($\alpha_i=\langle i|H|i\rangle$) integrals with geometry lead to changes in the energies of the molecular orbitals, and generate the associated adiabatic potential surfaces (Fig. 4a).

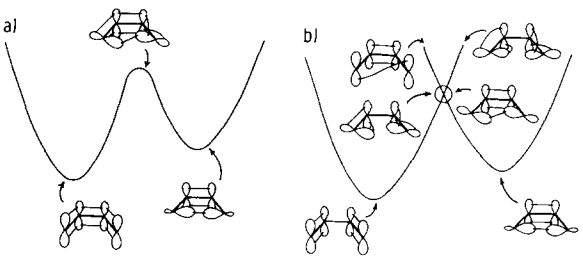

Fig. 4. Schematic adiabatic (a) and quasiadiabatic (b) potential surfaces describing the conrotatory interconversion of cyclobutene and butadiene. The lines connecting orbitals indicate those interactions included in the calculation. These interactions may, of course, range from large to zero (as shown by the magnitude of β_{12} in the adiabatic calculation).

Two different Hamiltonians are used for computing the quasiadiabatic states for butadiene and cyclobutene; neither is that used for the adiabatic calculation. For butadiene we take β_{23} and β_{14} to be zero, regardless of the nuclear configurations, to exclude from the quasiadiabatic electronic state of butadiene the bonding interactions characteristic of cyclobutene (Fig. 4). Similarly, the quasiadiabatic Hamiltonian for cyclobutene has β_{34} and β_{12} equal to zero to exclude the bonding interactions characteristic of butadiene.

$$\left|\begin{array}{cccc} \alpha_1-E & \beta_{12} & 0 & 0 \\ & \alpha_2-E & 0 & 0 \\ & & \alpha_3-E & \beta_{34} \\ & & & \alpha_4-E \end{array}\right| \begin{array}{l}\text{quasiadiabatic "butadiene"} \\ = 0\end{array}$$

$$\left|\begin{array}{cccc} \alpha_1-E & 0 & 0 & \beta_{14} \\ & \alpha_2-E & \beta_{23} & 0 \\ & & \alpha_3-E & 0 \\ & & & \alpha_4-E \end{array}\right| \begin{array}{l}\text{quasiadiabatic "cyclobutene"} \\ = 0\end{array}$$

This way of constructing the quasiadiabatic states gives the correct electronic symmetry of both butadiene and cyclobutene. Having imposed the conditions which characterize this pair of quasiadiabatic calculations, we can calculate potential surfaces relevant to the interconversion of butadiene and cyclobutene by varying appropriate parameters but the shape of these surfaces will depend on the parameters varied. Thus, calculations in which only the distance between C^1 and C^4 is allowed to vary will produce excited states of butadiene and cyclobutene which differ significantly in shape; calculations in which the torsional angles Φ around the C^1—C^2 and C^3—C^4 bonds are also allowed to vary produce structures that are more closely related geometrically. We shall discuss later, in more detail, the importance of this difference for the rate of the reaction[*].

3. The Transition Probability for Chemical Reactions

3.1. General Theory

A reaction can be treated as an electronic transition between two different electronic states corresponding to two different quasiadiabatic potential surfaces, one for reactants and one for products. The reactant system is taken to be in a given quasiadiabatic electronic state and in a given nuclear state (specified in terms of the rotation, vibration, and relative motion of reactants) corresponding to the given total energy of the reacting system. This energy may be determined by an equilibrium thermal distribution or by a non-equilibrium photoexcitation. *The state of the reactants, constructed as described to exclude the bonding interactions that characterize reaction, is not a stationary (time-independent) state of the complete Hamiltonian.* A stationary state description, based on the available quasiadiabatic wave functions, would require mixing of reactant and product states. Since the reactants are not in a stationary state, there is a time-dependent probability that they will undergo a transition to a state of the product. The rate of the transition between reactant and product states (as between all non-stationary states in quantum mechanics) is calculated in terms of an integral of the form $\langle\psi^{product}|\text{Operator}|\psi^{reactant}\rangle$ [Eq. (2)]; the practical problem is to define the appropriate operator for the reaction and to try to develop methods of estimating the magnitude of this integral without resorting to detailed computation.

It is helpful in describing the techniques used to calculate these transition probabilities from reactants to products (*i.e.* rates of reaction) to begin by describing an analogous and more familiar problem: *viz.* that of the electronic excitation of a molecule by the absorption of a photon[12]. The excitation is a transition between different electronic states (that is, between different adiabatic potential energy surfaces). The interaction of the dipole moment of the molecule and the electromagnetic field of the light provides the driving force for the transition: the dipole moment operator is the required operator. Two familiar assumptions are usually used in obtaining an expression for the transition probability: first, that the motion of the electrons is so much faster than that of the nuclei that only the nuclear positions influence the electronic wave functions and that the nuclear movements are not important (the Born-Oppenheimer approximation); second, that the electronic transition is sufficiently rapid that the nuclei are effectively motionless during the transition (the Franck-Condon approximation). The selection rules of optical spectroscopy follow from consideration of the symmetry properties of the initial state, the final state, and the dipole moment operator. We emphasize that these selection rules reflect approximations made concerning wave functions (Born Oppenheimer and Franck-Condon approximations, neglect of spin-orbit coupling, *etc.*) and the mechanism of interaction of light with the molecule (dipole moment approximation). If different assumptions are made, different selection rules may result. In general, the less drastic the assumptions, the weaker are the resulting selection rules.

Any given set of approximations yields a set of selection rules. If the system is not adequately described by these approximations, however, lines appear in experimental spectra which are not predicted on the basis of these selection rules. Such lines are sometimes called "forbidden". This adjective essentially implies that an improved analysis containing less drastic approximations is required to reconcile experiment and theory; that is, that the analysis should take into account more interactions in the initial and final state and more complicated (and usually smaller) interactions between light and the molecule. Thus in optical spectroscopy there exists a hierarchy of selection rules depending on the level of analysis.

We find a similar situation for chemical reactions. Symmetry rules such as the W-H rules can be derived as selection rules for the electronic transition from the quasiadiabatic electronic state of the reactants to that of the products. The essential difference between the W-H rules and the spectroscopic selection rules is the difference between the operator which causes the transition of interest: for spectroscopy it is, in the simplest case, the dipole moment operator, while for chemical reaction it is, again in the simplest case, an operator whose properties are outlined below. Since we are concerned here only with the development of symmetry rules for chemical reactions, it will be necessary to describe this operator only in sufficient detail to establish its symmetry properties and the symmetry properties of its constituent parts. Much of what follows will involve qualitative arguments, and mathematical development will be held to the minimum required to sketch the form of the important integrals. Detailed discussions of the basis for these arguments can be found elsewhere[6g, 13].

As the basis for our discussion of the influence of symmetry on reaction rates, we assume that for a reaction of interest, the appropriate quasiadiabatic potential surfaces and wavefunctions are available for reactants and products. We further assume the reaction to be concerted and mean thereby that only two quasiadiabatic surfaces are important for the transition from reactants to products (Fig. 1b). Although in most cases this definition corresponds closely to the one commonly used (a concerted reaction is one taking place in one step,

[*] Quasiadiabatic descriptions make it possible to consider most reactions as electronic transitions; this feature is convenient in the study of the role of the electronic symmetry on rates. There are, however, reactions ($CO_2 \rightarrow CO + O$ is one example) which actually include a transition from one electronic *adiabatic* surface to another (here spin angular momentum is not conserved) [11]. In such unusual cases the situation is reversed: the adiabatic states make it possible to consider the reaction as an electronic transition while the quasiadiabatic ones for this example would describe the reaction as a continuous evolution over a potential barrier located between reactants and products.

without intermediates) a detailed discussion of the relation between the two definitions will be deferred to a later section of this paper. The rate of the reaction—that is, the rate at which reactants are converted into products—is calculated from the probability of a transition from each state of the reactants (electronic and nuclear) to each state of the products. The probability of that transition is proportional to the square of a quantity T, called the transition matrix. The reaction rate constant is obtained by taking the average of $|T|^2$ over the thermal (Boltzmann) population of all states of the reactants. The transition matrix T can be written as the sum of three terms [Eq. (4)][13]:

$$T = T_1 + T_2 + T_3 \tag{4}$$

In this expression, T_1 is the term that gives rise to electronic orbital symmetry rules; T_2 contains contributions to the rate from non-Born-Oppenheimer terms; T_3 describes spin-orbit contributions.

The term T_1 is given by Eq. (5),

$$T_1 = \langle\langle \Phi_N^r(R) | \langle \psi_e^p(r,R) | O | \psi_e^r(r,R) \rangle | \Phi_N^r(R) \rangle\rangle \tag{5}$$

where the superscripts r, p refer to reactants and products respectively. This expression differs from those normally encountered in electronic theory of molecules in that it depends on both electronic ($\psi_e(r,R)$) and nuclear ($\Phi_N(R)$) wave functions. The integration over the electronic coordinates r is indicated by single brackets

$$\langle \psi_e^p(r,R) | O(r,R) | \psi_e^r(r,R) \rangle \equiv \int \psi_e^{p*}(r,R) | O(r,R) | \psi_e^r(r,R) \, dr \tag{6}$$

and the integration over the nuclear coordinates R by double brackets[14]:

$$\langle\langle \Phi_N^p(R) | O'(R) | \Phi_N^r(R) \rangle\rangle \equiv \int \phi_N^{p*}(R) | O'(R) | \Phi_N^r(R) \, dR \tag{7}$$

A detailed definition of the operator O requires complicated arguments, and is neither within the scope of this article nor required for an understanding of the influence of molecular symmetry on reaction rate. In what follows, we will simply assert without proof the results of development and simplification of the expression for T_1 given by Eq. (5), and for corresponding expressions for T_2 and T_3. The mechanics of this development is described elsewhere[6g, 13, 28]. Thus, the electronic part of Eq. (5) is given by

$$\langle \psi_e^p(r,R) | O(r,R) | \psi_e^r(r,R) \rangle = \langle \psi_e^p(r,R) | H_e(r,R) | \psi_e^r(r,R) \rangle \tag{8}$$

+ other (neglected) terms[*].

[*] The terms left unspecified originate from the fact that we have confined the model to only two electronic states, one for products and one for reactants, and disregarded the possible (but usually unlikely) contributions of electronically excited states; and from the fact that the electronic quasiadiabatic states of the reactants are not necessarily orthogonal to those of the products [13]. Terms due to lack of orthogonality have the same symmetry properties as the term written in Eq. (8) and hence may for simplicity be omitted. The operator $H_e(r,R)$ is the electronic Hamiltonian of the complete reacting system (including all interactions between all nuclei and electrons).

The second term in the transition matrix T is given by

$$T_2 = -\frac{\hbar^2}{2} \sum_i \frac{1}{M_i} \left\{ \left\langle\left\langle \Phi_N^p(R) \left| \left\langle \psi_e^p(r,R) \left| \frac{\partial}{\partial R_i} \right| \psi_e^r(r,R) \right\rangle \frac{\partial}{\partial R_i} \right| \Phi_N^r(R) \right\rangle\right\rangle \right.$$
$$\left. + \left\langle\left\langle \Phi_N^p(R) \left| \left\langle \psi_e^p(r,R) \left| \frac{\partial^2}{\partial R_i^2} \right| \psi_e^r(r,R) \right\rangle \right| \Phi_N^r(r,R) \right\rangle\right\rangle \right\} \tag{9}$$

Here M_i is the mass of the i-th nucleus and the summation extends over all the nuclei. Notice that both the operator $\partial^2/\partial R_i^2$ in Eq. (9) and the electronic Hamiltonian $H_e(r,T)$ in Eq. (8) are totally symmetric, which means that the terms $\partial^2\psi(r,R)/\partial R_i^2$ and $H_e(r,R)\psi(r,R)$ have the same symmetry as $\psi(r,R)$. The second term in Eq. (9), therefore, has the same symmetry properties as T_1. Due to this symmetry equivalence and to the fact that this term is generally much smaller than the first one in Eq. (9), we shall neglect it. The remaining first term in Eq. (9) represents the contribution to the transition probability (and hence to the rate) from any coupling of the motion of the nuclei to that of the electrons. Such terms, called non-Born-Oppenheimer terms, appear in an analogous way in spectroscopy[12].

There is a simple way of seeing the origin of the coupling term involving the operator $\partial/\partial R_i$ in the non-Born-Oppenheimer contribution T_2. In quantum chemistry the electronic wave functions and energies are calculated with an electronic Hamiltonian in which the nuclei are usually held fixed. In most cases, the electronic states thus calculated (Born-Oppenheimer states) are an excellent approximation. Within that approximation, the system is confined to a single electronic state and transitions between electronic states are not possible. The removal of the approximation of fixed nuclei must take into account the velocity (hence, kinetic energy) of the nuclear motion. The velocity of the nuclei is represented by an operator proportional to $\partial/\partial R_i$ which appears in T_2 and induces transitions between the Born-Oppenheimer states.

The third term in the transition matrix, T_3, describes contributions to the rate from spin-orbit interactions and is given by

$$T_3 = \langle\langle \Phi_N^p(R) | \langle \psi_e^p(r,R) | H_{SO} | \psi_e^r(r,R) \rangle | \Phi_N^r(R) \rangle\rangle \tag{10}$$

where H_{SO} is the spin-orbit Hamiltonian. This term could, in principle, be expanded to include contributions to the rate from other couplings of angular momentum terms. For instance, the various interactions between electronic spin, nuclear spin, and molecular motion that determine the rates of processes important in CIDNP experiments could be included here. Spin-orbit interactions may become important whenever electron spin and orbital angular momentum are coupled, characteristically in radicals having heavy atoms.

We shall show that electronic symmetry rules for reaction rates of the W-H type originate in the T_1 term and that for reactions classified as "symmetry forbidden" by the W-H rules T_1 is small. T_2 and T_3 may, however, be sufficiently large, compared to T_1, to make a symmetry forbidden reaction proceed rapidly. The success of W-H rules depends in part on the fact that contributions to the rate from T_2 and T_3 are normally negligibly small. Even if T_2 and T_3 are small, however, it is not necessarily the case that the relative magnitude of T_1 (and

hence of T) for two competitive processes can always be deduced solely from symmetry considerations.

3.2. Electronic Symmetry Rules of the Woodward-Hoffmann Type

In the remainder of this section we derive the conditions which lead to symmetry rules, and discuss certain conditions under which these rules fail.

We emphasize that the form of these rules depends on the level of approximation with which the system is described. In particular, the W-H rules emerge from the most simplified treatment, in which virtual transitions among excited electronic states of reactant and products, the non-Born-Oppenheimer terms, and spin-orbit coupling are ignored; the Franck-Condon approximation is used; and the electronic wave functions are generated by the Hückel method. Various other possible approximations are discussed in Section 4.

3.2.1. The Role of Nuclear Overlap

Using Eqs. (5) and (8) we can write T_1 as:

$$T_1 = \int \Phi_N^R(R)\Phi_N^r(R)dR\langle\psi_e^p|H_e|\psi_e^r\rangle \qquad (11)$$

The term $\langle\psi_e^p|H_e|\psi_e^r\rangle$ depends on the electronic wavefunctions and the electronic Hamiltonian and will be referred to as the electronic part of T_1; the product $\Phi_N^R(R)\Phi_N^r(R)$ depends on nuclear wave functions only and will be called the nuclear part of T_1. A similar classification can be made for T_2 and T_3, given by Eqs. (9) and (10). The W-H and other electronic symmetry rules originate from the electronic part of the transition matrix. The existence of such rules presupposes, however, certain properties for the nuclear part. These properties are discussed in this subsection.

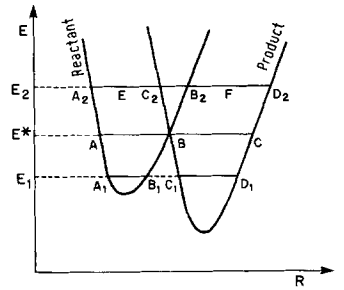

Fig. 5. Illustration of regions of substantial nuclear overlap for reactants and products. The heavy lines represent the quasiadiabatic energy surfaces of reactants and products. The light lines represent the nuclear configurations at which, for a given total energy of the reacting system, the nuclear wave functions (either one or both) are different from zero. For this qualitative discussion we neglect the small classically forbidden regions outside the wells of the heavy lines. At energy E_1, Φ_N^r is non-zero between A_1 and B_1 and Φ_N^R is non-zero between C_1 and D_1. The product $\Phi_N^r\Phi_N^R$ is therefore zero for all nuclear coordinates. At energy E_2, Φ_N^r is non-zero for nuclear configurations between A_2 and B_2, and Φ_N^R is non-zero for nuclear configurations between C_2 and D_2. Hence $\Phi_N^r\Phi_N^R$ is non-zero only between C_2 and B_2.

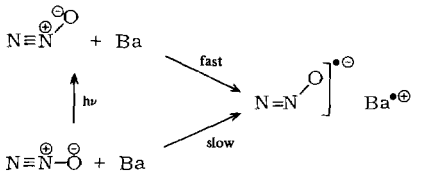
The functions $\Phi_N^R(R)$ and $\Phi_N^r(R)$ describe the nuclear positions and momenta[13]. The integral (11) for T_1 is non-zero only for those energies for which the two nuclear wavefunctions have an appreciable overlap (Fig. 5): that is, when the positions and momenta of the nuclei in the reactant and product configurations described by the chosen quasiadiabatic wavefunctions are similar. The nuclear overlap is zero at low energies, first becomes non-zero near the energy E^* at the crossing of the two quasiadiabatic surfaces, and then generally grows with the energy. We denote by $\Delta(E)$ the set of all nuclear configurations R for which, at a given total energy E, the product $\Phi_N^r(R)\Phi_N^R(R)$ is not zero. In the illustrative example presented in Figure 5, $\Delta(E_2)$ is the set of all nuclear configurations between C_2 and B_2. The integral (11) can be taken over $\Delta(E)$ only; no other nuclear configurations contribute to the integral T_1 since $\Phi_N^r(R)\Phi_N^R(R)$ is zero for R outside $\Delta(E)$,

$$T_1 = \int_{\Delta(E)} \Phi_N^R(R)\Phi_N^r(R)dR\langle\psi_e^p|H_e|\psi_e^r\rangle \qquad (12)$$

The immediate conclusion from this analysis is that the rate of reaction is zero if $\Delta(E)$ is zero, and that the energy of crossing, E^*, corresponds to the activation energy of transition state theory, since $\Delta(E) \neq 0$ for $E \geq E^*$ (Fig. 5). The physical picture which emerges from Eq. (12) is the following. If the energy is less than E^*, the nuclear overlap and the contribution to the rate from T_1 are zero. If the energy is greater than E^* the nuclear overlap is not zero and the reaction rate is therefore not restricted to zero by the nuclear wavefunctions. (We neglect discussions of tunneling, which do not alter the argument substantially.) If thermal or optical excitation increases the energy of reactants to E_2 (Fig. 5), the state of reactants will be $\psi_e^r(r,R)\Phi_N^r(R)$ and the nuclei will oscillate between A_2 and B_2 on the quasiadiabatic energy surface of reactants (corresponding to ψ_e^r). Since this state is not a stationary state of the total Hamiltonian, a transition may occur to the state of the products, described by the wavefunction $\psi_e^p(r,R)\Phi_N^R(R)$ (Fig. 5). In this state the nuclei will oscillate between C_2 and D_2 on the quasiadiabatic energy surface of the products. The probability of this transition is proportional to $|T_1|^2$. Loss of energy from the product at energy E_2 will produce a stable species with energy less than E^*, and complete the conversion of reactant to product.

This analysis of T_1 can be easily extended to T_2 and T_3 and indicates that regardless of the corresponding electronic parts of these terms, reaction occurs only if $\Delta(E) > 0$, and only at nuclear configurations contained in $\Delta(E)$. Since $\Delta(E)$ represents those nuclear configurations which are accessible from both reactant and product state we reach the following conclusions: regardless of how favorable the electronic conditions may happen to be, a reaction occurs only through conformations in which reactants and products have similar shapes. If the reacting molecules are excited specifically, so that the region of nuclear configurations $\Delta(E)$ available to both reactants and products is increased, the reaction will be faster. If the attainment of a common nuclear configuration for reactants and products is prevented by, say, a bulky group, then the reaction rate will be decreased.

These conclusions can be illustrated by a pertinent example provided by the reaction[15a]



$$N_2O + Ba \rightarrow N_2 + BaO^*$$

BaO is produced in an electronically excited state and the rate of the reaction can be monitored, in a molecular beam

experiment, by measuring the light emission from BaO*. The mechanism is assumed to be

$$N_2O + Ba \rightarrow N_2O^{\bullet\ominus} + Ba^{\bullet\oplus} \rightarrow N_2 + BaO^*$$

where both the charge transfer and the molecular rearrangement occur in a single collision. Since N_2O is linear and $N_2O^{\bullet\ominus}$ is bent, then according to the above discussion the reaction rate should increase if the N_2O bending vibration ν_2 is excited. Experiments show indeed a substantial increase of the rate with excitation of this vibration. Similar arguments

underlie the theory of electron-transfer reactions developed by *Marcus*[15b].

3.2.2. The Role of Electronic Symmetry; Franck-Condon Approximation

After clarifying qualitatively the role of the nuclear part in the transition matrix, let us analyze the role of the electronic term in T_1

$$F_1(R) \equiv \langle \psi_e^p | H_e | \psi_e^r \rangle = \int \psi_e^p(r,R) H_e(r,R) \psi_e^r(r,R) dr$$

Through Eq. (11), the values of $F_1(R)$ for all nuclear coordinates in $\Delta(E)$ influence the rate. Suppose, however, that the major contribution to T_1 comes from nuclear configurations in a small range of nuclear coordinates around R_0 so that we can reasonably assume that the electronic term $F_1(R)$ may be evaluated with sufficient accuracy by taking into consideration only the region around R_0. (This assumption is equivalent to the Franck-Condon approximation.) We further assume that the nuclear configuration R_0 has some useful symmetry. Since the electronic Hamiltonian is totally symmetric, the electronic wave functions of reactants and products have the same symmetry properties as the nuclei (that is they belong to the irreducible representations of the group generated by R_0). If the electronic wave function of reactants has a different symmetry than that of the products (that is, if reactants and products belong to different representations) we call the reaction symmetry forbidden. All other reactions are symmetry allowed. To avoid confusion, we should emphasize that the precise meaning of such a statement depends upon the electronic functions ψ_e^r and ψ_e^p chosen to describe the system; Hückel wave functions would lead to slightly different conclusions than SCF ones. We discuss this issue in detail later.

Let us now return to Eq. (11) for T_1 and see under what conditions symmetry forbidden reactions are slow. For some symmetrical nuclear configuration R_0 for which reactants and products have different electronic symmetry we have for the electronic integral

$$F_1(R_0) \equiv \langle \psi_e^p(r,R_0) | H_e(r,R_0) | \psi_e^r(r,R_0) \rangle = 0 \qquad (13)$$

The expression $F_1(R)$ contributes to the rate T_1 [Eq. (11)] not only through its value at R_0, however, but also through its value at all nuclear configurations R contained in $\Delta(E)$. By continuity, if $\langle \psi_e^p | H_e | \psi_e^r \rangle$ is zero at R_0 it will be very small close to R_0. If $\Delta(E)$ is just such a small neighborhood of R_0 (that is, if the Franck-Condon approximation holds), then we can predict from the fact that ψ_e^r and ψ_e^p have different symmetries that T_1 is very small. If $\Delta(E)$ is large, however, we cannot make such a statement since nuclear configurations R which are inside $\Delta(E)$ but far from R_0 may result in a substantial value for T_1.

We can summarize this discussion with the following symmetry rule: a symmetry forbidden reaction will have a very small rate if T_2 and T_3 are negligible, and $\Delta(E)$ is small (corresponding closely to the Franck-Condon approximation made in spectroscopy). Of course, in order to be able to speak of a symmetry forbidden reaction in the first place, $\Delta(E)$ must contain a symmetrical nuclear configuration. For reactions which occur through nonsymmetric nuclear configurations there are no symmetry restrictions. We note also that the various approximations needed to derive the symmetry rules break the coupling of the total angular momentum[6g]. Hence symmetry rules are obtained if the components of the total angular momentum (electron spin, electronic orbital, nuclear, *etc.*) are conserved separately.

The general electronic symmetry rules derived contain as a particular case the Woodward-Hoffmann rules. The success of the latter, in dealing with many examples, indicates that the conditions of validity established are satisfied in most cases. There are, however, situations when these conditions are not satisfied. One example has been already presented: excitation of the bending mode of N_2O increases both $\Delta(E)$ and $\Phi_N^r \Phi_N^r$ and leads to an increase in the rate of the reaction

$$Ba + N_2O \rightarrow BaO^* + N_2$$

although the *electronic part* of T *has remained unchanged.*

We must emphasize that the symmetry of the electronic wave functions can tell us, under the circumstances specified above, whether a symmetry forbidden reaction is very slow. If, however, the reaction is allowed by symmetry (*i.e.*, if ψ_e^r and ψ_e^p have the same symmetry), it is not necessarily true that $\langle \psi_e^r | H_e | \psi_e^p \rangle$, and the rate, are large. Poor overlap may cause $\langle \psi_e^r | H_e | \psi_e^p \rangle$ to be small.

3.3. Violations of Electronic Symmetry Rules

We have seen that electronic symmetry rules are valid if we neglect coupling of electronic spin (T_3 small), make the Born-Oppenheimer approximation (T_2 small), and a Franck-Condon approximation [see Eqs. (11), (12) and accompanying discussion]. When any one of these conditions is not satisfied, then the electronic symmetry rules are violated and "forbidden reactions" may have large rates. Here we analyze these violations for the purpose of clarifying their origin and finding ways of increasing the rate of symmetry forbidden reactions.

3.3.1. Violations Caused by the Interaction of Electronic and Nuclear Motion (Vibronic Violations)

Let us analyze a symmetry-forbidden reaction for which the spin-orbit coupling contribution to the rate is unimportant ($T_3 \approx 0$). If we assume that $\Delta(E)$ is small, then the term T_1

will be practically zero. Under these conditions the rate is given by $T \approx T_2$; if T_2 is very small the forbidden reaction is slow. If T_2 is large the "forbidden" reaction is fast, in violation of the predictions of electronic symmetry rules.

The term T_2, given by Eq. (9) has a structure which is very similar to that of T_1, and it is useful again to speak of a nuclear contribution $\langle\langle \Phi_N^p | \partial \Phi_N^r / \partial R_i \rangle\rangle$ and an electronic contribution $\langle \psi_e^p | \partial \psi_e^r / \partial R_i \rangle$. As in the case of T_1, it is possible to make some qualitative predictions about the behavior of these terms. The contribution from the nuclear part can be increased by exciting those nuclear motions that make more nuclear configurations accessible to both reactants and products. The magnitude of the electronic term has not been calculated for quasiadiabatic states. It is, however, generally considered to be small for adiabatic states and is probably also small for quasiadiabatic ones. Its small magnitude does not preclude it from playing an important role in *large molecules* where the number of nuclear states is enormous and the contribution of a small electronic term is summed over all the nuclear states involved; the compounded effect may be significant. In fact, this term is known to cause fast radiationless transitions in large molecules[16]. In solids, which we may consider to be large molecules with periodic symmetry, these electronic integrals are responsible for important effects like superconductivity[17], exciton migration[18], electrical resistance[19], *etc.*

In the case of T_1 the magnitude of the electronic contribution depends on the symmetry of the electronic functions. The magnitude of the electronic part of T_2 is not determined by symmetry except for special situations. To justify this assertion, we use the fact that for small displacements around some symmetrical configuration, R_0, the symmetry coordinates Q_i and the nuclear positions R_i are linear combinations of each other[20]:

$$Q_j = \sum_i A_{ji} R_i$$

Here A_{ji} are numerical coefficients. Hence

$$\left\langle \psi_e^p \left| \frac{\partial}{\partial R_i} \right| \psi_e^r \right\rangle = \sum_j \left\langle \psi_e^p \left| \frac{\partial}{\partial Q_j} \psi_e^r \right\rangle \frac{\partial Q_j}{\partial R_i} = \sum_j A_{ji} \left\langle \psi_e^p \left| \frac{\partial \psi_e^r}{\partial Q_j} \right\rangle \right.$$

At a symmetric nuclear configuration R_0, the terms $\psi_e^p(r, R_0)$, $\psi_e^r(r, R_0)$, and Q_i have a definite symmetry[20, 21], and some, *but not all*, of the integrals $\langle \psi_e^p | \partial \psi_e^r / \partial Q_j \rangle$ are zero (by symmetry). Hence

$$\left\langle \psi_e^p \left| \frac{\partial}{\partial R_i} \right| \psi_e^r \right\rangle = \sum_j A_{ji} \left\langle \psi_e^p \left| \frac{\partial \psi_e^r}{\partial Q_j} \right\rangle \right.$$

where now the summation eliminates those Q_i for which symmetry annihilates the corresponding integral. Since the summation on the right of this equation is not constrained to be zero by symmetry, we cannot predict the magnitude of T_2 from consideration of symmetry. *Only in the special case in which one symmetry coordinate is adequate to describe the reaction can T_2 be estimated from symmetry.* For example, in a reaction of the type $A + BA \rightarrow AB + A$ this reaction coordinate may be $A \rightarrow \leftarrow B - A \rightarrow$, which indeed tends to break the molecule in the desired way. Let us assume that the displacements $A \leftarrow B \rightarrow A$ and $\begin{array}{c} \uparrow \\ A - B - A \\ \downarrow \quad \downarrow \end{array}$ are not capable of promoting the reaction, since they are not likely to create nuclear configurations that are accessible to the product. Hence we should consider that only $\langle \psi_e^r | \partial \psi_e^p / \partial Q_1 \rangle$, in which Q_1 denotes the symmetry coordinate $A \rightarrow \leftarrow B \rightarrow A$, contributes to T_2 in Eq. (9). If the reaction is symmetry forbidden and ψ_e^r and ψ_e^p have different symmetry, $\langle \psi_e^r | \partial \psi_e^p / \partial Q_1 \rangle$ need not be zero. In fact, Q_1 and therefore $\partial / \partial Q_1$ are of symmetry $\sum_u^+$. Assume, for example, that the electronic states are of symmetry $\sum_g^+$ and $\sum_u^+$. The integral $\langle \sum_g^+ | \partial / \partial Q_1 | \sum_u^+ \rangle$, which appears in T_2, need not be zero since Q_1 is of symmetry $\sum_u^+$, and the derivative $\partial / \partial Q_1 \sum_u^+$ is totally symmetric. In this illustrative example the electronic symmetry, through $\langle \psi_e^p | H_e | \psi_e^r \rangle$, causes T_1 to be very small while there is no indication that the term T_2, with electronic part $\langle \psi_e^p | \partial \psi_e^r / \partial Q_1 \rangle$, has to be small. If in this example the reaction is symmetry allowed, and the electronic states have the same symmetry, say $\sum_g^+$, the electronic contribution to T_2 is $\langle \sum_g^+ | \sum_u^+ | \sum_g^+ \rangle$ and it is zero. In this case T_2 must be negligible, for symmetry reasons, while T_1 is not. The argument is qualitative: it clearly is not possible to estimate the magnitude of T_2 relative to T_1 using these considerations. Nonetheless, the argument establishes a link between molecular symmetry and T_2 that corresponds to different "rules" than those of T_1 (which are essentially of Woodward-Hoffmann type) and is potentially useful in simple reactions in suggesting types of vibrational motions that might contribute to increasing the rate of those reactions which are forbidden according to electronic symmetry rules.

3.3.2. Interaction between Electron Spin and Electron Orbital Motion

Let us now analyze a symmetry forbidden reaction for which T_1 and T_2 are both zero, so that the rate depends on T_3 only. If T_3 is large the symmetry forbidden reaction is fast and we have what is called a spin-orbit violation of symmetry rules. It is usually assumed that the spin-orbit coupling is small and a negligible part of the Hamiltonian, as far as the rate of chemical reactions is concerned. This assumption is not necessarily correct. Assume that the reactant electronic wavefunction ψ_e^r is a singlet and the product ψ_e^p is a triplet. In this situation the electronic parts of T_2 and T_3, *i.e.*, $\langle \psi_e^p | H_e | \psi_e^r \rangle$ and $\langle \psi_e^p | \partial \psi_e^r / \partial R_i \rangle$, are zero, due to the orthogonality of the spin part of the wavefunction. The only surviving term in T is T_3. Hence

$$T = T_3 = \int_{\Delta(E)} \Phi_N^r(R) \Phi_N^p(R) \mathrm{d}R \langle \psi_e^p | H_{SO} | \psi_e^r \rangle \qquad (13a)$$

The rate of the reactions between singlet and triplet states is determined by T_3 (spin-orbit coupling) only. Since the spin-orbit coupling Hamiltonian H_{SO} is *not* totally symmetric[22], T_3 does not have to be small when the reaction is forbidden according to electronic symmetry rules (ψ_e^r and ψ_e^p have different symmetries). As an example consider the reaction[11]

$$CO_2(^1\sum_g^+) \rightarrow CO(^1\sum^+) + O(^3P)$$

Schematic energy surfaces are presented in Figure 6. The reactant state is singlet and the product state is triplet. Therefore T (=T_3) is given by Eq. (13a). The spin-orbit coupling term can be estimated from spectroscopic measurements to be about 50 cm^{-1}. The nuclear wavefunction can be computed for a simple model. The resulting rate coefficient agrees well with the measured one[11], indicating that the spin-orbit coupling is indeed the necessary interaction for this reaction.

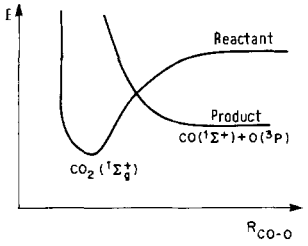


Fig. 6. Schematic energy surfaces for the reaction $CO_2(^1\Sigma_g^+) \rightarrow CO(^1\Sigma^+) + O(^3P)$.

The spin-orbit coupling may be enhanced in the presence of heavy atoms and inclusion of heavy atoms in reactants should increase the probability that they will take part in symmetry forbidden reactions.

3.3.3. The Role of Nuclear Motion. Violation of Electronic Symmetry Rules Due to Dynamics

We have already stressed the importance of the properties of the nuclear wave functions. If $\Delta(E)$ [see Eq. (12)] is very large and the nuclear overlap is very large, predictions of the magnitude of T_1, based on electronic symmetry alone, become doubtful. The difficulties in computing the nuclear wave functions make it impractical to propose any general calculational approaches to predicting violations of symmetry rules due to dynamics. Qualitatively, however, such violations occur when it is possible for the reactants to "look" like the product or *vice versa:* that is, for instance, when readily accessible vibrational states of the reactant(s) produce nuclear positions that closely resemble those of accessible vibrational states of the product(s). This results in an increase of the nuclear overlap, and in an increase in T_1 [Eq. (11)]. This qualitative consideration suggests that a plausible approach to increasing the rate of a symmetry forbidden reaction is to increase the vibrational energy of the reactant, most simply (but inefficiently) by heating, but also possibly by selective laser excitation of particular vibrational modes. A particularly pertinent example is provided by the reaction of H_2 and I_2. This reaction proceeding through a C_{2v} trapezoidal configuration is symmetry forbidden[23] (Fig. 7). Classical mechanical calculations[24] of reactive collisions indicate that as long as I_2 is in the vibrational ground state the reaction does not occur through a trapezoidal nuclear configuration, in agreement with the prediction of the W-H symmetry rules. If I_2 is, however, vibrationally excited, half of the reactive trajectories go through the trapezoidal configurations, contrary to the predictions of W-H rules.

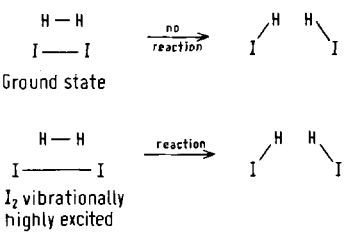

Fig. 7. Possible violation of the symmetry rules; a forbidden reaction is made possible by vibrational excitation.

4. Hierarchy of Symmetry Rules: *cis*-Butadiene—Cyclobutene Conversion

4.1. Molecular Orbital Description of Electronic Wave Functions

In the discussion of the previous Section we derived electronic symmetry rules without specifying any particular procedure for generating electronic wave functions. We shall now schematically illustrate the computation of the electronic part of T_1 for a specific example (butadiene → cyclobutene) and state the electronic symmetry rules in terms of the symmetry properties of Hückel *molecular orbitals* (as opposed to the symmetries of the *total electronic wave functions* used in the discussions of the previous section). We neglect here any contributions to the rate from T_2 and T_3. The reliability of the predictions resulting from these procedures depends on the quality of the electronic wave functions: different predictions might emerge, for example, from consideration of Hückel and SCF wave functions[13]. In such instances, it is worthwhile to understand the origin of the discrepancy and the ways of determining the correct prediction.

We begin our analysis by evaluating the relative magnitudes of the electronic part of T_1 [Eq. (13)] for four cases—thermal and photochemical conrotatory and disrotatory ring closures—and compare the procedure with that used in a W-H analysis. The W-H rules predict that the conrotatory pathway is thermally allowed and photochemically forbidden, and that the disrotatory pathway is thermally forbidden and photochemically allowed.

4.1.1. Thermal Reactions

The classification of the Hückel molecular orbitals for butadiene and cyclobutene orbitals by symmetry is too familiar to require discussion, but is summarized in Figure 8 for reference. One typical wavefunction for ground-state butadiene

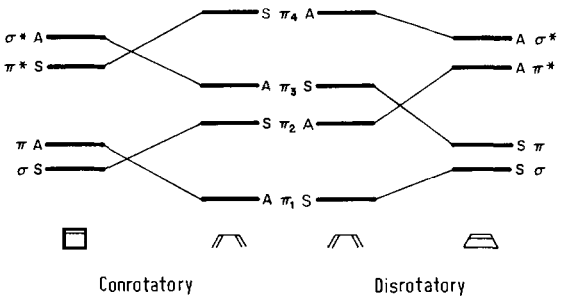

Fig. 8. Correlation diagram for Hückel molecular orbitals used for quasi-adiabatic description of conrotatory and disrotatory ring closure of butadiene.

is Eq. (14): In this expression, $\pi_1(1)$ indicates that the π_1 orbital contains an electron arbitrarily labeled 1. Eq. (14)

neglects the fact that it is not permissible to label electrons: equally valid distributions of electrons would be those given by Eqs. (15a) and (15b). The correctly antisymmetrized wave function for butadiene is therefore given by the appropriate Slater determinant [Eq. (16)].

$$\psi_r' = \pi_1(1)\pi_1(2)\pi_2(3)\pi_2(4)\Phi_N^r(R) \tag{14}$$

$$\psi_r'' = \pi_1(3)\pi_1(4)\pi_2(1)\pi_2(2)\Phi_N^r(R) \tag{15a}$$

$$\psi_r''' = \pi_1(3)\pi_1(1)\pi_2(4)\pi_2(2)\Phi_N^r(R) \tag{15b}$$

$$\psi^r = \frac{1}{\sqrt{4!}} \begin{vmatrix} \pi_1(1)\ \pi_1(2)\ \pi_1(3)\ \pi_1(4) \\ \pi_1(1)\ \pi_1(2)\ \pi_1(3)\ \pi_1(4) \\ \pi_2(1)\ \pi_2(2)\ \pi_2(3)\ \pi_2(4) \\ \pi_2(1)\ \pi_2(2)\ \pi_2(3)\ \pi_2(4) \end{vmatrix} \Phi_N^r(R)$$

$$\equiv \det\{\pi_1(1)\pi_1(2)\pi_2(3)\pi_2(4)\}\,\Phi_N^r(R) \tag{16}$$

Similar equations can be written for cyclobutene. Thus, using a one-electron Hamiltonian, Eq. (17), we can express Eq. (12) explicitly, for the reaction of interest, as Eq. (18):

$$H_e(r,R) = \sum_{i=1,4} H_i(r,R) \tag{17}$$

$$T_1 = \int_{\Delta(E)} \Phi_N^s(R)\Phi_N^r(R)\,dR\,\langle \det\{\sigma(1)\sigma(2)\pi(3)\pi(4)\} \left| \sum_{i=1,4} H_i(r,R) \right| \det\{\pi_1(1)\pi_1(2)\pi_2(3)\pi_2(4)\}\rangle \tag{18}$$

This expression for T_1, fully expanded, contains an inconveniently large number of terms. Fortunately it is unnecessary to evaluate all of these terms explicitly. Since we are interested initially only in the influence of molecular symmetry on T_1, we need only estimate the largest terms in this expression. To find these largest terms, consider two typical terms, for a thermal, conrotatory process as given in Eqs. (19) and (20); for convenience, these terms are also presented in a simplified form in which only the symmetry[*] of the appropriate molecular orbital is indicated.

$$\langle\sigma(1)|H_1|\pi_1(1)\rangle\langle\sigma(2)|\pi_1(2)\rangle\langle\pi(3)|\pi_2(3)\rangle\langle\pi(4)|\pi_2(4)\rangle = \\ = \langle S|H|A\rangle\langle S|A\rangle\langle A|S\rangle\langle A|S\rangle \tag{19}$$

$$\langle\sigma(1)|\pi_2(1)\rangle\langle\sigma(2)|H_2|\pi_2(2)\rangle\langle\pi(3)|\pi_1(3)\rangle\langle\pi(4)|\pi_1(4)\rangle = \\ = \langle S|S\rangle\langle S|H|S\rangle\langle A|A\rangle\langle A|A\rangle \tag{20}$$

Evaluation of these products of integrals requires remembering that $\langle S|H|A\rangle = \langle A|H|S\rangle = \langle A|S\rangle = \langle S|A\rangle = 0$: thus, on the basis of symmetry considerations above, all four terms in Eq. (19) are zero (at the chosen fixed, symmetrical nuclear configuration which serves to classify the MOs according to symmetry) and none of the four in Eq. (20) need be zero.

In general, for a system with n electrons: Expansion of the expression analogous to (18) affords a large number of terms [analogous to (19) and (20)], each being the product of n integrals of type $\langle\phi^p(i)|\phi^r(i)\rangle$ and (once per term) of type $\langle\phi^p(i)|H_i|\phi^r(i)\rangle$. *One* such integral is to be assigned to *each* of the n electrons in *each* term. ϕ^r is a singly or doubly occupied reactant orbital in the given reactant configuration, ϕ^p is a singly or doubly occupied product orbital in the given product configuration; all possible permutations of the orbitals occur in the various terms on assignment of these reactant and product orbitals to the electron i. However, each individual term reflects the given reactant and product configuration: a reactant orbital which is doubly occupied in the reactant will appear *twice* in the n integrals of each term, a singly occupied one *once*, and an unoccupied one *not at all*; the same applies to the product orbitals. The largest, *i.e.* dominant, terms obtained on expansion are those in which most of the n integrals $\langle\phi^r(i)|\phi^p(i)\rangle$ and $\langle\phi^r(i)|H_i|\phi^p(i)\rangle$ are characterized by the orbital ϕ^r and the orbital ϕ^p having the same symmetry; hence, it immediately follows that one of the dominant terms is obtained by making maximum possible use in its integrals $\langle\phi^p(i)|\phi^r(i)\rangle$ and $\langle\phi^p(i)|H_i|\phi^r(i)\rangle$ of those reactant orbitals ϕ^r and product orbitals ϕ^p which correlate with one another in the W-H orbital correlation diagram for the two reactant and product configurations under discussion! In what follows, we discuss only these largest terms which are easily determined by inspection of a W-H orbital correlation diagram. The number of integrals in a possible dominant term which are equal to zero for symmetry reasons is, of course, equal to the number of electrons which have to change orbitals in an orbital correlation diagram (formally, say at an orbital crossover point) in order that a given reactant configuration be transformed into a given product configuration along the correlation diagram.

For a thermal disrotatory ring closure, inspection of the correlation diagram (Fig. 8) immediately yields the following representative dominant term:

$$\langle\pi_1(1)|H_1|\sigma(1)\rangle\langle\pi_1(2)|\sigma(2)\rangle\langle\pi_2(3)|\pi(3)\rangle\langle\pi_2(4)|\pi(4)\rangle = \\ = \langle S|H|S\rangle\langle S|S\rangle\langle A|S\rangle\langle A|S\rangle \tag{21}$$

Since this ring closure (*i.e.* transition from the reactant configuration $\pi_1^2\pi_2^2$ to the product configuration $\sigma^2\pi^2$) involves changeover of two electrons from the π_2 orbital into the π orbital, two integrals in term (21) must be equal to zero for symmetry reasons, as is confirmed by inspection of this term.

The expressions in Eqs. (20) and (21), which represent the electronic part of T_1 for thermal conrotatory and disrotatory ring closure respectively, are qualitatively different: two of the terms in Eq. (21) are zero by symmetry; none is zero in Eq. (20). Since the magnitude of T_1 is related to the rate, the relative magnitudes of these expressions estimate the relative contributions to the rate attributable to molecular symmetry. Since Eqs. (20)—(21) represent the electronic part of T_1, they determine the rate through integrals over the nuclear coordinates [see Eq. (11)]; for the thermal disrotatory ring closure, for example, the appropriate integral is:

$$T_1(E) = \int_{\Delta(E)} \Phi_N^s \Phi_N^r \{\langle S|H|S\rangle\langle S|S\rangle\langle A|S\rangle\langle A|S\rangle\}\,dR$$

The terms $\langle A|S\rangle$ are zero for a symmetric nuclear configuration inside $\Delta(E)$. Since $\Delta(E)$ is assumed small, the values of $\langle A|S\rangle$ for all nuclear coordinates inside $\Delta(E)$ are very small: we designate the contribution of each of those small terms to T_1 by ε, and classify the size of T_1 by the number of the terms of magnitude ε which appear in the integral. Thus, T_1 for the thermal disrotatory reaction is of order ε^2, since two small terms appear in T_1. The same argument indicates that the magnitude of T_1 for the thermal conrotatory

[*] S stands for symmetric and A for antisymmetric.

ring closures, whose electronic part is given by Eq. (18), is of order $\varepsilon^0 = 1$. (In Section 4.1.2, which is concerned with the photochemical reaction, we show that T_1 for conrotatory and disrotatory photochemical ring closure is of order ε.) Then, since $|T_1|^2$ is the quantity related to rate, it is possible to classify the different types of conversions of butadiene to cyclobutene in terms of their "degree of forbiddenness", which is the exponent of ε in T_1. On grounds of symmetry alone, the quantity ε is a small number compared to integrals like $\langle S|S\rangle$ or $\langle A|A\rangle$; the greater the exponent of ε the smaller will be the value of $|T_1|^2$ due to the electronic integral. Qualitatively, there will be as many terms of magnitude ε in $T_1(E)$ as there are electrons that cross, in going from reactants to products, between orbitals of different symmetry.

This treatment thus differs from the standard W-H treatment in permitting "degrees of forbiddenness" rather than restricting reactions to the two categories of "symmetry allowed" and "symmetry forbidden". One should however be aware of the qualitative nature of this argument. Though each "symmetry forbidden" matrix element $\langle S|A\rangle$ or $\langle S|H|A\rangle$, contributes with a very small term ε, it is possible that different reaction pathways give ε's of different magnitude. If this difference of magnitude is large, though both ε are very small, our classification according to the powers of ε is not useful. Also, terms like $\langle S|S\rangle$ or $\langle A|A\rangle$ which need not be small by symmetry may be small for other reasons. Our classification based on powers of ε implicitly assumes that $\langle A|S\rangle \ll \langle S|S\rangle$ or $\langle A|A\rangle$. A test of these conditions for the case at hand is necessary before accepting this classification.

4.1.2. Photochemical Reactions

Since photochemical disrotatory and conrotatory ring closure have been the subject of numerous discussions and calculations[25], which sometimes seem to indicate the inadequacy of W-H rules in describing these reactions, we shall analyze such reactions in detail from the point of view of the present paper. Past discussions of these matters involved the details of the adiabatic energy surfaces and we find it useful to explore, for this particular example, the connection to our quasiadiabatic description. We shall use here quasiadiabatic wavefunctions which give a reasonable description of the two electronic states in the region of nuclear configuration in which the reactant resembles the product. For this purpose we modify the method described in Section 2 and choose the wavefunctions for the disrotatory, photochemical reaction to be:

$$S_1 = a_1 \det\{\pi_1 \pi_1 \pi_2 \pi_2\} + b_1 \det\{\sigma \sigma \pi^* \pi^*\} \quad (22)$$

$$A_1 = a_2 \det\{\pi_1 \pi_1 \pi_2 \pi_3\} + b_2 \det\{\sigma \sigma \pi^* \pi\} \quad (23)$$

$$S_2 = a_3 \det\{\pi_1 \pi_1 \pi_3 \pi_3\} + b_3 \det\{\sigma \sigma \pi \pi\} \quad (24)$$

Here, for example, S_1 corresponds to the ground state of butadiene when $a_1 = 1$ and $b_1 = 0$. The molecular orbitals used to form the determinants are those summarized in Figure 8. The second determinant in this expression serves to characterize the system in a state (for example, at high energy) which resembles cyclobutene sufficiently that MOs derived from butadiene no longer provide an adequate description: in these intermediate states, both a_1 and b_1 are non-zero. Variations in a_1 and b_1 provide a method of describing the system at any point in-between ground-state butadiene and cyclobutene in the corresponding doubly excited configuration. Equations (23) and (24) provide analogous descriptions of states which correspond at one extreme ($a = 1$, $b = 0$) to singly-excited and doubly-excited configurations of butadiene.

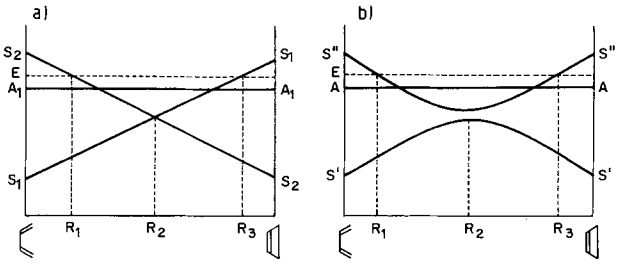

Fig. 9. Schematic quasiadiabatic (a) energy surfaces for the photochemical disrotatory electrocyclic reaction of butadiene to cyclobutane and corresponding adiabatic surfaces (b).

In Figures 9a and 9b we represent schematically the corresponding quasiadiabatic and adiabatic surfaces. The adiabatic surfaces resemble the results of van der Lugt and Oosterhoff[25].

The mechanism of reaction in the quasiadiabatic representation is as follows. Since only A_1 carries oscillator strength, the reaction starts with the molecule excited to A_1, at some energy E (see Fig. 9a). Because the energy surface of A_1 is fairly flat, as can be seen from the schematic correlation diagram Figure 9a or from the Lugt and Oosterhoff calculation, the molecule undergoes large amplitude oscillations along the reaction coordinate. For nuclear positions located at the right of R_1 (Fig. 9a) the electronic transition $A_1 \rightarrow S_2$ which generates vibrationally excited products becomes possible. In direct competition with this process, for nuclear configurations to the left of R_3, the transition $A_1 \rightarrow S_1$ is possible: this transition generates vibrationally excited reactants. If we assume that vibronic and spin-orbit contributions are small, then the rates of these transitions are determined by T_1. For the case $A_1 \rightarrow S_2$

$$T_1 = \int_{\Delta(E)} \Phi_N^P \Phi_N^R \langle A_1|H_e|S_2\rangle \, dR$$

Let us analyze the electronic part $\langle A_1|H_e|S_2\rangle$ from the point of view of the symmetry of the molecular orbitals. We see that A_1 is composed of two determinants [Eq. (23)] and inspection of Figure 8 indicates that both determinants have the same symmetry. The same is true for the determinants used in S_2. Hence all the terms in $\langle A_1|H_e|S_2\rangle$ have the same symmetry properties as:

$$\alpha \equiv \langle \det\{\pi_1 \pi_1 \pi_2 \pi_3\}|H_e|\det\{\sigma \sigma \pi \pi\}\rangle$$

If we repeat the analysis of Section 4.1.1, we find that the largest terms in α are represented by

$$\langle \pi_1|H_e|\sigma\rangle\langle \pi_1|\sigma\rangle\langle \pi_2|\pi\rangle\langle \pi_3|\pi\rangle = \langle S|S|S\rangle\langle S|S\rangle\langle A|S\rangle\langle S|S\rangle \sim \varepsilon^1$$

Thus the photochemical disrotatory ring closure is of order of forbiddenness one. By contrast, our previous analysis indicated that T_1 for the thermal disrotatory ring closure is of order ε^2 and this reaction is of order of forbiddenness two.

Hence, a disrotatory ring closure is predicted to take place more readily by a photochemical than by a thermal path.

There is no contradiction between this description of the reaction and that resulting from the adiabatic representation[25]: the latter however hides the role of symmetry. The quasiadiabatic process $A_1 \rightarrow S_2$ (see Fig. 9a) becomes in the adiabatic picture (Fig. 9b) $A \rightarrow S''$ (at configurations to the right of R_1) followed by $S'' \rightarrow S'$, at configurations around R_2. These transitions are due to non-Born-Oppenheimer coupling (between the *adiabatic states*) which may be quite important at R_2 since the electronic gap between S' and A is small. This adiabatic description of the reaction may seem different from that provided by the correlation diagrams and this apparent discrepancy has created some confusion. The adiabatic description is however equivalent to the quasiadiabatic one, which in turn is equivalent to the one provided by the correlation diagrams.

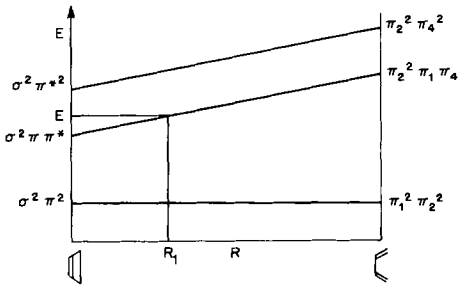

Fig. 10. Quasiadiabatic states for the conrotatory photochemical opening of cyclobutene to give butadiene.

The quasiadiabatic states for the conrotatory ring opening are presented in Figure 10. Since reactant and product states do not cross there is no possibility of an electronic transition which will lead to excited products.

We have ignored in the analysis kinetic factors that may become important in photochemical reactions, like radiative or radiationless de-excitation of the reactant state.

The discussion in this section serves to illustrate the electronic symmetry rules at the simplest level possible, when a Hückel description is used for the electronic wave function. Such rules are valid when $\Delta(E)$ is very small and the non-Born-Oppenheimer and spin orbit coupling are negligible. Under these circumstances we derive all the conclusions obtained from the original W-H rules. The rules derived here give more details about the reaction, indicating the possible existence of degrees of forbiddenness, and point out the important role that the overlap of the molecular orbitals plays in the electronic part of T_1, and hence in the rate.

4.2. Hierarchy of Symmetry Rules

We have emphasized at various places in this paper the fact that the predictions made by using the electronic symmetry rules depend on the degree of information that we have about the quasiadiabatic electronic wave functions. We illustrate this point now with the example of the ring closure reaction of butadiene. We represent the wave functions of both reactant and product, schematically, by indicating the symmetry of the molecular orbitals used to construct them. For the thermal disrotatory ring closure the reactant wave function is represented (Section 4.1.1) by SSAA, and that of the product by SSSS. As we have already discussed, when we know the symmetry of *each molecular orbital*, we can predict for this reaction an order of forbiddenness of two. Now let us assume that we want to use the electronic symmetry rules to predict the rate, but we know only the symmetry of *the wave functions* of the reactants and products (from spectroscopic measurements, for example) and know nothing about the symmetry of the molecular orbitals from which the wave function is built. For the disrotatory thermal ring closure the wave functions of reactants and products are both symmetric (the SSAA behaves upon reflection in the symmetry plane like SSSS since AA does not change sign). Therefore based on this information alone, using electronic symmetry rules, we see that the reaction is allowed; to be precise, this means that we cannot use electronic symmetry to state that the reaction is slow. Obviously the two predictions are different and the one based on the knowledge of the symmetry of the MOs is more useful. Different degrees of information need not lead to different conclusions. For example, in the case of reactions which can be represented as transitions from SSSA to SSSS or SAAA to SSSS, the symmetry of the electronic wave function of the reactants is different from that of the products and if we do not know the symmetry of the MOs we predict that both reactions are forbidden. The same prediction is made if the symmetry of the MOs is known and used, but in this case we gain the additional information that the first reaction (SSSA→SSSS) has an order of forbiddenness one while the second (SAAA→SSSS) has an order of forbiddenness three.

These examples illustrate how additional knowledge of the symmetry of MOs provides us with additional information which can change our ability to predict the outcome of the reaction. Thus a hierarchy of rules is possible, according to the details of knowledge of the symmetry of the wave function. This point has been made by *Silver*[6h] in a discussion based on a different approach.

4.3. The Role of the Electronic Interactions

In the previous subsection we have seen how the use of Hückel MO theory, which gives information about the symmetry of MOs, aids in learning more details about the rate of reaction. Hückel theory has, however, the disadvantage that it ignores to a large extent the interaction between electrons. In this section we discuss the effect that inclusion of electronic interactions, at the level of Hartree-Fock theory, has upon the predictions of reaction rates based on electronic symmetry.

It is very simple to take account of this interaction in the present approach in the electronic Hamiltonian H_e, which appears in the electronic part of T_1. If we write $H_e = H_e^{(1)} + H_e^{(12)}$, for the one- and two-electron parts ($H_e^{(12)}$ are the coulomb interactions between electrons), the two-electron operator contributes to T_1 terms of the form $\langle \psi_e^g | H_e^{(12)} | \psi_e^r \rangle$. For the thermal disrotatory reaction, for example, $\psi_e^r = \det\{SSAA\}$ and $\psi_e^g = \det\{SSSS\}$ and a representative two-electron term in $\langle \det\{SSSS\} | H_e^{(12)} | \det\{SSAA\} \rangle$ is $\langle SS|H_e^{(12)}|AA\rangle\langle S|S\rangle\langle S|S\rangle$. The one-electron contribution is, as already discussed, $\langle A|S\rangle\langle A|S\rangle\langle S|H_e^{(1)}|S\rangle\langle S|S\rangle$. The two-electron term has an order of forbiddenness zero, since SS

has the same symmetry as AA; the one-electron term has an order of forbiddenness two. In this particular case, the symmetry thus does not require that T_1 be small, although the one-electron contribution to T_1 is, in fact, very small. If the two-electron term is important (in other words, if the Hückel approximation is very poor) we will observe violations of the W-H rules. The success of W-H rules indicates that the joint contribution of all two-electron terms to T_1 is generally small. One should, however, keep them in mind as potential sources of violation of the rules. Notice also that for a reaction which can be described as SSSA→SSSS, and which has an order of forbiddenness one, the two-electron terms behave like the one-electron ones. Indeed both $\langle SA|H_e^{(12)}|SS\rangle$ and $\langle S|H_e^{(1)}|A\rangle$ are of order ε. Therefore the electronic interactions may change the predictions of the symmetry rules, based on one-electron terms, only in the case or reactions with order of forbiddenness two.

4.4. Role of Orbital Overlap

The principle of maximum bonding, which states that the reaction pathway is likely to be along the pathway of maximum MO overlap, is intimately connected to the symmetry rules by the present approach. In fact, in our approach the symmetry of molecular orbitals is used to determine whether the overlap between the MOs of the quasiadiabatic wave function of reactant and products is small. Poor overlap makes T_1 very small and leads to the same effect as selection rules based on the symmetry of the electronic wave function. Since the overlap between two MOs may be zero even if the symmetry does not require it to be so, it is useful to analyze the overlap whenever possible. For example let us compare again the disrotatory photochemical reaction with the disrotatory thermal reaction.

Figure 8 shows that the leading term in the electronic part of T_1 for the disrotatory photochemical reaction is

$$\langle\pi_1|H_e|\sigma\rangle\langle\pi_1|\sigma\rangle\langle\pi_2|\pi\rangle\langle\pi_3|\pi\rangle=\langle S|S|S\rangle\langle S|S\rangle\langle A|S\rangle\langle S|S\rangle$$

while that for the disrotatory thermal reaction is

$$\langle\pi_1|H_e|\sigma\rangle\langle\pi_1|\sigma\rangle\langle\pi_2|\pi\rangle\langle\pi_2|\pi\rangle=\langle S|S|S\rangle\langle S|S\rangle\langle A|S\rangle\langle A|S\rangle$$

The only difference is the replacement of $\langle\pi_3|\pi\rangle=\langle S|S\rangle$ in the expression for the photochemical reaction by $\langle\pi_2|\pi\rangle=\langle A|S\rangle$ to obtain the thermal one. Since $\langle A|S\rangle$ must be very small by symmetry and $\langle S|S\rangle=\langle\pi_3|\pi\rangle$ does not have to be, the symmetry rules predict that the thermal reaction is the slower of the two. This prediction will be inaccurate if the overlap of $\langle S|S\rangle=\langle\pi_3|\pi\rangle$ is very poor so that this term is in fact as small as $\langle\pi_2|\pi\rangle$. In this simple case, however, the overlap is large and the conclusion derived by using symmetry alone correct. In general, in comparing the photochemical (one electron excitation) with the thermal reaction, on pathways of the same symmetry (*e.g.*, both disrotatory), one has to compare the overlaps ⟨HOMO reactant|HOMO product⟩ and ⟨LUMO reactant|HOMO product⟩. If the latter is larger, then the photochemical reaction is faster.

The principle of maximum overlap has a broader validity than the electronic symmetry rules. The latter may be viewed as a particular case of the former in which the symmetry of the MOs is used to establish the existence of a very poor overlap. The principle of maximum overlap has the same limitations as the electronic symmetry rules in that both neglect possible coupling of electron spin, and both require the Born-Oppenheimer and Franck-Condon approximation. Thus both are restricted to consideration of electronic motion only; the neglect of nuclear motion limits the predictive value of these analyses of chemical kinetics.

5. Concerted and Nonconcerted Reactions

A definition of "concerted" and "nonconcerted" reactions is an integral part of any examination of symmetry rules for reaction rates, because these rules are usually applied to concerted reactions[26]. The traditional view is that a concerted reaction is one in which there is no intermediate. All bonds that break or form during the reaction do so simultaneously. A nonconcerted reaction is one in which there is an intermediate. These are useful qualitative notions. The discussions of the preceeding sections provide a framework with which to give operational definitions of both concerted and nonconcerted reactions.

We define a concerted reaction as one which consists of a *single* electronic transition from the quasiadiabatic state of reactants to that of the products. A nonconcerted reaction is one in which at least *two uncorrelated electronic transitions* are needed to complete the reaction. The most common situation which may give rise to a nonconcerted process is one in which three quasiadiabatic electronic states are required to describe the conversion of reactants to products (Fig. 11b). One describes the reactants, one the products and the third one (denoted I in Fig. 11b) is called the intermediate. The two electronic transitions required to make the reaction nonconcerted are, in this case, the transition from the state of reactants to that of the intermediate and a second transition from the intermediate state to that of the products. In this section we discuss nonconcertedness as it appears in reactive processes that may be characterized by three electronic states only. The need to consider more electronic states may arise but the discussion of such a situation is a straightforward generalization of the three-state case.

The points to be discussed here qualitatively are: 1) Since we define a nonconcerted reaction as one which requires two electronic transitions to complete the reaction, we must explain why the electronic symmetry rules break down for nonconcerted reactions and what the new symmetry rules are, if any. 2) How can one establish by a simple calculation whether a reaction is nonconcerted? 3) What is the connection between the present definition of nonconcertedness and the ones existing in the literature?

To answer the first question, let us consider the case presented in Fig. 11b. For energy E_t (the energy at R_1) the direct transition reactant→product by a single electronic transition is not possible since the overlap of the nuclear wave functions is extremely small. It is, however, possible to have a transition reactant→intermediate since the nuclear overlap is fairly substantial around the nuclear configuration R_1, cor-

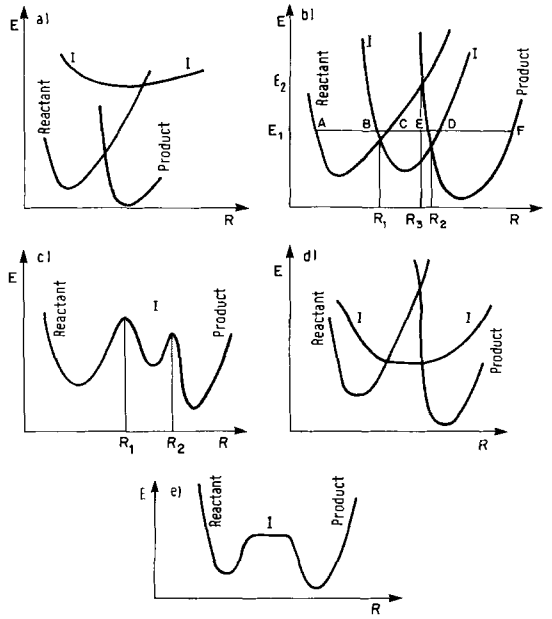

Fig. 11. a) A reaction for which the third electronic state (intermediate) (I) is too high to be accessible. The state I is not populated and the reaction is concerted. b) The third quasiadiabatic electronic state is low enough and the transitions R→I and I→P are energetically possible. At energy E_1 the reaction is nonconcerted. At energies around E_2 the reaction is both concerted and nonconcerted (see text for details). c) Adiabatic energy surface corresponding to the case of Fig. 11b. d) A flat intermediate quasiadiabatic energy surface which may be expected in the case of a diradical. e) The flat barrier on the adiabatic energy surface corresponding to Fig. 11d.

responding to the crossing of the energy surfaces of reactant and intermediate (Fig. 11b). Once the system is in the electronic state I the nuclei undergo oscillatory motion with the amplitude BD. Within a period of oscillation (10^{-13} s) the nuclei visit the region ED, in which the nuclear wave function in the state I overlaps well with that in the state P. A transition from I to P becomes possible and when this happens the reaction is completed. One can show that the electronic part of the transition probability for two uncorrelated transitions, corresponding to the part T_1 for concerted reactions, is of the type[13, 28]:

$$\langle\psi_e^P|H_e|\psi_e^I\rangle_{R_2}\langle\psi_e^I|H_e|\psi_e^R\rangle_{R_1} \tag{25}$$

where the subscripts R_1 and R_2 indicate that only the nuclear configurations located around R_1 and R_2 need to be considered. The derivation of the electronic symmetry rules for concerted reactions has been based on the fact that the electronic part of the transition matrix has the form $\langle\psi_e^P|H_e|\psi_e^I\rangle_{R_1}$ and the electronic states of *reactants and products* appear in the same matrix element. Integrals of this form do not occur in descriptions of the electronic part of a nonconcerted reaction, given by Eq. (25), and therefore the simple electronic symmetry rules which apply to concerted reactions do not apply. Other rules are, however, possible[28]. We can regard the two terms of Eq. (25) as electronic parts of two independent concerted reactions, one represented by R→I and the other by I→P. Hence symmetry rules apply for each of these terms separately. If, for example, R_1 is very close to a symmetric nuclear configuration R_1^0, and the wave functions ψ_e^R and ψ_e^I have different symmetry (they belong to different irreducible representations of the group generated by R_1^0), the reaction R→I is forbidden. Its rate, and correspondingly the rate of the nonconcerted reaction will be slow. The same argument applies separately to the "step" I→P, at nuclear configurations R_2. More details may be found in Ref.[28].

Concerning the second question: After clarifying how the involvement of a third state can make the reaction nonconcerted, let us indicate very briefly how one can test whether a given process is concerted or not. One should start by listing the chemical structures that are likely candidates for an intermediate. Then quasiadiabatic states should be constructed for each intermediate, at the level of simple Hückel theory. For example, in the case of butadiene ring closure one may think of a diradical with unpaired electrons at C^1 and C^4. A quasiadiabatic state for the diradical can be constructed by using a $2p_z$ orbital on each of the carbons labeled 2 and 3 and two localized orbitals for the single electrons on C^1 and C^4[29]. The electronic energy surface may be located with respect to the reactants and products as shown in Figure 11a. In this case the reaction is concerted. If the results are as shown in Figure 11b then at energies $E \approx E_1$ the reaction is nonconcerted. If the energy is raised (thermally or through laser induced vibrational excitation) close to E_2 the concerted reaction R→P starts competing with the nonconcerted one. This possibility of simultaneous coexistence of concerted and nonconcerted pathways has been inferred from experimental data[30].

Regarding the third question: Previous definitions of nonconcertedness[26a-d, 27] can be all derived from the present one. The adiabatic surface corresponding to the nonconcerted reaction (Fig. 11b) is shown in Figure 11c. We see that the presence of the intermediate state in Figure 11b creates a well in the adiabatic state of Figure 11c located between reactants and products. One of the early definitions of nonconcertedness required such a well (for a discussion of this see Ref. [27b]). There is, however, a possibility that the intermediate state may have a flat or a sloped shape between the points of intersection with the reactant and product surfaces. Computations show that a flat surface is very likely, for example, in the case of diradical intermediates[27a, 29]. Such a situation can be seen in Figure 11d which represents a nonconcerted reaction. The corresponding adiabatic surface is flat (Fig. 11e) and does not have a well. The possibility that a flat barrier, or an adiabatic surface, can be associated with nonconcertedness has been proposed in the literature[27a]. Finally, our description of a nonconcerted process fully agrees with and substantiates, in an obvious way, the one proposed by *Doering* and *Sachdev*[27c] which involves in the intermediate a set of vibrational states.

Thus, this formalism for reaction rates incorporates naturally inferences drawn from experimental studies concerning the characteristics required for a reaction to be nonconcerted. It does not answer explicitly[28] the question of the minimum lifetime required for the definable existence of an intermediate, but instead indicates that this question is not a useful one, since there is a smooth continuum of possible processes ranging from concerted to nonconcerted.

This work was supported in part by the National Science Foundation and the Energy Research and Development Administration.

[14] Since the purpose of this paper is limited to an analysis of symmetry rules of the W-H type which require some details of the electronic states, we can ignore all but some qualitative properties of the nuclear wavefunctions. These functions satisfy very complicated equations which will not be given here. In lowest order approximation, however, the nuclear wave function of reactants, for example, is equal to the wave function of the nuclei moving under the influence of the quasiadiabatic electronic energy of the reactants. Higher order calculations must of course include the fact that the state of products is also present.

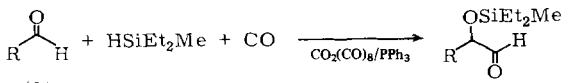
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Catalytic Conversion of Aldehydes into Higher α-Siloxy Aldehydes by Hydrosilane and Carbon Monoxide[**]

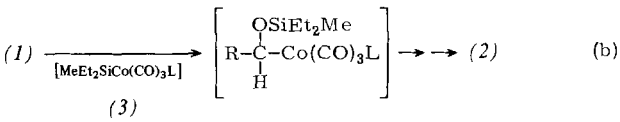


By *Shinji Murai, Toshikazu Kato, Noboru Sonoda, Yoshio Seki,* and *Kazuaki Kawamoto*[*]

Among the reactions belonging to the hardly explored realm of carbon monoxide chemistry, carbonylation at the carbonyl carbon of an aldehyde or a ketone [eq. (a)] is one of the most interesting.

(a)

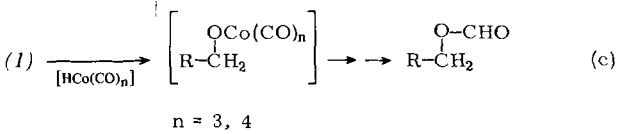
Only a few ambiguous examples of reactions of type (a) have been reported: catalytic conversion of formaldehyde with CO and H_2 into α-hydroxyacetaldehyde in moist solvents[1] and that of acetaldehyde with CO and H_2O into α-hydroxypropionic acid[2]. These reactions, however, most likely proceed indirectly *via* hydrated aldehydes or poly(oxymethylenes)[3]. This paper describes a definite example of the catalytic reaction (a).



(1) *(2)*

(a), R = n-C_3H_7
(b), R = n-C_6H_{13}
(c), R = c-C_6H_{11}

The reaction of heptanal with $MeEt_2SiH$ (molar ratio 3:1) and CO (50 kg/cm²) in the presence of $Co_2(CO)_8$ and PPh_3 gave α-[diethyl(methyl)siloxy]octanal *(2b)* in 50% yield[4]. Similar results were obtained with butanal *(1a)* and cyclohexanecarboxaldehyde *(1c)*[4] (yields 49 and 54%, respectively). The use of an excess of the starting aldehyde is essential, since 1,2-bis(siloxy)alkenes are otherwise formed[5].—The reaction products, α-siloxyaldehydes *(2)* are useful intermediates in organic synthesis that are otherwise difficult to prepare.



We suggest that the active catalyst is a silylcobalt complex *(3)*, L = CO or PPh_3, and the key intermediate is α-siloxyalkylcobalt compound *(4)* [eq. (b)]. The high affinity of the silyl group for the oxygen function may force bond formation between carbon and cobalt [eq. (b)]; this contrasts with the reaction of aldehydes *(1)* under oxo conditions (H_2 and CO) to give formates [eq. (c)], with $HCo(CO)_n$ as active catalyst[6].

(3)

(4), L = CO, PPh_3

(b)

n = 3, 4

(c)

The insertion of carbon monoxide into α-siloxyalkylmanganese has very recently been reported[7]. Reactions involving α-oxyalkyl-metal compounds such as this and *(4)* are important in relation to the mechanism of the Fischer-Tropsch reaction[8] and Union Carbide's ethylene glycol synthesis[9].

Experimental

Synthesis of *(2b)*: A solution of *(1b)* (4.2 ml, 30 mmol) diethyl(methyl)silane (1.02 g, 10 mmol), $Co_2(CO)_8$ (0.136 g, 0.4 mmol), and PPh_3 (0.104 g, 0.4 mmol) in benzene (20 ml) was placed in a 100-ml stainless steel autoclave. The autoclave was flushed with N_2 (50 kg/cm²) and CO (50 kg/cm²), then charged with CO (50 kg/cm²) and immersed in an oil bath preheated to 100°C and held at this temperature with stirring for 20 h. Analysis of the reaction mixture by GLC [Silicon OV-1, 5%, on Uniport KS, 3 m, 140°C, n-tetradecane as internal standard] showed it to contain *(2b)* in 50% yield. An analytical sample was obtained by distillation (b.p. 122–132°C/10 torr) and preparative GLC [Silicon OV-1, 170°C][4].

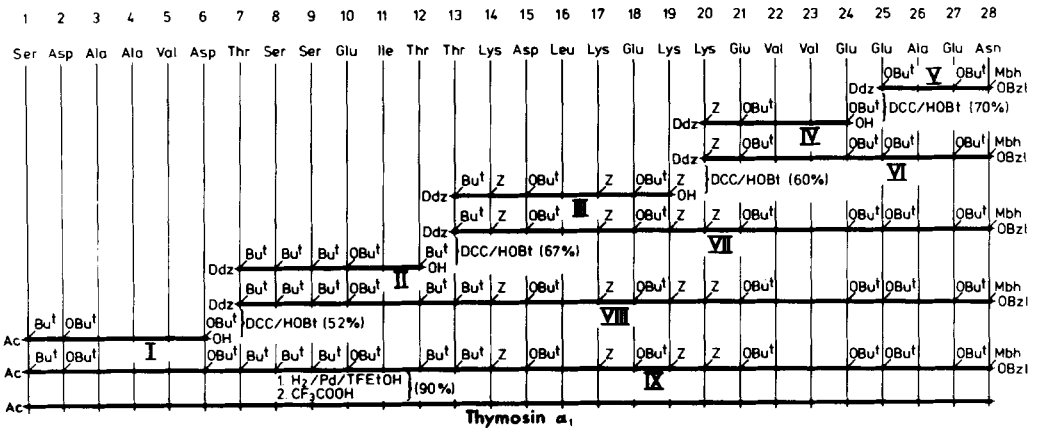
Synthesis of Thymosin α_1, a Polypeptide of the Thymus[**]

By *Christian Birr* and *Ulrich Stollenwerk*[*]

The regulation of the immune defense mechanism of the body by polypeptides of the thymus gland is presently being studied with increasing interest.

It has been demonstrated by injection of cell-free protein extracts from calf thymus in genetically athymic mice (or after thymectomy) that immunologial deficiency diseases such as increased susceptibility to infection, higher probability of tumor formation, accelerated aging and diminished rejection of skin grafts could be suppressed with varying degrees of success[1].

With the aid of a purified "protein fraction no. 5" from calf thymus it could also be demonstrated that the differentiation of immature thymus-dependent immune defense cells (T-cells, T-lymphocytes) could be stimulated to form mature immune-competent T-lymphocytes[2]. This "protein fraction no. 5" was named "thymosin" and is administered in several clinical tests against different types of cancer[3]. Separation of thymosin by electrofocusing yielded an acidic polypeptide, thymosin α_1 (pI = 4.2)[4a]. The sequence of thymosin α_1 has been determined, but an announced description of its synthesis (*Wang et al.*, 1977) has not, as yet, been published[4b].



In the following we briefly outline a method for the synthesis of the sequence given for thymosin α_1[4] (scheme 1). Alternative routes and biological data will be published elsewhere[5].

The peptide was built-up by fragment condensation with dicyclohexylcarbodiimide/1-hydroxybenzotriazole (DCC/HOBt)[6] from 5 segments: I (1—6), II (7—12), III (13—19), IV (20—24) and V (25—28). All segments were synthesized fully protected by stepwise N-terminal sequence elongation. The syntheses were carried out in solution using an excess of the mixed anhydrides of the Ddz-amino acids prepared from isobutyloxycarbonyl chloride/*N*-methylmorpholine[7]. This resulted in the benzyl esters of segment I (67%) and V (39%), and the methyl esters of II (20%), III (31%) and IV (56%), respectively (overall yields in brackets). After alkaline saponification in aqueous dioxane, condensation of segment IV in dimethylformamide with V (after Ddz-deprotection with 1% trifluoroacetic acid/dichloromethane (v/v)) for 24 h afforded fragment VI in 70% yield.

Segment III, after saponification in aqueous tetrahydrofuran/methanol, was coupled with VI in dimethylformamide for 6 h, giving fragment VII in 60% yield. After Ddz-deprotection (as in V), VII was N-terminally elongated in 18 h at 0°C and 10 h at *ca.* 20°C with segment II (saponified in dioxane/H_2O 8:2 (v/v)) to give VIII in 67% yield.

Before the final condensation, the benzyl ester group was cleaved from the N-terminal acetyl segment I by hydrogenation (Pd/C) in 2-propanol/acetic acid. The free acid of I was coupled in the final condensation with VIII in *N*-methylpyrrolidone/dimethylformamide 2:1 (v/v) for 24 h, thus affording the completely protected end-product IX in 52% yield. IX was chromatographically purified on Sephadex LH 20 in 2,2,2-trifluoroethanol. Amino acid analysis (theor. values in brackets; 6 N HCl/110°C/24 h): Asp 4.11 (4); Thr 2.64 (3); Ser 2.38 (3); Glu 6.80 (6); Lys 4.59 (4); Ile 1.13 (1); Leu 1.23 (1); Ala 2.51 (3); Val 2.41 (3).

In three final reactions IX was liberated from all of its protecting groups: For cleavage of the benzyloxycarbonyl protecting groups and the C-terminal benzyl ester, the polypeptide IX was hydrogenated with Pd/C in 2,2,2-trifluoroethanol (96% yield). The resulting product was treated with trifluoroacetic acid/dichloromethane 1:1 (v/v) in the presence of 10% anisole for 30 min to cleave mainly the *tert*-butyl esters. After removal of volatile components *in vacuo* at room temperature, the residual polypeptide/anisole was treated with pure trifluoroacetic acid for the final cleavage of *tert*-butyl and 4,4'-dimethoxybenzhydryl protective groups (120 min, *ca.* 20°C). Precipitation and subsequent washing with ether yielded synthetic thymosin α_1, which was chromatographed on Biogel P-6 for purification and characterization. For this purpose the column

Scheme 1: Synthesis of thymosin α_1 by condensation of the fragments I—VIII. Double amounts of the N-terminal fragments were employed; yields are based on the C-terminal component. Protective groups: Ac: acetyl; Bu^t: *tert*-butyl; Bzl: benzyl; Ddz: 3,5-dimethoxy-α,α-dimethyl-benzyloxycarbonyl; Mbh: 4,4'-dimethoxybenzhydryl; Z: benzyloxycarbonyl.

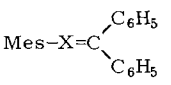
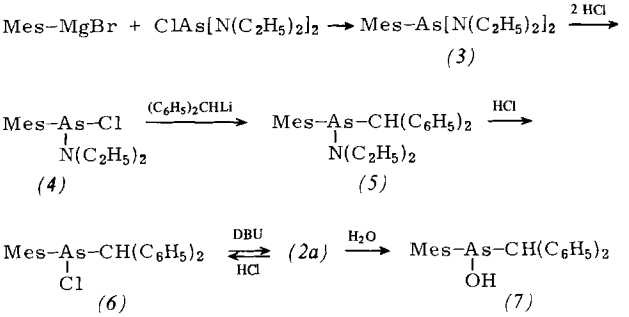
Mesityl(diphenylmethylene)arsane[**]



By *Theo C. Klebach, Hans van Dongen*, and *Friedrich Bickelhaupt*[*]

Dedicated to Professor Egbert Havinga on the occasion of his 70th birthday

Consistent with the empirical "double bond rule" and theoretical arguments, the tendency to form the pπ-hybridized state with coordination number 2 in Group 5 is still less pronounced with arsenic than with phosphorus. Relatively few compounds with two-coordinate arsenic are known, and they are less stable than those of phosphorus[1]. The requisite stabilization in the arsamethinecyanines[2] and in arsabenzene[3] and its derivatives is primarily due to delocalization. The only known stable compound with apparently localized As=C bonding is phenyl[2,2-dimethyl-1-(trimethylsiloxy)propylidene]arsane *(1a)*[4]; however, the extent to which the oxygen atom influences this bonding is still unclear.



(1a), X = As
(1b), X = P

(2a), X = As
(2b), X = P
(2c), X = N

It therefore seemed worthwhile investigating whether a compound with a localized As=C bond substituted by carbon only is thermally stable. We have now been able to synthesize mesityl(diphenylmethylene)arsane *(2a)*, after it had been shown with the corresponding phosphorus compound *(2b)* that the mesityl group is suitable for steric shielding of the reactive P=C bond[5].

Reaction of mesitylmagnesium bromide with chlorobis(diethylamino)arsane in tetrahydrofuran (THF) afforded a solution of *(3)*, which was directly treated with two equivalents of HCl in THF at −40°C to give *(4)* [yield 40% based on chlorobis(diethylamino)arsane; b. p. 85—89°C/10^{-3} torr]. Reaction of *(4)* in THF with diphenylmethyllithium (20% excess) yielded *(5)*, which on passage of gaseous HCl reacted further to give *(6)* [yield *ca.* 50% based on *(4)*; m. p. 58—62°C after chromatographic purification on Al_2O_3 (Brockmann, Act. 2—3, toluene/chloroform 9:1) and sublimation (140°C/10^{-3} torr)]. Elimination of HCl from *(6)* with diazabicycloundecene (DBU) in THF (25°C, 3 h) proceeded almost quantitatively; after filtration from DBU-HCl, evaporation of the solution and extraction with cyclohexane afforded *(2a)* as a bright yellow viscous oil, which is stable at room temperature in the absence of air. Pure *(2a)* could hitherto be obtained only in a sealed high-vacuum system.

The spectral data of *(2a)* [Table 1; MS: $m/e = 360.0867$ (M^+, 15%), calc. 360.0859] confirm the assigned structure. Characteristic is the ^{13}C-NMR signal for the carbon of the As=C bond, which by its position at very low field reflects the hybridization of the carbon ($sp^2\pi$) and the effect of the neighboring arsenic[6]. As in the case of *(1a)* and *(1b)*[7], this signal lies at lower field in the arsenic compound *(2a)* than in the phosphorus compound *(2b)*. The UV maximum of *(2a)*, which is assigned to a n→π* transition[8], is shifted, as expected, to longer wavelength than that of *(2b)*.

As in *(2b)*, the steric hindrance to polymerization is apparently the most important factor determining the stability in *(2a)*. Attempts to synthesize phenyl(diphenylmethylene)ar-

Table 1. Spectral data of *(2a)* and *(2b)*.

sane afforded only polymeric material, even though the coplanarity, and thus the configuration of the aromatic rings is expected to be more favorable than in *(2a)*.—The X-ray structure analysis[9] of the nitrogen analogue *(2c)*[5] showed that the planes of the mesityl groups and *syn*-phenyl groups form a relatively large angle (73° and 60°, respectively) with the plane of the N=C bond.

From investigations carried out so far, the chemical behavior of *(2a)* would appear to resemble that of *(2b)*[5], but *(2a)* is certainly more reactive. In THF, *(2a)* adds HCl to give *(6)*, with arsenic expectedly functioning as the more positive partner of the As=C bond. However, whereas the addition of methanol to *(2b)* does not take place without base-catalysis and *(2b)* is stable under nitrogen, *(2a)* even adds traces of water under these conditions to give *(7)*. This reaction apparently proceeds more rapidly than atmospheric oxidation.

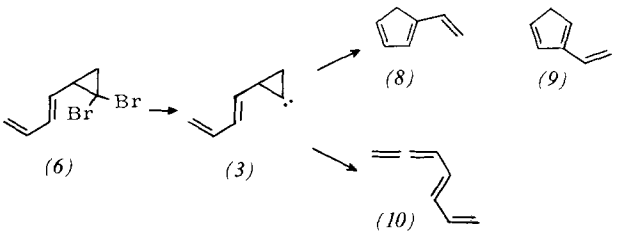
Carbene-Carbene Rearrangements of *cis*- and *trans*-2-(1,3-Butadienyl)cyclopropylidene[**]

By *Udo H. Brinker* and *Ilona Fleischhauer*[*]

Carbene-carbene rearrangements[1] in which the migrating divalent carbon retains its identity (Type II) are, with one exception[2], limited to the reorganizations of vinylcyclopropylidenes *(1)* into 3-cyclopentenylidenes *(2)*[3].



The formation of *(2)* is formally the result of a 1,3-shift of the C1—C3 bond in *(1)* to C5[1,2,4]. *(2)* gives 1,3-cyclopentadiene *via* a subsequent 1,2-hydrogen shift. Replacement of the vinyl group in *(1)* by a 1,3-butadiene unit affords the configurational isomers 2-(1,3-butadienyl)cyclopropylidenes *(3)* and *(4)*[5], which should be suitable as model compounds for the study of carbene-carbene rearrangements involving 1,3- and/or 1,5-carbon shifts. While the 1,3-shift can take place in *(3)* and *(4)*, only the *cis*-isomer *(4)* has the structural prerequisites for the 1,5-shift of the divalent carbon not yet observed.

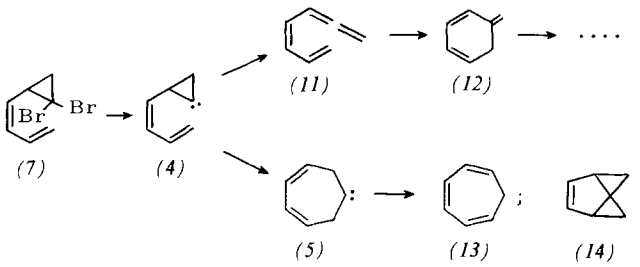
We report here on the generation of *(3)* and *(4)* and their carbene-carbene rearrangements, which proceed with remarkable regiospecificity.

Addition of dibromocarbene to *trans*- and *cis*-1,3,5-hexatriene affords the two monoadducts[6] *(6)* and *(7)* in 42 and 37% yield, respectively. Reaction of *(6)* with methyllithium (molar ratio 1:1.5; ether, 0°C) gives the isomeric vinylcyclopentadienes[7] *(8)* and *(9)* in 52% yield and the previously

unknown 1,2,4,6-heptatetraene *(10)*[6] (see Table 1) in 48% yield. Consequently, in the *trans*-isomer the competing processes—carbene-carbene rearrangement with 1,3-carbon shift and cyclopropylidene-allene rearrangement[1]—take place, as expected, to a comparable extent.

Table 1. Physical data of compounds *(6)*, *(7)*, and *(10)*. The ^{1}H-NMR spectra were recorded at 60 MHz in CCl_4.

(6), ^{1}H-NMR: $\delta = 6.00$—6.70 (m, 2 olefinic H), 4.85—5.70 (m, 3 olefinic H), 1.40—2.55 (m, 3 cyclopropane H); UV (*n*-hexane): $\lambda_{max} = 229.5$ nm ($\varepsilon = 22400$)
(7), ^{1}H-NMR: $\delta = 6.00$—7.05 (m, 2 olefinic H), 4.95—5.50 (m, 3 olefinic H), 1.35—2.80 (m, 3 cyclopropane H); UV (*n*-hexane): $\lambda_{max} = 231$ nm ($\varepsilon = 18200$)
(10), ^{1}H-NMR: $\delta = 5.50$—6.65 (m, 4 olefinic H), 4.80—5.35 (m, 4 olefinic H); IR (CCl_4): $\nu = 1940\,cm^{-1}$ (C=C=C); UV (*n*-hexane): $\lambda_{max} = 250$ nm, sh ($\varepsilon = 30700$), 257 (39400), 268 (32800)



Surprisingly, no 1,3-shift, which should again afford the isomers *(8)* and *(9)*, is observed on reaction of the *cis*-isomer *(7)* under the same conditions. However, 1,3,5-cycloheptatriene *(13)* (17%) is formed as a major product, along with 5-methylene-1,3-cyclohexadiene *(12)* (14%), the arene derivatives toluene (10%), ethylbenzene (14%), and benzaldehyde (17%), as well as the diastereoisomeric *cis*- and *trans*-1-bromo-1-methyl-2-(1,3-butadienyl)cyclopropanes (21%) and 1-bromo-2-(1,3-butadienyl)cyclopropanes (7%). The last-mentioned products could be formed by methylation and protonation, respectively, of the organometallic intermediate formed on metalation.

The independent synthesis of *(12)*[8a] and studies on its reactive behavior under the conditions employed in the reaction of *(7)* confirmed that the aromatic compounds (toluene[8b], ethylbenzene, benzyl hydroperoxide → benzaldehyde[8c,d]) are secondary products of *(12)*. The formation of *(12)* can be initiated by cyclopropylidene-allene rearrange-

ment *(4)*→*(11)*. However, while the *trans*-1,2,4,6-heptatetraene *(10)* formed from *(6)* is stable under the reaction conditions, the *cis*-configurated allene *(11)* could be stabilized by electrocyclic ring closure to *(12)*. In the presence of tetracyanoethylene, *(12)* was trapped in the form of its known ene adduct[9].

For the formation of 1,3,5-cycloheptatriene *(13)* several alternative mechanisms have to be considered: insertion of the divalent carbon into the terminal vinylic C—H bond to give norcaradiene, which rapidly rearranges into the valence isomer *(13)*; to our knowledge, however, this insertion-type mechanism has hitherto not been reported for carbenoids. Intramolecular addition of the divalent carbon to the terminal double bond of *(4)* could afford tricyclo[4.1.0.0^{1,3}]hept-4-ene *(14)*, which either decomposes in a cheletropic retro-carbene addition to 3,5-cycloheptadienylidene *(5)* whereupon it forms stable *(13)*, or can undergo fragmentation and hydrogen shift to give cycloheptatriene *via* diradical intermediates; thermochemical estimates, however, show both processes to be endothermic. A plausible explanation for the formation of *(13)* is afforded by the novel carbene-carbene rearrangement with a 1,5-carbon shift in *(4)* to give 3,5-cycloheptadienylidene *(5)* followed by a 1,2-hydrogen shift.

(3) and *(4)* constitute the first pair of configurational isomers of carbenes which behave regiospecifically in carbene-carbene rearrangements.

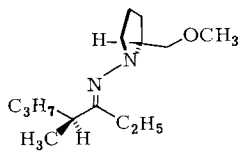
Asymmetric Synthesis of Ant Alarm Pheromones—α-Alkylation of Acyclic Ketones with almost Complete Asymmetric Induction[**]

By *Dieter Enders* and *Herbert Eichenauer*[*]

(+)-(*S*)-4-Methyl-3-heptanone (*S*)-*(4b)* has been identified as an alarm pheromone in four ant genera in the subfamily *Myrmicinae*[1a]. It is the principal alarm pheromone of the leaf-cutting ant *Atta texana*, being 400 times more active than its optical antipode[1c]. Thus it was shown for the first time that insects can distinguish between enantiomers[1b]. The synthesis of enantiomerically pure *(4b)* formerly required numerous steps and/or a time-consuming and uneconomical resolution[1c, 2]. A profitable route for the synthesis of acyclic ketones of high enantiomeric purity would be the asymmetric α-alkylation *(1)*→*(4)*. In contrast to the reactions with cyclic ketones and aldehydes, initial reactions of this type *via* metalated hydrazones of (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP)[3] gave only unsatisfactory optical yields[3a, 4].

Using a somewhat modified approach, we have now succeeded in alkylating acyclic ketones enantioselectively and with practically complete asymmetric induction. To this end, diethyl ketone *(1b)*, for example, is converted into the corresponding hydrazone (*S*)-*(2b)*, which is metalated with lithium diisopropylamide (LDA) in ether at 0 °C followed by treatment of the suspension of the lithium compound with *n*-propyl iodide at −110 °C. The resulting hydrazone (*ZSS*)-*(3b)* is subjected to acid cleavage *via* its *N*-methyl iodide in a two-phase system (3 N HCl/*n*-pentane). The optical purity of the product (*S*)-*(4b)* prepared by this three-step procedure (overall yield 60 %) consistently exceeded 99 % in several preparations.



In order to confirm this exceptionally high degree of asymmetric induction, we have examined not only the rotation of the final product but also the diastereomeric purity of the hydrazone *(3b)*. For this purpose a 1:1 diastereomeric mixture of (*SS*)-*(3b)* and (*SR*)-*(3b)* (*E*:*Z*=70:30) (Fig. 1a)

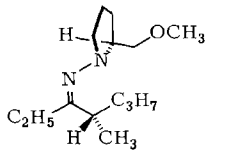
was prepared from racemic 4-methyl-3-heptanone *(4b)*[5] and SAMP, and the OCH_3 singlet region of the ^{1}H-NMR spectrum compared, after addition of the shift reagent Eu(fod)$_3$, with that of the hydrazone *(3b)* prepared from *(2b)* (Fig. 1b). Of the four possible diastereomers, alkylation *(2b)*→*(3b)* gives almost exclusively (*ZSS*)-*(3b)* which undergoes partial isomerization to the thermodynamically more stable (*ESS*)-*(3b)* in solution. No (*SR*)-*(3b)* could be found within the limit of detection (≥2%).



(*ESS*)-*(3b)*

(*ESR*)-*(3b)*

(*ZSR*)-*(3b)*

(*ZSS*)-*(3b)*

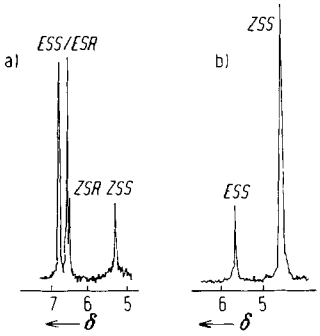


Fig. 1. 100-MHz ^{1}H-NMR spectra [$CDCl_3$, Eu(fod)$_3$] of the region of the OCH_3 singlets. a) 1:1 (*SS*)-*(3b)*/(*SR*)-*(3b)* diastereomeric mixture, E:Z≈70:30 [from racemic *(4b)*]. b) (*SS*)-*(3b)* from (*S*)-*(2b)*, E:Z≈20:80 (*ca.* 5:95 at the start of measurement). The high *Z* content reflects the Z_{CN} configuration of the lithium compound obtained from (*S*)-*(2b)* [6].

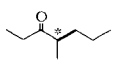
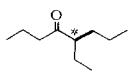
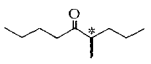
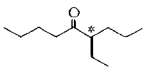
In a similar way, we have prepared several other acyclic ketones *(4)*, including another ant alarm pheromone [*(4a)*, *Manica*][7] in high enantiomeric purity (Table 1).









The extent of asymmetric induction varies considerably according to the solvent used. Thus the enantiomeric excess of *(4b)* was 99.5% in ether, 93% in dimethoxyethane, 85% in tetrahydrofuran, and 20% in tetrahydrofuran/hexamethylphosphoramide. The glass surface of the equipment was deactivated with chlorotrimethylsilane to avoid possible racemization during distillation of the ketones.

The asymmetric electrophilic substitutions *via* metalated SAMP-hydrazones described above demonstrate the extremely high stereoselectivity of the deprotonation of *(2)*[6] and of the alkylation to give *(3)*, as well as the absence of racemization on cleavage in the two-phase system hydrochloric acid/*n*-pentane. The absolute configuration of the ketones *(4)* is predictable with a considerable degree of certainty owing to the unique reaction mechanism[9].

Procedure

Synthesis of (*S*)-*(4b)*: Diethyl ketone *(1b)* (2.23 ml, 21 mmol) is added to SAMP (2.6 g, 20 mmol) with stirring at 20°C and the mixture is warmed to 60°C for 20 h. A solution of the crude product in CH_2Cl_2 is dried with Na_2SO_4, concentrated in a rotary evaporator, and distilled. (*S*)-*(2b)* (3.45 g, 87%) is obtained as a colorless oil of b.p. 47°C/0.05 torr, $[\alpha]_D^{20} = +297°$ (*c*=1, benzene). To a stirred solution of LDA [8.5 mmol, prepared from 1.57 N *n*-butyllithium solution (5.4 ml) and diisopropylamine (1.2 ml) in ether (40 ml) at 0°C] is added dropwise at 0°C (*S*)-*(2b)* (1.59 g, 8 mmol). After 10 h, the mixture is cooled to −110°C and *n*-propyl iodide (0.86 ml, 8.8 mmol) is added dropwise. Stirring is continued

for 1 h, the temperature is allowed to rise to 20 °C, and the product is worked up with CH_2Cl_2, dried over Na_2SO_4, and concentrated in a rotary evaporator. The crude product is treated with methyl iodide (1.9 ml, 30 mmol) and refluxed (60 °C) for 16 h. Excess methyl iodide is removed in a rotary evaporator and the residual oil stirred vigorously with 3 N HCl (40 ml)/*n*-pentane (200 ml) for 30 min. The organic phase is separated off, dried over Na_2SO_4, and carefully evaporated down. Molecular distillation over quartz wool [130—140 °C (oil-bath temperature)/110 torr] affords 0.71 g (69 %) of practically enantiomerically pure (*S*)-*(4b)*.

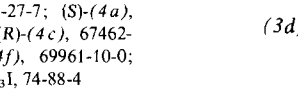
A Metalated Allylurea with Sterically Protected Carbonyl Group as Novel d^3-Reagent

By *Tillmann Hassel* and *Dieter Seebach*[*]

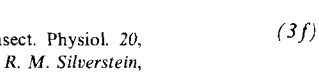
On reaction with *n*-butyllithium in tetrahydrofuran (THF) the urea *(1)* (b.p. 107 °C/0.001 torr)—which is readily accessible from 2,2,6,6-tetramethyl-4-piperidone ethylene acetal (TMPA), phosgene, and allylmethylamine[1]—undergoes metalation[2] to give *(2a)*. Like most heterosubstituted allyllithium derivatives[3], *(2a)* reacts with electrophiles at the positions α *and* γ to the hetero atom to give a mixture of

(1)

R = 



(2a), M = Li
(2b), M = MgBr



(3)

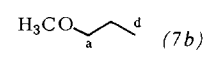
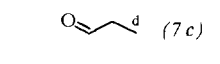
products. Normally, replacement of lithium by a less electropositive metal (Mg, Zn, Cd)[3,4] leads to increased α-reactivity. In contrast, the magnesium compound *(2b)* obtained from *(2a)* and $MgBr_2$·ether reacts with all hitherto employed electrophiles almost exclusively at the γ-position to give the *cis*-enamides *(3)* (cf. Table 1). Like other TMPA derivatives[1], these products solvolyze on acid-catalysis at room temperature: thus *(3b)*, *(3d)*, and *(3f)* in anhydrous methanol in the presence of a few drops of sulfuric acid form the acetals *(4)*[5], *(5)*[6], and *(6)* (b.p. 150 °C/17 torr), respectively [total yields from *(1)* with iodooctane, benzaldehyde, and cyclohexanone are 62, 60, and 75 %, resp.]. Hence, *(2b)* is demonstrated as being a d^3-reagent[7] [see the synthons *(7a)*—*(7c)*].



(3b) → $(H_3CO)_2CH{-}C_{10}H_{21}$ *(4)*

(3d) →  *(5)*



(3f) →  *(6)*

(7a)

(7b)

(7c)

Table 1. Products *(3a)*—*(3f)* from the magnesium compound *(2b)* and the electrophiles: iodomethane, iodooctane, propionaldehyde, benzaldehyde, 2-butanone, cyclohexanone, and benzophenone (yields of analytically pure chromatographed samples). All spectroscopic data are consistent with the given structures; the ^{1}H-NMR spectra show a *cis*-coupling of the vinyl-H atoms.

	Products	Yield	M.p. [°C]
(3)	E	[%]	
(3a)	CH_3	80	38
(3b)	*n*-C_8H_{17}	— [a]	oil
(3c)	$C_2H_5CH(OH)$	83	glass
(3d)	$C_6H_5CH(OH)$	85	63
(3e)	$C_2H_5C(OH)CH_3$	54	60
(3f)	$(CH_2)_5C(OH)$	87	82
(3g)	$(C_6H_5)_2C(OH)$	63	131

[a] This product also contains the α-isomer; it was transformed without separation into *(4)*.

Procedure

A stirred solution of *(1)* (1.48 g, 5 mmol) in 25 ml THF is treated with 5.5 mmol *n*-BuLi (1.5 M in hexane) at −80 °C. After 90 min an equivalent amount of $MgBr_2$·ether is added and the mixture warmed until the precipitate is completely dissolved. The solution is then cooled to the temperature of dry-ice. After addition of 5.5 mmol of the electrophile the mixture is allowed to warm overnight to room temperature and then worked up with ether/water. Analytically pure samples (see Table 1) are obtained by chromatography on silica gel (cyclohexane/ethyl acetate or pentane/ether). The crude *(3)* can be methanolyzed directly: a solution of *(3)* in 15—20 ml anhydrous methanol is treated with 10 drops of conc. H_2SO_4 and stirred for 8 h at room temperature. The mixture is then treated with solid anhydrous K_2CO_3 and stirring continued for a further 12—15 h. Extraction with pentane/water and subsequent chromatography (SiO_2, pentane/ether 4 : 1) furnishes the pure acetals, *e.g. (4)*—*(6)* [0.46 g (82 %) *(6)* from 1.29 g of pure *(3f)*].

Ligand Concentration-Control in the System Nickel(0)/Triphenylphosphane/Butadiene[**]

By *Frank Brille, Paul Heimbach, Joachim Kluth*, and *Hartmut Schenkluhn*[*]

In the cyclooligomerization of butadiene on nickel catalysts the degree of oligomerization and distribution of isomers can be controlled by addition of suitable phosphanes and phosphites[1]. The isolation of some intermediary complexes in the cyclotrimerization[2] and in the cyclodimerization[3] opens up the possibility of elucidating the elementary steps of the catalytic process. We have now attempted with the aid of ligand-concentration control maps to explain how the nature and number of the elementary steps are influenced *in situ* by addition of the controlling ligands.

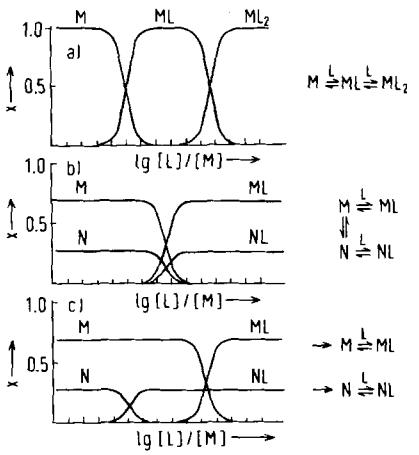

Fig. 1. Typical titration curves for (a) the stepwise twofold association of the ligand L to the metal complex M, (b) the association of L and two metal complexes M and N in equilibrium, and (c) the association of L to two metal complexes M and N not in equilibrium (kinetically separated).

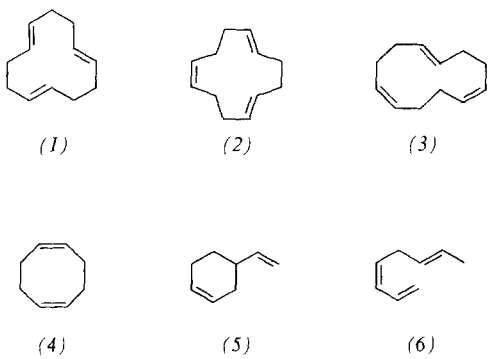
[**] Control of Metal-Catalyzed Reactions, Part 6. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.—Part 5: *H. Bandmann, P. Heimbach, A. Roloff*, J. Chem. Soc. (S) *1977*, 261; (M) *1977*, 3055.



[+] Authors to whom correspondence should be addressed.

We have carried out the nickel-catalyzed cyclooligomerization of butadiene with different concentrations of the directing ligand and determined the changing product pattern gas-chromatographically. For the graphical representation the logarithm of the ligand/metal ratios ($lg[L]_0/[M]_0$) is plotted on the abscissa and the product distribution in mol-% on the ordinate.

Assuming that the product ratios are proportional to the concentration of the intermediary complexes and that switching-on and switching-off phenomena may be neglected, the product curves, in analogy to classical titration curves, afford information on the number of the intermediate products, their relation to one another, and their concentration in the steady state.

Figure 1 shows three frequently occurring association schemes and the corresponding titration curves.

Figure 2 is the ligand-concentration control map for the system nickel/triphenylphosphane/butadiene[4]. The six products *(1)*—*(6)*[5] are formed in varying amounts, depending on the $lg[L]_0/[Ni]_0$ ratio. At low $lg[L]_0/[Ni]_0$ ratios the cyclotrimers *(1)*—*(3)* predominate, at higher ratios the cyclodimers *(4)*—*(6)* [*(6)* is not shown in Fig. 2 since its amount

is too small; besides 1,*cis*-3,-*trans*-6-octatriene, 1,*trans*-3,*trans*-6-octatriene is also formed.

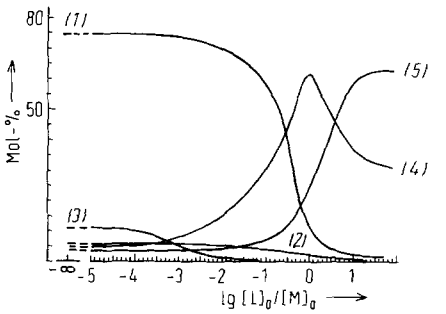


Fig. 2. Ligand-concentration control map for the catalytic system nickel/triphenylphosphane/butadiene; product distribution in mol-% referred to totally converted butadiene. T = 60°C, $[Ni]_0$ = 40 mmol/l, t = 15 h, $[Ni]_0$:[butadiene]$_0$ = 1:70, toluene as solvent.

The catalytic reactions were carried out on the 10-ml scale, and $lg[L]_0/[Ni]_0$ was determined gas-chromatographically *via* the ratio of two internal standards (tetralin/*n*-dodecane) (for experimental details, see [6]).

To obtain information on the control of the degree of oligomerization the distribution of the cyclotrimers and cyclodimers was plotted against $lg[L]_0/[Ni]_0$ on a partial control map (Fig. 3a). An almost typical titration curve is obtained[4]; the curve largely corresponds to a single ligand-association process (cf. Fig. 1a; for the partial control map of the trimers see [6]).

© *Verlag Chemie, GmbH, 6940 Weinheim, 1979*

0570-0833/79/0505-0400 $ 02.50/0

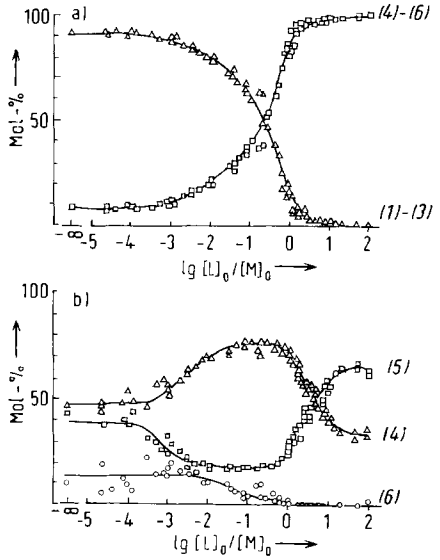

Fig. 3. Partial control maps (a) for the distribution of oligomers: product distribution in mol-% referred to converted butadiene; (b) the distribution of dimers: sum of dimers equals 100%.

Figure 3b shows the ratio of the dimers *(4)*—*(6)* as a function of $\lg[L]_0/[Ni]_0$. Several association processes are recognizable. The controlling first association of the ligand occurs at different ligand/metal ratios depending upon the product. Consequently, the respective intermediary complexes should be kinetically separated according to Figure 1c. It is interesting, moreover, that in the case of *(4)* and *(5)* there are two different association processes[7] (cf. Fig. 1a). Thus, for interpretation of this finding it is necessary to postulate multiple associations of the controlling ligand and several partially kinetically separated intermediary complexes for which the range of existence can be given[8].

In the case of homogeneous metal-catalyzed reactions the concentration-control maps can be used not only for the analysis of the mechanisms (minimum number of intermediary complexes and their coupling) but also for the following: 1) optimization of the catalyzed processes, 2) comparison of catalysts, 3) determination of the limiting conditions for separation of the thermodynamic and kinetic selectivity as prerequisite for recognition of property-specific control and thus *e.g.* separation of the steric and electronic influence of ligands[9].

Separation of Steric and Electronic Effects in the Reaction Enthalpies of Association of Phosphorus Ligands[**]

By *Hartmut Schenkluhn, Walter Scheidt, Bruno Weimann*, and *Manfred Zähres*[*]

In homogeneous transition-metal catalysis the addition of Lewis bases (*e.g.* phosphanes and phosphites) plays an important role, since the catalytic reactions can then be varied within wide limits. Hence, data for characterization of the metal-ligand bonding are of special interest for gaining an insight into the directing influence of such ligands.

Only very few quantitative results have so far been reported in this connection. An attempt has been made to describe the bonding character in rhodium(I) complexes by resolution into predominant covalent and electrostatic components[1].

A parametrization of the "electronic" and "steric" ligand influences has been described by *Tolman*[2]. Using this method the first examples for the dominance of steric ligand influences could be found in calorimetric investigations on platinum(II)[3a] and nickel(0) complexes[3b]. We have now established that these ligand parameters are suitable not only for the qualitative estimation but also for the quantitative determination of the "steric" and "electronic" ligand influences. This is illustrated here for the reaction enthalpy of the association of Lewis bases to di-μ-methylbis[1-methyl-1—3-η-(2-butenyl)]dinickel *(1)*[4] (Table 1).

A slightly modified calorimeter for differential thermal analyses in solution[5] was used for the determination of the enthalpy of reaction. The values were determined at 0°C in a 0.05 M solution of *(1)* in tetralin and the data thus obtained were corrected for the heat of mixing of the ligands, since ligand addition was carried out from 1 M solution.

A plot of the measured values z_j against the electronic ligand parameter χ_j and against the steric ligand parameter Θ_j gave no definite indication of a functional relationship. We therefore attempted a separation of the electronic and steric components by regression analysis.

There already is a good approximation for the polynomial

$$z(\chi_j, \Theta_j) = 172.0 + 1.65\,\chi_j - 0.56\,\Theta_j$$

since the quotient of the variance of fit ($S^2 = 18$) and the variance of the measured data ($\sigma^2 = 16$) is approximately unity[6]. In Figure 1[7] each ligand L (χ_j, Θ_j) is characterized

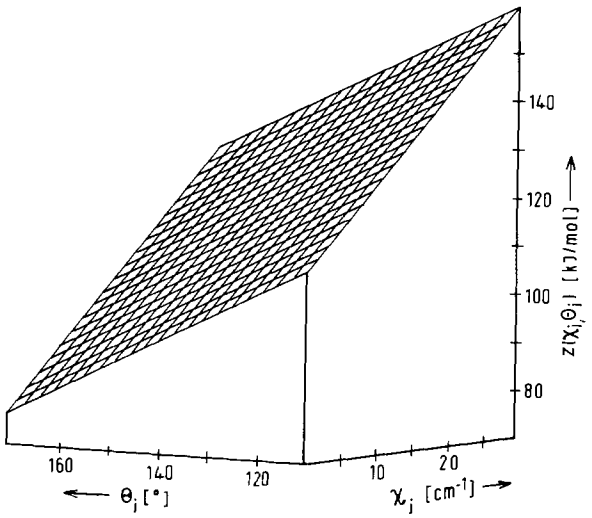

Fig. 1. Threedimensional representation of the reaction enthalpies of association of phosphorus ligands to the nickel complex *(1)* as a function of the electronic χ_j and steric Θ ligand parameters [2a].

by a point in the x,y-plane; the respective measured value z_j is given in the z-direction. An intersection vertical to the abscissa corresponds to the separated steric influence, while an intersection vertical to the ordinate corresponds to the separated electronic influence; surprisingly, in the former case there is a simple linear relationship for both parameters. Collectively, the calculated enthalpies of association span a range of 82 kJ/mol, of which 48 kJ/mol is ascribed to the electronic influence and 34 kJ/mol to the steric influence (electronic to steric ratio of 60 : 40). In the regression analysis the phosphorus ligands PPh_3, PPh_2OEt, PPh_2Et, and $P(benzyl)_3$ show the worst approximation. This would indicate that a description of the bonding character with the aid of the two chosen ligand parameters does not suffice in the case of overwhelmingly covalent bonding[8]. A still undefined "mesomeric effect" may have to be taken into consideration, corresponding to the parameterization of the substituent effects in organic chemistry.

[6] For the regression, the polynomial expression

$$z_{m,n}(\chi_j, \Theta_j) = \sum_{i=0}^{m} a_i \chi_j^i + \sum_{i=1}^{n} b_i \Theta_j^i$$

with the variance of fit

$$S^2_{m,n} = \frac{\sum_{j=1}^{m} (z_{m,n}(\chi_j, \Theta_j) - z_j)^2}{N - m - n - 1}$$

was chosen; m, n were optimized with the quotient $S^2_{m,n}/\sigma^2$ and a Chi^2 test (σ^2 = variance of measured value).
[7] This plot is related to *Tolman*'s "steric and electronic box" [2b].
[8] Similar observations were made in the analysis of a series of catalytic experiments on nickel ligand catalysts (*P. Heimbach, J. Kluth, H. Schenkluhn*, unpublished). The fact that we could, on the other hand, satisfactorily resolve *e. g.* the results on platinum(II) complexes [3a] into the electronic and steric ligand influence with incorporation of P(benzyl)$_3$ and P(phenyl)$_3$ is due to the extremely small electronic influence (20 % with respect to the total ligand property control, 26 ligands, polynomial degree m, n = 3, 3).

Regiospecific Synthesis of Disubstituted Benzene Derivatives[**]

By *Guy Félix, Jacques Dunoguès*, and *Raymond Calas*[*]

We have been able to extend application of the "organosilicon method"[1], which had previously been employed only in individual cases[2] for the regiospecific synthesis of benzene derivatives, to the synthesis of numerous disubstituted benzene derivatives. The method proposed by us is based on the stepwise exchange of the trimethylsilyl groups of the readily accessible[3] *o*-, *m*-, or *p*-bis(trimethylsilyl)benzenes *(1o)*, *(1m)*, and *(1p)*, respectively (see reaction scheme and Table 1).

[a] From ethanol. [b] Hygroscopic crystals. [c] Sodium salts were recrystallized from ethanol.

The diverging influence of the first substituents on the orientation of the second substituents is circumvented.

All the nitro(trimethylsilyl)benzene derivatives *(2)*[4] as well as the amino- *(5)*[4a, 5a–e] and the acetylamino-derivatives *(6)*[5] are known. We have used the route proposed by *Deans* and *Eaborn*[4c] for the synthesis of *(2)* from *(1)*. *(2m)* and *(2p)* could be readily reduced to *(5m)* and *(5p)*, respectively[4a,c,d,f]; the reduction of *(2o)* to *(5o)* *via* this route was difficult (see Procedure).

In contrast, attempts by *Hashimoto*[5e] to carry out regiospecific reactions of disilylbenzene derivatives had proved unsuccessful. Thus the bromination and nitration of *(6m)* [prepared from *(1m)*] led respectively to the undesired compounds 3,4-$Br_2C_6H_3NHAc$ and 2-O_2N-5-Me_3Si—C_6H_3NHAc as major product under the conditions given by the author.

We have been able to replace the second trimethylsilyl group in *(2)* and *(6)* by iodine and by the sulfo group.

Although the compounds *(3)*, *(4)*, *(6)* and *(11)* are all well-known, their synthesis was previously very difficult in some cases because of the substituent effects in the second substitution. Thus, the direct sulfonation is not always satisfactory or convenient and iodination often requires the reaction sequence : nitration → reduction → diazotization → reaction with alkali-metal iodide.

Besides the high yields, the regiospecificity of this method makes it very attractive for the synthesis of *o*-disubstituted benzene derivatives [*(3o)* can be obtained by oxidation of *(8o)*][9]. For example, the hitherto difficultly accessible[6] *o*-aminobenzenesulfonic acid *(10o)* and its sulfonamide *(11o)* can now be obtained quite easily. The method has also proven convenient for the preparation of *m*-iodoaniline *(8m)*.

Procedure

The synthesis of *(1)* and the iodinations were carried out according to [2b], the synthesis of *(2)* according to [4c]. For the sulfonation a mixture of equimolar amounts of *(2)* and $ClSO_3SiMe$ in CCl_4 (25 ml per 50 mmol of reactants) was heated under reflux for 2 h; after hydrolysis with NaOH the sodium salt of *(4)* was isolated according to the procedure given in [2a].

Hydrogenations were carried out by stirring a solution of *(2)* (5 g) in benzene (50 ml) under hydrogen pressure (*ca.* 1 atm) in the presence of 100 mg Pd/C (10 % Pd) until hydrogen absorption had ceased. After filtration through SiO_2 and removal of solvent, *(5)* was isolated by distillation (cf. also [5e]).

For the acylation a solution of *(5)* (1.7 g, *ca.* 10 mmol) in pyridine (20 ml) was treated dropwise with 0.8 g (≈10 mmol) acetyl chloride and the mixture heated under reflux for 3 h. After cooling, ether (50 ml) was added and the mixture was washed several times with 100 ml of weakly acidic saturated aqueous NaCl solution and then with pure cold water. The ethereal layer was dried over $MgSO_4$ and, after removal of ether, the acetanilides *(6)* were recrystallized from ethanol.—*(6)* was sulfonated according to the procedure given in [2a].

The acetanilides *(7)* and *(9)* were hydrolyzed under the usual conditions[7] to *(8)* and *(10)*, respectively; for conversion into the sulfonamides *(11)* the sodium salts of *(9)* were treated with (i) PCl_5 and (ii) NH_3 (see [8]).

Unsymmetrical Binuclear Complexes of Tungsten with Three OR Bridges, η^3-$C_7H_7(CO)_2W(OR)_3W(CO)_2$-$\eta^4$-$C_7H_8$ [**]

By *Wolfgang Schulze, Klaus Weidenhammer*, and *Manfred L. Ziegler*

On allowing η^7-$C_7H_7Mo(CO)_2Br$ to react with sodium alkoxides or phenoxides in the corresponding alcohols or CH_2Cl_2 we obtained species of the type η^7-$C_7H_7Mo(OR)_3$-$Mo(CO)_2$-η^3-C_7H_7 *(1)*[1]. Attempts to carry out this reaction with the analogous tungsten system η^7-$C_7H_7W(CO)_2I$ *(2)* surprisingly led to compounds of the type η^3-$C_7H_7(CO)_2W$-$(OR)_3W(CO)_2$-η^4-C_7H_8 *(3)* [R = CH_3 *(3a)*, C_2H_5 *(3b)*, C_3H_7 *(3c)*, C_6H_5 *(3d)*]. To our knowledge these compounds constitute the first triply OR-bridged binuclear complexes of tungsten; also unusual is the η^4-bonded cycloheptatriene ring, as was previously assumed merely in the case of $C_7H_8Fe(CO)_3$[2]. The compounds *(3)* were characterized by elemental analysis, IR, ^{1}H-NMR, and mass spectra, and in the case of *(3a)* also by X-ray analysis[3] (Fig. 1).

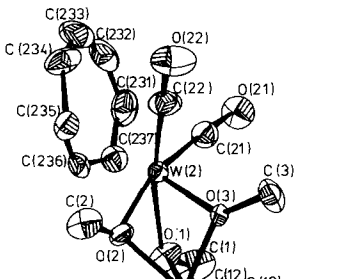

Fig. 1. Crystal structure of η^3-$C_7H_7(CO)_2W(OCH_3)_3W(CO)_2$-$\eta^4$-$C_7H_8$ *(3a)*; the thermal ellipsoids correspond to a probability of 50 %.

The compounds *(1)* and *(3)* are examples which neatly illustrate how the homologues molybdenum and tungsten solve electron problems of the same type in different ways. The odd number (nine) of electrons which are transferred to the two central atoms by the three bridge ligands is not balanced in the molybdenum system; the paramagnetic mixed valence compounds *(1)* are formed. In the tungsten system, on the other hand, a cycloheptatrienyl ligand is reduced to a cycloheptatriene ligand by uptake of a hydride ion. η^4-Bonding leads to formation of the diamagnetic complex *(3)*, in which the 18-electron rule applies for both tungsten atoms. As expected the CO bands of *(3)* are shifted to lower wave numbers as compared to those of *(2)*[4]. In the mass spectrum (Varian MAT CH7, temperature of ion-source 150 °C, ionization energy 70 eV, vaporization temperature 148 °C) the fragments $(M-CO)^+$, $(M-2CO)^+$ and $(M-3CO)^+$ appear with weak intensity only in the case of *(3b)*.

The ^{1}H-NMR spectra[5] reveal that the ring ligands, in contrast to those in *(2)*, are no longer η^7-bonded. Two of the signals for the methoxo protons in *(3a)* are comparable with those of similarly triply methoxo-bridged molybdenum compounds[6]; the position of the third signal ($\delta = 4.85$) indicates that this methoxo-group is situated in a different chemical environment. According to X-ray structure analysis, O(3) bridges the two W atoms in a sp^2 configuration.

In the synthesis of *(3a)* hydride transfer to the cycloheptatrienyl ligand is effected by the solvent methanol; on reaction of *(2)* with $NaOCD_3$ in CD_3OD under argon η^3-$C_7H_7(CO)_2W(OCD_3)_3W(CO)_2$-$\eta^4$-$C_7H_7D$ *(4a)* could be isolated. The positions and intensities of the ν_{CO} bands of *(4a)* are identical with those of *(3a)*[4].

Of the multiplets for the methylene protons of the cycloheptatriene ring of *(3a)*, only one still appears in the ^{1}H-NMR spectrum of *(4a)* at $\delta = 2.31$, corresponding to the >CHD group. The remaining signals of *(4a)* are identical to those of *(3a)*[5]; the signals of the methoxo groups are absent.

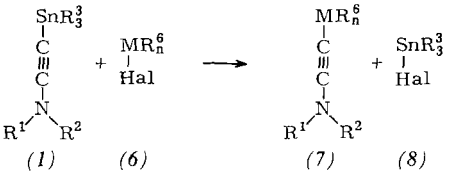
β-Stannylated Ynamines as Aminoethynylation Reagents

By *Gerhard Himbert*[*]

(Stannylethynyl)amines *(1)* are readily accessible, can be purified by recrystallization (R^3 = Ph) or distillation (R^3 = Me, Bu), and can be stored for several weeks in a refrigerator without decomposition[1]. They add azides[1a], and react with heterocumulenes[2] and acetylenedicarboxylates[1b,c] by (aminoethynyl)metalation to give novel ynamines.



We have now found that the stannylated ynamines *(1)* react in a preparatively simple way with acyl chlorides *(2)* and imidoyl chlorides *(3)* to give the substituted ynamines *(4)* and *(5)* in good yields. The reaction mechanism can plausibly be explained in terms of an addition-elimination sequence.

(1) *(2)*, X = O; *(3)*, X = NR^5 → $-[R^3_3SnCl]$ → *(4)*, X = O; *(5)*, X = NR^5

So far only very few acylynamines *(4)* have been synthesized[3,4]. The salient features of the new method of synthesis are the freedom of choice of acyl components *(2)*, the ease of handling and isolation, and the high yields (cf. Table 1).

Reaction of *(1)* with *(2)* or *(3)* in ether or acetonitrile is complete within 1—3 h at room temperature; the new ynamines *(4)* and *(5)* are (in most cases) isolated by addition of petroleum ether, cooling, and rubbing. Carboxylic anhydrides can replace the acid chlorides; however, in most cases workup is inconvenienced by the sparing solubility of the stannylcarboxylates.

(1) *(6)* → *(7)* *(8)*

The (stannylethynyl)amines *(1)* undergo metathesis with the element halides *(6)*. The germanium derivative *(7a)* and arsenic derivative *(7b)* are cited here (Table 1) as examples.

The structures of *(4)*, *(5)*, and *(7)* are confirmed by the spectra (Table 1), the analytical data, and, in the case of *(7a)*[1a] and *(7b)*[5], by comparison of the IR data with those of authentic samples.

Experimental

Synthesis of (*E*)-5-(*N*-methylanilino)-1-phenyl-1-penten-4-yn-3-one *(4c)*: The mixture of *N*-methyl-*N*-(tributylstannylethynyl)aniline[1d] (4.2 g, 10 mmol) and cinnamoyl chloride (1.7 g, 10 mmol) in ether (30 ml) is stirred for 3 h at room temperature. After addition of 30 ml petroleum ether (40—70 °C) *(4c)* crystallizes within 10 min.

Synthesis of *N*-(diphenylarsinoethynyl)-*N*-methylaniline *(7b)*: The mixture of *N*-methyl-*N*-(tributylstannylethynyl)aniline (4.2 g, 10 mmol) and chloro(diphenyl)arsane (2.7 g,

Discovery of an Exceptionally Long Unbridged Carbon-Carbon Bond[**]

By *Walter Littke* and *Ulrich Drück*[*]

Substituted ethane compounds show a greater or lesser degree of thermal lability, depending on the nature and size of the substituents[1]: anomalous bond lengths and angles can be expected for bulky molecules.

We have examined 5,6-dibutyl-5,6-diphenyldecane *(1)*. Well-formed single crystals could be grown from an ethanol

(1)

solution (conditions[2]); crystal data[3]: $a = 8.04_3$, $b = 10.06_2$, $c = 10.42_1$ Å; $\alpha = 75.36$, $\beta = 116.95$, $\gamma = 120.20°$; $V = 649.4$ Å^3; $Z = 1$; space group $P\bar{1}$; $\rho_{exp.} = 1.05$, $\rho_{calc.} = 1.04$ g cm^{-3}[4]. The unit cell was chosen such that it contains as many atoms of the same molecule as possible. The center of inversion lies at the center of the molecule and the unit cell, and the phenyl groups are thus arranged in the *anti* conformation.

The thermal vibrations of the atoms increase with increasing distance from the centroid of the molecule. The maximum elongation of the vibrational ellipsoids of the central C atoms 1 and 1′ occurs preferentially in the direction of the labile ethane bond; overall, however, the thermal effects on the molecule are much less pronounced ($0.0347 < U_{11} < 0.1361$ Å^2) than would be expected for a thermolabile compound. As shown by molecule packing studies, this is attributable to strong intra- and intermolecular van der Waals interactions between the H atoms. The ten C atoms 5 to 5′ of the decane chain shown vertical in Figures 1 and 2 lie almost exactly in a single plane; the greatest deviation from the least-squares plane is found for C2 (−0.071 Å) and C2′ (0.071 Å). The torsional angles of the phenyl groups are −86.14° and 86.14° (relative to bonds 1/10 and 1′/10′).

The molecule exhibits numerous intramolecular H/H contacts; the H/H distances are up to 15% shorter than the

Table 1. Intramolecular H/H contacts arranged in order of increasing interpenetration. The distances of the symmetrically equivalent H/H contact pairs are not included.

H/H Contact pair	Contact distance [Å]	H/H Contact pair	Contact distance [Å]
42/53	2.391	21/32	2.289
21/72	2.387	131/141	2.286
141/151	2.384	62/82	2.272
81/93	2.378	62/111	2.254
71/62	2.357	22/151	2.105
41/52	2.349	32/72	2.100
32/41	2.335	22/62′	2.057
111/121	2.289	62/22′	2.057

expected van der Waals distance (2.40 Å). Extensive interpenetration of some of the H/H atom pairs (Table 1) leads to enormous strain within the molecule and thus to anomalous bond lengths and angles as well as thermal instability. The close double contact 22/62′ = 62/22′ (2.057 Å) is particularly remarkable. It lengthens the central C—C bond to 1.638(6) Å: this is the longest known unbridged C—C bond. The strain also extends to the bonds 1/2 and 1′/2′, albeit to a much lower degree.

Further anomalies visible in Figures 1 and 2 are due entirely to steric effects. Thus the lengthened distances 1/6 and 1/10 arise on the one hand from the H/H contact 62/111 (2.254 Å); on the other hand, the distance 1/6 undergoes further elongation due to the close H/H contact 32/72 (2.100 Å) and the C7—C6—C1 angle is widened to 119.11°—an unusually large value for an sp^3-hybridized C atom. The close H/H contact 22/151 (2.105 Å) not only increases the distance 1/10 but also effects a slight shift of C2 out of the plane of the decane chain. The slightly increased tetrahedral angle at C7 (111.40°) is attributable to the contact 62/82.

Attempts to calculate the exact length of the central C—C bond by the EFF method using force fields according to *Allinger*[6] and *Engler-Schleyer*[7] failed to give accurate results: the value converged to 1.60 Å[8]. This is due to the empirical nature of the method.

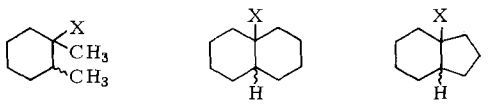
Regio- and Stereospecific Hydroxylation of Alicyclic Hydrocarbons with Substituted Perbenzoic Acids

By *Walter Müller* and *Hans-Jörg Schneider*[*]

Selective oxidations of alkanes RH→ROH by peroxycarboxylic acids have so far claimed interest not only as reaction steps in syntheses[1] but also as models for reactions of monooxygenases[2]. Reaction of trifluoroperacetic acid with molecules containing secondary and tertiary C—H bonds leads to product mixtures[3] whose formation cannot be hindered

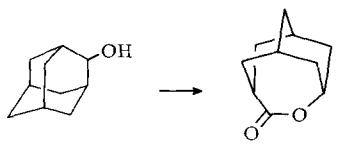


(1a) *(1b)* *(1c)* *(1d)*

even under mild conditions[4]. On the other hand, on reaction with substituted perbenzoic acids *(1a)*—*(1d)* of medium acidity, hydrocarbons [*e.g. (2)*—*(4)*, X=H] are converted directly with high regioselectivity and with retention of configuration into the monohydroxy compounds *(2)*—*(4)*, X=OH[5] (Table 1).

Table 1. Hydroxylation of the alicyclic hydrocarbons *cis-* and *trans-(2)* through *cis-* and *trans-(4)*, X=H, with *p*-nitroperbenzoic acid to the alcohols *cis-* and *trans-(2)* to *-(4)*, X=OH.

	(2)	*(3)*	*(4)*
trans-Compounds, X=H→X=OH			
Regiospecificity [a]	97	95	95
Stereospecificity [b]	97	100	95
cis-Compounds, X=H→X=OH			
Regiospecificity [a]	98	96	96
Stereospecificity [b]	98.5	99	100



[a] $\sum$*sec*-alcohol + *tert*-alcohol = 100%. [b] Retention of configuration in %.

(2) *(3)* *(4)*

The rate of reaction increases with increasing acidity of the peracid; this and the deactivating effect of a hydroxy group already incorporated in the alkane underscores the electrophilic character of the substitution. Possible participation of a radical side reaction is revealed *e.g.* by the formation of chlorobenzene from *(1b)* and a concomitant proportional decrease in regio- and stereoselectivity; this side reaction can be largely inhibited by addition of iodine (*ca.* 1 mg/ml).

Under the reaction conditions secondary hydroxy groups are oxidized to ketones, and thence according to a Bayer-Villiger reaction; thus, *e.g.* the 4-oxa-4-homo-5-adamantanone *(6)* is formed from 2-adamantol *(5)*.

(5) *(6)*

Hydroxy groups can, however, be readily protected by acylation and then, like other electronegative substituents, serve to direct the reaction of alkanes containing several tertiary C—H bonds.

Procedure

Synthesis of *cis-(3)*, X=OH: A mixture of *cis-(3)*, X=H (20 g, 0.145 mol) and *(1a)* (20.3 g, 0.108 mol) (98 %, iodometric) in $CHCl_3$ (100 ml) is heated under reflux for 7 h; after further addition of *(1a)* (20.3 g, 0.108 mol) and $CHCl_3$ (30 ml), refluxing is continued for a further 16 h. The reaction mixture is then allowed to cool to room temperature, filtered, and the filter-cake washed with 350 ml ether. The resulting organic phase is washed with 1 N NaOH and H_2O, and dried over Na_2SO_4. The residue remaining after removal of solvent by distillation is found (gas-chromatographically) to contain 82 % *cis-(3)*, X=OH. Distillation in a saber side-arm flask (b.p. 120—135 °C/20 torr) furnishes 15.6 g (69 %) of *cis-(3)*, X=OH, which is contaminated with 5 % each of hydrocarbon and side-products.

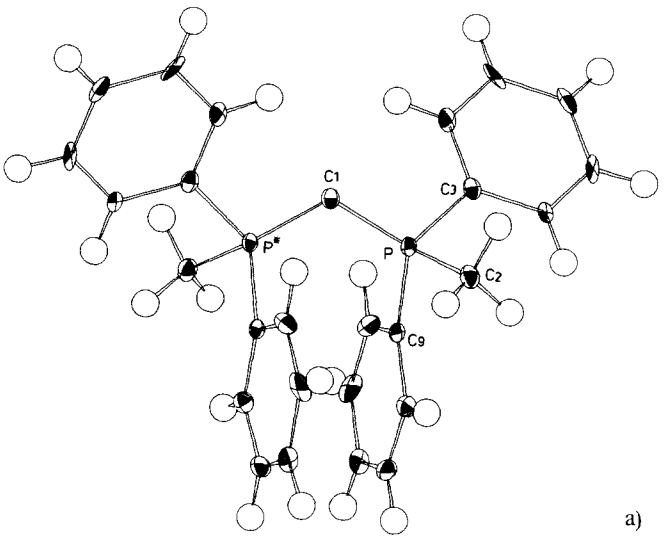
Problem of the Structure of Carbodiphosphoranes, R_3PCPR_3: New Aspects



By *Hubert Schmidbaur, Georg Hasslberger, Ulrich Deschler, Ulrich Schubert, Charles Kappenstein*, and *Albin Frank*[*]

"Carbodiphosphoranes" R_3PCPR_3, which are formal derivatives of bis(phosphoranediyl)methane, have posed many a riddle since their discovery, some of which have hitherto remained unsolved. The longest known representative with R=C_6H_5 *(1)*[1] exhibits triboluminescence in one of its crystal forms, and its derivatives are photochromic[2a]. X-Ray structure analysis of the triboluminescent modification showed that the unit cell contains two different molecules with widely differing PCP bond angles of 130.1(6) and 143.8(6)°[3]. On the other hand, another modification of *(1)* shows only one kind of molecule with a PCP angle of 131.7(4)°[2b]. Electron diffraction experiments on the hexamethyl compound *(2)*[4] revealed a high degree of flexibility of the PCP angle in the gaseous state; an apparent angle of 148° is observed as a result of a shrinkage effect[5]. Since the triboluminescence has been correlated, *e.g.*, with angular deformation in the crystal[2], we looked for further interesting structural features.

$(C_6H_5)_3P{=}C{=}P(C_6H_5)_3$ *(1)* $(CH_3)_3P{=}C{=}P(CH_3)_3$ *(2)*

$CH_3(C_6H_5)_2P{=}C{=}P(C_6H_5)_2CH_3$ *(3)*

Surprisingly, we discovered that the crystals[6] of the deep yellow dimethyl(tetraphenyl) compound *(3)*[7a] contain molecules with an exceptionally small PCP angle of 121.8(3)°, deviating by only 1.8° from the ideal value for sp^2 hybridization of the central C atom (Fig. 1). This finding provides the first evidence that formula *(A)* is entirely appropriate for describing the bonding in carbodiphosphoranes. It is also in accord with the latest measurements of dipole moments in ylides[8]. The almost exclusively employed formulation *(B)* would rather suggest a stretched molecular skeleton.

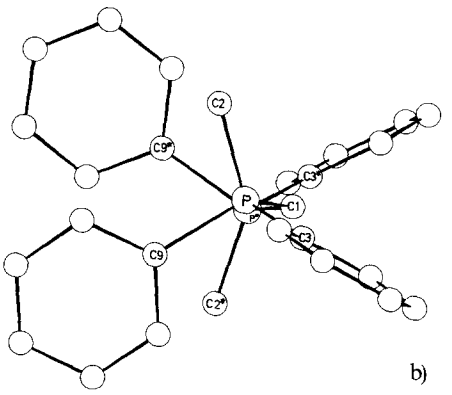


Figure 1. Molecular structure of $MePh_2PCPPh_2Me$ *(3)*: a) front view, b) side view.

The structure of *(3)* reveals yet another important detail: two of the C_6H_5 rings are arranged in parallel planes in such a way that the π-systems just fail to interpenetrate (Fig. 1). Their mutual separation of 328 pm is considerably shorter than the van der Waals separation of aromatic compounds (340 pm, cf. [7b]). Any further compression of the PCP bond in *(3)* or mutual twisting of the PC_4 tetrahedra must therefore lead to strong perturbation of the electronic states, and we suspect that this is the reason for the mechanically induced photoeffects. The few other known cases of triboluminescence of organometallic and organic compounds are similarly characterized by relatively large π-systems in a parallel arrangement[2c, 9]. It should be noted that the triboluminescence of such "molecular" examples could not yet be interpreted unequivocally—apart from an indication of strong piezoelectric charging[2c, 9].

(A) *(B)*

Moreover, crystallization experiments on *(1)* in benzene gave a new modification, the diffraction data of which are compatible with a *cubic* structure[10]. This result again shows that the packing of *(1)* in the crystal lattice is possible in a variety of ways and that the molecular geometry of carbodiphosphoranes can readily adapt to a given situation without incurring large energy losses. The angular flexibility deduced from slight energy differences between *(A)* and *(B)* has parallels in the isoelectronic cations $R_3PNPR_3^{\oplus}$, which were also found to have widely varying bond angles between 134.6 and 180°[11]. Concerning the relative energy levels of the two isosteric series, mention should be made of a recent theoretical publication[12]; the predictions of the influence of electron-donating substituents contradict our structural findings [*(1)*/*(3)*]. On the basis of the polar formulation *(A)*, both the complexing properties of carbodiphosphoranes[13a] and their manifold organic reactions become immediately understandable[13b].

Cyclobutadiene-Metal Complexes as Potential Intermediates in Alkyne Metathesis: Flash Vacuum Pyrolysis of Substituted η^4-Cyclobutadiene-η^5-cyclopentadienylcobalt Complexes[**]

By *John R. Fritch* and *K. Peter C. Vollhardt*[*]

The mechanism of alkyne metathesis [eq. (a)] is a matter of unresolved controversy. The actual process has only been observed at relatively high temperatures in the gas phase[1] and in solution[2] over mostly heterogeneous tungsten and molybdenum catalysts. However, the literature abounds with examples in which the final product of the interaction of an alkyne with a transition metal appears to be derived from initially metathesized or "dichotomized" starting material[3]. The logical intermediate *(1)* in this reaction[1], has been discounted due to the "unusual stability" of cyclobutadienemetal complexes, in addition to the fact that their condensed phase thermal decomposition *fails to give alkyne products*[4].

(1)

We would like to report that: (1) cyclobutadiene-cyclopentadienylcobalt complexes cleanly decompose on heating in the gas phase to regenerate their component acetylenes; (2) these decompositions require intermediate bis(alkyne)cobalt complexes; (3) rotation and reclosure of the complexed alkynes to cyclobutadiene rings competes with decomplexation; and (4) migration of cobalt along the two triple bonds of diyne ligands does not occur.

Flash pyrolyses at short contact times (*ca.* 0.005 s, *ca.* 10^{-5} torr) were carried out as described earlier[5]. Product yields were independent of the amount of material pyrolyzed and of whether or not the pyrolysis tube was cleaned before reuse, thus ruling out wall effects, in particular secondary cobalt-catalyzed wall reactions. η^4-Tetraphenylcyclobutadiene-η^5-cyclopentadienylcobalt *(2)*[6] was pyrolyzed at 726 °C to give (at 47% conversion) 89% of isolated diphenylacetylene. The pyrolyses of the substituted diethynyl derivatives *(3)*—*(6)* summarized in Table 1 are instructive, particularly under conditions of incomplete conversion.

(4) [b, i]	780	[h]	0.29	0.06	[h]	74.8	1.1
	682	0.03	17.8	1.1	0.07	59	0.58
	652	0.04	34.7	1.2	0.06	43.7	0.16
	640	0.13	49.2	1.7	0.05	31.9	0.20
(5)	676	[h]	0.02	34.8	2.90	17.4	11.9
(6)	701	≤0.03	[h]	7.17	30.71	30.9	5.70

[a] A cobalt mirror formed on the surface of the pyrolysis tube. Traces of acetylene were (incompletely) trapped in all reactions. In addition to the alkyne products indicated, compounds derived from the cyclopentadienyl moiety were isolated and identified: cyclopentadiene, dihydrofulvalenes, and naphthalene [7]. No cyclobutadiene dimers were detected. [b] These starting materials polymerize on standing and were freshly chromatographed before each run. [c] At the center of the tube. [d] Determined by GC and NMR integration. Polymer forms at both entrance and exit to the oven, accounting for incomplete mass balances. [e] *(3)* leads to *(5)* *via* the diethynylcyclobutadiene rearrangement [5a]. [f] The absence of butadiyne, hexatriyne, trimethylsilylethyne, trimethylsilylhexatriyne, bis(trimethylsilyl)ethyne, and bis(trimethylsilyl)butadiyne was ascertained by FID-GC and GC/mass spectroscopy. [g] Identified by GC mass spectroscopy and independent synthesis [lithiation followed by trimethylsilylation of 1,3-diethynylcyclobutadiene-cyclopentadienylcobalt [5a]: *(6)*: yellow crystals; m.p. 156—158°C; *m/e* 368 (M^+, 100%), 124 (CpCo, 54%); τ (CCl_4) 4.97 (s, 5H), 5.45 (s, 2H), 9.81 (s, 18H); IR: 2135 cm^{-1} (C≡C). [h] Undetectable by GC/mass spectrometry and FID-GC. [i] *(4)* was erroneously reported [5a] to be stable to 700°C under the pyrolysis conditions; correct is 600°C.

Several features are noteworthy. Firstly, efficient conversion of the cyclobutadiene ring to the corresponding alkynes is observed. Second, as demonstrated by the control pyrolysis of *(5)*, *(3)* is decomposed largely *via* the intermediacy of

Scheme 1. Pyrolysis of *(3)*—*(6)*. R = $Si(CH_3)_3$; * = detected compound.

(5) reached by the low-energy and mechanistically totally distinct "diethynylcyclobutadiene rearrangement"[5a]. Third, the free energies of activation[8] for the decomposition of *(2)* and *(4)*—*(6)* ($\Delta G^+ \approx 47$—50 kcal/mol) are appreciably higher than that for the *(3)*→*(5)* rearrangement ($\Delta G^+ = 37$ kcal/mol) but considerably lower than the CpCo-bond strength (64 kcal/mol)[9]. Fourth, unprecedented mutual interconversion (but not complete equilibration) of the cyclobutadiene starting complexes is observed.

The reproducibility of the data, absence of wall effects, known stability of free cyclobutadiene to flash pyrolysis conditions[10] even above 800°C, and the low pressures employed ruling out bimolecular reaction pathways[11] suggest the mechanism in Scheme 1 to rationalize the results.

Isomer *(3)* pyrolyzes *via* *(5)* and the postulated complexes *(9)* and *(11)* to give the observed major products *(8)* and *(12)*, respectively. The new cyclobutadiene isomer *(6)* is derived from *(9)* by rotation and reclosure. The absence of bis(trimethylsilyl)ethyne indicates a relatively high activation energy to decomposition of *(3)* *via* this pathway. The detection of small quantities of *(4)* demonstrates the accessibility of intermediate *(7)* from *(3)*. Isomer *(4)* enters the reaction manifold through *(7)*, giving mainly trimethylsilylbutadiyne *(8)*. It can also reclose to *(3)*, the latter rapidly giving *(5)* and its decomposition products *via* the diethynylcyclobutadiene rearrangement[5a]. The presence of traces of *(6)* shows the possibility of completing two opening-rotation-reclosure sequences in the time scale of the experiment. Decomposition of *(6)* gives products consistent with this picture, again implicating intermediates *(9)* and *(11)*.

The fact that the yield of *(8)* is always much greater than the yield of *(6)* [from *(3)* or *(5)*] and of *(5)* [from *(4)* or *(6)*] indicates that decomplexation from the bisalkyne complexes is more facile than recyclization. The absence of other cyclobutadiene isomers and their ultimate alkyne products in the pyrolyzates of *(3)*—*(6)* (see Table 1, footnote [f]) makes diacetylene shifts (*e.g.* *(7)*⇄*(9)*, *(9)*⇄*(10)*, *etc.*) unlikely.

Scheme 1 suggests that cyclobutadiene-metal complexes are potential intermediates in alkyne methatheses.

1,2,4,5-Tetrahydrodicyclobuta[*b*,*e*]pyridine[**]

By *Alaric Naiman* and *K. Peter C. Vollhardt*[*]

Benzenoid hydrocarbons fused to strained rings have been the target of recent synthetic efforts aimed at the preparation of aromatic rings in which bond fixation or other perturbations of aromaticity might be observed. So far evidence for the former has been tenuous[1]. The decreased aromaticity of pyridine [estimated at 21 kcal/mol][2] when compared with benzene suggests that it might more easily be subjected to bond localization. Some support for this is found in the physical and chemical properties of cyclobuta[*b*]- and cyclobuta[*c*]pyridine[3]. We report the synthesis of *(2)*, presently the most strained annelated pyridine.

Flash vacuum pyrolysis (800°C, 10^{-4} torr) of dichloride *(1)*[4] proceeds through double HCl-elimination[5], providing on basic workup the pyridine *(2)* in *ca.* 50% yield. Fractional sublimation (40°C, 10^{-3} torr) to separate *(2)* from *(1)* furnished colorless crystals (m.p. 117.5—118.5°C). The structural assignment follows from spectral data and chemical properties[6].

(1) *(2)* *(3)*

Reaction of *(2)* with neat bis(trimethylsilyl)acetylene (200°C, 12h) followed by oxidation with dichlorodicyano-*p*-benzoquinone (in benzene, 80°C, 2h) and desilylation (conc. H_2SO_4, 80°C, 1 min.) gave acridine.

The isolation of *(2)* under conditions conducive to equilibration with the ring-opened *o*-quinodimethane ("*o*-lutidylene") *(3)* suggests appreciable residual aromaticity in *(2)*. This is also indicated by the nuclear magnetic resonance data and the electronic spectrum. As might be expected, the latter shows bathochromic shifts and larger extinction coefficients in comparison with suitable bisannelated models[7]. The significant ring strain experienced by *(2)* is likewise reflected in the ^{13}C-NMR chemical shifts and ^{13}C-H coupling constants[8].

Cyanohalophosphates(III)—Hypervalent Anions Containing λ^5-Phosphorus(III)[**]

By *Alfred Schmidpeter* and *Franz Zwaschka*[*]

One of the typical reactions of halide ions is their combination with a halogen molecule X_2 to give the linear trihalide ions X_3^-. If different halogen atoms are involved, then the more electropositive one assumes the central position[2]. In accord with its postulated pseudohalogen character[1], the dicyanophosphide ion *(1)* adds bromine and iodine at room temperature to give anions *(3)* of X_3^- type with $P(CN)_2$ as central member. These hypervalent anions are dicyanodihalophosphates(III). Their crown ether-sodium salts can be isolated in crystalline form.

Oxidative addition of halogen to *(1)* can be resolved, at least formally, into two steps:

$$\underset{(1)}{P(CN)_2^-} + X_2 \rightarrow \underset{(2)}{P(CN)_2X} + X^- \rightarrow \underset{(3)}{P(CN)_2X_2^-}$$

It is surprising that the reaction does not lead merely to dicyanohalophosphanes *(2)* but beyond that to the hypervalent species *(3)*[3]. The ion *(3)*, X = Br or I, does not dissociate in solution, as is apparent from the characteristic upfield shift of the ^{31}P-NMR signal (see Table 1). Under the same conditions, addition of chlorine to *(1)* gives only *(2)*, X = Cl.

Addition of cyanogen bromide or iodide instead of halogens gives the tricyanohalophosphates(III) *(4)*, X = Br or I.

$$\underset{(1)}{P(CN)_2^-} + XCN \rightarrow \underset{(4)}{P(CN)_3X^-}$$

These results suggest that phosphorus tricyanide *(5)* ≅ *(2)*, X = CN, might add halide ions to form the hypervalent anions *(4)*:

$$\underset{(5)}{P(CN)_3} + X^- \rightleftharpoons \underset{(4)}{P(CN)_3X^-}$$

Compound *(5)* does indeed react with crown ether-sodium chloride, bromide, and iodide to form mobile equilibria with *(4)* (NMR spectroscopy). The chemical shift δ^{31}P decreases linearly with addition of halide until the equivalence point is reached, and then stays essentially constant. All the equilibria (including that with X = Cl) lie far to the right, and all three crown ether-sodium salts can also be isolated as crystals.

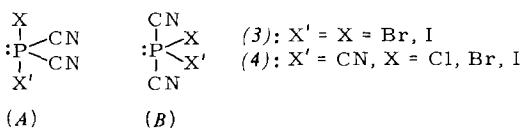
[**] Cyanophosphorus Compounds, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 1: [1].



© Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0505-0411 $ 02.50/0

Table 1. δ^{31}P data for *(2)*, *(3)*, and *(4)* (in tetrahydrofuran, with H_3PO_4 as standard).

X	*(2)*	*(3)*	*(4)*
Cl	−32 −33.5 [4]		−176
Br	−64.2 [4]	−165	−182
I	−115.8 [4]	−172	−164

In spite of the interest in hypervalent phosphorus(III) compounds as substitution intermediates[5], little is known about their geometry. Although it has not been established to what extent the phosphorus lone pair is sterically effective in *(3)* and *(4)*, we assume a pseudotrigonal-bipyramidal ligand arrangement in these species. The νCN values fail to show any more extensive shift of charge from P to CN than already exists in *(1)*.

There are two possible ligand distributions, *viz. (A)* and *(B)*:

(A) *(B)*

(3): X′ = X = Br, I
(4): X′ = CN, X = Cl, Br, I

Since two CN bands generally appear in the IR spectrum (solid state), *(B)* can be ruled out. The bent $P(CN)_2$ arrangement of *(1)* is retained in *(A)*, which corresponds to the linear structure of a trihalide and is in accord with the structure of $(SeCN)_3^-$ in particular[2].

Procedure

Synthesis of [18]crown-6·Na^+·*(3)*: Solutions of [18]crown-6-sodium dicyanophosphide (20 mmol) and bromine or iodine (20 mmol) in tetrahydrofuran (THF) (20 ml each) are united. The color of the halogen disappears instantaneously and almost completely; only near completion of addition of iodine does the solution remain reddish brown. After evaporation to about half the original volume *in vacuo* and standing for several days at −20 °C, the salt of *(3)* crystallizes. A further crop can be isolated by diluting the mother liquor with diethyl ether. The crystals become opaque *in vacuo*: initially blue-black crystals of the complex of *(3)*, X = I, release iodine and turn pale yellow; 40—85 % yield.

Synthesis of [18]crown-6·Na^+·*(4)*: Solutions of $P(CN)_3$ (10 mmol) in THF (20 ml) and of [18]crown-6-sodium bromide or iodide (10 mmol) in acetonitrile (30 ml) are combined and evaporated to dryness *in vacuo*. The residue is taken up in THF (50 ml), and diethyl ether is added to the solution until it becomes turbid. On cooling to −20 °C the salt of *(4)* precipitates as colorless crystals; yield 40—90 %. For X = Cl, a suspension of finely powdered NaCl in THF and an equivalent amount of crown ether are used. The mixture is filtered after 2d and then evaporated down to half its volume; the initial unidentified fraction is separated off and the solution evaporated to dryness. The residue crystallizes on dissolution in a small volume of THF; yield 20 %. All the crystals turn opaque *in vacuo*.

1*H*-1,2,3σ^2-Diazaphospholes — Bond Delocalization in σ^2-Phospholes[**]

By *Josef Helmut Weinmaier, Jörg Luber, Alfred Schmidpeter*, and *Siegfried Pohl*[*]

1*H*- and 2*H*-1,2,3σ^2-diazaphospholes [like *(3)* and *(2)*] having localized π-bonds would correspond to imino- and methylene-phosphanes, respectively, and should accordingly differ in their chemical and physical properties. These differences should diminish if the diazaphospholes qualify as "good phosphapyrazoles", *i.e.* pyrazoles whose 6π delocalization is not interrupted by the σ^2-phosphorus.

So far, only 2*H* isomers such as 2,5-dimethyl-2*H*-1,2,3σ^2-diazaphosphole *(2)*[1] have been reported. This is formed *via* the hydrochloride by condensation of acetone methylhydrazone *(1)* with PCl_3. We have now found that the 1*H* isomer *(3)* is also formed to a lesser extent in this reaction. It can be separated by virtue of its higher boiling point. Subsequent rearrangement of *(2)* to *(3)* was impossible.

(1) + PCl_3 − 2 HCl

(2)·HCl *(3)*·HCl

+ HCl ⇅ − HCl

(2) *(3)*

Reaction of cyclopentanone methylhydrazone and PCl_3 likewise gave not only *(4)*[1] but also a comparable amount of the isomer *(5)*. Separation was possible by fractional sublimation of the hydrochlorides.

(4)  (5) 

Table 1. Chemical shifts (downfield shifts positive) and coupling constants J [Hz] in $CDCl_3$ (standard: ^{31}P-NMR, H_3PO_4; ^1H-NMR, TMS).

	(3)·HCl	(5)·HCl	(3)	(5)
$\delta^{31}P$	211.0	195.2	223.0	204.1
$\delta^1H(NCH_3)$	4.47 (d)	4.42 (d)	3.86 (d)	3.81 (d)
J_{PNNCH}	2.1	2.6	1.1	1.4
$\delta^1H(CCH_3)$	2.73 (d)		2.38 (d)	
J_{PCCCH}	1.7		1.8	
$\delta^1H(CH)$	8.00 (d)		7.22 (d)	
J_{PCH}	40.2		32.0	

The ^{31}P downfield shift of *(3)* and *(5)* (Table 1) is characteristic of σ^2-phospholes; it approaches the value for *(2)* and *(4)* (228.9 and 204.4, respectively)[1]. While addition of HCl leads to a further downfield shift in the case of *(2)* and *(4)*, an upfield shift is observed for *(3)* and *(5)*. A slight increase in the bond angle at phosphorus due to protonation at N-1 is also observed in *(2)* and *(4)*[2]; this angle should decrease on protonation of *(3)* and *(5)* at N-2. The positions of the methyl groups are established by the phosphorus coupling. The PCH coupling constant in *(3)* is considerably smaller than in *(2)* (43.7 Hz)[1]; the difference expectedly vanishes in the hydrochlorides.

(3) + PCl_3 $\xrightarrow[-HCl]{}$  *(6)*

Like *(2)*, compound *(3)* can be substituted by PCl_3 at C-4[3] to form the dichlorophosphino derivative *(6)* [$\delta^{31}P = 230.5$ (σ^2P), 157.0 (σ^3P), $J_{PCP} = 52.0$ Hz].

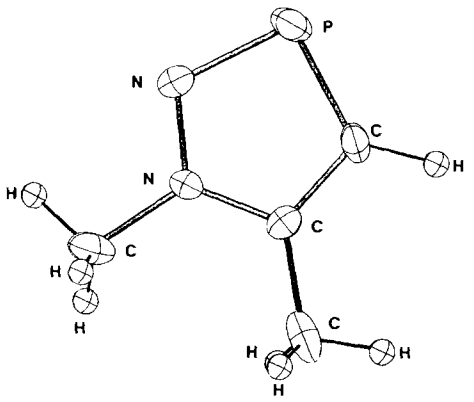

Fig. 1. 1,5-Dimethyl-1*H*-1,2,3σ^2-diazaphosphole *(3)* in the crystalline state at −130°C; vibrational ellipsoids represent 50% probability (except for H atoms) [4]. Bond angles [°] and lengths [pm] in the ring:

NPC	92.9(2)	PN	165.4(3)
PCC	109.3(3)	PC	172.3(3)
CCN	110.6(3)	CC	138.1(5)
CNN	117.0(3)	CN	135.6(4)
NNP	110.2(2)	NN	133.0(4)

Comparison of the molecular structure of *(3)* (Fig. 1) with that of 2*H*-diazaphospholes[2, 5] clearly reveals the shift of the double bond by way of the shortening of the PN and lengthening of the PC bond. However, the differences (about 2 pm) are only about as large as those between the formal C—N/C=N and the C—C/C=C bonds in pyrazole[6]; this suggests similar delocalization in the diazaphospholes. In acyclic σ^2P systems, on the other hand, the P—N/P=N difference is some 12 pm[7, 9] and the P—C/P=C difference some 15 pm[8, 9].

Procedure

Compound *(1)* (43 g, 0.5 mol) is allowed to react with PCl_3 (344 g, 2.5 mol) (for procedure, see [1]). The crude mixture of hydrochlorides is suspended in benzene (300 ml) and triethylamine (50.5 g) is added with vigorous stirring. The triethylammonium chloride is separated off after 2 h, the benzene is stripped off, and the residue is fractionated: 31.1 g (54%) *(2)* at 45—60°C/80—90 mbar; 6.7 g (12%) *(3)* at 40—50°C/10^{-3} mbar, m.p. ≈30°C.

The mixture of hydrochlorides obtained in a similar manner from cyclopentanone methylhydrazone (28 g, 0.25 mol) and PCl_3 (172 g, 1.25 mol) is sublimed: 17.6 g (40%) of *(4)*·HCl at 60°C (bath temperature); 22.0 g (50%) of *(5)*·HCl at 100°C (bath temperature)/10^{-3} mbar; m.p. 156—158°C. *(5)* is liberated therefrom as above: b.p. 82°C/0.2 mbar.

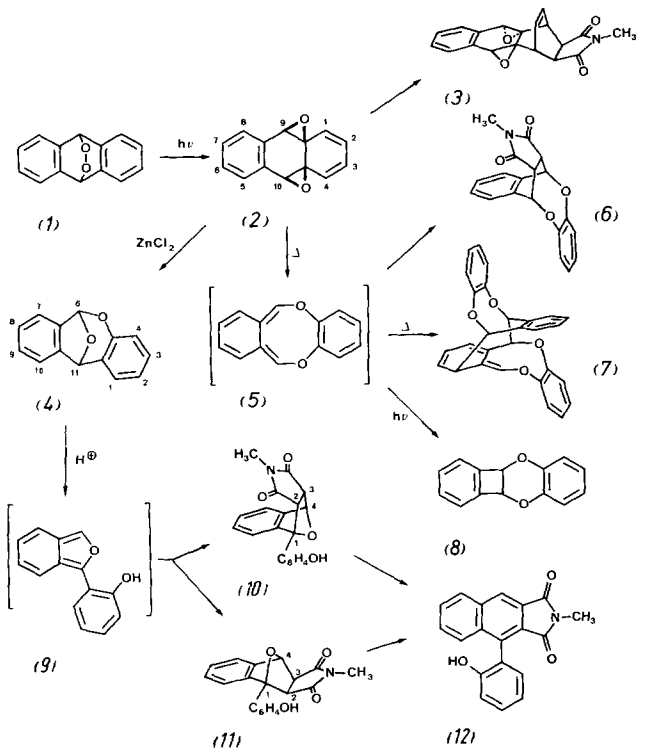
syn-Anthracene 4a,10:9,9a-Dioxide

By *Jean Rigaudy, Albert Defoin*, and *Joële Baranne-Lafont*[*]



Dedicated to Professor Egbert Havinga on the occasion of his 70th birthday

The rearrangement of epidioxides (endoperoxides) to compounds having two epoxide groups is a well-known reaction in cycloalkadiene chemistry; it can be induced either thermally or photochemically[1]. Thermolabile 1,4-endoperoxides of anthracenes (and naphthalenes) with bridgehead alkoxy groups have also been shown to give isolable isomeric dioxides on irradiation[2]. In contrast, dioxides could not be isolated on rearrangement of *meso*-endoperoxides (*e.g.* 9,10-anthracene endoperoxide) but only trapped with dienophiles such as *N*-methylmaleimide (NMM). This is exemplified by the rather unstable diepoxide arising from 9,10-diphenyl-9,10-anthracene endoperoxide by photoisomerization[3], and most clearly by the *syn*-dioxide *(2)* which is the primary product of thermal

© *Verlag Chemie, GmbH, 6940 Weinheim, 1979* *0570-0833/79/0505-0413 $ 02.50/0*

isomerization of 9,10-anthracene endoperoxide *(1)*. At the temperature required for reaction, *(2)* affords the dimer *(7)* or the tetracyclic compound *(8)* *via* the *o*-quinodimethane diether *(5)*[4].

It has now proved possible to prepare the dioxide *(2)* by prolonged irradiation of *(1)* with light of wavelength $\lambda > 435$ nm.

A solution of *(1)* (0.5 g, 2.4 mmol) in dry benzene (120 ml) is irradiated in a water-cooled Pyrex flask at 5—6 °C for 40 h with an external xenon lamp (Philips CSX 1600 W); wavelengths below $\lambda = 435$ nm are cut off by a Schott GG 455 filter[5]. After irradiation, a small amount of sodium carbonate is added, and the mixture is shaken, filtered, and cooled until it freezes. The solvent is stripped off at 0.5 torr. The residual colorless flakes are washed twice with cold benzene and once with cold ether; yield 0.39 g (78 %) of dioxide *(2)* (Table 1). Compound *(2)* prepared in this way is pure and must be stored at −20 °C.

Dropwise addition of *(2)* to boiling benzene leads instantaneously to the dimer *(7)*[4] (yield 70 %). In the presence of NMM [1.1 mol per mol of *(2)*] a mixture of *(3)* (8 %) and *(6)* (79 %) results; thermal isomerization of *(1)* under the same conditions leads to the same mixture[4]. The half-lifetime of *(2)* is 6.5 h at 28 °C. Thus *(2)* is less stable than benzene dioxide[6].

Addition of protic acids or Lewis acids to *(2)* effects immediate isomerization. Thus *(2)* is transformed by picric acid or $ZnCl_2$ (in dry benzene) into the bicyclic acetal *(4)* (Table 1). Acetals of this type have already been obtained from 9,10-disubstituted 9,10-anthracene endoperoxides[7]. Strong acids such as trifluoroacetic acid isomerize *(4)* further to the unstable isobenzofuran derivative *(9)* which can be trapped with NMM in chloroform [1.5 mol NMM per mol of *(9)*] as a mixture of *endo*- and *exo* adducts [*(10)* and *(11)* respectively] with the *in-situ* dehydration product *(12)*[8] (Table 1).

Table 2. Yields [%] of compounds isolated after photoisomerization of *(1)*; c = 20 mmol l^{-1} in benzene, 10—15 °C; source, Philips S.P.500; $\lambda > 435$ nm; irradiation time, 40 h. NMM = *N*-methylmaleimide, An = anthraquinone, Hy = 10-hydroxyanthrone.

Run	NMM [a]	Yield [%] *(1)*	*(2)*	*(3)*	*(6)*	*(7)*	*(8)*	An	Hy
1	3 [b]	—	—	94	2	—	—	3	1
2	3 [c]	9	—	64	1	—	4	4	—
3	0	—	60	13 [d]	—	—	4	6	—
4 [e]	0	—	83	7.5 [d]	—	—	2.5	2	1

[a] Moles of NMM per mole of *(1)*. [b] NMM added prior to irradiation. [c] NMM added after irradiation. [d] With addition of NMM to the mother liquors after isolation of *(2)*. [e] Irradiation carried out at 5—6 °C, source, Philips CSX 1600 W xenon lamp.

The results obtained under various irradiation conditions are compiled in Table 2. It is seen that the behavior of *meso*-acene endoperoxides such as *(1)* closely parallels that of endoperoxides of cyclic dienes as long as retrodienic dissociation remains unimportant[1].

SN Ring with Di-, Tri-, and Tetra-Coordinated Sulfur Atoms by Nucleophilic Substitution[**]

By *Herbert W. Roesky, Michael Witt, Bernt Krebs*, and *Hans-Jürgen Korte*[*]

Although the chemistry of cyclic sulfur-nitrogen compounds has long been a topic of study, nucleophilic substitution reactions have remained in the realm of speculation[1]. We have now succeeded, for the first time, in trapping the product of such a reaction of the S_4N_4 derivative *(1)*[2] with sodium methoxide and isolating it.

(1)

$$+ \ NaOCH_3 \longrightarrow \underset{(2)}{\left[S_4N_4O_2OCH_3\right]^-Na^+}$$

Which atom of the ring system suffers nucleophilic attack? The electron-withdrawing action of the SO_2 group would strongly suggest that this role is assumed by the adjacent sulfur atoms. A corresponding charge distribution also results from a CNDO/2 calculation, in which the S_3N_4 structure is regarded as a 10π-electron system coupled to an SO_2 group[3]. On the other hand, electron density changes are known to be favored in SN systems when the sulfur and nitrogen atoms are di-coordinated. Thus the sulfur atom most distant from the SO_2 might also be attacked by the nucleophile; the resulting product would then have a symmetrical electron distribution. The sodium of salt *(2)* was replaced by a tetraphenylphosphonium ion for single crystal structure analysis.

$[(C_6H_5)_4P]^+[S_4N_4O_2(OCH_3)]^-$ forms monoclinic crystals (space group $P2_1/n$) with $a = 15.866(8)$, $b = 11.277(6)$, $c = 15.907(8)$ Å, $\beta = 108.78(4)°$, $Z = 4$. X-Ray structure analysis (diffractometer data, $R = 4.7\,\%$) gave a conformation of the eight-membered ring resembling that of S_4N_4 and revealed almost ideal C_s symmetry of the anion, in which one of the two transannular interactions (2.482(2) Å) is still present (Fig. 1). The S_4N_4 skeleton can therefore be regarded as consisting of two annelated five-membered rings with a weak central S—S bond. The bond angles in the ring are ($\sigma = 0.2°$): N—$S(O_2)$—N 101.7, N—S—N 116.6 (average value), N—S(OR)—N 107.1, $S(O_2)$—N—S 116.0 (average value), S(OR)—N—S 122.9° (average value). Many reactions in the SN field can readily be explained on the basis of this contribution.

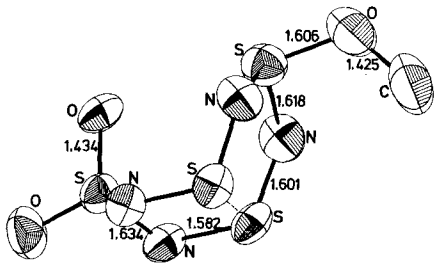

Fig. 1. Structure of the $[S_4N_4O_2(OCH_3)]^-$ ion in the crystal, bond lengths in Å ($\sigma = 0.002$—0.006 Å).

Procedure

A solution of $NaOCH_3$ (0.02 mol) in a small volume of methanol is added dropwise to a cooled suspension of *(1)* (0.02 mol) in anhydrous methanol (50 ml). The reaction product *(2)* can be isolated from the deep-violet mixture either by precipitation with benzene or by crystallization at −70 °C. The reaction is practically quantitative.—The salt *(2)* can be converted into the corresponding phosphonium salt by treatment with tetraphenylphosphonium chloride in methanol or cold water; this salt was purified by recrystallization from methanol at −70 °C (yield 60 %).

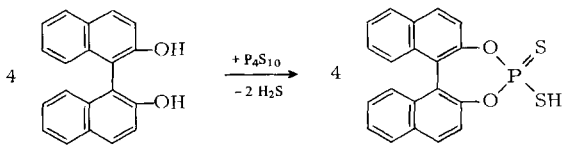
$(-)_{579}$-Bis[(*S*)-(+)-*O,O'*(1,1'-binaphthyl-2,2'-diyl)-dithiophosphato]nickel(II) — The First Dithiophosphato Complex to Have Axial Chirality



By *Ernst W. Hoffmann, Wilhelm Kuchen, Wolfgang Poll*, and *Hartmut Wunderlich*[*]

Metal complexes of dithiophosphoric acids $[(RO)_2P(S)S]M/n$ and dithiophosphinic acids $[R_2P(S)S]M/n$ are of interest mainly on account of their potential industrial applications[1], *e.g.* as additives to mineral oils[2], and have proved to be valuable adsorbents for chromatographic separation of Lewis bases[3]. We have now obtained the first axially chiral complex of this class in optically active form, *viz.* the title compound, and determined its absolute configuration by X-ray structure analysis.

Reaction of stoichiometric amounts of tetraphosphorus decasulfide and the axially chiral compound 2,2'-dihydroxy-1,1'-binaphthyl *(1)* in boiling chlorobenzene (1 h) gives *O,O'*-(1,1'-binaphthyl-2,2'-diyl)dithiophosphoric acid ("bndtpH") *(2)*, m. p. 242—243 °C (toluene/hexane), in about 80 % yield.

(1) *(2)*

Fractional crystallization of the (+)-methylbenzylammonium ("MBA") salt of the racemic acid *(2)* from isopropyl alcohol/water (1:3, v/v) permitted its resolution into the less soluble (+)MBA-(+)bndtp *(3a)* and its diastereomer (+)MBA-(−)bndtp *(3b)* from which the enantiomeric acids (+)-*(2)* and (−)-*(2)* could be liberated by the action of 8 N HCl. The ORD spectrum of (+)-*(2)* showed a negative Cotton effect at $\tilde{\nu}=35000\,cm^{-1}$, which suggested that this enantiomer has the (*S*) configuration[4, 5].

Reaction of *(3a)* and nickel(II) acetate in glacial acetic acid afforded the title compound (*S,S*)-*(4)* (Fig. 1), whose absolute ligand configuration could be confirmed by X-ray methods.

Hence it follows that the rules proposed by *Mislow, Djerassi, et al.*[4] for the configurational assignment of variously bridged biaryls on the basis of their ORD spectra are also applicable to [*d,f*]-annelated 1,3,2-dioxaphosphepin derivatives.

Acid-catalyzed trans-esterification with isopropyl alcohol[6] transforms *(3b)* in essentially quantitative yield into optically pure (*R*)-(+)-2,2'-dihydroxy-1,1'-binaphthyl (+)-*(1)*[7], m. p. 207—209 °C, $[\alpha]^{25}=+33°$ ($c=0.103$, THF), which thus becomes readily accessible.

Synthesis and crystal structure analysis of (S,S)-(4)

A 0.1 M solution of nickel(II) acetate in glacial acetic acid (1 ml) is added to a solution of optically pure MBA salt *(3a)*, $[\alpha]_{578}^{25}=+1404°$ ($c=0.01$, ethanol) (100 mg, 0.2 mmol) in the same solvent (10 ml). The precipitate of (*S,S*)-*(4)* formed in *ca.* 80 % yield is purified by dissolution in a small volume of hot toluene and, after filtration, reprecipitation by addition of hexane. Diamagnetic, brownish violet crystals which darken above *ca.* 320 °C. ^{31}P-NMR ($CDCl_3$, $c=0.1$ %): $\delta_P=+104.0$; $[\alpha]^{25}$ ($c=0.0187$ and 0.00187, $CHCl_3$; λ [nm] in parentheses): +57° (750), −600° (579), −96° (500), −17700° (330), +44000° (280); UV/VIS: $\tilde{\nu}$ (logε): 14000 (1.98), 18700 (2.05), 25500 (3.05, sh), 31400 (4.69) cm^{-1}.

The nickel complex forms rhombic crystals, space group $P2_12_12_1$ (D_2^4), $a=963.0(3)$, $b=1017.1(4)$, $c=3748.9(13)$ pm, $Z=4$, $\rho=1.48$ mg/mm^3. The crystal structure was determined from diffractometer data ($Cu_{K\alpha}$ radiation, ω scan, 2928 significant reflections) and refined to an *R* value of 0.053. The absolute configuration could be unequivocally determined by considering the anomalous dispersion of the Ni, P, and S atoms (Fig. 1).

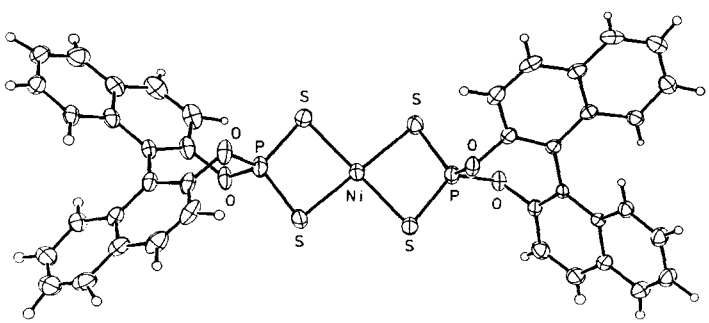

Fig. 1. Molecular structure [8] of (−)$_{579}$-bis[(*S*)-(+)-*O,O'*-(1,1'-binaphthyl-2,2'-diyl)dithiophosphato]nickel(II), (*S,S*)-*(4)* in the crystal.

The Ni atom is in a square-planar environment of four S atoms. The average bond lengths and angles in the four-membered rings are: Ni—S 224.1 and P—S 197.0 pm, and SNiS 89.5, NiSP 81.0, and SPS 106.5°. In the two halves of the molecule, the dihedral angles at the CC bond linking the naphthyl groups are found to be +53.5 and +52.1°.

Structural Isomers of Palladium Complexes of Type $C_5H_5Pd(2\text{-}RC_3H_4)L$ — A Case of Simultaneous π/σ and σ/π Rearrangement of Two Organic Ligands[1]

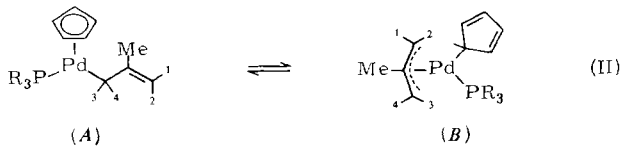
By *Helmut Werner* and *Alfred Kühn*[*]

Synthesis of the dinuclear complexes *(3)* according to Scheme (I)[2a] involves a 1:1 adduct *(2)* which can be isolated in some cases[2]:

(1) (I) *(3)*

(2a), R = *t*Bu, L = $P(iPr)_3$
(2b), R = *t*Bu, L = $P(cC_6H_{11})_3$
(2c), R = *t*Bu, L = $P(tBu)Ph_2$
(2d), R = Me, L = $P(iPr)_3$
(2e), R = Me, L = $P(cC_6H_{11})_3$
(2f), R = Me, L = $P(cC_6H_{11})_2Ph$

Investigation of the properties and the structure of compounds *(2)* surprisingly revealed that the two organic ligands C_5H_5 and $2\text{-}RC_3H_4$ are coordinated to the metal in a differing fashion depending upon R and L.



The ^{1}H-NMR spectra of the yellow crystalline complexes *(2a)*—*(2c)* show the cyclopentadienyl ligand to be *monohapto*- or σ-bonded and the allyl ligand to be *trihapto*- or π-bonded. The data of the allylic protons corresponds to those of the known compounds $(2\text{-}RC_3H_4)Pd(L)X$ (X=Cl,

Br, I)[3]. The C_5H_5 protons give rise to one sharp doublet (J_{PH} = 1.3—1.5 Hz) in the temperature range −60 to +90 °C, from which we deduce that *(2a)*—*(2c)* possess a fluxional structure *in solution*, *i.e.* undergo a very fast metallotropic rearrangement [migration of the (2-RC_3H_4)PdL group around the ring according to a 1,2-shift[4]]. The *monohapto* coordination of the cyclopentadienyl ring *in the crystal* has been established by X-ray structure analysis in the case of *(2a)*[5].

The room-temperature ^{1}H-NMR spectra of the complexes *(2d)*—*(2f)* closely resemble those of *(2a)*—*(2c)*. However, if their solutions in [D_8]toluene are cooled to −60 °C, the picture changes completely: *Two* signals now appear in the region of the C_5H_5 protons, and more than four signals for the protons of the allyl ligands. Detailed analysis of the low-temperature spectra demonstrates the presence of two isomers in equilibrium [eq. (II)].

(A) (B) (II)

Isomer *(A)* contains, together with L, a *pentahapto*-bonded cyclopentadienyl and a *monohapto*-bonded allyl ligand, resulting in an 18-electron configuration of the metal atom. In contrast, *(B)* has a *monohapto*-bonded five-membered ring and a *trihapto*-bonded allyl ligand, and the metal thus possesses a 16-electron configuration.

The intensity of the proton signals of *(A)* and *(B)* (Table 1) show that *(B)* predominates at −60 °C. This isomer ratio alters with rising temperature. Since the coalesced C_5H_5 proton signal observed at room temperature lies roughly half-way between the two peaks observed at −60 °C, we assume a 1:1 ratio of *(A)* and *(B)* to hold under these conditions. The data recorded for the allyl protons of *(2d)* at −60 and +35 °C support this result.

Detailed analysis of the C_5H_5 signal of *(2f)* at various temperatures (Table 2)[6] provided quantitative information about the ligand reorientation process of eq. (II).

π/σ rearrangements of organic ligands have repeatedly been observed both for π-cyclopentadienyl- and for π-allyl-metal complexes. Addition of a new ligand L to the metal is generally regarded as the initiating step. The reverse reaction is also known, *i.e.* rearrangement of a σ-C_5H_5 to a π-C_5H_5 ligand, and of a σ-2-RC_3H_4 to a π-2-RC_3H_4 ligand[7]. However, to our knowledge, the process described in eq. (II) is the first example of an isomerization reaction in which π/σ and σ/π rearrangement of a cyclopentadienyl ring and an allyl group, respectively, occur *simultaneously*.

Catalysis of Hydrogen Formation from an Organic Radical in Aqueous Solution by Colloidal Silver[**]

By *Arnim Henglein*[*]

Reactions between free radicals in homogeneous solution, such as combination, disproportionation, and dismutation, proceed with minimum rearrangement. Such reactions are usually very fast. Organic radicals having a high negative redox potential[1] should be capable of reducing water or of eliminating hydrogen among themselves. Reactions of this kind have not yet been observed because they are too slow to compete with the above-mentioned radical-radical reactions.

It has now been found that 1-hydroxy-1-methylethyl radicals form hydrogen in the presence of colloidal silver Ag_n in aqueous solution:

$$2(CH_3)_2\dot{C}OH \xrightarrow{Ag_n} 2(CH_3)_2CO + H_2 \quad (1)$$

The yellow colloidal silver was produced by complete reduction of 5×10^{-4} M Ag^+[2], the solution also containing 1×10^{-3} M sodium dodecylsulfate as stabilizer. In order to generate the organic radicals, acetone and 2-propanol (each 0.1 M) are added and the solution exposed to γ-radiation with exclusion of air. The primary radicals resulting from radiolysis of the water react under these conditions according to

$$e_{aq}^- + (CH_3)_2CO + H^+ \rightarrow (CH_3)_2\dot{C}OH \quad (2)$$

$$\dot{O}H + (CH_3)_2CHOH \rightarrow (CH_3)_2\dot{C}OH + H_2O \quad (3)$$

$$H + (CH_3)_2CHOH \rightarrow (CH_3)_2COH + H_2 \quad (4)$$

The yield of hydrogen corresponds to formation of one molecule of H_2 per two 1-hydroxy-1-methylethyl radicals (corrected for the small amount of H_2 liberated from the water by the action of the radiation). The effects observed can be interpreted in terms of the following mechanism:

$$2(CH_3)_2\dot{C}OH + Ag_n \rightarrow 2(CH_3)_2CO + 2H^+ + Ag_n^{2-} \quad (5)$$

$$Ag_n^{2-} + 2H_2O \rightarrow Ag_n + H_2 + 2OH^- \quad (6)$$

$$2H^+ + 2OH^- \rightarrow 2H_2O \quad (7)$$

$$2(CH_3)_2\dot{C}OH \rightarrow H_2 + 2(CH_3)_2CO \quad (1)$$

The organic radicals charge the silver particles by electron transfer, more than two electron being transferred [eq. (5)], until decomposition of water occurs [eq. (6)]. The silver particles thus assume the role of a pool of electrons which can be released, singly or pairwise, on demand to suitable acceptors[3]. Reaction (5) appears reasonable because 1-hydroxy-1-methylethyl radicals exhibit an anodic polarographic wave which extends to more than -1.0 V[1] at negative potentials (*vs.* standard hydrogen electrode). A negatively charged colloidal particle is to be regarded as a microelectrode at a negative potential according to the above mechanism.

These experiments show that short-lived free radicals can be forced to undergo unusual reactions if they are generated in the presence of a metal colloid catalyst in aqueous solution.

BOOK REVIEWS

Intermolecular Interactions: From Diatomics to Biopolymers. Edited by *B. Pullman*. John Wiley & Sons, London 1978, 1st edit., ix, 447 pp., bound, £ 19.50.

The book begins with a contribution by *D. Buckingham*, which is chiefly concerned with multipole expansion and its role in the theory of intermolecular forces, treating other aspects of the theory very briefly. We sense a little of the fascination of the theory of intermolecular forces, with its unexpected snares and its problems which are in part still unsolved or have only recently been solved, when we turn to *P. Claviere*'s report, and in particular to the first part, which deals with the basic aspects of the theory. The author can in part refer to his own work here. The second part is concerned with the derivation of approximate formulas for individual contributions to intermolecular forces in large molecules. The bibliography is impressive. In *R. Rein*'s article, so broad is the theme of the book, he describes the interactions of nucleic acids, and in particular hydrogen bridges and dispersion forces between superimposed base pairs. Finally, *P. Schuster* gives a very useful survey of *ab initio* calculations for hydrogen bridges. He begins with a critical assessment of calculations on isolated components, and goes as far as hydrogen fluoride polymers $(HF)_n$. A whole series of physical properties and the way in which they are affected by hydrogen bridges are discussed; much attention is paid to an analysis of the calculations and to a qualitative interpretation of the results.

In all, the book can be recommended to anyone interested in the theory of intermolecular forces.

Werner Kutzelnigg [NB 454 IE]

Fourier Transform Infrared Spectroscopy. Vol. 1. Applications to Chemical Systems. Ed. by *J. R. Ferraro* and *L. J. Basile*. Academic Press, New York 1978, 1st edit., viii, 311 pp., bound, $ 25.00.

This is the combined work of a series of well-known authors. It is divided into seven chapters, which are largely concerned with applications:

1. Study of matrix-isolated species (*D. W. Green, G. T. Reedy*);
2. Study of synthetic and biological macromolecules (*L. D'Es-*

© Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0505-0418 $ 02.50/0

posito, J. L. Koenig); 3. Emission measurements (*J. B. Bates*); 4. GC/IR Coupling (*P. R. Griffiths*); 5. Study of materials under high pressures (*J. L. Lauer*); 6. Far infrared spectroscopy (*J. R. Durig, A. W. Cox*); 7. Environmental protection, space research and energy research (*J. R. Ferraro, L. J. Basile*).

Each chapter describes the application of IR spectroscopy to the solution of specific and demanding problems, and is illustrated with many examples. Most of these problems have been known for some time, and were dealt with in the sixties and earlier by means of conventional dispersive IR spectrophotometry. To do this, it was often necessary to operate at or beyond the capability limits of the instruments. The introduction of the Fourier technique considerably extended the possible applications of IR spectroscopy. The aim of the present book is to demonstrate these wider applications, and this is certainly achieved qualitatively. The book also offers many valuable technical tips not directly connected with the Fourier technique (cell construction, sample preparation, evaluation of the spectra, *etc.*). However, it is a pity that there is no chapter dealing in general terms with the advantages and disadvantages of the Fourier technique as opposed to the conventional dispersive method, where the various problems (microsamples, FIR range, heavy background losses, rapid measurements, *etc.*) could be considered. Without such a chapter an impartial reading of this quite heterogeneous work could lead to the conclusion that any problem which can fit into any of the seven chapters requires the use of the Fourier technique. Such a conclusion is undoubtedly valid in the case of GC/IR coupling and in the problems of space research, to name but two examples, but it is completely unjustified *e.g.* in the case of the study of matrix-isolated species and of synthetic macromolecules in the medium IR range. This is shown by the flood of excellent papers which describe work in this field, where the conventional dispersive instruments are used just as much as ever. The book should have provided a clearer answer to the question when a user might need, or be able to exploit, the dearly bought advantages of the Fourier technique.

Erich Knözinger [NB 449]

Stereochemie und Konformationsanalyse (Stereochemistry and Conformational Analysis). By *J. Dale*. Verlag Chemie, Weinheim 1978. xii, 208 pp., bound, DM 38.00.

From its title the book promises to be a comprehensive presentation on these two important sectors of chemistry; the promise, however, is fulfilled only as far as the second part of the title is concerned. Conformational analysis is treated in detail taking as a basis the physical methods used. Almost half of the book is devoted to the conformational analysis of cyclic compounds. This section is logically arranged, and both students and experienced scientists and lecturers can learn something from it.

In the first part of the book, however, the geometric foundations of stereochemistry are missing. No effort is made to present clear definitions. The use of models, a requirement in all scientific work, is especially important in stereochemistry. This certainly does not mean that rigid geometric objects can give a true-to-life representation of molecules (or of large numbers of molecules), but geometric models do make it possible, with the necessary degree of caution, to work out the fundamentals of modern stereochemistry. This is true not only for the structure, configuration, and conformation of molecules, but also for the symmetry relationships of constitutionally identical groups within a molecule. These relationships play an important role, for example, in NMR spectroscopy and in enzymology. When we find the assertion on page 32 that "The presence of a chirality center allows the geminal protons or groups to be nonequivalent (*diastereotopic* or *prochiral*)" then we understand why clear definitions of these expressions have been avoided.

On the other hand, the physical methods, and in particular the spectroscopic techniques used to determine molecular properties, are described carefully and in detail. The section on asymmetric induction is inserted somewhat unexpectedly after the section on cyclization of polyenes (p. 100).

Although the book is not written in such a way as to arouse any great enthusiasm, it can be recommended to interested readers. One should not, however, be under the illusion that the long-awaited standard work on stereochemistry has at last arrived.

Janos Rétey [NB 465 IE]

Surfactants and Interfacial Phenomena. By *M. J. Rosen*, John Wiley & Sons, New York 1978. 1st edit., 304 pp., bound, $ 30.45.

Because of the increasing importance of interfacial phenomena, particularly in connection with detergents, the literature concerned with these problems has increased markedly over the past few years.

The present book attempts to provide a compact summary of the most important interfacial and colloid chemistry aspects of the use of surfactants. In ten chapters the author discusses the general properties and structures of surfactants, their adsorption at interfaces, micelle formation, solubilization, reduction of surface tension, wetting, foam properties, emulsification, dispersion, and washing.

The author has succeeded very well in his aim of providing the essential information for the interested reader in a restricted space. Careful selection of the material permits the important relationships to be recognized; the book is not weighed down with marginal data and information.

The work is intended for advanced students and for practising scientists who want a compact guide to the properties of surfactants. At the end of each section there is a selection of literature references to enable the topic to be studied further. It is worth noting that the literature references cover the appropriate European and Japanese literature, which is not always the case with English-language monographs.

The present book will completely fulfil its purpose of offering both the interested subject specialist in the chemical industry and also the advanced student the opportunity of obtaining the essential information on surfactants and their behavior at interfaces.

M. J. Schwuger [NB 447 IE]

Internal Rotation and Inversion. An Introduction to Large Amplitude Motions in Molecules. By *D. G. Lister, J. N. Macdonald* and *N. L. Owen*. Academic Press, London 1978, 1st edit., xii, 246 pp., £, 11.50.

This book attempts (in itself a praiseworthy aim) to present the multiplicity of specific experimental and theoretical methods for the investigation of the internal mobility of molecules, together with the results and insights gained therefrom, to a broad non-specialist audience. Vibration and rotation spectroscopy, and also small rotation barriers, are treated in comparative detail, while the methods for the barrier range of 25 to 100 kJ mol^{-1} are only mentioned cursorily. One chapter contains a few remarks about empirical force-field and quantum-chemical calculations of barriers. The book closes with a discussion of atomic inversions, pseudorotations, and other motions in rings, and with a brief look at macromolecules of biological significance.

Within a compass of 240 text pages we might have expected, in view of the profusion and diversity of the material, a purely descriptive treatment. The authors strive for more and manage to achieve less. They feel the need to protect the chemist, as far as possible, from the hardships of a coherent mathematical treatment, but on the other hand they do not wish to forego embellishing their work with mathematical decorations. The results of such an approach are of necessity unsatisfactory. There remain about 130 pages which the non-specialist may read with some profit; provided, however, that he is not disturbed by the many imprecise formulations, *e.g.* statements that a secular determinant and secular equations mean the same thing, that Hamiltonian eigenfunctions behave either in a symmetric or antisymmetric fashion with respect to symmetry operations, that a methyl group attached to nitrogen is an electron attractor, that the inversion barrier in NH_3 is 5.8 kJ mol^{-1}, or that the barrier to restricted rotation in *N*,*N*-disubstituted amides has a typical value of 40 kJ mol^{-1}.

There has long been an urgent need for a modern survey of this extensive and important field. The book that will satisfy this need is yet to be written.

Gerhard Binsch [NB 453 IE]

Transform Techniques in Chemistry. Edited by *P. R. Griffiths*. Plenum Press, New York 1978. xviii, 385 pp., bound, $ 47.40.

The present new volume from the series "Modern Analytical Chemistry" offers, for the first time in one volume, a survey of the entire range of applications of transform techniques in chemistry. Several authoritative writers describe the specific applications in concise review articles. It thus becomes clear that Fourier transform techniques in particular have an astonishing degree of universality. Some emphasis is of course given to spectroscopic applications, but there are also interesting possibilities in the fields of the processing and analysis of chemical data.

The book is intended for non-specialists and is therefore written in an easily understandable style. Because of the enormous range of applications, only the basic features could be covered; however, the book is suitable as a first survey of the many possibilities. Up to now the applications of transform techniques have largely developed independently of one another. It is therefore particularly good to see that an attempt has been made here to interrelate the individual fields of application.

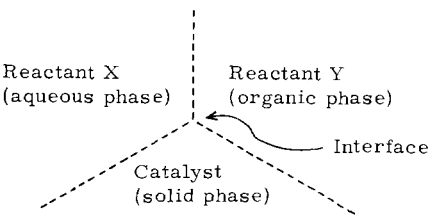
Triphase Catalysis

New synthetic methods (27)

By Steven L. Regen[*]

Triphase catalysis (TC) has recently been introduced as a unique form of heterogeneous catalysis in which the catalyst and each of a pair of reactants are located in separate phases. Based on this concept, new synthetic methods have been developed for aqueous phase–organic phase reactions using a solid phase catalyst. Although it is only at an early stage of development, TC shows considerable potential for practical use. Our mechanistic understanding of these highly complex catalytic systems is at present very limited and detailed examination will be required before their relationship to phase-transfer, micellar, and interfacial catalysis becomes clear.



1. Introduction

A significant and recurring problem facing the synthetic organic chemist is how to effectively carry out reaction between a water-soluble reagent and a water-insoluble substrate. When reaction is attempted as an aqueous–organic biphase process, very low rates are usually observed due to the low concentration of at least one of the compounds in each phase. Rapid stirring has been shown, in certain cases, to have an accelerating effect by increasing the surface contact between the layers and thereby increasing the interfacial component of the reaction[1]. Alternatively, reaction rates may be increased by the use of a cosolvent which, by conferring homogeneity upon the system, increases the effective concentration of the reactants. As a consequence of the third solvent, however, the organic reactant is not only more accessible to the reagent, but at the same time has greater contact with water. This situation can lead to undesired by-products by furnishing a competing hydrolytic pathway. Furthermore, work-up and product isolation are made more difficult when a cosolvent is employed. Finally, soluble ammonium and phosphonium salts[2] as well as crown ethers[3], cryptands[4], and surfactants[5] have proven extremely useful in catalyzing aqueous–organic biphase reactions. Interest in such phase-transfer and related two-phase catalytic techniques continues to grow in synthetic and mechanistic organic chemistry[6]. This topic has been the subject of recent comprehensive reviews and will not be discussed here[7].

2. Concept of Triphase Catalysis (TC)

It occurred to us that the development of a technique which used insoluble catalysts to accelerate aqueous–organic phase reactions would not only be an interesting possibility but could also provide the basis for synthetic methods competitive with or even superior to existing ones (Scheme 1).

Two immediate advantages would be (1) simplified product work-up and (2) easy and quantitative catalyst recovery. From the standpoint of industrial applications, this concept is a

Scheme 1. Triphase catalysis.

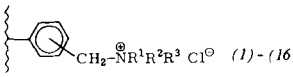
very attractive one due to low energy and capital requirements for processing. In addition, such a technique would be ideally suited for continuous flow methods.

3. Development of Triphase Catalysts



Crosslinked polystyrene resins and silica gel have received considerable attention as supports for insolubilizing synthetically important catalysts and reagents[8]. Thus far, all of the triphase catalysts introduced are based on these materials. In the following discussion we have divided the catalysts into three different categories based on the nature of the active site: 1) ion-exchange groups; 2) crown ethers and cryptands; and 3) cosolvents.

3.1. Classes of Catalysts

3.1.1. Insolubilized Ammonium and Phosphonium Salts

The feasibility of triphase catalysis was first demonstrated by the reaction of cyanide ion with 1-bromo- and 1-chlorooctane in water–benzene systems using a crosslinked polystyrene resin *(1)* bearing quaternary ammonium groups as the catalyst (Scheme 2)[9, 10]. Control experiments showed that in the absence of *(1)* or in the presence of its unfunctionalized counterpart no reaction took place and that *(1)* did not dissolve in the medium or decompose to yield a soluble catalyst. The experimental set-up is shown schematically in Figure 1. A series of related polystyrene-based catalysts *(2)*—*(16)* were prepared and tested for their ability to catalyze the reaction of sodium cyanide with 1-bromooctane (Table 1)[11].

Table 1. Dependence of catalyst activity in the triphase reaction (a) upon resin structure [11]. DVB = divinylbenzene.

(1)-*(16)*

Catalyst	Polystyrene backbone	DVB [%]	Ring substitution [%]	$R^1=R^2$	R^3	k [s^{-1}] [a]
(1)	Microporous	2	10	CH_3	n-C_4H_9	2.2
(2)			1			1.9
(3)			21			2.2
(4)			10	CH_3	CH_3	3.0
(5)			46			0.015
(6)			76			≤0.015
(7)			10	CH_3	n-C_8H_{17}	4.4
(8)			10	CH_3	n-$C_{12}H_{25}$	3.0
(9)			9	CH_3	n-$C_{14}H_{29}$	3.7
(10)			8	C_2H_5	C_2H_5	1.5
(11)			9	CH_3	$CH_2C_6H_5$	2.6
(12)			8	CH_3	C_2H_4OH	1.1
(13)	Microporous	1	10	CH_3	n-C_4H_9	2.2
(14)	Microporous	4	9			2.7
(15)	Macroporous	8	8			0.22
(16)	"Popcorn"		10			2.5

[a] Observed first-order rate constant divided by the molar amount of quaternary ammonium groups.

From this work it was concluded that:

1) At 8—10% ring substitution, the structure of the quaternary ammonium group and the type of support material used (microporous, macroporous, and "popcorn") are not of major importance in determining the catalyst's activity.

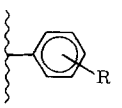
(1)



(a)

Scheme 2. Microporous polystyrene resin *(1)*, crosslinked with 2% divinylbenzene and with 10% ring substitution, as catalyst for the triphase reaction (a).

2) Commercial ion-exchange resins which swell extensively in water and have little or no compatibility with organic solvents appear to be very poor triphase catalysts. Thus, commercial Bio-Rad AG1-X2 whose structure is nearly identical with *(6)* failed to show any triphase activity.

In a similar study, *Cinquini et al.*[12] examined resins *(17)*—*(22)* for their usefulness in converting 1-bromooctane into 1-iodooctane and octanecarbonitrile in toluene/resin/water systems. Polymer-anchored phosphonium salts exhibited greater activity than analogous ammonium-based resins. Moreover, all the triphase reactions proceeded slower than comparable transformations carried out using a phase-transfer catalyst. The crosslink density of the support was also shown to be important: more extensive crosslinking led to lower catalytic activity.

Brown and *Jenkins*[13] prepared resins *(23)*—*(27)* and used them for triphase catalysis of the *O*-alkylation of 2-naphthoxide with benzyl bromide [reaction (b)].

(23), $Z = CH_2OCO[CH_2]_{11}$; 98% ring substitution, microporous
(24), $Z = CH_2OCO[CH_2]_{11}$; 46% ring substitution; Rohm and Haas XE305, macroporous
(25), $Z = CH_2OCO[CH_2]_5$; 100% ring substitution, microporous
(26), $Z = CH_2OCO[CH_2]_5$; 40% ring substitution, Rohm and Haas XE305, macroporous
(27), $Z = CH_2$; ring substitution not specified, microporous

Lengthening the alkyl chain between the support and the onium groups significantly improved the yield of *O*-alkylated product. Also, macroreticular resins were found to be more active than microporous ones. Catalysts *(23)* and *(24)* were also effective in promoting cyanide displacement [eq. (a)].

(b)

In a systematic study, *Molinari et al.*[14] examined how the length of the pendant chain used to attach phosphonium groups to polystyrene influenced the activity of the resulting catalyst. Resins *(28)*—*(31)* were synthesized and tested as

(28)-(31)

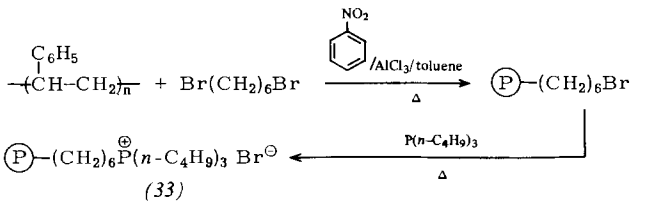
(32)

catalysts for the displacement reaction between iodide and thiophenoxide and 1-bromooctane. The order of catalyst activity was *(31)* > *(30)* > *(29)* > *(28)*. With resin *(31)*, observed rates approached those measured under similar conditions using phase-transfer catalyst *(32)*.



Zadeh et al.[15] have applied triphase procedures to the *C*-alkylation of nitriles using commercial ion-exchange polymers of structures *I* and *II* [cf. *(27)* and *(12)*]. Although

I *II*

it was demonstrated that triphase catalysis was possible, direct comparison with phase-transfer catalysis using soluble ammonium and phosphonium salts showed the latter to be the preferred method. This is not surprising, however, since commercial ion-exchange resins similar to those used in this study have already exhibited very poor triphase catalytic activity in nucleophilic substitution reactions[11,12].

Recently, *Tundo* reported a readily available and economically attractive triphase catalyst, *(33)* (Scheme 3)[16]. This resin swells extensively in dichloromethane and has a catalytic capacity comparable with the analogous phase-transfer catalyst *(32)* for alkylation of ketones as well as some simple nucleophilic displacement reactions (Table 2).

(33)

Scheme 3. Synthesis of the triphase catalyst *(33)*. Ⓟ = polystyrene.

Silica-based triphase catalysts have been reported by two groups. *Rolla et al.*[17] demonstrated that solids derived from ammonium and phosphonium salts covalently attached to glass surfaces [*(34)*—*(43)*] could be used to convert 1-bromohexane into 1-iodohexane under triphase conditions [eq. (c)].

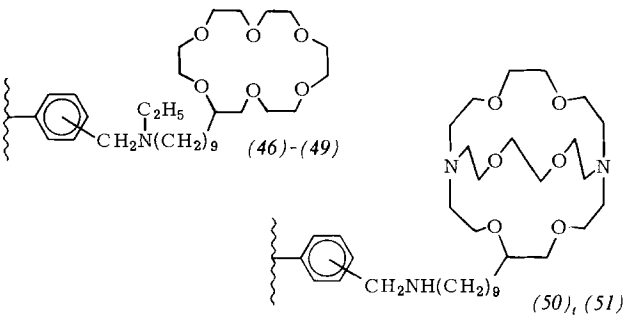
Dilute solutions and vigorous stirring were required to achieve catalysis. The size of the alkyl groups bonded to nitrogen did not significantly influence catalyst activity. Not surprisingly, *(34)*—*(43)* were unstable in alkaline solution.

Tundo similarly showed that *(44)* and *(45)* were effective in catalyzing halogen exchange reactions and reduction of ketones by $NaBH_4$ under triphase conditions[18]. Interestingly,

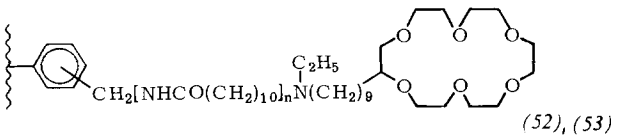


(44), Z = $P^{\oplus}$; *(45)*, Z = $NHCO(CH_2)_{10}\ P^{\oplus}$

(44) and *(45)* exhibited *greater* activity than the analogous phase-transfer agent *(32)* in the reduction of 2-octanone.

3.1.2. Insolubilized Crown Ethers and Cryptands

This class of catalyst has received limited attention thus far. Only nine resins have been described in the literature for use in triphase systems. *Cinquini et al.*[12] have reported the preparation of polymers *(46)*—*(51)* and their use as

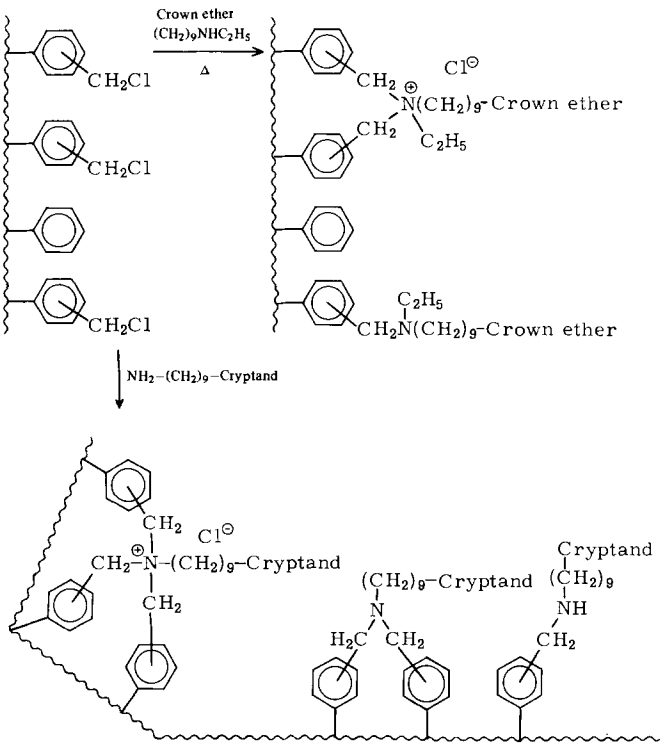


(46)-*(49)* *(50)*, *(51)*

Microporous polystyrene-based catalyst, crosslinked with 2% divinylbenzene [4% for *(49)*]

(46), 5% ring substitution
(47), 10% ring substitution
(48), 33% ring substitution
(49), 20% ring substitution
(50), 3% ring substitution
(51), 5% ring substitution

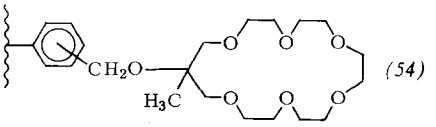
catalysts in the reaction of cyanide and iodide with 1-bromooctane. Polymer-anchored crown ethers and cryptands, like supported phosphonium salts, were more useful than supported ammonium salts owing to their higher activity and thermal stability. Related studies using resins *(52)* and *(53)* for the



(52), *(53)*

Microporous polystyrene-based catalysts, crosslinked with 2% divinylbenzene, 17% ring substitution *(52)*, $n=1$; *(53)*, $n=2$

conversion of 1-bromooctane into 1-iodooctane and *n*-octyl phenyl sulfide indicated that increasing the length of the pendant chain used to bind the crown ether to the polymer backbone led to increased catalytic activity[14].

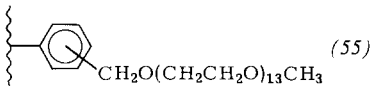


There is a certain ambiguity associated with these catalysts, however, which must be recognized. Polymers *(46)*—*(51)* were synthesized by reaction of the appropriate amine form of the crown ether or cryptand with a chloromethylated polystyrene resin. Since the polymer backbone is flexible[19,20], and since there must be a certain percentage of neighboring chloromethylstyryl units in the copolymer, there is a high probability that these resins contain at least a small fraction of ammonium groups (Scheme 4).

Scheme 4. Side reactions in the production of catalysts of type *(46)*—*(51)*.

Furthermore, quaternization may also occur during the catalysis by alkylation of amine groups by one of the reactants (1-bromooctane). A similar ambiguity is present with catalysts *(52)* and *(53)*. Thus, a clear assessment of the participation of the crown ether and cryptand moieties in these systems is not possible.

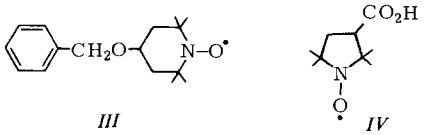
That a polymer-supported crown ether could function as a triphase catalyst was firmly established in very recent work by *Tomoi et al.*[21]. Polymer *(54)* was shown to have significant activity for the triphase conversion of 1-bromooctane into 1-iodooctane.



(54)

Macroreticular polystyrene resin, crosslinked with 10% divinylbenzene; 1.8 mmol of crown ether units/g of polymer

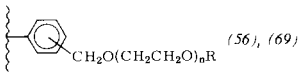
3.1.3. Insolubilized Cosolvents



In an effort to expand the utility of TC, catalysts having cosolvent-like properties have been developed. Thus, a graft copolymer *(55)* derived from poly(ethylene glycol monomethyl ether) and microporous crosslinked polystyrene proved effective for the hydrolysis of *tert*-butyl chloride and 1-bromoadamantane and also for the reaction between phenoxide and 1-bromobutane in water–toluene systems[22].

(55)

Microporous polystyrene-based catalyst, crosslinked with 2 % divinylbenzene, 11 % ring substitution



Studies using spin-labeled *III* and *IV* showed that *(55)* can act as a cosolvent by influencing the polarity and motional freedom of the microenvironment within the solvent channels[23]. Additional support for cosolvent behavior has recently come from a kinetic comparison of the closely related graft copolymers *(56)*—*(69)* used in catalyzing the hydrolysis of 1-bromoadamantane[24]. The activation parameters summarized in Table 3 indicate a considerable variation in $\Delta H^{\neq}$

III *IV*

accompanied by a compensating fluctuation in $\Delta S^{\neq}$. The free energy of activation, $\Delta G^{\neq}$, for all the catalytic systems was nearly identical ($\Delta G^{\neq} = 30.1$ kcal mol^{-1}) and approximately 2 kcal mol^{-1} lower than for the uncatalyzed reaction.

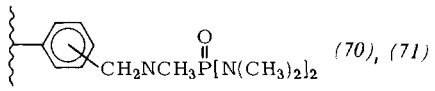


Table 3. Graft polymers as triphase catalysts for hydrolysis of 1-bromoadamantane [24].

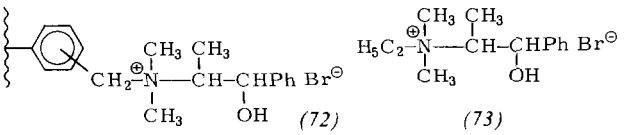
(69)	4			21.14 ± 0.53	−24.96 ± 1.41

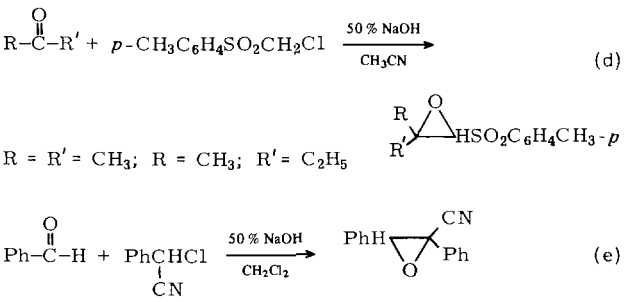
Another type of solid phase cosolvent has been prepared by attachment of hexamethylphosphoramide to a polymer support[25]. Resins *(70)* and *(71)* proved useful in triphase catalytic displacement reactions by cyanide and chloride ion on 1-bromooctane. These copolymers also catalyzed the hydrolysis of 1-bromoadamantane under triphase conditions.



(70), (71)

Microporous polystyrene-based catalyst, crosslinked with 1 % divinylbenzene *(70)*, *(71)* with 92 and 17 % ring substitution, respectively

3.2. Chiral Triphase Catalysts



Colonna et al.[26] have prepared an ephedrinium-based chiral triphase catalyst *(72)* and used it to perform Darzens condensations [eq. (d) and (e)]. Asymmetric induction was achieved with optical yields as high as 23 %. Although the products derived from *(72)* were of lower optical rotation than those from the soluble analog *(73)*, the polymer-supported catalyst had the advantage of being easily and completely removed from the product mixture by filtration.

In a brief report, *Chiellini* and *Solaro* confirm the feasibility of asymmetric induction using chiral triphase catalysts[27].

(72) *(73)*

Microporous polystyrene-based catalyst, crosslinked with 1 % divinylbenzene, 12 % ring substitution

(d)

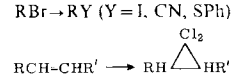
(e)

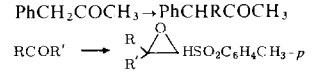
3.3. Catalyst Stability

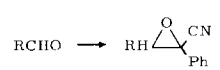
In order for TC to be of real practical value, the catalysts must be reasonably stable. *Dou et al.*[28] have examined the stability of two commercial ammonium ion-exchange resins (Dowex 1 × 8 and Dowex 11) in the presence of anions of thiophenol and phenylacetonitrile generated under triphase conditions. Significant polymer decomposition occurred, apparently through a dequaternization process. In order to put the significance of these results into proper perspective, however, two additional points must be considered. Firstly, these experiments were performed *in the absence of a competing alkylating reagent* (normally a desired reactant). *Herriott* and *Picker* have made kinetic measurements of the alkylation of thiophenol by 1-bromooctane using several ammonium catalysts and failed to find any evidence of catalyst decomposition[29]. Second, it has been shown[11–13,15] that commercial anion exchange resins of this type are very poor triphase catalysts. What relevance these stability data have with regard to *active* triphase catalysts is unclear.

Present indications are that many of the useful ammonium and phosphonium-based catalysts have stabilities ranging from good to excellent[12,14,16,17,21,26,30]. For this class of catalysts, stability will depend on the exact structure of the phosphonium or ammonium group and also the inherent reactivity of the reagent and substrate.

From the standpoint of stability, insolubilized crown ethers, cryptands, and cosolvents are more attractive since they avoid the potential dequaternization problem; however, their synthetic scope has not yet been established. More studies with these catalysts are needed.







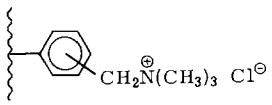
3.4. Selectivity Features of Polystyrene-Based Catalysts

Polystyrene resins are known to impart a modest size-selectivity to attached catalysts and reagents in solid/liquid biphase reactions[31,32]. Preliminary studies in our laboratory indicate that similar selectivity is possible with polystyrene-based triphase catalysts in liquid/solid/liquid reactions. The magnitude of the selectivity observed for triphase catalyzed reactions of phenoxide ion with a homologous series of primary organic bromides was high for cosolvent and modest for ion-exchange type catalysts[33]. Both diffusional barriers imposed by the polymer matrix and absorption equilibria appear to be important factors. Comparable phase-transfer experiments yielded no detectable selectivity.

4. Synthetic Applications

Table 4 summarizes most of the synthetic applications of TC which have appeared in the literature.

Table 4. Triphase catalysis, synthetic applications.



Reaction	Solvent	Catalyst	Ref.
RX→RCN (X=Br, Cl)	benzene/H_2O	*(1)*, *(70)*, *(71)*	[10, 25]
RX→RY (X=Cl, Br, I; Y=Cl, Br, I)	toluene/H_2O	*(1)*	[34]
RBr→ROR′	toluene/H_2O	*(1)*	[34]
RBr→ROR′	toluene/H_2O	*(59)*	[22]
RBr→RY (Y=I, CN)	toluene/H_2O	*(17)*—*(22)*, *(46)*—*(51)*	[12]
RBr→RY (Y=I, SPh)	toluene, chlorobenzene or heptane/H_2O	*(28)*—*(31)*, *(52)*, *(53)*	[14]
RBr→ROR′	substrate/H_2O	*(23)*—*(27)*	[13]
RBr→RI	substrate/H_2O	*(44)*, *(45)*	[18]
RBr→RI	toluene/H_2O	*(34)*—*(43)*	[17]
RBr→RY (Y=I, CN, SPh)	toluene or CH_2Cl_2/H_2O	*(33)*	[16]
	$CHCl_3/H_2O$	*(1)* and related resins	[27, 34]
RCHBrCHBrR′→RCH=CHR′	toluene/H_2O	*(1)*	[34]
ROH→RCl	$CHCl_3/H_2O$	*(1)*	[34]
$R_2CHOH→R_2CO$	toluene/H_2O	*(1)*	[34]
$RCH_2CN→RCHR'CN$	substrate/H_2O	various ammonium polymers	[27]
$RCH_2CN→RCHR'CN$	substrate/H_2O	commercial anion exchange resins	[15]
$PhCH_2COCH_3→PhCHRCOCH_3$	substrate/H_2O	*(33)*	[16]
	substrate/H_2O	*(72)*	[26]
	CH_2Cl_2/H_2O	*(72)*	[26]

5. Mechanistic Studies

Our mechanistic understanding of triphase catalysis is still very limited. Only one kinetic investigation of a triphase system has been reported; *i.e.*, reaction of cyanide ion with 1-bromooctane in the presence of catalyst *(1)* [eq. (a)][11]. The rate of displacement exhibited a first-order dependency on the 1-bromooctane concentration and was linearly dependent on the amount of catalyst used. Comparison of the catalytic activity for similar resins having 1, 10, and 21 % ring substitution indicated that, within this range, resin activity is directly related to the number of quaternary groups present. The catalyst isolated after triphase reaction had undergone complete ion-exchange to the cyanide form.

In this study it was assumed that chemical reaction is rate limiting; no consideration was given to diffusion. In principle, the overall rate for such transformations could be limited by film diffusion, chemical reaction throughout the polymer matrix, and/or chemical reaction at the particle surface.

We have since examined the kinetic features of the triphase reaction between cyanide ion, benzyl chloride, and the resin *(74)*. Taken together, the data obtained favor chemical reaction as being the rate limiting step[35].

(74)

Microporous polystyrene, crosslinked with 1 % divinylbenzene, 17 % ring substitution

A rate-limiting chemical reaction occurring throughout the resin should be characterized by: 1) a first-order dependence on benzyl chloride concentration; 2) a rate which is directly proportional to the amount of catalyst used; 3) a rate which is independent of stirring; 4) a significant activation energy ($>10\,kcal\,mol^{-1}$); and 5) a rate which is independent of particle size.

For a diffusion-controlled process, 1) and 2) should apply along with the *converse* of 3), 4), and 5)[36]. Thus, examination of stirring and particle size effects on rate along with activation energy measurements provide a means of identifying the rate-controlling step. For the reaction of cyanide with benzyl chloride we have observed a first-order dependence on benzyl chloride and a rate constant, k_{obs}, which is directly proportional to the amount of resin used. The apparent activation energy was 19.9 ± 1.6 kcal mol^{-1}. Changing the stirring speed from 0 to 750 RPM produced only a slight increase in rate ($\approx 20\,\%$). Increasing the resin surface area by grinding to a fine powder resulted in a *decrease* in catalyst activity. Although these observations are most consistent with a rate-limiting chemical reaction, the decrease in activity on reducing particle size is puzzling and leads to some uncertainty in establishing whether reaction takes place throughout the matrix or just on the bead surface. It should be noted that the fact that triphase catalysts can, at least in certain cases, exhibit close to maximum activity as an unstirred system may have important technological consequences. Minimal stirring is important in order to maintain the physical stability of the catalyst; it is also desirable for continuous flow methods.

6. Factors Affecting Catalyst Activity

Although TC is very simple from a synthetic standpoint, it is highly complex mechanistically. It incorporates a multitude of parameters, many of which are likely to be interdependent. This technique is still in its infancy and much more work will be required before a complete understanding is possible. The discussion presented in this section is not intended to furnish the potential investigator with a critical mass of information necessary for the rational design of new catalysts, but is instead aimed at stimulating further synthetic and mechanistic research.

6.1. Resin-Based Catalysts

Crosslinked polystyrene resins in microporous form have received the most attention as support material in TC[37]. The following applies not only to this specific class of resins but to solvent-swellable crosslinked polymers in general.

The rate-limiting step for TC using resin-based catalysts should be: 1) diffusion of reactants across a thin liquid layer surrounding the solid phase (Nernst or film diffusion); 2) chemical reaction at the particle surface; or 3) chemical reaction throughout the polymer matrix. If chemical reaction proceeds at a much higher rate than the diffusion of reactants through the Nernst layer, 1) will control the rate. In contrast, if chemical reaction is much slower, then the rate would be governed by either 2) or 3). When diffusion of reactants through the resin (matrix diffusion) is very slow relative to chemical reaction and film diffusion is rapid, then reaction takes place exclusively at the particle surface; if matrix diffusion is fast, chemical reaction occurs throughout the polymer.

If the rate of a triphase process is controlled by chemical reaction, three principal factors will influence the observed activity of the catalyst: 1) the effective concentration of catalytically active sites; 2) the effective concentration of reactants; and 3) the free energy of activation for the reaction. In terms of efficient TC, it is desirable that all or as many as possible of the active sites located within the polymer participate in the catalysis. Experimentally, this can be controlled by adjusting the swelling of the resin. The greater the degree of swelling, the faster the rate of diffusion of reactants through the matrix and thus the greater the efficiency of the catalyst. Swelling is determined by the nature of the liquid solvents used, the composition of the polymer, and the crosslink density. Organic solvents having a structure similar to that of the resin tend to swell the resin to a greater extent. Also, for any given choice of solvents, swelling varies inversely with the crosslink density. It is important to realize that slight structural modification of a resin can lead to pronounced changes in its swelling properties.

The effective concentration of neutral reactants within the resin will depend on their concentration in the external liquid phases and their coefficient of absorption. For ionic reactants, complexation and ion-exchange equilibria will also be important factors when catalysts bearing crown ether, cryptand, quaternary ammonium or phosphonium groups are used. Activation parameters for TC depend on the type of active site, the nature of the reactants, and the microenvironment.

6.2. Inorganic-Based Catalysts

Only two reports have appeared thus far describing inorganic-based (silica gel) triphase catalysts[17,18]. Although it is somewhat premature to speculate on these systems, factors which would seem likely to be important in affecting their activity are surface area, coefficient of adsorption of the reactants, complexation and ion-exchange equilibria (for ionic reactants when crown ether, cryptand, quaternary ammonium or phosphonium groups are employed), and also the free energy of activation of the reaction as defined by the type of reactive site and nature of the reactants and microenvironment.

6.3. Location of Catalyst Relative to the Liquid/Liquid Interface

Another factor which may be relevant to a catalyst's activity is its location relative to the liquid/liquid interface. All of the polymers prepared in our laboratory which have proven active as triphase catalysts reside at the liquid phase boundary, some protruding more into the organic phase than others (cf. Fig. 1). Resins which could not be maintained as a suspension between layers (in the absence of stirring) were found to be inactive. How resin distribution at the interface affects triphase activity needs to be clarified. Interestingly, the inorganic solids *(34)—(43)* required vigorous stirring in order to achieve catalysis. This fact suggests that agitation is needed to mechanically shuttle this type of catalyst from one liquid phase to the other.

6.4. Surface Area Catalysis

Finally, we wish to mention a simple physical phenomenon which, if present, may make important contributions to certain TC transformations. We shall refer to it as "surface area catalysis". Figure 2 is a schematic representation of a polymer generating microscopic aqueous and organic pools, the composition of which is either similar or identical to the external bulk phases.

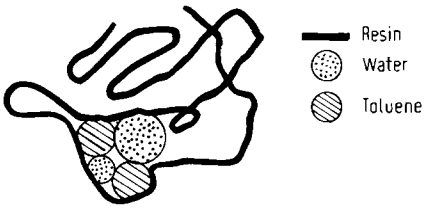


Fig. 2. Schematic representation of "surface area catalysis" for a toluene/resin/water system.

Resins used in TC may operate in part by generating extensive "pool/pool phase boundaries" thereby increasing the rate of interfacial reaction. In effect, the polymer serves as a *pseudo high speed stirrer*. Although this concept is highly speculative and there is no existing evidence which supports it, there is, similarly, no firm data to rule it out.

6.5. Empirical Observations

From the available experimental data, two factors appear to be particularly important in the design of useful triphase catalysts: 1) a high compatibility of the resin with organic solvents, and 2) a long pendant chain used to anchor the catalytic site. More studies, however, are needed to understand these observations.

7. Relationship of Triphase to Phase-Transfer Catalysis

The term, "phase-transfer catalysis", was originally introduced by *Starks* to characterize a process in which: "reaction is brought about by the use of small quantities of an agent which transfers one reactant across the interface into the other phase so that reaction can proceed"[38]. It is an attractive phrase, but one which carries with it clear mechanistic implications. Some elegant work by *Starks et al.*[39] and *Landini et al.*[40] provide very strong support for this concept. Recently, however, there has been some concern over its appropriateness in describing certain aqueous–organic phase reactions using a soluble catalyst[6] (*e.g.*, evidence is beginning to appear in support of an interfacial process for dihalocarbene reactions[1b]). Reference to the solid phase catalysts reviewed here as heterogeneous or immobilized phase-transfer catalysts is unwarrantable on the basis of the limited data available and their classification as such should be avoided. All of these systems will require detailed examination before their relationship to phase-transfer[7], micellar[41], and interfacial[1b,42] catalysis becomes clear. The term triphase catalysis transmits no mechanistic information, yet it serves as an adequate description of the technique. We encourage its use[*].

[*] Note added by Prof. *E. Dehmlow*, Berlin: A detailed discussion took place at the Euchem Conference held at Gargnano [6] whether only mechanistically unequivocal phase transfer catalyst reactions should be designated as such, as proposed by *Regen* and others. It was held that this would not receive the support of most chemists; in particular, the proliferation of new concepts with only minor differences of meaning would not be in the interests of utilizable documentation and literature search systems. Accordingly, the term phase transfer catalysis should embrace all reactions between solid or aqueous ionic compounds and organic compounds in organic solvents, provided that these reactions are made possible or accelerated by catalysts and are not unequivocally classifiable as mere surface catalysis or micellar catalysis. This definition would characterize triphase catalysis as a subcategory of phase transfer catalysis. It remains to be seen which definition becomes accepted.

8. Outlook

Triphase catalysis has been established as a synthetic technique for accelerating aqueous–organic phase reactions. The inherent complexity associated with three phase catalytic systems makes this a particularly challenging and intriguing new area for the mechanistic chemist who is interested in testing his ingenuity for designing meaningful experiments in unconventional systems. Moreover, the practical potential of this technique for laboratory as well as industrial applications is great. Active, economically attractive and reasonably stable catalysts have already been prepared [*e.g. (33)*] and should find immediate use. Preliminary studies in our laboratories further reveal that a high degree of selectivity toward reactants is possible using certain polystyrene-based triphase catalysts. In brief, it appears highly probable that TC will expand significantly over the next few years along synthetic and mechanistic lines.

The author wishes to thank the Division of Basic Energy Sciences of the Department of Energy, the Army Research Office, and the National Science Foundation for support of his work. The author is also grateful to co-workers listed in the references for their contributions and to Drs. Jacques Besse and Alok Nigam for critical discussions and their assistance with the preparation of this article.

Key Building Blocks of Natural Product Biosynthesis and Their Significance in Chemistry and Medicine[**]

By Burchard Franck[*]

The principal features of the biosynthesis of natural products have been elucidated during the past thirty years by the use of isotopic methods. It was discovered that large groups of natural products originate from the same biosynthetic precursor—the key building block. The conversion of key building blocks into biologically active natural products serves as a model for the development of more efficient syntheses in chemistry. In medicine, information about key building blocks permits the elucidation and therapy of metabolic diseases.

1. Introduction

Natural products are defined as carbon compounds which are formed in plants, microorganisms, animals, and man. Many of these natural products, *e. g.* vitamins and antibiotics, are indispensable for man's existence.

The number of structurally elucidated natural products has increased greatly in recent years. This is due, on the one hand, to the great interest shown in biologically active substances and, on the other hand, to the highly developed methods available for their isolation and structural determination. Thus, approximately 20000 natural products are known[1]; that is less than 1% of all organic compounds. From the point of view of man and other organisms, however, they are an elite group of compounds which have been selected out during the course of evolution for the necessities of life.

Natural product biosynthesis is an important field of research in modern natural product chemistry[3-6]. Work in this field led, primarily, to an understanding of the diversity of organic natural products, gave an insight into metabolism and induced the development of simpler syntheses[4,6-10].

The biosynthesis of natural products was elucidated by isotopic labeling[8]. Surprisingly, it was discovered that entire groups of natural products originated from the same biosynthetic precursor. These precursors are the *key building blocks* of natural product biosynthesis. Information about a few key building blocks is sufficient to obtain an overall view of the diversity of natural products.

The key building blocks of biosynthesis occupy an important position in the metabolism of living organisms. Numerous diseases are caused by a modification of the biosynthetic steps involving the key building blocks[9]. In medicine, information about a few key building blocks thus allows elucidation and treatment of several metabolic diseases.

A knowledge of the key building blocks led to a revolutionary development in the chemical synthesis of natural products. Many natural products can be synthesized in the laboratory by using key building blocks as starting materials[4,5,10,11]; such syntheses, which utilize biosynthesis as a model, are often superior to the customary natural product syntheses.

In the following, a greatly simplified survey of natural product biosynthesis will first be given. The application of biogenetic findings to chemical syntheses and in medicine will then be dealt with using topical examples. Finally, it will be discussed why natural product biosynthesis proceeds *via* certain key building blocks.

2. Biosynthesis of the Main Groups of Natural Products

The 20000 natural products can be divided into four large groups according to their biosyntheses. Three typical compounds of each of these groups are given as examples in Table 1.

Table 1. The four main groups of natural products (with examples).

1. Carbohydrates	2. Arenes
D-Glucose	Flower pigments
Vitamin C	Vitamin K_1
Cellulose	Lignin
3. Acetogenines	**4. Nitrogen-containing natural products**
Fatty acids	Nucleosides
Vitamin D	Blood pigment
Caoutchouc	Proteins

The biosynthesis of all these natural products starts with atmospheric carbon dioxide, water and nitrogen (Fig. 1). Carbon dioxide and water are converted, with the assistance of sunlight and chlorophyll, into D-glucose by the process of photosynthesis elucidated by *Calvin*[12]. This simple sugar (D-glucose) not only acts as a key building block for the very large group of carbohydrate natural products, but also for the three other groups. These three other groups result from D-glucose *via* the key building blocks shikimic, acetic, and amino acids. Ammonia is formed from atmospheric nitrogen in a reaction sequence—nitrogen fixation[13]—which is only found in a few microorganisms. D-Glucose is thus the central key building block of natural product biosynthesis. The quantities of glucose produced annually in photosynthesis far exceed those of any other technically or biologically synthesized organic compound.

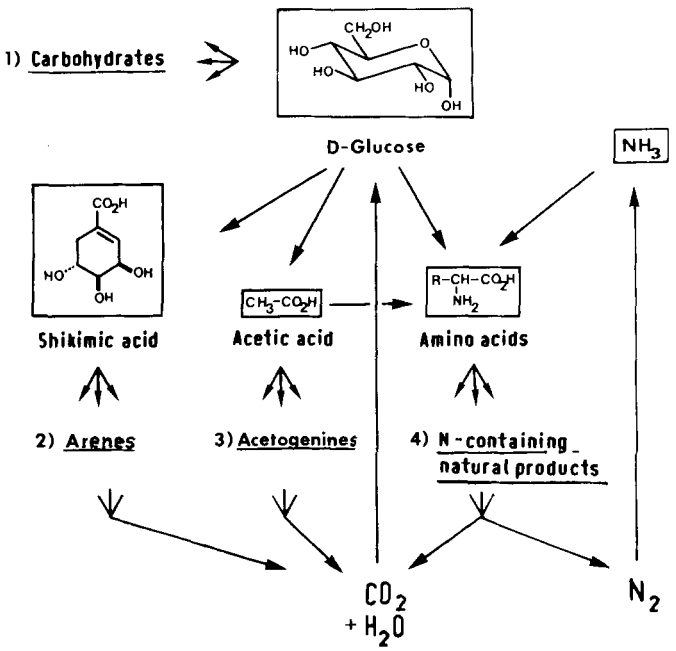

Fig. 1. Biosynthesis of the four main groups of natural products *via* the key building blocks D-glucose, shikimic acid, acetic acid and amino acids.

During the course of biosynthesis, the key building blocks shown in Figure 1 are followed by further key building blocks which are precursors for smaller natural product groups. All of these natural products undergo reactions which finally end in biological degradation and reformation of carbon dioxide, water and nitrogen. Thus, there is a fluent transition between biosynthesis and biological degradation.

Figures 2 and 3, respectively, show situations in which the first step of biosynthesis and the last step of biological degradation proceed at their highest possible intensities.

Fig. 2. Rice plantation on the Philippines in a state of full photosynthesis (photograph: BASF).

3. Problems in Natural Product Synthesis

The first synthesis of a natural product was accomplished 150 years ago by *Friedrich Wöhler* in Berlin; this was his famous urea synthesis[14]. The then current dogma that natural products could only be formed in living organisms was thus refuted. Chemical natural product synthesis has made a great deal of progress since then. This is apparent if urea *(1)* is compared, for example, with erythronolide B *(2)*. The complete synthesis of erythronolide was recently achieved by *Corey* and co-workers[15]. Erythronolide B is an aglycon of the erythromycin antibiotics. As it contains ten chiral carbon atoms in a relatively flexible ring system, its total synthesis was regarded as an almost "hopelessly complex" task twenty years ago[*].

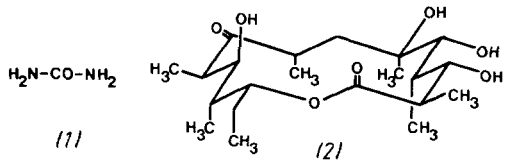

Figure 4 shows a sample of *Wöhler*'s first urea together with his publication in Poggendorffs Annalen[14]; the urea was sealed and labeled by *Wöhler* himself; he gave it to his friend *Emanuel Merck* in Darmstadt. *Wöhler* had purified his preparation so thoroughly that, according to its modern IR spectrum, it is as pure as "Merck" analytical urea (Fig. 5).

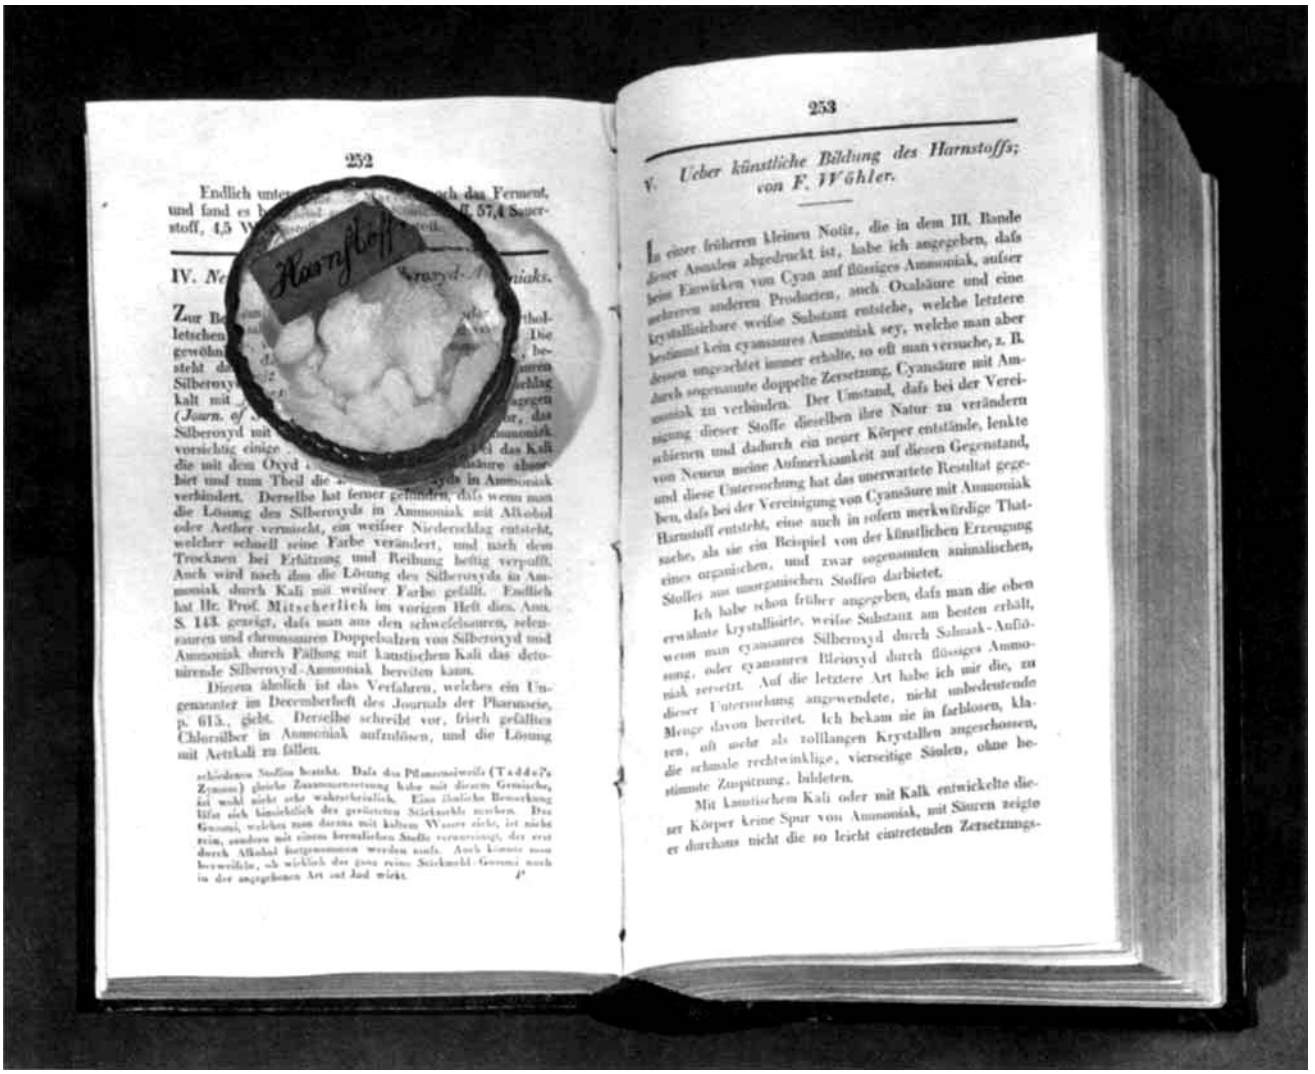
[*] *R. B. Woodward* (1956) [16]: "Erythromycin, with all our advantages, looks at present quite hopelessly complex, particularly in view of its plethora of asymmetric centers...".

Fig. 3. Degradation of residual substances of natural product biosynthesis by bacteria in a modern sewage plant (photograph: BASF).



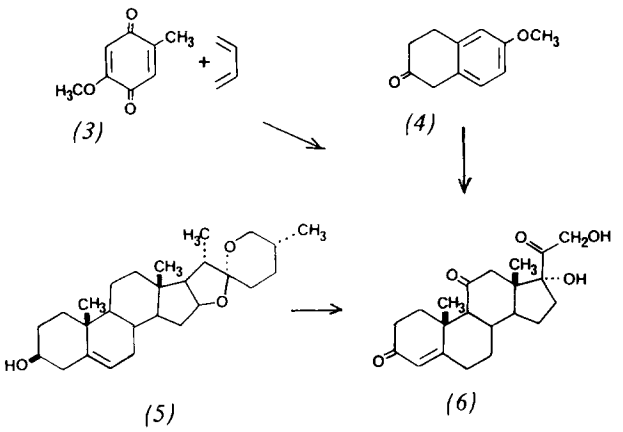


Fig. 4. Original sample of *Wöhler*'s first synthetic urea and his publication in Poggendorffs Annalen [14] (photograph: Merck).

Despite the development of impressive total syntheses, natural product synthesis is still in a dilemma. Syntheses suitable for the technical production of natural products are only available in relatively few cases. Most total syntheses of the more complicated natural products require so many reaction steps that the total yield becomes vanishingly low. This can best be illustrated by the example of the medically important steroid hormone, cortisone *(6)*.

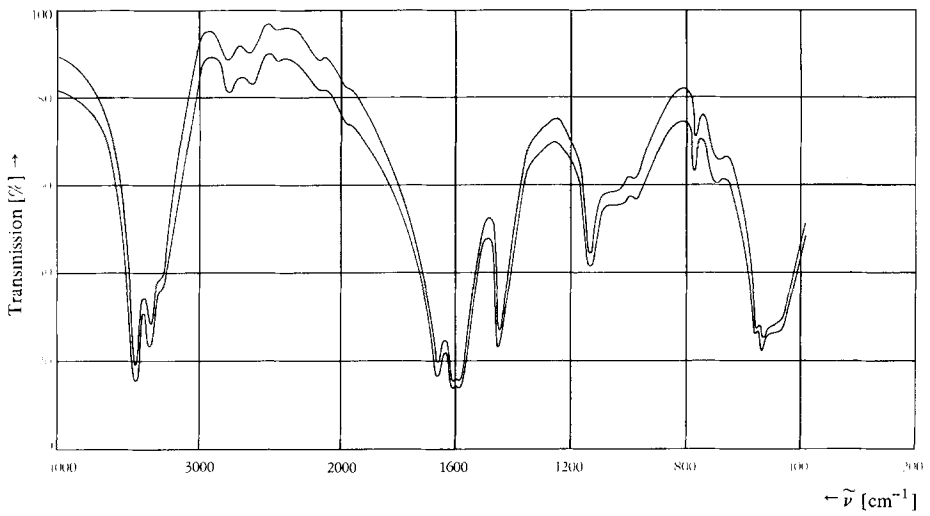
Woodward[17] was the first to succeed in performing the sensational, total synthesis of this natural product with its six chiral carbon atoms in 1952. The synthesis started with methoxytoluquinone *(3)* and proceeded *via* 49 steps, the total yield was less than 10^{-5}%. This does not detract in any way from the great scientific significance of this achievement. The further efforts of industrial laboratories were then directed towards improving yields by reducing the number of steps. The 27-step synthesis developed by Roussel in France from a tetralone (4) gave a technically interesting total yield of 1%[18]. A synthesis performed by Syntex in the USA[19] (13 steps, 3.3% total yield) starts with the readily available steroid natural product, diosgenin *(5)*, and is thus not a total synthesis.

Table 2 shows the relationship between the number of reaction steps and the total yields in multistep syntheses. If the average yield is 70% per reaction step—which can be considered as very good—the total yield decreases drastically as the number of reaction steps increases. As multistep syntheses with such yields are of no use in practice, either the average yield must be increased (to 99%) or the number of reaction steps must be greatly reduced. These requirements can be met if natural syntheses are based on biosynthetic models with the utilization of key building blocks. Such *biomimetic syntheses* are generally characterized by a small number of steps and a high total yield. Furthermore, it is generally important that they are carried out under mild conditions and that the formation of by-products is avoided by means of high selectivity.

Table 2. The dependence of the total yields [%] in multistep syntheses on the average yields and number of steps.

Steps \ Average Yield [%]	99	90	70
1	99	90	70
10	90	35	2.8
20	82	12	0.08
30	74	4.2	0.0023
40	67	1.5	0.000064
50	61	0.52	0.0000016

The first definitive example of a natural product synthesis based on a biosynthetic model was the laboratory synthesis of the alkaloid, tropinone *(8)*. *Willstätter*[20] synthesized this, then regarded as problematic, bridged heterocycle from suberic acid *(7)* in a 15-step total synthesis. The yield was only 0.76%. The one-step synthesis based on biosynthetic concepts developed by *Robinson* and *Schöpf* provided an impressive



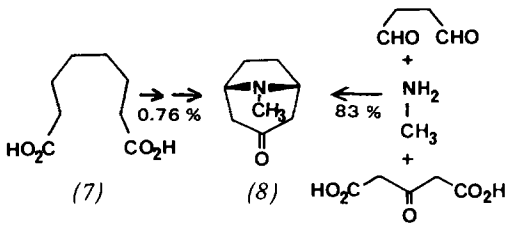


Fig. 5. IR spectra of *Wöhler's* urea (upper spectrum) and "Merck" analytical urea (lower spectrum) in KBr (photograph: Merck).

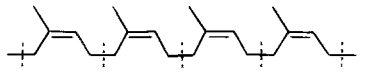
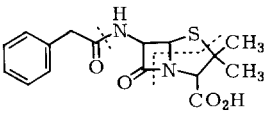
comparison; the yield was over 80%[21]. Stimulated by this success, intensive efforts were then initiated to work out simple, efficient syntheses for alkaloids and other natural products using the key building blocks of biosynthesis.

4. Elucidation of the Key Building Blocks



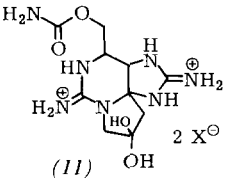
Isotopic methods are indispensable for the elucidation of the key building blocks of natural product biosynthesis. The four isotopes of carbon are most important; these are available as a result of highly developed enrichment and nuclear transformation techniques (Table 3). The two most important, the stable ^{13}C and the radioactive ^{14}C, complement one another with respect to their possible applications[22]. Biosynthetic experiments in which the reliable determination of labeled products at high dilutions is important can be performed with ^{14}C due to its extremely low natural abundance. ^{13}C allows (with, however, a considerably lower detection sensitivity) very simple determination of labeling positions in molecules by means of ^{13}C-NMR spectroscopy. The short-lived ^{11}C is utilized in medicine for metabolic investigations.

Table 3. Radioactive and stable isotopes of carbon.



C isotope	Abundance [%]	Half-life
^{11}C	—	20.4 min
^{12}C	98.89	∞
^{13}C	1.11	∞
^{14}C	10^{-10}	5600 years

The main features of the biosynthesis of natural products have been elucidated over the past 30 years by using isotopic methods[8]. With the help of this information, it is now usually simple to recognize the key building blocks of a natural product and the main group to which it belongs. This is illustrated by the formulas for rubber *(9)* (isoprene)[23] and the antibiotic, penicillin *(10)* (cysteine and valine)[24]. The biosynthesis of some novel natural products from marine organisms, *e. g.* the extremely toxic saxitoxin *(11)*[25], is less evident.



The synthesis and function of more complex key building blocks are still under intensive investigation. Although these compounds give rise to smaller natural product groups than do the basic key building blocks, they furnish very useful information for chemistry and medicine. This topic will be discussed for four groups of biologically active natural products in the following sections. The unsaturated hydrocarbon, squalene *(12)*, is the key building block for the steroids and triterpenes[26,27]. Numerous, structurally related compounds (anthraquinoids) are derived from the anthraquinone emodin *(13)*[28]. Many isoquinoline alkaloids, *e. g.* morphine, are formed from the key building block reticulin *(14)*[29]. The structurally complex uroporphyrinogen III *(15)* is the precursor for heme[30], vitamin B_{12}[31] and similar natural products.

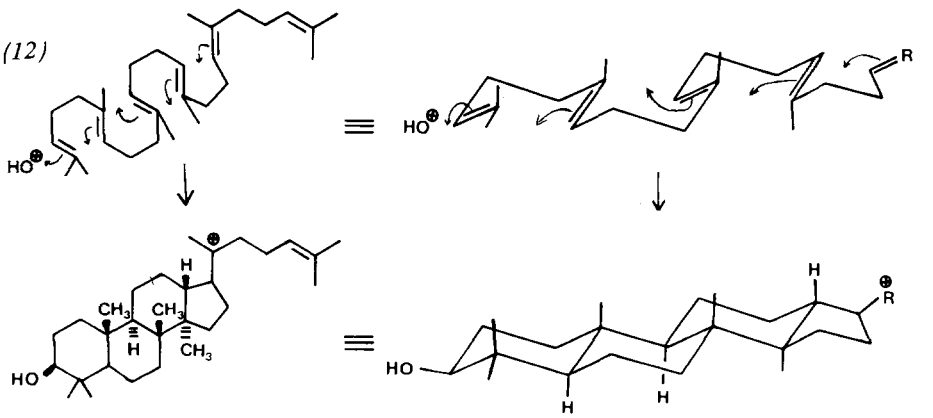
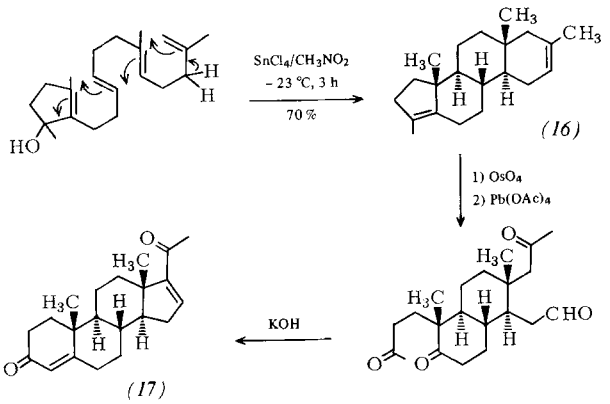
(12)

(13)



(14)

(15)



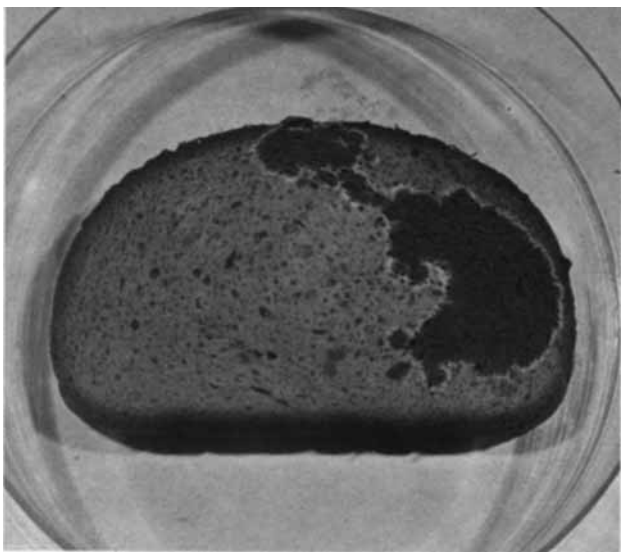
5. Key Building Blocks of Acetogenine Biosynthesis

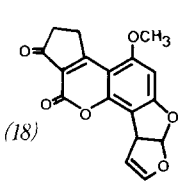
The cyclization of squalene *(12)* to the tetracyclic steroid molecule is a fascinating biosynthetic reaction. Four rings are closed and eight centers of chirality are formed in a concerted reaction; this is triggered by hydroxy cation *via* a terminal epoxidation. In order to account for the stereospecific-

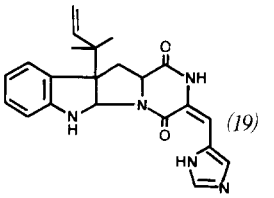
(12)

ity of such a complicated reaction sequence, it is assumed that the carbon chain of the squalene in solution prefers an arrangement in which the individual rings of the steroid molecule are, as it were, preformed[32]. The cyclization of the key building block, squalene, understandably represented a challenge to the chemist to synthesize the medically valuable steroids in a similar fashion. *W. S. Johnson et al.*[32] have achieved remarkable results; the simple biomimetic synthesis of 16,17-didehydroprogesterone *(17)* is shown as an example. The elegant construction of a steroid-like ring system *(16)* was accomplished under mild conditions starting with a precursor similar to the key building block, squalene. The steroid hormone *(17)* was obtained from this in three further steps. This strategy of biomimetic synthesis has already proved to be of value in other steroid syntheses.

Emodin *(13)*, a key building block which, like squalene *(12)*, is formed from acetic acid, is involved in the biosynthesis of a group of toxins produced by mold fungi. Many molds found in food contain poisonous substances whose danger is partially increased by their accumulation in the organism and their lingering action[33]. Figure 6 shows a pure culture of such a fungus on bread. The strongly active aflatoxin B_1 *(18)* from *Aspergillus flavus* and the weakly active roquefortin *(19)* from *Penicillium roqueforti* are examples of fungal toxins from food molds[34,35].







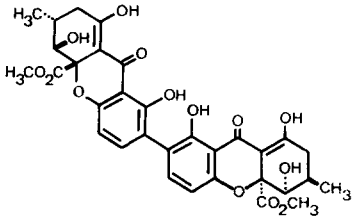


Fig. 6. A pure culture of *Penicillium islandicum* on bread (from [36]).

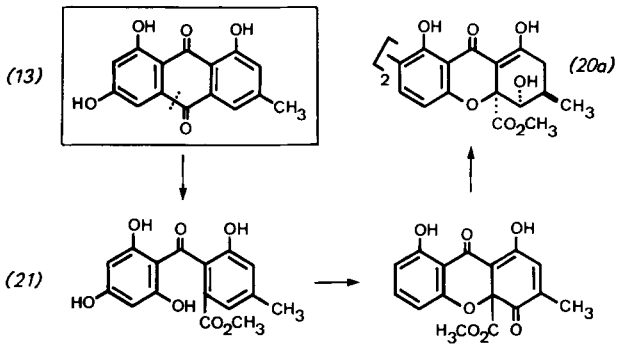
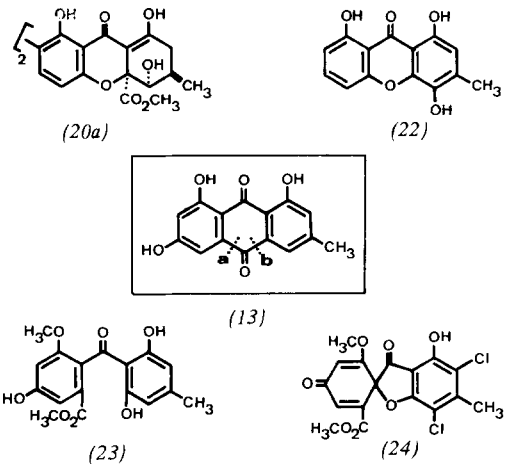


(18)

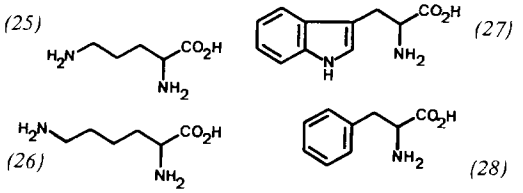
(19)



Our laboratory has also been very involved with work on one of these groups of fungal toxins, the ergochromes. The ergochromes[37] are produced by molds mainly found in rye, maize and rice. In rye they form the sclerotia known as ergot. As the structure of the most important ergochrome secalonic acid A *(20)* shows, these compounds are dimeric xanthone derivatives[38,39].

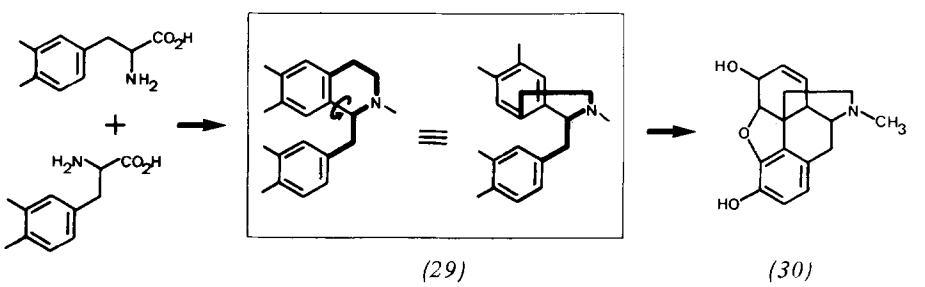
(20)

13 ergochromes have so far been isolated from molds and lichens[38,40-45]. It appeared likely that these ergochromes could be prepared *via* a novel biosynthetic route in which emodin *(13)* is the key building block. Each half of the ergochrome molecule might be formed in a few steps in which



emodin is first cleaved oxidatively to give benzophenone *(21)*. Subsequent cyclization, together with reductive reactions, would then furnish the xanthone derivative *(20a)*

found in the ergochromes. We have studied this hypothesis using emodin derivatives labeled with C and H isotopes. After feeding molds with labeled anthraquinones, these compounds were indeed converted into ergochromes in high yields *via* a benzophenone intermediate [cf. *(21)*][46-48]. This is the first evidence for oxidative ring opening of an anthraquinone in biosynthesis[49]. It was later discovered that further natural products, are also derived from emodin *(13)*, which is thus an especially versatile key building block, by ring cleavage at a or b. *Gatenbeck et al.*[50] demonstrated that the benzophenone sulochrin *(23)* is a seco-anthraquinone[46]. Using isotopically labeled precursors, we were further able to show that the antibiotic geodin *(24)*[51] and ravenelin *(22)*[52] can also be classed as seco-anthraquinones. Emodin *(13)* could be converted into *(21)* and products of type *(20a)* in biomimetic syntheses[53,54]. The formulas again show how completely different structures can be related to one another by means of their origin from the same key building block in biosynthesis.

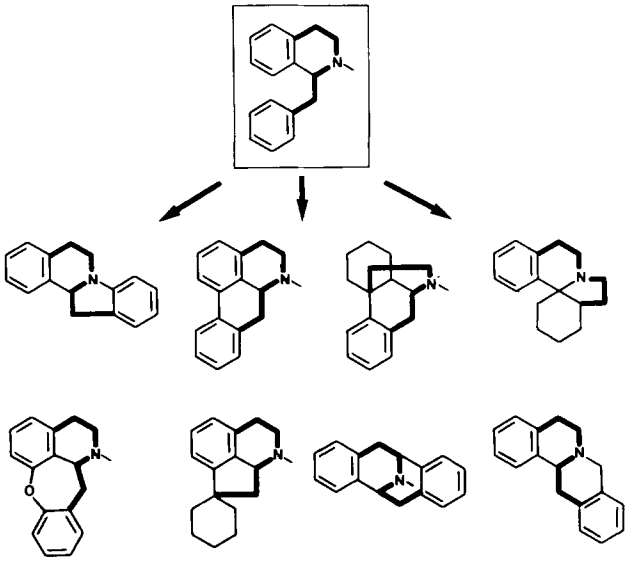


6. Key Building Blocks of Alkaloid Biosynthesis

Alkaloids, as the name suggests, are natural products with basic properties. They are mainly produced by plants and are distinguished by their specific pharmacological effects on human and animal nervous systems. This fact has long been made use of by man. Approximately 5000 alkaloids are known. Considering their varied structures, it is surprising that almost all of them are formed from only four amino acids or their derivatives[55]; these are ornithine *(25)*, lysine *(26)*, tryptophan *(27)* and phenylalanine *(28)*.

The biosynthesis of morphine will be taken as an example. Two phenylalanine derivatives split off carbon dioxide and ammonia to form benzyltetrahydroisoquinoline *(29)* as key building block[55,56] which can undergo especially diverse reactions [cf. reticulin *(14)*]. The three-dimensional ring system of morphine *(30)* results after 180° rotation around the bond indicated and subsequent ring linkage.

The key building block *(29)* enclosed within the rectangle gives rise to additional basic skeletons from which a total of approximately 2000 alkaloids are derived (Fig. 7).



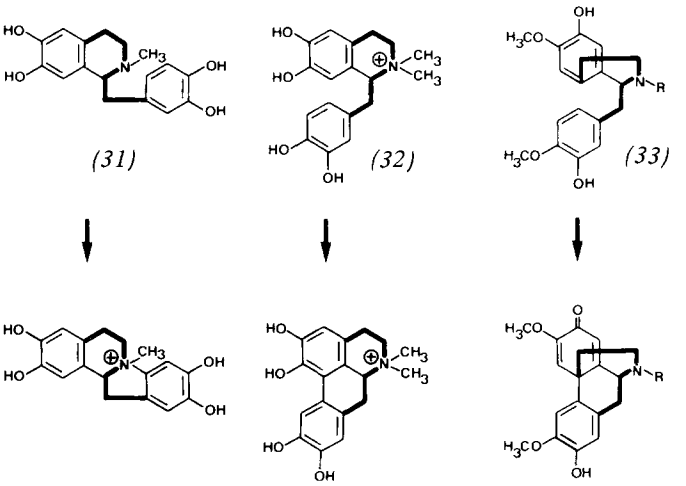


Fig. 7. Eight basic alkaloid skeletons which are derived from derivatives of the key biosynthetic building block, benzyl tetrahydroisoquinoline (enclosed within the rectangle). The alkaloids are of the following types (upper row): crytaustoline, aporphine, morphine, erythrinane; (lower row): cularine, proaporphine, pavine, protoberberine (from left to right in each case).

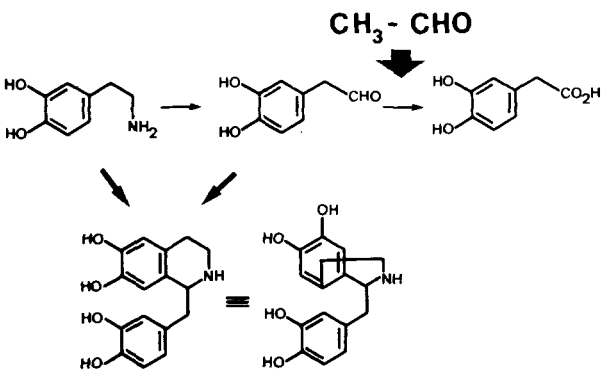
The economy of this biosynthetic scheme is impressive and it is an ideal model for the technical production of a range of chemical products. In the past 40 years, numerous groups of workers have thus tried to simulate this scheme in the laboratory. The first experiments were carried out independently by *Schöpf*[57] and *Robinson*[58]. They oxidized ben-

zyl tetrahydroisoquinoline *(31)* in the hope that they would obtain an aporphine or a morphinane. Ring closure with a 70% yield was achieved but resulted in a cryptaustoline de-

rivative. We later found that the oxidative ring closure could be steered to give the desired aporphine in 62% yield by quaternization at the nitrogen [*(31)*→*(32)*][59]. This was the first biomimetic synthesis of the basic aporphine skeleton from which numerous alkaloids with diverse pharmacological effects are derived.

Biomimetic synthesis of the basic morphinane skeleton was more difficult. *Barton*[60] first demonstrated that ring closure could be achieved by oxidative condensation of the key building block *(33)*. The yield could be increased to 4% by using a two-phase oxidation system[61] and to 40% by utilizing vanadium oxide trichloride as oxidizing agent[62], thus making this reaction suitable for synthetic purposes. It should be mentioned in this context that morphine, which is indispensable in medicine, is still obtained from poppy plants. Misuse cannot be ruled out. It is therefore urgent that a method be found in which morphine can be produced industrially under supervisable conditions.

The finding that aporphine and morphine alkaloids can be relatively easily produced from their key building blocks raises the question as to whether this synthesis can also take place spontaneously or undesirably in living organisms. According to recent results, this is indeed the case in chronic alcoholism. The first reports of a connection between alcohol and opium addiction first appeared several years ago[63]. It is now certain that the similarity between the disease symptoms in alcoholism and opium addiction is of chemical origin[64-66] (Fig. 8). The alcohol consumed is dehydrated in the liver to



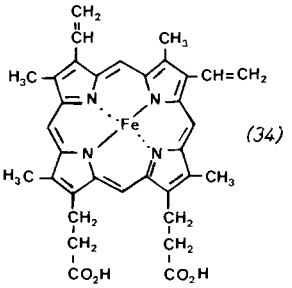


Fig. 8. Opiate formation in chronic alcoholism.

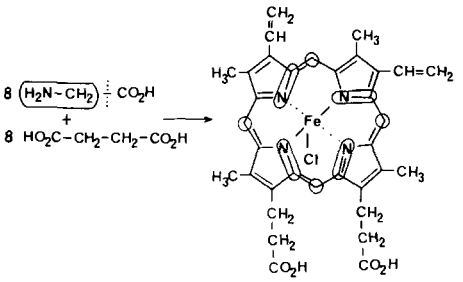
acetaldehyde which, depending on its quantity, then blocks to a lesser or greater extent the normal degradation of phenylalanine in the organism. Phenylethylamine and phenylacetaldehyde derivatives are thus produced in higher concentrations which then condense spontaneously to give the key building block for aporphine and morphine biosynthesis [see *(29)*]. Formation of the key building block and the alkaloids derived from it have been clearly demonstrated in experiments on animals. These results are extremely important for the preventive, psychological, and medicinal therapy of chronic alcoholism[66].

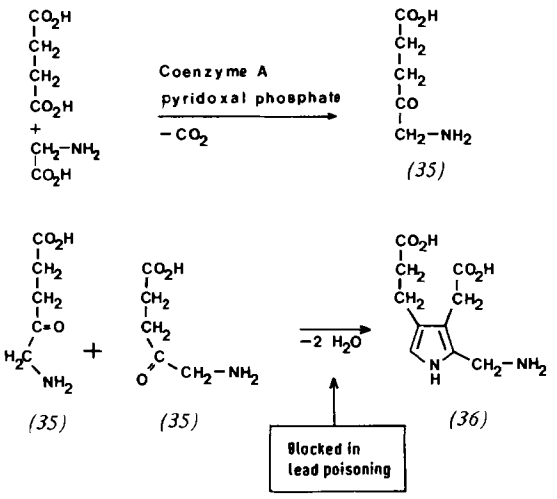
7. Key Building Blocks of Porphyrin Biosynthesis

Key building blocks have an especially impressive role in the biosynthesis of the blood pigment heme and related compounds. The basic heme skeleton is a porphyrin. The porphyrins belong to the most interesting systems which nature has produced. Porphyrins existed on the surface of the earth 2.5 billion years ago[67], they catalyze vital metabolic processes in almost all organisms. As far as man is concerned, heme *(34)* is the most important porphyrin[68]. It is a component of the proteid hemoglobin, which is responsible for the transport of oxygen from the lungs to the cells within the body. Minor modifications in heme biosynthesis cause lethal blood diseases[9, 70].

(34)

The blood pigment heme and related natural products originate from two very simple compounds—glycine and succinic acid. The first information concerning heme biosynthesis is to be found in the pioneering studies of *Shemin*[69]. This work started 30 years ago with an experiment which, on the basis of the then current knowledge, was rather risky. *Shemin* synthesized 66 g glycine labeled with ^{15}N and swallowed it. He subsequently showed that the glycine nitrogen was directly incorporated into the heme of his blood. Further biosynthetic experiments—with duck blood—demonstrated that heme is produced from eight molecules of glycine and eight of succinic acid (Fig. 9).





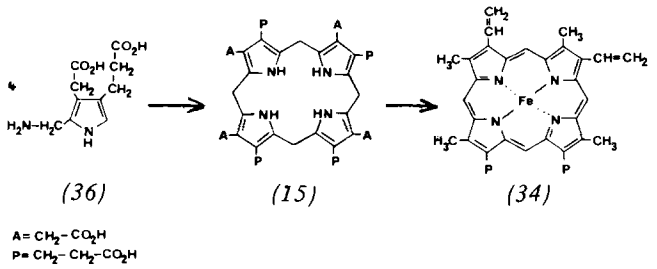


Fig. 9. Biosynthesis of heme from glycine and succinic acid [69]. The encircled atoms are derived from glycine, the others from succinic acid.

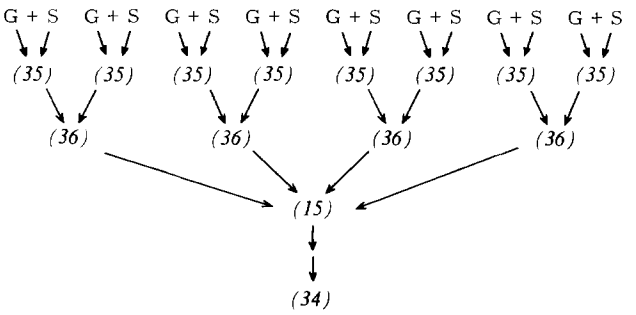
Succinic acid and glycine first condense with decarboxylation to give 5-aminolevulinic acid *(35)*. Two molecules of 5-aminolevulinic acid then give the pyrrole derivative, porphobilinogen *(36)*. This reaction step is inhibited, for example, in lead poisoning[70]; the detectable concentration of 5-aminolevulinic acid in urine is a direct calibration of the degree of lead poisoning. In this way, less heme is synthesized. This results in damage due to oxygen deficiency which first affects the brain[71]. Four molecules of the very reactive porphobilinogen *(36)* are then assumed to condense to form the porphyrin.

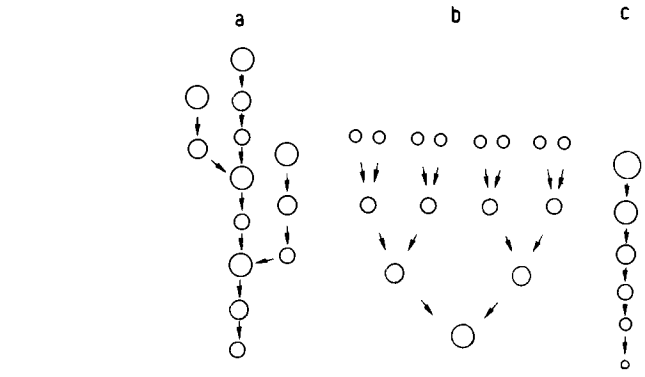


Until fairly recently, there were many possible explanations for this condensation[72]. Several years ago we were able to show for the first time by total synthesis of radioactively labeled uroporphyrinogen III *(15)*[73] and its conversion to heme by enzymes in duck blood, that uroporphyrinogen III is the direct biosynthetic precursor of the blood pigment

heme *(34)*[30]. *Scott et al.*[31] subsequently found that the vitamin B_{12} ring system is also formed from uroporphyrinogen III. Chlorophyll is probably synthesized in a similar way. Uroporphyrinogen III may thus be a biogenetic key building block which is of central importance for all organisms. Its synthesis from the monopyrrole porphobilinogen *(36)* is now

being intensively investigated by several groups of workers[74-77]. A simplified scheme containing the most important parts of heme biosynthesis starts with eight molecules of both glycine and succinic acid ("G + S"). These condense in pairs to give aminolevulinic acid *(35)*, two molecules of which then furnish the monopyrrole building block, porphobilinogen *(36)*. After this, the reaction pathway leads to uroporphyrinogen III *(15)* and heme *(34)*. This biosynthetic scheme constitutes an ideal model for a rational natural product synthesis. This embodies perfectly the important principle of "converging" synthesis in which a high total yield is attained with as small a number of successive, linear synthesis steps as possible (Fig. 10).

As is the case with alkaloids and steroids[78], there are also biomimetic syntheses for the porphyrins which are distinguished by their simplicity and good yields. Porphobilinogen *(36)* in dilute acid can be converted in high yields into porphyrins[79]. The main product is uroporphyrinogen III *(15)*, the key building block of heme biosynthesis[80]. The reaction product contains, however, smaller quantities of the three other isomers of this key building block. The high specificity of reaction is surprising; for example, open-chained condensation products or ring systems with more than four pyrrole units are not produced[81]. Simple syntheses for known, biologically active and also novel porphyrins have been developed with the help of these very efficient, biomimetic porphyrin syntheses[31-33]. Examples[82] are the highly strained,



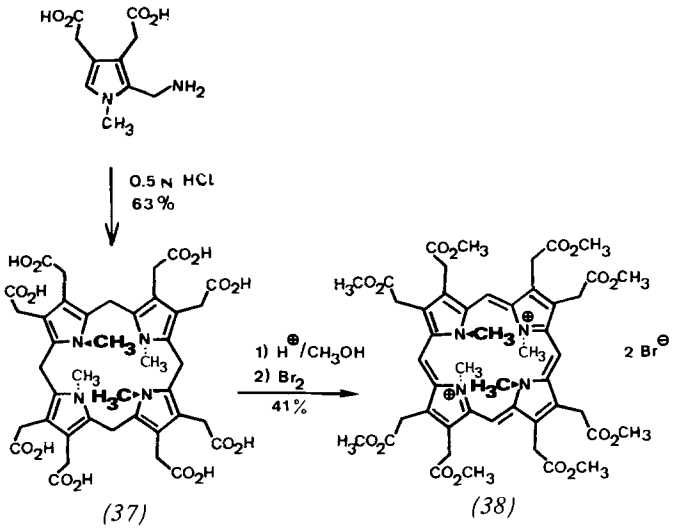


Fig. 10. Strategies for multistep syntheses: a) branched, b) converging, c) linear (taken from [89]).

non-planar[84] *N,N,N,N*-tetramethylporphyrinogen *(37)* and its green dehydration product called *N,N,N,N*-tetramethylporphyrin *(38)*[82] whose syntheses have been attempted for 40 years.

8. Conclusion

The question as to why natural product biosynthesis proceeds *via* relatively few key building blocks and in essentially a similar fashion in all organisms deserves special attention. One reason may be that it would be rational if a large range of natural products were formed *via* as few as possible versa-

tile intermediates. Organisms whose metabolism did not develop in accordance with this principle would then be inferior and would disappear during evolution. A further possible explanation may be that most of the key building blocks of natural product biosynthesis already existed on the surface of the earth over three billion years ago.

In experiments on the simulation of the "primeval atmosphere"[85, 86] (water, methane, hydrogen, ammonia), it was shown that, under the influence of radiant energy, a "primeval soup" was formed. This "primeval soup" contained prac-

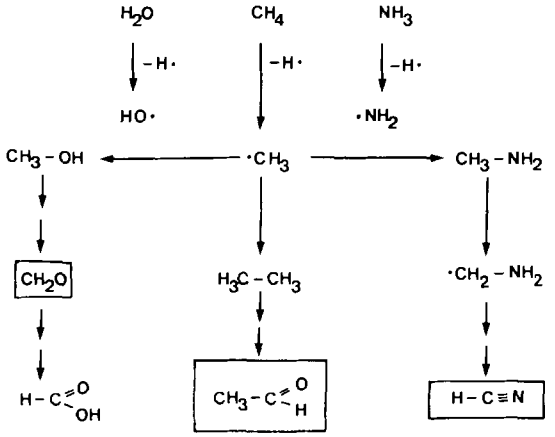

Fig. 11. Fundantental prebiotic reactions.

tically all the substances (amino acids, fatty acids, sugars, purine bases, porphyrins *etc.*) which, as is now known, are necessary for the metabolism of living organisms. Synthesis of all these compounds is, according to modern mechanistic concepts, easy to explain (see *e. g.* Fig. 11, 12[86–88]).

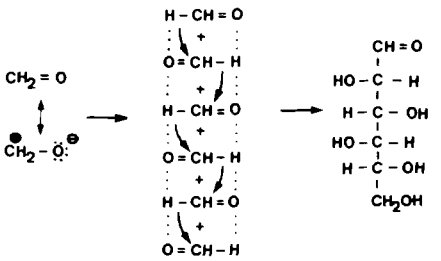

Fig. 12. The synthesis of hexoses from formaldehyde in a simulation experiment.

The aim of this article has been to show what the key building blocks of natural product biosynthesis are and their significance in chemistry and medicine. Research on key building blocks in natural product chemistry has led to a plethora of interesting results with many different applications. Many—even complex—natural products are apparently compounds which were selected out during evolution not only for their biological activity but also on account of their especially simple mode of formation. An understanding and simulation of this mode of formation could, in the future, lead to simple total syntheses of useful, biologically active natural products.

I am especially indebted to the co-authors of our publications cited. Their enthusiasm for thematically and methodically multifarious problems made possible the exploration of the relationships described. Generous support by the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung in Nordrhein-Westfalen, and the Fonds der Chemischen Industrie is gratefully acknowledged.

[1] Up until 1961, 4423 plant products (excluding alkaloids) had been registered in the handbook of *Karrer et al.* [2]; of these, 1754 were recorded in the period 1956–1961. Thus an increase of approximately 1800 over a five-year period, or of 6000 from 1961 to 1978 may be assumed for these products, giving a total number of 10000 plant products. The number of alkaloids and animal products so far known are each estimated to be approximately 5000. The total number of natural products is thus approximately 20000.

Photochemical Reactions of Surfactant Molecules in Condensed Monolayer Assemblies—Environmental Control and Modification of Reactivity[**]

By David G. Whitten[*]

An investigation of the effects of a controlled microenvironment on reactivity has been carried out by the synthesis and study in organized monolayers of surfactant molecules containing photochemically reactive chromophores. Reactions where substantial environmental effects have been observed include the *cis-trans* isomerization of olefins, ketone photoeliminations, ligand substitution processes, excimer and photodimer formation, and photoredox reactions. Both reactions occurring within the organized assemblies as well as interfacial phenomena have been investigated. Results obtained in these studies suggest possible extensions and applications for the development of new catalyst systems, biological models and controlled syntheses.

1. Introduction

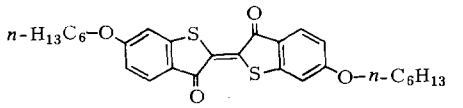
The phenomenon of monolayer film formation at an air-water interface has been known and studied for a long time. Such films are formed when molecules containing a hydrophilic group, for example a carboxyl group, and a sufficiently long hydrophobic chain are brought onto the surface of water; these molecules are referred to as surface active (or as surfactants). Techniques for the study and manipulation of such films were developed by *Pockels*[1], *Blodgett*[2,3], and *Langmuir*[3] and later extended by numerous other investigators. *Langmuir* found in 1917 that films spread on water could be transferred to solid supports[4]; later studies developed and refined the techniques for depositing several consecutive film layers. In recent years the techniques for the preparation and study of monolayers have been greatly elaborated and at the same time simplified, largely due to the elegant investigations of *Kuhn et al.*[5–10]. The possibilities for preparing assemblies of a known and controlled molecular architecture have been developed and used to investigate a wide range of phenomena ranging from electronic energy transfer and polymerization to protein-membrane interactions and photographic sensitization[5].

A number of investigations have dealt with chemical reactions occurring within monolayer films or assemblies or occurring between a reactant contained in a monolayer and another present in an adjacent phase. Reactions investigated in some early studies include hydrolysis reactions[11,12], oxidations[13], and polymerizations[14]. In a number of investigations the occurrence of specific reactions has indicated that considerable but frequently retarded penetration of monolayers by various reagents from adjacent bulk phases can occur[15]. These observations as well as other evidence emphasize the intermediacy of the properties of compressed layers between those of liquids and solids. Thus the spacing indicated by surface pressure-area relationships in many condensed monolayers is regular and close to that occurring in highly ordered hydrocarbon crystals, yet the same monolayers can be penetrated by relatively large organic reagents such as α-naphthol[5,15].

Our interest in examining a variety of chemical processes and photoreactions in monolayers was stimulated by the attractive possibility of having reactive molecules present in a specific orientation and in a known and controlled microenvironment. The close resemblance of monolayer films and assemblies to biological membranes further suggested that phenomena occurring in monolayers might in some cases provide reasonable models for processes occurring within membranes or at membrane-solution interfaces. In our investigations of reactions occurring in monolayer films and assemblies and at monolayer interfaces, we have examined a variety of processes and in many cases we have been able to make comparisons between reactivity in solution, the solid state, monolayers and other organized media. Our results indicate that the microenvironment of a molecule after incorporation in a monolayer film or assembly can produce striking effects on reactivity that can be explained in terms of concentration and orientation effects, hydrophilic-hydrophobic relationships, restricted diffusion and packing phenomena. While most of the reactions examined to date have been carried out on an extremely small scale, the rather pronounced effects observed would justify the future development of practical applications.

2. Unimolecular Reactions in Monolayers

2.1. Photoisomerization of Olefins



One of the most widely studied of all photoreactions is the *cis-trans* isomerization of olefins[16]. Although this reaction generally does not occur in crystalline solids it occurs readily in fluid solution. In most cases isomerization occurs *via* rapid relaxation of *cis* or *trans* excited states to a twisted intermediate which can decay to ground states of both isomers. In viscous solutions photoisomerization is sometimes retarded and in certain cases selective restriction of the isomerization in one of the two directions occurs[16,17]. For example, in the much investigated stilbenes, it has been observed that an increase in viscosity of the medium retards the *trans* to *cis* process selectively while allowing the reverse process to pro-

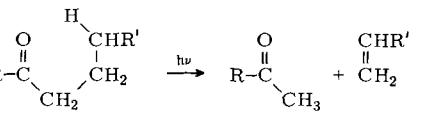
ceed[17]. This viscosity effect has been ascribed to an increase in molecular volume along the path of the *trans* to *cis* process. Such an effect might be expected to play a major role in highly condensed monolayer systems, and for this reason we have examined the behavior of olefins *(1)*—*(3)*, all of which can be incorporated into monolayer films and assemblies but in rather different environments[18-21].

(1)

(2)

(3)

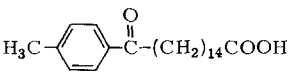


All three olefins (as well as their non-surfactant analogs) undergo facile *cis-trans* photoisomerization in both directions in solution. For *(1)* and *(2)* selective wavelength irradiation of solutions enables preparation of monolayer films and assemblies rich in one or the other isomer. For *(3)* only the photobehavior of the *trans* isomer has been investigated[21]. The photoisomerization behavior of *(1)* in films and assemblies has been the most extensively investigated[18]. The thioindigo chromophore absorbs strongly in the visible region and the spectra of the two isomers in assemblies are only slightly altered from those in solution. From measurements of the absorption spectrum with polarized light, in analogy to results obtained by Kuhn *et. al.*[5] with structurally related cyanine dyes, we conclude that the chromophore of *(1)* lies at or near the hydrophilic interface parallel to the surface in films and assemblies. On irradiation of films or assemblies containing *cis-(1)* a rapid and irreversible conversion to *trans-(1)* is observed. In contrast films or assemblies containing *trans-(1)* were found to be photostable and no conversion to the *cis* isomer or other photoreaction was detected even on relatively long term irradiation. A study of the pressure-area isotherms of spread films of *cis-* and *trans-(1)* on the water surface indicates that a greater cross sectional area per molecule is required for the *cis* isomer and that a significant reduction in pressure occurs when films of *cis-(1)* are irradiated and undergo conversion into *trans-(1)*. Thus there appears to be a very reasonable parallel between the behavior of *(1)* in the films and assemblies and the viscosity effects previously observed with olefins such as the stilbenes[17]. A similar behavior has been observed for the stilbazole derivative *(2)* in films and assemblies. This positively charged analog of stilbene evidently also resides at a site at or near the hydrophilic interface. Irradiation of *cis-(2)* in monolayer assemblies results in rapid and irreversible formation of the *trans* isomer. The *trans* isomer does not form *cis-(2)* on irradiation in the assemblies; however, in this case the *trans* isomer undergoes photoreaction to form other products (cf. Section 3.2)[19,20]. That a restriction to increased molecular volume caused by tight packing plays the major role in inhibiting the *trans* to *cis* process in *(1)* and *(2)* rather than simple orientation effects is indicated by the finding that *(2)* undergoes efficient isomerization in both directions *(trans* $\rightleftharpoons$ *cis, cis* $\rightleftharpoons$ *trans)* as its chief photoreaction upon incorporation into cationic micelles.

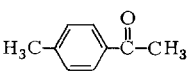
The surfactant styrene *(3)* also readily forms monolayer films and assemblies[21]; however, for this compound the olefinic chromophore lies at the end of a hydrocarbon chain in a highly hydrophobic environment. The behavior of *(3)* in films and assemblies closely resembles that of *(2)*. Irradiation of *trans-(3)* leads rapidly and cleanly to a photoproduct, but no isomerization to the *cis*-isomer occurs[21]. A pressure-area study of *trans-(3)* suggests that highly compressed films and assemblies are formed which can not easily expand to accomodate the bulkier *cis* isomer.

The similar behavior of the three rather different olefinic systems described here would indicate that partial inhibition of isomerization could be a fairly general phenomenon in highly condensed assemblies owing to the effective high pressures caused by close packing of the paraffin chains and hydrophilic (head) groups.

2.2. Photoreactions of Ketones in Monolayers



We have recently investigated another intramolecular photoreaction in monolayers which should be extremely sensitive to the environment: the Norrish type II photoelimination of ketones [eq. (a)]. This reaction, which occurs with moderate quantum efficiency, is the dominant photoreaction of most aliphatic and aromatic ketones possessing abstractable γ-hydrogens in solution[22,23]. The reaction proceeds *via*

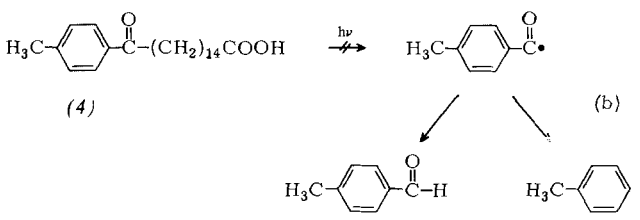


(a)

γ-hydrogen abstraction in a cyclic six-membered transition state followed by cleavage of the diradical to form an enol of the methyl ketone and an olefin. The reaction has been examined in micelles[24] and in several polymer systems[25,26]. Studies on polymers have shown that the rates of reaction and efficiencies are relatively high in polyethylene and vinyl ketone copolymers above the glass transition point[26]. At low temperatures below the glass transition point and in some crystalline solids very little reaction *via* the type II process is observed because the rigidity of the medium makes it difficult to achieve the proper geometry for reaction to occur[26].

In our investigations of the type II process [eq. (a)] in monolayers we used the oxo acid *(4)*, which was expected to form films and assemblies with the ketone in a somewhat ordered hydrophobic region. It was found that *(4)* does in fact form good films and assemblies in 1:1 mixtures with arachidic acid[27]. In compressed films formed from these mix-

(4)

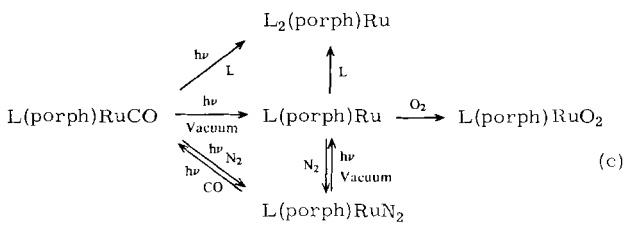


(5)

tures the area per molecule of *(4)* is 20 Å^2; this corresponds closely to the cross sectional area of a paraffin chain. Irradiation of *(4)* in benzene solution gives the expected methyl ketone *(5)* as the chief volatile product with a quantum efficiency (ϕ) of 0.2. In contrast irradiation of *(4)* in assemblies leads to disappearance of the ketone chromophore (as meas-

ured by spectral changes in the ultraviolet or infrared) with a quantum efficiency of 0.06[27]. However, the methyl ketone *(5)* is only a minor product formed in low yield. Thus, the quantum yield for the type II elimination ranges from 0.0001–0.03 (depending on assembly architecture), down considerably from the value in solution. The low quantum efficiency for the type II elimination in monolayer assemblies can be attributed to a perpendicular (zig-zag) arrangement of the paraffin chains which cannot be easily distorted to allow the cyclic transition state necessary for γ-hydrogen abstraction to be attained.

The contrast between the extremely low quantum yield for the reaction of *(4)* in the type II process [eq. (a)] and the moderate quantum yield for the disappearance of *(4)* suggests that other photochemical reactions occur. One such process which might be anticipated is the photoelimination of type I (α-cleavage) [eq. (b)]. This would be expected to result in chain scission of *(4)*, leading to either or both *p*-methylbenzaldehyde and toluene. However, analysis of the volatile products obtained on photolysis of *(4)* in the assemblies

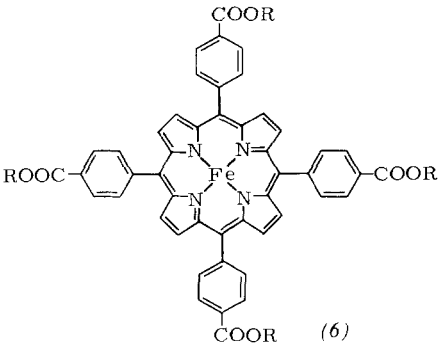


reveals that neither product is formed in detectable yield. The lack of type I cleavage products [eq. (b)] is perhaps surprising but also reasonable if the monolayer environment prevents diffusion of free radicals formed by α-cleavage such that only recombination occurs. The disappearance of *(4)* must therefore be accounted for by other reactions; a reasonable possibility is intermolecular hydrogen abstraction from a paraffin chain in close proximity to the carbonyl group. Such a process could lead to net photoreduction of the keto group or to a cross-linking reaction. We are currently examining the non-volatile products in order to determine precisely the major reaction path.

We are also examining reactions of the oxo acid *(4)* as a structural probe in other organized media and in modified monolayer assemblies. In anionic sodium dodecyl sulfate (SDS) micelles we find that *(4)* undergoes Norrish type II photoelimination to give the methyl ketone *(5)* as the only volatile product. The quantum yield for the process in SDS micelles is 0.8, four times the value obtained in hydrocarbon solution. This value is comparable to those obtained for non-surfactant ketones solubilized in cationic micelles[24]; in these studies it was inferred that the increase in quantum efficiency in micelles was consistent with location of the ketone chromophore in a relatively polar environment, since the Norrish II photoelimination in solution increases markedly in alcohols or other polar solvents[22,23]. A reasonable inference from the present results is that for *(4)* in SDS micelles the polymethylene chain is coiled back on itself so that both ends (carbonyl and carboxy group) may lie near the micellar surface. The high value obtained for the photoelimination of *(4)* in SDS micelles ($\Phi_{II} = 0.8$) emphasizes the contrast in order and rigidity or microviscosity between monolayers and micelles. Thus, even though both media are formed by self-organization of amphipathic molecules, the one structure closely resembles a crystalline solid in many of its properties while the other is essentially solution-like.

2.3. Ligand Exchange Processes in Metalloporphyrin Complexes

Previous indications that the microenvironment provided by deposited monolayer assemblies is intermediate between a crystalline solid and a viscous solution suggested that ligand exchange processes would be a particularly attractive class of reactions to study in these media. Both thermal and photochemical ligand exchange reactions have been observed for a wide variety of transition metal complexes; while the former may involve both association and dissociation processes, photochemical reactions almost invariably involve ejection of a ligand to generate an intermediary, highly reactive coordinatively unsaturated metal center. In solution such intermediates are usually very short-lived; the reactive complex is normally consumed rapidly by reaction with ligating solvent or solute molecules or by recapture of the ejected fragment. We hoped that ligand photoejection in organized monolayer assemblies might permit the isolation and selective reaction of the reactive complexes thus formed. Our investigations in this area have centered around ligand exchange processes occurring with metalloporphyrin complexes.



The photoejection of bound CO from iron(II) porphyrin complexes such as carboxyhemoglobin and carboxymyoglobin as well as simpler synthetic complexes has been observed in numerous investigations[28,29]; more recent work has shown that photoejection processes involving other ligands as well as other metals can occur in porphyrin complexes[30-33]. We have investigated the photoejection of CO from ruthenium(II) and osmium(II) porphyrin complexes in solution[30]. In these investigations the overall reaction observed was replacement of the departing CO by a new ligand. The CO-free metalloporphyrin which is formed in the photoejection cannot be isolated in solution even though it can be detected by flash photolysis. In our studies with surfactant metalloporphyrins in monolayer assemblies we found that the carbonylruthenium(II) complex of the dioctadecyl ester of mesoporphyrin IX (porph) forms good monolayer assemblies in which the porphyrin is photochemically active[34]. The complex can be introduced into assemblies as either the aquo-CO or pyridine-CO complex; both complexes exhibit similar photochemical behavior. Irradiation of dry monolayer assemblies containing these complexes, L(porph)RuCO (where L is pyridine or water), *in vacuo* leads to isolation of the CO-free complex. This complex, L(porph)Ru, is extremely reactive on exposure to air, nitrogen, oxygen, pyridine or CO, but it is fairly stable in a highly evacuated cell. The reactions we have observed to date are summarized in Scheme (c)[34]. The absence of ligating molecules in the dry

(c)

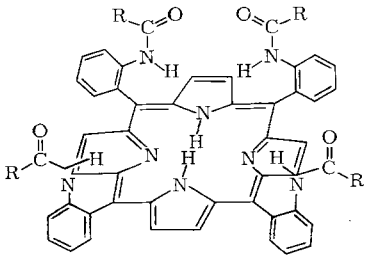
and evacuated monolayer environment permits isolation of the otherwise unobtainable L(porph)Ru and thus its exploitation for the directed synthesis of novel nitrogen and oxygen complexes[34]. It is interesting to note that, subsequent to these investigations, solution studies on the photolysis of similar carbonylruthenium(II) porphyrin complexes in weakly ligating solvents such as acetonitrile have led to the production of labile oxygen complexes having spectra similar to those of the oxygen complexes L(porph)RuO_2 isolated in the monolayers[35]. Here a labile L_2(porph)Ru species is evidenced as intermediate in the formation of the oxygen complex.

We have also examined ligand exchange processes with surfactant iron porphyrins in monolayer assemblies[36]. Assemblies are generally prepared by introducing the air-stable iron(III) complex into the monolayer film and reducing the complex after it has been incorporated into a multilayer assembly. We have found that the iron(III) porphyrins in monolayer assemblies can be reduced to the corresponding iron(II) complex by two rather different procedures. Exposure of dry, evacuated assemblies to the reducing ligand piperidine leads to quantitative reduction to the iron(II) complex. With the surfactant iron(II) porphyrin *(6)*, R = cholestanyl [cf. *(18b)*], we find that exposure to oxygen or carbon monoxide in the monolayer assemblies leads to the formation of substituted iron(II) complexes and not to the corresponding iron(III) complex. Both the oxygen- as well as the carbonyl-complex regenerate the unsubstituted iron(II) complex on evacuation of the assembly[36]. We have also found that reduction of iron(III) porphyrins can occur through addition of other ligand-reducing agent systems. Addition of NO to evacuated assemblies results in formation of an NO complex having a characteristic iron(II) NO^+ spectrum. This complex can be decomposed by addition of methanol to give the iron(II) complex [eq. (d)][36].

(6)

$$(porph)Fe^{II}NO^{\oplus}Cl^{\ominus} + CH_3OH \rightarrow (porph)Fe^{II} + CH_3ONO + HCl \quad (d)$$

Reactions of iron(II) complexes prepared in assemblies by this method are currently under investigation.



3. Bimolecular Reactions in Monolayer Films and Assemblies

3.1. Dimer Formation and Aggregation

Investigations with surfactant dyes and other compounds with strongly absorbing chromophores have indicated that considerable aggregation occurs in monolayer films and assemblies[5-7]. This can frequently be observed both in pure and in mixed monolayers and can involve both inter- and intra-layer interactions. The aggregation can most easily be established by comparison of the absorption and emission spectra of the molecules under investigation in dilute solution and in the condensed monolayer assemblies. Aggregation can result as a consequence of several factors, depending upon the system under investigation and the techniques used to form the monolayer assembly[37]. In many cases studies of isotherms obtained from separate and mixed monolayers indicate that the latter are not homogeneous but consist of domains or patches of separate monolayers[38,39]. While in certain cases separate phases may result from differences in solubility of the components in the spreading solvent, in other systems the occurrence of separate phases may be due to nonmixing or nonideality in the spread film[39]. Such factors are evidently much more severe in organized media than in conventional solutions; it has recently been shown, for example, that in micelles formed from mixtures of fluorocarbon and hydrocarbon surfactants there is a nearly complete segregation into distinct phases of the individual components[40]. Even where the components of mixed monolayers are completely miscible in the spread film, in cases where both components are present in anywhere near equimolar amounts the effective local concentrations obtained in the films can be quite high. Thus, the films and assemblies frequently provide a means for obtaining concentrations much higher than in solution, such that dimer formation or aggregation is conceivable even if there is only relatively weak attraction between the molecules. The tight packing of components in condensed monolayers may also lead to an interlocking or association of groups which might not associate in solution, particularly if facilitated by the spatial arrangements in the component surfactants. Examples where such factors have been demonstrated as being important include the packing of surfactant cyanine dyes into Scheibe aggregates[5-7] and the interlocking functional units consisting of an azobenzene dye oriented perpendicular to a cyanine dye which have recently been prepared by *Polymeropoulos, Möbius* and *Kuhn*[41].

Our work in this area has demonstrated the importance of dimerization and aggregation for several different surfactant molecules in monolayer films and multilayer assemblies. Some of our first investigations involved a study of monolayers formed from various porphyrins and their metal complexes. In solution studies we were able to show that porphyrins and their zinc complexes form dimers at low temperatures in moderately dilute (10^{-6} M) hydrocarbon solutions[42]. When the same porphyrin chromophore is incorporated into a surfactant molecule we find in several cases that the resulting monolayer assembly formed by transfer of several film layers from water gives a temperature-independent absorption spectrum nearly identical to that of the dimer obtained in solution at low temperatures[42]. Such dimers, which are formed by contact of the chromophores of neighboring layers can easily be distinguished from the dimers formed within a layer in which dye layers are separated by intercalated fatty acid layers. Hence, for several surfactant porphyrins the dimerization, *i. e.* association of two chromophores, is a purely intralayer phenomenon such that identical spectra are obtained both from multilayers in contact and

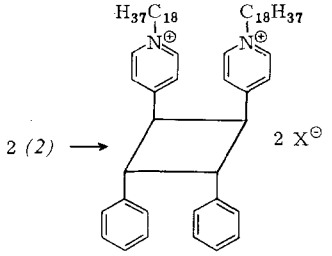
those in which "inert" arachidate "spacer layers" separate the layers containing porphyrin. However with certain porphyrins, most notably those of the "picket fence" type such as *(7)*, the dimers obtained in multilayers are exclusively or predominantly interlayer as determined by the "spacer layer" technique[43]. The fact that *(7)* and some closely related "picket fence" porphyrins form interlayer dimers indicates that the porphyrin must lie at the hydrophilic interface in a rather well-defined site. We are currently attempting to take advantage of this property to construct assemblies of controlled architecture in which two different metal complexes are in close proximity with each another.

(7), R = $C_{15}H_{31}$

The tendency of porphyrins to associate in monolayer films and assemblies led to interesting but troublesome results in our attempts to study iron porphyrins in assemblies[44]. Since iron(II) porphyrins are not air-stable in solution, it was anticipated that assemblies should be constructed from the corresponding iron(III) complexes which could then be reduced by various reagents. As outlined in Section 2.3, for certain complexes this procedure has proven feasible. However, for several surface-active iron porphyrins it was found that spreading of films from the chloroiron(III) porphyrin led to immediate and irreversible formation of the corresponding μ-oxo compounds [eq.(e)][44]. This reaction which can be viewed as a simple three-step substitution process [eqs (f)—(h)], occurs in solution, but only at high pH... and then rather slowly[45-47]. In contrast, we found that in the monolayer films the reaction is complete and irreversible even where the subphase is strongly acidic (down to pH = 2)[44]. The results can be fairly easily interpreted by

$$2\,(\text{porph})\text{FeCl} + 2\,\text{OH}^{\ominus} \rightarrow (\text{porph})\text{FeOFe}(\text{porph}) + \text{H}_2\text{O} + 2\,\text{Cl}^{\ominus} \quad \text{(e)}$$

$$(\text{porph})\text{FeCl} + \text{OH}^{\ominus} \rightarrow (\text{porph})\text{FeOH} + \text{Cl}^{\ominus} \quad \text{(f)}$$



$$(\text{porph})\text{FeOH} + \text{OH}^{\ominus} \rightarrow (\text{porph})\text{FeO}^{\ominus} + \text{H}_2\text{O} \quad \text{(g)}$$

$$(\text{porph})\text{FeO}^{\ominus} + (\text{porph})\text{FeCl} \rightarrow (\text{porph})\text{FeOFe}(\text{porph}) + \text{Cl}^{\ominus} \quad \text{(h)}$$

assuming that reaction (h) is highly favored in the dimers (or aggregates) formed in the spread film while steps leading to decomposition of the μ-oxo dimer should be rendered slower and more difficult. The net effect of the microenvironment provided by the monolayer film in this case is to produce a rather pronounced alteration of both rate processes and equilibria.

3.2. Excimer and Photodimer Formation

The *trans* isomers of olefins *(2)* and *(3)* can be incorporated into monolayer films and assemblies in which the usual solution photoreaction, *trans* to *cis* isomerization, does not occur. For the stilbazole derivative *(2)* it was found that the absorption spectrum in the assemblies is nearly identical to that obtained for dilute acetonitrile solutions of *(2)*[20] (see Section 2.1). Consequently, there is little indication that complex formation in the ground state is important. Compound *(2)* fluoresces strongly both in solution and in monolayer assemblies; however, the fluorescence in the assemblies is shifted about 50 nm to longer wavelength as compared to acetonitrile solutions. Although *(2)* does not undergo *trans*→*cis* isomerization in assemblies upon irradiation, it undergoes a rapid photobleaching which was shown to be due to dimer formation[19,20]. A similar red-shifted fluorescence and rapid photobleaching was also observed for crystals of *(2)*, X = *p*-chlorobenzenesulfonate or *p*-bromobenzenesulfonate. For these crystals it was found that the dimers were of the cyclobutane-type *(8)*, formed from parallel addition of two molecules of *(2)*[19]. The formation of the photodimers in crystalline *(3)* and in monolayers appears to be closely related—though there are some notable differences. In all cases the occurrence of dimerization is accompanied by a red-shift in the fluorescence. Consequently, it can be inferred that the red-shifted fluorescence is due to an excimer, which is probably an intermediate in the formation of *(8)* [eqs. (i)—(l)].

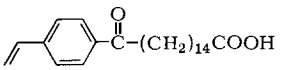
(8)

$$(2) \xrightarrow{h\nu} (2)^* \quad \text{(i)}$$

$$(2)^* + (2) \rightarrow [(2)\ldots(2)]^* \quad \text{(j)}$$

$$[(2)\ldots(2)]^* \rightarrow (2) + (2) + h\nu \quad \text{(k)}$$

$$[(2)\ldots(2)]^* \rightarrow (8) \quad \text{(l)}$$



While excimer formation is frequently observed in solution as a diffusion process, excimer formation in crystals and monolayer assemblies of *(2)* must involve pre-formed units in which relatively little molecular motion occurs following excitation.

Interestingly, no excimer fluorescence has been detected for *(2)* or similar stilbazole quaternary salts in solution, although photodimerization to give a number of cyclobutane dimers of different stereochemistry than *(8)* has been observed[20,48]. As pointed out above, excimer fluorescence and photodimer formation are coupled in crystals of *(2)*; while both processes are observed for some anions, other anions yield crystals that are photostable and show only monomer fluorescence. For monolayers of *(2)* the photobehavior is independent of the anion used (this may simply reflect rapid exchange with the anions in the aqueous phase); however, a strong dependence upon assembly architecture has been observed. Thus, when *(2)* is diluted with increasing amounts of an inert surfactant such as tripalmitine or arachidic acid, a reduction in both the rate and extent of the photoreaction is observed[19]. This is, of course, reasonable in view of the need for "pre-formed" dimer sites to afford the possibility of reaction. Furthermore, it was found that both the rate and extent

of photoreaction are reduced when assemblies are constructed with the layers containing *(2)* separated by inert "spacer layers" of tripalmitine or arachidate[19]. The two observations indicate that for *(2)* in monolayers the dimerizable sites can be formed both within single layers and between adjacent layers. Although it has not yet been verified, it may be anticipated that interlayer dimerization would produce a dimer having a different stereochemistry from that of *(8)*.

The fact that excimer fluorescence and photodimer formation for *(2)* are observed in solid crystals and monolayers but not in concentrated solutions suggests that the tight packing in the former phases may play a major role in this phenomenon. *Schmidt et al.* have made extensive investigations of solid-state photoaddition and photodimerization reactions in which it has been shown that properly aligned monomer units must be within a distance of *ca.* 4.2 Å of one another[49]; this is the typical interchain spacing determined for ordered hydrocarbons to permit reactions[50]. When photoactive crystals of *(2)* (X=*p*-chlorobenzenesulfonate) are heated it is found that reversible loss of excimer fluorescence occurs at temperatures considerably below the melting point[20]. One possible explanation for this would be a "melting" of the hydrocarbon chains with a corresponding release of the chromophores from close proximity to one another. It is frequently observed that phospholipids and similar substances undergo phase transitions below their melting points; the hydrocarbon chains become more disordered and liquid-like with an increase in the interchain separation[50]. Self-organization alone of hydrophilic and hydrophobic regions in an organized assembly is not sufficient for excimer formation in the olefin *(2)*. This is indicated by the fact that no photodimerization or excimer formation is observed when *(2)* is incorporated into cationic cetyltrimethylammonium bromide (CTAB) micelles[20]. Appreciable concentrations of *(2)* in micellar CTAB can be obtained, indicating that there are several molecules/micelle as well as *(2)*:CTAB ratios corresponding to the *(2)*:surfactant ratios in monolayer assemblies where both excimer fluorescence and photodimerization are observed. For these micelles, however, only monomer fluorescence and relatively efficient *trans→cis* photoisomerization of *(2)* are observed[20].

We have recently investigated photochemical and thermal reactions of the surfactant styrene derivatives *(3)* and *(9)* in different media including the solid state, monolayer films, deposited monolayer assemblies, micelles and solution[21].

(9)

Like the oxo acids *(4)* these compounds possess a potentially reactive chromophore in what would be anticipated to be a highly hydrophobic site in organized media. Both *(3)* and *(9)* form good films which can be easily manipulated and transferred to yield deposited monolayer assemblies. The styrene *(3)* exhibits especially favorable properties, forming good films from the pure compound which yield compressed monolayers very similar to those of saturated fatty acids such as arachidate. The area per molecule *(3)* in a monomolecular film is 19 Å^2 for a surface pressure of 20 dyn/cm[21]. The UV absorption spectrum of monolayers of *(3)* is altered considerably as compared to the solution spectrum (cf. Fig. 1); thus in this case—in contrast to the surfactant *(2)*—there is evidently

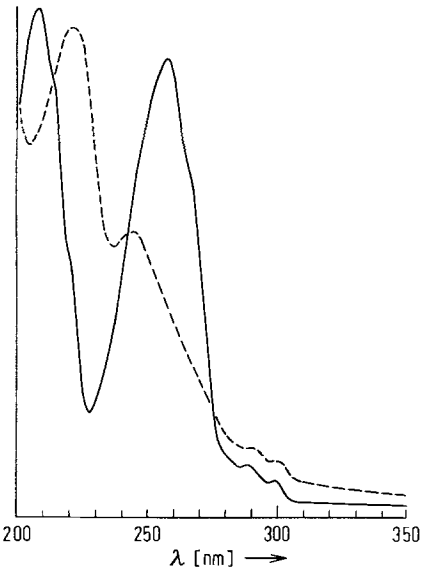


Fig. 1. Comparison of absorption spectra of styrene *(3)* in hexane solution (——) and in quartz supported multilayers (---).

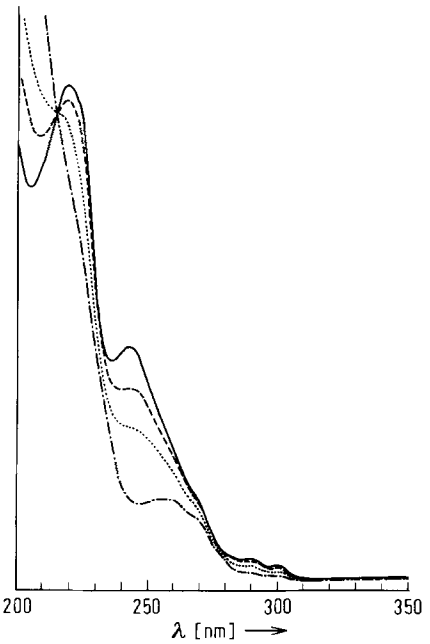

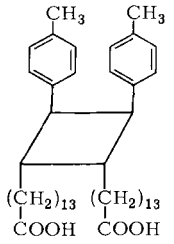

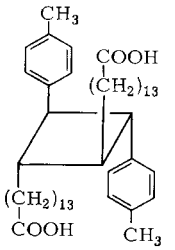

Fig. 2. Spectra of styrene *(3)* in quartz supported multilayers. (——), and after 5 min (---), 15 min (····) and 60 min (·–·) irradiation.

considerable interaction between the chromophores, even in the ground state. On irradiation of assemblies containing *(3)* at wavelengths between 254—300 nm there is a rapid bleaching of the styrene absorption (cf. Fig. 2). Good isosbestic points are obtained throughout the reaction, suggesting that only a single reaction is taking place. A similar bleaching occurs when films of *(3)* are irradiated at an air-water interface. The bleaching is due to formation of a photodimer similar to that obtained from *(2)* in crystals and monolayer assemblies. The product could be isolated by preparative scale irradiation of large slides containing several styrene multilayers or by recovery of material from several films spread and irra-

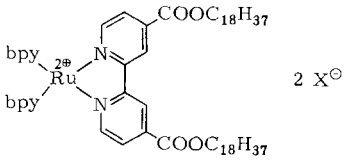
diated at an air-water interface. The product was found to consist of a single product having NMR, IR and mass spectral data in accord with those expected for a cyclobutane structure as in *(10)* or *(11)*.

(10)

(11)

Irradiation of *(3)* in solution, in SDS micelles, and in crystals also leads to the formation of dimeric products which are evidently cyclobutane derivatives[21]. However, preliminary indications are that products having different stereochemistry are formed in the solid state and in SDS micelles. The reactions in solution and micelles also appear to produce more than one product. Although we have not yet obtained conclusive evidence, it appears that the product formed from *(3)* in the monolayers is the *trans-syn-trans* dimer *(10)* resulting from the parallel alignment of the chromophore in the monolayer[21]. The fact that only a single product is formed in relatively high quantum yield ($\phi = 0.14$) affords reasonable confirmation of the extended regular structure of the hydrocarbon chain expected for the compressed monolayer. The results obtained in this case seem quite analogous to the "topological control" observed in the solid-state photochemical dimerization and addition reactions investigated by *Schmidt, Cohen et al.*[49,51,52].

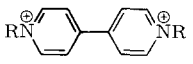
Although the scale for the reactions in monolayer films or assemblies is obviously somewhat limited, the results obtained with *(3)* suggest a number of exciting possibilities for obtaining regio- and stereospecific control of reactions by the construction and use of especially tailored surfactants. A particular advantage illustrated by the reactions of both *(2)* and *(3)* is that hydrophobic-hydrophilic interactions and the close packing of the hydrocarbon chains dictate the structure of the films and assemblies in a predictable fashion. Thus, it appears that reactions in monolayers offer many of the same possibilities obtainable in the solid state by "crystal engineering" with the possible advantage that monolayer structure may be somewhat easier to predict and control.



3.3. Photoinduced Electron Transfer Reactions in Monolayer Assemblies

Photoinduced electron transfer reactions of transition metal complexes, dyes and other substances having relatively low excitation energies have been the subject of extensive investigation during recent years. It has been found that excited states of metal complexes, for example, can be quenched by electron donors or electron acceptors in redox processes that can involve efficient conversion of light energy into chemical energy in the form of energy-rich products. Both the initial photoreactions and subsequent "dark" processes have been well-characterized for several systems[53-57]. In most cases, the quenching-energy conversion processes [eqs. (m) and (o)] are followed by energy-wasting back reactions which regenerate ground states of the starting species [eqs. (n) and (p)]. The obvious potential utility of reactions of this type for energy conversion and storage has led to several investigations in which means have been sought to capture or utilize the high energy redox products or otherwise avert the back reactions[58-63]. Our own work in this area has included extensive investigations in solution as well as in monolayer assemblies.

$$MC^{n\oplus *} + Ox \rightarrow MC^{(n+1)\oplus} + Ox^{red} \quad (m)$$
$$MC^{(n+1)\oplus} + Ox^{red} \rightarrow MC^{n\oplus} + Ox \quad (n)$$
$$MC^{n\oplus *} + Red \rightarrow MC^{(n-1)\oplus} + Red^{ox} \quad (o)$$
$$MC^{(n-1)\oplus} + Red^{ox} \rightarrow MC^{n\oplus} + Red \quad (p)$$

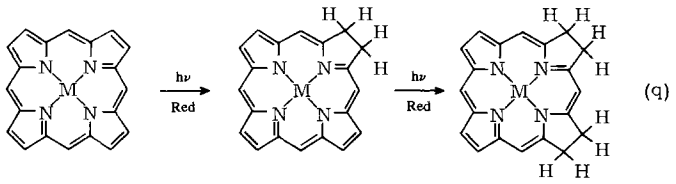


$MC^{n\oplus *}$ = excited metal complex, Ox = oxidant, Ox^{red} = reduced oxidant, Red = reductant, Red^{ox} = oxidized reductant.

One of the most widely used metal complexes in studies of electron transfer reactions has been tris(2,2′-bipyridyl)ruthenium(II), ($Ru(bpy)_3^{2+}$). This complex is strongly luminescent in fluid solution and reasonably photostable; hence, the quenching of its luminescence by electron donors and acceptors has proven to be a convenient means for studying these reactions. Our interest in studying electron transfer quenching processes in monolayer assemblies led us to prepare the hydrophobic surfactant complex *(12)*. This complex

(12)

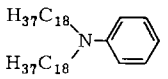
was found to form monolayer films which could be transferred to solid supports[64]. We found that dry assemblies containing *(12)* exhibited intense luminescence similar to that of $Ru(bpy)_3^{2+}$ in solution. Since its luminescence is strongly quenched by electron acceptors such as the dication paraquat *(13a)*, we decided to investigate quenching of the luminescence of *(12)* in monolayer assemblies with the surfactant counterpart of paraquat, *(13b)*. Assemblies were constructed



(13a), R = CH_3
(13b), R = $C_{18}H_{37}$

with *(12)* and *(13b)* in the same layer and with *(12)* and *(13b)* in adjacent layers having hydrophilic-hydrophilic contact. In both cases significant quenching of the luminescence of *(12)* was observed[65]. Separation of layers containing *(13b)* from those containing *(12)* by two or more layers of cadmium arachidate generally resulted in no quenching of the luminescence—as might be expected for an electron transfer process requiring near-contact of donor and acceptor. In cases where there was quenching of the luminescence of *(12)* no permanent bleaching was observed, at least on short term irradiation[65]. This suggests that oxidative electron transfer in the assemblies is followed in this case by rapid reverse electron transfer [cf. eq. (n)] analogous to the solution behavior. Sub-

sequent to our investigations more extensive studies on electron transfer quenching in monolayers have been reported[66]. In these investigations it has been found that quenching of the luminescence of several cyanine dyes occurs over statistical spacings of up to $R = 75$ Å in contrast to the average quenching distance between *(12)* and *(13b)* of 10 Å. These very interesting results indicate a correlation between the distance and the ionization energy of the excited state of the electron donor[66].



One case where electron transfer quenching of an excited state leads to formation of permanent products, albeit rather inefficiently, is the photoreduction of metalloporphyrins by various reducing agents. It has been found, for example, in solution that a number of metal porphyrin complexes *(14)* including those of tin(IV), germanium(IV), zinc(II), platinum(II) and palladium(II) can be photoreduced sequentially to chlorin (dihydroporphyrin) *(15)* and tetrahydroporphyrin *(16)* products [eq. (q)] with reducing agents (Red) such as stannous chloride, ascorbic acid and tertiary amines[67-70].

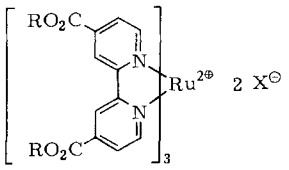
(q)

(14) *(15)* *(16)*

The reduction of palladium(II) porphyrins with tertiary amines has been extensively investigated; evidently the initial step involves electron transfer from the amine to the excited porphyrin[71]. Depending upon the medium, subsequent steps may involve proton transfers, secondary electron transfer steps and free radical processes. In an effort to determine whether such a sequence of reactions can occur in monolayer assemblies we have examined reactions of the palladium(II) complexes of surfactant porphyrins *(6)* and *(7)* with the sur-

(17)

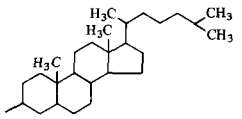
factant tertiary amine *(14)*[71]. In very recent experiments we have found that both dry assemblies and assemblies immersed in water undergo partial conversion as outlined in eq. (q) when the amine *(17)* and palladium porphyrin are present in a 1:1 ratio in the same layer with an excess of arachidate host. We have also observed similar reactivity for assemblies in which *(17)* and palladium porphyrin are present in adjacent layers with hydrophilic-hydrophilic contact[71]. In both cases only partial conversion has been observed. Fairly rapid conversion occurs on initial irradiation, resulting even in formation of some tetrahydroporphyrin *(16)*, but prolonged irradiation results in little additional conversion. Evidently here, as with the dimerization phenomena observed with *(2)*, there are some sites capable of reaction while others are non-reactive; once the "reactive sites" are exhausted no further reaction can occur. We are currently exploring different combinations of porphyrin reductant and host surfactant to define what constitutes a reactive or an unreactive site.



4. Interfacial Phenomena: Monolayer Solution and Monolayer-Gas Reactions

Recently, considerable interest has centered around interfacial processes in which an immobilized reactant or catalyst interacts with a reagent present in a contacting solution or vapor phase. The relative ease of constructing monolayer assemblies on various supports would suggest that this might be an area where monolayers could offer considerable utility both for mechanistic studies as well as practical applications. Our initial interest in this area centered around the possibility of carrying out heterogeneous light-induced electron transfer processes involving an immobilized light absorbing complex and potential oxidants or reductants in solution. The first system planned for investigation involved monolayer assemblies containing the ruthenium complex *(12)* and aqueous solutions of various electron acceptors. Initial experiments with assemblies containing an outer hydrophobic layer of *(12)* revealed that the strong luminescence observed from the dry assemblies was almost completely quenched upon immersion of these assemblies in water[64]. The absorption spectrum of *(12)* in the assemblies was little altered by this process and we found that gentle heating in a vacuum restored the luminescence to nearly its original intensity[64,65]. In contrast we found that the luminescence of *(12)* in organic solvents was virtually unaffected by addition of considerable amounts of water, aqueous acid or aqueous base.

The observation that water quenched the luminescence of monolayer assembly-bound *(12)* suggested the possibility that a photoreaction involving *(12)* and water could be occurring. Initial experiments on the irradiation of monolayer assemblies of the surfactant ruthenium complex *(12)* in the presence of water led to the production of hydrogen in an apparent light-induced cleavage of water by the monolayer-bound complex[64]. Although slides containing monolayers formed from the initial preparation of *(12)* repeatedly gave sustained gas evolution upon irradiation, irradiation of assemblies formed from subsequent preparations of the complex under identical conditions has not produced comparable results[65,66,72]. It is now clear that light-induced water cleavage does not occur with pure *(12)* in monolayer assemblies; the underlying reason behind the initial results remains as yet an unsolved mystery. The original preparation of *(12)* was found to contain several impurities including other surfactant ruthenium(II) complexes and it seems likely that the net process of water cleavage in the layers may require at least two different complexes. Attempts to prepare useful systems with the complex *(12)* in assemblies have been somewhat disappointing because of the extreme sensitivity of its film properties to impurities—especially anions—and to its rapid degradation on contact with water[65,66]. Although different samples of carefully purified complex have been thoroughly investigated in several different laboratories, there still remain significant discrepancies regarding its photobehavior in monolayer films and assemblies[65,66,72].



The instability of *(12)* in monolayers in the presence of water led us to focus our studies on interfacial electron transfer processes in monolayers on other metal complexes; however, our work with *(12)* initiated numerous other studies on structurally related hydrophobic ruthenium(II) complexes in solution[63,73,74]. We have found that the photochemical reac-

tivity of these complexes having the general structure *(18)* is significantly different from that of the parent complex $Ru(bipy)_3^{2+}$. This renders them potentially useful in energy storage applications and at the same time provides some insight into how the original preparation may have functioned. We have prepared and studied a series of complexes *(18)* in which the parent complex $Ru(bpy)_3^{2+}$ is surrounded by hydrophobic groups ranging in size from isopropylcarbonyl in *(18a)* to cholestanyloxycarbonyl in *(18b)*[73]. All of these

(18a), R = $-CH(CH_3)_2$

(18b), R =

complexes are insoluble in water but can be readily studied in a variety of organic solvents. The presence of the electron-withdrawing carboxyester groups on the bipyridine ligands shifts the redox potentials of the complexes to more anodic values as compared to that of $Ru(bipy)_3^{2+}$. Figure 3 compares the redox potentials in the ground state and in the excited state. An interesting consequence of the shifted redox poten-

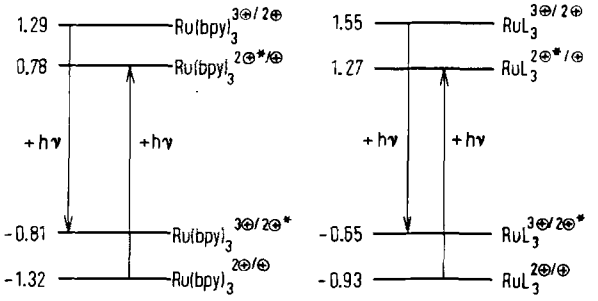


Fig. 3. Formal redox relationships for ground and excited states of ruthenium(II) complexes: left: $Ru(bipy)_3$, right: hydrophobic complexes *(18)*. Energy in volts referred to SCE.

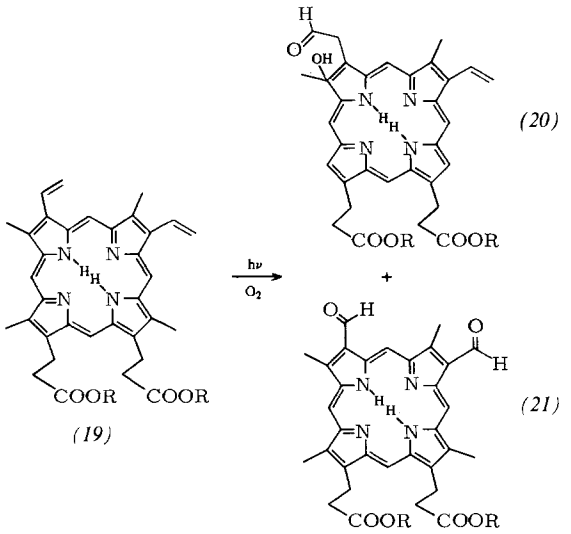
$$RuL_3^{2\oplus *} + RuL_3^{2\oplus} \rightarrow RuL_3^{3\oplus} + RuL_3^{\oplus} \quad (r)$$

$$RuL_3^{2\oplus *} + RuL_3'^{2\oplus} \rightarrow RuL_3^{3\oplus} + RuL_3'^{\oplus} \quad (s)$$



tials for the hydrophobic complexes is that while both $Ru(bipy)_3^{2+}$ and the various hydrophobic complexes should be stable towards self-quenching electron transfer processes [cf. eq. (r)], a quenching process with one of the hydrophobic complexes *(18)* as an electron acceptor and $Ru(bipy)_3^{2+}$ as a donor should be energetically favored [cf. eq. (s)]. Although we have not yet obtained evidence for the reaction according to eq. (s), we have found evidence that efficient light induced electron transfer processes involving the complex *(18)* can result in irreversible reactions for both oxidative[74] and reductive quenching[63,73,74]. Although it is beyond the scope of this paper to report in detail on reactions of hydrophobic complexes *(18)* in solution, it is worth noting that the hydrophobic groups produce significant effects on the course of excited state electron transfer processes and subsequent events. Thus both excited state quenching and reverse electron transfer processes involving *(18a)* and *(18b)* are slowed down considerably in several cases as compared to those in the case of $Ru(bipy)_3^{2+}$. The bulky groups evidently retard approach by several reagents—especially cationic species—such that while both efficient but slower oxidative [cf. eq. (m)] and reductive [cf. eq. (o)] quenching processes occur, the back-transfer of electrons is rendered sufficiently slow to permit other processes to compete[73,74]. Thus considerable energy can be stored in the form of one or both of the high energy products produced in eqs. (m) and (o).

Returning to interfacial processes occurring in monolayer assemblies we have recently examined reactions of monolayer-bound porphyrins with potential reducing agents present in a contacting aqueous solution[71]. As with the results reported in Section 3.3, most of our studies in this area have involved palladium(II) complexes of the surfactant porphyrins *(6)* and *(7)* (see Section 3.3). We have found that irradiation of multilayer assemblies containing the palladium porphyrins in contact with aqueous solutions of *N,N*-dimethylaniline or triethylamine can result in reduction of the porphyrin as outlined in eq. (q). The reaction has been examined using assemblies having different architecture. It has been found that a photoreduction takes place both in multilayer assemblies of porphyrins *(6)* or *(7)* as well as in systems containing only a single outer hydrophilic or hydrophobic layer; however, reaction is considerably more rapid when assemblies containing only 1—4 outer monolayers of palladiumporphyrin are irradiated[71]. The fact that both porphyrins react at comparable rates is interesting since porphyrin *(6)* is believed to lie in a relatively more hydrophobic environment than *(7)*, which lies at the hydrophilic interface. It seems reasonable that in this case the moderately polar amines can penetrate both hydrophobic and hydrophilic portions of the monolayer assembly. Such penetration most likely involves a temporary "dissolving" of microscopic portions of the assembly; in agreement with this it is found that addition of excess amine to the contacting aqueous solution can result in removal of the mutlilayer from the support. The occurrence of considerable reaction in multilayers without removal of porphyrin would indicate that penetration through several layers can occur.

In contrast to the lack of discrimination between reactivity of porphyrins at hydrophilic *vs* hydrophobic sites in the case of amine-mediated photoreduction, there is a pronounced site-dependence upon the interfacial incorporation of metal ions from aqueous solutions contacted with monolayer-bound surfactant porphyrins. Thus, while all the surfactant porphyrins examined readily incorporate Cu^{2+} in solution, we find the microenvironment provided by the monolayer produces major effects in both spread films and multilayer assemblies[43]. Films or assemblies containing porphyrins such as *(7)*, which evidently reside in a highly hydrophilic site, are rapidly metalated by aqueous Cu^{2+}. In contrast *(6)* and other porphyrins which are located in more hydrophobic regions are totally inert towards Cu^{2+} incorporation in films and assemblies. The different rates of Cu^{2+} incorporation in *(7)* can also be correlated with the relative hydrophilicity of the site[43]. We have found that monolayer-incorporated porphyrin *(7)* incorporates several other divalent metal ions from aqueous solution, but the relative ease of metal ion incorporation differs substantially from that observed in homogeneous solution[43]. Thus while the rate of incorporation of metal ion for a number of porphyrins in solution decreases along the series $Cu^{2+} > Zn^{2+} > Co^{2+} > Ni^{2+} \gg Mg^{2+}$[75],

we find that *(6)* incorporates Mg^{2+}, Co^{2+}, Ni^{2+} and Mn^{2+} from aqueous solutions but not Zn^{2+} or Fe^{3+}. The failure of zinc and iron to metalate in contrast with the facile incorporation of magnesium is especially striking. We are currently studying interfacial metalation phenomena with other more hydrophobic metalating reagents, but it is clear from the foregoing results that the microenvironment provided by the monolayer assembly can produce striking effects on reactivity, particularly when there is limited or selective penetration of one of the reagents from the solution.

In other studies of reactions involving surfactant porphyrins at an assembly-air or assembly-water interface we have likewise observed differences from the behavior of the same reagents in solution. One example where a substantial difference has been observed is the photooxidation of the protoporphyrin derivatives *(19)*[76]. In solution the major oxidation product obtained from irradiation of protoporphyrin IX esters in the presence of oxygen is the hydroxyaldehyde *(20)* (and its isomer where the other vinyl group has reacted)[77].

(19) *(20)* *(21)*

In contrast, irradiation of protoporphyrin esters in micelles, monolayer films or dry monolayer assemblies leads to production of the diformyl derivative *(21)* as the major product[77]. The ratio of the products *(21)*/*(20)* increases on going from micelles to spread films to condensed monolayer assemblies. Although formation of both *(20)* and *(21)* can be rationalized in terms of well-established singlet oxygen addition paths, it is clear that the path leading to *(20)* sould be favored in the absence of special effects. Although it is not possible to specify the precise cause of the change in product distribution for this reaction it appears once again that the microenvironment plays a major role in the organized media, either in controlling access of the incoming oxygen or in favoring or disfavoring formation of a reaction intermediate.

5. Summary

The results summarized in this review of reactions occurring in organized monolayer assemblies indicate that the particular microenvironment provided by the assemblies can often produce major changes in behavior compared to in solution and even other organized media. In view of recent interests in processes occurring in organized media it is particularly instructive to compare and contrast reactivity in monolayers with that occurring in micelles, bilayers, lipid vesicles and microemulsions. While the above examples include some cases where similar effects on reactivity are obtained in different media, there are more often striking differences between monolayers and the other media which can largely be attributed to differences in packing and the degree of molecular organization. Thus in many cases the particular environment produced by a monolayer assembly affords the opportunity for a specific and unique reaction. The examples discussed in this article include some reactive systems where the role of the microenvironment can be quite clearly defined as well as others where precise structure-reactivity relationships remain to be determined. The number of reactions investigated thus far represent only a beginning and it is clear that as more reactions are studied the role of the microenvironment will become sharply defined.

One of the most important future uses of monolayer assemblies will probably be the construction of increasingly more complex functional units in which reactions are mediated through cooperative interaction of the individual components. In this way it should be possible to build model systems of increasing complexity which hopefully will approach the structure and reactivity of biological systems. A number of simple systems such as mixed metal complexes of specific structure appear capable of realization as extensions of some of the present experiments. Certainly an interesting area for future study will be interfacial reactions involving interaction of such functional units with mobile substrates. The relative ease of construction of monolayer assemblies of different molecular architecture suggests that extended studies of interfacial reactions should be useful for the design and development of catalysts. Whether catalyst systems based on monolayers can be developed for practical purposes remains to be seen; certainly the fragility of the layers and the small amounts of material contained in the assemblies provide formidable problems.

The rather striking examples of topological control obtained in the photodimerization reactions suggests that considerable control and prediction of regio- and stereochemistry can be obtained in assemblies, in analogy to the "crystal engineering" proposed for solid state processes. In fact, in many ways the monolayer systems should be perhaps simpler to design and easier to construct than crystal-based systems. The major limitation on synthetic processes employing monolayer films and assemblies is the extremely limited scale of reaction possible with present techniques and equipment.

I am indebted to my co-workers, present and past, at the University of North Carolina, who carried out most of the experiments described in this article and who provided valuable insights into their interpretation. I am also indebted to Professor H. Kuhn and Dr. D. Möbius at the Max Planck Institut für biophysikalische Chemie in Göttingen for valuable discussion and advice in several aspects of this work and to the Alexander-von-Humboldt-Stiftung for a Senior U. S. Scientist Award (1975) which permitted extended collaboration with the Göttingen group.

The Chemistry of Isolated Cations

By Richard D. Bowen, Dudley H. Williams, and Helmut Schwarz[*]

Organic ions decompose in the field-free regions of a mass spectrometer after a relatively well-defined lifetime ($t \approx 10^{-5}$ s). This lifetime is very long compared with the time-scale of molecular bond vibrations and consequently the excess internal energy ("non fixed" energy) present in the transition state for dissociation is comparable with that found in solution experiments. In general, only the energetically most favorable decay routes are able to compete. Moreover, information concerning kinetic energy release (T) accompanying unimolecular decomposition may be obtained from a consideration of the metastable peak for the process; these extremely valuable data are inaccessible to solution experiments because of the effects of collisions. The chemistry of ions may therefore be investigated conveniently by generating the ions of interest in a mass spectrometer and analyzing the reactions which occur in metastable transitions.

1. Introduction

Mass spectrometry has found a wide variety of applications in analytical and organic chemistry. Most of the earlier work performed by organic mass spectroscopists was centered on the fragmentation patterns of ionized organic molecules. The mass spectrometer thus became a powerful tool for structure elucidation[1–5]. The observation of metastable peaks, which were known to arise from the dissociation of ions after acceleration[6], was regarded in some quarters as a nuisance. These metastable peaks sometimes obscure daughter ion peaks and occasionally cause counting problems. However, it later became apparent that because these peaks correspond to an actual dissociation, occurring under relatively well-defined conditions, they contain valuable information concerning the reactions of ions in the gas phase [7–9]. Indeed, it is now evident that an ideal method for investigating the chemistry of isolated cations is to generate the ions in question in a mass spectrometer and document the reactions which occur in the field-free regions[10]. Certain techniques, which may be applied, parallel some of those available to early solution organic chemists; for example, the extents to which various decompositions occur, isotope labeling, and energetic data. On the other hand, further information may be acquired for which there are no counterparts in solution chemistry; for instance, the observation of kinetic energy release accompanying a given dissociation.

In this article, the more important theoretical principles of the approach are discussed and some instructive examples are presented to illustrate the application of the method to study the chemistry of isolated organic cations.

2. Theoretical Principles

2.1. The Mass Spectrometer Time Scale

Figure 1 shows a schematic representation of a conventional mass spectrometer in which ions are transmitted by the electrostatic analyzer (ESA) before entering the magnetic analyzer (MA). The time required for an ion to reach the second field-free region of such an instrument depends on many parameters; however, this time is usually of the order of 10^{-5} s. The frequency of molecular vibrations is approximately 10^{13} to 10^{14} s^{-1}; hence, an ion which decomposes in the second field-free region will have undergone some 10^8—10^9 vibrations. Consequently, there will have been ample time for the available internal energy to fluctuate throughout the ionized molecule, which in turn will have had sufficient time to attain essentially all energetically accessible reacting configurations. Furthermore, because the lifetime of the ion is so long compared to the time scale of bond vibrations, only ions with just enough energy to undergo decomposition will dissociate in the second field-free region. Any ion with a large excess internal energy above that needed to promote dissociation will normally decompose before arriving at the second field-free region. Thus, the decomposition of *metastable* ions in the second field-free region occurs with relatively small excess internal energy ε^+ in the transition state[8a]. Moreover, since there is enough time for essentially all energetically accessible reacting configurations to be sampled, only the lowest energy processes are observed[11]. Precisely analogous arguments apply for ions which dissociate in the first field-free region, or to the decomposition of ions in the field-free regions of mass spectrometers with geometries different from that depicted in Figure 1 (for instance, "reversed geometry" instruments where ions traverse the magnetic analyzer before reaching the electrostatic analyzer).

The observation of primary deuterium isotope effects in the decomposition of many ^{2}H-labeled ions reveals that en-

ergy is indeed the dominant parameter in determining the occurrence or non-occurrence of a given decay route. For instance, the dissociation of all the metastable $CH_nD_{4-n}^{+\cdot}$ ($n=0$—4) ions have been reported[12]; exclusive $H^{\cdot}$ elimination is observed in each case, apart from $CD_4^{+\cdot}$ which is unique in losing $D^{\cdot}$. Large isotope effects are also encountered in the decomposition of other small hydrocarbon ions[13–15]; $CH_3CD_3^{+\cdot}$ eliminates $H^{\cdot}$ and $D^{\cdot}$ in a ratio of *ca.* 600:1[13].

2.2. Kinetic Energy Release (T)

Consider a general reaction, $A^+ \rightarrow B^+ + C$; suppose there is a reverse activation energy, E_r, which is composed of a translational component, E_t, and a vibrational and/or rotational component, E_i (Fig. 2). When A^+ decomposes into B^+ and

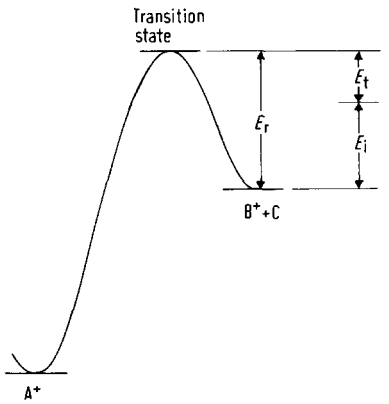

Fig. 2. Energy diagram for dissociation of A^+ into B^+ and C; the associated reverse activation energy, E_r, has a translational component E_t and an internal energy component E_i.

C in solution, collisions between the product molecules and other molecules (chiefly those of the solvent) result in the assimilation of the total energy released (E_r) into the overall Maxwell-Boltzmann energy distribution. It is therefore impossible to differentiate between the translational and vibrational/rotational component of any reverse activation energy owing to the effects of collisions. In contrast, in the absence of collisions (that is, in the gas phase and at low pressures), the occurrence of any translational component in the reverse activation energy will be evidenced by the product molecules B^+ and C repelling each other.

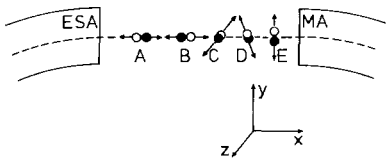

Fig. 3. Dissociation of metastable ions in the second field-free region of a mass spectrometer having the same basic geometry as that depicted in Fig. 1. "Closed" circles denote the daughter ion produced and "open" circles represent the neutral eliminated. A—E, see text.

Figure 3 shows the dissociation of a metastable ion of unit charge and mass m_1 in the second field-free region of a mass spectrometer having the same basic geometry as that depicted in Figure 1. (Similar arguments apply to decompositions taking place in the first field-free region or in the field-free regions of mass spectrometers with other geometries.) A daughter ion of mass m_2 ("closed" circles), together with a neutral species of mass $m_1 - m_2$ ("open" circles), is produced.

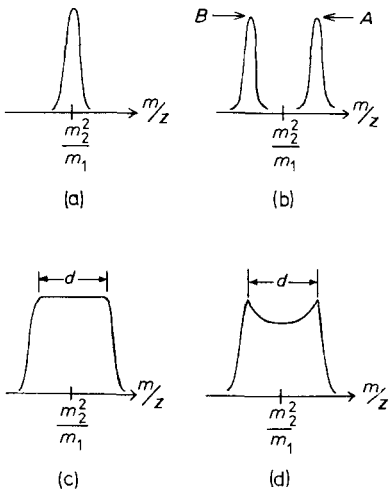

Fig. 4. Second field-free region metastable peaks corresponding to dissociation of ions shown in Fig. 3: a) with no large and specific kinetic energy release; b) with a large and specific kinetic energy release (only components for extreme orientations A and B are given); c) with a large and specific kinetic energy release (overall peak shape); d) with a large and specific kinetic energy release (overall peak shape with discrimination against "C" type ions owing to the finite length of the slits).

If there is no translational contribution to any reverse activation energy ($E_t=0$), there will be little or no kinetic energy release accompanying dissociation. Irrespective of the orientation (A, B, C, D, E, *etc.*) in which decomposition actually occurs, the daughter ion and neutral drift apart and a relatively narrow gaussian metastable peak results, which appears in the normal mass spectrum at an m/z value of m_2^2/m_1[6] (Fig. 4a). Suppose, however, that a relatively large and specific kinetic energy, T, is released upon dissociation. Decompositions occurring in orientation A (Fig. 3) give rise to daughter ions with slightly increased momentum, relative to that if no kinetic energy were released, because the ions thus formed are "pushed along the beam" (x direction). Consequently, these ions possess more momentum than normal ions and are deflected slightly less readily by the magnetic analyzer and so appear at an m/z value marginally higher than m_2^2/m_1. Conversely, dissociations occurring in orientation B result in the ions formed being "pushed back along the beam"; hence; they are deflected slightly more readily by the magnetic analyzer and so appear at an m/z value marginally lower than m_2^2/m_1 (Fig. 4b). Dissociations from intermediate orientations (for example C, D, and E in Fig. 3) also take place, thus giving rise to an "exploding sphere" of ions. The result is a flat-topped metastable peak (Fig. 4c). Mathematical analysis of the problem leads to a simple relationship between the width of the peak d and the kinetic energy release T[16,17]. In some cases, ions which dissociate in an orientation such as C (Fig. 3) are deflected so extensively by the momentum release that they are unable to pass through the slits (which are aligned in length along the z direction). This discrimination, against the transmission of daughter ions formed from decompositions occurring from orientations such as C, arises because of the finite length of the

slits[17] and results in a dish-topped metastable peak as shown in Figure 4d. However, the main point is that a flat-topped or dish-topped metastable peak indicates that a relatively large and discrete kinetic energy T is released upon dissociation. In contrast, a gaussian peak (Fig. 4a) reveals that decomposition takes place without releasing a large and relatively specific quantity of kinetic energy. Nevertheless, a value for the average kinetic energy release, T^{av}, may be computed from the width at half-height of a gaussian metastable peak[18]. This average kinetic energy release is sensitive to the excess internal energy (ε^*) present in the transition state for the dissociation step[8]; the greater the kinetic energy release, the greater the excess energy in the reaction coordinate.

Thus, it is apparent that the shapes of metastable peaks contain valuable information concerning the nature of the kinetic energy release which accompanies unimolecular dissociation of gaseous ions. The metastable peaks themselves comprise a "direct picture" of what happens when decomposition occurs. This is a unique advantage of conducting the experiments in the absence of interactions with other molecules.

2.3. Competing Reactions

Just as early organic chemists obtained structural information by degrading the compound of interest, so the actual dissociations undergone by organic ions in the gas-phase may be used to make deductions about the structure of the ion in question. Moreover, when ions undergo more than one dissociation, the approximate relative abundances of these decomposition channels may be easily obtained from the sizes of the corresponding metastable peaks. It may generally be assumed that these decay routes are available to each ion and that there is direct competition between the various channels on an energetic basis. This model takes no account of the possibility of the occurrence of isolated electronic states which could in principle interfere by preventing the competition between all possible dissociations or by giving rise to fast reactions. There are definite examples of the interference of isolated electronic states[8b,19]; however, these appear to be the exception rather than the rule. In the absence of such interference, the extent to which the competing decompositions occur may be used to determine the relative heights of the energy barriers towards interconversion and dissociation of two or more isomeric structures. Three general cases may be envisaged; these are shown in Figure 5.

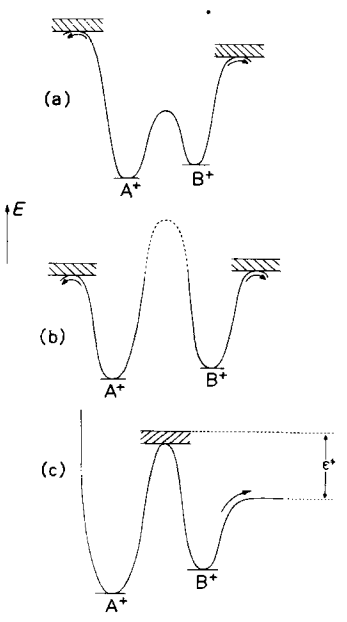

Fig. 5. Potential energy profiles corresponding to a) *complete* interconversion of A^+ and B^+ prior to dissociation; b) *no* interconversion of A^+ and B^+ prior to dissociation; and c) rate-determining isomerization of A^+ to B^+ prior to dissociation (arrows signify dissociation).

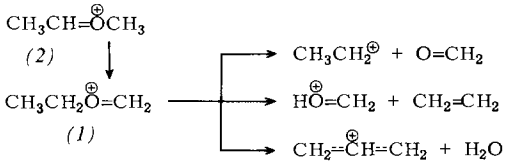
In Figure 5a the energy needed to cause dissociation of either ion, A^+ or B^+, is greater than that required to promote interconversion of the two isomers. Consequently, these ions undergo rapid and reversible isomerization *prior* to decomposition, from a common structure or mixture of structures, through the same transition states. An important historical example is the behavior of the carbenium ion, $C_6H_{13}^+$ [eq. (a)]. Irrespective of whether the incipient cation in the precursor has a primary, secondary, or tertiary structure, elimination of C_2H_4 and C_3H_6 is always observed in the same ratio (*ca.* 1:1.6)[11]. Other members of the $C_nH_{2n+1}^+$ homologous series of ions behave similarly[20] as do many other carbenium ions of varying degrees of unsaturation (for example $C_nH_{2n-1}^+$[21,22] and $C_nH_{2n-3}^+$[21,23,24]).

prim., sec., or tert. $C_6H_{13}X$

$$\downarrow \longrightarrow C_4H_9^{\oplus} + C_2H_4\ (\approx 40\%)$$
$$C_6H_{13}^{\oplus} \qquad\qquad (a)$$
$$\longrightarrow C_3H_7^{\oplus} + C_3H_6\ (\approx 60\%)$$

The potential energy profile of Figure 5b represents the opposite situation; here the energy needed to decompose either A^+ or B^+ is *less* than that required to bring about interconversion. In this case, A^+ and B^+ undergo different dissociations, through different transition states, in preference to equilibrating with each other. There are many examples of this behavior; a system of early importance is $C_2H_5O^+$, where two distinct classes of ions are observed[25]. Those of the first class are derived from precursors of general formula CH_3OCH_2X and presumably have the structure $CH_3\overset{+}{O}{=}CH_2$. These ions undergo essentially exclusive loss of CH_4. In contrast, the second group of $C_2H_5O^+$ ions loses C_2H_2 and CH_4 in an approximately constant ratio (1.9:1). These ions, which are formed from precursors containing a carbon-carbon bond (for instance CH_3CHXOH or XCH_2CH_2OH), probably comprise an interconverting mixture of $CH_3CH{=}\overset{+}{O}H$ and $\overline{CH_2CH_2}OH^+$. The overall potential energy diagram is extremely instructive (see Section 3.1).

The third possibility, that of Figure 5c, corresponds to a situation in which dissociation is energetically more favorable than isomerization for one ion, B^+, but not for the other, A^+. Thus, B^+ decomposes in preference to rearranging to A^+; however, starting from A^+, the lowest energy decay channel is isomerization to B^+[26]. The ion B^+, formed in this way, contains more internal energy than is needed to promote dissociation which therefore occurs relatively rapidly, with excess internal energy (ε^*) in the transition state for the final step. This excess energy may be partitioned in part as translation, hence causing an increase in the kinetic energy release associated with dissociation. Therefore, if A^+



and B^+ undergo any common decompositions, the kinetic energy release should be greater starting from A^+ than from B^+. The excess energy $\varepsilon^{\ddagger}$, present in the transition states when rearranged ions of original structure A^+ decompose, also causes a discrimination against any decay route of B^+ which has a stringent geometric requirement. This is because the rate-determining step (RDS) in decomposition of A^+ is rearrangement to B^+; after the rearrangement, energy ceases to be the dominant parameter in determining the occurrence of possible dissociation channels. Instead, the controlling factor is how fast a particular dissociation may occur given the amount of excess energy available. Consequently, since simple-bond cleavages may generally proceed *via* less ordered transition states than rearrangement processes, especially when the latter must involve a cyclic geometry, these reactions are likely to be favored starting from A^+. In contrast, energy remains the most important consideration for dissociation of ions generated originally as B^+. These ions do not therefore exhibit the discrimination against dissociation routes involving considerable rearrangements; indeed, such rearrangements are expected to occur to a considerable extent provided they are the lowest energy decay channels.

An example of this behavior is furnished by the isomeric $C_3H_7O^+$ ions *(1)* and *(2)* (Scheme 1)[26]. Starting from *(1)*, elimination of H_2O is the main reaction, accompanied by a small amount of C_2H_4 loss. These are the energetically most favorable decay channels; it is significant that H_2O loss is the dominant process, even though it must involve extensive rearrangement, because it has the lowest overall activation energy (Table 1). Loss of CH_2O from *(1)* is not observed, even though it may occur *via* simple cleavage of the C—O single bond, because it requires too much energy and is preempted by H_2O and C_2H_4 elimination.

Table 1. Relative abundances, average kinetic energy T^{av}, and thermochemical data for dissociation of isomeric $C_3H_7O^+$ ions *(1)* and *(2)*.

Products and ΔH_f [kcal mol^{-1}]		$\sum\Delta H_f$ [kcal mol^{-1}]	Abundance [a]		T^{av}[b] [kcal mol^{-1}]		Transition state energy [c] [kcal mol^{-1}]	
			(1)	*(2)*	*(1)*	*(2)*	*(1)*	*(2)*

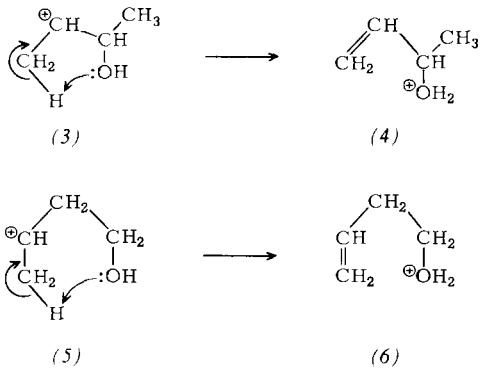
219 [30]	− 28 [28]	191	0	12	—	—	—	212

[a] Measured by metastable peak area for dissociations occurring in the second field-free region and normalized to a total of 100 units [26]. [b] Measured from first field-free region metastable peak widths [26]. [c] Obtained from appearance potential measurements on metastable ions dissociating in the first field-free region [26].

Scheme 1

In contrast, starting from *(2)*, H_2O loss becomes only a very minor process; the main dissociation is now C_2H_4 loss and, moreover, CH_2O is also eliminated to a significant extent. This suggests that *(2)* undergoes rate-determining rearrangement to *(1)* which then dissociates relatively rapidly. Consequently, there is discrimination against H_2O loss which requires extensive rearrangement after the rate-determining step; C_2H_4 and CH_2O losses, which may proceed without much rearrangement, are therefore the main dissociations of *(2)* because they can occur faster. Further evidence in favor of this rate-determining rearrangement stems from the kinetic energy release associated with H_2O and C_2H_4 losses from *(1)* and *(2)*. In each case, a greater average kinetic energy accompanies decomposition of *(2)* (Table 1); this is consistent with *(2)* dissociating through the same transition states as *(1)* but with a greater excess energy. Finally the measured activation energies for H_2O and C_2H_4 losses from *(1)* are different; as expected from the preferential elimination of H_2O from *(1)*, this process has the lower transition state energy (Table 1). In contrast, starting from *(2)*, H_2O and C_2H_4 eliminations require the same energy, which now reflects only the height of the energy barrier towards rearrangement to *(1)*. Furthermore, this energy is greater than that needed to dissociate *(2)* and is more than enough to cause CH_2O loss which is no longer precluded for energetic reasons.



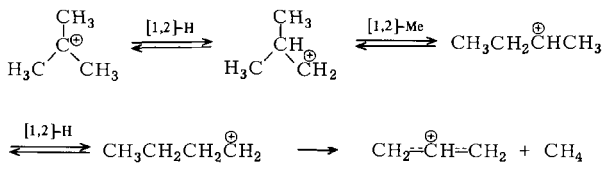
The above examples serve to give a brief illustration of how the unimolecular reactions of isolated organic ions may be interpreted in terms of a potential energy profile approach[10]. The three basic types of potential energy profiles (Fig. 5) described above may be combined to produce more complex energy profiles. Before giving examples of these more sophisticated energy diagrams (Section 3), it is instructive to examine some of the other methods which are available to investigate the structures and reactivities of organic ions in the gas phase.

2.4. Energetics

The use of energetic data and energy measurements in constructing potential energy profiles is in many ways self-evident; some of these uses may be seen from the analysis of the two $C_3H_7O^+$ isomers, *(1)* and *(2)*, discussed above. When accurate values for the heats of formation of all relevant species are known, these data may be used, in conjunction with the organic chemist's concept of reaction mechanism, to produce a complete energy level diagram for the system. This procedure frequently explains the reactions of previously investigated ions and is often of predictive use[10, 20, 22, 24, 31–35].

However, it is comparatively rare that reliable thermochemical data are available for all the species of interest; in such cases appearance potential measurements may be made, or, alternatively, recourse may be made to quantum mechanical calculations or estimation techniques. The disadvantage of the former is that, unless specialized mass spectrometers are employed, it may result in unreliable results owing to systematic errors in analyzing the data[36,37]. Nevertheless, it ought to be possible to detect large differences in transition state energies in this way. The problem with calculated or estimated heats of formation is that these values may easily be in error and, moreover, it is preferable to use experimental values whenever possible. Notwithstanding this, when the data are inaccessible to experimental methods, calculated[38] or estimated values must be used; the latter are often obtained from results for lower homologues by means of a group equivalent approach[39], or from isodesmic[40] substitutions[40,41].

It is frequently also necessary to estimate the energy required to cause an isomerization to occur. For example, the occurrence of 1,2-hydride or alkyl shifts is commonly postulated in the reactions of organic ions. Solution NMR experiments show that these reactions usually occur with activation energies close to the enthalpy differences involved[42]; quantum mechanical calculations suggest that a similar situation prevails in the gas phase[38]. Hence, it is reasonable to assume that these symmetry-allowed[43] rearrangements may occur without significant energy barriers other than those associated with the inherent difference in stability of the ions concerned. In contrast, 1,3-hydride shifts occurring in even electron cations [in a four-electron system, *e. g. (2)→(1)*] appear in some cases to involve very large energy barriers[26]; presumably these energy barriers originate from the symmetry-forbidden nature of the reactions. An intermediate position is occupied by hydrogen transfer occurring through five and six-membered ring transition states (Scheme 2). An activation energy of *ca.* 10 kcal mol^{-1} is required to cause the rearrangement *(3)→(4)*; however, *(5)→(6)* has an essentially negligible activation energy[34]. Similar conclusions may be reached in analogous[35] or homologous systems[33].



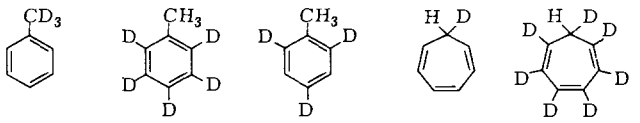
Scheme 2

Fortunately, the range of ions for which accurate heats of formation are available is increasing. Reliable values are known for numerous hydrocarbon cations and radical cations[27,28b,30,44-48], and a selection of oxonium ions $C_nH_{2n+1}O^+$[29,49]. More recently, proton affinity measurements have provided a wealth of new information; this method, which generates gaseous ions under equilibrium conditions, is relatively accurate and potentially very extensive in scope[50-54].

2.5. Isotope Labeling

There are two main uses of stable isotopes in elucidating the reactions undergone by organic ions in the gas phase.

a) The loss of identity of labeled ions may furnish information as to which atoms in the ions may become equivalent, *via* reversible rearrangement processes, prior to decomposition. Suppose two ions may interconvert *via* a series of 1,2-hydride shifts; if all the hydrogen atoms in the molecule are able to participate in these shifts at some stage, then the rapid interconversion of the two ions leads to loss of identity of all the hydrogen atoms. When dissociation eventually takes place, any of the hydrogen atoms may therefore be eliminated even through the actual decomposition channel may involve the selection of a hydrogen atom attached to a specific site. This effect is common and is sometimes referred to as "scrambling" or "randomization" of the label. These expressions are potentially misleading because they may be construed to mean that the chemistry of the system is not understood. Moreover, the observation of random selection of atoms from labeled ions is occasionally taken to mean that the decomposition pathway must involve a symmetrical intermediate in which all the relevant atoms are equivalent. This is not necessarily the case; in some systems it is the equilibration of isomeric structures which leads to loss of identity of atoms in labeled species. Consider the case of the isomeric cations $C_4H_9^+$; these may be considered to interconvert *via* the series of 1,2-hydride and methyl shifts shown in Scheme 3. The heats of formation of each of the four "classical" isomers are known and dissociation to allyl cation and CH_4 requires more energy than interconversion. Hence, these ions are expected to equilibrate prior to decomposition. This is confirmed by experiment: irrespective of the precursor used to generate $C_4H_9^+$, CH_4 loss and a constant minor percentage of C_2H_4 loss are observed[55a]. Furthermore, the interconversion of the four isomers permits the hydrogen and carbon atoms to sample each possible site in each structure. Therefore the observed random elimination of methane[55] from ^2H- and ^{13}C-labeled analogues of $C_4H_9^+$ may be explained without postulating the existence of any symmetrical intermediate.



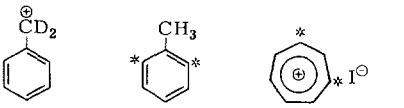
Scheme 3

There are many examples of this behavior[56-60]; the important point is that labeling may be used to discover which atoms in a given ion are able to exchange sites *via* isomerization processes that precede decomposition.

b) The observation of isotope effects in the decomposition of labeled ions may yield information concerning which bond (or which kind of bond) is broken in the rate-determin-

ing step. Thus, the large isotope effects which occur in hydrogen radical loss from some small hydrocarbon ions mentioned previously indicate that the cleavage of a C—H (or C—D) bond is indeed the rate-determining step for dissociation[12–15].

These isotope effects are frequently encountered in the unimolecular chemistry of organic ions in the gas phase; often an isotope effect is superimposed upon statistical selection of some (or all) of the atoms needed to make up the neutral which is eliminated. For example, the competition between $H^{\cdot}$ and $D^{\cdot}$ loss from the molecular ions of the ^{2}H-labeled toluenes, *(7)*—*(9)*, may be interpreted in terms of loss of any of the original H or D atoms together with an isotope effect of 2.8:1[61] or 3.5:1[62] favoring $H^{\cdot}$ loss. (The slight discrepancy between the magnitude of the isotope effects found in the two studies may be ascribed to a slight difference in ion lifetimes and hence average internal energies[62].) Similar behavior is observed for the radical cations of the ^{2}H-labeled cycloheptatrienes *(10)* and *(11)*[61]; this is consistent with interconversion of ionized toluene and cycloheptatriene prior to decomposition.



(7) *(8)* *(9)* *(10)* *(11)*

2.6. Collisional Activation (CA) and Ion Cyclotron Resonance (ICR)

These two techniques facilitate the detection of any ion structure which exists in a significant potential energy well. Collisional activation (CA) is the more commonly employed and has now become a routine method for investigating the structures of isolated non-decomposing ions[63]. A detailed discussion of CA is beyond the scope of this article; however, the basis of the method is to allow accelerated ions of low internal energy, which have not dissociated even after some 10^8 vibrations, to collide with an "inert" gas. These inelastic collisions cause excitation of the ions which acquire sufficient internal energy to undergo relatively fast dissociations. Since there is not usually enough time for extensive interconversion of isomeric ions to occur after collision, if two ions formed from different precursors exhibit the same CA spectra then they must have interconverted before collision ("fingerprint" criterion). Conversely, when isomeric ions have different CA spectra, this indicates that there is a fairly substantial energy barrier towards their interconversion. A difference in the CA spectra of two ions does not however preclude the equilibration of these ions at energies appropriate to slow unimolecular decompositions. This is because the energy barriers towards isomerization of the two ions may be less than those for dissociation but nevertheless sufficiently large to cause appreciable differences in the CA spectra.

Consider, for instance, the long-standing "benzyl *versus* tropylium" controversy; several $C_7H_7^+$ species with different CA spectra are observed[64]. The observation that $C_7H_5D_2^+$ ions of nominal structure *(12)* eliminate CD_2 in CA spectroscopy proves that such low energy ions do not collapse to tropylium structures.

Moreover, ICR experiments reveal the existence of two distinct $C_7H_7^+$ populations (presumably benzyl and tropylium cations) which exhibit different behavior in their ion/molecule reactions in the gas phase[65]. These data constitute strong evidence that both benzyl and tropylium cations exist in significant potential energy wells in the gas phase.

(12) *(13)*, * = ^{13}C *(14)*, * = ^{13}C

Notwithstanding this, higher energy ions, which decompose in the ion source or field-free regions, appear to interconvert between benzyl and tropylium structures before dissociation takes place[66–69]. For example, the molecular ion of [2,6-$^{13}C_2$]-toluene *(13)* fragments to form some unlabeled $C_5H_5^+$ and some $^{13}C_2H_2$. This cannot be interpreted in terms of dissociation of ionized *(13)* without prior rearrangement, nor by collapse to a tropylium-like structure which then decomposes without further isomerization. Similar behavior is observed for the cation of the tropylium salt *(14)*[68].

2.7. Predictive Capacity

Some of the more important methods which may be applied to study the chemistry of isolated organic ions are discussed above. The data furnished by these experimental methods may be used to construct a potential energy profile over which the ions under investigation may be considered to react. These potential energy profiles may frequently be used to explain the reactions of organic ions (having lifetimes $\geq 10^{-5}$ s) in the gas phase. In some instances, apparently inexplicable behavior may be easily understood in terms of this model[33,34]. Furthermore, when the necessary thermochemical information is available, it is possible to predict successfully the reactions undergone by previously uninvestigated ions[20,22,24,33,35]; these predictions are potentially extensive in scope. The test of all scientific theories lies in their capacity to formulate predictions in cases for which no results are known. In this respect, the potential energy profile approach has proved remarkably successful.

A few cogent examples of the application of the approach to rationalize or predict the slow reactions of gaseous ions are given below.

3. Examples of Potential Energy Profiles

3.1. The Ions $C_2H_5O^+$

The relative abundances of competing slow dissociations of isomeric $C_2H_5O^+$ ions and the kinetic energy release associated with these reactions are given in Table 2.

It is clear from the data of Table 2 that at least two distinct populations of ions, which do not interconvert appreciably at energies appropriate to slow reactions, are being formed. First, precursors of general formula CH_3OCH_2X produce $C_2H_5O^+$ ions (presumably with the $CH_3\dot{O}H{=}CH_2$ structure) which exclusively undergo CH_4 loss. In contrast, ions generated from other precursors (these ions are probably an inter-

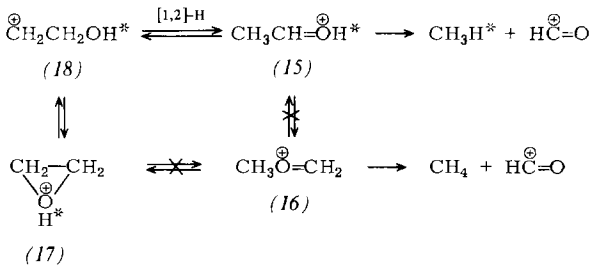


Table 2. Observed decompositions of some $C_2H_5O^+$ ions (data from ref. [25]).

Precursor	Ratio of C_2H_2 loss to CH_4 loss	T values for CH_4 loss [kcal mol^{-1}]
CH_3OCH_2X	0.01:1	<3 [a]
$HOCH_2CH_2X$	(1.8±0.2):1	11.5±0.9 [b]
CH_3CHXOH	(1.9±0.1):1	10.1±0.5 [b]

converting mixture of $CH_3\overset{\oplus}{C}H{=}\dot{O}H$ and $\overset{\oplus}{C}H_2CH_2\dot{O}H$) lose C_2H_2 and CH_4 in the ratio of approximately 1.9:1. Moreover, CH_4 loss from the two classes of ions is evidenced by metastable peaks of completely different shapes. Elimination of CH_4 from $CH_3\dot{O}{=}CH_2$ gives rise to a gaussian metastable peak whereas the other type of ions lose CH_4 with a large and relatively specific kinetic energy release as shown by the dish-topped metastable peak for this process[25]. Furthermore, the measured transition state energies for the two separate CH_4 loss channels, although only approximate, are widely different[70]. Finally, ^{2}H-labeling studies reveal that CH_4 loss from $CH_3\dot{O}{=}CH_2$ proceeds with random selection of any of the original five hydrogen atoms[26,70]. In contrast, CH_4 loss from ions generated as $CH_3CH{=}\dot{O}H$ involves specific elimination of the hydrogen atom originally bound to oxygen, which does not lose its identity to a significant extent, together with any three of the four carbon-bound hydrogen atoms[58,60].

These data constitute conclusive evidence that $CH_3\dot{O}{=}CH_2$ reacts over a potential energy profile which is distinct from that over which $CH_3CH{=}\overset{\oplus}{O}H$ and $\overset{\oplus}{C}H_2CH_2\dot{O}H$ interconvert and dissociate. The potential energy profile of Figure 6 may be constructed using known[28,29,49,71,72] and estimated[41] heats of formation. The observed interconversion of $CH_3CH{=}\overset{\oplus}{O}H$ *(15)* and $\overset{\oplus}{C}H_2CH_2\dot{O}H$ *(17)* prior to dissociation may be understood because these ions may isomerize, *via* $^+CH_2CH_2OH$, at a lower energy than is needed to cause decomposition. Scheme 4 also explains why all the carbon-bound hydrogen atoms and both carbon atoms of *(15)* become equivalent prior to CH_4 loss[58–60] whereas the hydrogen atom attached to oxygen retains its identity[70]. Rapid interconversion of *(15)* and *(17)*, *via (18)*, results in random distribution of carbon-bound hydrogen atoms and both carbon atoms but allows the hydrogen atom bound to oxygen to remain distinct.

Scheme 4

However, rearrangement of *(15)* or *(17)* to *(16)*, or *vice versa*, requires more energy than elimination of CH_4; this is because some very high energy species, such as the diradical $\dot{C}H_2\dot{O}H\dot{C}H_2$, must be involved. Consequently, *(16)* dissociates over a separate potential energy profile from *(15)* and *(17)*. Moreover, C_2H_2 loss can plausibly occur only from

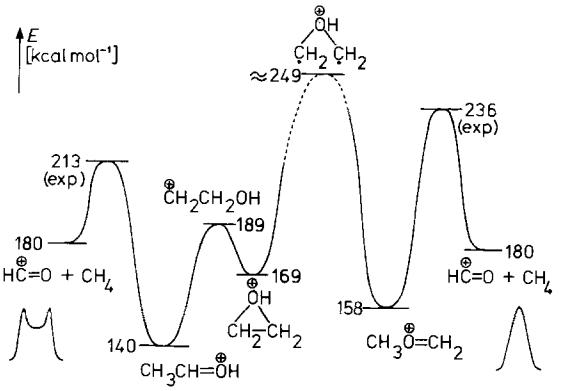

Fig. 6. Potential energy profile for CH_4 loss from the $C_2H_5O^+$ isomers $CH_3CH{=}\dot{O}H$ *(15)* and $CH_3\dot{O}{=}CH_2$ *(16)*; metastable peaks associated with dissociation of *(15)* and *(16)*.

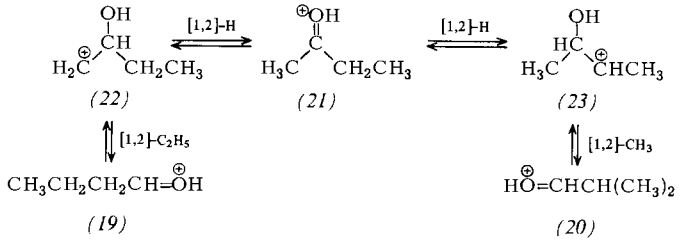
some structure of $C_2H_5O^+$ in which the two carbon atoms are directly linked, such as $CH_2{=}CH\dot{O}H_2$. This type of ion is really only accessible *via (15)*, *(17)*, or *(18)*; hence, the non-occurrence of C_2H_2 loss from *(16)* may be rationalized because this ion prefers to eliminate CH_4[70].

3.2. The Ions $C_4H_9O^+$



It is also instructive to consider the behavior of three isomers of $C_4H_9O^+$, which is a higher homologue of $C_2H_5O^+$. Relevant data concerning the decomposition of these ions, which are all protonated aldehydes or ketones, are given in Table 3.

Table 3. Observed decompositions of some isomers of $C_4H_9O^+$ *(19)*—*(21)* (data from ref. [73]).

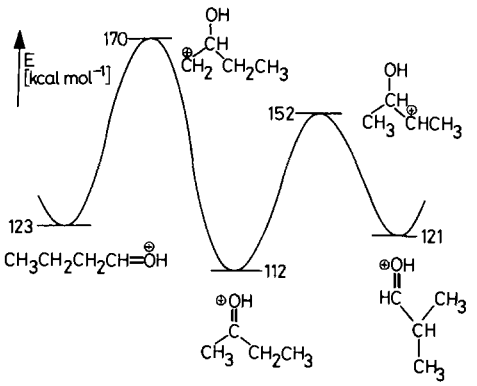
Ion		Neutral lost [a] H_2O	C_2H_4	CH_2O
$CH_3CH_2CH_2CH{=}\dot{O}H$	*(19)*	99	1	0
$(CH_3)_2CHCH{=}\dot{O}H$	*(20)*	90	3	7
$CH_3CH_2(CH_3)C{=}\dot{O}H$	*(21)*	89	3	8

[a] Abundances normalized to a total of 100 units.

The data shown in Table 3 reveal that *(20)* and *(21)* interconvert prior to dissociation but *(19)* reacts over a separate potential energy profile. This conclusion is further strengthened by a consideration of the kinetic energy release which accompanies dissociation, the energy required to promote decomposition, and the results of ^{2}H-labeling[34,73]. It seems rather strange at first sight that protonated butanone *(21)* should interconvert with protonated isobutyraldehyde *(20)* but not with protonated *n*-butyraldehyde *(19)* prior to decomposition. However, when the mechanism whereby *(19)*, *(20)*, and *(21)* may interconvert is considered (Scheme 5) this apparent anomaly may be readily explained.

Scheme 5

Clearly *(20)* and *(21)* may interconvert *via* the *secondary* carbenium ion *(23)*; in contrast, *(21)* may only rearrange to *(19) via* the *primary* carbenium ion *(22)*. Starting from *(21)*, rearrangement to *(20)* is therefore energetically more favorable than isomerization to *(19)*; the relevant potential energy profile, constructed using known[53] or estimated[41] heats of formation, is depicted in Figure 7[34]. Analysis of the potential energy profiles over which *(19)*, *(20)*, and *(21)* may actually dissociate, reveals that decomposition of *(20)* and *(21)* requires more energy than interconversion of the two but less energy than rearrangement to *(19)*. Hence, *(20)* and *(21)* equilibrate prior to dissociation but do not rearrange to *(19)*. Starting from *(19)*, decomposition is energetically more favorable than isomerization to *(20)* and *(21)*; therefore, *(19)* dissociates without rearranging to *(20)* or *(21)*. Similar behavior is observed for the nitrogen analogues of *(19)*, *(20)*, and *(21)*[35].



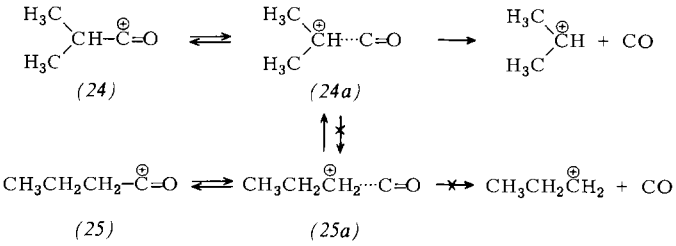


Fig. 7. Potential energy profile for isomerization of the $C_4H_9O^+$ isomers $CH_3CH_2CH_2CH{=}\dot{O}H$ *(19)*, $CH_3CH_2(CH_3)C{=}\dot{O}H$ *(21)*, and $(CH_3)_2CHCH{=}\dot{O}H$ *(20)*.

3.3. Carbenium Ion Rearrangements

The rearrangement of carbenium ions has often intrigued organic chemists. In most simple cases, small hydrocarbon ions undergo facile isomerizations before decomposition occurs in the gas phase[20-24,55-57]. It would clearly be of interest if these isomerizations could be observed *directly*. In the gas phase, this may be done by generating the ion of interest bound to a suitable leaving group which effectively serves to protect the ion from rearrangement until dissociation actually begins to take place. A convenient leaving group is CO and the case where this group is attached to the two isomeric propyl cations is considered in Scheme 6.

Starting from *(24)*, simple bond breaking may proceed to the energetically most favorable products, $i\text{-}C_3H_7^+$ and CO, without rearrangement. This reaction channel may plausibly involve a negligible reverse activation energy and thus *(24)* → products is probably continuously endothermic. The metastable peak for this dissociation is very narrow correspond-

Scheme 6

ing to an average kinetic energy release of only 0.2 kcal mol^{-1}[74]. On the other hand, the corresponding process in *(25)* results in the formation of the energetically unfavorable *n*-propyl cation. Although such a reaction would probably proceed without appreciable reverse activation energy, it can be pre-empted by isomerization of the incipient *n*-propyl cation and subsequent formation of $i\text{-}C_3H_7^+$ and CO. This rearrangement of the incipient *n*-propyl cation to the thermochemically more stable isopropyl cation [*(25a)*→*(24a)*] releases approximately 18 kcal mol^{-1} of potential energy[30] which then causes rapid dissociation to form $i\text{-}C_3H_7^+$ and CO. The corresponding metastable peak is broadened owing to the conversion of part of the liberated potential energy into kinetic energy release accompanying CO loss[26,74]. The average kinetic energy released when *(25)* eliminates CO is 2.0 kcal mol^{-1}, essentially an order of magnitude greater than that accompanying CO loss from *(24)*. The metastable peaks for these processes are depicted in Figure 8; the broad peak for CO loss from *(25)* may be taken as diagnostic evidence that the incipient carbenium ion undergoes an exo-

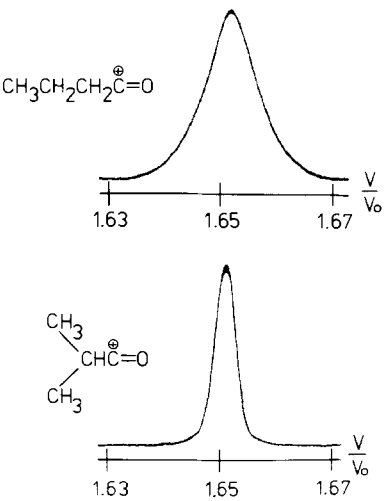

Fig. 8. First field-free region metastable peaks for CO elimination from $CH_3CH_2CH_2^+CO$ *(25)* and $(CH_3)_2CH^+CO$ *(24)*. The abscissae are in units of V/V_0 where V_0 is the accelerating voltage employed to transmit the main beam and V is the corresponding voltage required to transmit $C_3H_7^+$ ions formed in the first field-free region.

thermic isomerization before CO loss occurs. Indeed, appearance potential measurements establish that CO loss from *(25)* requires less energy than that needed to produce an *n*-propyl cation together with CO. Similar effects are observed when CO is lost from higher homologues of *(24)* and *(25)*; in

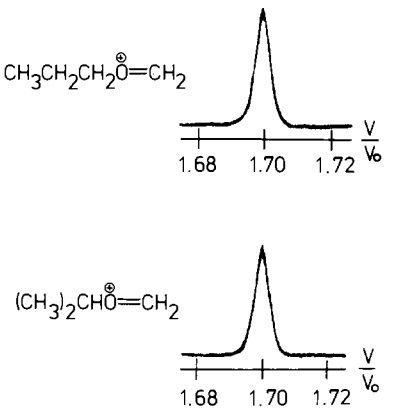

Fig. 9. First field-free region metastable peaks for CH_2O elimination from $CH_3CH_2CH_2\dot{O}{=}CH_2$ *(27)* and $(CH_3)_2CH\dot{O}{=}CH_2$ *(26)* (the abscissae have a similar significance to those in Fig. 8).

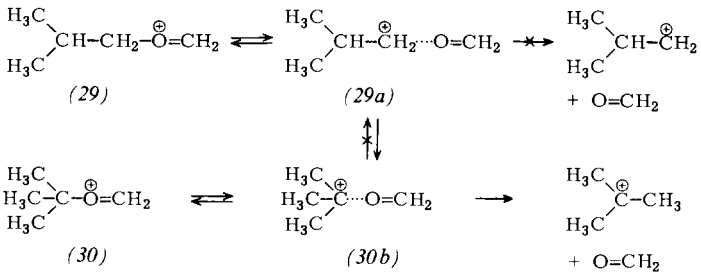
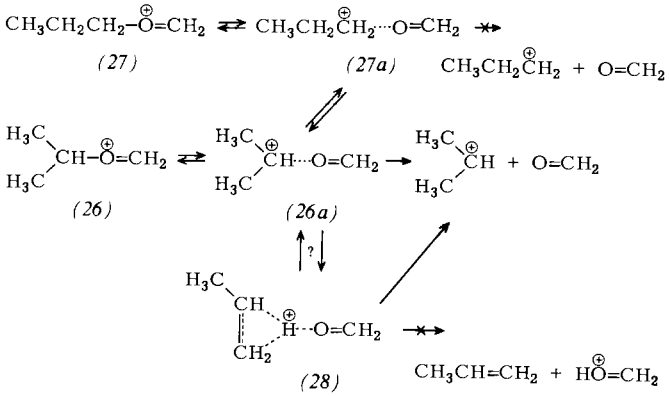


general, incipient primary carbenium ions rearrange to thermochemically more stable isomers prior to dissociation, as evidenced by the broader metastable peaks for these processes. This behavior also occurs when leaving groups other than CO are employed, for example loss of Br• from ionized alkyl halides[74]. It is usually found that any incipient cation which would not be expected to exist in a potential energy well undergoes rearrangement to a more stable structure (or structures)[74,75]. In contrast, narrow peaks, thus indicating the absence of rearrangement in the potential cation, are generally found for cases where the relevant cation ought to be in a potential energy well (that is, tertiary and most secondary alkyl carbenium ions). The kinetic energy release accompanying dissociation of cations bound to suitable leaving groups may therefore be used to investigate which of a set of isomeric ions exist in potential energy wells. This method is frequently a useful complementary probe to CA spectroscopy[75].

When the CO leaving group in *(24)* and *(25)* is replaced by CH_2O, however, identical metastable peaks are observed starting from either $C_4H_9O^+$ ion with *n*- or isopropyl groups [*(27)* and *(26)*, respectively] (Fig. 9). These data, together with conclusions from more detailed investigations of *(26)* and *(27)*[73,76], show that reversible rearrangement of the incipient $C_3H_7^+$ ion may occur prior to CH_2O loss (Scheme 7). In particular, energy measurements reveal that CH_2O loss from *(26)* and *(27)* requires essentially the same energy in each case and this energy corresponds almost exactly to that expected if *i*-$C_3H_7^+$ and CH_2O were the products[76].



The most likely explanation of this striking change in behavior, relative to *(24)* and *(25)* where rate-determining rearrangements are observed, is that *(26a)* and *(27a)* are stabilized by a sizeable ion-dipole interaction[77]. The magnitude of this stabilization can theoretically be as great as 18 kcal mol^{-1} even when the C···O bonds of *(26a)* and *(27a)* are sufficiently stretched (to a length of 3 Å) that the covalent bonds are essentially broken. Experimental evidence is also available which supports an ion-dipole stabilization of similar size in higher homologues of *(26a)* and *(27a)*[78]. This stabilization of *(26a)* and *(27a)* is greater than (or equal to) the energy released when a primary carbenium ion isomerizes to a secondary carbenium ion. Hence, when *(27)* rearranges to *(26a)*, *via (27a)*, the combination of isopropyl cation and CH_2O is still sufficiently stable to avoid rapid dissociation. Interconversion of *(26)* and *(27)* may thus occur prior to CH_2O loss.

The ion dipole stabilization of *(26a)* and *(27a)* arises because CH_2O has a fairly large permanent electric dipole[79]. In contrast, CO and Br• have negligible or zero electric dipoles; hence, rate-determining rearrangements of the incipient *n*-propyl cation occurs in these cases[74].

However, the rearrangement of an incipient primary carbenium ion to a tertiary isomer would release approximately 32 kcal mol^{-1}[30]. This should be more than enough to overcome the attractive ion-dipole interaction, thus resulting in a relatively large kinetic energy release. This is found to be the case for incipient butyl cations having tertiary and iso structures (Scheme 8). As expected, the metastable peak for CH_2O loss from *(29)* is much broader than that starting from *(30)* (Fig. 10).

Scheme 8

Scheme 7

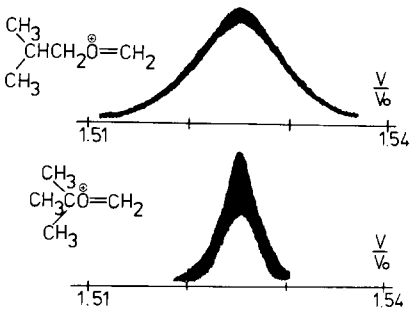


Fig. 10. First field-free region metastable peaks for CH_2O elimination from $(CH_3)_2CHCH_2\dot{O}{=}CH_2$ *(29)* and $(CH_3)_3C\dot{O}{=}CH_2$ *(30)* (the abscissae have a similar significance to those in Fig. 8).

A final point in connection with the isomerization and dissociation of *(26)* and *(27)* and homologous ions is that rearrangement of *(26a)* or *(27a)* to *(28)* might take place. This species is effectively a complex in which C_3H_6 and CH_2O are bound to a common proton. Breakdown of *(28)* may then occur so that the neutral having the greater proton affinity keeps the proton. This mechanism may be used to explain, or predict successfully, the decomposition of numerous oxonium ions, related to *(26)* or *(27)*, *via* loss of olefins or carbonyl compounds. [In *(28)*, this corresponds to the formation of $i\text{-}C_3H_7^+/CH_2O$ rather than $CH_3CH{=}CH_2/H\overset{+}{O}{=}CH_2$[77].]

3.4. The Concept of a Hierarchy of Reactions in Homologous Ions

When the dissociations undergone by members of a homologous series of ions are compared, it is frequently found that the decay routes observed for lower members of the series are pre-empted by energetically more favorable processes for higher ions. Thus, for example, H_2 loss is a common decomposition channel for many small hydrocarbon ions; however, a significant amount of H_2 loss is rarely observed for larger homologous ions[20-24,31]. This effect arises because, as more CH_2 residues are inserted into the first member of the series, new dissociation pathways are opened up which require less energy. An example of this behavior is given in Table 4 which lists the energies required to cause decomposition of the first four members of the homologous series of protonated aldehydes, $C_nH_{2n+1}O^+$. The first member of the series, protonated formaldehyde, eliminates H_2 with an activation energy of 80 kcal mol^{-1}. However, energetically less demanding pathways are available for the next homologue, protonated acetaldehyde, which does not eliminate a significant amount of H_2 in slow reactions. These processes, loss of CH_4 and C_2H_2, are themselves pre-empted for protonated propionaldehyde which requires much less energy to eliminate H_2O and C_2H_4 than is needed to dissociate the lower homologues. Another substantial drop in the activation energy needed to cause the most facile dissociation is found in progressing to protonated *n*-butyraldehyde. It may be noted in passing that H_2O loss from protonated *n*-butyraldehyde is a different process from H_2O loss from protonated propionaldehyde because it is characterized by a different kinetic energy release[34,81].

Table 4. Activation energies for dissociation of some $C_nH_{2n+1}O^+$ ions.

Ion	Neutral lost	Act. energy [kcal mol^{-1}]
$CH_2{=}\dot{O}H$	H_2	80 [80]
$CH_3CH{=}\dot{O}H$ *(15)*	CH_4	73 [70]
	C_2H_2	73 [70]
$CH_3CH_2CH{=}\dot{O}H$	H_2O	42 [81]
	C_2H_4	48 [81]
$CH_3CH_2CH_2CH{=}\dot{O}H$ *(19)*	H_2O	27 [34]

4. Conclusion

The theoretical principles and examples of potential energy profiles discussed above serve to illustrate how the slow unimolecular reactions ($k \approx 10^5\ s^{-1}$) of gaseous organic ions may be investigated using a mass spectrometer. A major advantage associated with conducting the experiments in the absence of collisions is that information concerning the kinetic energy release accompanying dissociation is directly accessible from the shape of the corresponding metastable peak. *These metastable peaks constitute a "direct picture" of what happens when decomposition takes place.* In common with solution chemistry, the rate-determining step in dissociation is not always the final step but may be a slow prior isomerization which is then followed by relatively rapid decomposition. In such cases, a broadening of the metastable peak is observed; numerous examples of this behavior have been reported recently and it would appear to be a fairly general phenomenon[26,33 35,70,74 78,81,82].

The precise definition of those structures of carbenium ions (in solution) which are associated with potential energy minima has been a vexing and controversial problem[83]. In the gas phase, the study of the kinetic energy release associated with carbenium ion formation can give important information about the shape of the potential energy profile; morever, in many cases it is possible to detect whether cation formation is associated with the participation of bonding electrons which may be somewhat remote from the site of the [carbon]—[leaving group] bond. The nature of such participation processes may be uncovered, since the structure of the carbocation which is finally formed is established by collision-induced decomposition of the cation.

A further important feature of the method is that it deals with the energies, the reactions, and the transition state properties of isolated ions. It is precisely such experimental properties which are required for comparison with those molecular properties which are derived by "computer chemistry"[84]. Additionally, comparison of the properties and chemistry of isolated cations with those associated with the corresponding cations in condensed phases will allow a clearer understanding of solvation effects[85]. Finally, if the energetics of unimolecular decompositions can be clearly defined then, in those cases where the principle of microscopic reversibility is applicable, an understanding of the energetics of the reverse bimolecular process has been established.

It appears that in the future the technique will help in answering fundamental questions about one of chemistry's most basic problems—the unimolecular reactions undergone by isolated molecules.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

An Easily Prepared, Air-Stable Compound with a Triple Metal-to-Metal (MoMo) Bond[**]

By *Avi Bino* and *F. Albert Cotton*[*]

Since double, triple, and quadruple metal-to-metal bonds were first recognized, in 1963, 1966, and 1964, respectively, hundreds of compounds containing such bonds have been reported and scores of them have been structurally characterized by X-ray crystallography. Nonetheless it appears that many chemists tend to think of compounds containing such bonds, especially the triple and quadruple ones, as constituting chemical *exotica*. Nothing, of course, could be farther from the truth, as many such compounds are actually among the most easily prepared and stable ones formed by the elements in question. However, some such compounds, especially those with Mo≡Mo and W≡W bonds[1], are indeed highly reactive or thermally unstable and some contain relatively uncommon ligands, such as R_2N—, RO— or Me_3SiCH_2—.

This communication reports a striking example of how easy it can be to prepare an air-stable, thermally stable compound containing an Mo≡Mo triple bond.

The compound $Cs_2[Mo_2(HPO_4)_4(H_2O)_2]$ is prepared by first dissolving $K_4Mo_2Cl_8 \cdot 2H_2O$[2] in 2 M H_3PO_4. The resulting solution is then allowed to mix slowly, by diffusion through a glass frit, with a solution of CsCl in 2 M H_3PO_4. Over a period of a week a beautifully crystalline, purple solid is precipitated. All these operations are conducted at *ca.* 25 °C in vessels open to the laboratory atmosphere. The compound appears to be stable indefinitely in ordinary laboratory air.

Figure 1 shows the result of routine X-ray crystallography[3]. The structure of the $[Mo_2(HPO_4)_4(H_2O)_2]^{2-}$ unit is reminiscent of that found for $[Mo_2(SO_4)_4(H_2O)_2]^{3-}$ and also for $Mo_2(SO_4)_4^{4-}$[4], but there are significant differences in detail. One of the most interesting differences is the long MoMo distance [2.223(2) Å, as compared to 2.164(2) Å and 2.111(1) Å in the two sulfato species, respectively] which tells us quite clearly that we are dealing with a triple bond between the molybdenum atoms. The loss of one δ electron in the sulfato system increased the MoMo distance by 0.053 Å;

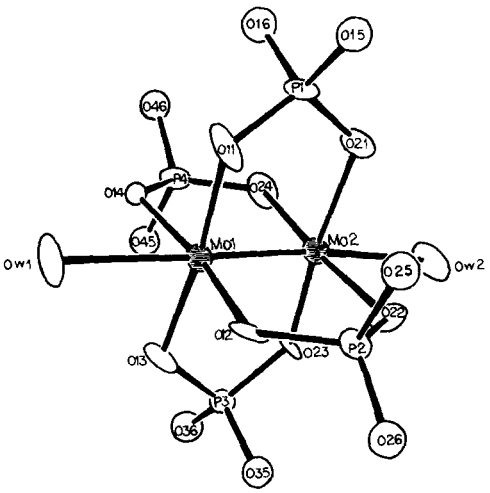

Fig. 1. Structure of the $[Mo_2(HPO_4)_4(H_2O)_2]^{2-}$ ion in crystal.

if we assume that the phosphato system can be compared directly with the sulfato ones, a further increase of 0.053 Å upon loss of the second δ electron would give a predicted triple bond distance of 2.164 + 0.053 = 2.217 Å in excellent agreement with the observed value. The Mo≡Mo distance found here is also close to those found in a variety of other molecules such as $Mo_2Cl_2(NMe_2)_4$ (2.201(2) Å) and $Mo_2(OC_4H_9)_4(O_2COC_4H_9)_2$ (2.241(1) Å)[1].

The hydrogen atoms of the HPO_4 groups were not found directly, but their locations are clearly indicated by the P—O bond lengths, O—P—O angles, and the hydrogen bonding. The eight P—O bonds to coordinated oxygen atoms (*endo* oxygens) range from 1.51 to 1.56 Å, with a mean of 1.54 ± 0.015 Å. The P—*exo*-O distances clearly fall into two sets. On each phosphato unit there is one such bond with a length of 1.48 ± 0.01 Å and another with a length of 1.56 ± 0.02 Å. The former can be assigned to P=O and the latter to P—OH. Moreover, each O atom of the P—OH groups is hydrogen bonded to an O atom of a P=O group of an adjacent molecule, with O···O distances of 2.48 to 2.53 Å, and P=O···HO angles of 113 to 120°.

The water molecules are quite loosely bound to Mo at distances of 2.46(1) Å and 2.53(1) Å and each of them also forms one strong (2.70 Å or 2.78 Å) and one weak (*ca.* 2.90 Å) hydrogen bond to phosphate oxygen atoms of adjacent molecules.

Since the $[Mo_2(HPO_4)_4(H_2O)_2]^{2-}$ unit is not subject to any crystallographic symmetry element and the existence of only a triple bond imposes no barrier to internal rotation, it is pertinent to examine the rotational conformation. The four torsional angles (dihedral angles between OMoMo′ and MoMo′O planes) that should be equal to zero for the ideal eclipsed structure have values of 0.5°, 1.6°, 2.1°, and 2.1°; the structure is thus essentially eclipsed, presumably because this conformation is favored by the ligands.

This substance belongs to the still rare but growing class of compounds containing simple triple M≡M bonds[5] in an environment of four-fold ligation of each metal atom. These include $La_4Re_2O_{10}$[6] as well as several molecules that result

from addition of donors to Mo_2L_6[7a] or W_2L_6[7b] molecules. $Cs_2[Mo_2(HPO_4)_4(H_2O)_2]$ is unique, however, in the simplicity and ease with which it can be prepared and in its chemical stability. It is also the first definite example of phosphato bridging of a bonded pair of metal atoms. In view of the possibility of adjusting the overall charge by changing the degree of protonation of the *exo* oxygen atoms, phosphato-bridged species may prove to be numerous and diverse.

[5] It must be kept in mind that there are two principal types of MM triple bonds: 1) those with no δ bond ($\sigma^2\pi^4$) and 2) those in which there is cancellation of the δ bond by electrons occupying the δ* orbital ($\sigma^2\pi^4\delta^2\delta^{*2}$). We refer to the former as *simple* triple bonds and only they are considered in our present discussion.

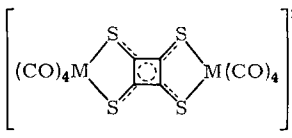
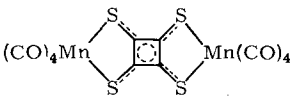
Transition Metal Complexes with the Tetrathiosquarate Dianion as Bridging Bischelate Ligand

By *Franz Götzfried, Wolfgang Beck, Anton Lerf*, and *Angelika Sebald*[*]

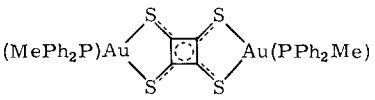


Organometallic compounds having chain structures are of interest as potential one-dimensional electrical conductors[1]. Tetrathiosquarate dianion $C_4S_4^{2-}$[2] appears to be especially suitable for the production of such *catena* complexes on account of its high symmetry (D_{4h}) and readily polarizable S atoms.

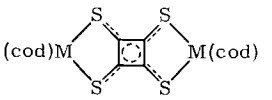


Anionic thio ligands often act as bridging ligands[3], and d^8 metal ions such as Ni^{II} are known to form polymeric complexes with, *e. g.*, ethylene tetrathiolate[4].

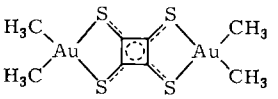
Whereas squaric acid[5a] and its dianion $C_4O_4^{2-}$[5b] do not occur as *O,O*-chelate ligands in transition metal complexes[5c], the dithiosquaric dianion $C_4O_2S_2^{2-}$ can form *S,S*-chelate complexes[5d]. We have now found that the dianion of tetrathiosquaric acid forms numerous compounds having bischelate structure with transition metals.



Thus the highly air-sensitive compounds *(1)* are formed by reaction of hexacarbonyl-6A metals with the potassium salt



(1a), M = Cr
(1b), M = Mo
(1c), M = W
} Ph_4As– salts, violet



(2), red

(3), orange

(4a), M = Rh, red-brown
(4b), M = Ir, brown

(5), red

$C_4S_4K_2 \cdot H_2O$[2] in diglyme at 120 °C and subsequent precipitation with Ph_4AsCl; the neutral complexes *(2)*—*(5)* are obtained from the corresponding halometal derivatives by stirring for several hours with the thioligand at 20 °C in tetrahydrofuran (THF).

The IR, NMR, and mass spectra are in agreement with the expected structures:

(1a): ν(CO) = 1985 m, 1887 s, 1861 vs, 1820 s cm^{-1}; *(1b)*: ν(CO) = 1998 m, 1894 s, 1863 s, 1822 s cm^{-1}; *(1c)*: ν(CO) = 1992 m, 1886 s, 1861 s, 1825 m cm^{-1} (in THF); ^{13}C-NMR (in D_6-DMSO, int. TMS): δCO, C_4S_4 = 171.27 (s), 176.85 (s), 179.21 (s); *(2)*: ν(CO) = 2093 m, 2023 s, 2002 s, 1956 s cm^{-1} (solid in Nujol); *(3)*: ^{1}H-NMR (in $CDCl_3$, int. TMS): $\delta CH_3 = 2.17$ (d, $J_{PH} = 10$ Hz); *(5)*: ^{1}H-NMR (in $CDCl_3$, int. TMS): $\delta CH_3 = 1.17$ (s); MS (70 eV): $m/e = 630$ (M^+), correct isotope pattern

The characteristic intense C···C···S stretching vibration is always observed at higher wave numbers (max. 1305 cm^{-1}) in the complexes *(1)*—*(5)* than for the free ligand ($\nu_{C\cdots C\cdots S} = 1235$ cm^{-1}); the broad band is often split into several intense sharp bands.

Complex *(5)* can be irreversibly reduced in two steps (at −0.75 and −1.52) by voltammetry[6]. The reduction of squaric acid derivatives is particularly interesting, because it must ultimately lead to substituted cyclobutadienes! In contrast to $C_4O_4^{2-}$[7], the $C_4S_4^{2-}$ dianion can be smoothly reduced polarographically[8] in two one-electron steps (half-wave potentials: −1.53 V and −1.79 V) in aqueous solution to the tetraanion $C_4S_4^{4-}$.

Reaction of aqueous solutions of $NiCl_2$ or Na_2PdCl_4 with $K_2C_4S_4$ affords diamagnetic products

$Ni_{25}(C_4S_4)_{26}K_2 \cdot xH_2O$ ($x \approx 8$) *(6)*, dark-red
$Pd_{10}(C_4S_4)_9Cl_4K_2 \cdot xH_2O$ *(7)*, brownish black

The composition of these lustrous compounds is in agreement with a chain structure, the chain terminals being saturated with tetrathiosquarato ligands in *(6)* and by chloro ligands in *(7)*. K_2PtCl_4 or $(PhCN)_2PtCl_2$ react with $K_2C_4S_4$ to give blackish green complexes *(8)* containing Pt and C_4S_4 in the ratio of 1:1 and also varying amounts of K, O, Cl, and H, depending upon the reaction conditions.

Meiserstrasse 1, D-8000 München 2 (Germany)
Dr. A. Lerf
Institut für Tieftemperaturforschung
Hochschulgelände, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

In addition to the bands at 1250 cm^{-1}, the IR spectrum of *(7)* and *(8)* contain weak ν(CO) absorptions at 1720 and 1740 cm^{-1}, which are attributable to partial replacement of S by O (ν(Ni—S) of *(6)*: 338, 267 cm^{-1}).

The electrical conductivity of the compressed powders *(6)*—*(8)* are comparable with corresponding values for neutral or anionic "metal dithiolenes"[1]; the resistance of the powders shows the same temperature dependence as semiconductors.

Polymer	Electrical conductivity at 20 °C δ [Ω^{-1} cm^{-1}]
(6)	5×10^{-4}
(7)	3×10^{-7}
(8)	6×10^{-7}

Given a parallel arrangement of the chains in *(6)*—*(8)*, interactions could occur between the metal atoms of neighboring chains which suggest electron delocalization perpendicular to the chain direction. A similar structure was recently suggested for a Ni^{II}-tetrathionaphthalene complex with semiconductor properties[9].

$Ag_{10}Si_4O_{13}$—The First Tetrasilicate[**]

By *Martin Jansen* and *Hans-Lothar Keller*[*]

On surveying the silicate structures discovered so far, the absence of a smooth transition from single chains ($^1_\infty SiO_3^{2-}$) to layers ($^2_\infty Si_2O_5^{2-}$) is noted[1]. A similar situation is encountered in the concatenation of individual (SiO_4^{4-}) tetrahedra to give chain-type anions: ortho- and disilicates are common, but trisilicates are much rarer. We have now succeeded in the first synthesis and characterization of a tetrasilicate.

$Ag_{10}Si_4O_{13}$ was obtained by reaction of the binary components Ag_2O and SiO_2 (low-temperature quartz) under oxygen pressure as a homogeneous, vermilion, moisture-insensitive powder [$P(O_2) = 2$—4.5 kbar, $T = 500$—600 °C, $t = 1$—3 d]. None of the neighboring phases $Ag_6Si_2O_7$ (I)[2] and $Ag_6Si_2O_7$ (II)[3] having a slightly higher silver content was detectable in the product. Crystals could be grown starting from the binary oxides in a silver nitrate melt by a previously described method[4] using an oxygen pressure of *ca.* 4.5 kbar at 600 °C.

$Ag_{10}Si_4O_{13}$ forms triclinic crystals, space group $P\bar{1}$[5]. The Si—O distances in the tetrasilicate anion (Fig. 1) vary between 158.9 and 168.3 pm, with average values of 161.6 pm for terminal and 165.0 pm for bridging bonds; the three Si—O—Si angles are 146.5, 137.7, 128.4°.

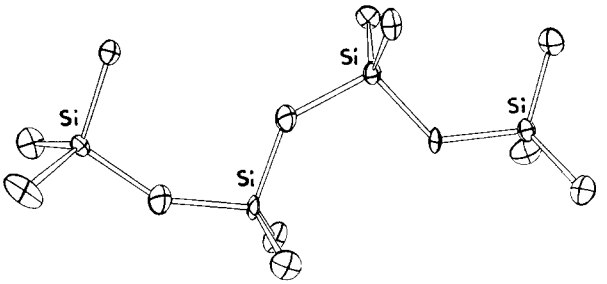

Fig. 1. Structure of the $Si_4O_{13}^{10-}$ anion in the silver salt.

The apparent preference for certain kinds of silicate anions could be attributable to the fact that most of the known structures are those of minerals formed under conditions in which the variety of available cations was limited by geochemical selection. Thus, it cannot be ruled out that synthetic approaches may lead to further unusual silicates, as in the case of the present silver silicate.

Chemical Synthesis of Human Blood Group B Antigenic Determinant: Type 2 Tetrasaccharide[**]

By *Marie-Louise Milat* and *Pierre Sinaÿ*[*]

The "imidate procedure"[1] introduced by our group has recently enabled, *inter alia*, a high-yield synthesis of the trisaccharide *(1)*[2], which is considered as the antigenic determinant of the human blood group B in the AB0 system. We

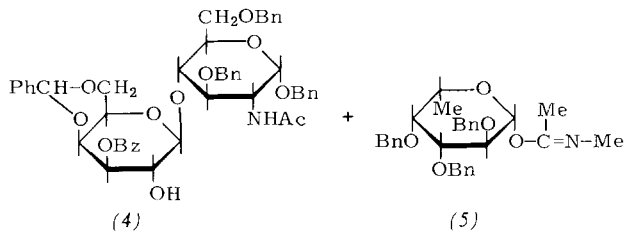
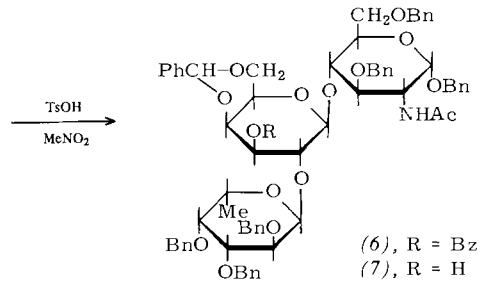
have now succeeded in synthesizing the corresponding terminal tetrasaccharide *(10)* of type 2.



(1)



(2) *(3)*

As a key starting material we used the readily accessible[3] benzyl 2-acetamido-3,6-di-*O*-benzyl-2-deoxy-α-D-glucopyranoside which, on condensation with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide ($HgBr_2$, dichloromethane, molecular sieve 4 Å[4]) and subsequent deacetylation (MeONa in methanol), afforded the disaccharide *(2)*. Reaction of *(2)* with benzaldehyde in the presence of zinc chloride gave the benzylidene compound *(3)*, which was then selectively benzoylated[5] (*N*-benzoylimidazole in dichloroethane) to the derivative *(4)*. 1-*O*-[1-(Methylimino)ethyl]-2,3,4-tri-*O*-benzyl-β-L-fucopyranoside *(5)*[6] was condensed (*p*-toluenesulfonic acid/nitromethane) with *(4)* to provide, after debenzoylation (MeONa in methanol), the protected trisaccharide *(7)*. The structure of *(7)* was confirmed by complete deblocking (catalytic hydrogenolysis; Pd/C in pure acetic acid) to the known[7] trisaccharide of type 2. Further proof of the structure was provided by the NMR spectrum of the benzoate *(6)*.

(4) *(5)*

(6), R = Bz
(7), R = H

The expected protected tetrasaccharide *(9)* was obtained by reaction of 1-*O*-[1-(methylimino)ethyl]-2,3,4,6-tetra-*O*-benzyl-β-D-galactopyranoside *(8)*[2] with *(7)*. The tetrasaccharide chain *(10)* of the blood group substance B (type 2) is finally generated by hydrogenolytic cleavage of *(9)* with Pd/C in glacial acetic acid. This tetrasaccharide has been isolated from the alkaline degradation products of a human blood-group B substance[8]. Physical data of some of the compounds are listed in Table 1.

Table 1. Physical data of the compounds *(2)*—*(4)*, *(6)*, *(7)*, *(9)* and *(10)*.

Facile, Highly Selective Synthesis of α- and β-Disaccharides from 1-*O*-Metalated D-Ribofuranoses[**]

By *Richard R. Schmidt* and *Manfred Reichrath*[*]

Dedicated to Professor Hellmut Bredereck on the occasion of his 75th birthday

Stereoselective formation of the glycosidic bond in disaccharide syntheses is generally achieved by nucleophilic displacement of a readily cleavable group at the anomeric center of the sugar[1].

The direct 1-*O*-alkylation of furanoses and pyranoses[2] or corresponding metalated derivatives[3], especially with methyl iodide and dimethyl sulfate, is already well-known, but has previously not been exploited for the chemically and stereochemically highly selective synthesis of α- or β-disaccharides[4]. We report here on an especially simple method for the synthesis of disaccharides [*(5)* and *(6)*] with high β- and α-stereoselectivity using as example the reaction of 1-*O*-metalated D-ribofuranoses *(2)* and *(3)* with 5-*O*-trifluoromethanesulfonyl-D-ribofuranosides *(4)*[6].

Stereochemical control of the reactions was accomplished by selective variation of the substituents on C-5 of the D-ribofuranose *(1)*. The ribofuranose *(1)*, R = H, reacts with potassium *tert*-butoxide in tetrahydrofuran to give the potassium salt *(2)*, which on reaction with the readily accessible trifluoromethanesulfonates *(4a)*[7] and *(4b)*[7] affords almost exclusively the β-coupled D-ribofuranosyl-(1→5)-D-ribofuranosides *(5a)* and *(5b)*[8], respectively (see Table 1). The high stereoselectivity has been discussed in terms of an intramolecular complexation in the anion of *(2)*[9].

By incorporation of a bulky protecting group on C-5, α-coupled disaccharides could be obtained. Thus, reaction of *(1) via* the sodium salt *(3a)*[9] with the trifluoromethanesulfonates *(4a)* and *(4b)* in dioxane afforded exclusively the α-disaccharides *(6a)* and *(6b)* in excellent yields[8]. The readily cleavable 5-*O*-*tert*-butyl(dimethyl)silyl group could also be used instead of the 5-*O*-trityl group: reaction of *(3b)*[9] with *(4a)* and *(4b)* furnished *(6c)* and *(6d)*, respectively, which on treatment with tetrabutylammonium fluoride could be converted almost quantitatively into the 5'-unprotected disaccharides *(6e)* and *(6f)*[8] (see Table 1).

General procedure

Compounds of type *(1)* dissolved in tetrahydrofuran or dioxane are deprotonated at 0—5 °C to *(2)* or *(3)* with equimolar amounts of potassium *tert*-butoxide or a *ca.* three- to fivefold excess of sodium hydride. After addition of base the reaction mixture is stirred for *ca.* 15 min at room temperature before adding an equimolar amount of *(4a)* or *(4b)* at 0 to 5 °C. The reaction time at room temperature is generally 5 to 20 h. [Synthesis of *(5b)*: +4 °C, 4 d, *(1)* in 1.5-fold excess.] Workup involves: extraction with $CHCl_3/H_2O$ [*(5a)*]; silica-gel filtration [*(6a)*, petroleum ether (low boiling):ethyl acetate = 7:3; *(6d)*: petroleum ether (low boiling):ethyl acetate = 8:2; *(6e)*, *(6f)*: first $CHCl_3$:ether = 9:1, then $CHCl_3:CH_3OH$ = 9:1]; bulb-to-bulb distillation [*(6c)*, 180 °C (oven temp.)/10^{-2} mbar]; chromatography on silica gel [*(5b)*: benzene:acetone = 92:8; *(6b)*: petroleum ether (low boiling):ethyl acetate = 7:8].—*(5a)*, *(5b)* and *(6a)*—*(6e)* were obtained as highly viscous oils; *(6f)*: m.p. 96 °C, from petroleum ether (low boiling).

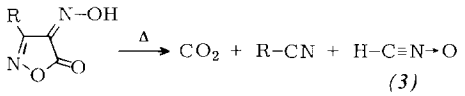
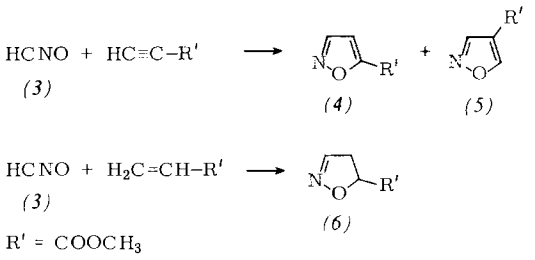
A New Synthesis of Fulminic Acid[**]



By *Curt Wentrup, Bernd Gerecht*, and *Horst Briehl*[*]

All useful syntheses of fulminic acid, HCNO, involve the dangerously explosive metal fulminates[1]. Moreover, preparation of the pure acid in bulk is extremely difficult. We now wish to report a safe and facile synthesis producing chemically pure fulminic acid in essentially quantitative yield.

The method is based on flash thermolysis of 4-substituted isoxazol-5(4*H*)-ones *(1)*, which we have previously used to prepare acetylenes, isocyanides, aminoisocyanides, and ketenimines[2]. By analogy with *(1)*, the oximes *(2)*[3] could be expected to fragment to the unknown molecule HO—NC, a tautomer of fulminic acid. However, we failed to obtain HO NC, isolating instead fulminic acid, HCNO *(3)*.

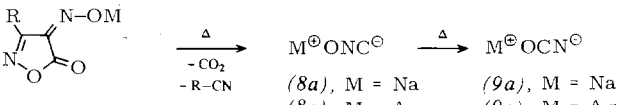


(1)

(3)

(2a), R = CH_3
(2b), R = C_6H_5

The gas-phase decomposition of *(2a)* between 200 and 800 °C gives only CO_2, acetonitrile, and HCNO. These products were isolated in a cold-trap cooled in liquid N_2 and HCNO was identified by comparison of its infrared spectrum in the gas-phase with that reported by *Beck et al.*[4a]. HCN and HNCO (isocyanic acid) were not detectable. It was also possible to observe the ν_{as}(CNO) vibration at 2190 cm^{-1} immediately upon dissolving the cold (−196 °C) pyrolyzate in CCl_4. At room temperature in solution, this absorption disappeared within a few seconds. On warming up to room temperature the fulminic acid underwent spontaneous polymerization to the known[5] mixture of tri- and tetramers.



(3) *(4)* *(5)*

(3) *(6)*

R′ = $COOCH_3$

For further identification, the pyrolysis product was treated in the cold-trap with methyl propiolate and methyl acrylate. After slow warm-up to room temperature, the expected 1,3-dipolar cycloaddition products of HCNO, *(4)* and *(5)*, and *(6)*, respectively, were isolated. Notably, the ratio *(4)*/*(5)* = 84:16 was the same as from fulminic acid prepared by other means[6].

In order to obtain the chemically pure acid, it is better to use *(2b)* rather than *(2a)* as starting material. At an oven temperature of 450 °C and a sublimation temperature no higher than 120 °C, CO_2, benzonitrile, and HCNO are formed and collected in liquid N_2. CO_2 is pumped off at −80 °C, and HCNO is distilled into a second cold-trap by slow warm-up to *ca.* −10 °C in high vacuum. When sublimation temperatures higher than 120 °C were used in the pyrolysis of *(2b)*, significant amounts of HNCO were formed as a by-product. HNCO was identified by its infrared spectrum, and by its trimerization to cyanuric acid.

(7a), R = C_6H_5, M = Na
(7b), R = CH_3, M = Na
(7c), R = CH_3, M = Ag

(8a), M = Na
(8c), M = Ag

(9a), M = Na
(9c), M = Ag

The salts *(7)* of the oximes *(2)* explode when rapidly heated over a flame. Evaporation of solutions of *(7a)* occasionally resulted in non-violent decomposition with formation of benzonitrile, CO_2, and sodium cyanate, identified by their infrared spectra. This suggested initial fragmentation to sodium fulminate *(8a)*, which thermally isomerizes to the cyanate *(9a)*[4b]. When dry *(7b)* was allowed to decompose *in vacuo* at 50—55 °C (7 h) a mixture of *(8a)* and *(9a)* was formed, as identified by infrared comparison with authentic samples. Pure silver fulminate *(8c)* was formed in quantitative yield by allowing dry *(7c)* to decompose *in vacuo* at 70 to 110 °C[7].

Experimental

Fulminic acid *(3)*: The flash pyrolyses were carried out in a 30 × 2 cm electrically heated horizontal quartz tube at 10^{-3}—10^{-4} torr as previously described[8]. *(2a)* (4.0 g, 0.03 mol) was sublimed into the 450 °C pyrolysis tube from a flask held at 100—120 °C in the course of 10 h. The products were collected in a liquid N_2 trap. After bringing the system to atmospheric pressure, allowing slow warm-up to room temperature, and removing acetonitrile *in vacuo*, 1.3 g (97%) of the polymer[5] of fulminic acid was isolated. Alternatively,

Lahnberge, D-3550 Marburg (Germany)

[**] Fulminates, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the cold (−196 °C) pyrolyzate was treated with methyl acrylate (5.4 g, 0.06 mol). The mixture was allowed to warm up to room temperature, and acetonitrile and excess methyl acrylate were removed *in vacuo*, yielding 4.0 g (99%) of *(6)*, b. p. 70 °C/10^{-3} torr (^{1}H-NMR, see [6]).

Silver fulminate *(8c)*: Powdered *(6c)* (106 mg; 0.45 mmol) was heated at 100—110 °C for 11 h with pumping at 10 torr. The volatile products (acetonitrile and CO_2) were isolated in a cold-trap. The solid residue (68 mg, 100%) consisted of dangerously explosive silver fulminate (identified by IR comparsion with a sample prepared according to *Nef*[9]). Though no explosions have occurred during this preparation, due safety precautions should be taken.

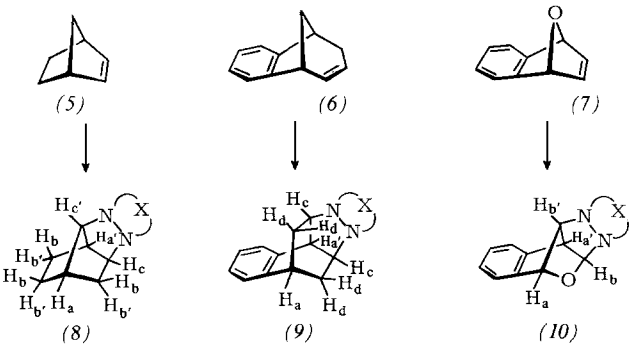
Polycyclic Azoalkanes *via* Dipolar Cycloaddition of 4-Phenyl-1,2,4-triazoline-3,5-dione with Strained Bicyclic Olefins[**]

By *Waldemar Adam, Ottorino De Lucchi,* and *Ihsan Erden*[*]

We required a convenient synthesis of the previously unknown tricyclic azoalkane *(4)* for the generation of the corresponding diradical, which is a potential intermediate of the di-π-methane rearrangement of benzonorbornadiene *(2)*[1].



Since the highly reactive 4-phenyl-1,2,4-triazoline-3,5-dione *(1)* is known to undergo cycloaddition with strained polycyclic olefins[2], we undertook the reaction of *(1)* with the bicyclic species benzonorbornadiene *(2)*; the cycloadduct *(3)* could be reduced to *(4)* (Scheme 1). This cycloaddition could also be applied to compounds *(5)*—*(7)*.

Refluxing of stoichiometric amounts of *(1)* and *(2)* ($CHCl_3$, 30 min) led to complete decoloration of the red *(1)*. Evaporation of the $CHCl_3$ and column chromatography on Florisil,

Scheme 1

elution with CH_2Cl_2, and recrystallization from ethanol afforded the pure adduct *(3)*. Refluxing of *(3)* with KOH in isopropyl alcohol (90 min under N_2), neutralization with 3 N HCl, and treatment with $CuCl_2$ in CH_3OH, followed by 3 N NaOH, afforded the azoalkane *(4)*. It was purified by sublimation (60 °C/0.2 torr) and recrystallization from hexane.

X = –CO–NPh–CO–

Similarly, refluxing a solution of stoichiometric amounts of norbornene *(5)* with *(1)* (CH_2Cl_2, 3 h) afforded the crude cycloadduct *(8)*, which was purified by column chromatography on Florisil (eluant; CH_2Cl_2) and recrystallization from ethanol. This example clearly established that benzoannelation is not necessary for the reaction.

Refluxing of the olefin *(6)* with *(1)* in $CHCl_3$ gives the adduct *(9)* which was isolated by column chromatography on Florisil and recrystallization from ethanol[6]. Clearly the cycloaddition must involve dipolar species (cf. Scheme 1) since bromine addition to *(6)* proceeds *via* a similar cationic rearrangement[3].

Stirring stoichiometric amounts of *(7)*, *i.e.* the oxa analogue of *(2)*, and *(1)* (CH_2Cl_2, *ca.* 12 h) affords the cycloadduct *(10)*. It was purified by Florisil chromatography (CH_2Cl_2 as eluant) and recrystallization from EtOH. Physical data of all the new compounds are compiled in Table 1.

We thank Mr. *P. Hernández,* undergraduate research participant in the NIH sponsored SUBE program, for technical assistance.

Table 1. Physical data of the new compounds *(3)*, *(4)*, *(8)*—*(10)*. All compounds gave correct elemental analyses.

(3): m.p. 179—180°C; yield 95%; ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 1.53$ (d, $H_{b'}$; B part of AB system), 2.28 (d, H_b; A part of AB system), 3.75 (m, H_a, $H_{a'}$), 4.61 (m, H_c, $H_{c'}$), 7.15 (br. s, C_6H_4), 7.39 (br. s, C_6H_5); ^{13}C-NMR ($CDCl_3$): $\delta = 129.17, 128.36, 128.03, 127.11, 125.43, 124.08, 120.45, 76.84, 58.64, 53.43, 46.12, 34.53$ (CO resonances not recorded); IR (KBr): 3020, 1785, 1715, 1500, 1412 cm^{-1}

(4): m.p. 74—75°C; yield 74%; ^{1}H-NMR (CCl_4, TMS): $\delta = 1.20$ (m, H_b, $H_{b'}$), 2.78 (m, H_a), 3.21 (m, $H_{a'}$), 4.63 (m, H_c), 5.26 (m, $H_{c'}$), 6.88 (m, C_6H_4); IR (CCl_4): 3100, 3020, 2985, 2960, 1495, 1470, 1383, 1267, 1220 cm^{-1}

(8): m.p. 133—134°C; yield 17%; ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 1.2$—2.0 (m, $3H_b$, $3H_{b'}$), 2.60 (m, H_a, $H_{a'}$), 4.25 (m, H_c, $H_{c'}$), 7.25 (m, C_6H_5); IR (CCl_4/$CDCl_3$): 2960, 1775, 1725, 1505, 1410, 910 cm^{-1}

(9): m.p. 202—203°C; yield 31%; ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 1.98$ (m, $4H_d$), 3.07 (m, H_a), 3.48 (t, $H_{a'}$; $J(H_{a'}—H_c) = 4.0$ Hz), 4.35 (m, $2H_c$), 7.0 (br. s, C_6H_4), 7.22 (m, C_6H_5); IR ($CDCl_3$): 3080, 3060, 3040, 2960, 1770, 1705, 1600, 1500, 1400 cm^{-1}

(10): m.p. 145—146°C; yield 60%; ^{1}H-NMR $CDCl_3$, TMS): $\delta = 4.25$ (m, $H_{b'}$), 4.35 (m, $H_{a'}$), 5.22 (br. s, H_b), 5.41 (br. s, H_a), 7.08 (m, C_6H_4), 7.20 (m, C_6H_5); IR (KBr): 3040, 1790, 1710, 1600, 1495, 1400, 1320, 1260, 1230, 1150, 1090 cm^{-1}

The reactions reported here provide a synthetic entry into azoalkanes which would be difficult to prepare by classical methods and are of interest as precursors of diradical intermediates postulated in photochemical transformations.

tetrahedro-Tetraphosphorus as Monodentate Ligand in a Nickel(0) Complex

By *Paolo Dapporto, Stefano Midollini*, and *Luigi Sacconi*[*]

The existence of a P_4 unit was proposed in some rhodium complexes by *Ginsberg* and *Lindsell* but it was not clear how the P_4 was bound[1]. We have now prepared and structurally characterized a nickel(0) complex *(2)* containing as ligands the tritertiary phosphane tris(2-diphenylphosphinoethyl) amine (np_3) and a *tetrahedro*-tetraphosphorus (P_4) molecule. The P_4 unit is bonded to the metal atom by an apical P atom. The complex $[(np_3)Ni(P_4)]$ *(2)* is readily precipitated by reaction of the trigonal pyramidal complex of nickel(0)[2] *(1)* with white phosphorus in tetrahydrofuran (THF). The yellowish brown compound is diamagnetic and only slightly sensitive to air. It is insoluble in all common organic solvents.

(1) *(2)*

An X-ray diffraction analysis[3] has shown that the central nickel atom is bound in a quite regular tetrahedral geometry to the three phosphorus atoms of the np_3 ligand and to one phosphorus atom of the P_4 unit (Fig. 1). The nitrogen atom is not bonded to the metal atom (Ni...N = 3.09 Å). The Ni—P1 distance, shorter by *ca.* 0.2 Å than the sum of the covalent radii, suggests a d_π-d_π interaction between nickel and phosphorus. The nickel atom appears to attain the 18 electron configuration.

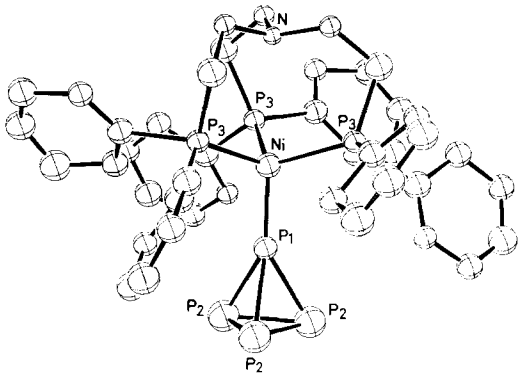

Fig. 1. ORTEP plot of $[(np_3)Ni(P_4)]$ *(2)*. Bond lengths: Ni P1 = 1.99(1), Ni P3 = 2.24(2), P1 P2 = 2.20(3), P2 P2 = 2.09(3) Å. Bond angles: P1 Ni P3 = 109.7(7), P3 Ni P3 = 109.3(7), P2 P1 P2 = 56.8(10)°.

Experimental

All operations were performed under N_2 and in oxygen-free THF. A solution of white phosphorus, P_4 (120 mg, 1 mmol) in THF (50 ml) was added to a solution of *(1)* (710 mg, 1 mmol) in THF (120 ml) at about 0 °C over a period of 15 min. Brown crystals were deposited, filtered off, washed with tetrahydrofuran and dried in a current of N_2 at room temperature (yield *ca.* 70%).

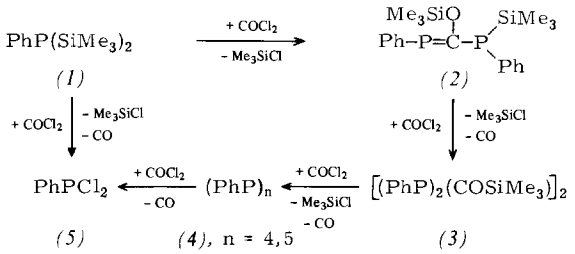
Stepwise Reaction of Phenylbis(trimethylsilyl)phosphane with Phosgene—Isolation of a (Phosphinomethylene)phosphane[1]

By *Rolf Appel* and *Volker Barth*[*]



As a proven chlorinating agent in phosphorus chemistry, phosgene smoothly transforms triorganylphosphanes and triorganylphosphane oxides into the corresponding dichlorophosphoranes[2]. In contrast, its reaction with phenylbis(trimethylsilyl)phosphane *(1)* leads *via* elimination of chlorotrimethylsilane to the dichloro(phenyl)phosphane *(5)*, which

[*] Prof. Dr. L. Sacconi, Dr. P. Dapporto, Dr. S. Midollini

fails to undergo further reaction with phosgene. Temporary appearance of a precipitate during this reaction prompted us to undertake a detailed study, especially since *Becher* and *Langer*[3] had already obtained carbonyl bis(diphenylphosphide) as an unstable product from phosgene and diphenyl(trimethylsilyl)phosphane at $-110\,^{\circ}C$.

We found that *(1)* reacts stepwise with $COCl_2$ *via* several isolable intermediates: at a molar ratio of 2:1 in pentane, these reactants first give a yellow oil shown by elemental analysis, molecular weight (cryoscopy and mass spectrometry), ^{31}P- and ^{13}C-NMR, to be phenyl[(phenyltrimethylsilylphosphino)trimethylsiloxymethylene]phosphane *(2)*. Evidence for migration of a silyl group to oxygen and for a methylenephosphane structure comes from the doublets at $\delta = +164$ and -37 in the ^{31}P-NMR spectrum and the double doublet at $\delta = 205$ in the ^{13}C-NMR spectrum[4].

Addition of $COCl_2$ to a pentane solution of *(2)* (1:2) leads to precipitation of a colorless solid substance of composition *(3)*. The signal of dicoordinate phosphorus is absent from the ^{31}P-NMR spectrum of *(3)*; a temperature-dependent AA'BB' spin system is observed which is interpretable in terms of various proposed structures. An X-ray structure determination is still in progress.

Further action of $COCl_2$ leads to dissolution of the fine precipitate of *(3)*, with simultaneous production of chlorotrimethylsilane and CO gas. The two new ^{31}P-NMR signals at $\delta = -5.9$ and -49.5 were previously observed on reaction of *(1)* with phosgene by *Baudler et al.*[5], and assigned to the cyclophosphanes *(4)*. The intermediates *(4)* are chlorinated by $COCl_2$ *via* CO elimination to give dichloro(phenyl)phosphane *(5)* as the stable final product.

Preliminary investigations show that phosgene analogues react similarly with *(1)* and that acyclic compounds having P=C bonds[4,6] are no longer mere *curiosa*.

Experimental

Phosgene (10.7 g, 108 mmol; slight excess) is condensed at 0 °C within 6 h into a stirred solution of *(1)*[7] (50.8 g, 200 mmol) in *p*-pentane (400 ml) in an evacuated vessel. After 12 h at room temperature, the solution is evaporated down to *ca.* 100 ml and stirred for another 12 h. Filtration and stripping off the solvent gives *(2)* almost quantitatively as a yellow oil which cannot be distilled without decomposition. The compound can be stored for several weeks at 0 °C in the absence of oxygen and moisture. $^{31}P\{^1H\}$-NMR (C_6D_6, 85% H_3PO_4 ext.): $\delta = +164.0$ [d, $^2J(P^aP^b) = 72.8$ Hz, P^a=C], -37.0 [d, $^2J(P^bP^a) = 72.8$ Hz, P^b—Si].—$^{13}C\{^1H\}$-NMR (CD_2Cl_2, TMS int.): $\delta = -1.0$ [dd, $^2J(P^bC) = 12.4$, $^4J(P^aC) = 6.3$ Hz, P^bSiC], $+0.3$ [dd, $^4J(P^bC) = 2.9$, $^4J(P^aC) = 0.3$ Hz, OSiC], $+205.3$ [dd, $J(P^aC) = 78.9$, $J(P^bC) = 37.7$ Hz, P^aC]; the complex spectrum of the phenyl groups was not evaluated.—$^{29}Si\{^1H\}$-NMR (CD_2Cl_2, TMS int.): $\delta = +3.7$ [dd, $J(P^bSi) = 21.0$, $^3J(P^aSi) = 12.2$ Hz, P^bSi], $+23.6$ [d, $^3J(P^bSi) = 5.0$ Hz, OSi].

Phosgene (4.95 g, 50 mmol) is condensed under similar conditions into a solution of *(2)* (39.0 g, 100 mmol) in *n*-pentane (400 ml). Since CO is liberated the reaction vessel must be equipped *via* a reflux condenser ($-60\,^{\circ}C$, cryostat cooling) with a Hg safety valve. The solution is concentrated to *ca.* 100 ml, whereupon *(3)* precipitates. Filtration over a sealed frit, washing with a small volume of *n*-pentane, and vacuum drying affords 15 g (47%) of spectroscopically pure product, m.p. 148—150 °C, which can be recrystallized from CH_2Cl_2/*n*-pentane or CH_2Cl_2/CH_3CN.—Alternatively, *(3)* can be prepared directly from *(1)* and $COCl_2$ in the molar ratio 4:3.

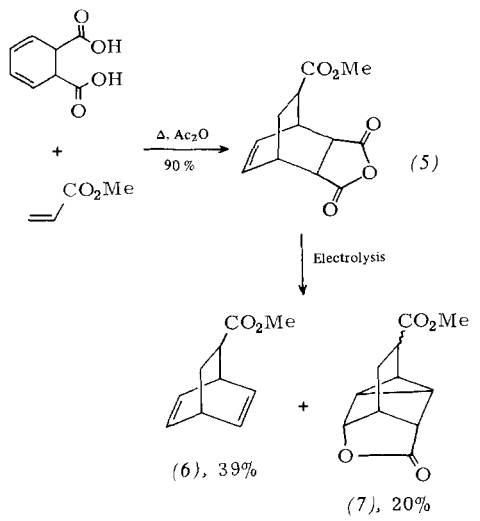
Bicyclo[2.2.2]octa-5,7-diene-2-carboxylic Acid and 7-Methylenebicyclo[2.2.2]octa-2,5-diene[**]

By *Rudolf Gompper* and *Karl-Heinz Etzbach*[*]

Dedicated to Professor Hellmut Bredereck on the occasion of his 75th birthday

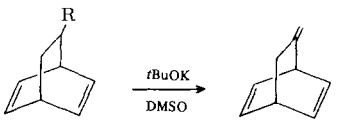
In the alkylation of the alkali-metal salts of bicyclo[2.2.2]octanone derivatives, *e.g.* those of barrelenone *(1)*, it can be calculated from the *O/C*-product ratio that an antiaromatic effect prevails, *e.g.* in the anion of *(2)*[1]. It can be expected that similar electronic circumstances are present in the anions of *(2)* and *(4)* (cf. [2]). 7-Methylenebicyclo[2.2.2]octadiene *(3)*, the potential starting material for *(4)*,

(1) *(2)* *(3)* *(4)*



has been obtained in "very low yields" together with other products on irradiation of a solution of allene in benzene[3]. The methods developed for the synthesis of barrelenone *(1)*[1] should enable the synthesis of *(3)* on a preparative scale and, moreover, provide general access to 7-substituted bicyclo[2.2.2]octadienes.

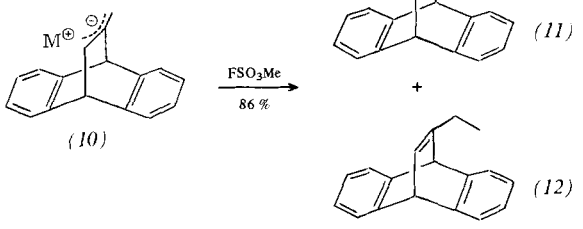
Diels-Alder reaction of dihydrophthalic acid and methyl acrylate (cf. [4]) affords the anhydride *(5)*, subsequent electrolysis of which (10 mmol anhydride: 180 ml pyridine, 30 ml water, 5 ml triethylamine; cf. [1,5]) gives methyl bicyclo[2.2.2]octa-5,7-diene-2-carboxylate *(6)* and the tetracyclic



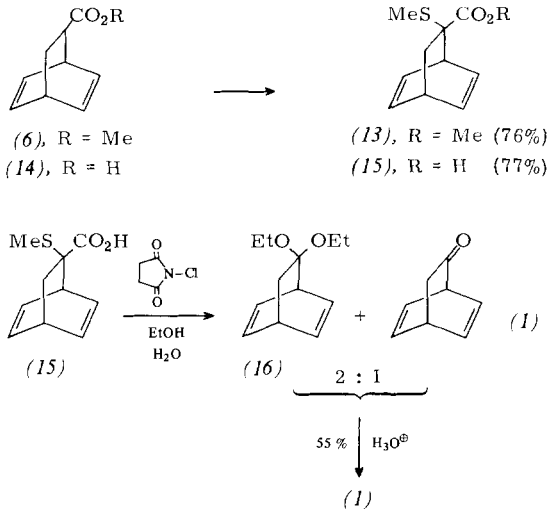
[*] Prof. Dr. R. Gompper, Dipl.-Chem. K.-H. Etzbach
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie. We are grateful to BASF for supplying the dihydrophthalic acid.

lactone *(7)* (consistent with the proposed structure[6]). *(6)* decomposes above 80 °C into benzene and acrylic ester.



(6) can be reduced with lithium tetrahydroaluminate to the alcohol *(8)*, which without purification reacts with toluenesulfonyl chloride to give the tosylate *(9)* (chromatographic workup; silica gel, chloroform). On treatment with potassium *tert*-butoxide in dimethyl sulfoxide, *(9)* is converted into *(3)*, a colorless mobile liquid.



(6), R = CO_2Me
(8), R = CH_2OH(82%)
(9), R = CH_2OTos(75%)

(3) is difficult to deprotonate. It reacts with *n*-butyllithium/potassium *tert*-butoxide[7] to give, at least partially, *(4)*; further reaction with methyl fluorosulfonate affords a mixture of products which contains 7-methyl-8-methylenebicyclo[2.2.2]octadiene, together with *(3)* and an unidentified compound. More understandable is the behavior of the dibenzo derivative[8] of *(3)*. Here, reaction with *n*-butyllithium/potassium *tert*-butoxide in tetrahydrofuran (THF) at −78 °C furnishes quantitatively the deep-red salt *(10)*, which reacts

with methyl fluorosulfonate to give a 9:1 mixture of *(11)* and *(12)*. Alkylation of *(4)* and *(10)* proceeds similarly to that of *(2)* and related salts.

Sulfenylation[9] of *(6)* with (i) lithium diisopropylamide in THF/hexamethylphosphoric triamide (HMPT) at −78 °C and (ii) dimethyldisulfane affords the methylthio derivative *(13)* (chromatography on silica gel; ether). On attempted distillation (bath temperature up to 120 °C) *(13)* decomposes into benzene and α-methylthio(methyl acrylate). Since *(13)* is difficult to saponify it is advisable to obtain the carboxylic acid *(14)* [(i) 2 N NaOH, (ii) 2 N HCl, 81% yield] from *(6)* first for the preparation of *(15)*. *(14)* decomposes *via* retro Diels-Alder reaction within a few days, even at room temperature.

The dilithium salt of *(14)* can be smoothly sulfenylated to *(15)* [(i) 2 $LiN(iPr)_2$ in THF/HMPT at 0 °C; (ii) MeSSMe]. Oxidative decarboxylation[9] of *(15)* leads to a mixture of *(16)* and *(1)*. Acid hydrolysis finally yields barrelenone *(1)*. The physical data of a few compounds are given in Table 1.

Table 1. Physical data of compounds *(3)*, *(5)*, *(7)*, *(9)*, *(13)*, *(14)*.

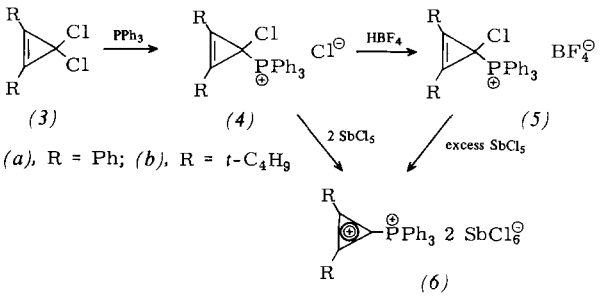
Structure and Formation of Triorganylphosphoniocyclopropenylium Ions[**]

By *Robert Weiss, Claus Priesner,* and *Hilmar Wolf*[*]

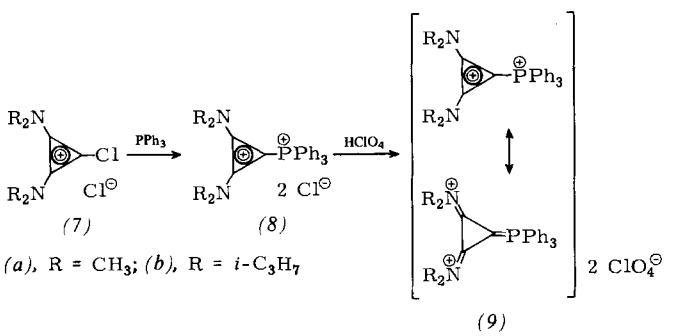


Hetero[3]radialenes *(1)*, in which X, Y, and/or Z are hetero atom functions, constitute a hitherto unexplored class of substances which could be of interest particularly in connection with ring fragmentation[1]. We have now synthesized systems of type *(2)* for the first time.

(1) *(2a)* *(2b)*

A triorganylphosphonio group served as acceptor A and the donor group Do was varied.

Reaction of the covalent dichlorides *(3)*[2] with triphenylphosphane gives quantitative yields of the cyclopropenylphosphonium salts *(4)* which can be precipitated as stable salts *(5)* from CH_2Cl_2 with ethereal HBF_4. The position of the double bond follows from spectroscopic data (Table 1). Compounds *(4)* and *(5)* are transformed by the strong Lewis acid $SbCl_5$ into the bis(hexachloroantimonates) *(6)*.



(3) *(4)* *(5)*

(a), R = Ph; *(b)*, R = t-C_4H_9

(6)

Under the same reaction conditions, the salt-like dichlorides *(7)*[3] react immediately with triphenylphosphane to give the bis(dialkylamino)triphenylphosphoniocyclopropenylium dichlorides *(8)* which can be isolated in high yield as stable bis(perchlorates) *(9)* after addition of $HClO_4$ (Table 1).

(7) *(8)*

(a), R = CH_3; *(b)*, R = i-C_3H_7

(9)

While alkyl- and aryltriphenylphosphonium salts show ^{31}P-NMR signals in the range $\delta = -20$ to -35[4], *(6b)* gave a signal at $\delta = -53.6$ and *(9a)* and *(9b)* signals at $\delta = -6.66$ and -8.44, respectively (CD_3CN; H_3PO_4 internal). The strong shielding of the phosphorus in the dications *(9)* relative to that in the system *(6b)* suggests extensive participation of the [3]radialene resonance structure in *(9)* according to the general form *(2b)*. This possibility of stabilization is reserved for systems having strong $+M$ substituents on the three-membered ring and occurs only to a limited extent, if at all, in the salts *(6)*.

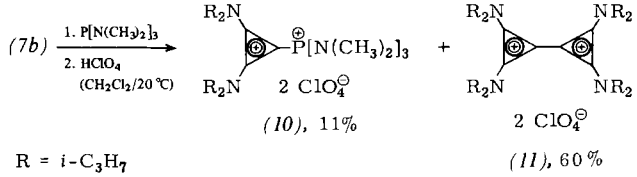


Table 1. Data of new compounds.

	M.p. [°C] [a]	IR (KBr) [cm^{-1}]	UV λ_{max} (log ε)	^{1}H-NMR τ values [b]
(5a)	163—165	1592 (m), 1485 (m), 1445 (s), 1328 (s)	310 (4.28)	2.3 (s, 10H), 2.62 (s, 15H)
(5b)	151—153	1834 (m), 1481 (m), 1438 (s), 1367 (m)	269 (3.83)	2.4 (mc, 15H), 8.88 (s, 18H)

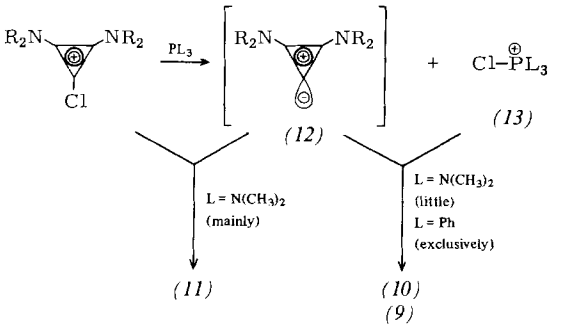
[a] All compounds decompose on melting.
[b] *(5a)*, *(5b)* in $CDCl_3$; *(9a)*, *(9b)*, *(10)* in CD_3CN.

The radialene character of *(9)* is also manifested in a high rotational barrier about the C—N bond. The ΔG^+ value of *(9a)* was found to be >24 kcal/mol[5], whereas that for bis(dialkylamino)cyclopropenylium systems without acceptor substituent lies between 17 and 20 kcal/mol[6]. The increase in positive charge of the nitrogen functions is manifested in a downfield shift of the alkyl signals by *ca.* 0.15 relative to reference systems without acceptor substituents such as *(7a)*[3].

The mode of formation of the dications *(6)* could be classified as an *addition/elimination reaction.* This would also provide a formal explanation of the formation of the dications *(9)*. However, the strong formation tendency of *(9)* is surprising in view of the high ground state stabilization of the cation *(7)* and the high-energy 1,2-bis(dialkylamino)cyclopropene intermediates postulated. In fact, the formation of the dications *(10)* and *(11)* strongly suggests that the systems *(9)* are actually produced by an *elimination/addition reaction* of a kind hitherto undescribed for the C_3^+ system.

(10), 11% *(11)*, 60%



R = i-C_3H_7

Thus, reaction of *(7b)* with tris(dimethylamino)phosphane, which is more nucleophilic than PPh_3, under otherwise identical conditions no longer affords the dication *(10)*[5b] [corresponding to *(9b)*] as major product but instead the known triafulvalene dication *(11)*. These observations indicate the reaction course shown in Scheme 1.

Scheme 1. R = i-C_3H_7.

A crucial step is the nucleophilic attack of PL_3 at the σ^* orbital or the C—Cl bond in *(7b)* with liberation of the nucleophilic carbene *(12)* and formation of the chlorophosphonium ion *(13)*. The electrophilic character of *(13)* which can be varied by way of L probably determines the further course of the reaction. The reaction observed with L = Ph is strongly reminiscent of that between CCl_4 and $P(Ph)_3$[8]. With L = $N(CH_3)_2$ this course only plays a minor role because of the greatly reduced electrophilic character of *(13)*, for *(7b)* can then successfully compete for *(12)* to give the triafulvalene dication in a coupling reaction of known kind[7b]. This reaction is also of preparative interest.

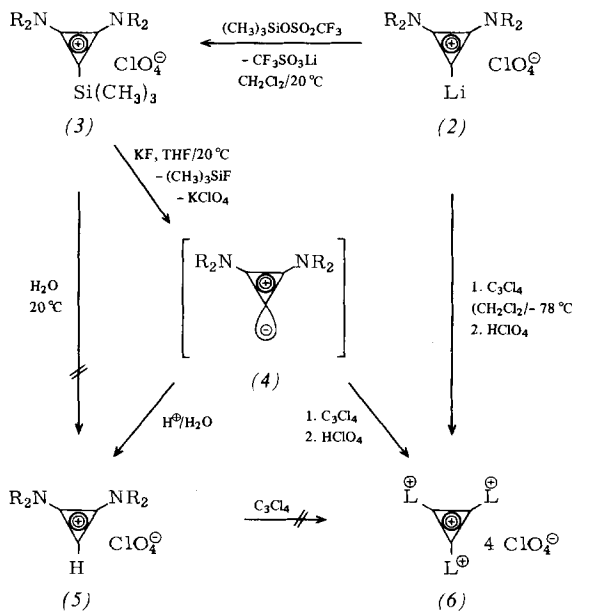
Synthesis of a Donor-Substituted Tris(cyclopropenylio)cyclopropenylium Salt[**]

By *Robert Weiss, Marion Hertel,* and *Hilmar Wolf*[*]

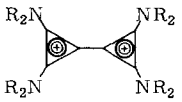


As a result of cyanine resonance, the bis(dialkylamino)cyclopropenylium group *(1)* can assume the character of a $+M$ substituent[1]. We have now exploited this property of *(1)* in order to synthesize novel polycationic cyclopropenylium systems.

Reactions of trichlorocyclopropenylium salts with arenes to form triaryl-substituted cyclopropenylium salts have been known for some time[2]. We wish to report a novel variant of this structural type in which the aromatic donor ligands are themselves cyclopropenylium systems of type *(1)*. For this purpose the carbenoid *(2)*[3a], which has meanwhile become readily accessible, was treated with trimethylsilyl trifluoromethylsulfonate (Scheme 1), giving an 82% yield of the first silyl-substituted cyclopropenylium system *(3)* as thermally stable salt showing considerable resistance to water [m.p. 131 °C; IR (KBr): 1845 (m), 1587 (m), 1535 (s), 1453 (w), 1373/1348 (m) cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\tau = 5.95$ (mc, 4H), 8.64/8.74 (d, 24H; $J = 6$ Hz), 9.58 (s, 9H)].

Compound *(3)* is a potential precursor of the nucleophilic cyclopropenylidene *(4)* (cf. ref. [1]) which has so far defied attempts at generation in the free state[3a]. The method of choice is F^--induced desilylation which has already proved of value in the case of the trimethylsilyltropylium system[4]. *(3)* is rapidly and quantitatively desilylated to *(5)* at room temperature in water on addition of one equivalent of F^-[5].

These results suggest the occurrence of the free nucleophilic carbene *(4)* (Scheme 1). Only one of the possible trapping reactions will be mentioned. While *(3)* fails to react with tetrachlorocyclopropene (C_3Cl_4) in tetrahydrofuran, in the presence of F^- ion under otherwise identical conditions the highly symmetrical stable tetracationic salt (6) is formed in *ca.* 40% yield within 24 h. This system can also be obtained in *ca.* 80% yield directly from *(2)* and C_3Cl_4 in CH_2Cl_2; however, the product thus obtained is contaminated by highly persistent dark-colored by-products.



Scheme 1. R = i-C_3H_7, $L^{\oplus} = [(i\text{-}C_3H_7)_2N]_2C^{\oplus}_3$.

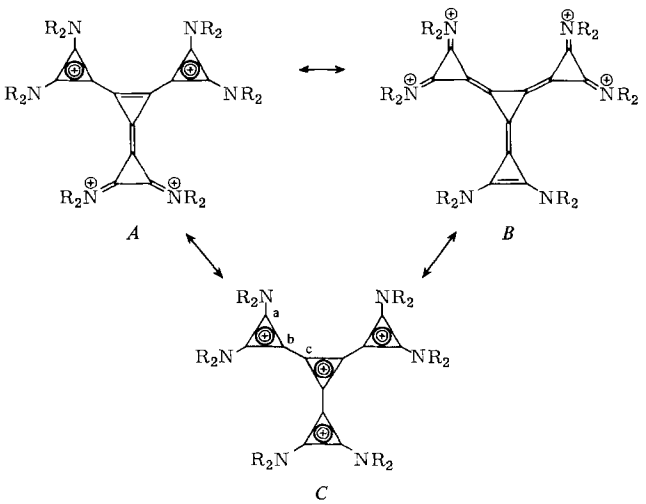
[**] Functional *cyclo*-C_3 Derivatives, Part 8.—This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 7: ref. [1].

Evidence supporting the structure of *(6)* as tris[bis(diisopropylamino)cyclopropenylio]cyclopropenylium tetraperchlorate comes not only from its mode of formation and its correct elemental analysis but also from the sum of the spectroscopic data. The IR spectrum shows the expected characteristic ring vibrations of the peripheral cyclopropenylium systems at 1885 (A′) and 1580 cm^{-1} (E′); the IR-active E′ vibration of the central ring cannot be assigned to any particular band owing to superposition. Important structural information comes from the UV spectrum. Simple bis(dialkylamino)cyclopropenylium systems exhibit a longest wavelength UV absorption around 225 nm ($\log\varepsilon = 4.07$—4.32)[6,7] and triafulvalene dications *(7)* show one around 250 nm ($\log\varepsilon = 4.2$)[7,8]; the longest wavelength band at 347 nm ($\log\varepsilon = 4.52$) in the system *(6)* establishes the presence of a considerably more extended π-system. The 1:1 splitting of the signals of the isopropyl protons in the ^{1}H-NMR spectrum indicates hindrance to rotation of all peripheral dialkylamino groups [^{1}H-NMR: $\delta = 5.82$ (mc, 12H), 8.42/8.52 (d, 36 H; $J = 6$ Hz), 8.47/8.57 (d, 36 H; $J = 6$ Hz)] (cf. [3b]). This rotational hindrance of the donor groups is even clearer from the ^{13}C-NMR spectrum, in which two singlets each in the ratio 1:1 are observed for the quaternary ($\delta = -58.8$ and -56.1) and for the primary C atoms ($\delta = -21.4$ and -20.0) of the alkyl groups. Moreover, three signals in the ratio 2:1:1 are recorded for quaternary C atoms ($\delta = -138.5$, -88.9, and -120.3) which are to be assigned to the three ring positions a, b, c (see Scheme 2, resonance structure C). Assignments for positions a and b are based on comparison with a series of bis(dialkylamino)-substituted cyclopropenylium compounds[7]. The chemical shift of the ^{13}C-NMR signals for the ring C atoms of cyclopropenylium compounds[9] appears to



(7), R = Alkyl

(8a), R = H
(8b), R = C_6H_5
(8c), R = $N(CH_3)_2$

be highly charge dependent. Comparison of the value of $\delta = -120$ found for the central ring position c with the corresponding values of the symmetrically substituted cations *(8a)*—*(8c)* ($\delta = -175$, -154, and -117.9, respectively) leads to the conclusion that *(1)* has a donor strength comparable with that of a dialkylamino group.

Scheme 2. Resonance structures for the cation of *(6)*. R = *i*-C_3H_7.

(6) contains the first isolated tetracarbenium ion; it is essentially stabilized by the peripheral dialkylamino groups after the manner of the resonance structures A, B, and C (Scheme 2). Radialenoid, fulvenoid, and aromatic resonance structures can be formulated for each of the four rings.

In view of the pronounced stability of this compound we consider the synthesis of even more highly charged and extended polycationic polyaryls not to be impossible.

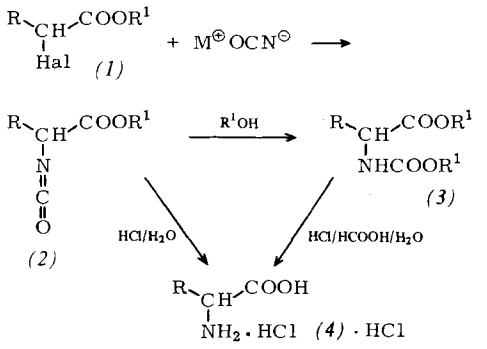
New Synthesis of Amino Acids from Halogenated Carboxylic Esters[**]

By *Franz Effenberger* and *Karlheinz Drauz*[*]

Dedicated to Professor Hellmut Bredereck on the occasion of his 75th birthday

Synthetic natural and unnatural α-amino acids are gaining increasing importance in medicine and in the fortification of foods and animal feeds[1].

Direct amination of α-halo carboxylic acids with aqueous ammonia in many cases leads to secondary and tertiary amino compounds. This multiple alkylation can be largely suppressed by addition of ammonium salts or by working in liquid ammonia[2]; separation of the various salts, though, from the amino acids also present as salt mixtures, often causes considerable experimental difficulties.—Contrary to earlier reports[3], reaction of 2,6-dihalocapronic acids with ammonia, even in the presence of ammonium salts and urotropin, yields mainly 2-piperidinecarboxylic acid, and no lysine.



We have now found that halogenated carboxylic esters *(1)* give high yields of amino acids *(4)* on treatment with alkali cyanates in the presence of alcohols (Table 1). As in the Gabriel synthesis, the amino function is introduced in a protected form [isocyanato or alkoxycarbonylamino group in *(2)* and *(3)*, respectively], yet in a simpler and less expensive way, and the protecting group can be cleaved off under milder conditions. Scattered reports of the reaction between alkali cyanates and alkyl halides in the presence of alcohols, giving urethanes, have already been published[4]. Nothing was known, though, about reactions with derivatives of halo-

genated carboxylic acids, or about the scope of this method for the preparation of primary amines.

The isocyanato esters *(2)* formed initially from the monohalo compounds *(1)* can be isolated and hydrolyzed to the amino acids; the cyanate-catalyzed oligomerization which is the predominant reaction of 2,6-diisocyanatohexanoic esters under standard conditions can be largely suppressed by addition of alcohol. The urethanes *(3)* can be readily isolated and purified, and are hydrolyzed almost quantitatively to analytically pure amino acid hydrochlorides, *(4)* · HCl (Table 1).

[a] $COOC_2H_5$ in place of $COOCH_3$ in *(1)* and *(3)*; $NHCOOC_2H_5$ in place of $NHCOOCH_3$ in *(3)*. [b] *(4)* · 2HCl.

The predominant formation of isocyanates *(2)* as well as the influence of the solvent and of the nature of the cation all suggest a S_N2 mechanism for this reaction. This assumption also rationalizes the observation that additional alkyl groups at the substitution center or increasing steric hindrance at the adjacent carbon atom reduce or even preclude substitution in favor of elimination, as in the case of methyl α-bromoisobutyrate. Preferred elimination thus disqualifies the method for the amination of β-halo- and β-phenyl-α-halo carboxylic esters [see, *e.g.*, *(1c)*].

Synthesis of DL-lysine from ε-caprolactone in an overall yield of 52% is an important application of the new amination procedure.

Experimental

Halo carboxylic ester *(1)* (10 mmol) in anhydrous dimethylformamide (DMF) is heated to 100 °C with stirring with finely ground and dried potassium cyanate and alcohol R^1OH (15 mmol and 35 mmol, respectively, per halogen atom to be replaced; 40—60 min for bromine compounds, 30 h for chlorine compounds). After filtration and removal of DMF by distillation, acetone (30 ml) is added to quantitatively separate the salts. The monourethanes are fractionated in a high vacuum, and the diurethanes are purified by liquid chromatography[6]. The pure urethanes *(3)* are hydrolyzed by refluxing with a mixture of equal parts of conc. hydrochloric acid, 100% formic acid, and water for 20 h at 125 °C. After removal of the mixture of acids, the residue is washed several times with acetone, and the crystalline amino acid hydrochlorides are filtered off and dried in a high vacuum.

The Sequences of the Membrane-Modifying Peptide Antibiotic Trichotoxin A-40

By *Hans Brückner, Wilfried A. König, Michael Greiner*, and *Günther Jung*[*]

The amphiphilic polypeptide antibiotics alamethicin[1], suzukacillin[2], and trichotoxin[3] can produce fluctuating, voltage-dependent ionic current with action potentials in lipid membranes and are therefore of interest as a model system for nerve conduction. The pores formed by aggregation of these peptides can adopt different conductance values and are especially suited for studying the mechanisms of transport phenomena.

Sequencing experiments on alamethicin[4] and suzukacillin[5] were made especially difficult by their high α-aminoisobutyric acid (Aib) content, acetylation of their N-terminals, and the presence of amino alcohols at their C-terminals.

We obtained very pure trichotoxin by extraction of the lyophilized fungal mycelium of *Trichoderma viride* NRRL 5242 with dichloromethane, chromatography on Sephadex LH-20 with methanol and separation of trichotoxin A-40[6] from A-50 by multiplicative countercurrent distribution in 2-butanol/0.015 M ammonium acetate (pH = 8.9) (see Fig. 1)[7]. We found that trichotoxin A-40 and A-50 contained the additional components isovaline (Ival) and valinol which have not previously been described. The L-configuration of the amino acids and the amino alcohols was established by chiral phase gas chromatography and separation *via* diastereomeric derivatives[8] (Ival as a (−)-enantiomer, *i.e.* D-Ival[9]).

Earlier sequencing of alamethicin, together with our own observations on suzukacillin, indicated that the peptide bond linked to the carboxy group of the α-aminoisobutyric acid was remarkably labile towards aqueous hydrochloric acid. In systematic experiments, anhydrous trifluoroacetic acid proved to be a mild, selective cleaving reagent at room temperature. The Aib-Pro bond in antiamoebin and alamethicin was also split by trifluoroacetic acid[4c].

We were able to preferentially split trichotoxin A-40 with trifluoroacetic acid in only 3 h at 37 °C into a *N*-acylated dodecapeptide (peptides I, II, III with exchange of Gly/Ala and Ala/Aib) and a C-terminal hexapeptide which began with proline and contained the amino alcohol valinol (peptides IV, V with exchange of Aib/Ival) (Fig. 1). Further acidolysis of the dodecapeptide gave Ac-Aib-OH and an undecapeptide with a free amino group. After 19 h treatment with trifluoroacetic acid, the tripeptide Ala-Aib-Aib was released from the C-terminal of the undecapeptide. This acidolysis could be reproduced with model peptides. For example, cleavage of Ac-Aib-Pro-NH_2 was approximately 50% after 15 min, that of Ac-Aib-Gly-OH and Ac-Aib-Ala-OH was

approximately 50% after 3 h; in contrast, Ac-Ala-Aib-OMe was only slightly attacked even after 6 h.

The trichotoxin A-40 utilized appeared to be completely homogeneous in ten TLC systems; it also showed a largely integral amino acid ratio. According to the behavior of its cleavage products on thin layer chromatography, there were, however, a total of three *N*-acetylated dodecapeptides (I, II, III) with analogous sequences and two hexapeptides (IV and V) both beginning with proline. These five peptides were separated by silica gel column chromatography and by multiplicative countercurrent distribution.

The sequences of the peptides (Fig. 1) were determined by GLC/MS analyses of the trifluoroacetylated and esterified partial hydrolyzates. The molecular weight of the hexapeptides was obtained by field desorption mass spectrometry. The α-linkage of the valinol was demonstrated by comparison of the mass spectroscopy fragmentation patterns with those of synthetic L-Gln-valinol and L-Glu(valinol)NH_2. In these experiments we observed an unusual quantitative α/γ transpeptidation.

The methods used provided sufficient quantities of defined partial sequences for ^{13}C-NMR investigations and activity studies. According to CD measurements, the helical part of trichotoxin is located, similarly to alamethicin[10], in the N-terminal dodecapeptide. The purification, cleavage, and sequencing methods can be applied to all peptide antibiotics (alamethicins, suzukacillins, *etc.*) which contain Aib.

Titanocene Dichloride—The First Metallocene with Cancerostatic Activity[**]

By *Hartmut Köpf* and *Petra Köpf-Maier*[*]

Dichlorobis(η^5-cyclopentadienyl)titanium(IV) (titanocene dichloride) *(1)* was first reported some 25 years ago[1], yet its cytostatic activity has remained uninvestigated. We expected *(1)* to possibly show such an activity, since it contains a *cis*-dichlorometal moiety in the neutral complex, like the well-known antitumor agent[2] *cis*-diamminedichloroplatinum(II) *(2)*. Further chemical analogies between *(1)* and *(2)* include,

(1) *(2)*

for example, the ability to undergo hydrolytic dimerization *via* oxo-[3] or hydroxo-bridges[4] and the selective reaction with aqueous ammonium polysulfide leading to the pentasulfide chelates $(C_5H_5)_2TiS_5$[5] and $(NH_4)_2[Pt(S_5)_3]$[6], respectively.

To test the antitumor activity of *(1)* we have so far carried out a series of five trial experiments on female CF_1 mice. About 6×10^6 Ehrlich ascites tumor cells[7] were implanted in each mouse by intraperitoneal injection. 24 hours after transplantation (a.t.) the mice were treated (likewise intraperitoneally) with varying amounts of *(1)* or *(2)* in 0.4 ml solution (dimethyl sulfoxide and saline 1:9 (v/v)).

In one representative experiment 84 mice were collected into groups of six animals and treated with *(1)* in doses varying between 10 and 140 mg/kg. Figure 1 shows the number of deaths caused by tumors and by toxicity as well as the proportion of surviving, apparently cured animals, up to day 30 a.t. Twelve animals served as untreated controls (0.4 ml DMSO-NaCl solution; exitus resulting from tumor growth on average 14.25 days a.t.). A further six animals were used as positive controls (10 mg/kg *(2)*; no macroscopically recognizable tumor development up to day 30 a.t.).

In other series of tests, mice treated with *(1)* have survived for ten weeks without any sign of tumor development.

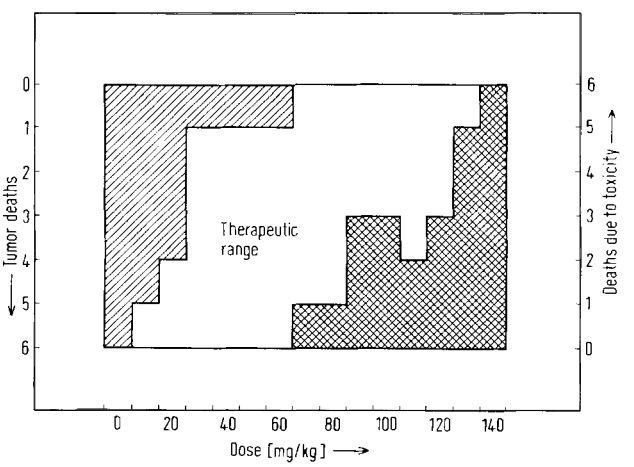

Fig. 1. Survival of mice 30 days after tumor transplantation and 29 days after treatment with *(1)* at the doses given on the abscissa. ▨ Tumor deaths without signs of substance toxicity. ▩ Deaths caused by toxicity (deaths within 8 days a.t. without macroscopically visible tumor development). □ Animals surviving on the 30th day a.t. (therapeutic range).

According to these results *(1)* is an effective antitumor agent with a cure rate in the therapeutic range of over 80%. *(1)* is the first titanium complex and the first metallocene derivative exhibiting cytostatic properties—presumably without the heavy-metal toxicity observed in the case of *(2)*.

Thermal Generation of Pteridines and Flavines from Amino Acid Mixtures

By *Bettina Heinz, Walter Ried,* and *Klaus Dose*[*]

Dedicated to Professor Hermann Hartmann on the occasion of his 65th birthday

The thermal treatment of amino-acid mixtures[1] leads to formation of high-molecular products and to some hitherto unidentified heterocyclic impurities. In addition, a vivid blue fluorescence has frequently been observed[1b].

In order to elucidate the structures of the heterocycles we heated equimolar mixtures of three of the following six amino acids: glycine, alanine, valine, lysine, aspartic acid, and glutamic acid in an oil-bath (4—6 h, 160—200 °C) or metal bath (1—2 h, 180—350 °C) (cf. [1a]). The UV absorption spectra of the blue to green fluorescing material (λ_{max} *ca.* 250, 320—390, 450 nm) and the fluorescence spectra (λ_{exc} 365 nm, λ_{em} 420—480 nm), as well as the chromatographic analysis (cellulose, silica gel, aluminum oxide, Sephadex G 15 and Zipax ion-exchanger for HPLC) of the material isolated by dialysis and fractional extraction, indicated the presence of pteridine derivatives. Supporting evidence for the presence of such derivatives was also provided by chemical reactions (murexide reaction, coupling to diazotized sulfinic acid, color reaction with polytungstatophosphoric acid).

With the help of mass spectrometry we were able to detect definite pteridines; molecular ions and characteristic fragments of hydrogenated oxopteridines and aminooxopteridines (*e.g.* lumazine, xanthopterin, and isoxanthopterin) could be identified. In the case of sample 1, a strong molecular peak at $m/e = 241$ and a weaker peak at $m/e = 256$ suggest the fragmentation pattern of a lumichrome derivative *(1)* (see Table 1). For comparison, we used spectral data from the literature[2,3] and spectra of authentic samples.

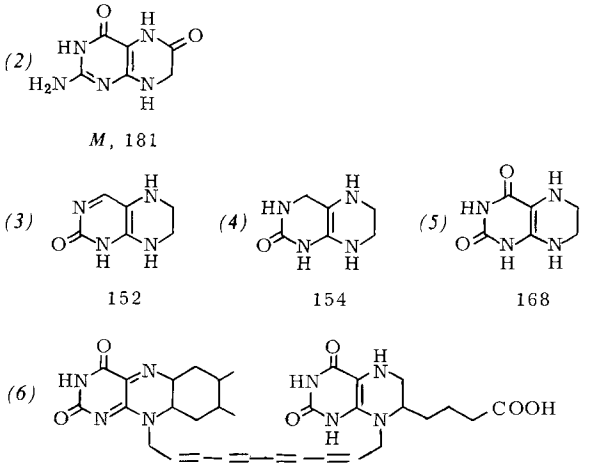

Table 1. Results of the thermolysis experiments. The starting material was fused in an oil bath (180 °C, 6 h; sample 3 under N_2). Compounds *(1)*, *(6)*, and *(7)* were isolated by gel filtration (Sephadex G-15).

en by xanthopterin, isoxanthopterin, and lumazine investigated under the same conditions.

The UV spectra of the eluates were compared with those of authentic samples and showed identical absorption bands.

(7)

The concentrated eluates were dried over P_2O_5 at 60 °C *in vacuo* and then subjected to elemental analysis. From samples 1, 2, and 3 we were able to isolate the compounds *(1)*, *(6)*, and *(7)*.

Several pteridine derivatives can be synthesized on a preparative scale by the classical method of *Isay*[4], *i.e.* by fusion-condensation of 4,5-diaminopyrimidines and dicarbonyl compounds. The pteridine skeletal structure could be formed under prebiotic conditions from amino acids and the compounds allophanic acid, guanidinoformic acid, biuret, and guanidinoformamidine obtained from NH_3, CO_2 and H_2O.

Owing to the special reactivity of the amino acids we presume that the mixtures described here ("pteridine proteinoids" and "flavoproteinoids") play a significant role in the origin of life. In contrast to thermally untreated amino acid mixtures they are especially effective nutrients for microorganisms.

[2+4]-Cycloadditions with Di-*tert*-butyl Acetylenedicarboxylate[**]

By *Gisela Weber, Klaus Menke*, and *Henning Hopf*[*]

Dialkyl esters of acetylenedicarboxylic acid have long been valued as reaction partners in Diels-Alder additions as well as 1,3-dipolar and numerous other addition reactions[1]. Investigating the addition behavior of the recently described di-*tert*-butyl ester *(1)* with dienes *(2)*[2], it was observed that primary adducts of type *(3)* readily lose isobutene and water on warming, either directly or in the presence of catalytic amounts of *p*-toluenesulfonic acid, and are converted into anhydrides *(4)*. The ester *(1)* is thus equivalent to the unknown oxide of carbon, acetylenedicarboxylic anhydride (C_4O_3)[2], and could in principle be useful for the direct incorporation of the anhydride function. A communication published at the beginning of the year on the renewed preparation of *(1)*, and in which the ready cleavability of the product ester without base is also described[3], prompts us to publish a preliminary communication on further [2+4]-cycloadditions with *(1)*[4].

(1) *(2)* *(3)*, $R^5 = COOC(CH_3)_3$

(4) *(5)*

Table 1. Anhydrides *(4)* and monoacids *(5)* formed by decomposition of the primary adducts *(3)* [a].

	X X	R^1	R^2	R^3	R^4	*(3)* Yield [%]	Product Yield [%]
a	2 H	H	H	H	H	75	*(4a)* 99
b	2 H	H	CH_3	H	H	73	*(4b)* 100
c	2 H	H	CH_3	CH_3	H	75	*(4c)* 99
d	2 CH_3	CH_3	H	H	CH_3	0	—
e	O	H	H	H	H	71 [b]	*(5e)* 100
f	CH_2CH_2	H	H	H	H	51	*(5f)* 40

[a] Decomposition in the presence of catalytic amounts of *p*-toluenesulfonic acid at 60—100 °C. On thermal decomposition of the neat substance small amounts of aromatic compounds are also formed. [b] Small amounts of the four possible 2:1 adducts of furan and *(1)* are also produced.

As shown in Table 1 acyclic and cyclic model dienes *(2)* afford the esters *(3)* in good yields; the monocyclic esters *(3a)—(3c)* decompose quantitatively to the anhydrides *(4)*. In the case of the furan and 1,3-cyclohexadiene adducts *(3e)* and *(3f)*, however, the reaction stops after loss of one equivalent of isobutene: instead of the expected anhydrides *(4)*, the monoacids *(5)* are formed, which so far could not be converted into *(4)*.

For determination of the relative reactivity of *(1)* compared to that of dimethyl acetylenedicarboxylate[1] usually employed in cycloadditions we allowed both dienophiles to compete for a substoichiometric amount of 2,3-dimethyl-1,3-butadiene *(2c)*. After 16 h at 120 °C the diene had disappeared, and the two [2+4]-adducts *(3c)*, $R^5 = COOC(CH_3)_3$ and $R^5 = COOCH_3$, respectively, were formed in the ratio 26:74. Thus the ester *(1)* is *ca.* three times less reactive than its dimethyl analog towards this diene. Reactivity differences of this order of magnitude possibly suffice to terminate additions at the 1:1-adduct stage in diene systems which normally lead to 2:1 or higher Diels-Alder products[5].

Methylidynetris(dimethylphosphane)[1]

By *Hans Heinz Karsch, Ulrich Schubert*, and *Dietmar Neugebauer*[*]

Alkyl-substituted methylidynetrisphosphanes were hitherto unknown. The sole example of this chemically important class of compounds is the little-characterized hexaphenyl derivative[2]. Although the analogous silicon compounds are known[3], the method adopted for their synthesis from readily accessible precursors is not applicable to the alkyl-substituted methylidynetrisphosphanes.

$$\underset{(1)}{(H_3C)_2PCH_2P(CH_3)_2} \xrightarrow[-\,BuH]{t\text{BuLi/Pentane}} \underset{(2)}{Li\{HC[P(CH_3)_2]_2\}}$$

$$(2) + (CH_3)_2PCl \xrightarrow[-\,LiCl]{Ether} \underset{(3)}{(H_3C)_2P\text{–}CH(P(CH_3)_2)\text{–}P(CH_3)_2}$$

The simplest compound, the hexamethyl derivative *(3)*, has now been obtained for the first time by metalation of the recently synthesized methylenebis(dimethylphosphane) *(1)*[4] and subsequent reaction with $(CH_3)_2PCl$.

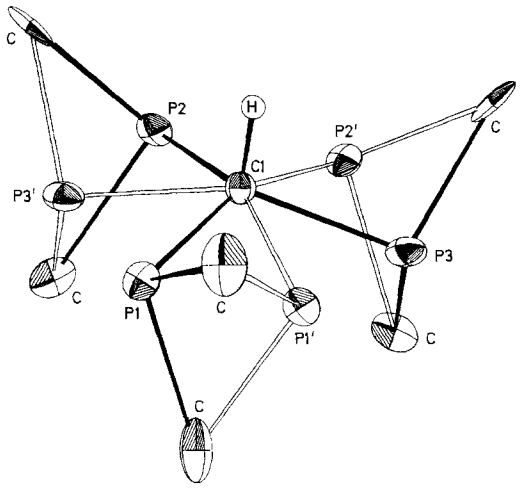

Fig. 1. View of *(3)*. The assigment to each of the two sets of atomic positions (hydrogens not shown; see text) follows from the different marking of the bonds. The C1–H group is common to both sets of positions.

(3) crystallizes from pentane in the form of colorless needles (m.p. 45–47 °C)[5]. On resublimation *in vacuo* large strongly-refracting crystals are obtained.

In the crystal[6], *(3)* is disordered. Referred to the positions of the common CH-group and the methyl carbons, the phosphorus atoms adopt a left-handed arrangement in one molecule and a right-handed arrangement in the other (see Fig. 1). C1 is surrounded by a distorted tetrahedral arrangement of three phosphorus atoms and one hydrogen atom with mean angles P1–C1–P of 115.4(3)° and H–C1–P of 102.6(4)° and a mean P–C1 bond length of 185.6(7) pm. The mean value of the C–P–C angle is 101.3°; the phosphorus atoms are therefore in a pseudotetrahedral arrangement.

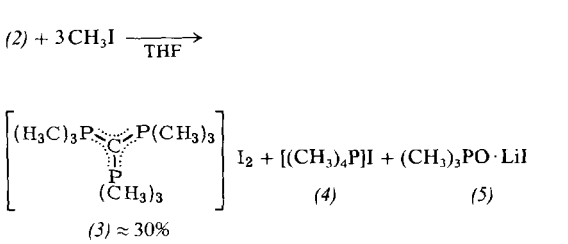
A Phosphorus Ylide with Symmetrical Resonance-Stabilized sp^2-Carbanion[1]

By *Hans Heinz Karsch, Beate Zimmer-Gasser, Dietmar Neugebauer*, and *Ulrich Schubert*[*]

Silyl substituents *(A)* considerably stabilize trialkylmethylenephosphoranes[3a]. The same applies for the iso-electronic phosphonium group *(B)*, which enables further stabilization owing to better charge delocalization and resonance[3b]. On introducing a further phosphonium group *(C)* this effect ought to be decisively increased as a result of the symmetrical geometry.



The isolation of methylidynetris(dimethylphosphane) *(1)*[2] suggested a possible access to *(3)*, the first symmetrically resonance-stabilized phosphorus ylide derivative[4], by reaction with CH_3I, but only products of a P–C cleavage reaction were obtained.

$$\underset{(1)}{[(CH_3)_2P]_3CH} + t\text{BuLi} \xrightarrow[-\,BuH]{\text{Pentane}} \underset{(2)}{Li\{C[P(CH_3)_2]_3\}}$$

[*] Dr. H. H. Karsch, D. Neugebauer, Dipl.-Chem. B. Zimmer-Gasser, Dr. U. Schubert
Anorganisch-Chemisches Institut der Technischen Universität München
Lichtenbergstr. 4, D-8046 Garching (Germany)

However, conversion of *(1)* into its lithium salt *(2)* and subsequent quaternarization with CH_3I produces a lower positive charge on the phosphorus, hence reducing the tendency for P–C bond cleavage and therefore enabling the isolation of *(3)*[5].

Owing to its lower solubility in methanol, *(3)* can easily be separated from the other products; it crystallizes from water as colorless needles. A comparison of *(B)*, $R = CH_3$[3b], and *(3)* reveals the considerable gain in stability: the decomposition point increases from ≈240 to ≈330 °C; whereas *(B)*, $R = CH_3$, is only moderately air-stable and is decomposed by water, *(3)* is stable towards air, water and even trifluoroacetic acid.

The NMR spectra (in D_2O) afford no conclusive information on the configuration of *(3)*. The ^{1}H-NMR spectrum [δPCH_3: +2.85, "filled-in doublet", N = 13.1 (distance between outer lines)] and the $\{^1H\}$-^{13}C-NMR spectrum [δPCH_3: +18.2, symmetrical 6-line multiplet, N = 73.2 Hz (distance between outer lines)] would indicate a symmetrical configuration containing at least two $-\overset{+}{P}(CH_3)_3$ groups, but no resonance is observed for the central C-atom. The chemical shift of the $\{^1H\}$-^{31}P resonance ($\delta P = +19.6$ s), lying between the values for $[P(CH_3)_4]^+$ and $(CH_3)_3P{=}CH_2$, is equally not conclusive enough regarding proof of structure.

The trigonal-planar configuration could however be confirmed by X-ray structure analysis[6] (see Fig. 1).

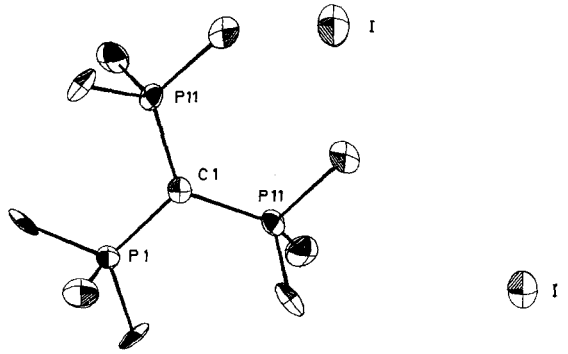


Fig. 1. View of *(6)*. The molecule has mirror symmetry. The hydrogen atoms are not shown. Bond lengths: P1–C1 = 175, P11–C1 = 175, P1–C = 180, P11–C = 178 pm; bond angles: P1–C1–P11 = 116.7, P11–C1–P11 = 126.5, C1–P1–C = 112.6, 112.6, 112.9, C1–P11–C = 115.9, 113.3, 112.5°.

The C1–P bond lengths approach those observed in other stabilized phosphorus ylides[7]. In the crystal there are at most only weak interactions between the cation and the iodide ions (minimum I...H distance: 296 pm).

Asymmetric Epoxidation of Simple Olefins with an Optically Active Molybdenum(VI) Peroxo Complex[**]

By *Henri B. Kagan, Hubert Mimoun, Christoph Mark*, and *Volker Schurig*[*]

The importance of chiral epoxides in biochemistry and synthetic chemistry has warranted the search for simple methods of access to this interesting class of compounds. The abiotic asymmetric epoxidation of prochiral olefins has so far been carried out with optically active peracids (optical yields 0.6—7.5%[1a]), with achiral hydroperoxides in the presence of optically active metal-complex catalysts (5—44% e.e.[1b]), and with H_2O_2 by phase-transfer catalysis with quaternized alkaloids (25% e.e.[1c]). These reactions succeeded only with activated CC double bonds (styrenes, allyl alcohols, conjugated ketones, quinones). We describe here a novel method for the asymmetric epoxidation of simple *unfunctionalized* olefins by an optically active metal-peroxo complex.

Molybdenum(VI) oxodiperoxo complexes $MoO(O_2)_2L$ (L = hexamethylphosphoric triamide HMPA, pyridine) epoxidize olefins stoichiometrically and diastereospecifically[2]. We have synthesized a stable optically active complex *(1)*[3] containing the bidentate chiral ligand (*S*)-*N*,*N*-dimethyllactamide (= L). According to X-ray structural analysis[4], the compound has the pentagonal-bipyramidal geometry *(1)* with sevenfold coordinated molybdenum.

by *(1)* in nitrobenzene at 20 °C/1 bar (Table 1). The chemical yield (70%), the enantiomeric excess (up to 34% ee), and the configuration of the dominant oxirane enantiomer (in all cases *R*) were determined by complexation gas-chromatography on nickel(II) bis(3-heptafluorobutyryl)-1*R*-camphorate[5]. This methodology also permitted continuous kinetic monitoring of the asymmetric synthesis.

Table 1. Asymmetric epoxidation of prochiral olefins *(2)*—*(6)* by molybdenum(VI) oxodiperoxo-(*S*)-*N*,*N*-dimethyllactamide *(1)* to the oxiranes *(7)*—*(11)*. *(1)* (30 mg, ≈0.1 mmol) is suspended in nitrobenzene (3 ml) at 20 °C/1 bar. After addition of 1 mmol olefin the mixture becomes homogeneous.

Olefin		Oxirane		Enantiomeric excess [%] (±1%)	Configuration [a]
Propene	*(2)*	Methyloxirane	*(7)*	28.8	*R*
1-Butene	*(3)*	Ethyloxirane	*(8)*	31.1	*R*
3-Methyl-1-butene	*(4)*	Isopropyloxirane	*(9)*	15.5	*R*
trans-2-Butene	*(5)*	*trans*-Dimethyloxirane	*(10)*	34.8	2*R*, 3*R*
2-Methyl-2-butene	*(6)*	Trimethyloxirane	*(11)*	5.1 30.2 (−5 °C)	*R*

[a] Configuration of the dominant enantiomer. For all oxiranes, during complexation gas-chromatography on nickel(II) bis(3-heptafluorobutyryl)-1*R*-camphorate the larger peak is eluted first. Assignment of configuration: for *(7)* and *(10)* by independent synthesis; for *(8)*, *(9)*, and *(11)* by an empirical quadrant rule [5]

While a marked increase in enantiomeric yield [oxirane *(11)*] is observed on reducing the reaction rate by lowering the temperature, the increasing steric hindrance of the alkyl group [olefin *(4)*] surprisingly leads to a decrease in the asymmetric induction. The continuously monitored enantiomeric composition of the oxiranes *(2)*—*(5)* during the reaction remained constant within the experimental accuracy. This shows that the olefin epoxidation is asymmetrically induced and that no enrichment of the enantiomers of the epoxide that is formed takes place by kinetic resolution. Control experiments showed, moreover, that the slow degradation of the racemic epoxides *(2)*—*(5)* by the complex *(1)* takes place without enantiomer enrichment. The consecutive oxidation of the epoxides by *(1)* is suppressed by an excess of olefin[2]. The rate of epoxidation of olefins by *(1)* increases by about two orders of magnitude along the series ethene (48 h) < 1-butene < *trans*-2-butene < 2-methyl-2-butene (15 min). The strength of π-complexation of these olefins with $MoO(O_2)_2(HMPA)$[6] increases along the same series. The observed asymmetric induction is most likely due to enantiofacial discrimination of prochiral olefins by optically active *(1)*.

Krypton and Xenon Inclusion Compounds of Complex Metal Cyanides

By *Manfred Kämper, Madlon Wagner*, and *Armin Weiss*[*]

Noble gas inclusion compounds—known as gas hydrates and as hydroquinone clathrates—are often stable only at low temperature and high pressure. Strictly speaking, they are not true clathrates because the host lattices are not stable on their own. We now describe the compounds $CdPt(CN)_6 \cdot 1.046$ Kr and $CdPt(CN)_6 \cdot 1.128$ Xe which exhibit high stability and vacant cage structure.

This cage structure is generally encountered in hexacyanometalates of the transition metals. Here the metal atoms are linked by the CN groups to form a three-dimensional network. The resulting Prussian blue-type cubic face-centered structure is fourfold primitive and contains eight cubic subunits per unit cell; hence two cavities exist per $MM'(CN)_6$ formula unit.

We have now found that hexacyanopalladates(IV)[1] and hexacyanoplatinates(IV)[2] of divalent transition metals, especially Mn, Zn, and Cd, are anhydrous and must therefore have vacant cavities. The compounds mentioned are obtained as large perfect cubes on gel crystallization: they also allow definite proof of their anhydrous nature.

The edge length of the cubic subunit of $CdPt(CN)_6$ (Table 1), *viz.* $a/2 = 5.47$ Å, and the diameter of a CN group (*ca.* 3.0 Å[3]) show the window in the cubic subunit to have an edge length of *ca.* 2.5 Å. Hence inclusion can only take place during growth of the compound. It also follows from the data for $CdPt(CN)_6$ that spherical atoms or molecules with a maximum diameter of *ca.* 4.7 Å (which would include H_2O) can be accommodated by the cavities. It therefore appears all the more surprising that the compounds mentioned are anhydrous although they are crystallized from water. Water molecules obviously prefer the hydrogen-bonded clusters of the solvent to being caged in the cavities of the host lattice for energetic reasons.

The cavities must be regarded as hydrophobic and thus suitable for incorporation of hydrophobic molecules from an aqueous reaction medium.

Experiments with the noble gases krypton, $d = 3.96$ Å, and xenon, $d = 4.36$ Å, yielded such inclusion compounds. Crystals of the host compound $CdPt(CN)_6$ were grown in the presence of the noble gas at 64 bar in an autoclave. The compounds obtained were characterized by analysis, mass spectrometry, and X-ray methods (Table 1).

Table 1. X-Ray data of the host compound and of the krypton and xenon inclusion compounds.

	Host compound	Kr compound		Xe compound	
Formula	$CdPt(CN)_6$	$CdPt(CN)_6 \cdot 1.046$ Kr		$CdPt(CN)_6 \cdot 1.128$ Xe	
Axis of unit cell	10.938 Å	10.955 Å		10.980 Å	
Number of reflections measured	1651	1662		1662	
Independent reflections	350 (Fm3m)	563	(F 23)	563	(F 23)
		356	(Fm3m)	356	(Fm3m)
R value	1.96%	2.95%	(F 23)	1.90%	(F 23)
		2.71%	(Fm3m)	1.89%	(Fm3m)
Occupation of site (based on formula)	—	0.614 / 0.470	(F 23)	0.566 / 0.562	(F 23)
		1.046	(Fm3m)	1.128	(Fm3m)

In compliance with the space group Fm3m the host compound $CdPt(CN)_6$ contains four formula units and eight cavities in its unit cell. However, only four cavities are occupied by noble gas atoms. Given strictly alternating occupation this corresponds to a lower tetrahedral symmetry of space group F 23; the eightfold site of the host compound resolves into two fourfold sites.

Calculation yields the same occupation of the two fourfold sites for the xenon compound, *i. e.* it becomes identical with a description in the space group Fm3m. This corresponds to two structural variants, *viz.* a purely random arrangement and a subdivision of the macrocrystal into domains each of which has one of the possible alternating occupations. No experimental distinction is possible.

The F 23 structural approach leads to 1 a slightly unsymmetrical occupation of the two fourfold sites in the case of krypton; the *R* value is slightly poorer than for the Fm3m description. However, these small deviations are hardly significant, particularly in view of the small scattering power of krypton.

Finally, these compounds could provide a technically interesting alternative to the storage of gases in steel cylinders. In the krypton compound, the krypton is present at a density corresponding to that of an ideal gas at 118 bar. If all the cavities are occupied by preparation at higher pressure this value even rises to 216 bar.

A New Lithium-Nickel Polynuclear Complex: $Ni(C_{12}H_{17}NiLi)_2(THF)_4$

By *Klaus Jonas, Carl Krüger*, and *Janine C. Sekutowski*[*]

The conversion of the binary nickel(0)-olefin complexes $(C_8H_{12})_2Ni^0$ (C_8H_{12} = 1,5-cyclooctadiene) and $C_{12}H_{18}Ni^0$ ($C_{12}H_{18}$ = *all-trans*-1,5,9-cyclododecatriene) into the corresponding dilithium-nickel-olefin complexes $(C_8H_{12})_2NiLi_2(THF)_4$ (THF = tetrahydrofuran) and $C_{12}H_{18}NiLi_2(TMEDA)_2$ *(1)* (TMEDA = *N,N,N',N'*-tetramethylethylenediamine) by reaction with metallic lithium is accompanied by side reactions. This is particularly marked in the case of cyclododecatriene-nickel(0) (yields: *(1)*, *ca.* 50%; $(C_8H_{12})_2NiLi_2(THF)_4$, 80—90%).

We have now found that one of the products of the lithiation of $C_{12}H_{18}Ni^0$ is the novel polynuclear lithium-nickel complex $Ni(C_{12}H_{17}NiLi)_2(THF)_4$ *(3)*. This species is also formed if *all-trans*-cyclododecatriene-nickel(0) is allowed to react at 0 °C with a THF solution of *(1)* and precipitates out of the initially clear solution in the form of dark red crystals (30%).

$$\underset{(1)}{C_{12}H_{18}NiLi_2(TMEDA)_2} \xrightarrow[-TMEDA]{+C_{12}H_{18}Ni^0,\ +THF} \underset{(3)}{Ni(C_{12}H_{17}NiLi)_2(THF)_4}$$

We assume that *(3)* is the product of a transmetalation reaction in which, instead of exchange of lithium between two different $C_{12}H_{18}Ni^0$ molecules [eq. (a)], the metalating agent *(1)* has attached the C H bonds of the complexed double bonds of two $C_{12}H_{18}Ni^0$ molecules [eq. (b)].

$$\underset{(1)}{C_{12}H_{18}NiLi_2} + C_{12}H_{18}Ni' \rightleftarrows C_{12}H_{18}Ni + \underset{(1)'}{C_{12}H_{18}Ni'Li_2} \quad (a)$$

$$\underset{(1)}{C_{12}H_{18}NiLi_2} + 2\,C_{12}H_{18}Ni \longrightarrow \underset{(2)}{C_{12}H_{18}NiH_2} + 2\,C_{12}H_{17}NiLi \quad (b)$$

$$C_{12}H_{18}NiH_2 \longrightarrow C_{12}H_{20} + \underset{(3)}{Ni(C_{12}H_{17}NiLi)_2(THF)_4}$$

$C_{12}H_{18}$ = cyclododecatriene
$C_{12}H_{20}$ = cyclododecadiene
The n-donors bonded to lithium are shown only for isolated *(3)* in eq. (a) and (b).

(1) is converted into the unstable complex $C_{12}H_{18}NiH_2$ *(2)* which, as can be shown by protolysis of *(1)* with alcohol or by the reaction of $C_{12}H_{18}Ni^0$ with H_2[3], normally decomposes to give metallic nickel and cyclododecadiene ($C_{12}H_{20}$) or cyclododecane ($C_{12}H_{24}$). However, under the reaction conditions described here *(2)* is stabilized by reaction with two molecules of $C_{12}H_{17}NiLi$ and loss of $C_{12}H_{20}$, giving the polynuclear complex *(3)*.

Characteristic for *(3)*[3] is the linear arrangement of the Ni_3 skeleton with metal-metal interactions (Fig. 1). The central nickel atom Ni1, which occupies a crystallographic inversion center and is in an essentially planar environment, occupies a fourth coordination site at Ni2 and forces this atom *ca.* 0.5 Å out of the trigonal ligand plane of the twelve-membered

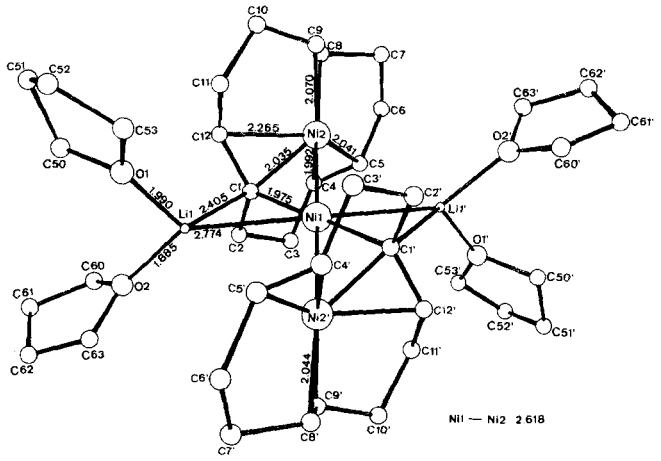

Fig. 1. Structure of the complex $Ni(C_{12}H_{17}NiLi)_2(THF)_4$ *(3)*. Bond lengths in Å.

ring[4]. A hetero-metal multicenter bond[5] is observed for the five-coordinated carbon atom (C1) of the twelve-membered ring which is bonded to Ni2 through three π-bonds. This leads to an acute angle of 78° for Ni···C1···Li which is typical for electron deficient bonds and is accompanied by considerable distortion of the π-bonded interaction Ni2C1C2 (Fig. 2).

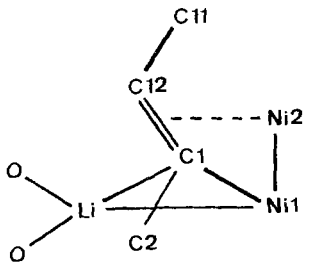

Fig. 2. The bonding situation at the site of the heterometal multicenter bond.

The molecular symmetry $\bar{1}$ (C_i) is perturbed by disorder of the aliphatic carbon atoms of the complexed twelve-membered ring. The lithium atom which interacts only with two perpendicularly oriented THF ligands appears to be coordinatively unsaturated.

The ^{13}C-NMR spectrum[6] of *(3)* in [D_6]benzene exhibits a total of eleven signals for the two identical twelve-membered rings. Six can be assigned to methylene C-atoms ($\delta = 54.5$, 44.0, 42.5, 41.8, 40.7, and 38.8 ppm, all t) and five to the C-atoms of the complexed double bonds ($\delta = 109.0$, 85.6, 84.1, 78.7, and 75.7 ppm, all d). The failure to observe the sixth olefinic C-atom (C1) is associated with its quaternary nature.

Nickel(0)-Induced Synthesis of Ethyllithium from Lithium, Hydrogen, and Ethylene

By *Klaus Jonas* and *Klaus Richard Pörschke*[*]

In general high reaction temperatures are necessary for the synthesis of alkali-metal hydrides from the elements[1], although sodium hydride can be formed at room temperature and normal pressure in tetrahydrofuran if both naphthalene and titanium isopropoxide are present[2]. We wish to report here, *inter alia*, on the "lithium hydride" complex $(COD)_{1.5}NiLi_2H_2(THF)_x$ (COD = 1,5-cyclooctadiene).

Reaction of binary nickel(0)-olefin complexes with metallic lithium yields well-defined dilithium-nickel-olefin complexes[3, 5], for example as in eq. (a), containing reactive lithium[4, 5]. Thus $(COD)_2NiLi_2(THF)_4$ *(2)*, which is relatively soluble in THF or dimethoxyethane (≈0.25 mol/l at room temperature), reacts with molecular hydrogen (1 atm) even at −60 °C. One H_2 per Li_2Ni-unit is taken up with elimination of 0.5 COD/Li_2Ni to produce the sparingly soluble bright-yellow powder *(3)* [eq. (b)][4].

$$(COD)_2Ni + 2\,Li \xrightarrow[-30\text{ to }0\,°C]{THF} (COD)_2NiLi_2(THF)_4 \qquad (a)$$

(1) *(2)*

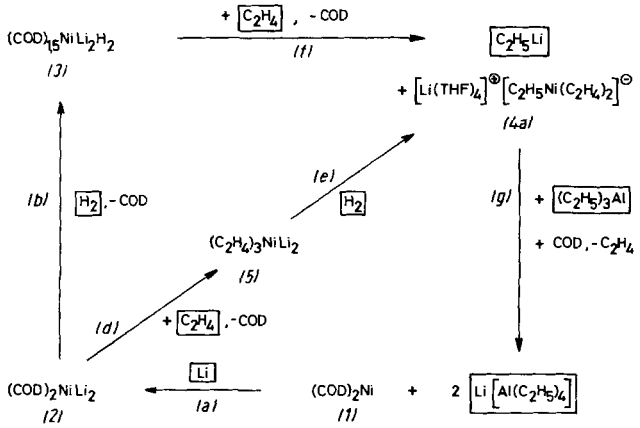
$$(2) + 1\,H_2 \xrightarrow[-60\text{ to }-40\,°C]{THF} (COD)_{1.5}NiLi_2H_2(THF)_x + 0.5\,COD \qquad (b)$$

(3)

(3) contains the unchanged ligand 1,5-cyclooctadiene, as shown by reactions with cyclooctatetraene or CO in which *(3)* is dissolved and cyclooctadiene is liberated in high yield. Hydrogen is not evolved. *(3)* also dissolves in the presence of organometallic Lewis acids such as $(C_2H_5)_3Al$ if COD is added. The Li and H atoms in *(3)* are transferred from the complex to the $(C_2H_5)_3Al$ as lithium hydride [eq. (c)]. Both $Li[Al(C_2H_5)_3H]$ (75% isolated as $[Li(TMEDA)_2]^{\oplus}$-$[Al(C_2H_5)_3H]^{\ominus}$, TMEDA = *N,N,N',N'*-tetramethylethylenediamine) and *(1)* (90%) are formed in high yields.

$$(COD)_{1.5}NiLi_2H_2 + 2(C_2H_5)_3Al + 0.5\,COD \xrightarrow[-30\,°C]{THF} \qquad (c)$$

(3)



$$(COD)_2Ni + 2\,Li[Al(C_2H_5)_3H]$$

(1)

Combination of equations (a), (b), (c) gives a reaction sequence in which lithium, H_2, and $(C_2H_5)_3Al$ produce $Li[Al(C_2H_5)_3H]$ stoichiometrically at −30 °C and normal pressure. An attempted nickel(0)-catalyzed synthesis of $Li[Al(C_2H_5)_3H]$, in which *(1)*, lithium, and $(C_2H_5)_3Al$ were allowed to react at −30 °C, was unsuccessful since *(2)* does not complex with hydrogen in the presence of $(C_2H_5)_3Al$. However, the $(COD)_2Ni$ *(1)* re-formed according to eq. (c) can be re-lithiated to start the cycle again. Thus it is possible to synthesize $Li[Al(C_2H_5)_3H]$ in stages pseudocatalytically in a one-pot process.

[*] Dr. K. Jonas, Dr. K. R. Pörschke
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr (Germany)

Whereas pure lithium hydride prepared from lithium and H_2 does not add to C=C double bonds, the "lithium hydride" bound in *(3)* proves to be more reactive, *e. g.* with norbornene, propylene, or ethylene.

(3) dissolves in an ethylene-saturated THF-solution even at $-60\,^{\circ}C$ [eq. (f)]. Cooling the clear reaction solution to $-78\,^{\circ}C$ leads to the crystallization of *(4a)*, or of $[Li(TMEDA)_2]^{\oplus}[C_2H_5Ni(C_2H_4)_2]^{\ominus}$ *(4b)* if TMEDA is added, while C_2H_5Li remains in solution. Reaction of C_2H_5Li and *(4a)* with $(C_2H_5)_3Al$ and COD affords $Li[Al(C_2H_5)_4]$ and $(COD)_2Ni$ *(1)* according to eq. (g); lithiation of *(1)* leads to regeneration of *(2)* [eq. (a)]. For the preparation of *(4a)*/C_2H_5Li from *(2)*, there is a further route other than *via (3)* [eqs. (b) and (f)]. This second route also involves two steps, firstly displacement of the COD in *(2)* by ethylene, leading to the sparingly soluble *(5)*[3,4] [eq. (d)] and, secondly, treatment of *(5)* with hydrogen [eq. (e)] to give a clear solution from which *(4a)* crystallizes on cooling to $-78\,^{\circ}C$.

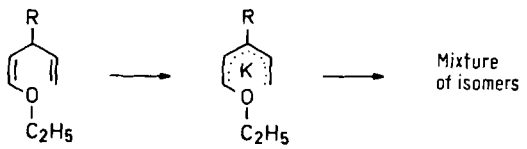
Metalation of Pyrans and Dihydropyridines: When is an 8 π-System Cost Effective?[**]

By *Manfred Schlosser* and *Philippe Schneider*[*]

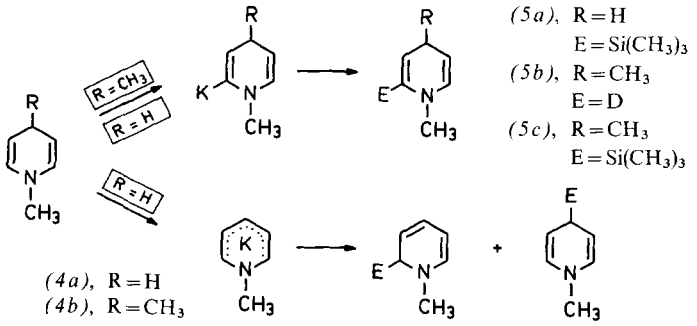


Powerful metalating agents[1] such as butyllithium in the presence of potassium *tert*-butoxide or trimethylsilylmethylpotassium promote slow hydrogen/potassium exchange at the position next to the oxygen atom, in both 4*H*-pyran *(1a)*[2a] and 4-methyl-4*H*-pyran *(1b)*[2b]. Subsequent treatment with methyl iodide, ethyl bromide, bromomethyltrimethylsilane, or chlorotrimethylsilane in petroleum ether affords 4% 2-methyl- *(2a)* and 22% 2-trimethylsilyl-4*H*-pyran *(2b)*, or 14% 2-ethyl- *(2c)*, 23% 2-trimethylsilylmethyl- *(2d)* and 48% 2-trimethylsilyl-4-methyl-4*H*-pyran *(2e)*, respectively[3].

(1a), R = H
(1b), R = CH_3

(2a), R = H, E = CH_3
(2b), R = H, E = $Si(CH_3)_3$
(2c), R = CH_3 E = C_2H_5
(2d), R = CH_3, E = $CH_2Si(CH_3)_3$
(2e), R = CH_3, E = $Si(CH_3)_3$

Thus, upon treatment with organometallic reagents the pyrans *(1a)* and *(1b)* behave like 3,4-dihydro-2*H*-pyran, in which the olefinic hydrogen adjacent to the oxygen atom can—again slowly and accompanied by side reactions—be replaced by lithium and sodium[4a]. In contrast, the open-ring analogs *(3a)* and *(3b)* are rapidly and exclusively deprotonated at the double-allylic position[4b].



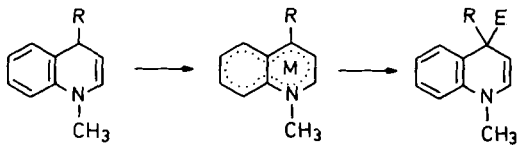
(3a), R = H
(3b), R = CH_3

Upon reaction with butyllithium and potassium *tert*-butoxide in pentane, 1,4-dimethyl-1,4-dihydropyridine *(4b)*[5] is also metalated only at the position adjacent to the heteroatom. Subsequent reaction with deuterium oxide or chloromethylsilane leads to 82% of the 2-deuteriated *(5b)* or 41% of the 2-trimethylsilylated derivative *(5c)*, respectively. On the other hand, the homologous 1-methyl-1,4-dihydropyridine *(4a)*[5] can be deprotonated, depending on the selected metalating agent[6], either again at the "geometrically acidified"[7] olefinic position or, alternatively, at the "electronically acidified"[7] methylene group. Reaction with butyllithium and potassium *tert*-butoxide in pentane followed by addition of chlorotrimethylsilane afforded 3% 1-methyl-2-trimethylsilyl-1,4-dihydropyridine *(5a)* as the sole volatile product besides starting material and resins[3]. Using trimethylsilylmethylpotassium in tetrahydrofuran, however, we were able *for the first time to remove a proton from the allylic position of a dihydropyridine derivative and thus generate an organometallic 8 π-system*[8]. The intermediate, moderately stable at $-50\,^{\circ}C$, reacts with methyl iodide or chlorotrimethylsilane to give, respectively, a 1:1 mixture of 1,2-dimethyl-1,2-dihydropyridine *(6a)* and 1,4-dimethyl-1,4-dihydropyridine *(7a)* in 55% yield or 1-methyl-4-trimethylsilyl-1,4-dihydropyridine *(7b)* (6%)[3,9].

The differing behavior of the two *N*-methyldihydropyridines *(4a)* and *(4b)* is not particularly surprising. Introduction

[*] Prof. Dr. M. Schlosser, Dipl.-Chem. P. Schneider
Institut de Chimie Organique de l'Université
Rue de la Barre 2, CH-1005 Lausanne (Switzerland)

[**] This work was supported by the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung (Project 2.467.0.75 and 2.693.0.76).

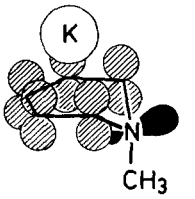


(5a), R = H, E = $Si(CH_3)_3$
(5b), R = CH_3, E = D
(5c), R = CH_3, E = $Si(CH_3)_3$

(4a), R = H
(4b), R = CH_3

(6a), E = CH_3 *(7a)*, E = CH_3
(7b), E = $Si(CH_3)_3$

of an alkyl substituent reduces the thermodynamic and, in particular, the "kinetic acidity"[7] of CH-groups. The attack at the double-allylic site being hindered by the additional methyl group [in *(4b)*], the otherwise [in *(4a)*] uncompetitive metalation at the olefinic position once again becomes more advantageous. On the other hand, attack at the site flanked by double bonds remains dominant, even after introduction of a methyl group, if the resonance area is extended, thus improving the delocalization of excess electrons. Both 1-methyl- *(8a)* and 1,4-dimethyl-1,4-dihydroquinoline *(8b)*[10] are smoothly deprotonated at the benzylic position by trimethylsilylmethylpotassium in tetrahydrofuran at −80 °C. The reaction of the two 12π-organometallic species with chloromethylsilane leads to 25% 1-methyl- *(9a)* and 47% 1,4-dimethyl-4-trimethylsilyl-1,4-dihydroquinoline *(9b)*[11], respectively.



(8a), R = H
(8b), R = CH_3

(9a), *(9b)*, E = $Si(CH_3)_3$

The precise structure of the metalated heterocycles having a cyclic conjugated π-system is still unknown. The 8π-species *N*-methyldihydropyridylpotassium should, however, we assume, exist in an "envelope conformation" *(10)*, in which the horse-shoe shaped pentadienyl moiety serves as an η^5-ligand.

An analogous 8π-pyranylmetal species would present a much less favorable situation, since, due to the now unavoidable axial orientation, the second "free" electron pair on the heteroatom (O instead of N–CH_3) would produce a strong, conjugatively destabilizing ("antiaromatic") interaction with the 6π-pentadienyl system[12].

[11] In unpublished experiments *H. Ahlbrecht* and *K. Reucker* (cf. *K. Reucker*, Dissertation, Universität Giessen 1977) were able to deprotonate 1,3-dimethyl-2-phenyl-1,4-dihydroquinoline, activated by an additional aromatic moiety, at the methylene group and to obtain a series of 4-substituted derivatives.
[12] Evidence for the instability of 8π-pyranylmetal compounds was obtained by *R. R. Schmidt, U. Burkert, R. Prewo*, Tetrahedron Lett. *1975*, 3477; 2,4,6-triphenyl-4*H*-pyran, when establishing the acid/base equilibrium in the presence of lithium diisopropylamide at −80 °C, is deprotonated (at position 4) to the extent of only 50%. Under the same conditions, 2,6-diphenyl-4*H*-pyran does not undergo any noticeable change.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0606-0490 $ 02.50/0

Ullmanns Encyklopädie der technischen Chemie. Editorial board: *E. Bartholomé, E. Biekert, H. Ley* (deceased), *W. M. Weigert* (deceased), and *E. Weise.* Verlag Chemie, Weinheim—New York 1978, 4th Edit. Vol. 15: Korrosion bis Lacke (Corrosion to Paints and Varnishes). xv, 726 pp., bound, DM 475.00.—Vol. 16: Lagerwerkstoffe bis Milch (Bearing Materials to Milk). x, 734 pp., bound, DM 425.00.

With the appearance of Volumes 15 and 16, ten of the eighteen planned alphabetical volumes (7—24) of the 4th edition of Ullmann are now available[*]. The next few years will see the completion of this new edition of the encyclopedia—a truly impressive accomplishment by the editors, editorial board, and publisher.

Almost half of Volume 15 (302 pages) is devoted to the keyword plastics which merely considers general properties and processes—individual kinds of plastics are described under their own headings. The subject matter is presented in the following sections: historical (4 pages), introduction (35 pages), states of order and properties (34 pages), additives (21 pages), coloring (5 pages), processing (73 pages), testing (16 pages), analysis (26 pages), standardization (4 pages), economic significance and applications (9 pages), utilization of wastes (9 pages), plastics with special properties (28 pages), plastics as electrical insulators (38 pages). The introduction provides a terse survey of physicochemical and physical fundamentals of polymers, *i.e.* thermodynamics, reaction kinetics, and structure of macromolecular materials. The section on utilization of wastes deals with a highly topical development which is becoming more and more important (references up to 1978!).

Other keywords in Volume 15 are: corrosion (59 pages), crystals (83 pages with sections on crystallography and crystal properties), copper (100 pages, including copper alloys and copper compounds), cresols and xylenols (17 pages), artificial leather (8 pages), artists' colors (7 pages), paints and varnishes (138 pages).

Like the entry on plastics, those concerned with crystals and paints and varnishes have the character of introductory monographs. The large number of literature references given here, and elsewhere in Ullmann, are of great value in penetrating further into the field in question.

Volume 16 contains a great variety of keywords. For example lithium (17 pages), magnesium (39 pages), manganese (56 pages), with their alloys and compounds, and metallurgy (17 pages) come from the realm of inorganic chemistry. Organic chemistry is represented by maleic acid, malonic acid, melamine, methacrylic acid and methacrylates, methane, methanol, methylamines, organometallic compounds, and dyestuffs chemistry by methine dyes (35 pages), leuco vat dyes, metal complex dyes, and microscopy stains. From the field of natural products we have leather (69 pages), lignin, foodstuffs (76 pages, including sections on general aspects, preservation, additives, and packaging), milk and milk products (37 pages), lecithin, margarines and shortenings. Entries having a more technological slant will be found under inorganic phosphors (29 pages), generation of light (38 pages), magnetic materials (38 pages), magnetic media, solvents (33 pages), membranes (21 pages), microcapsules, bearing materials, soldering and brazing, protection of materials, metals/surface treatment.

Of course, entries under comprehensive keywords such as organometallic compounds and foodstuffs deal only with facts common to the whole field and with fundamental relationships; this is immediately apparent from the number of pages (*e.g.* 21 pages on organometallic compounds). More specialized information (say about organomagnesium compounds) will be found in the relevant entries (magnesium in the case mentioned).

As always, the individual keywords provide useful information about economic aspects (including production and consumption figures), quality demands, environmental problems, safety questions, and legal requirements. In this connection, special mention should be made of two tables from the contribution on solvents in this volume, which list physical properties as well as safety and physiological data.

It only remains to say that these two volumes fully comply with the high standard of presentation and product set by previous volumes of Ullmann.

Ulfert Onken [NB 467 IE]

Kirk-Othmer: Encyclopedia of Chemical Technology. Editors: *H. F. Mark, D. F. Othmer, C. G. Overberger,* and *G. T. Seaborg.* John Wiley & Sons, New York 1978, 3rd Edit. Vol. 2. Alkoxides, Metal to Antibiotics (Peptides). xxv, 1036 pp., bound, £ 50.00.—Vol. 3. Antibiotics (Phenazines) to Bleaching Agents. xxv, 958 pp., bound, £ 50.00.

Volumes 2 and 3 of the new edition of *Kirk-Othmer*[*] are now available. Both volumes are again distinguished by a purposeful selection of keywords, skilful subdivision, and a remarkable balance within the individual entries.

This can be seen in the article about ammonia (Vol. 2), which contains sections on: the physical and chemical properties of ammonia; thermodynamic and kinetic fundamentals of its production; production of synthesis gas (from coal, heavy hydrocarbon fractions, or natural gas); ammonia synthesis (including energetic and environmental aspects); storage and shipment of ammonia; production capacities and quantities together with production costs and prices; specifications, analytical methods, and questions of safety; uses (especially for production of fertilizers, plastics, and explosives).

A similar subdivision is found under the heading "benzene" (Vol. 3), where there are sections on: physical and chemical properties of benzene; production from petroleum (by reforming processes and cracking), from coal, and from other sources; production capacities and quantities, with prices; specifications, analytical methods, and aspects of safety; uses (*e.g.* for production of ethylbenzene, cumene, cyclohexane, nitrobenzene/aniline, maleic anhydride, chlorobenzene, *etc.*).

All the other entries concerned with substances (*e.g.* alkyl resins, aluminum/aluminum alloys, amines, amino acids, anthraquinone/anthraquinone derivatives, antibiotics, antistatics, asphalt, azo dyes, biopolymers) and with methodology and other topics (*e.g.* analytical methods, azeotropic and extractive distillation, batteries and electric cells) are without exception first-class presentations.

Ozonation in Organic Chemistry. Vol. 1: Olefinic Compounds. By *P. S. Bailey*. Academic Press, New York 1978. xiv, 272 pp., bound, £ 18.50.

Many summaries have appeared on the ozonolysis of alkenes, but up to now there has been no authoritative representation and discussion of the current state of affairs. The present monograph fills this gap. It is a fitting tribute to *Rudolf Criegee*, "a true gentleman, a dedicated scientist and teacher"; the author received the decisive stimulus for his scientific work in the Karlsruhe Laboratory.

Unlike "Organic Syntheses", the book is not a collection of recipes intended for hurried searchers; it is rather a conscientious account of a slice of chemical history. Ozonolysis is a prime example of the way in which mechanistic thinking acts as a stimulus to new experiments. The reviewer feels that the central part of the book consists of Chapters VI and VII, which describe the dramatic development in the determination of the mechanism of ozonolysis over the last 15 years.

Ozonides are formed by 1,3-dipolar cycloaddition, followed by a 1,3-dipolar cycloreversion of the primary ozonide and a renewed 1,3-dipolar cycloaddition of the carbonyl oxide to the carbonyl bond. If the carbonyl oxide had been generally recognized as a 1,3-dipole, the analogy with nitrones would have allowed the *syn,anti* isomerism to have been foreseen and have saved some false trails; the alternative mechanisms proposed by *Story* and *Murray* have not stood up to testing. *Criegee* himself lived to see the reinstatement of his mechanism of ozonolysis, and contributed to it with some brilliant experiments.

Much effort is still being devoted to the question of how the structure and the reaction conditions affect the *cis,trans* ratio of ozonides.

Advances in the oxidation and reduction of ozonides over the last two decades are also reported in detail (Chapter VIII), as are the numerous types of anomalous ozonolysis reactions (Chapter IX). The competition between ozonide formation and epoxidation (Chapter XI) can now be regarded as well understood, while gas phase ozonation (Chapter XII) is still very unclear in its mechanism and, because of the low yields, is also unattractive.

The literature (717 references) has been covered until the end of 1976. This volume is to be followed by a second, which will deal with the ozonation of alkynes, arenes, and heterocyclics, and with the reactions of ozone with nucleophilic agents and the CH bond. This first volume, in itself, deserves wide circulation.

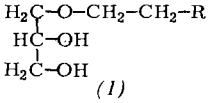
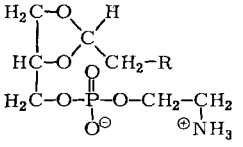
Synthesis and Biosynthesis of Alkoxylipids[**]

By Helmut K. Mangold[*]



Chromatographic methods have shown that lipids with long alkyl or 1-alkenyl chains—called alkoxylipids or ether lipids—are widely distributed in human and animal tissues. These compounds comprise neutral alkoxylipids, *i.e.* 1-*O*-alkyl or 1-*O*-(1-alkenyl)-2,3-di-*O*-acylglycerols, and alkoxylipids which are linked by a phosphate residue at C-3 to aminoethanol, choline or serine. 1-*O*-Alkylglycerols, 1-*O*-(1-alkenyl)glycerols and other natural alkoxylipids can be synthesized in high yields. 2-Alkyl, 1,3-dialkyl and trialkylglycerols which are not found in nature are also accessible by synthesis. The neutral alkoxylipids are employed in biomedical investigations, *e.g.* as substrates in acyl-hydrolase systems or in fat absorption studies. The principal features of alkoxylipid biosynthesis have been elucidated. The alkyl residue is derived from a saturated or monounsaturated fatty acid *via* the corresponding alcohol. 1-*O*-(1-alkenyl)-2-*O*-acylglycerophosphoryl aminoethanols ("plasmalogens") are apparently formed from the appropriate 1-alkyl compounds; this is not possible in the case of the choline series. Both "aminoethanol" and "choline" plasmalogens are, nevertheless, present in most tissues.

1. Introduction



Water-soluble alkali salts of the higher fatty acids together with glycerol are formed almost exclusively after alkaline hydrolysis—"saponification"—of most plant and animal fats and oils which mainly consist of tri-*O*-acylglycerols ("triglycerides"). Saponification of lipids from tissues and organs of many marine animals results, on the other hand, in a high proportion of water-insoluble, neutral compounds which can be extracted from the aqueous alkaline reaction mixture with organic solvents. The unsaponifiable substances in the liver lipids of marine fish and mammals are chiefly hydrocarbons, particularly squalene[1], sterols[2] and long-chain alcohols with one[3] or more hydroxy groups[2,4].

In 1922 *Tsujimoto* and *Toyama*[5] discovered two compounds in the "unsaponifiable material" from the liver oils of sharks and rays which they called "batyl" and "selachyl alcohols". *Toyama*[6], who isolated a similar compound, "chimyl alcohol", from the liver of the ratfish *(Chimaera monstrosa)* suspected these three compounds to contain ether linkages formed from glycerol and long-chain alcohols but their structures were first elucidated by *Heilbron et al.* between 1928 and 1933[7–9]. Chimyl, batyl and selachyl alcohols are indeed 1-*O*-alkylglycerols *(1)* [hexadecyl, octadecyl and *cis*-9-octadecenylglycerols, respectively; strictly speaking selachyl alcohol is a 1-*O*-(9-alkenyl)glycerol][9]. *Baer* and *Fischer*[10] synthesized the D and L forms of chimyl and batyl alcohols and established that the natural compounds belong to the D series—they are 1-*O*-alkyl-*sn*-glycerols[10].

In 1924 *Feulgen* and *Voit*[11] discovered substances in animal tissues—"plasmalogens"—from which long-chain aldehydes could be liberated with acid. In the late thirties *Feulgen* and *Bersin*[12] isolated "aldehydogenic lipids" from bovine skeletal muscle to which they assigned an acetal phosphatide *(2)* structure. *Baer* and *Fischer*[10] advanced the hypothesis that alkylglycerols *(1)* and acetal phosphatides *(2)* might be biogenetically related.

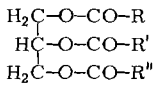
Klenk and *Debuch*[13] obtained alkylglycerol derivatives by catalytic hydrogenation of plasmalogens. Since they could also detect acyl residues in the plasmalogens, they ruled out

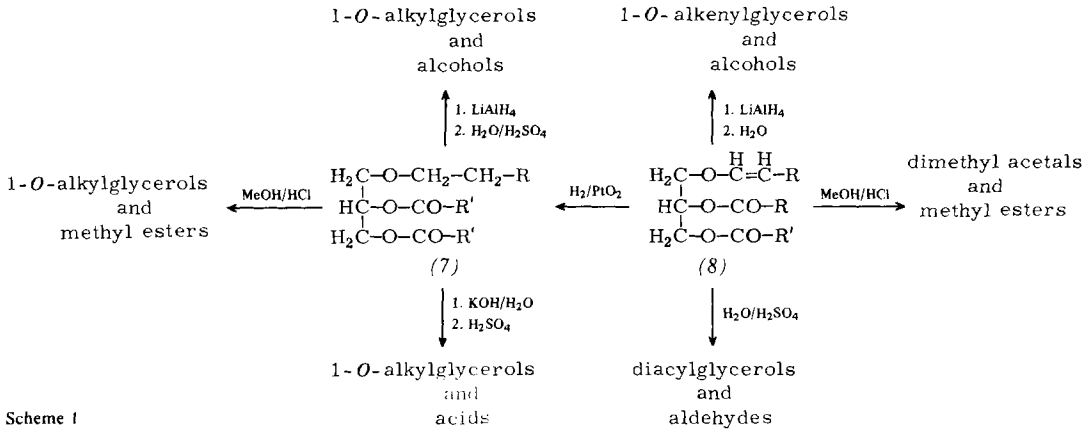


(3), R'' = CH=CH–R
(4), R'' = CH_2–CH_2–R
(5), R'' = CO–CH_2–R

the acetal phosphatide structure *(2)*. Studies in several laboratories[14-17] showed that plasmalogens are 1-*O*-(1-alkenyl)-2-*O*-acylglycerophospholipids such as *(3)*; in human and animal tissues they are always present together with the corresponding 1-*O*-alkyl compounds such as *(4)* as minor compounds associated with the 1-2-diacyl derivatives of type *(5)*[18]. It should be noted that "alkyl" and "1-alkenyl" alkoxylipids include substances which contain one double bond in the chain and/or one in the vinyl ether group.

In addition to compounds *(3)*—*(5)*, corresponding phospholipids have been found, particularly in central and peripheral nervous tissue, which contain choline or serine instead of ethanolamine. Human and animal depot fats have, in addition to triacylglycerols *(6)*, a usually small proportion of 1-*O*-alkyl- *(7)* and 1-*O*-(1-alkenyl)-2,3-*O*-diacylglycerols *(8)*[19] (cf. Scheme 1).

(Squalus acanthias) contains, in addition to 54% triacylglycerols *(6)*, approximately 38% alkyldiacylglycerols *(7)* and 0.5% alkenyldiacylglycerols *(9)*[29]. The liver lipids of the atlantic and pacific ratfish *(Chimaera monstrosa* and *Hydrolagus colliei*, respectively) consist of 66% *(7)* and 6% *(8)*[29,31].



(6)

Compounds of type *(6)*—*(8)* can be separated from one another by thin-layer chromatography[21,30,33]. The neutral alkoxylipids in human adipose depots, as well as animal tissues and organs represent a fraction of less than 0.5%[30,32]; they are first concentrated by chromatography on "thick" layers of silica gel and then isolated from the concentrate[31,33].

The lipids of human and animal tumors contain considerably higher proportions of alkyldiacylglycerols *(7)* than normal tissues[34].

Ionic alkoxylipids are mainly found in the brain and peripheral nervous tissue of higher animals. The chromato-

Scheme 1

Ionic, *e.g. (3)* and *(4)*, and neutral derivatives of alkyl- and alkenylglycerols, *e.g. (7)* and *(8)*, were always identified earlier in mixtures by means of their cleavage products. These usually rather difficult studies were simplified considerably when, in 1960, complex mixtures of alkoxylipids and acyl lipids were resolved by thin-layer chromatography into classes of compounds[20-22]; each of these classes was subsequently separated into its components by gas chromatography[22-24]—or the acyl, alkyl and alkenyl residues could at least be analyzed. Methods for the synthesis of alkyl- and alkenylglycerols were soon greatly improved[25,26] and radioactively labeled alkoxylipids were synthesized[27]. In 1972 *Snyder*[28] published a comprehensive volume on the alkoxylipids.

2. Distribution, Isolation and Characterization of Alkoxylipids

The neutral alkoxylipids occur in especially high proportions in the liver of cartilaginous fish. The liver of the dogfish

graphic behavior of these phospholipids is chiefly determined by their polar groups; the influence of the long-chain residues is slight. Neither compounds *(3)*—*(5)*, nor the three corresponding choline or serine forms could be separated from one another. Mixtures of non-polar derivatives of these compounds can, however, be resolved into their diacyl, alkylacyl and alkenylacyl forms[35]. For analytical purposes it is, however, much more convenient to first split off the polar groups with phospholipase C from *Bacillus cereus*[36], then to acetylate the disubstituted glycerols[20,36] and fractionate the acetyl derivatives. The products can be completely separated from one another by adsorption chromatography[36,37].

Diacylglycerophospholipids such as *(5)* are more quickly saponified by dilute alkali than the alkoxylipids, the latter can thus be concentrated on a preparative scale[38]. Alkylacyl- and alkenylacylglycerophosphoryl cholines can be obtained by employing preferential hydrolysis of diacylglycerophosphoryl cholines with phospholipase C from *Clostridium welchii*[17] or phospholipase D from cabbage[39]. The ionic alkoxylipids can also be isolated after selective hydrolysis of

the 1-acyl residues of *(5)* or the corresponding cholines with pancreatic lipase[40,41].

IR[30,42] and NMR spectra[43] of alkoxylipids are of little use for the identification and characterization of these compounds. The characteristic, strong absorption band at 1667–1670 cm^{-1} is very useful for recognition of *cis*-1-alkenyl ethers[17,44].

The alkoxylipids, like most long-chain compounds, are polymorphous[45,46]. Hexadecyldipalmitoyl- and octadecyldistearoylglycerol both occur in two forms, (1-hexadecenyl)dipalmitoyl- and (1-octadecenyl)distearoylglycerol each exist in four forms[45]. These polymorphic lipids are well characterized by their critical solution temperatures with nitromethane or acetonitrile[47].

Very dilute chloroform solutions of batyl alcohol *(1)*, R = octadecyl, are weakly dextrorotatory, 10 percent solutions exhibit no optical activity whereas more concentrated solutions are weakly levorotatory[10,48]. The diacetates and the isopropylidene derivatives of 1-*O*-alkylglycerols have a considerably higher specific rotation than batyl alcohol[10]. Alkyldiacyl- *(7)* and alkenyldiacylglycerols *(8)* from the liver of the ratfish have a higher specific rotation than the nonacylated compounds[49].

Gas chromatographic analysis with "internal standards"[50] is the most reliable technique for the quantitative estimation of neutral and ionic lipids containing alkyl or alkenyl residues. Using the isotopic derivative technique[20], alkyl and alkenyldiacetylglycerols with labeled acetyl residues are resolved by thin-layer chromatography and determined radiometrically[51].

The acyl, alkyl and alkenyl residues of alkoxylipids such as *(7)* and *(8)* are usually analyzed by gas chromatography in the form of methyl esters, alkylisopropylideneglycerols, or aldehydes or dimethyl acetals. Scheme 1 shows how the alkoxylipids can be converted into these derivatives[30,52].

Specific reactions and separations are required for the analysis of the acyl residues of ionic alkoxylipids in mixtures of glycerophospholipids containing the same base[53].

Alkyl- and 1-alkenylglycerols can be obtained from neutral[30,31] and ionic alkoxylipids[54,55] by using water to split the complexes formed with $LiAlH_4$. This deacylation reaction is suitable for the isolation and analysis of alkyl- and 1-alkenylglycerols from very small quantities of material.

The alkylglycerols are purified by thin-layer chromatography and then separated by gas chromatography after having been converted into alkylisopropylideneglycerols[30,56] or alkylglycolaldehydes[24,57].

In order to analyze the 1-alkenyl groups, mixtures of aldehydes are obtained by acid-catalyzed hydrolysis of the neutral *(8)* or ionic plasmalogens, *e.g. (3)*[30,58], or mixtures of dimethyl acetals are produced by reaction with methanol[30,52]. The aldehydes[30,52] and their dimethyl acetals[30] can easily be separated by gas chromatography. Interference due to formation of *cis*- and *trans*-1-alkenylalkyl ethers[59] can be overcome by reducing the aldehydes to alcohols, which are then acetylated and analyzed[30,31].

If the acid-catalyzed hydrolysis of the 1-alkenyl derivatives is carried out directly on the thin-layer chromatogram, the reaction products can be separated from one another and from the unmodified diacyl- and alkylacylglycerolipids[60].

Whereas in the lipids of human and animal tissues saturated and unsaturated fatty acids with up to six double bonds are esterified[52], the alkyl and 1-alkenyl residues of the alkoxylipids contain a maximum of one double bond, besides a vinyl ether double bond. Table 1 shows a typical example.

Apart from alkyl and 1-alkenyl moieties with 16 or 18 carbon atoms, only small quantities of residues with other chain lengths are found. In the light of these findings, a biogenetic relationship between lipids which contain alkyl and 1-alkenyl moieties[10] seems indeed to be reasonable. This hypothesis is supported by the fact that alkyl and 1-alkenyl moieties with 18 carbon atoms in alkoxylipids from the liver of cartilaginous fish have their additional double bond mainly in the 9-position[62,63], the additional double bond of residues with 20 carbon atoms is in the 13-position[62]. Surprisingly, the 1-*O*-acyl, -alkyl and -1-alkenyl residues from the neutral lipids of liver of the ratfish contain a relatively large proportion of branched chains (2.6, 5.0 and 16.4% respectively) whereas the 2-*O*-acyl residues are almost all unbranched[37]. The alkoxylipids of the heart and milk of ruminants are also rich in branched alkyl and alkenyl moieties[53,64].

A variety of glyceroglycolipids in human and animal tissues are also derived from 1-*O*-alkylglycerols[65].

The unsaponifiable fraction of the neutral and ionic lipids from the liver of the Greenland shark *(Somniosus microce-*

phalus)[66] and other marine organisms[67] contains 1-*O*-(2-methoxyhexadecyl)- and 1-*O*-(2-methoxyoctadecyl)glycerols. Derivatives of these methoxyalkylglycerols also occur in bone marrow, in the erythrocytes and milk of humans and various animals[68]. Particularly in the liver of the Greenland shark—as opposed to almost all animal tissues so far studied—there are also lipids with polyunsaturated methoxyalkyl residues[67]. In addition to the esters of 1-*O*-alkyl- and 1-*O*-(2-methoxyalkyl)glycerols, the liver oil of the Greenland shark contains 1-*O*-(2-hydroxyalkyl)glycerol esters[69]. The Harderian gland of the rabbit contains hydroxysubstituted alkyldiacylglycerols whose hydroxy groups are esterified with long-chain fatty acids and are located in the middle of the alkyl chains[70].

Very small quantities of the phospholipids which are derivatives of 1,2-di-*O*-alkyl-*sn*-glycerols are found in human[71] and bovine[72] heart. The halophilic bacterium *Halobacterium cutirubrum* contains relatively high proportions of phospho- and glycolipids derived from 2,3-di-*O*-phytanyl-*sn*-glycerol[73,74]. Similar compounds have been found in *Sulfolobus acidocaldarius*[75] and *Thermoplasma acidophilum*[76].

The tissues of marine invertebrates and also other organisms contain, in addition to lipids with a glycerol backbone, long-chain diol derivatives with two to five carbon atoms. These "diol lipids" together with diol phospholipids and glycolipids are widely distributed in the plant and animal kingdoms[77,78]. The starfish *Distolasterias nipon* is especially rich in diol lipids[78]. Approximately 35% of its lipids are derived from ethanediol; they contain—in addition to diacylethanediols *(11)*—alkylacyl- *(10)* and 1-alkenylacylethanediols ("neutral diol plasmalogens") *(9)*[78]. The diol lipids are generally identified indirectly *via* their cleavage fragments[77,78], but at least the neutral ones can be separated from the corresponding glycerol derivatives[79,80].

It remains to be mentioned that alkyl ethers of cholesterol[81] are present in bovine heart and that very small quantities of the corresponding 1-alkenyl ethers are found in bovine and pig heart[82]. The jaw of the dolphin *Phocoena phocoena* also contains unusual alkoxylipids, di-*O*-alkylpentanediols whose alkyl moieties have almost exclusively 18 carbon atoms[83].

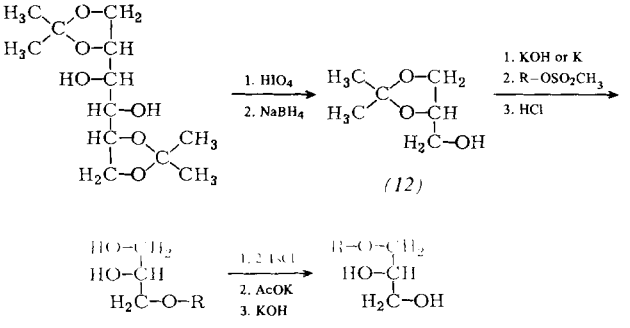
Methods for isolating and identifying natural alkoxylipids have been described in detail[84].

The natural alkoxylipids and often their symmetrical analogs are used in biomedical investigations. Methods for the characterization and analysis of these unusual lipids have been developed[85–87]. The trialkylglycerols which are accessible by synthesis only[88] are utilized, especially in fat absorption studies and clinical tests. A lipid fraction from the preputial gland of the mouse which was considered to consist of trialkylglycerols[89], was identified as a mixture of alkyl acetates[90].

3. Synthesis of Alkoxylipids

As chromatographic methods became available for lipid analysis, it was possible to study the synthesis of these natural products with better prospects of success. Systematic syntheses for natural alkoxylipids and related compounds were developed in the sixties.

3.1. Alkyl Ethers



Methods for synthesizing 1-*O*-alkylglycerols *(1)* are of special interest because many other alkoxylipids can be obtained from these compounds relatively simply.

An earlier procedure based on alkylation of allyl alcohols with long-chain alkyl halides and subsequent oxidation of the alkyl allyl ethers[2,91] is, of course, only suitable for the synthesis of saturated alkylglycerols—as racemic mixtures. The classical synthesis starts with isopropylideneglycerol *(12)* which is alkylated with alkyl iodides[10] or tosylates[92]. The 1-*O*-alkylglycerols *(1)* are obtained from the alkylisopropylideneglycerols after splitting off the protecting group with aqueous inorganic acid[10,92]. Since, in the synthesis of selachyl alcohol according to the above method, most of the *cis*-9-octadecenyl moiety is converted into the *trans* moiety, the compound is obtained by reacting isopropylideneglycerol tosylate with sodium *cis*-9-octadecenoate[93]. Transalkylation occurs however[25], so that a dialkyl ether is formed as the main product and the yield of selachyl alcohol is under 20%[93].

Alkylation of the two optically active isopropylideneglycerols *(12)* with alkyl iodides or tosylates forms the basis for investigations which permit the configurational characterization of the natural alkylglycerols. They belong to the D series and are thus 1-*O*-alkyl-*sn*-glycerols[10].

A comparison of methods for the synthesis of these compounds led to the development of a procedure[25] which has since been used almost exclusively: isopropylideneglycerol *(12)* is condensed with an alkylmethanesulfonate ("alkyl mesylate") in boiling benzene in the presence of potassium; if this reaction is performed in xylene in the presence of potassium hydroxide then the water produced is removed by azeotropic distillation[25]. 1-*O*-Alkylglycerols *(1)* are obtained with yields of up to 80% by cleavage of the protecting group with hydrochloric acid. This procedure is suitable for the synthesis of saturated, mono- and polyunsaturated 1-*O*-alkylglycerols, also in their optically active forms[49] (Scheme 2). In this way we were able to synthesize a useful, radioactively labeled compound, 1-*O*-[1'-^{14}C]hexadecylglycerol.

Scheme 2 also shows how the naturally occurring D-isomers can be obtained from the easily accessible "unnatural" 3-*O*-alkyl-*sn*-glycerols, the L-isomers: Walden inversion of the L-*(1)* tosylate with potassium acetate in ethanol and subsequent alkaline hydrolysis leads to the desired products[94].

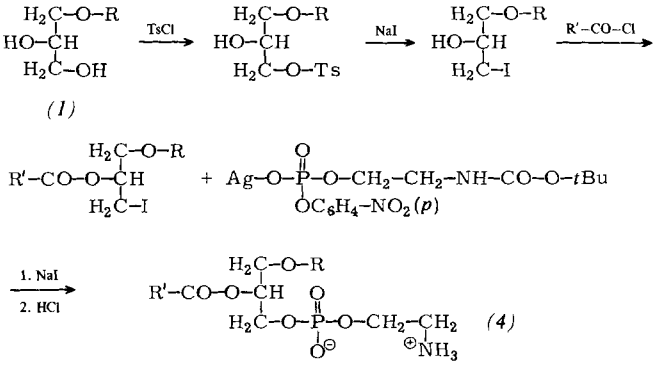
Scheme 2 L-*(1)* D-*(1)*

1-*O*-(2′-Methoxyalkyl)glycerols[66,67] can be obtained from methyl 2-bromopalmitate *via* methyl 2-methoxypalmitate, 1-methoxyhexadecanol, subsequent reaction of the tosylate or mesylate with isopropylideneglycerol *(12)* and cleavage of the protecting group[66,95]. 1-*O*-(2-Hydroxyalkyl)glycerols have also been synthesized[96].

The symmetrical 2-*O*-alkylglycerols, which have not as yet been detected in nature, have proved to be of value in biomedical investigations. 2-*O*-Alkylglycerols—also those with double bonds — can easily be synthesized by alkylation of 1,3-benzylideneglycerol with alkyl iodides[97], tosylates[98] or in especially good yields with alkylmethanesulfonates[87] and subsequent acid-catalyzed cleavage of benzaldehyde.

The isomeric alkylglycerols can be converted into their diesters with acyl chlorides in benzene/pyridine[85,87,99]; 1-*O*-alkyl-2-acylglycerols[100] and 1-acyl-2-*O*-alkylglycerols[87] result from the diesters by enzymatic hydrolysis of the ester bond in the α-position.

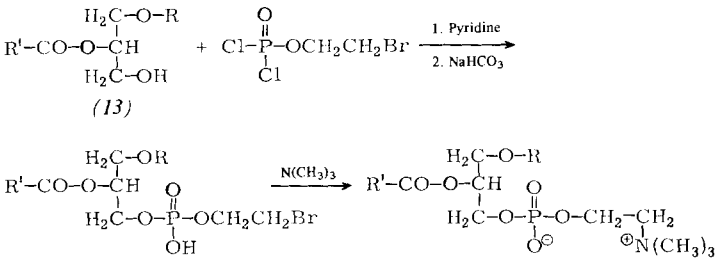
The 1,2-di-*O*-alkylglycerols can be obtained by alkylation of α-trityl[73,101] or α-tetrahydropyranylglycerol[102] and cleavage of the protecting group. Both methods are suitable if optically active glycerol derivatives are used as starting materials and also for the synthesis of enantiomeric 1,2-di-*O*-alkylglycerols; they cannot be used, however, if two different alkyl residues are to be introduced into positions 1 and 2 of glycerol. Such "mixed" compounds can be produced by alkylation of 1-*O*-alkyl-3-*O*-tritylglycerols and cleavage of the protecting group[88].



1,3-Di-*O*-alkylglycerols can be synthesized by partial alkylation of 1-*O*-alkylglycerols[88] or by alkylation of 2-*O*-benzylglycerol and subsequent hydrogenolytic cleavage of the protecting group[103]. The first procedure leads, however, to mixtures which must be separated by chromatography whilst the second method can only be used for the synthesis of saturated compounds. 1,3-Di-*O*-alkylglycerols, and also those with double bonds, are furnished by reaction of 1,3-dichloropropanol with sodium alkoxides; the yields, however, are not satisfactory[87].

The synthesis of trialkylglycerols is relatively complicated. It has not yet been possible to alkylate glycerol with alkyl halides or mesylates in good yields, nor to react alkoxides with tribromopropane or tri-*O*-mesylglycerol to give trialkylglycerols. This is not due so much to the different solubilities of the reaction partners but to steric hindrance. It seems worthwhile, however, to try out the phase transfer technique. The isomeric alkylglycerols[87,88], like the isomeric dialkylglycerols[87,102], can be further alkylated in approximately equally good yields. Ideally, triacylglycerols *(6)* should be converted directly into trialkylglycerols. Reduction with $LiAlH_4$ and BF_3 in ether affords the desired compounds but with yields of under 5%[104].

Glycol cleavage of 1-*O*-alkylglycerols with sodium periodate in pyridine[57] gives alkylglycolaldehydes which can be reduced with $LiAlH_4$ to *O*-alkylethanediols[79]; both reactions are quantitative. Di-*O*-alkylethanediols and dialkyl ethers of other diols can be obtained by alkylation of diols[105] or alkyl diols[79].



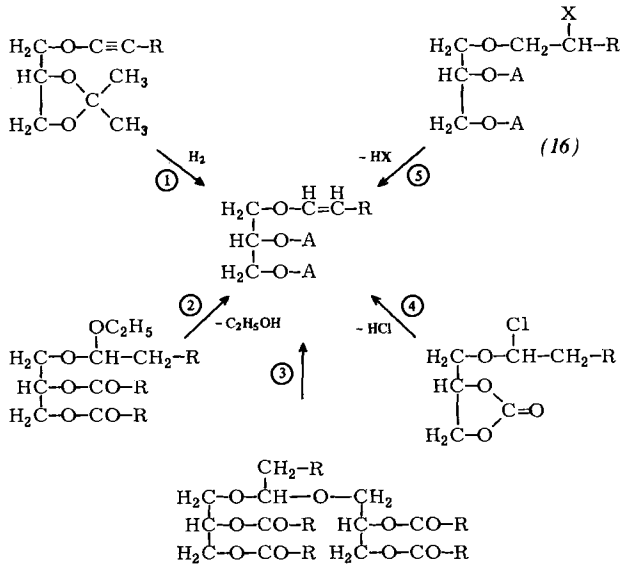
Alkyl ethers of cholesterol are produced in good yields if mesylates are reacted with cholesterol in the presence of potassium hydroxide in boiling benzene[106].

Methods for the synthesis of diacylglycerophosphoryl aminoethanols *(5)* and cholines are also suitable for the synthesis of alkylacyl- and dialkylglycerophospholipids (see [107,108]).

(1) *(4)*

These and similar phospholipids can be synthesized by condensation of disubstituted glycerophosphoric acid with a "protected" aminoethanol[100,109].

(13)

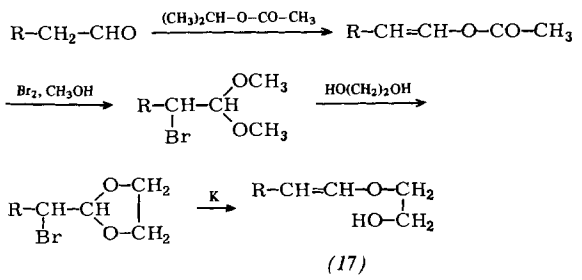


Disubstituted glycerophosphoryl cholines[110] such as 1-*O*-alkyl-2-acyl- *(14)*[100,108], 1-acyl-2-*O*-alkyl-[41,111], 1,2- and 1,3-di-*O*-alkylglycerophosphoryl cholines[112,113] together with the lyso compounds (*e. g.* 1-*O*- and 2-*O*-alkylglycerophosphoryl cholines[114]) can be produced from the glycerol derivatives *(13)*.

Phosphorylation of *(13)* with phosphorus oxide chloride and reaction of the product with choline chloride in pyridine yields disubstituted glycerophosphoryl cholines[94].

The methods described are also suitable for the synthesis of diol phospholipids. In addition to the natural ionic alkoxylipids, analogous compounds are often used in biochemical investigations. The synthesis of these substances has been described in two reviews[115].

3.2. 1-Alkenyl Ethers



Several groups of workers have tried to synthesize 1-*O*-(1-alkenyl)glycerols (Scheme 3, A = H or CO R). Attempts to obtain these substances by partial hydrogenation of a 1-alkynyl derivative with the Lindlar catalyst (method 1) failed[116]. Elimination of ethanol (method 2) or cleavage of diacylglycerol (method 3) from the acetals *(15)* proved to be of limited use[117,118]. On thermal decomposition of such acetals, *trans*-1-alkenyl derivatives are formed almost exclusively[119], whereas the natural plasmalogens have a *cis* configuration[17,44]. Elimination of hydrogen chloride from 1-*O*-(1-chloroalkyl)glycerol carbonate (method 4) can be utilized[119]. *Cis-trans* mixtures are also formed in this reaction but there is a relatively large proportion of the desired *cis* compound and it can be isolated by argentation chromatog-

Scheme 3 (15)

raphy[120]. This synthesis (method 4) also provides optically active substances corresponding to the natural 1-*O*-(1-alkenyl)-*sn*-glycerols and the neutral and ionic plasmalogens[120,121]. As is the case with the enantiomeric 1-*O*-alkylglycerols *(1)*[94], the *sn*-1 and *sn*-3 isomeric 1-*O*-(1-alkenyl)glycerols can be converted into one another by Walden inversion *via* their ditosylates (see Scheme 2)[122]. The elimination of *p*-toluenesulfonic acid or hydrogen iodide from the substituted derivatives *(16)* (method 5) is suitable for the synthesis of 1-*O*-(1-alkenyl)glycerols and their esters *(8)*[123]. Plasmalogens of type 3[124] and a "cardiolipin plasmalogen"[125] have been synthesized by this procedure.

The synthesis of neutral and ionic diol plasmalogens is much simpler than that of the corresponding glycerol derivatives. In the synthesis of 1-alkenylethanediols *(17)*, *cis-trans* mixtures are produced which can be separated by chromatography on silver-nitrate-impregnated silica gel[126]. Acylation of *cis* and *trans (17)* gives neutral diol plasmalogens and their *trans* isomers [cf. *(9)*][127].

(17)

Syntheses which include a reaction with a halogen or hydrogen halide are not suitable for compounds containing an additional double bond in their 1-alkenyl residues. Such glycerol and ethanediol derivatives can, however, be easily obtained from animal tissues. Hydrogenolysis of the total lipids from bovine heart gives a mixture of alcohols, alkylglycerols and 1-alkenylglycerols—providing the resulting complexes with $LiAlH_4$ are cleaved with water and not acid (cf. Scheme 1)[55]. The 1-alkenylglycerols can be easily isolated as a class of lipids by silica gel chromatography; the pure compounds can then be isolated by reversed-phase chromatography. Periodate cleavage of 1-*O*-(1-alkenyl)glycerol mixtures in pyridine gives the 1-alkenyl derivatives of glycolaldehyde; reduction of these compounds furnishes 1-alkenylethanediols which can be separated by chromatography[55]. The isolation of alkenylglycerols and their conversion to alkenylethanediols has, in contrast to all purely synthetic methods, the advantage that separation of the desired *cis* compounds from the *trans* isomers is not necessary. An interesting chapter is devoted exclusively to the chemistry of the "aldehydogenic lipids"[128].

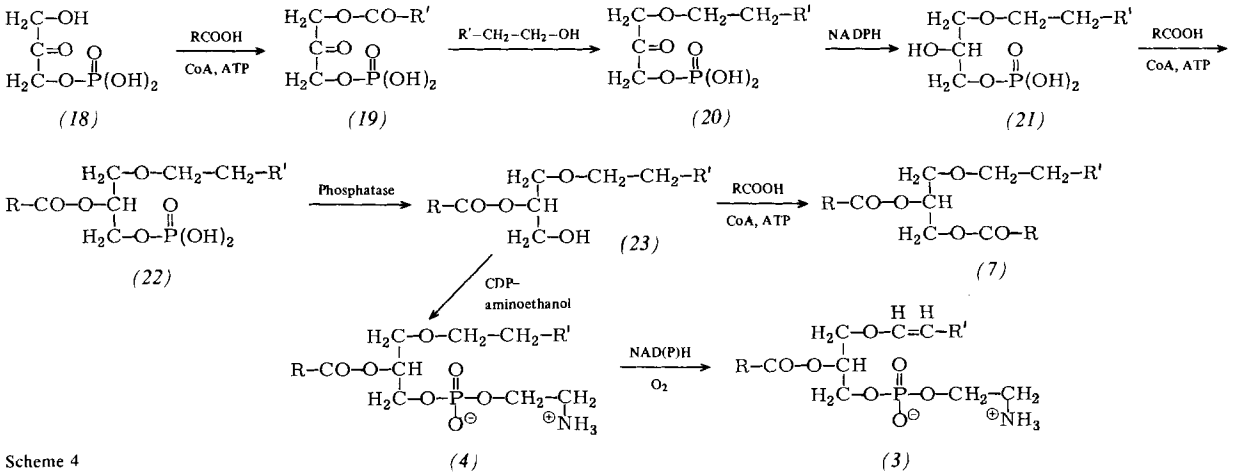
4. Biosynthesis and Metabolism of Alkoxylipids

1-*O*-Alkylglycerols are synthesized relatively quickly in the animal organism and then undergo further reactions. In the mid-fifties, radioactively labeled substrates had already been used to demonstrate that the starfish *Asterias rubens* incorporated glycerol and acetate into its acyl lipids (ester lipids) and alkoxylipids (ether lipids)[129]. The rat absorbs alkylglycerols administered with its food almost completely in the small intestine[130]. In the gastrointestinal tract some of these compounds are esterified and some are cleaved; the corresponding fatty acids are formed in the presence of molecular oxygen[130,131].

4.1. Biosynthesis

The prime interest in investigations aimed at elucidating alkoxylipid biosynthesis was to answer the following questions:

1. What is the relationship between the alkoxylipids (ether lipids) and the acyl lipids (ester lipids)?
2. Are the alkyl residues formed from 1-alkenyl residues or *vice versa*?
3. Why do the alkyl and 1-alkenyl residues contain, in addition to the vinyl ether double bond a maximum of one double bond, while the acyl residues can be polyunsaturated?



Comparison of the double bond positions in the monounsaturated chains of the neutral alkoxylipids from the liver of the ratfish showed there was a great deal of similarity between the structures of the alkyl, 1-alkenyl and acyl chains[62]. This finding supported the hypothesis that the long-chain alkyl and 1-alkenyl residues are formed from the corresponding fatty acids (cf. also[63,132]).

The results from experiments on dog heart-lung preparations indicated that saturated long-chain alcohols are incorporated into the 1-alkenyl residues of ionic plasmalogens more quickly than aldehydes or acids[133]. The same applies to the digestive organ of the starfish *Asterias forbesi*[134] and the isolated shark stomach[135]. Experiments on the snail *Arion ater* and on *Tetrahymena pyriformis* finally demonstrated that derivatives of 1-*O*-(1-alkenyl)glycerols — plasmalogens—can be produced from 1-*O*-alkylglycerols[136]. According to metabolic studies with radioactively labeled palmitic or stearic acid or the corresponding aldehydes, alcohols or alkylglycerols, the alkyl and 1-alkenyl moieties of alkoxylipids are apparently synthesized as follows:

Fatty acid → aldehyde → alcohol → alkyl chain → 1-alkenyl chain

"Free" aldehydes have been detected in rat and dog heart[137]. In addition, the corresponding "free" alcohols have been isolated from bovine heart[138]. The alcohols and aldehydes in animal tissues are always saturated or monounsaturated and they mostly have chains with 16 or 18 carbon atoms[90, 137, 139].

About ten years ago systematic investigations in several laboratories led to the elucidation of alkoxylipid biosynthesis in animal tissues (see Scheme 4). If liver mitochondria or

(18) (19) (20) (21) (22) (23) (7) (4) (3)

Scheme 4

heart microsomes are incubated with dihydroxyacetone phosphate *(18)* and a long-chain alcohol in the presence of ATP, CoA, NaF and Mg^{2+}, 1-*O*-alkyldihydroxyacetone phosphate *(20)* is formed[140]. The same reaction is inhibited by *p*-chloromercuribenzoate in microsomes from the intestinal mucosa of the rat[141]—glyceraldehydephosphoric acid does not act as an acceptor for the alkyl residue[142].

If an acyldihydroxyacetone phosphate *(19)* is used as alkyl acceptor, the 1-*O*-alkyl derivative *(20)* is formed in the absence of CoA[143]. Compounds of type *(20)* have been characterized as intermediates in alkoxylipid biosynthesis[144] but it is still not clear how acyl/alkyl exchange is achieved. If [^{18}O]-hexadecanol is employed as substrate *in vivo* or *in vitro*, ^{18}O is found in the alkoxy groups of the alkoxylipids which are produced[145]. In the reaction *(19)*→*(20)*, a hydrogen atom is released from C-1 of the *sn*-glycerol residue[146] and replaced by a hydrogen atom from the medium[147]; the configuration of the substituents at C-1 is retained[148]. 1-*O*-Alkyl-*sn*-glycero-3-phosphate *(21)* results from 1-*O*-alkyldihydroxyacetone phosphate *(20)* in a NADPH-dependent reaction which is catalyzed by a microsomal enzyme[149]; *(21)* is acylated to *(22)*[140, 149]. This compound is dephosphorylated by a Mg^{2+}-dependent microsomal enzyme to 1-*O*-alkyl-2-*O*-acyl-*sn*-glycerol *(23)*[150]; neutral and ionic 1-*O*-alkylglycerol derivatives, *e.g. (7)* and *(4)*, are synthesized from *(23)* by reactions which are known from the biochemistry of the 1-2-diacylglycerols[150].

It has been shown that the alkyl residues are not formed from 1-alkenyl residues[151, 152].

Experiments on animal tissues[100, 152] and cell-free systems[153, 154] have demonstrated that the 1-*O*-alkyl-2-*O*-acyl-*sn*-glycerophosphoryl aminoethanols *(4)* are the direct precursors of the 1-*O*-(1-alkenyl) derivatives ("aminoethanol plasmalogens") *(3)*. The 1-alkenyl residues are produced by *cis*-elimination of the (1*S*) and (2*S*) hydrogen atoms of the alkyl residue[155]. The enzyme catalyzing this reaction is bound to the microsomal membrane. It requires molecular oxygen and NAD(P)H as cofactors[153, 154] and probably also cytochrome b_5[154, 156]. This desaturase is stimulated by proteins[153, 157].

The cholines *(14)* corresponding to the aminoethanols *(4)* are not dehydrated to plasmalogens[153, 158].

Each step of alkoxylipid biosynthesis has been studied exclusively with substrates which have saturated chains with 16 or 18 carbon atoms. It cannot therefore be seen from Scheme 4 why the alkyl and 1-alkenyl moieties of the alkoxylipids contain, in addition to the vinyl ether double bond, at the most one double bond.

If food rich in lipids containing polyunsaturated fatty acids or aldehydes are given to rats, this does not influence the composition of the alkyl and 1-alkenyl residues[159, 160]. If the animals are fed, however, with polyunsaturated alcohols[159, 161], polyunsaturated chains are found in these residues[159-163].

The lack of polyunsaturated alkyl and 1-alkenyl residues in the alkoxylipids of human and animal tissues is apparently due to the fact that their precursors, *i.e.* polyunsaturated alcohols, are not present in these tissues. It seems reasonable to assume that, as has long been known[164], saturated fatty acids are reduced to alcohols in the organism—probably *via* aldehydes; the same applies to monounsaturated but not to polyunsaturated fatty acids.

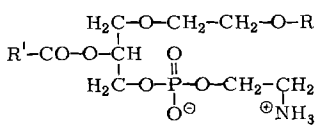
Several authors have indeed demonstrated that the CoA derivatives of saturated fatty acids are reduced to aldehydes[165] and also that aldehydes are reduced to alcohols[166, 167]. It is thus understandable that only saturated and monounsaturated alcohols can be found in animal tissues[139] and excrement[159, 168, 169], even if the animals have ingested highly unsaturated triacylglycerols[159] or fatty acids[168].

Several groups of workers have recently investigated the substrate specificity of the enzymes involved in alkoxylipid biosynthesis. Equimolar mixtures of acids[169] and also equimolar mixtures of aldehydes[170], alcohols[171] and alkylglycerols[172] were fed to rats and the incorporation of these compounds in the alkoxylipids of the intestinal mucosa determined. One group of these mixtures consisted of saturated substances with 13, 15, 17 and 19 carbon atoms whilst the other group contained compounds with 19 carbon atoms and 0, 1 and 2 double bonds[173]. Since the lipids of rat tissues

only contain very small proportions of chains with an odd number of carbon atoms, it is easy to follow the metabolism of the compounds in the mixtures given by gas chromatographic analysis of the alkyl, 1-alkenyl and acyl groups. It has to be assumed, of course, that the components of the mixed substrates are not converted into one another. This condition is satisfied, at least in the case of the aldehydes, alcohols and alkylglycerols.

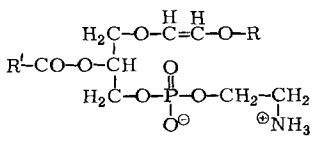
Analysis of the alkyl and 1-alkenyl residues in the ionic alkoxylipids of the rat intestinal mucosa showed that the enzymes involved in the biosynthesis of the alkoxylipids from fatty acids exhibit strong substrate specificity as regards both chain length and the number of double bonds in the precursors[159, 162, 170, 172].

Metabolic studies on complex lipids should therefore not be performed solely with substrates of a defined chain length and containing a defined number of double bonds—and also not only with minute quantities of radioactively labeled compounds. If the components do not react with one another, it would seem advantageous to feed a mixture of substrates instead of single compounds. In contrast to metabolic studies employing radioactively labeled compounds, substrate saturation in such a nutritional experiment is assured.



The possibility of modifying lipid composition by dietetic methods and thus of altering the absorption properties of the intestinal mucosa may be of interest for the therapy of diseases of the alimentary canal.

Long-chain 1,2-diols are incorporated into 1-*O*-(2-hydroxyalkyl)glycerophosphoryl aminoethanols and cholines in rat brain[174]; long-chain ketoalcohols give rise to the corresponding 1-*O*-(1-oxoalkyl)glycerols[175].



(24)

It may be expected that the 1-alkenyl derivatives of ethanediol such as *(17)* can, like the glycerol compounds, result from alkyl ethers of type *(24)*. This is, however, not the case; the derivatives *(24)* are treated by the organism like simple long-chain alcohols[176]. 1-(2-Alkoxyethyl)-2-*O*-acylglycerophosphoryl aminoethanol *(25)* is thus formed which can also be dehydrogenated to the plasmalogen analog *(26)*[176].

(25)

(26)

In addition to *(25)*, a choline derivative is also produced; however, in analogy with the glycerophospholipids, this is not dehydrogenated to a plasmalogen analog[175].

4.2. Metabolism

1-*O*-Alkylglycerols[161, 172, 177] and their esters[178] given in food are well tolerated by man and animals, even in relatively large amounts. Some of the alkylglycerols are absorbed in their unmodified form[130, 161, 179] and some are cleaved whereby the alkyl residues give rise to the corresponding fatty acids[130, 179]. It is remarkable that the natural 1-*O*-alkyl-*sn*-glycerols are acylated in the intestinal mucosa but the "unnatural" 3-*O*-alkyl-*sn*-glycerols are not[180]. 1-*O*-Alkylglycerophosphoryl aminoethanols and cholines are also rapidly acylated in the mucosa[100]. Plasmalogens are synthesized from 1-*O*-alkyl-2-*O*-acylglycerophosphoryl aminoethanols *(4)* but not from the corresponding cholines *(14)*[100]. Alcohols added to feed are found in the alkyl residues but not in the 1-alkenyl residues of the alkoxylipids in the blood of experimental animals[181]; the alcohols do not seem to penetrate the blood-brain barrier[182]. Little is known about the behavior of 2-*O*-alkylglycerols and their esters in animal organisms.

The toxicity of the isomeric di-*O*-alkylglycerols and their esters has not yet been studied. By using radioactively labeled 1,2- and 1,3-di-*O*-alkylglycerols it has been established that absorption of these compounds does not depend on the position of the alkyl residues but to a great extent on their chain lengths. Over 50% of the two isomeric dioctylglycerols but only 10% of the dioctadecylglycerols are absorbed intact[112]. The 1,2-di-*O*-alkylglycerols are acylated more quickly in the digestive tract than their symmetrical isomers[112]. 1,2-Di-*O*-alkylglycerophosphoryl aminoethanols and cholines are poorly absorbed[112]. It is interesting that the absorption of sterols is inhibited by dialkylglycerophosphoryl cholines[183].

The trialkylglycerols are not toxic[184, 185, 188]. As long as these compounds have chains with more than 12 carbon atoms they are not hydrolytically cleaved in the alimentary canal of the rat[186, 188] or the pig[187] but are excreted in unmodified form[186, 188]. As trialkylglycerols do not affect the absorption of fats and fat-soluble vitamins[188], edible fats can be "diluted" with these "non-fattening fats"—and thus their nutritional value can be reduced—without significantly changing their physical and organoleptic properties[184]. The utilization of trialkylglycerols in the food industry is hindered by the high cost of these substances. Moreover, the trialkylglycerols are oxidized much more easily than the triacylglycerols, the proper "fats"[185, 189].

It is not yet known what the function of the alkoxylipids in the organism may be.

5. Use of Alkoxylipids in Biomedical Investigations

Alkoxy- and acyl-lipids have similar physical properties; they behave differently, however, towards acids, bases and lipolytic enzymes. Lipids which contain alkyl moieties can normally be used as stable model substances in biological systems in which acyl lipids are enzymatically cleaved.

The stereospecificity of lipoprotein lipase from human and animal tissues has been studied with enantiomeric alkyldiacylglycerols containing ^{3}H- and ^{14}C-labeled alkyl or acyl chains[190]. 1,2-Di-*O*-alkyl-3-*O*-acylglycerols and 1,3-di-*O*-alkyl-2-*O*-acylglycerols with radioactively labeled acyl residues were similarly used to determine the positional specificity of lipoprotein lipases[191, 192]. According to these experiments, the specificity of these enzymes encompasses the substrate configuration, the position of the acyl group at the glycerol, the chain length and the number of double bonds[192, 193].

Radioactively labeled 1-*O*- and 2-*O*-alkylglycerols[194] together with 1,2- and 1,3-di-*O*-alkylglycerols[112] have been employed in research on fat absorption. It was deduced from absorption studies with labeled trialkylglycerols[187, 188, 195] that triacylglycerols, "fats", cannot be absorbed intact, *e.g.* by pinocytosis[186].

After it had been appreciated how unreliable the ^{131}I-triolein test was for quantitative determination of fat malabsorption[196], clinical methods of investigation were developed which were based on the utilization of radioactively labeled trialkylglycerols[187, 197, 198]. It was recommended that patients be given ([9,10-$^3H_2$]hexadecyl)didodecylglycerol as a non-absorbable indicator together with ([1-^{14}C]trioleoyl)glycerol as "fat". The proportion of fat absorbed can be calculated from the change in the isotope ratio (^{3}H:^{14}C) after passage of the two compounds through the alimentary canal[197].

1-*O*-Alkylglycerophosphoryl cholines and their derivatives[199], together with 1-*O*-alkyl-2-acyl- *(14)* and 1,2-di-*O*-alkylglycerophosphoryl cholines[200] have been used in studies on lipid-lipid and lipid-protein interactions; these investigations should provide a contribution towards the understanding of the construction and function of biological membranes.

6. Outlook

Many questions are still open: Why do plant tissues not contain any or only small quantities of alkoxylipids? What are the functions of the plasmalogens in the brain? Which physiological processes can be influenced by changing the alkoxylipid composition of the organs? Why do cancerous cells have considerably larger proportions of alkyldiacylglycerols than normal cells?

Reports concerning the amazing actions of alkoxylipids have appeared repeatedly for over 30 years. Alkylglycerols are supposed to have bactereostatic action, protect against radiation, aid in the healing of wounds and inhibit tumor growth. Until recently, these effects were obtained solely with substances isolated from animal tissues. Synthetic compounds were, on the other hand, inactive. The biological effects so far observed are probably due to impurities in the alkoxylipids.

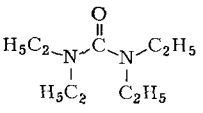
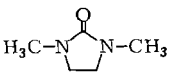
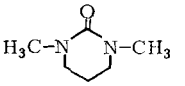
Ureas as Solvents for Chemical Investigations



By Barbara J. Barker, Joseph Rosenfarb, and Joseph A. Caruso[*]



N-Alkylated ureas, including cyclic derivatives, are readily obtained pure. These stable compounds are already used as industrial solvents owing to their considerable solvent power, their wide liquid range, and their favorable dielectric constants and dipole moments. They are being increasingly employed as reaction media for electrochemical and analytical studies.



1. Introduction

Since *Lüttringhaus* and *Dirksen*[1] published their article on tetramethylurea (TMU), a considerable number of investigations into the behavior of this substance and other ureas have been undertaken in order to determine the usefulness of liquid ureas as nonaqueous media. Other solvents of primary interest are tetraethylurea (TEU), which is also acyclic like TMU, as well as the cyclic analogs 1,3-dimethyl-2-imidazolidinone ("dimethylethyleneurea", DMEU) and 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone ("dimethylpropyleneurea", DMPU). All of these substances are liquid at room temperature because hydrogen bridges are prevented by alkyl substitution on the nitrogen. Notable physical properties (with respect to the potential of ureas as electrolytic solvents) include wide liquid ranges as well as favorable dielectric constants and dipole moments.

TMU

TEU

DMEU

DMPU

Since there has been increasing dependence on nonaqueous solvents as media for inorganic and organic reactions, fundamental investigations of the general physical properties of ureas and of electrolyte behavior in these solvents warrant attention. Titrimetric and electroanalytical studies suggest possible analytical applications of the liquid ureas. Presented here is a comprehensive review of advances made since the authoritative article by *Lüttringhaus* and *Dirksen*[1] appeared some 14 years ago.

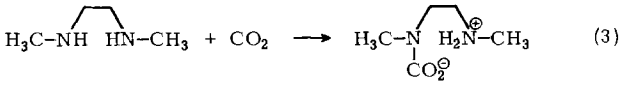
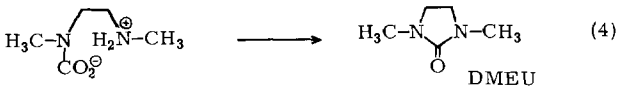
2. Preparation and Purification



Tetramethylurea (TMU) and tetraethylurea (TEU), which are available commercially from various chemical suppliers, can be purified by vacuum distillation through a column packed with a suitable drying agent such as granular barium oxide[2,3]. TMU is somewhat hygroscopic; however, both purified solvents retain a very low specific conductance for months when stored under nitrogen. The purified solvents usually have a water content of less than 0.01%. There are several methods of preparing TMU (cf. [1]); an especially useful one is aminolysis of aryl carbonates [eq. (1) and (2)].

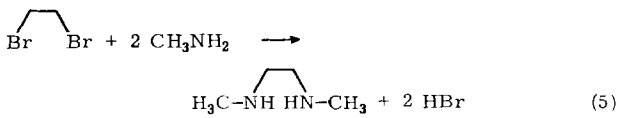
$$(C_6H_5O)_2CO + HN(CH_3)_2 \rightarrow C_6H_5O{-}CO{-}N(CH_3)_2 + C_6H_5OH \quad (1)$$



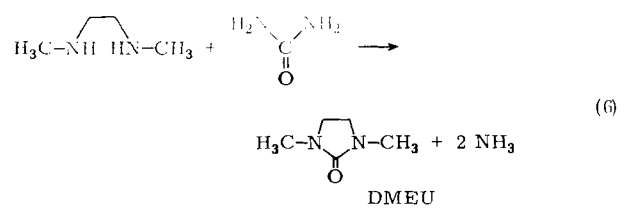
$$C_6H_5O{-}CO{-}N(CH_3)_2 + HN(CH_3)_2 \rightarrow (CH_3)_2N{-}CO{-}N(CH_3)_2 + C_6H_5OH \quad (2)$$

TMU

The cyclic ureas DMEU and DMPU may be synthesized by a variety of established methods, and are also commercially available. A procedure developed by *Mulvaney* and *Evans*[4] employs cyclization of the respective carbamate (made by the addition of carbon dioxide to the appropriate alkylamine) at elevated temperatures and pressures.



(3)



DMEU (4)

Reactions (3) and (4) have proved suitable for industrial preparation of the solvent. (Acyclic ureas have also been prepared from carbon monoxide and alkylamines at elevated temperatures and pressures[5].) *Rosenfarb, Huffman,* and *Caruso*[6] have described the synthesis of several *N,N*-dimethyl-substituted cyclic ureas by a modified procedure based on that reported earlier by *Jansen* and *Stokes*[7]. This preparation involved alkylation of the nonalkylated cyclic ureas in aqueous formaldehyde/formic acid media. *Lien* and coworkers prepared numerous alkylated ureas by adding the appropriate α,ω-dibromoalkanes to an alkylamine and by subsequently adding urea to the system [eq. (5) and (6)][8-11].

(5)

DMEU (6)

Other syntheses of cyclic ureas exist[12-14]; however, many of them require elaborate conditions and apparatus.

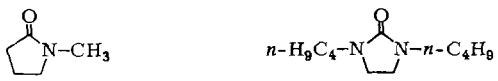
Purification of the cyclic ureas is readily accomplished by vacuum distillation over barium oxide[2,3,6]. Fractional freezing has been shown to be very useful for purifying DMEU[6] since its freezing point is 8.2 °C. Among the cyclic ureas, DMEU has been shown to be the most stable to heating[15]; however, the ureas in general are fairly stable under reflux conditions.

3. Physical Properties

Of the many ureas, only TMU, TEU, DMEU, and DMPU have been thoroughly studied with respect to their physical properties. These four ureas are clear and colorless when carefully purified, and each has a characteristic sharp odor. Table 1 presents selected physical properties.

Table 1. Physical properties of liquid ureas.

	TMU [1, 2]	TEU [3, 6]	DMEU [6]	DMPU [6]
B.p. [°C/torr]	176.5/760	81–82/7	220/754	230/754
M.p. [°C]	−1.2	—	8.2	< −20
Density [g/ml] at 25 °C	0.9619	0.9027	1.0519	1.0596
Viscosity [cP] at 25 °C	1.401	2.363	1.944	2.934
Dielectric constant (1 MHz) at 25 °C	23.45	14.39	37.60	36.12
Specific conductance [Ω^{-1} cm^{-1}] at 25 °C	2×10^{-8} – 8×10^{-8}	7×10^{-9} – 15×10^{-9}	1×10^{-8} – 7×10^{-8}	2×10^{-8} – 9×10^{-8}
Dipole moment [Debye]	3.37	3.45	4.09	4.23
Index of refraction at 25 °C	1.4493	1.4448	1.4707	1.4881



The dielectric constants and dipole moments[6,8] of the cyclic ureas are greater than those of the acyclic compounds[1,2,6,7]. An increase in chain length of the *N*-alkyl group(s) within a series of compounds normally decreases the dielectric constant; this may be seen on comparing the dielectric constants of DMEU/DMPU and TMU/TEU. A similar trend has been observed within homologous series of amides[16]. Although DMPU has a large liquid range, moderate dielectric constant, and high polarity, its higher viscosity may limit its use as a solvent, as compared to the lower viscosity, equivalent dielectric constant medium, DMEU. Likewise, the lower dielectric constant and higher viscosity of TEU limit its use as a solvent, when compared to TMU. Molecular associations have been investigated in several of the liquid ureas[6]. The parallel dipole-dipole associations suggested in the liquid ureas cannot be substantiated, since the Kirkwood *g* factors[17] were only slightly greater than unity.

4. Industrial and Pharmacological Applications

The acyclic ureas have been utilized to a greater extent than their cyclic homologs as industrial solvents[1,18,19]. However, liquid ureas in general have been commercially used in lubrication[20], in detergent production[21], as slow acting fertilizers[5], and in pre-treatment of catalysts[22] and textiles, especially in "permanent press" finishing[23-25].

Several alcohols derived from cyclic ureas (DMEU and DMPU, for example) have shown promise as bacterial growth inhibitors for textile materials. TMU and TEU have been used as catalysts for industrially significant reactions[26,27], including the reaction of elemental tin with alkyl halides and that of thionyl chloride with dibasic acids.

Lien and co-workers have investigated the pharmacological activities of a number of ureas[8, 11]. In studies with white rats, DMEU and DMPU appear to have a toxicity comparable with that of *N*-methyl-2-pyrrolidone[28], a widely used "universal" solvent. However, 1,3-dibutyl-2-imidazolidinone ("dibutylethyleneurea", DBEU) has a considerably higher toxicity[8] as a depressant on the central nervous system.

DBEU

Small amounts of TMU have been shown to increase the solubility of drugs[29]. (Generally, an increase in *N*-methylation also appears to increase the solubility of a variety of biologically active compounds.) TMU may be quite useful for drug titrations[30] although the recovery data (97.5 to 101.5%) were not as desirable as those for other organic compounds[31, 32]. TMU is a differentiating solvent for barbiturates and a leveling solvent for sulfa drugs.

A number of acid-base titration studies have been undertaken in tetramethylurea. These include potentiometric[30, 31] and indicator[30, 32] titrations of phenols, carboxylic acids, barbiturates and sulfa drugs with tetrabutylammonium hydroxide as the titrant. Typical curves for potentiometric titrations are shown in Figure 1; water levels as high as 5% in TMU could be tolerated without significantly affecting the results.

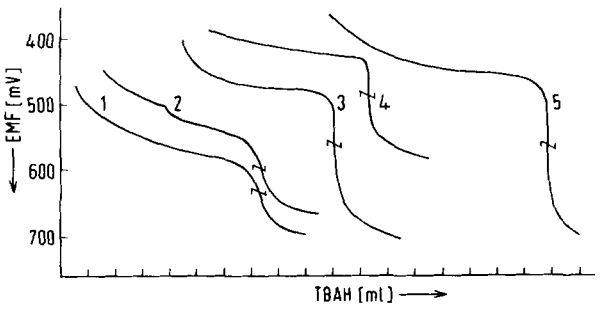


Fig. 1. Titration curves of some weak monoprotic acids against tetrabutylammonium hydroxide (TBAH) in tetramethylurea (TMU). 1, phenol; 2, benzoic acid + phenol; 3, 1-nitroso-2-naphthol; 4, *p*-nitrophenol; 5, benzoic acid.

In the indicator titrations, thymol blue was found to be suitable for analysis of carboxylic acids and bromophenol blue was a good indicator for the bases.

Satisfactory recoveries were also obtained from conductometric titrations with diphenylguanidine (DPG) as the titrant for *p*-nitrobenzoic, *o*-nitrobenzoic, and picric acids in TEU[3]. 2,4-Dinitrophenol and benzoic acid could not be determined with sufficient accuracy by this technique.

5. Fundamental Investigations

5.1. Conductance Studies

As in other nonaqueous solvents, conductance methods have been used to investigate the behavior of alkali metal and tetraalkylammonium salts in TMU[2, 33], TEU[3], DMEU[34, 35], and DMPU[34, 35]. The behavior of these salts in solution has been discussed in terms of limiting equivalent electrolyte (Λ_0) and ionic ($\lambda_0\pm$) conductances, association constants (K_A), and electrolyte "sizes" in solution (a_j, d). Conductance data in these studies were evaluated by:

1) the Fuoss-Shedlovsky y-x and Λ_0'-C methods[36]

$$1/\Lambda S_z = 1/\Lambda_0 + C\Lambda S_z f^2 K_A/\Lambda_0^2$$
$$y = 1/\Lambda S_z \text{ and } x = C\Lambda S_z f^2$$
$$\Lambda_0' = (\Lambda + \beta C^{1/2})/(1 - \alpha C^{1/2})$$

2) the Fuoss-Onsager equation for associated and unassociated electrolytes[37]

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma \log C\gamma + JC\gamma - K_A C\gamma\Lambda f^2$$

3) the Fernández-Prini expanded form[38] of the Pitts[39] and Fuoss-Hsia[40] equations

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma \log C\gamma + J_1 C\gamma - J_2(C\gamma)^{3/2} - K_A C\gamma\Lambda f^2$$

4) the full Pitts equation[39, 41] (see previous studies[35])[*].

As Table 2 reveals, the limiting equivalent conductances in the series of alkali metal ions generally increase as the crystallographic radii of the cations increase. As the crystallographic radii increase, the effective size of the cations decreases because of decreasing solvation. However, in TMU (and TEU), the λ_0^+ value of the sodium ion is about 0.5 unit higher than that of the potassium ion. In DMEU and DMPU, the sodium and potassium ions are isoconducting. The unusual conductance behavior of sodium salts found in the ureas is also observed in other structurally similar nonaqueous solvents such as dimethylacetamide[42], dimethylpropionamide[43], dimethylbutyramide[44], and *N*-methyl-2-pyrrolidone[45]. As expected, the limiting equivalent conductances of the tetraalkylammonium ions decrease as the crystallographic radii of these ions increase. The order of magnitude of λ_0^+ indicates that the effective size of the solvated alkali metal ions in the ureas investigated is comparable with that of the large tetraalkylammonium ions.

Table 2. Ionic limiting equivalent conductances (λ_0^+) (butyl(triisoamyl)ammonium tetraphenylborate as reference electrolyte) at 25 °C (cf. [2]).

	TMU [2, 33]	DMEU [34, 35]	DMPU [34, 35]
Na^+	15.74	11.46	6.96
K^+	15.26	11.51	7.00
Rb^+	15.63	11.46	7.36
Cs^+	16.52	12.52	8.00
NMe_4^+	22.22	16.92	11.30
NEt_4^+	21.61	16.78	11.01
NPr_4^+	16.60	12.46	8.03
NBu_4^+	15.00	10.73	6.89
SCN^-	33.44	23.28	16.66
I^-	29.12	19.52	13.68
ClO_4^-	28.71	20.30	14.01

Correlations between the properties of an electrolyte and a solvent and the extent of association are limited. Generally in the acyclic ureas, association within an alkali metal salt series increases slightly and association within a tetraalkylammonium salt series decreases as the crystallographic radii of the cations increase. Given the same cation[2, 3], association in

[*] S, S_z, E, J, J_1, J_2 = physical constants of the electrolyte and solvent, c = concentration, f = activity coefficient, α, β = physical constants of the solvent, γ = degree of dissociation.

TMU and TEU decreases along the series $NO_3^- > Br^- > SCN^- > I^- > ClO_4^- > BPh_4^-$. The lower dielectric constant of TEU causes much greater association in that solvent than in TMU. In contrast, the cyclic solvents DMEU and DMPU, with their higher dielectric constants, are excellent dissociating media for electrolytes (see Fig. 2).

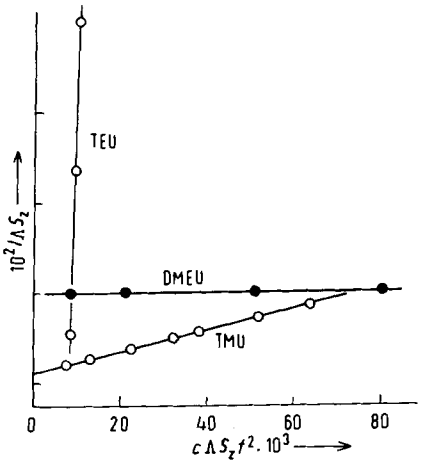

Fig. 2. Conductance behavior of NaSCN in different urea solvents. The slope of the curve is a measure of the association.

5.2. Spectroscopic Studies

Although several ^1H-, ^{13}C-, and ^{23}Na-NMR studies have been undertaken in liquid ureas[23,46-49], few systematic NMR investigations have been reported. TMU has been shown to be a water structure breaker[19] and TEU should have similar properties since the dipole moments and sizes of these molecules are comparable. ^{13}C-NMR data measured by Fourier transform methods[47,48] are listed in Table 3. The

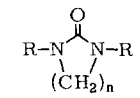

Table 3. ^{13}C-NMR shifts (δ values, TMS as standard) [47].

	C O	CH_3	N CH_2
TMU	165.7	38.6	–
TEU	164.4 [50] 164.1 [48]	13.4 [48]	42.6 [48]
DMEU	161.3	31.3	45.0
DMPU	156.7	35.6	48.1

decreasing order of carbonyl shift for heterocyclic solvents generally appears to be *N*-methyl-2-pyrrolidone > TMU, TEU > DMEU > 3-methyl-2-oxazolidone > DMPU, ethylene carbonate[48]. Such an order suggests a decreasing availability of the carbonyl oxygen for cation interaction. The carbonyl shifts for the acyclic ureas are also close to those for the acyclic amides[50]. ^{23}Na-NMR data for salts dissolved in TMU[49] indicate that ions appear to be "freely solvated" in TMU and that TMU's donor ability approximates that of DMSO. The donor ability of TMU is greater than that of pyridine even though the donor number of the former (28.9 as estimated from ^{23}Na experiments) is less than that of the latter (33.0).

Other spectroscopic investigations have included ultraviolet (UV)[8,51], nuclear quadrupole resonance (NQR)[52], and

Table 4. IR frequencies of cyclic ureas [6]. (The O(C N) band of DPPU has only medium intensity.)

	R	n	νC O [cm^{-1}]	νO(C N) [cm^{-1}]

DMBU	CH_3	4	1631	1326

infrared (IR)[9,53,54] studies of numerous acyclic and cyclic ureas (see Table 4). Some of these studies have attempted to correlate common functional group shifts with pharmacological activity[9]. Inorganic complexes of the ureas, *e.g.* with lanthanides and the uranyl groups[55,56], also have been synthesized and examined by IR techniques. ^1H-NMR data pertaining to solute-solvent interaction in DMEU[57] support conductivity data[34,35] indicating ion dissociation in DMEU.

6. Summary

In conclusion, it appears likely that the ureas, especially TMU, DMEU and DMPU, will be useful solvents for further chemical investigations. Of the acyclic substances, TMU has a greater dielectric constant than TEU which suggests that it is better suited as an electrolytic solvent; among the cyclic compounds, DMEU has a lower viscosity than DMPU. In both classes of ureas there exist reasonable solubilities for many electrolytes; their solvation behavior varies widely. Of the two groups, the cyclic ureas are clearly the better dissociating media, as expected from consideration of their higher dielectric constants and dipole moments. These physical properties and the wide liquid ranges of about 250 °C indicate much future potential for cyclic ureas.

We can expect more fundamental and applied research into this class of dipolar-aprotic solvents in the future. Many important physical properties, as well as data about long-term toxicities for most of the available liquid ureas, are still needed. The solubilities of many inorganic, organic, and significant biological substances in the ureas have still not been determined. The behavior of electrolytes and nonelectrolytes in solution, as well as solution structure determinations studied by electrochemical, spectroscopic, and kinetic experiments, likewise await investigation. Studies presently in progress in this area include: fast kinetics, ^{13}C-NMR analysis of solute-solvent interaction, and fundamental acid-base studies. Interestingly, the ureas provide a significant addition to

previously studied sets of homologous heterocyclic solvents such as the pyrrolidones, oxazolidones, and carbonates. In order to elucidate the behavior of nonaqueous solvents as media for chemical investigations, there is a need for systematic studies on series of homologous compounds; the liquid ureas are such a series.

The Chemistry of Iodine Azide

By Kurt Dehnicke[*]

Whereas chlorine azide and, to a lesser extent, bromine azide have long been used as preparative reagents in spite of their explosive nature, little is known about the properties of iodine azide although it was actually discovered before the other two compounds. *Hantzsch*'s warning to beware of this material, uttered in 1900, still seems to be widely observed. Only recently has iodine azide been isolated as a pure substance, thus promoting its more detailed investigation. Proper use of this highly labile reagent opens up new vistas in synthetic chemistry.

1. Mode of Formation and Preparation of Iodine Azide

Iodine azide was first obtained as very unstable ethereal solutions and as crystals contaminated with iodine by *Hantzsch* and *Schümann* on reaction of iodine with silver azide[1]:

$$AgN_3 + I_2 \xrightarrow{\text{Ether}} IN_3 + AgI \qquad (a)$$

Whereas the solutions decompose quickly forming iodine and nitrogen, the crystalline residue left on evaporation of the ether, "would explode regularly and violently on touching with a spatula"[1].

Although some of the less sensitive heavy metal azides are also suitable for the production of iodine azide, the first synthesis (a) is still the most effective one even today. However, an important factor affecting the stability of the product is the exclusion of oxygen-containing solvents. Solutions of iodine azide in dichloro- or tetrachloromethane, freon, benzene, *etc.* are by far more stable, and can be handled easily when moisture is excluded; according to our experience they can be handled safely at concentrations below 3%, and can even be dried over diphosphorus pentoxide[2].

As silver azide is safe only when moist, while even traces of water decompose iodine azide the reaction gives best yields if a suspension of silver azide in dichloromethane is treated with a desiccant, *e.g.* sodium sulfate, before adding iodine. This procedure gives a very pure solution of iodine azide, from which golden and needle-shaped crystals (Fig. 1) can be isolated by careful evaporation of the solvent. Larger crystals can be grown by sublimation onto a cold finger in a current of dry nitrogen[2].

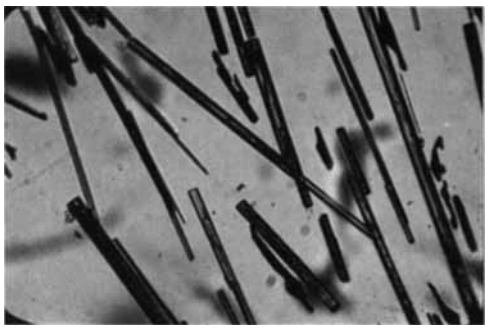

Fig. 1. Crystals of iodine azide. Magnification 25 ×.

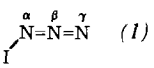
Analogous reactions of $Pb(N_3)_2$ and of freshly precipitated TlN_3 with iodine proceed much slower and do not go to completion[3]. Most probably, iodine azide is also formed in the reaction of ICl with NaN_3 in acetonitrile, pyridine, and solvents of comparable polarity. Such solutions are used by *Hassner et al.* for the addition of iodine azide generated *in situ* to olefinic double bonds (cf. Section 3.1)[4].

It is an experimental advantage that the solutions of iodine azide, the concentration of which can be determined iodometrically, can be dosed very exactly: the IN_3 solution is shaken with excess aqueous sodium thiosulfate and the residual $S_2O_3^{2-}$ is back-titrated[3].



$$IN_3 + 2S_2O_3^{2-} \rightarrow I^- + N_3^- + S_4O_6^{2-} \qquad (b)$$

The smooth course of reaction (b) suggests a redox potential close to that of I_2 (0.535 V).

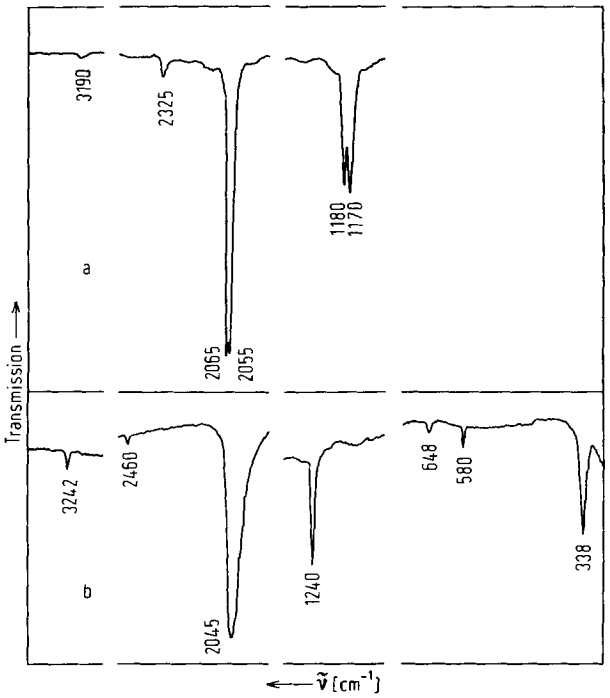
2. Physical Properties

2.1. Vibrational Spectrum

The IR spectrum of iodine azide is known for the polycrystalline phase, the benzene solution[2], as low-temperature matrix spectrum in CH_2Cl_2[5], and—partly—in the gas phase[6]. The spectra are in accord with the C_s symmetry of molecule *(1)*, bent at the N_α atom.

(1)

This is confirmed by the Raman spectrum which, owing to photochemical cleavage of IN_3 by the laser beam (6741 Å), could not be recorded in solution, but only in the solid state in a dichloromethane matrix[5]. Iodine formed on decomposition affects the band maxima; this is explained in terms of formation of a iodine-iodine azide complex[5].



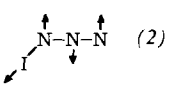


Fig. 2. IR spectrum of iodine azide: a) in the gas phase, 10 torr IN_3/750 torr N_2; b) in nujol.

In the series fluorine azide to iodine azide the nitrogen-halogen stretching vibration shows an anomalous shift to lower wave numbers in iodine azide:

	FN_3[7]	ClN_3[7,8]	BrN_3[7]	IN_3[2]
νN X [cm^{-1}]	869	719	687	338

This effect is certainly due in part to coupling with the A′ in-plane bending vibration of the N_3 group *(2)*. In the homologues FN_3, ClN_3, and BrN_3 this frequency ($\approx$650 cm^{-1}) is lower than the nitrogen-halogen stretching frequency but higher in iodine azide. Thus in the case of IN_3 the whole N_3 group may be treated as a point mass[9].

(2)

On the other hand, the extremely low frequency of the νN I vibration indicates a significant polarity of the iodine-nitrogen bond *(3)*.

(3)

Both the UV data of the halogen azides[10] (cf. Section 2.2) and the reactivity of iodine azide favor this interpretation.

2.2. UV Spectrum

The electronic spectrum of iodine azide recorded in hexane solution[10] shows three maxima (Table 1); one of them lies in the visible range and is thus responsible for the golden yellow color of IN_3 solutions. This band corresponds to an electronic transition of the I component of iodine azide; it is shifted to higher energies compared to that of iodine (517 nm)[11]. This result indicates a positive partial charge of the iodine atom, as is shown by the remarkably low wave number of the νN I vibration (cf. Section 2.1).

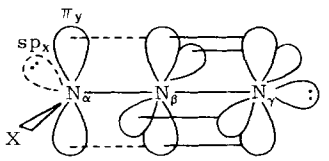

Table 1. UV spectrum of iodine azide in hexane.

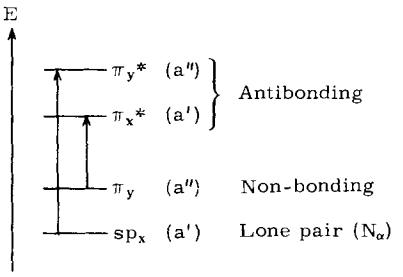
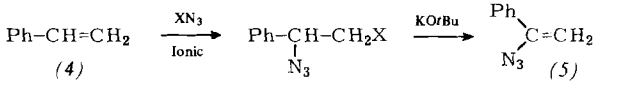


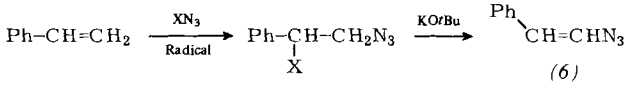
λ_{max} [nm]	ε [l·mol^{-1}·cm^{-1}]	Half width [nm]	Assignment
209	870	11	$sp_x \rightarrow \pi_y^*$
243	615	26	$\pi_y \rightarrow \pi_y^*$
350	40	60	[a]

[a] Compare text for assignment.

Comparison of the corresponding band of chlorine azide (380 nm) with the absorption maximum of chlorine (332 nm)[12] shows that it is shifted bathochromically, indicating a slight negative partial charge on the chlorine atom in ClN_3. This difference correlates well with some chemical properties of the two compounds[13].

In the UV region, IN_3 exhibits two maxima which are approximately equivalent in wavelength and extinction to those of other covalent, monomeric azides[14], *e.g.* alkyl azides, which absorb at about 285 and 215 nm. As in covalent azides of the type XN_3, bonding in the N_3 group can be described by two σ bonds, one localized π bond N_β N_γ, one delocalized π-bond N_α N_β N_γ and two lone pairs at the N_α- and the N_γ atom (symmetry C_s), these bands are assigned to the possible transitions $\pi_y(a'') \rightarrow \pi_y^*(a')$ and $sp_x(a') \rightarrow \pi_y^*(a'')$, by *Closson* and *Gray*[15], *i.e.* transitions from the two highest occupied orbitals to the lowest unoccupied antibonding π orbitals.

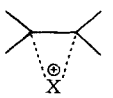




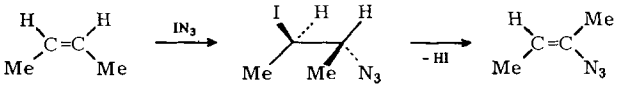
In the more highly symmetrical azide ion ($D_{\infty h}$ symmetry) these transitions become degenerate, so only one band is observed[14]. As in iodine azide the energy difference between the two transitions is significantly smaller (34 nm) than in the alkyl azides ($\approx$70 nm), thus providing more evidence for the polarity of the iodine-nitrogen bond *(3)*.

3. Chemical Properties

3.1. Addition to Olefinic Double Bonds

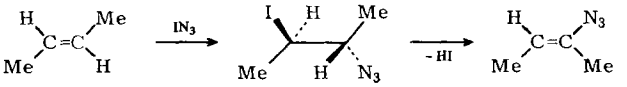


The addition of iodine azide to olefinic double bonds may be used for the synthesis of simple vinyl azides, which are obtained from the iodine- and azido-substituted primary products by elimination of HI with potassium *tert*-butoxide[4]. Iodine azide adds preferentially by an ionic mechanism, whereas chlorine and bromine azide frequently add by a radical mechanism. Thus the regioisomeric vinyl azides *(5)* and *(6)* are accessible from styrene *(4)*.



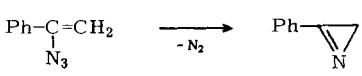
Whether the addition follows an ionic or a radical course depends on the polarity of the solvent. *Hassner et al.*[4] obtained iodine azide in presence of the olefin *in situ* from sodium azide and iodine monochloride and investigated its reactions mostly in highly polar solvents such as acetonitrile, dimethyl formamide, and pyridine. This experimental technique had essentially been applied by *Birckenbach et al.*[16] when they reacted cyclohexene with iodine in the presence of silver salts, such as AgNCO, $AgNO_2$, and $AgClO_4$, and found evidence for the addition of INCO, INO_2, and $IClO_4$ respectively, to the olefinic double bond.

The tendency towards homolytic cleavage increases along the series $IN_3 < BrN_3 < ClN_3$[4]; this is in accordance with the UV[10] and IR spectra[2, 13] of the halogen azides. The same trend is also observed in their reactions with numerous inorganic agents.

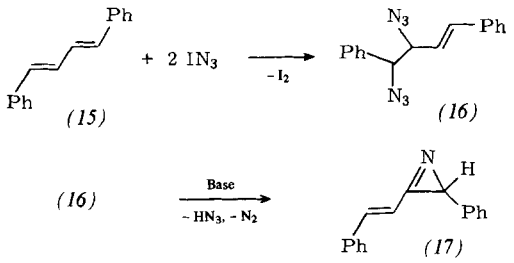


(7)

The ionic addition of iodine azide to olefins involves the intermediacy of a halogenium ion *(7)*. This becomes evident from the stereospecific reaction of *cis*- and *trans*-2-butene to



(8), *cis* — *(9)*, *threo* — *(10)*, *trans*



(11), *trans* — *(12)*, *erythro* — *(13)*, *cis*

form *threo- (9)* and *erythro*-2-azido-3-iodobutane *(12)*, respectively, the dehydrohalogenation of which yield *trans- (10)* and *cis*-vinyl azide *(13)*[17, 18].

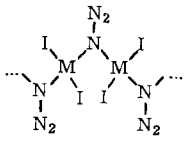
Vinyl azides are interesting starting materials for pyrolytic or photolytic syntheses of azirines *(14)*[19, 20].

Thus the synthesis of the first 2-vinylazirine *(17)* was accomplished by reaction of iodine azide with diphenylbutadiene and basic cleavage of HN_3 from the primary diazide *(16)*[21].

3.2. Reactions with Metal Iodides

The significant polarity of the $\overset{\delta+}{I}\ \overset{\delta-}{N}$ bond in iodine azide suggests substitution reactions with metal iodides, with charge neutralization between the I^+ and I^- species involved providing the driving force. Such reactions proceed smoothly and very fast in benzene solution[22]; in contrast, chlorine azide reacts much slower with metal chlorides[13].

$$\overset{\delta+}{M}I_3 + \overset{\delta+}{I}\overset{\delta-}{N}_3 \rightarrow I_2MN_3 + I_2 \qquad (c)$$



M = B, Al, Ga *(18a—c)*

Whereas aluminum- *(18b)* and gallium azide diiodide *(18c)* were found to be quite stable and resistant to thermal and mechanical stress[22], the boron compound *(18a)*, which is presumably associated like its trimeric homologues $[Cl_2BN_3]_3$[23,24] and $[Br_2BN_3]_3$[23] decomposes slowly *in vacuo* at room temperature:

$$I_2BN_3 \rightarrow BN + I_2 + N_2$$
(18a)

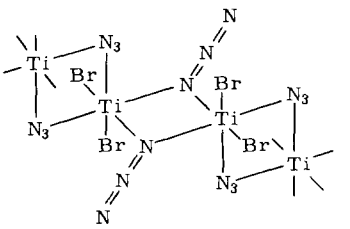
IR spectra show $[IBNI]_n$ to occur as intermediate. The instability of this species, which is isoelectronic with hexaiodobenzene, is attributed to a difference in the polarity of the iodine ligands $B\ \overset{\delta-}{I}\ /\ N\ \overset{\delta+}{I}$. *(18a)* decomposes explosively on contact with water, yielding iodine and nitrogen[22].

Aluminum- *(18b)* and gallium azide diiodide *(18c)* are shown by their solubility and their vibrational spectra to be polymeric species, associated *via* the N_α atoms of the N_3 groups (type *(19)*).

(19)

Titanium azide triiodide I_3TiN_3[25], accessible from titanium tetraiodide and iodine azide, also seems to be associated by way of azido bridges. In contrast to the explosive Cl_3TiN_3, which is easily converted into very pure TiNCl by elimination of N_2 and Cl_2[26], I_3TiN_3 is much less sensitive to mechanical and thermal stress. Striking thermal stability is also found with MoI_2N_3, which is prepared from MoI_3 and iodine azide, and is shown by the absence of the $\nu_s N_3$ mode in the IR spectrum to contain azide ions[25].

Because the iodine ligand is sensitive to oxidation, the metal azide iodides are very easily converted into metal azide bromides by reaction with an excess of bromine[22].



$$I_2AlN_3 + Br_2 \rightarrow Br_2AlN_3 + I_2$$
(18b) *(20)*

3.3. Reactions with Metal Bromides

We recently discovered a direct entry to metal azide bromides by reaction of an iodine azide solution with metal bromides:

$$TiBr_4 + 2IN_3 \rightarrow Br_2Ti(N_3)_2 + 2IBr$$
(21)

Titanium tetrabromide yields exclusively the diazide *(21)*, which according to the vibrational spectrum is associated *via* azide bridges. Titanium has the coordination number six and *cis*-positioned bromine ligands[25]. Thus a structural relationship exists with Cl_3TiN_3, which contains alternating azido- and chloro bridges[27] in keeping with its modified composition.

(21)

Interesting products result from the reaction of iodine azide with molybdenum tetrabromide. Although this reaction again initially forms a molybdenum azide bromide which is highly explosive, it slowly releases nitrogen in solution and thus turns into molybdenum bromide nitride *(22)*[28]:

$$Br_3MoN_3 \rightarrow MoNBr_3 + N_2 \qquad (d)$$
(22)

Monomeric $MoNBr_3$ is observed in the mass spectrum. In the solid state, however, it is most probably associated, containing Mo≡N Mo groups, like $[MoNCl_3]_4$[29,30] which was obtained previously by a different method. Characteristically the Mo≡N stretching frequency in the IR is found at 1025 cm^{-1} (νMoN in $MoNCl_3$: 1045 cm^{-1})[29]. The metal-nitrogen triple bond, which is at the center of current interest owing to its possible role in nitrogen assimilation, is understood as resulting from overlap of unoccupied d_{xy}, d_{x^2} orbitals of molybdenum with the occupied, doubly degenerate π orbital of the nitride ligand.

$WNBr_3$ can be obtained from WBr_5 and iodine azide [cf. eq. (d)][31].

Donor molecules like phosphorus oxide trichloride and tribromide react with $MoNBr_3$ to form the complexes $MoNBr_3 \cdot OPCl_3$ and $MoNBr_3 \cdot OPBr_3$, whereas tetramethylammonium bromide gives compound *(23)*, which contains a terminal triply bonded nitride ligand (symmetry C_{4v})[25]:

$$MoNBr_3 + NMe_4Br \rightarrow NMe_4[Br_4Mo \quad N]$$
(22) *(23)*

Upon heating to 200 °C *in vacuo*, $MoNBr_3$ releases bromine to give $MoNBr_2$ *(24)*, also not reported previously. In a closed system, this procedure gives single crystals of $MoNBr_2$; the transport reaction (e) is probably involved in their formation:

$$MoNBr_{2(s)} + \tfrac{1}{2}Br_2 \rightleftharpoons MoNBr_{3(g)} \qquad (e)$$
(24) *(22)*

The reduction to Mo^V causes a low energy shift of the Mo≡N stetching frequency in $MoNBr_2$ to 953 cm^{-1}[25].

3.4. Reactions with Metal Chlorides

The preparative applications of the reaction of chlorine azide with metal chlorides were reviewed in 1967[13]. Use of iodine azide instead of chlorine azide as a reagent with metal chlorides has a number of advantages. Apart from the exact dosage, it is mainly the higher reactivity of iodine azide which enhances the range of application and also permits some reactions to be carried out at low temperatures. In some reactions of iodine azide with metal chlorides the N I bond is even preserved.

A pertinent example is the reaction of vanadium tetrachloride with iodine azide in tetrachloromethane to give *N*-iodo vanadium trichloride nitride *(25)*[32]:

$$VCl_4 + 2IN_3 \xrightarrow{CCl_4} Cl_3V \quad N \quad I + 2\tfrac{1}{2}N_2 + ICl \qquad (f)$$
(25)

(25) is only slightly soluble in CCl_4 and can be isolated as very dark brown needles which are sensitive to moisture and oxygen. The course of reaction (f) is understood as a primary addition of iodine azide to the Lewis acid VCl_4 followed by spontaneous elimination of N_2 from *(26)*:

$$Cl_4VN \quad \overset{I}{N_2} \xrightarrow[-N_2]{} Cl_3V \quad N \quad I + \tfrac{1}{2}Cl_2$$
(26) *(25)*

Simultaneously a (presumably radical) extrusion of one chlorine ligand occurs, most probably in the *trans* position relative to the VN multiple bond.

With an excess of bromine, *(25)* is converted into the bromide *(27)*[32]:

$$Cl_3VNI + Br_2 \rightarrow Cl_3VNBr + IBr$$
(25) *(27)*

The IR spectra show the three *N*-halo vanadium trichloride nitrides to contain V≡N triple bonds:

	Cl_3VNCl[33]	Cl_3VNBr	Cl_3VNI
νVN [cm^{-1}]	1110	1032	963

The decrease in the wave number of the VN stretching vibration on going from the NCl to the NI compound is caused by the weakening of the coupling with the nitrogen-halogen stretching vibration in the above order.

The reaction of iodine azide with molybdenum pentachloride leads to a surprising result[32]:

$$MoCl_5 + IN_3 \xrightarrow{CCl_4} MoNCl_4 + ICl + N_2$$
(28) *(29)*

According to magnetic measurements, the chloride nitride *(29)* contains molybdenum(v) ($\mu_{eff} = 1.6\,\mu_B$); the IR spectrum reveals no N Cl group, but Mo N multiple bonds are deduced from a doublet of bands at 1005/1023 cm^{-1}. Hence $MoNCl_4$ has to be formulated as a dimeric molecule[32]:

$$Cl_4Mo \quad N \quad N \quad MoCl_4 \leftrightarrow Cl_4Mo \overset{1}{} \quad N \quad N \quad Mo\overset{1}{}Cl_4$$
(29)

From the viewpoint of bonding theory, the group Mo≡≡N N is related to the isodiazene derivatives synthesized by *N. Wiberg et al.*[34] and *Veith*[35], *e.g.* Cp_2V N $N(SiMe_3)_2$, to compounds of the type $[Cl_4W{\equiv\equiv}N \quad C_2Cl_5]_2$[36] or $[Cl_3PO \quad WCl_4{\equiv\equiv}N \quad CCl_3]$[37], and with carbyne complexes containing the M ≡C R group, investigated by *E. O. Fischer et al.*[38,39]. Expulsion of chlorine by boiling in tetrachloromethane converts *(29)* into $MoNCl_3$ *(30)*, the structure of which is known[29,30]:

$$MoNCl_4 \xrightarrow[80\ ^\circ C]{CCl_4} MoNCl_3 + \tfrac{1}{2}Cl_2$$
(29) *(30)*

Tungsten hexachloride, however, reacts with iodine azide to form $WNCl_3$ *(31)* directly:

$$WCl_6 + IN_3 \rightarrow WNCl_3 + ICl + Cl_2 + N_2 \qquad (g)$$
(31)

Reaction (g) gives quantitative yields and is complete within a few minutes. It is therefore preferred over the synthesis of *(31)* with chlorine azide[29].

The pronounced reactivity of iodine azide even permits the preparation of $CrCl_2N_3$ from the kinetically very stable chromium trichloride[58].

3.5. Reaction with Halometalates

The tetraphenylarsonium hexahalometalates $AsPh_4[MX_6]$ of niobium and tantalum with X = Cl, Br, I, also react with iodine azide in dichloromethane, undergoing substitution and forming azidopentahalometalates *(32)*[6]:

$$[MX_6]^{(-)} + IN_3 \rightarrow [X_5MN_3]^{(-)} + IX$$
M = Nb, Ta *(32)*

On the other hand, $[WSCl_5]^{(-)}$ causes exclusive spontaneous catalytic decomposition of iodine azide[31] (cf. Section 3.7).

The anions *(32)* can be decomposed photochemically in the presence of $AsPh_4X$ in the molar ratio 1:1 in acetonitrile, to form the tetrahalonitridometalates *(33)*, the first compounds to contain a terminal Nb≡N and Ta≡N triple bond respectively[6]:

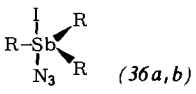
$$[X_5MN_3]^{(-)} + X^{(-)} \xrightarrow{h\nu} [X_4M \quad N]^{(-)} + N_2 + X_2$$
(32) *(33)*

3.6. Oxidative Additions

The oxidative addition of iodine azide to tin(II) chloride yields tin(IV) diazide dichloride *(34)*[40], also obtained by substitution from $SnCl_4$ and Me_3SiN_3[41]:

$$2\,SnCl_2 + 2\,IN_3 \rightarrow \underset{(34)}{SnCl_2(N_3)_2} + \text{"}SnCl_2I_2\text{"} \qquad (h)$$

Reaction (h) is assumed to involve primary formation of $SnCl_2IN_3$ which however reacts further *via* ligand exchange, favored by azido bridge formation. This is supported by the fact that in the presence of chloride ions, reaction (h) gives the mixed ligand complex *(35)*[42]:



$$2\,NMe_4Cl + SnCl_2 + IN_3 \rightarrow \underset{(35)}{[NMe_4]_2[SnCl_4IN_3]}$$

The octahedral shielding of the tin atoms by complexation prevents intermolecular bridging and thus rules out the possibility of ligand transfer. In an analogous way antimony trichloride reacts with iodine azide to form the highly explosive $SbCl_3(N_3)_2$.

Trimethyl- and triphenylantimony also undergo oxidative addition with iodine azide[43]:

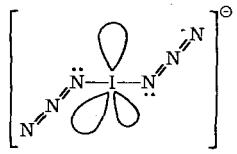
$$\underset{R = CH_3,\ C_6H_5}{R_3Sb + IN_3} \rightarrow \underset{(36a,\ b)}{R_2SbIN_3} \qquad (i)$$

Determination of the molecular weight and vibrational spectra show both antimony compounds *(36a, b)* to be monomeric in solution as well as in the solid, the coordination number of antimony being five. The ligand arrangement was determined by ^{121}Sb Mössbauer spectroscopy[43]:

(36a,b)

Eq. (i) demonstrates the pseudohalogen character of iodine azide: chlorine, bromine, and iodine also react with triorganoantimony compounds *via* oxidative addition[44,45].

3.7. Halo- and Pseudohalo Complexes of Iodine Azide



The distinct polarity of the I–N bond in iodine azide [see *(3)*] suggested the iodine atom to exhibit Lewis acidity. This was verified by the behavior of IN_3 in reactions with halide and pseudohalide ions, which, on account of their negative charge might serve as Lewis bases.

Tetramethylammonium azide, suspended in dichloromethane, reacts smoothly with stoichiometric quantities of iodine azide, forming diazidoiodate(I) *(37)*[46], which is readily soluble in CH_2Cl_2 (orange solution):

$$NMe_4N_3 + IN_3 \xrightarrow{CH_2Cl_2} \underset{(37)}{NMe_4[I(N_3)_2]} \qquad (k)$$

(37) forms red, hygroscopic, and highly explosive crystals. In laser light (5145 Å) their solution decomposes with evolution of nitrogen. The anion $[I(N_3)_2]^{\ominus}$ is isoelectronic with the hypothetical xenon diazide $Xe(N_3)_2$. As an example of a xenon-nitrogen compound is already known, *viz.* $XeN(SO_2F)_2$[47], it is conceivable that $Xe(N_3)_2$ might also be capable of existence.

Interaction of the lone pairs at the iodine atom with those of the N_α atoms should lead to a dihedral angle of 120° for the N_3 groups [cf. *(38)*].

(38)

The resulting low symmetry C_2 is confirmed by the appearance of in-phase and out-of-phase vibrations in the IR spectra[46].

Reactions analogous to (k) are also observed with tetramethylammonium halides, -cyanides, -cyanates, and -selenocyanates. The results are compiled in Table 2.

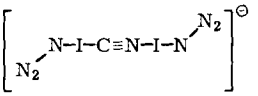
Table 2. Pseudohalo complexes $NMe_4[X–I–N_3]$.

Compound	Symmetry of anion	Color
$NMe_4[F–I–N_3]$	C_s	yellow
$NMe_4[Cl–I–N_3]$	C_s	orange
$NMe_4[Br–I–N_3]$	C_s	orange red
$NMe_4[I–I–N_3]$ *(39)*	C_s	deep purple
$NMe_4[N_3–I–N_3]$ *(37)*	C_2	orange red
$NMe_4[OCN–I–N_3]$	C_1	ocher
$NMe_4[NCSe–I–N_3]$	C_1	orange red
$NMe_4[NC–I–N_3]$	C_s	orange
$NMe_4[N_3–I–NC–I–N_3]$ *(40)*	C_1	orange

On the other hand, tetramethylammonium thiocyanate spontaneously eliminates nitrogen from iodine azide even at −60 °C in CH_2Cl_2. This is reminiscent of the well known "iodine azide reaction", in which iodine in the presence of traces of $S_2O_3^{2-}$, CS_2, H_2S, $S_nO_6^{2-}$ ($n = 4, 5, 6$), cysteine, and related compounds, effects spontaneous evolution of nitrogen from aqueous solutions of hydrazoic acid. This is a very sensitive test for the above sulfur compounds[48,49]:

$$2\,HN_3 + I_2 \rightarrow 3\,N_2 + 2\,HI \qquad (l)$$

The kinetics of reaction (l) have also been thoroughly investigated[49–51].



The pseudohalo complexes $NMe_4[X–I–N_3]$ (Table 2) crystallize readily, yet are sensitive to laser light (5145 Å); thus Raman spectra could not be recorded. In the solid state the compounds are explosive, but can still be handled with comparative safety. The complex $NMe_4[I_2N_3]$ *(39)*, obtained from NMe_4I and IN_3, was also prepared from iodine and tetramethylammonium azide[46]:

$$NMe_4N_3 + I_2 \rightarrow \underset{(39)}{NMe_4[I_2N_3]}$$

Being able to form linear bridges, *e.g.* between metal atoms, the cyanide ion can also act as a bridge between iodine azide molecules[46]:

$$NMe_4CN + 2\,IN_3 \rightarrow \underset{(40)}{NMe_4[CN(IN_3)_2]}$$

The structure of the complex anion of *(40)* is remarkable because of its linear axis of six atoms. As indicated in *(41)*, this anion is assumed to be bent at the N_α-atoms [cf. *(38)*].

(41)

3.8. Reactions with Carbonylmetal Complexes

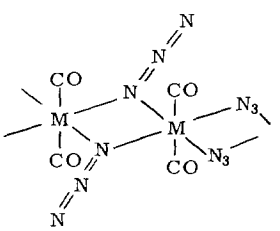
Iodine azide reacts with carbonylmetal complexes at even -40 to $-20\,^{\circ}C$ to form various products. Decacarbonyldimanganese or octacarbonyldicobalt yield the metal diazides[54], which are also accessible in other ways[52,53]:

$$Mn_2(CO)_{10} + 4IN_3 \rightarrow 2Mn(N_3)_2 + 10CO + 2I_2$$
(42)

With tetracarbonylnickel an equimolar mixture of nickel diazide and nickel diiodide is formed[54]:

$$2Ni(CO)_4 + 2IN_3 \rightarrow Ni(N_3)_2 + NiI_2 + 8CO$$
(43)

Presumably, these reactions initially yield azide iodides, which subsequently react to form the diazides by substitution with more iodine azide or by elimination of the iodine ligand. In the case of pentacarbonyliron, such an intermediate was isolated at $-20\,^{\circ}C$; being stable in the absence of solvent it could be characterized[54]:

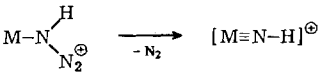


$$Fe(CO)_5 + IN_3 \rightarrow Fe(CO)_2IN_3 + 3CO$$
(44)

The iron atoms are linked by azido bridges, whereas the iodine ligands are of ionic character.

A new group of carbonylmetal derivatives, *viz.* carbonylmetal azides not containing iodine, result from the reaction of hexacarbonylmolybdenum or -tungsten with iodine azide[54]:

$$M(CO)_6 + 2IN_3 \rightarrow M(CO)_2(N_3)_2 + I_2 + 4CO$$
$M = Mo, W$ *(45a, b)*



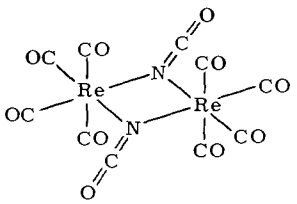
The compounds *(45a, b)* are hygroscopic and extremely sensitive solids, which explode upon application of the least mechanical stress. This immensely complicates their handling. Yet their characterization by IR spectroscopy has been accomplished. They form polymeric structures of type *(46)*, bridged by the N_α atoms of the N_3 groups. The extremely high frequency of $\nu_{as}N_3$ [*(45a)*: 2200 cm^{-1}, *(45b)*: 2220

(46)

cm^{-1}] indicates a distinct diazonium character of the N_3 groups.

It is interesting to note that the azides *(45a, b)* also explode violently on contact with traces of water. After brief exposure to moist air samples show a strong IR absorption band at $\approx 1000\ cm^{-1}$, which is characteristic for M≡N triple bonds. Both observations can be interpreted by assuming primary protonation at the N_α atom; formation of the diazonium group *(47)* initiates the secondary elimination of N_2 which leads to the metal-nitrogen triple bond in *(48)*[54]:

(47) *(48)*



The protonation of covalent azides is known; for instance, protonated hydrazoic acid can be isolated as hexachloroantimonate[55].

An entirely different mode of reaction with iodine azide is found for the carbonyl compounds of rhenium and osmium. Primary formation of an azide actually occurs, but this cannot be isolated because it eliminates nitrogen spontaneously and transforms into cyanate by migration of CO[54]:

$$Re_2(CO)_{10} + 2IN_3 \rightarrow [(CO)_4ReNCO]_2 + 2N_2 + I_2$$
(49)

$$Os_3(CO)_{12} + 3IN_3 \rightarrow Os_3(CO)_6(NCO)_3 + 3N_2 + 1\tfrac{1}{2}I_2 + 3CO$$
(50)

The formation of cyanates has occasionally been observed in the reaction of alkali metal azides with carbonylmetal compounds[56,57]. According to mass- and vibrational spectroscopic investigations the cyanate *(49)* is associated *via* the N

(51)

atoms of the cyanate groups [see *(51)*], which means octahedral coordination of the rhenium atoms. The structure of the osmium compound *(50)* has not yet been determined.

4. Summary

This paper has considered the chemistry of iodine azide, taking into account some representative groups of materials. Undoubtedly the types of reactions investigated can be varied in numerous ways; also new, hitherto unexplored reactions of iodine azide appear in outline. Its pronounced reactivity and its comparative stability are consequences of the polarity of the I N bond; the iodine atom has acceptor properties, and the N_α atom of the N_3 group can act as donor. The N_3 group introduced on substitution with iodine azide, can undergo frequently surprising secondary reactions on account of its high energy content.

The example of iodine azide was chosen to demonstrate how prejudice can be overcome by appropriate handling of a

compound known to be highly explosive, and how one can do preparative chemistry of a kind which has existed in oblivion for almost 80 years.

I am very much indebted to my daring and imaginative coworkers for their dedicated and thorough research in this field: Rainer Dübgen, Werner-M. Dyck, Kurt Fleck, Norbert Krüger, Wolfgang Liebelt, Werner Liese, Peter Ruschke. The Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie generously supported our experimental work reported here.

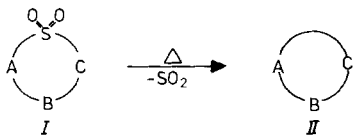
Pyrolysis of Sulfones as a Synthetic Method[1]



By Fritz Vögtle and Ludovica Rossa[*]

New synthetic methods (28)

Cyclic sulfones containing structural elements such as aromatic rings, heteroatoms, functional groups, and further SO_2-groups as ring members decompose on heating with cleavage of SO_2 and formation of a new C C bond. In the last decade this "sulfone pyrolysis" has been expanded into a generally applicable method even allowing the synthesis of sterically strained medium-membered and multi-membered cyclic and polycyclic systems containing aromatic rings. By the pyrolysis of sulfones which are only unilaterally activated by benzyl moieties, aromatic systems can be bridged by $(CH_2)_n$ chains of any desired length. In addition, $(CH_2)_n$ chains can be split off together with two SO_2 molecules, with recombination of the remaining centers, resulting in ring contraction by four to n atoms. However, sulfone pyrolysis is of importance not only as a ring-contraction method but also as a crucial final step in the synthesis of multi-membered hydrocarbon cycles, *e.g.* of the phane type.

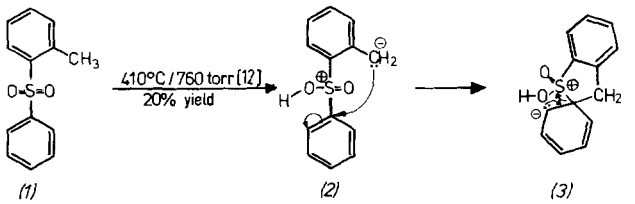
1. Introduction

This review concerns primarily the preparation of multi-membered, particularly angularly-strained and sterically overloaded ring compounds by thermal elimination of SO_2 from sulfones of the general type *I*[1]. A new C C bond is formed in the course of this reaction. A, B, and C are structural elements in the ring system, *e.g.* aromatic rings, heteroatoms, functional groups, and further SO_2-groups.

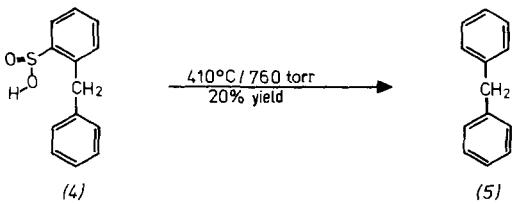
I *II*

Thermolyses had already been carried out with acyclic and three- to seven-membered cyclic sulfones[2-6], but the method acquired no general preparative significance.

2. Pyrolysis of Acyclic and Three- to Seven-Membered Cyclic Sulfones



The sulfones *III*, R^1, R^2 = alkyl, aryl, count among the most well-known organic compounds[7]. They are characterized, *inter alia*, by their generally simple synthesis, thermal stability, and chemical inertness. Simple sulfones can as a rule be distilled without decomposition, are stable to acids and bases even at higher temperatures, and other functional groups in the molecule can normally be oxidized without cleavage of the C S bond, since the sulfur is present in its highest oxidation state[7]. Nevertheless, it was observed at an early date that sulfones lose SO_2 on heating, and that depending on the reaction conditions the C-fragments may recombine with the formation of new C C bonds:

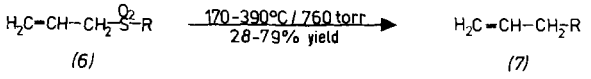


III *IV*

Studies on the thermal stability of acyclic dialkyl sulfones showed that the decomposition temperature increases in the sequence *tert-* < *sec-* < *prim*-alkyl[8,9]. Aryl alkyl sulfones are more stable than dialkyl sulfones; diaryl sulfones as a rule only decompose above 800 °C[10], though at lower temperatures in the presence of Al_2O_3/SiO_2 catalysts[10]. It is assumed that the basicity of the sulfones is sufficient to coordinate them in the transition state on the catalyst.

An ionic mechanism has also been suggested for the pyrolysis of *o*-alkyl-substituted diaryl sulfones such as *(1)*[11]: no recombination to biphenyl derivatives in accordance with the pattern *III*→*IV* is observed; but diphenylmethanes such as *(5)* are formed. A thermally generated carbanion could substitute the SO_2-group nucleophilically in a five-membered ring as an intermediate stage *(3)*.

(1) *(2)* *(3)*



(4) *(5)*

A radical mechanism is assumed for the elimination of SO_2 from diaryl sulfones without an *o*-methyl group[11].

Allyl and benzyl sulfones decompose at substantially lower temperatures than the purely aromatic sulfones: thus, allyl sulfones are pyrolyzed at 150—400 °C with rearrangement and loss of SO_2[13,14], any CN-, keto-, halogen and ester groups remaining unchanged. A systematic connection between the pyrolysis temperature and the structure of the sulfone was established here for the first time. The pyrolysis temperatures have been optimized for sulfones of the type *(6)* (R = *n*-alkyl, *tert*-alkyl, phenyl, benzyl).

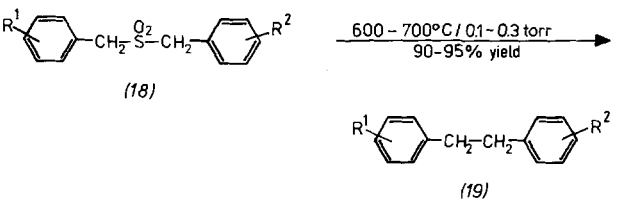
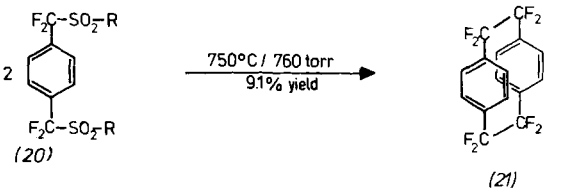
(6) (7)

The likewise unsymmetrically substituted benzyl isopropyl sulfone *(8)* has been pyrolyzed at 384 °C with the formation of isobutylbenzene, bibenzyl, toluene, and propene.



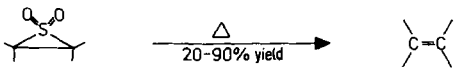
(8) (9) (10) (11) (12)

The mechanism of these pyrolysis reactions has also been assumed to be temperature-dependent. At lower temperatures[14] a cyclic transition state of the type *(14)* should appear; at higher temperatures radicals [*(16)* and *(17)*] seem to be involved.



(13) (14) (15) (13) (16) (17)

In 1903 *Fromm et al.*[16] did not obtain bibenzyl but stilbene and toluene[17] in the pyrolysis of dibenzyl sulfone at 290 °C[15]. *Leonard*[18] was able to pyrolyze dibenzyl sulfones of the type *(18)* for the first time in preparative amounts practically exclusively to bibenzyls. He assumed that at higher temperatures benzyl radicals are formed, which by means of H-abstraction give rise to toluene and stilbene. This secondary reaction can be circumvented by the use of low pressure (0.1—0.3 torr)[18] and by arranging a short residence time in the zone of pyrolysis (cf. Section 5.3.3).

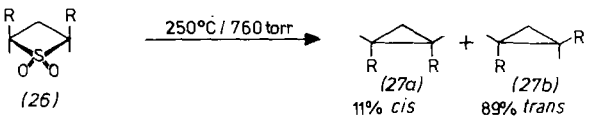


(18) (19)

The acyclic bis-sulfone *(20)*, R = C_2H_5, C_3H_7, or C_4H_9, forms the octafluorinated [2.2]paracyclophane *(21)*, with cleavage of SO_2[19]. The synthesis of strained hydrocarbon rings from acyclic bis-sulfones is so far restricted to this single example.

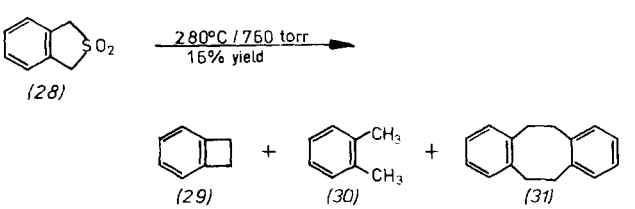
(20) (21)

The thermolysis of cyclic sulfones can lead to ring contraction, ring expansion, and fragmentation of the ring system, besides extrusion of SO_2: thiirane 1,1-dioxides *(22)*[20] are as a rule already split into alkenes and SO_2 at room temperature, with the result that their isolation often presents problems. Starting from pure *cis*- or *trans*-thiirane 1,1-dioxides *Z*- and *E*-alkenes are obtained; the thermodynamically more stable *E*-alkene is usually in excess[20].



(22) (23)

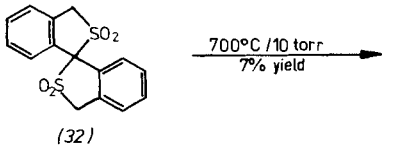
Thiirene 1,1-dioxides *(24)*[20] are more stable than the saturated three-ring sulfones. On pyrolysis they give alkynes with the elimination of SO_2.



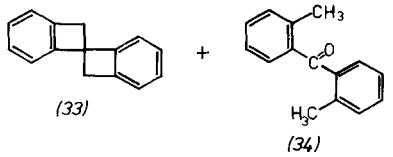
(24) (25)

Thietane 1,1-dioxide *(26)*[21] also loses SO_2 thermally, the stereochemistry of the four-ring sulfone again exerting no pronounced influence on the configuration of the resulting cyclopropane.

(26) (27a) (27b)

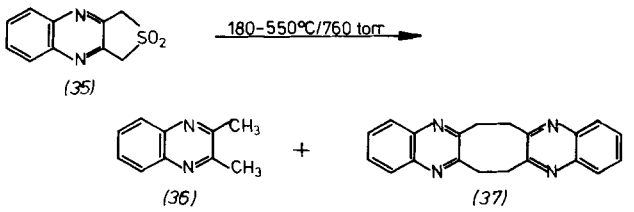


Pyrolysis of benzylic five-membered ring sulfones has been studied in detail by *Cava et al.*[22-26], who in 1959 used an apparatus[22] in which it was possible to decompose the sulfones under vacuum[27]. In the attempts to synthesize dihydrocyclobutabenzene *(29)*[22] and dihydrocyclobutanaphthalene[23] different products were obtained, depending on the reaction conditions[22]. Pyrolysis of *(28)* at 280 °C in the melt gave a liquid with an overall yield of 16%, containing 80% of *(29)* and 20% of *o*-xylene *(30)*. The dimer *(31)* could also be isolated (4%) from the polymeric residue (84%). If *(28)* is pyrolyzed in diethyl phthalate solution at 300 °C, *(31)* is produced in 48% yield. The best yields (59–63%) of dihydrocyclobutabenzene *(29)* were obtained by thermolysis at 460–670 °C/2 torr in the gas phase (cf. Section 5.3.2)[28,29].



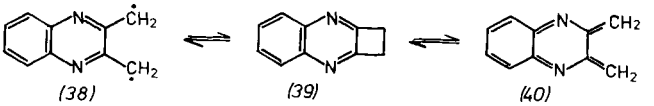
(28) (29) (30) (31)

This example shows the influence of apparatus factors and the pyrolysis conditions on the nature and yield of the products.

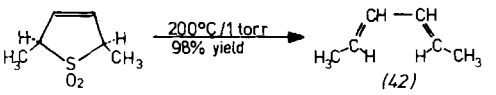


Sulfone pyrolysis has also proved successful as a general synthesis method in the production of the spiro-compound *(33)* by pyrolysis of the bis-sulfone *(32)*[25].

(32)

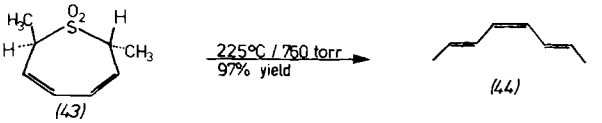


(33) *(34)*



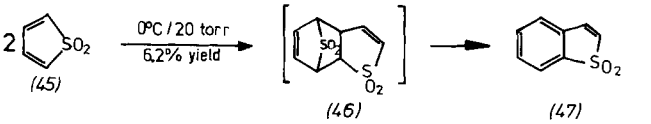
(35) *(36)* *(37)*

Moriconi et al.[30] investigated the thermal behavior of five-ring sulfones of the type *(35)* with an annelated quinoxaline system. *Inter alia* two SO_2-free compounds *(36)* (14%) and *(37)* (27%) containing the quinoxaline system were formed during the pyrolysis. The yield ratios were again strongly dependent on the pyrolysis temperature and on the solvent. A diradical *(38)* or a 1,3-diene *(40)* formed by concerted ring opening are possible intermediate stages, in equilibrium with the cyclobutane derivative *(39)*.



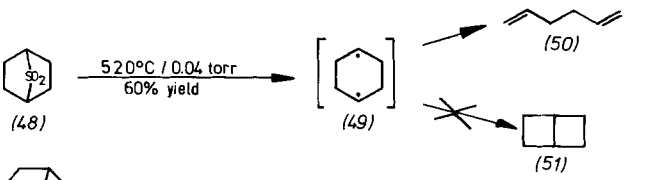
(38) *(39)* *(40)*

The elimination of SO_2 is a stereochemically uniform process in five-ring sulfones without an annelated aromatic system. The retro-Diels-Alder reaction[31,32] of 2,5-dimethyl-2,5-dihydrothiophene 1,1-dioxide *(41)* affords (*E,E*)-2,4-hexadiene *(42)*[33,34] in 98% yield.



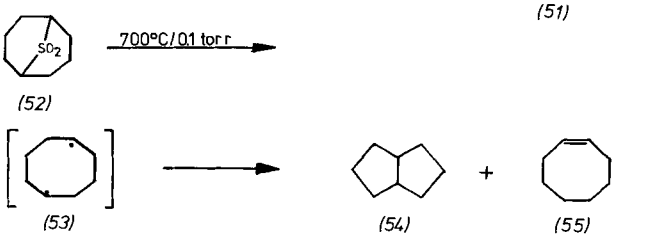
(41) *(42)*

The ring of 2,7-dimethyl-2,7-dihydrothiepine 1,1-dioxide *(43)* opens in the same way with elimination of SO_2 and with 97% stereospecifity[35].



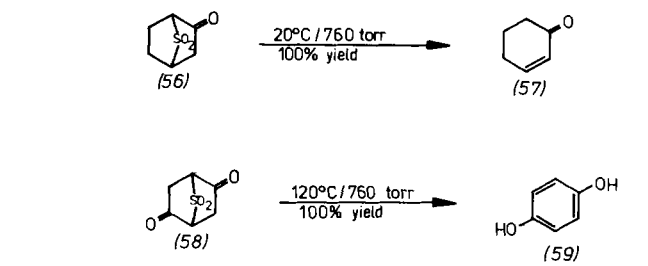
(43) *(44)*

Strained bicyclic five-ring sulfones are said to occur during the Diels-Alder dimerization of two thiophene 1,1-dioxide molecules *(45)*[36,37] conducted under very mild conditions with subsequent elimination of one SO_2 molecule.

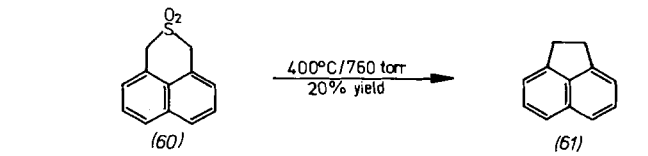


(45) *(46)* *(47)*

However, the thermal extrusion of SO_2 from the bicyclic sulfone *(48)*[38] requires a substantially higher temperature. The diradical *(49)* has been postulated as an intermediate stage. No recombination to the strongly strained bicyclo[2.2.0]hexane *(51)* has been observed.



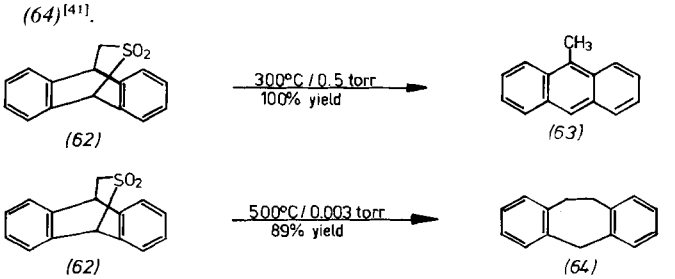
(48) *(49)* *(50)* *(51)*



(52) *(53)* *(54)* *(55)*

Still higher temperatures are necessary for the pyrolysis of 9-thia-bicyclo[3.3.1]nonane 9,9-dioxide *(52)*[38]. At 700 °C/0.1 torr, 40—50% of bicyclo[3.3.0]octane *(54)* and 10% of cyclooctene *(55)* are formed.

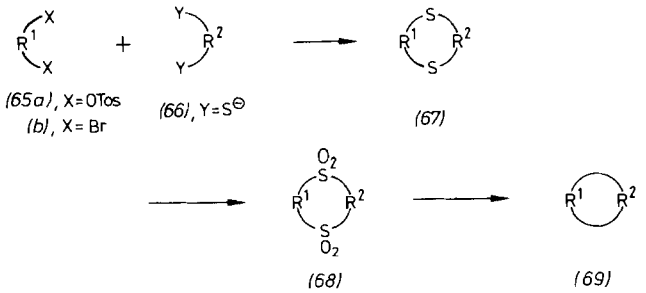
At 20 and 120 °C the bicyclic oxo-sulfones *(56)* and *(58)* lose SO_2 with formation of 2-cyclohexenone *(57)* and hydroquinone *(59)*, respectively. It is assumed that the SO_2 elimination proceeds *via* the enol form: a concerted mechanism appears possible[39]. The six-ring sulfone *(60)* fragments to acenaphthene *(61)*[40] with ring contraction and loss of SO_2.



(56) *(57)* *(58)* *(59)*

(60) *(61)*

In contrast to this, the strongly pressure- and temperature-dependent SO_2 elimination from the bicyclic sulfone *(62)* can proceed with rearrangement to *(63)* and ring expansion to *(64)*[41].



(62) *(63)* *(62)* *(64)*

3. Pyrolysis of Medium- and Multi-Membered Cyclic Sulfones

3.1. Principle of the Method, Special Features

In recent years interest has focussed on the pyrolysis of sulfones that, unlike the three- to seven-membered rings, lead to new medium-membered and multi-membered hydrocarbon cycles[42-45]. The known methods of synthesis were too awkward for such mixed aromatic/aliphatic mediocycles[46] or they required difficultly accessible starting substances.

The preparative pyrolysis of medium-membered and multi-membered cyclic mono- and oligosulfones discovered in 1969[17,42,47] opened up a novel, simple, and general entry to the cyclophane hydrocarbons. Sulfone pyrolyses in multi-membered systems are to be regarded as steps in ring-synthesis reactions in which, starting from acyclic educts *(65)* and *(66)*, the cyclic oligosulfide stage *(67)* is passed through as an intermediate; after its oxidation to the oligosulfone *(68)*, the desired multi-membered hydrocarbon *(69)* is obtained by pyrolysis.

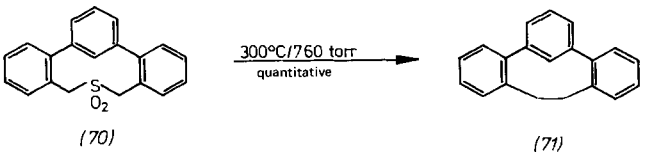
(65a), X=OTos
(b), X=Br

(66), $Y=S^{\ominus}$

(67)

(68)

(69)

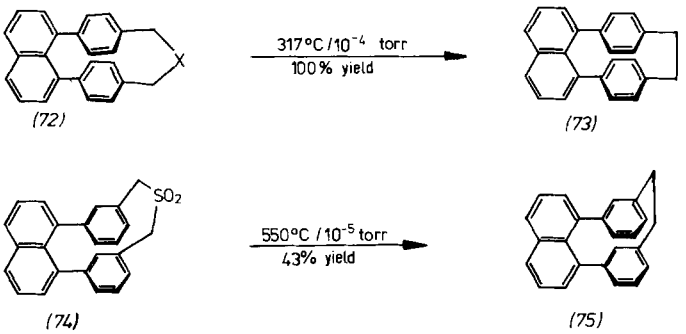


The sulfone pyrolysis is here the final step in a reaction sequence that also includes the important ring closure to the cyclic sulfide. Syntheses of this kind, with the use of sulfone pyrolysis, have given rise to many new ring systems enabling, *inter alia*, the investigation of steric[48] and electronic interactions[49,50].

3.2. Double Benzyl Sulfones

The pyrolysis of mediocyclic and macrocyclic sulfones opens a direct route to substituted, unsymmetrical, angularly-strained hydrocarbon rings. At first the method was restricted to sulfones with a bilaterally benzyl-bonded sulfur atom.

3.2.1. Monosulfones



Thermal desulfurization by sulfone pyrolysis was first performed on the ten-membered *m*-terphenyl ring system *(70)*[51] in diphenyl ether as solvent or in the melt at 300 °C (see Sections 5.1 and 5.2). The unexpected quantitative yield of the sterically strained nine-membered ring *(71)* stimulated further studies on pyrolysis in other ring systems.

(70)

(71)

The bridging of naphthalene in the 1,8-position by a 1,2-diphenylethane unit to give the likewise strained compound *(73)* was first achieved at a much later date by pyrolysis of the monosulfone *(72a)*, X=SO_2[52]. The reaction can also be carried out with the bis-sulfone *(72b)*, X=$O_2S(CH_2)_2SO_2$[97] (see Section 5.3.6).

(72)

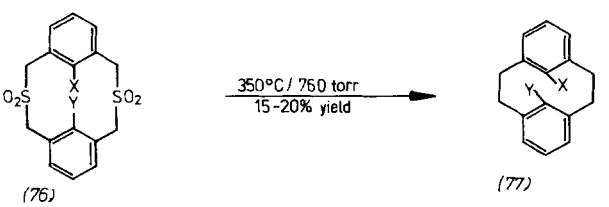
(73)

(74)

(75)

The ethano-bracket can also be fixed to other positions[53].

3.2.2. Bis-Sulfones



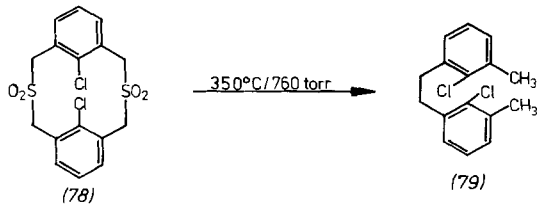
Many hydrocarbons with medium-membered to multi-membered rings can be synthesized by the pyrolysis of the appropriate bis-sulfones [cf. *(68)*→*(69)*]. Bis-sulfones *(68)* are obtained from bis-sulfides which can be prepared by cyclizing dibromides or ditosylates with dithiolates under dilution-principle conditions. Aromatic/aliphatic bis-sulfones with two SO_2-groups in the same monocycle were apparently unknown before 1965. Since then a large number of bis-sulfones have been described, whose pyrolysis products have been classified in this review according to ring structure.

[2.2]Phanes: According to the first experiments in 1969 with the ten-membered *m*-terphenyl system [*(70)*→*(71)*], the [2.2]metacyclophanes *(77)*[117] could be synthesized from the bis-sulfones *(76)* by extrusion of two SO_2 molecules.

Not only [2.2]metacyclophane *(77a)* itself, but also derivatives such as *(77b)*—*(77d)*, additionally sterically strained by intraannular substituents, can be obtained under very simple pyrolysis conditions[42]. The yields of the products are surprisingly high, particularly in comparison with the yields of the organometallic syntheses[46].

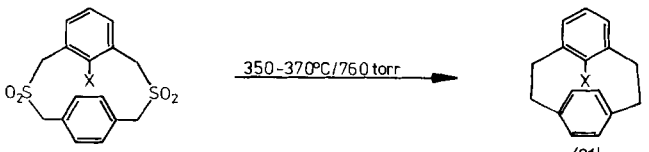
The rapid and simple preparation of such variously substituted [2.2]metacyclophanes made possible detailed studies into the steric interactions[54] of atoms not directly bound to one another[48,55].

With only simple apparatus, the pyrolysis of *(78)* leads to *(79)* with opening of the ring[42]; it is assumed that if the pyrolysis technique is improved (see Section 5), it will be possible to obtain the desired dichloro[2.2]metacyclophane.



(76)

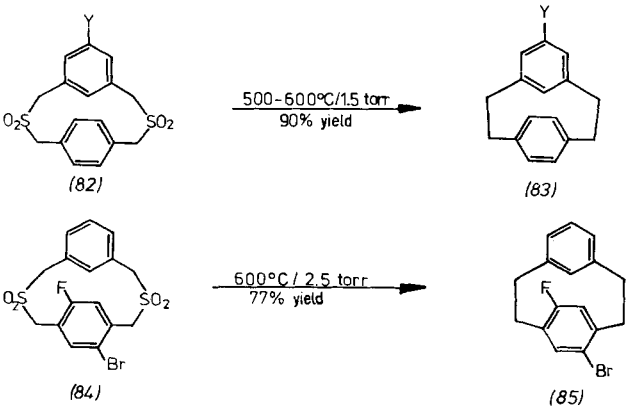
(77)



(a), X=H, Y=H; (b), X=H, Y=F;
(c), X=F, Y=F; (d), X=H, Y=Cl

The observation that no crossover products are formed from *(76b)* and *(76d)* indicates a strictly intramolecular course of the C C bonding[42]. The sulfone-pyrolysis step is thus suitable for the directed syntheses of unsymmetrical polynuclear phanes. A mono-sulfone with a C C bond already coupled on one side could be detected mass-spectrometrically as early as this stage[47].

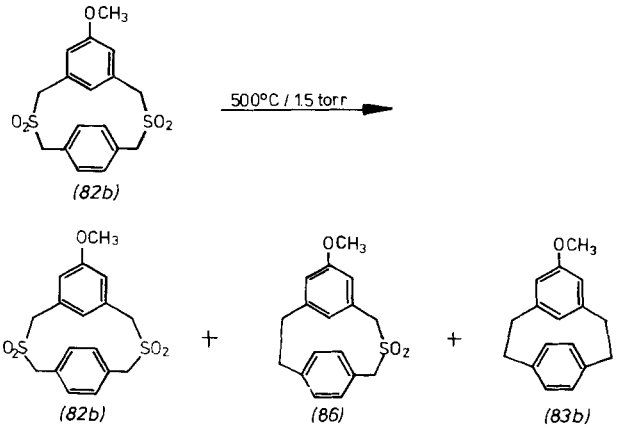
(78) *(79)*



[2.2]Metacyclophane *(77a)* was later obtained in the same way in a higher yield (64%)[56]. This may be ascribed to the improved pyrolysis conditions (cf. Section 5). In 1969 the [2.2]metaparacyclophane *(81a)* previously prepared in other ways[57,58] was produced from the sulfone *(80a)* by thermal elimination of SO_2 in a simple pyrolysis apparatus[17] (see Section 5.3.1). The advantage of this ring-contraction method over conventional synthesis methods lies in the fact that preparative (gram) quantities of [2.2]metaparacyclophane *(81a)* can be obtained quickly and comparatively easily from readily available starting substances. When larger amounts of *(81a)* became available, the temperature-dependence of the ^{1}H-NMR-spectrum was observed and the mechanism of the conformational changes was hence derived[17,59,60].

(80) *(81)*

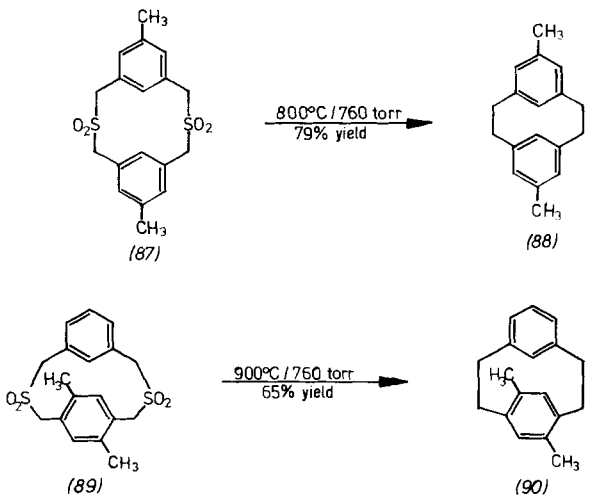
(a), X = H; (b), X = F; (c), X = CH_3



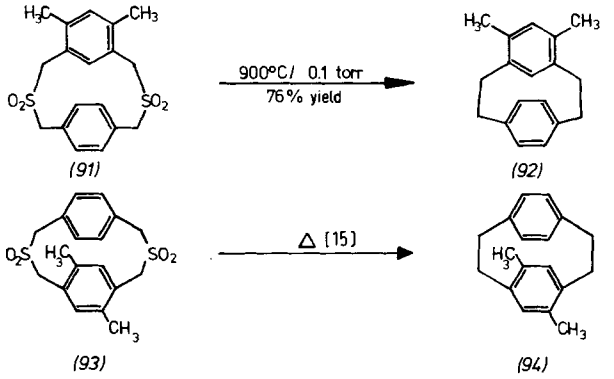
The advantage of the sulfone pyrolysis method was clearly demonstrated in attempts at the synthesis of the intraannularly methyl-substituted phane *(81c)*[61]: all earlier attempts had been unsuccessful or had given unsatisfactory yields, whereas the thermal decomposition of *(80c)* at 500 °C[15] afforded *(81c)* in a yield of 90%; large quantities are thus accessible. Further substituted [2.2]metaparacyclophanes, interesting because of the steric interactions within the eleven-membered ring[48], were synthesized by an analogous method[62].

(82) *(83)* *(84)* *(85)*

(a), Y = F; (b), Y = OCH_3; (c), Y = NO_2; (d), Y = Br



The general applicability of the sulfone pyrolysis method is clearly demonstrated by the conversions of *(82)* into *(83)* and of *(84)* into *(85)*: as a rule good yields with a high selectivity are obtained (without crossover products), even in the presence of various substituents and functional groups that interfere in other methods of synthesis (*e.g.* halogens and esters in reactions with organometallic compounds), provided that a suitable temperature and pressure have been selected.

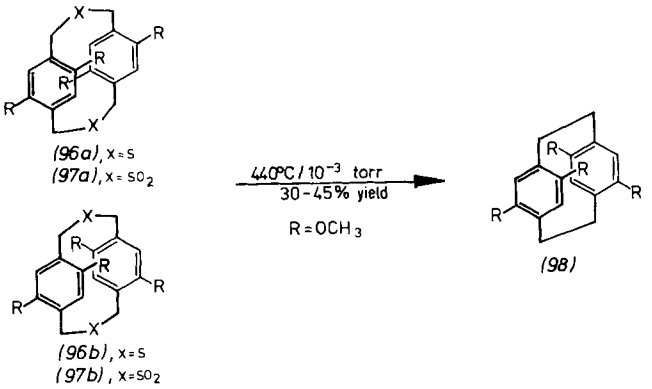


(82b) *(82b)* *(86)* *(83b)*

The ratio of the pyrolysis products of *(82b)* is clearly temperature-dependent[58]: pyrolysis at 600 °C/1.5 torr leads exclusively to *(83b)*, while at 500 °C in addition to considerable quantities of the initial sulfone *(82b)* and the desired phane *(83b)* traces of the cyclic monosulfone *(86)* are also detectable. From this it is concluded[62] that the loss of one SO_2 molecule from the monosulfone *(86)* to *(83b)* occurs more rapidly than the loss of the two SO_2 molecules from the bis-sulfone *(82b)*. The authors interpret this as a consequence of the higher strain energy of the monosulfone *(86)* in comparison with that of the bis-sulfone *(82b)*. An alternative plausible explanation is the formation of the already previously claimed diradicals[2] (see Section 2), whose C C recombination to the monosulfone is so strongly exothermic that the latter ends up in a state of high oscillation, resulting in spontaneous deactivation with loss of the second SO_2 group.

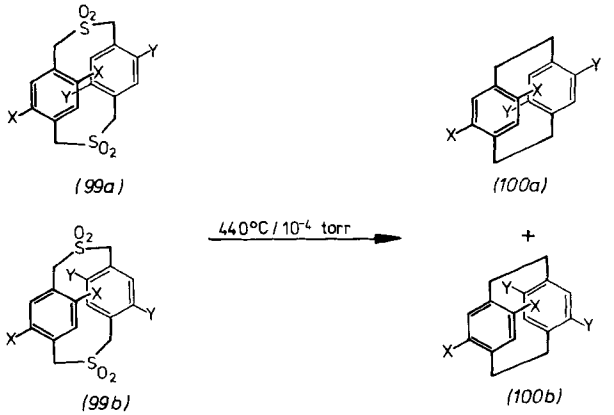
The synthesis of multilayered phanes[45,63-65] requires preparative quantities of methyl-substituted [2.2]phanes. Sulfone pyrolysis often proves to be the best method.

(87) *(88)* *(89)* *(90)*



(91) (92) (93) (94)

In the study of intramolecular charge-transfer interactions in [2.2]phanes the pyrolysis of sulfones was often an essential step *en route* to the intramolecularly bracketed quinhydrones such as *(95a)* and *(95b)*[49, 65, 67]:

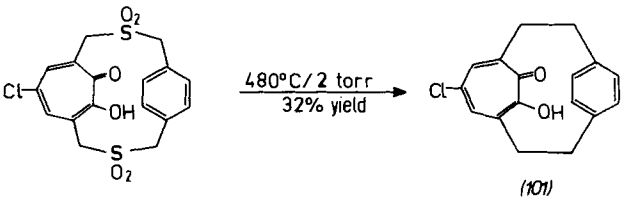


(95a) (95b)

Starting from the methoxy-protected dithia-compounds *(96a, b)*, the synthesis of the quinhydrone precursors *(98)* was possible in two ways: by photolysis of *(96a, b)* and by pyrolysis of the sulfones *(97a, b)*. Photolysis[68] proved to be the more suitable method. An important resolving factor for the mechanism of the pyrolysis is the observation that always only the (chiral) phane *(98)* is produced, irrespective of whether pure *(97a)* or *(97b)* or a mixture of these two sulfones is used as the starting substance[67].

(96a), X = S
(97a), X = SO2
(96b), X = S
(97b), X = SO2
(98)

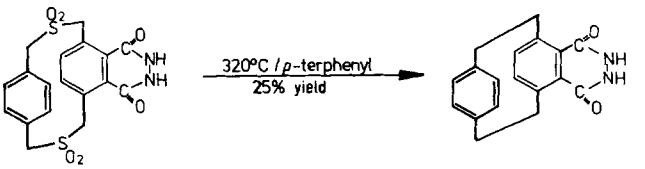
The pyrolysis of *(99a, b)* gives other results[49a]: a mixture of *(100a, b)* is isolated, regardless of whether *(99a)* or *(99b)* or



(99a) (100a) (99b) (100b)

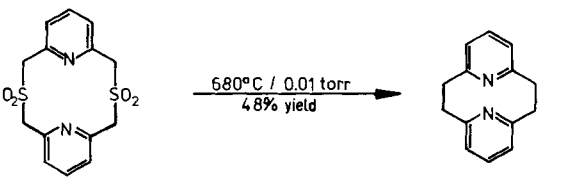
X = NO2, Y = OCH3

their mixture is pyrolyzed. The yields of *(100a)* and *(100b)* are respectively 1–2 and 4.5—9%.



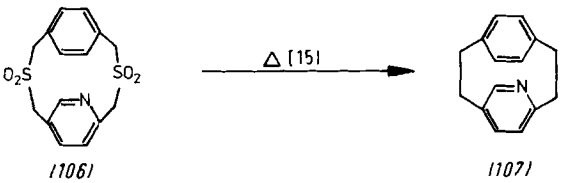
The results obtained in the synthesis of *(98)* and *(100)* have certain consequences for the mechanism of the sulfone pyrolysis (see Section 4).

In a similar connection — investigation of intramolecular charge-transfer interactions — non-benzoid [2.2]phanes[69] such as the tropolone derivative *(101)* were also synthesized by sulfone pyrolysis.



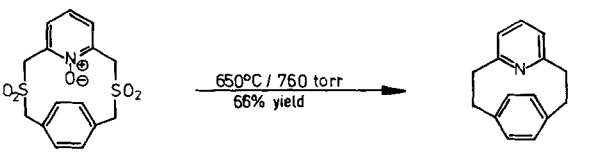
(101)

The phane *(103)* was prepared in a 12-fold amount of *p*-terphenyl as high-boiling solvent[70, 71] (see Section 5.1). In the absence of the terphenyl only a complex product mixture was obtained. This is explained by a matrix-like close-ordering effect of the *p*-terphenyl (b.p. = 383 °C).



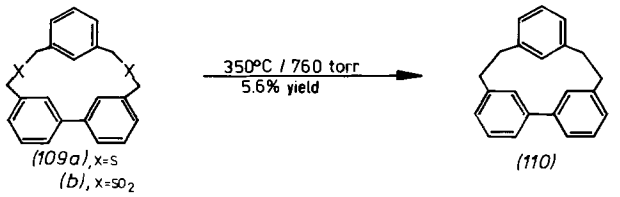
(102) (103)

Pyrolyses of pyridinophanes sometimes yielded poorer results. The bis-sulfone *(104)* can be converted, with ring contraction, into [2.2](2,6)pyridinophane *(105)*[72] under the conditions used for open-chain dibenzyl sulfones by *Leonard*[18].



(104) (105)

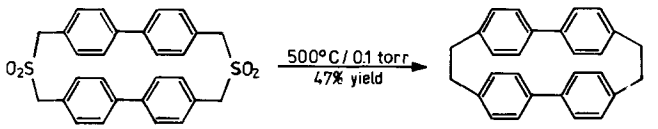
(106) (107)



Difficulties were encountered in the preparative scale application of the Curie-point pyrolysis of pyridinophane *(106)* to *(107)*, which was detected by GC/MS coupling[73].

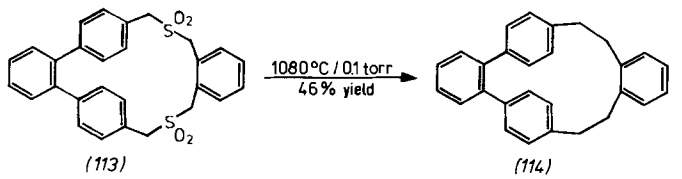
(108)

Pyridine *N*-oxides such as *(108)* not only lose two SO_2 molecules during pyrolysis but also the oxygen atom on the nitrogen[74].



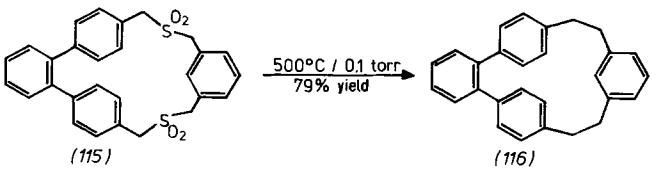
[2.2.n...]- and [2.n...]phanes; pyrolysis of multi-membered cyclic sulfones with more than two (non-annelated) aromatic rings: In addition to the bridging of two aromatic (non-annelated) rings, sulfone pyrolysis has also been used for synthesizing bi-, ter-, quater-, and quinquephenylophanes. The dimethylbiphenyl bridged with 1,3-benzene-bis(methanethiol) *(109a)*[47] could be oxidized to the bis-sulfone *(109b)*, which was pyrolyzed at 350 °C. The only product of this reaction was the strained hydrocarbon *(110)*, even though the (symmetrical) crossover products would be less strongly strained. Therefore, here too it is hardly likely that a synchronous elimination of two SO_2 molecules with the formation of two

(109a), X=S
(b), X=SO_2
(110)

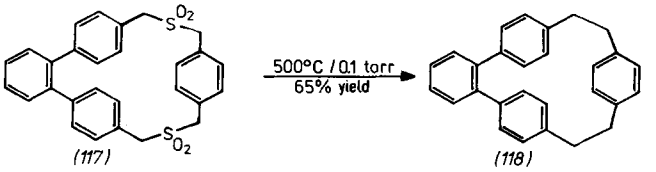


diradicals had taken place. The yield would probably be higher under the experimental conditions used nowadays[43].

[2.2](4,4')biphenylophane *(112)* was synthesized[43] by pyrolysis of the bis-sulfone *(111)*.

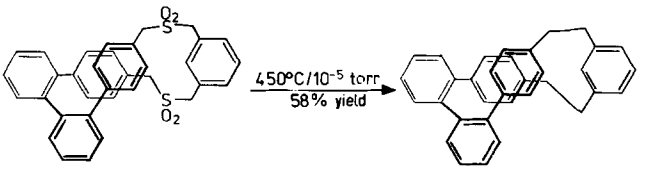


(111) *(112)*

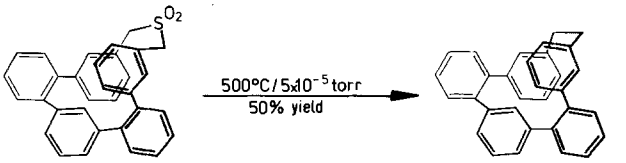


In 1975 it became possible for the first time to carry out the directed pyrolysis of multi-membered sulfones such as *(113)* containing *o*-xylylene-units. At very high temperatures (around 1000 °C) the darkening and carbonization of *(113)* frequently observed under other conditions is suppressed in favor of hydrocarbon formation[75]. The corresponding sulfones with *m*- and *p*-xylylene groups can be pyrolyzed at the usual temperatures.

(113) *(114)*

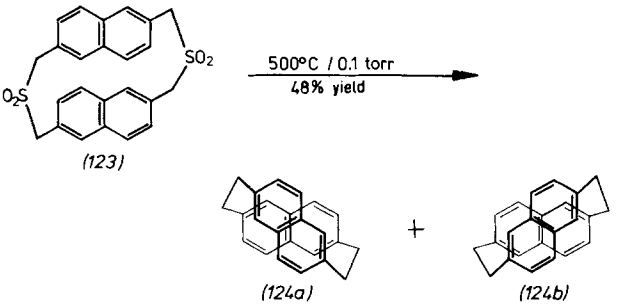


(115) *(116)*

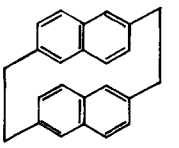


(117) *(118)*

Pyrolysis of the double benzylic quaterphenyl system *(119)* proceeds analogously[76], as does also the pyrolysis of the quinquephenyl system *(121)*[77].



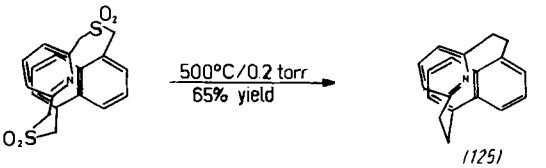
(119) *(120)*



(121) *(122)*

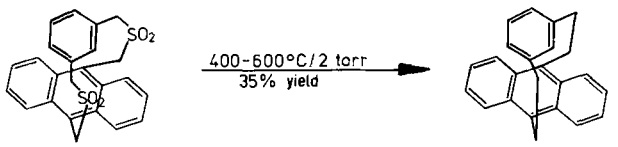
Pyrolysis of multi-membered cyclic sulfones with annelated aromatic rings: Sulfone pyrolysis has proved invaluable in the field of bridged annelated aromatic hydrocarbons. Thus, after other attempts at its synthesis had failed, [2.2]naphthalenophane *(124)*[43,44] was made accessible by sulfone pyrolysis. Of the two possible isomers only the (chiral) product *(124a, b)* [cf. *(97a, b)→(98)*] is formed. This is evidently due

(123) *(124a)* *(124b)*



to the fact that the strain energy of the chiral *(124a, b)* is lower than that of the symmetric (achiral) product. In *(124a, b)* the $-(CH_2)_2-$ bridges are oriented at an angle to the plane of the naphthalene rings:

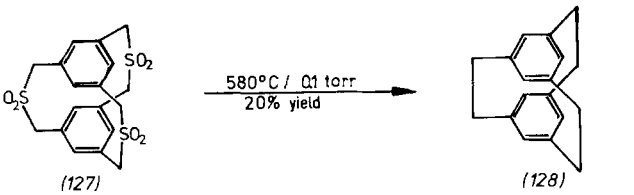
(124)



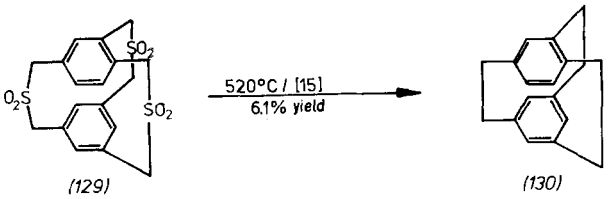
For the mechanism of the pyrolysis it must be assumed that at least on one side of the bis-sulfone a diradical with such long lifetime arises that rapid rotation of the naphthalene system is possible, whereby the preferred chiral phane is formed.

For the investigation of *n*-π interactions[78] (amine-aromatic exciplexes) the naphthalene system was bridged at the 1,5 position with a pyridine ring at the 2,6 position. Pyrolysis of this bis-sulfone gave the desired phane *(125)* in 65% yield.

(125)

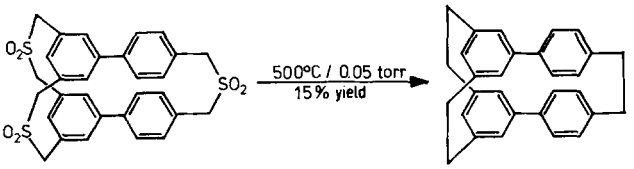


More highly condensed phane systems, *e.g.* anthracenophanes[74,79] and phenanthrenophanes[43a], have likewise been synthesized by pyrolysis.



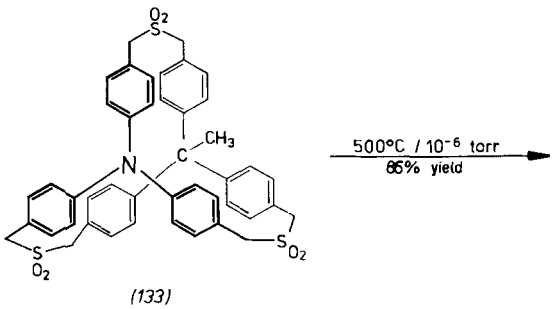
(126)

3.2.3. Tris-Sulfones



The most important triply-bridged benzenophanes have been synthesized by the pyrolysis of tris-sulfones. Thus, [2.2.2](1,3,5)benzenophane *(128)*[81] could be obtained from the tris-sulfone *(127)*[80]. The constitutionally isomeric cyclophane *(130)* was later synthesized in the same way[82]. The triply-bridged [2.2.2]biphenylophane *(132)*[83] has also been produced by pyrolysis of the corresponding tris-sulfone.

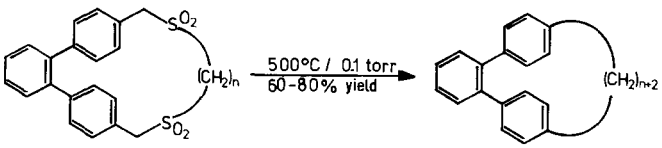
(127) *(128)*



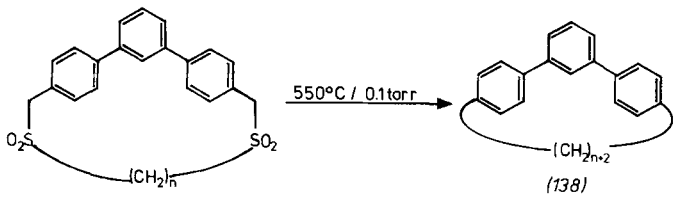
(129) *(130)*

(131) *(132)*

The tris-sulfone *(133)*[84], composed of one triphenylamine unit and one triphenylmethane unit, forms on pyrolysis the triply-bracketed propeller molecule *(134)*[85].



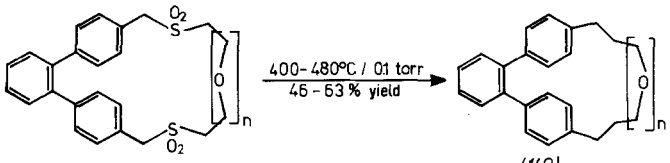
(133) *(134)*



3.3. Unilateral Benzyl Sulfones

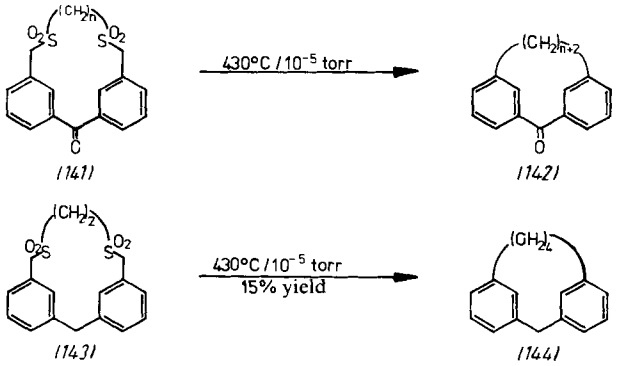
Whereas until a few years ago it had been assumed that a benzyl group is necessary on both sides of the SO_2-group in cyclic sulfones for the thermal elimination of SO_2 with C C-recombination, recently it was shown that the benzyl group is dispensable at least on one side, and that such "unilateral non-benzylic sulfones" split off SO_2 thermally in equally good yields with C C bond formation[75]. Pyrolysis of such sulfones allows the synthesis of hydrocarbon cycles bridged by longer chains.

Sulfone pyrolyses of this type were first tested on the terphenyl system; in *(136a-h)* n is 2 to 9, in *(138)* it is 10 or 11 (yields 67 and 77%)[75].



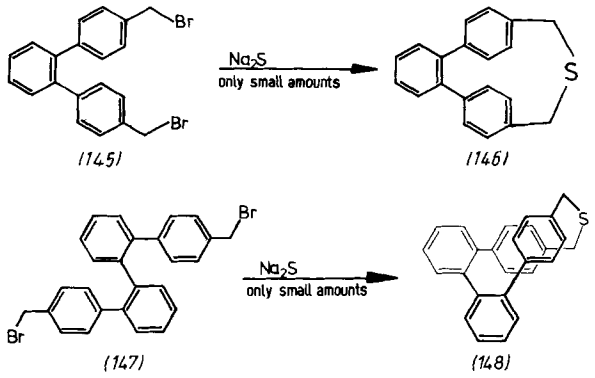
(135a-h) *(136a-h)*

(137) *(138)*



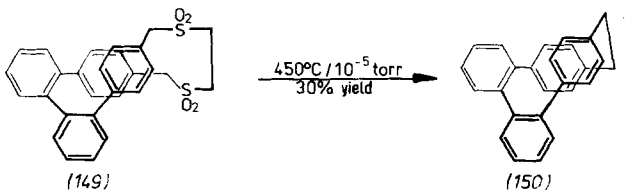
Oligoether structures in the aliphatic chain[75] remain unchanged in the course of thermolysis; this makes possible the

(139) *(140)*



syntheses of new lipophilic/polarophilic neutral ligands such as *(140)*, $n = 1$ to 3.

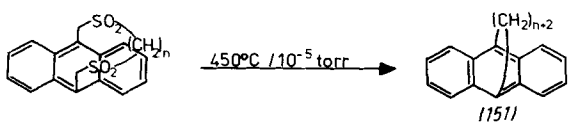
The bridged benzophenone and diphenylmethane systems[86b] *(142)* $n = 2$ and 3 (yields 7 and 47%) and *(144)*, necessary for studies on the conformative mobility of two-bladed molecular propellers, are also obtained by the pyrolysis of unilaterally benzyl-activated sulfones[86a].



(141) (142) (143) (144)

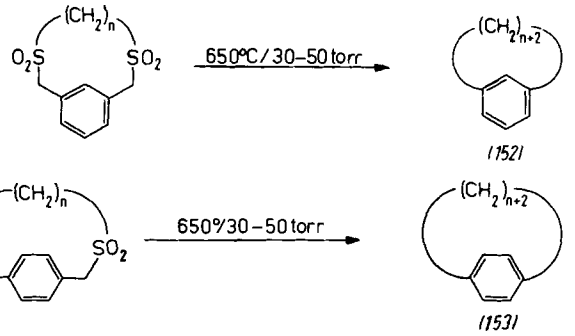
The cyclization of benzyl halides with Na_2S (or thioacetamide[87]) to monothiaphanes is often impossible, or only possible in unsatisfactory yield, if highly strained ring systems such as *(146)* and *(148)* are to be formed.

(145) (146) (147) (148)



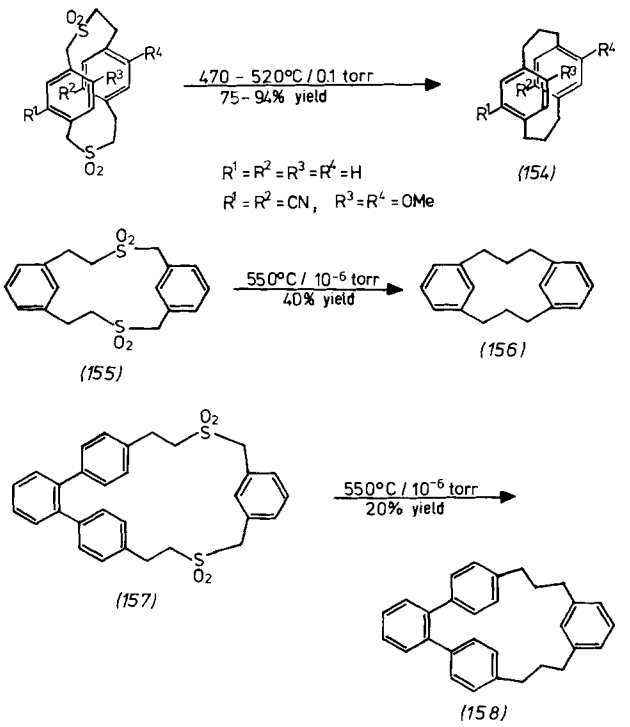
Cyclizations with short-chain alkanedithiols to dithiaphanes often provide the answer. By means of bridging *(147)* with 1,2-ethanedithiol and oxidation the unilateral benzyl bis-sulfone *(149)* is formed; on pyrolysis this gave, after elimination of two SO_2 molecules *and* the C_2H_4 unit, the quaterphenylophane *(150)*[76], which would also be expected in the pyrolysis of the—so far unknown—double benzyl monosulfone.

(149) (150)



Elimination of the C_2H_4 unit has also been observed in other ethano-bridged bis-sulfones of this type[53a,77,88].

Longer alkane bridges, however, were neither cleaved from anthracene-bis-sulfone[79,89] nor from the benzene-bis-sulfones[90]; the products were formed in high yields [*(151)*,

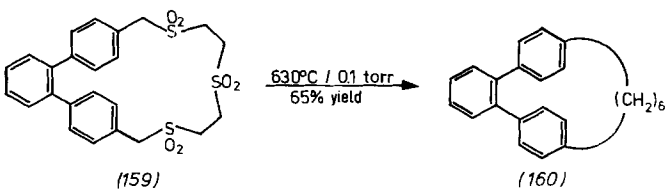


(151)

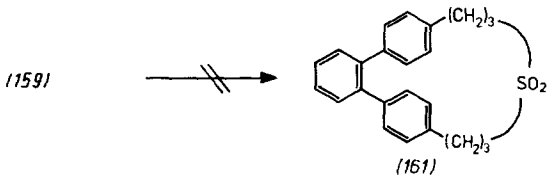
$n = 8$ and 12 (52 and 10%); *(152)*, $n = 7$ and 10 (53 and 56%); *(153)*, $n = 8$, 9, 10, 11, 12, or 14 (55, 65, 66, 67, 56, and 48%)]. The pyrolysis of unilateral benzyl sulfones was used at prac-

(152) (153)

tically the same time around 1977 by four teams for the synthesis of [3.3]phanes such as *(154)*, *(156)*, and *(158)*[90-94].



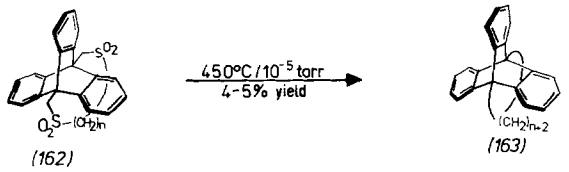
(154) (155) (156) (157) (158)



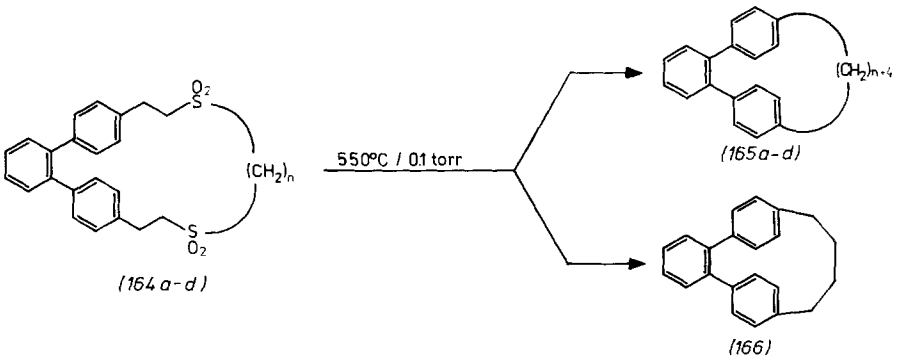
This type of sulfone pyrolysis was also used for the synthesis of multi-layered phanes[95]; the yields were occasionally very high[96].

3.4. Bilateral Non-Benzyl Sulfones

After the pyrolysis of the unilaterally benzylic sulfones had been achieved, the question arose whether bilaterally non-benzylic multimembered sulfones could also be pyrolyzed with the formation of C C bonds. Two observations, made in another context, provided the impetus for systematic studies[75,79]. The surprisingly smooth pyrolysis of the trissulfone *(159)*[75] which contains two unilaterally benzylic SO_2-groups and one bilaterally non-benzylic SO_2-group, with the loss of all three SO_2-groups and recombination of all C-fragments to give the hydrocarbon *(160)* [≡ *(136c)*], was at first regarded as a special case.



(159) (160)



(159) (161)

In spite of the apparently unfavorable steric relationships, the double non-benzyl sulfone pyrolysis of triptycene *(162)* was also successful, with the formation of *(163)*, $n=8$ and 12[79].

(162) (163)

Systematic investigations of the pyrolysis of bilateral non-benzyl sulfones were undertaken on the *o*-terphenyl skeleton[88], which proved to be a highly suitable model system for pyrolysis studies.

(164a-d) (165a-d) (166)

Educt	Products (Yield [%])			
(164a), n = 2	*(165a)* [a]	5	*(166)* [d]	15
(164b), n = 3	*(165b)* [b]	10	*(166)*	7
(164c), n = 6	*(165c)* [c]	15	*(166)*	5
(164d), n = 10	*(165d)*	10	*(166)*	5

[a] *(165a)* ≡ *(160)* ≡ *(136c)*. [b] *(165b)* ≡ *(136d)*. [c] *(165c)* ≡ *(136g)*. [d] *(166)* ≡ *(136a)*.

Cleavage of the alkane chain was also observed in some pyrolyses[53,76,77]. In every case a mixture of phanes with incorporated *(165)* and eliminated *(166)* alkane chains was formed. The ratio of the products depends, *inter alia*, on the lengths of the alkane chains. Further studies on the temperature dependence are still needed[97] (see Section 5.3.6[114]).

4. The Mechanism of Sulfone Pyrolysis

The mechanisms of thermal elimination of SO_2 are still far from completely understood. The most essential experimental findings are summarized in the following.

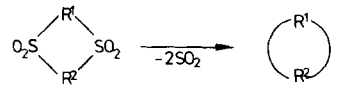
The majority of sulfone pyrolyses are regarded today as radical processes, though multicenter transition states and ionic intermediates have also been formulated[2,11,98,99]. A sharp delimitation of the mechanisms is difficult, since the outcome of the pyrolysis depends on the substrate structure, the pressure, the solvent, and in particular on the temperature.

4.1. Radical Mechanisms

4.1.1. Acyclic Sulfones

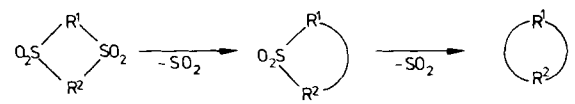
Radicals have long been assumed to be intermediates in pyrolysis reactions and numerous attempts have been made to detect them[14,18,98,99]. The thermal elimination of SO_2 from some acyclic *monosulfones* can be subdivided schematically into the following individual reactions:

$$R^1-SO_2-R^2 \rightarrow R^1-SO_2\cdot + R^2\cdot$$
$$R^1-SO_2\cdot \rightarrow R^1\cdot + SO_2$$
$$R^1\cdot + R^2\cdot \rightarrow R^1-R^2$$
$$2R^1\cdot \rightarrow R^1-R^1$$
$$2R^2\cdot \rightarrow R^2-R^2$$



Recombination of the C-radicals which are formed leads to a mixture of products, indicating the production of radicals[98].

4.1.2. Cyclic Monosulfones

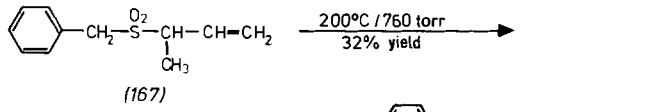


Although no radicals have yet been detected as reactive intermediates in the pyrolyses of cyclic monosulfones[42], it nevertheless seems likely that they do occur as intermediates at the temperatures used.

4.1.3. Cyclic Bis-Sulfones

Two radical mechanisms are conceivable in the thermolysis of cyclic bis-sulfones[43,44]: The two SO_2 molecules could be eliminated at approximately the same time in one step ("one-step mechanism")[43,44],

or the process could take place in two steps. After the first SO_2 molecule has been eliminated, the "diradical" could recombine before the other SO_2 group leaves the molecule ("two-step mechanism")[43,44].

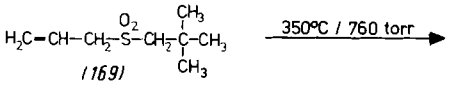


This intramolecular process was postulated as early as 1969 as an explanation for the absence of crossover products[17,42,47]. A good indication that some bis-sulfones eliminate SO_2 by this two-step mechanism is the fact that monosulfones are isolated, even if only in small quantities[47,62] [cf. Section 3.2.2, compound *(86)*].

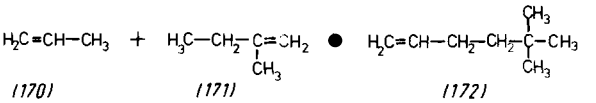
However, the two-step mechanism cannot account for all the experimental findings. For example, it cannot explain the elimination of alkane residues from unilaterally benzyl-activated bis-sulfones such as *(149)*[53a,76,77,88]. This observation is rather attributed to the one-step mechanism.

4.2. Reactions with Multicenter Transition States

4.2.1. Acyclic Monosulfones



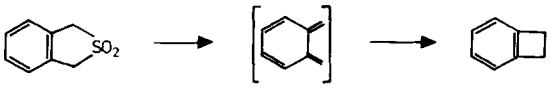
LaCombe and *Steward*[14] assumed that acyclic allyl sulfones eliminate SO_2 at temperatures above 150 °C in a multicenter reaction. This hypothesis is supported by two experimental findings: in the first place, benzyl-(1-methylallyl)sulfone *(167)* eliminates SO_2 with the formation of 32% of 5-phenylpentene *(168)*. No symmetric products have yet been detected that would indicate a radical mechanism. Secondly, the composition of the product mixture in the pyrolysis of



(167)

(168)

(169)



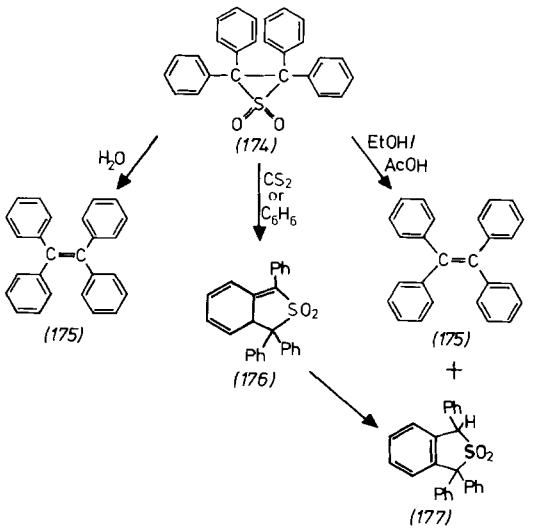
(170) *(171)* *(172)*

allyl neopentyl sulfones, *e.g.* the parent substance *(169)*, is temperature-dependent. At 350 °C, in addition to 5,5-dimethyl-1-hexene *(172)* larger amounts of propene *(170)* and 2-methyl-1-butene *(171)* are also produced. The formation of these substances, which can be interpreted as due to radicals, may possibly be suppressed by lowering the temperature.

4.2.2. Cyclic Sulfones

The thermal elimination of SO_2 from *cyclic monosulfones* such as *(41)* and *(43)* to give compounds with conjugated π-systems can be interpreted in terms of an electrocyclic ring opening. This type of sulfone pyrolysis is thus a special case of cheletropic reactions. In a concerted process the elimination of SO_2 follows the Woodward-Hoffmann rules[31,32]. The characteristic features—distinct stereospecific course of the reaction and mild conditions—suggest a mechanism of this kind.

The mechanism of the thermal elimination of SO_2 from *cyclic aromatic-aliphatic sulfones* is uncertain. As an example we may cite the synthesis of dihydrocyclobutabenzene *(29)* by *Cava*'s method[22] (cf. Section 2).



(28) *(173)* *(29)*

The intermediate *(173)* could be intercepted by a Diels-Alder reaction, but its existence gives no indication of the course of the actual cleavage of SO_2. It is quite possible that a radical mechanism and a reaction with a multicenter transition state are competing. Although the high pyrolysis temperature would suggest the formation of radicals, it could also be regarded as necessary to break up the aromatic system in a concerted mechanism.

4.3. Ionic Mechanisms

The pyrolysis of sulfones in which the SO_2-group is part of a three-membered ring can be interpreted as probably ionic, without the influence of bases or acids as catalysts[20,100]. Definite proof is difficult, because most of the thiirane 1,1-dioxides cannot be isolated but appear as intermediates in base-induced nucleophilic substitutions from α-halogenosulfones[20]. An SO_2 elimination starting from an isolated thiirane 1,1-dioxide was possible in the case of the tetraphenyl derivative *(174)*[100a].

Two types of reaction compete with each other in dependence on the solvent used: elimination of SO_2 to give the alkene and rearrangement without loss of SO_2. An ionic mechanism is suggested by the finding that in polar, ionizing solvents the formation of tetraphenylethene *(175)* takes precedence over rearrangement to *(177)*. In the same way, the pyrolyses of *o*-alkyl-substituted diaryl sulfones *(1)* to diphenylmethanes *(5)*[11] quoted in Section 2 can also be regarded as ionic. However, so far none of the necessary intermediates have been detected.

(174) *(175)* *(176)* *(175)* *(177)*

5. Experimental Description of Selected Sulfone Pyrolyses

In this section an account is given of some typical sulfone pyrolysis methods and apparatus. These methods and the apparatus used are suitable not only for the pyrolysis of these and other sulfones under similar conditions, but in principle also for the pyrolysis reactions such as the thermal elimination of CO_2[101,104], CO[101,105,107], and N_2[101,108].

5.1. Pyrolysis of Dissolved Sulfones

[2](2,2'')-m-terphenylophane (71)[51]: 2.6 g (8.10 mmol) of *(70)* was heated in 7 ml of diphenyl ether for 45 min to 290—

300 °C (oil bath temperature). The diphenyl ether was distilled off at 12 torr. The yield of the crystalline crude product (m.p. 148—150 °C) was quantitative. Recrystallization from ethanol gave practically colorless flakes (m.p. 153 °C), readily sublimable under vacuum.

[2.2]Paracyclophane-4,5-dicarboxylic acid dihydrazide (103)[71]: The sulfone *(102)* was mixed with a 12-fold amount of *p*-terphenyl and pyrolyzed at 325 °C. The *p*-terphenyl evidently exerts here a matrix-like short-range order effect, since the yield increases from a few percent of *(103)* in the absence of *p*-terphenyl to 25% in its presence.

5.2. Pyrolysis in the Melt

[2](2,2'')-m-terphenylophane (71)[51]: 1.0 mg (3×10^{-3} mmol) of *(70)* was heated in a melting-point tube to 290 °C, the substance melting and evolving gas. After about 5 min the melt was allowed to cool and crystallization was induced by rubbing with florists' wire at about 145 °C. The material was then reheated; it now melted at 150 °C, even on repetition of the melting point determination.

5.3. Pyrolysis Apparatus

5.3.1. Simple Apparatus

[2.2]Metaparacyclophane (81a)[17]: 1—3 g of *(80a)* was placed in a horizontally clamped modified bulb-tube and heated in an electrically heated aluminum block (Fig. 1) to a temperature of 350—370 °C, the pyrolysis products being distilled off and solidifying in the bulb. Re-crystallization from a mixture of chloroform and methanol followed by sublimation gave pure *(81a)*.

If we take into account the simplicity of the method and the strained ring system, the yield (18%) is astonishingly high. It may be possible to increase the yield with present-day apparatus[109], by the application of vacuum[18,22,43a] (the bulb-tubes used could be fitted to normal vacuum tubes), and division of the metal block into mobile ring furnaces[75]. However, this reaction has been selected to demonstrate the utter simplicity of the pyrolysis; smaller quantities of [2.2]phanes can be obtained readily and rapidly with means available in all laboratories and without ring furnace arrangements. The temperature of the metal block is adjusted as desired to the sublimation or decomposition temperature of the sulfone, so that the latter is pyrolyzed while still in the furnace during or shortly after the sublimation.

5.3.2. Pyrolysis Apparatus for Liquid Sulfones or Sulfones Melting without Decomposition

1,2-Dihydrocyclobutabenzene (29)[22]: The sulfone *(28)* is transferred to a 125 ml round-bottom flask fitted with a sleeve containing a nichrome heating coil and a cold finger cooled with acetone and dry ice located above the heating coil (Fig. 2). The apparatus is flushed out with N_2 and evacuated to 2 torr. The sulfone is slowly sublimed through the electrically heated coil ("gas-phase-vacuum" apparatus) and the product condenses on the cold finger. After warming the solid condensate to room temperature, slow equalization of pressure, and distillation under normal pressure, *(29)* is obtained as a colorless liquid (b.p. 149—150 °C) in a yield of 60%.

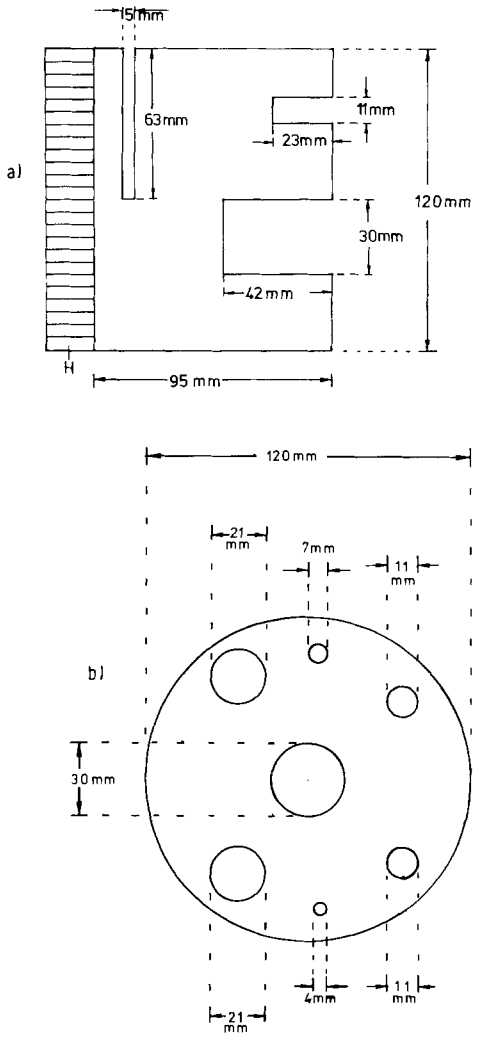


Fig. 1. Simple apparatus for sulfone pyrolysis (after [47]), with the original dimensions. a) Longitudinal section: the electric hot plate H is fitted with removable clamps. b) Top view of a similar pyrolysis furnace with drilled holes of various diameters for several bulb tubes of various diameters and for melting-point tubes, test tubes, and thermometers.

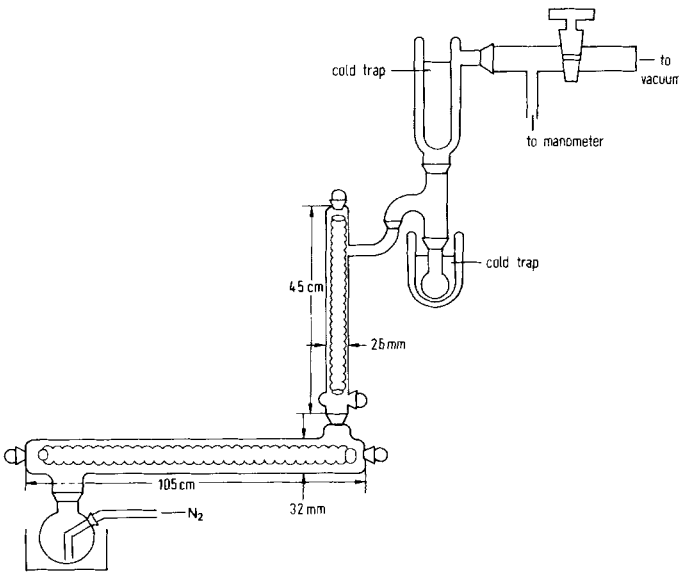

Fig. 2. Pyrolysis apparatus (with dimensions) after *Oliver* and *Ongley* [28].

5.3.3. Pyrolysis Apparatus with Stationary Ring Furnaces

Bibenzyl (19), $R^1=R^2=H$[18]: The pyrolysis apparatus consists of a tube about 700 mm in length and 25 mm in diameter, closed at one end. The open end is connected to a cold finger followed by two cold traps connected in series. The tube is enclosed by three electrically heated furnaces. The purpose of the first furnace is to distill the sulfone (temperature 50 °C above the melting point of the sulfone), while the second and third furnaces constitute the pyrolysis unit proper. 1.00 g (6.40 mmol) of dibenzyl sulfone *(18)*, $R^1=R^2=H$, was placed in a refractory boat which was pushed near the closed end of the tube. At 650 °C/0.1 torr it took 30 min for all the sulfone to be pyrolyzed to *(19)*, $R^1=R^2=H$ in a yield of 90%.

[2.2](4,4')Biphenylophane (112)[43,44]: After charging the boat with a total of 2.40 g (4.92 mmol) of *(111)* in portions of 300—500 mg, the apparatus (cf. Fig. 3) was evacuated with oil and mercury diffusion pumps to 0.1 torr; a current of argon was passed in through a capillary tube to maintain this pressure. The temperature of the pyrolysis furnace was raised to 500 °C and the evaporator furnace was quickly heated to 300 °C and in 2—3 h to 400 °C. 1.05 g (59%) of light yellow pyrolyzate condensed on the cold finger, leaving a brown, amorphous residue in the boat. Purification gave colorless needles (m.p. 247—249 °C).

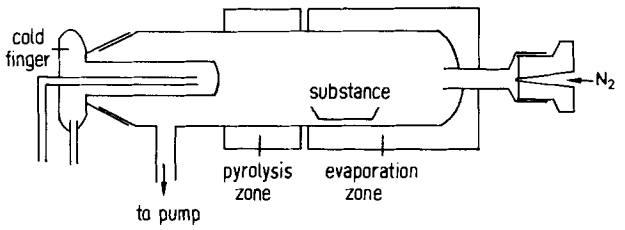

Fig. 3. Gas-phase-vacuum pyrolysis apparatus after *Staab* and *Haenel* [43, 44].

5.3.4. Apparatus with Freely Mobile Ring Furnaces

[4]-[11](4,4'')-o-Terphenylophanes (136a—h), n=2—9[75b]: The pyrolysis apparatus shown in Figure 4 was used for small quantities (50—100 mg) of the sulfone *(135a—h)*. The 250-mm long quartz pyrolysis tube had an internal diameter of 4 mm and was fused at one end. It opened *via* a screw connection with silicone seal into a further glass tube, into which a cold finger protruded from the other side, the cold finger providing the connection to the vacuum pump. Four ring furnaces served as the source of heat, mounted independently of one another and adjustable horizontally on a light metal support. Each furnace could be adjusted independently to the desired temperature.

After charging with 50—80 mg of *(135a—h)*, the ring furnaces were heated to about 500 °C. As a rule the first ring

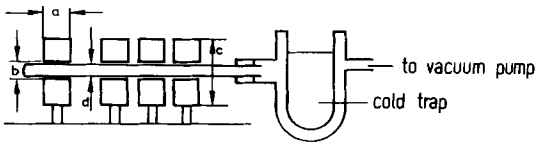

Fig. 4. Small pyrolysis apparatus, schematic [75]. Furnace: a = 10, b = 6, c = 18 mm; quartz tube: d = 4 mm.

furnace was used to sublime the sulfone while the other three ring furnaces, pushed closely together, jointly acted as a pyrolysis zone 40 mm in length. The pyrolysis product *(136a—h)* was deposited on the cold finger in a yield of 60—80%.

The pyrolysis furnace shown in Figure 5 was in principle no different from the furnaces of the micro-apparatus (Fig. 4). Apart from mechanical improvements[110], the only difference was that it was larger and thus particularly well suited for "medium" quantities (0.1—1 g) of the sulfone; the ring furnaces were controlled electronically and could be quickly adjusted to preselected temperatures without the risk of overheating[110].

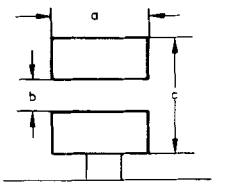

Fig. 5. Furnace of the medium-sized pyrolysis apparatus, schematic. a = 50, b = 12, c = 42 mm [110].

[2](2,4'''')-1,1';2',1'';3'',1''';2''',1''''-Quinquephenylophane[77]: 2,5-Dithia[6](2,4'''')-1,1';2',1'';3'',1''';2''',1''''-quinquephenylophane 2,2,5,5-tetroxide (735 mg, 1.30 mmol) was placed in the 40 mm-long quartz tube (diameter 8 mm) of the medium pyrolysis apparatus (Fig. 5). After evacuation of the tube to 5×10^{-5} torr with a diffusion pump, the 50-mm long mobile furnace was set at 600 °C. The sulfone pyrolyzed to the phane in a yield of 46%, with loss of SO_2 and C_2H_4.

[2.2]Paracyclophane[112]: The "macro-pyrolysis apparatus" shown in Figure 6 is suitable for larger amounts of sulfone. In this apparatus too the four ring furnaces can be moved in a longitudinal direction on ball-bearings[111]; their temperatures can be adjusted independently of one another.

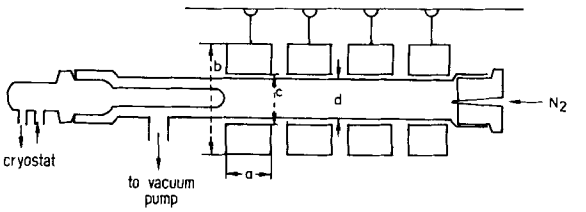

Fig. 6. Pyrolysis apparatus for larger quantities of the substance, schematic [111]. Furnace: a = 105, b = 117, c = 27 mm; quartz tube: d = 25 mm.

1.00 g (2.98 mmol) of *2,9-Dithia[3.3]paracyclophane 2,2,9,9-tetroxide (99a)*, X=Y=H, was mixed with 10 g of dried sea sand (p.a.) and the mixture placed in the 140 cm long quartz tube (diameter 25 mm). The ring furnaces were set as follows: evaporator furnace 380 °C, pyrolysis furnaces 450 °C. The pyrolysis was carried out under inert gas at a pressure of 0.1 torr. The (nonoptimized) yield was 18%.

5.3.5. Continuous Sulfone Pyrolysis for Larger Quantities of Substance[112]

Up to now in the pyrolysis of larger quantities of the substance it was usually necessary to open the apparatus after it had cooled and to recharge it. We have developed an apparatus in which additional sulfone can be added during the pyrolysis[112]. The principle is illustrated in Figure 7. The basic

components are inlet and outlet tubes fused perpendicularly into the pyrolysis tube, through which the starting material can be introduced and the residues can be removed without breaking the vacuum, together with a vacuum-tight solids-metering device.

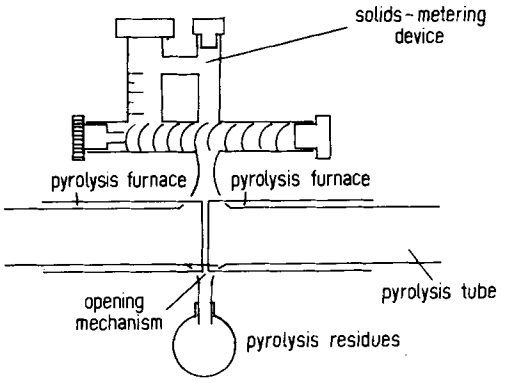

Fig. 7. Sulfone-pyrolysis apparatus for continuous operation (schematic) [112].

5.3.6. Coupling of Sulfone Pyrolysis with Gas Chromatography

The pyrolysis of mg amounts of a sulfone is required for a systematic study of the elimination-incorporation equilibrium in sulfones bridged with paraffin chains [cf. *e.g. (164)* → *(165)* + *(166)*]. A combination of pyrolysis apparatus and gas chromatograph is suitable for this purpose[113].

[2.0.0](1,4)Benzeno(1,8)naphthaleno(1,4)benzenophane (73) (see [52]): The apparatus used for the pyrolysis of the sulfone *(72b)*, $X = O_2S(CH_2)_2SO_2$[97, 114]— commercial Curie point[115] and Pyroprobe®-190 pyrolyzers[116]— was in each case connected directly to the injector of a gas chromatograph[117]. With a constant injector temperature of 450—900 °C (at intervals of 50 °C) the sulfone was injected into the injector space through the membrane. Pyrolysis occurred within about 10 msec, and the elimination of C_2H_4 increased with increasing temperature. The retention times of the products were compared with those of authentic samples. Some of the pyrolyses were repeated in the apparatus shown in Figure 4 so as to keep a check on the preparative scale performance; the temperature dependence of the product distribution proved to be comparable. The pyrolysis of multimembered sulfides with the elimination of sulfur and the formation of C C bonds was first discovered using this combination of equipment[113].

6. Outlook

The described examples of SO_2 elimination from sulfones allow an appraisal of the conditions for pyrolyses still untried. Given comparable mechanisms, it may be possible to cleave other fragments similarly to the elimination of SO_2 (*e.g.* CO_2[101-104], CO[101,105-107], N_2[101,108], SO[118,119], and S[113]. The ease with which the pyrolysis conditions may be varied, the solvent-free operations and the rapidity of the preparations make this technique a basically attractive one.

For our own results quoted in this article we are especially grateful to all co-workers cited in the accompanying references. We are also grateful to the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for their invaluable support and to Dipl.-Chem. R. Wingen for reading the manuscript.

[109] This simple apparatus was used for the synthesis of the [2.2.2](1,3,5)benzenophane *(128)* [80]; since the yields were low at 400—420 °C and normal pressure a water-flow vacuum was employed during pyrolysis, whereby the ratio of pyrolyzate collected in the receiver to remaining charred products could be considerably increased. Besides the [2.2.2]phane, 5,13-dimethyl[2.2]metacyclophane *(88)* could also be detected mass spectrometrically.
[110] We thank the electronics and instruments department of our institute, and in particular Ing. *W. Löhr, E. Obst* and *L. Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Generation of the *triangulo*-Group Mo^{V}-η-S_2 in the "Condensation" of $[Mo^{VI}O_2S_2]^{2-}$ to $[Mo^{V}_2O_2S_2(S_2)_2]^{2-}$

By *Walter Rittner* (deceased), *Achim Müller*, *Axel Neumann*, *Wolfgang Bäther*, and *Ramesh Chandra Sharma*[*]

In aqueous medium Mo^{VI} is reduced by S^{2-} and S_n^{2-} with formation of sulfur-rich polynuclear η-disulfido complexes such as $[Mo^{V}_2(S_2)_6]^{2-}$ and $[Mo^{IV}_3S(S_2)_6]^{2-}$ [1,2]. We have now found that the Mo^{V}-η-S_2 group is also formed from $[Mo^{VI}O_2S_2]^{2-}$ in H_2O by *a novel intramolecular redox process* (oxidation of ligands by the metal coordination center). This finding is of interest regarding the catalytic action of molybdenum in electron transfer processes in polynuclear metal-enzymes and in view of a possible key function of the S_2^{2-} group bound to molybdenum in various redox-enzymes[3]. A binuclear complex containing two η-S_2^{2-} ligands was hitherto unknown.

$[Mo^{VI}O_2S_2]^{2-}$ *(1)* (as NH_4^+ salt) "condenses" within a short period of time under physiological conditions to give polynuclear sulfur-bridged complexes with η-S_2^{2-} ligands ("polythiooxoanions" such as $[Mo^{V}_2O_2S_2(S_2)_2]^{2-}$ *(2)*)[4,5]. The reaction conditions would indicate participation of the following redox processes.

$$Mo^{VI} \xrightarrow{red} Mo^{IV} \qquad (Mo^{VI} + Mo^{IV} \rightarrow 2\,Mo^{V})$$

$$2\,S^{2-} \xrightarrow{ox} S_2^{2-}$$

The anion *(2)* can readily be isolated as the tetramethylammonium salt. The compound was characterized by elemental analysis, IR, Raman, UV/VIS, and ESCA spectra and by a complete single-crystal structure analysis[6] (cf. Fig. 1 and Table 1).

Bond lengths [6]	d(S—S) [Å]		2.090(6)
			2.075(7)

[a] Solid. [b] Solid (Nujol). [c] Solution in *N,N*-dimethylacetamide; first assignment of the transition of S_2^{2-} complexes being responsible for the color. [d] Referred to C_{1s} standard (285.0 eV).

The initial step in the reaction of *(1)* is protonation at the oxygen, which favors both the condensation as well as the intramolecular redox reaction (the effective electron density at the Mo center decreases with decreasing Mo O π-bond order, and consequently the oxidizing action and tendency of the central atom to coordinate increases). The formation of the η-disulfidomolybdenum(V) group in pure aqueous dithiomolybdate(VI) solutions under physiological conditions was detected spectroscopically, using the data for the tetramethylammonium salt of *(2)* (see [4]).

Experimental

A solution of $(NH_4)_2MoO_2S_2$ (1.8 g) in H_2O (25 ml) was heated to boiling for about 10 min. After addition of 0.5 g NaOH and 0.8 g $[(CH_3)_4N]Cl$ in 75 ml H_2O, cooling of the resulting reaction mixture led to precipitation of $[(CH_3)_4N]_2[Mo_2O_2S_2(S_2)_2]$, which was recrystallized from the mother liquor and washed with a small amount each of H_2O, methanol, and ether; yield: 0.5 g of orange-red crystals. – The salt can also be isolated at lower temperature and in higher yield by addition of H_2S-water [*(2)* has a higher S-content than *(1)*] to a saturated aqueous solution of $(NH_4)_2MoO_2S_2$ at *ca.* 50 °C and precipitation with $[(CH_3)_4N]Cl$ (but not pure).

[3] *E. I. Stiefel*, Prog. Inorg. Chem. 22, 1 (1977).
[4] The decomposition of *(1)* was monitored by measurement of the pH value and the UV/VIS, Raman, and IR spectra [precipitation of Me_4N^+ salts]. The "condensation reaction" is strongly dependent upon temperature. Whereas a substantial amount of unreacted *(1)* is still present after *ca.* 10 min at 40 °C, at 60 °C the reaction mixture consists almost exclusively of reduced products (investigations on saturated solutions of $(NH_4)_2MoO_2S_2$).

[5] Older data given in the literature on the formation of "polythioanions" [cf. *E. Diemann, A. Müller*, Coord. Chem. Rev. *10*, 79 (1973)], which we intend investigating systematically, are in need of revision since the possibility of redox processes (strongly temperature dependent owing to the high activation energy [4]) taking place simultaneously has not been taken into consideration.

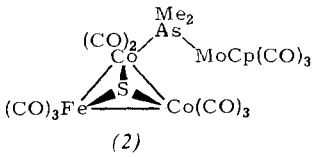
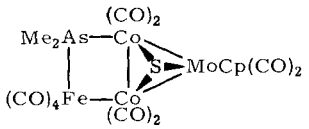
$FeCoMoWS(AsMe_2)Cp_2(CO)_7$: The First Cluster to Contain Four Different Metal Atoms[**]

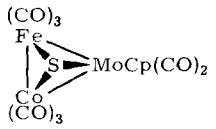


By *Felix Richter* and *Heinrich Vahrenkamp*[*]

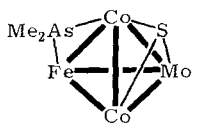
The directed synthesis of clusters is still in its infancy[1], and especially in the case of heteroclusters there are but few preparative pathways which owe their success more to strategy than to chance[2]. We discovered such a pathway in the replacement of carbonylcobalt groups by other organometallic fragments[3]. A detailed study of this reaction has provided an entry to a new class of compounds by leading to the synthesis of the first cluster to contain four different metal atoms.



On transformation[3] of the μ_3-bridged complex *(1)* into *(4)* the straightforward substitution product *(2)* previously described was found to be converted into a further isolable intermediate *(3)*[4]. This intermediate under mild conditions underwent not only elimination to give the trinuclear FeCoMo cluster *(4)* but also aggregation to form the tetranuclear $FeCo_2Mo$ cluster having the skeleton *(5)*[5]. A corresponding reaction sequence starting from *(4)* and the organometallic base $Cp(CO)_3W\quad AsMe_2$[6] led—as planned—to the tetranuclear cluster named in the title to which we assign the tetrahedral FeCoMoW skeleton *(6)*[7].

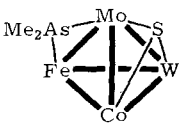


(1)



(2)

(3)



(4)

$FeCo_2MoS(AsMe_2)Cp(CO)_8$

(5)

$FeCoMoWS(AsMe_2)Cp_2(CO)_7$

(6)

The composition of compound *(6)* has been established by complete elemental analysis and FD mass spectrometry. Its ^{1}H-NMR spectrum reveals the nonequivalence of the two $AsCH_3$ groups by the appearance of two signals at $\delta = 1.72$ and 1.74, as well as the two distinct cyclopentadienyl ligands by the occurrence of two broad signals at $\delta = 4.36$ and 4.86 (benzene, TMS int. std.). The CO stretching bands (in cyclohexane 2003 m, 1987 vs, 1946 m, 1888 w, 1811 w, 1779 w, 1769 cm^{-1} w) indicate the presence of terminal and bridging carbonyl ligands. Owing to the different nature of each corner of the tetrahedral skeleton, compound *(6)* is chiral, like the starting compound *(4)*.

The bridging ligands $AsMe_2$ and S which permit the directed synthesis of *(6)* may prove obstructive in studies of the chemical properties of this novel tetranuclear cluster since they tend to "shield" the metal atoms. The versatility of *(6)* (each metal atom coordinated in a different way, six different metal-metal bonds) nevertheless makes it a stimulating object of study.

Procedure

Compound *(4)* (0.52 g, 0.98 mmol) and $Cp(CO)_3W\quad AsMe_2$ (0.43 g, 0.98 mmol) are heated under reflux for 1 d in benzene (20 ml). After evaporation to dryness the product is crystallized from a small volume of benzene/hexane (1:1) at −35 °C; yield 0.35 g (42%) of *(6)*, black crystals, m.p. 135 °C.

(Diazomethyl)cyclopropenes—Synthesis, Isomerization, and Carbene Reactions[**]

By *Manfred Regitz, Annemarie Heydt*, and *Berndt Weber*[*]

Individual cases of electrophilic substitution at carbon of diazomethyl compounds, such as acylation with acyl chlorides, have been known for a long time[1]; however, generalization of this reaction (halogenation, nitration, metalation, and alkylation) was accomplished only recently[2]. Introduction of Hückel-aromatic cations as electrophiles opens up new vistas.

Model reactions between the diazomethylphosphoryl compounds *(3a)* and *(3b)*[3] in dichloromethane/triethylamine (route *B*), or preferably their silver derivatives *(2a)* and

[**] Studies of Diazo Compounds and Azides, Part 34. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. —Part 33: *M. Regitz, A. M. Tawfik, H. Heydt*, Synthesis, in press.

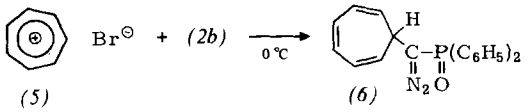
(2b)[3] in acetonitrile (route *A*), and the cyclopropenylium salts *(1a)*[4] and *(1b)*[5] give good yields of the fairly stable (diazomethyl)cyclopropenes *(4a)*—*(4d)*[6] whose structures were confirmed by IR and ^{1}H-NMR spectroscopic data (see Table 1).

(1a), R^1 = $C(CH_3)_3$
(1b), R^1 = C_6H_5

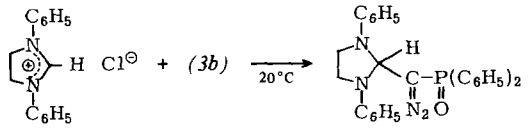
(2a), *(3a)*, R^2 = OCH_3
(2b), *(3b)*, R^2 = C_6H_5

(from toluene); IR (KBr), 2080 (C N_2), 1190 cm^{-1} (PO); ^{1}H-NMR ($CDCl_3$), δ = 3.50—4.20 (m, 4H), 6.25 (d, 1H, $^3J_{P,H}$ = 6 Hz)].

On heating in toluene, the (diazomethyl)cyclopropenes *(4b)* and *(4d)* undergo a novel isomerization to the pyridazines *(10a)* and *(10b)*, respectively (see Table 2). The cycloadduct *(9)* might function as intermediate; a synchronous transformation *(4)*→*(10)* cannot be ruled out.



Reaction of tris(dimethylamino)cyclopropenylium perchlorate *(11)*[7] and the diazo compounds *(3a)* and *(3b)* in the presence of 1,5-diazabicyclo[4.3.0]non-5-ene (CH_2Cl_2, 25 °C) also gives pyridazines [*(10c)* and *(10d)*] (see Table 2). The corresponding (diazomethyl)cyclopropenes are apparently so labile that they isomerize at room temperature[8].



Irradiation of *(4d)* in benzene generates the carbene *(12)* which reacts, partly in a kind of cheletropic reaction to give the acetylenes *(13)* (yield 52%; m.p. 58 °C) and *(14)* (yield

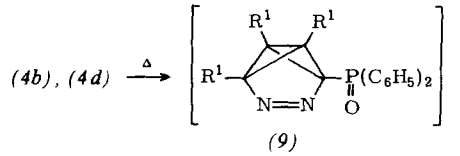


Table 1. Yields, melting points, IR and ^{1}H-NMR data of the (diazomethyl)cyclopropenes *(4a)*—*(4d)*.

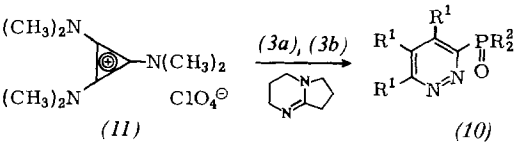
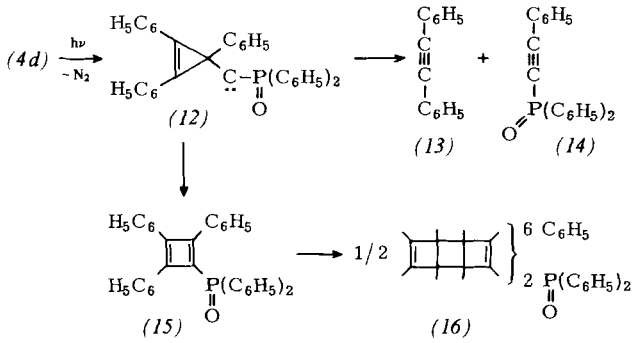


Cpd.	R^1	R^2	Yield [%] *A*	Yield [%] *B*	M.p. [°C] (Solvent)	IR (KBr) C N_2 [cm^{-1}]	^{1}H-NMR ($CDCl_3$, TMS int., δ values)
(4a)	$C(CH_3)_3$	OCH_3	93	43	Oil	2060	0.97 (s, 9H), 1.25 (s, 18H), 3.70 (d, 6H, $^3J_{P,H}$ = 12 Hz)
(4b)	$C(CH_3)_3$	C_6H_5	68	90	114 (Ether)	2050	0.96 (s, 9H), 1.20 (s, 18H), 7.3–7.8 (m, 10H)
(4c)	C_6H_5	OCH_3	75	– –	88 (Ether)	2070	3.48 (d, 6H, $^3J_{P,H}$ = 12 Hz), 7.1–7.8 (m, 15H)
(4d)	C_6H_5	C_6H_5	62	47	131 (Ethyl acetate)	2050	7.2–7.9 (m)

The possibility of extending this substitution to other stable carbocations is recognized. Thus tropylium bromide *(5)* reacts with *(2b)* in dichloromethane to give 7-[diazo(diphenylphosphoryl)methyl]cycloheptatriene *(6)* [yield 70%; m.p. 94 °C (from ether); IR (KBr), 2070 (C N_2), 1190 cm^{-1} (PO); ^{1}H-NMR ($CDCl_3$), δ = 2.60 (q by superposition of 2t, 1H, $^3J_{H^1,H^7} = {}^3J_{H^7,P} = 6$ Hz)]. 1,3-Diphenylimidazolium chloride *(7)* can be transformed similarly with *(3b)* in acetonitrile/triethylamine into 2-[diazo(diphenylphosphoryl)methyl]1,3-diphenylimidazolidine *(8)* [yield 43%; m.p. 169 °C



49%; m.p. 101 °C), and partly *via* ring enlargement to form the phosphorylated cyclobutadiene *(15)*[9], which dimerizes to *(16)* [yield 8%; m.p. 349 °C (from benzene/ether 2:1); MS (70 eV), m/e = 961 (M^+, 5%), 760 ($M^+ - PO(C_6H_5)_2$, 12%), 559 ($M^+ - 2PO(C_6H_5)_2$, 50%)][10]. The location of the substituents is still unknown.

Experimental

Synthesis of *(4b)*, route *A*[11]: Compound *(1a)*, X = Br[5] (1.5 g, 5 mmol) in acetonitrile (10 ml) is added dropwise to a stirred suspension of *(2b)* (1.0 g, 3 mmol)[3] in acetonitrile (10 ml) at 0 °C under nitrogen. After 3 h at 20 °C and addition of ether (30 ml), the mixture is filtered and evaporated down *in vacuo*. Chromatography of the crude product (1.3 g, m.p. 96 °C) over Woelm 0.05—0.2 mm silica gel (100 g, column dimensions 50 × 3 cm) with ethyl acetate (200 ml) gives *(4b)* (0.9 g, 68%) as yellow crystals of m.p. 114 °C.

Synthesis of *(10a)*[11]: A solution of *(4b)* (700 mg) in toluene (30 ml) is heated under reflux for 30 min (decoloration) and evaporated. Digestion of the residue with a small volume of ether and cooling gives compound *(10a)* (550 mg, 78%) of m.p. 161 °C (from ether).

Homogeneous Catalytic Vinylation of Cyclic Imides and Lactams for the Synthesis of *N*-Vinyl Monomers

By *Ernst Bayer* and *Kurt Geckeler*[*]

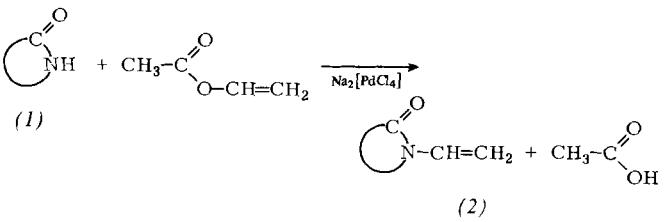
N-Vinyl compounds are starting substances for the synthesis of important polymers, *e.g.* poly(vinylpyrrolidinone)[1]. Convenient and general methods for the synthesis of *N*-vinyl compounds, however, were hitherto unknown.

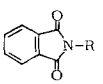
There are two important methods for the synthesis of cycloaliphatic *N*-vinylimides and -lactams: Reaction of imides and lactams according to *Reppe*'s method[1] with acetylene at high pressure and elimination of alcohol from the *N*-(1-alkoxyethyl) derivatives[2]. Procedures involving high pressures and elevated temperatures lead to formation of byproducts, and necessitate special safety precautions; the elimination process has the particular disadvantage that the starting compounds are accessible only by multistep synthesis.

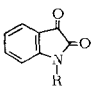
The transvinylation of nitrogen-containing heterocycles with vinyl acetate in the presence of mercury salts has been described[3-5]; in this method addition of oleum is essential. Moreover, this procedure has the disadvantage that the product must be isolated by column chromatography[3, 5].

Attempts by *Hopff et al.* to synthesize *N*-vinylimides by transvinylation with vinyl acetate at room temperature[3] or at 72 °C[4] gave negative results in the case of phthalimide and some other imides.

We have now found that cyclic *N*-vinyl compounds *(2)* are formed in one step and in high yields on reaction of imides and lactams with vinyl acetate in the homogeneous phase if







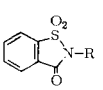


Table 1. Data for *N*-vinyl monomers *(2)*.

(2e)		79	7	131	131–132 [3]

sodium tetrachloropalladate is employed as catalyst (Table 1). The compounds *(2)* thus prepared were identified by NMR and IR spectroscopy and by thin-layer chromatography.

General procedure

To a stirred solution of the imide or lactam *(1)* (20 mmol) in vinyl acetate (50 ml) is added 50 mg of $Na_2[PdCl_4]$ and the mixture heated under reflux for 4—20 h with exclusion of moisture. After addition of 200 mg of activated charcoal the solution is shaken for 10 min, filtered free of solids, and the

Auf der Morgenstelle 18, D-7400 Tübingen 1 (Germany)

solvent removed by distillation in a high vacuum. The same amount of catalyst and reagent is then added again and the procedure repeated. For isolation of the vinyl compound, the solid is extracted with ether or petroleum ether, the solvent removed in a vacuum and the product recrystallized or distilled.

Manganese-Containing Heterocycles Having a λ^4-Thia-λ^5-phosphanorbornadiene Skeleton[1]

By *Ekkehard Lindner, Axel Rau*, and *Sigurd Hoehne*[*]

Metal-containing heterocycles are of interest in connection with organic syntheses, and especially with catalytic processes[2]. While looking for new pathways leading to metallacycles containing metal-carbon σ bonds, we obtained the manganacycles *(2)* having a thiaphosphanorbornadiene skeleton for the first time by reaction of the inorganic heterocycles *(1)*[3] with acetylene derivatives.

(1)

(2a), $R^1 = CH_3$, $R^2 = CO_2CH_3$
(2b), $R^1 = CH_3$, $R^2 = CO_2C_2H_5$
(2c), $R^1 = C_6H_5$, $R^2 = CO_2CH_3$
(2d), $R^1 = C_6H_5$, $R^2 = CO_2C_2H_5$

The yellow compounds *(2)* are readily soluble in polar solvents and melt with decomposition above 125 °C. They were characterized by complete elemental analysis, IR [each with three intense bands at *ca.* 2025, 1955, 1948 cm^{-1} (in CCl_4)], ^{31}P-NMR, and mass spectra [*m/e* (M^+): *(2a)* 516, *(2b)* 572, *(2c)* 640, *(2d)* 696]; *(2a)* was further characterized by X-ray crystal structure determination[4] (Fig. 1) and by its $^{13}C\{^1H\}$-NMR spectrum [$CDCl_3$, rel. to TMS: $\delta = 44.9$ (d, $J = 72$ Hz; C-4), 53.6 (s; C-1), 101.6, 103.1 (s; C-5, C-6)][5].

The angle between the planes through the atoms C1, C4, C5, C6 and C1, S, P, C4 is 46.9°. The ester groups (R^2) attached to C1 and C4 are twisted by 10 and 13°, respectively, out of the plane, and those attached to C5 and C6 by 3.5 and 2°, respectively; in a limiting structure the manganese is therefore linked by two σ bonds and one π bond to C1 and C4 and to C5 and C6, respectively[6]. In accord with the IR band ν(P S) at 530 cm^{-1} (in polyethylene), the P S distance corresponds to a value lying between that for a single

(214 pm) and that for a double bond (194 pm). The positive charge in the PS part of *(2)* is manifested in a strong downfield shift (≈ 74 ppm) of the ^{31}P-NMR signal (in CH_2Cl_2, rel. to 85% H_3PO_4 ext.).

Heating of *(2a)* in tetrahydrofuran (THF) to 100 °C under a CO pressure of 200 bar leads to elimination of the $Mn(CO)_3$ and the $P(CH_3)_2$ group, yielding the thiophene derivative *(3)*.

(3)

Procedure

Compound *(1)* (0.5 mmol) and $R^2C{\equiv}CR^2$ (4 mmol) are heated with stirring in THF (100 ml) within 1 h to 66 °C. The reflux temperature is maintained for 30 min. After stripping off the solvent, chromatography with benzene/ethyl acetate on Al_2O_3 (activity V) or silica gel (activity II) gives the organometallic compounds *(2a)* and *(2b)* and *(2c)* and *(2d)*, respectively in yields of 10 to 60% as oils which crystallize at −30 °C or on addition of diethyl ether.

A solution of *(2a)* (0.2 mmol) in THF (50 ml) is subjected to a CO pressure of 200 bar at 100 °C in an autoclave. After 12 h the solvent is stripped off and the residue chromatographed with benzene/ethyl acetate on silica gel. The thiophene *(3)* is obtained in *ca.* 80% yield.

Synthesis of Metallacycles with Reactive Metal-Carbon σ Bonds[1]

By *Ekkehard Lindner, Guido Funk*, and *Sigurd Hoehne*[*]

Metallacycloalkane derivatives play an important role in the activation of C–H bonds[2] and in transition-metal catalyzed reactions[3]. Most of these heterocycles have so far only been obtained with various Group 8 metals[4]. A new general procedure now also permits the synthesis of metallacycloalkanes with other metals, such as those from Group 7 whose weak metal-carbon σ bonds ensure that the products are highly reactive.

(1a), M = Mn, L = CO, m = 4, n = 3
(1b), M = Re, L = CO, m = 4, n = 3
(1c), M = Fe, $L_m = \eta^5$-C_5H_5 + CO, n = 3

β-Hydrogen elimination is avoided by performing the reaction in such a way that simultaneous α,ω attack of the difunctional alkylphosphane takes place on the metal (with elimination of CO and MgClBr). The metallacycles *(1)* are surprisingly stable owing to the chelate effect; they can be sublimed in a high vacuum, melt above 110 °C (except *(1c)*), and dissolve in all the common organic solvents. They were characterized by complete elemental analysis, IR, and mass spectra (Table 1). Further characterization of *(1a)* was by X-ray crystal structure analysis[5] (Fig. 1) and by its $^{13}C\{^1H\}$-NMR spectrum C_6D_6, rel. to TMS: δ = 18.1 (s; C-4), 31.0 (d, J = 15 Hz; C-3), 34.6 (d, J = 29 Hz; C-5).

Table 1. IR and MS data and colors of the new heterocycles *(1)* and *(2)*.

The five-membered ring of *(1a)* has an envelope conformation with a dihedral angle of 48.7°. The Mn–C3 distance is considerably greater than the sum of the single bond radii. The *trans* CO groups are bent towards the heterocycle (C8–Mn2–C9 = 166.6°). The coordination polyhedra of the manganese and the phosphorus atoms are strongly distorted as a result of ring strain.

P1–Mn2	229.5(2)	C5–P1–Mn2	105.9(3)

The weak M–C σ bonds in *(1a)* and *(1c)* are highly reactive: quantitative insertion of SO_2 to form the ring-expanded heterocyclic sulfinato-*S* complexes *(2a)* and *(2c)* is observed at as low a temperature as −60 °C [dec. >175 °C, $\nu_{as}(SO_2) = 1183$ and 1160 s, $\nu_s(SO_2) = 1040$ s cm^{-1} (KBr)].

(2a), (2c)

The composition of compounds *(2)*, which are soluble only in polar solvents, follows from elemental analysis and IR and mass spectra (Table 1).

Procedure[6]

(1a) is obtained by reaction of $(CO)_5MnBr$ (3 mmol) in tetrahydrofuran (THF) (10 ml) with a solution of $Ph_2P(CH_2)_3MgCl$ (3 mmol) in THF (100 ml) at 65 °C. After evolution of CO has ceased, the solvent is stripped off and the residue extracted with *n*-hexane. The solvent is again removed and *(1a)* is sublimed at 80 °C in a high vacuum; yield *ca.* 30%.

Compound *(1a)* (0.3 mmol) is treated at −60 °C with liquid SO_2 (40 ml) for 1 h. After evaporation of the SO_2, analytically pure compound *(2a)* is obtained quantitatively.

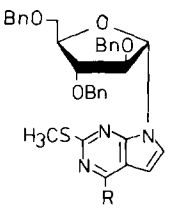
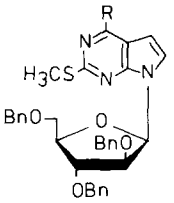
Preferred β-Glycoside Formation by Phase Transfer Catalysis in the Synthesis of D-Arabinofuranosyl-7-deazapurine Nucleosides

By *Frank Seela* and *Dieter Winkeler*[*]



We have found that 1-bromo-2,3,5-tri-*O*-benzyl-D-arabinofuranose *(2)* couples with 4-chloro-2-methylthio-7*H*-pyrrolo[2,3-*d*]pyrimidine *(1)*[1] (a key substance for the synthesis of 7-deazapurine nucleosides[2-4]) by phase transfer catalysis[5] to give the N^7-glycosides [*(3a)* + *(4a)*] in yields of over 85%. The method has the advantage that the anomeric mixture contains more than 80% of the β-anomer *(4a)*. Moreover, it eliminates the necessity of working with anhydrous reagents, and can also be used for the synthesis of other nucleosides.



(1)

(2)

(3a), R = Cl
(3b), R = OCH_3

(4a), R = Cl
(4b), R = OCH_3

Table 1. Data for the α-anomer *(3a)* and the β-anomer *(4a)*.

(3a), TLC (silica gel, $CHCl_3/CH_3OH$, 200:1): $R_f = 0.25$; ^{1}H-NMR (D_6-dimethyl sulfoxide): $\delta = 2.56$ (s, CH_3S), 3.67 (d, CH_2-5', $J = 5.0$ Hz), 4.28 (t, H-4', $J = 4.0$ Hz); 4.5—4.7 (m, H-3', 3 Benzyl-CH_2), 4.83 (t, H-2', $J = 4.0$ Hz), 6.40 (d, H-1', $J = 4.0$ Hz), 6.63 (d, H-5, $J = 4.0$ Hz), 7.1—7.3 (m, 15 arom. H), 7.75 ppm (d, H-6, $J = 4.0$ Hz).

(4a), TLC: $R_f = 0.20$; UV (CH_3OH): $\lambda_{max} = 253$, 276, 310 nm ($\varepsilon = 22400$, 6500, 6500); ^{1}H-NMR: $\delta = 2.56$ (s, SCH_3), 3.75 (d, CH_2-5', $J = 5$ Hz), 4.0—4.5 (m, H-2', H-3', H-4'), 4.55—4.75 (3 Benzyl-CH_2), 6.53 (d, H-5, $J = 4.0$ Hz), 6.73 (d, H-1', $J = 6.0$ Hz), 6.8—7.5 (m, 15 arom. H), 7.65 ppm (d, H-6, $J = 4.0$ Hz)

Starting from aglycon *(1)* and the halosugar *(2)*, both in the organic phase, and 50% sodium hydroxide as inorganic phase, *N*-glycosidation in the presence of benzyltriethylammonium chloride[5] is quantitative after 2 hours' vigorous mixing. The reaction mixture is worked-up chromatographically on silica gel with chloroform/methanol (200:1). For determination of the position of glycosidation and assignment of the anomers, the substance contained in the slowly migrating zone B (main product) was converted with methanolic sodium methoxide into the 4-methoxy compound. In the thin layer chromatogram (silica, chloroform/methanol, 200:1) this zone migrates like authentic *(4b)*[6] with $R_F = 0.17$. Since the ^{1}H-NMR spectrum of the 4-methoxy compound is also consistent with that of *(4b)*, it follows that the main product of the phase transfer catalysis is the N^7-coupled β-anomer *(4a)*. On the basis of the NMR spectrum of *(3b)*[6] the component of the rapidly migrating zone A (byproduct) can be assigned as the α-anomer *(3a)* (see Table 1). The anomeric ratio (β:α) can be influenced by the phase-transfer catalyst. For tetrabutylammonium hydrogen sulfate it is 6:4, for benzyltriethylammonium chloride 8:2.

[*] Prof. Dr. F. Seela, Dipl.-Chem. D. Winkeler
Universität Paderborn—Gesamthochschule
Fachbereich 13 (Organische Chemie)
Warburger Strasse 100, D-4790 Paderborn (Germany)

Procedure

Dry hydrogen bromide is passed into a solution of 2,3,5-tri-*O*-benzyl-1-*O*-*p*-nitrobenzoyl-D-arabinofuranose[7] (2.85 g, 5 mmol) in dichloromethane (15 ml) until no further *p*-nitrobenzoic acid precipitates. The acid is filtered off and washed with a small volume of cold dichloromethane. Evaporation of the combined filtrates affords *(2)* as a yellow viscous oil.—*(1)* (1.0 g, 5.0 mmol) is suspended in benzene (10 ml) and then just brought into solution by addition of a small volume of dimethoxyethane. The mixture is treated with benzyltriethylammonium chloride (0.3 g, 1.1 mmol) and the same volume of 50% aqueous sodium hydroxide and stirred for 5 min with a vibromixer.—A solution of the halosugar *(2)* in benzene (3 ml) is added dropwise (slowly) into the stirred (vibromixer) emulsion, and mixing continued for 2 h. The organic phase is separated off, extracted with water, dried with sodium sulfate, filtered, and the solvent removed by distillation *in vacuo*. The oily residue is dissolved in a little chloroform/methanol (200:1) and chromatographed in the same solvent on a silica gel column (70 × 5 cm, Kieselgel 60, Merck, 0.04—0.063 mm). The two main zones are separated; evaporation of the more rapidly migrating zone A affords 0.44 g (15%) *(3a)* and the more slowly migrating zone B 2.1 g (70%) *(4a)* as colorless viscous substances.

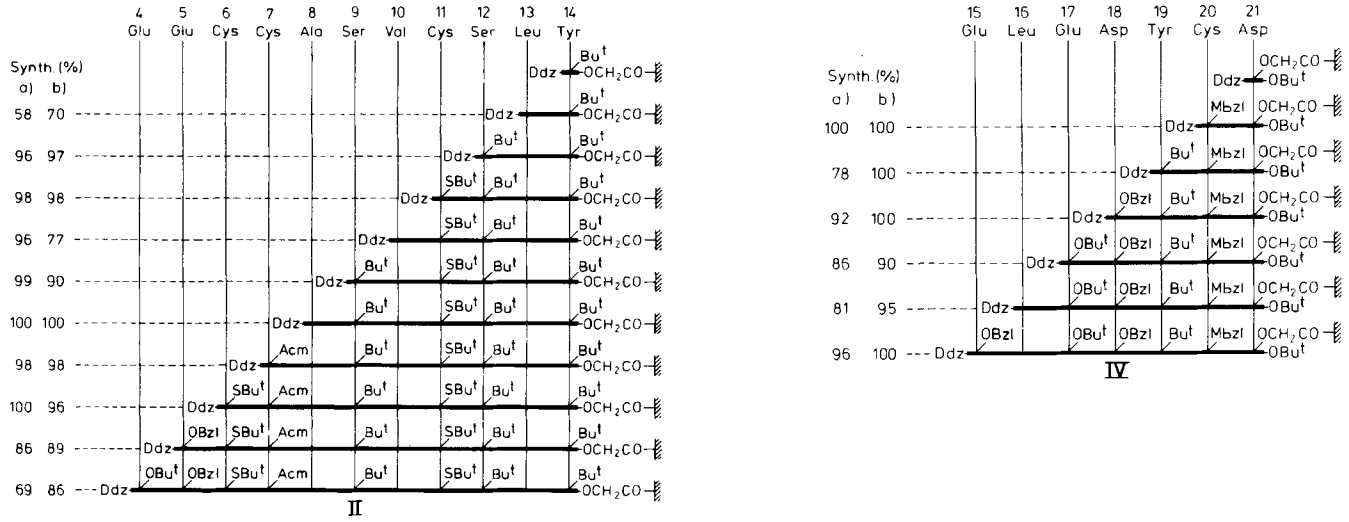
Fully Active Insulin by Selective Formation of the Disulfide Bridges between a Synthetic A-Chain and Natural B-Chain[**]



By *Christian Birr* and *Rüdiger Pipkorn*[*]

In the synthesis of insulin in *E. coli* by effective "genetic engineering"[1], A-chain and B-chain are synthesized in separate cultures and harvested as free polypeptides. Similarly as in earlier total syntheses the random disulfide oxidation to the insulin molecule is accompanied by high losses[2]. Recombination experiments with natural A- and B-chains (1:1) also gave insulin yields of only *ca.* 10%[3]. To improve the yields it is essential therefore that the three disulfide bridges be constructed selectively and not randomly.

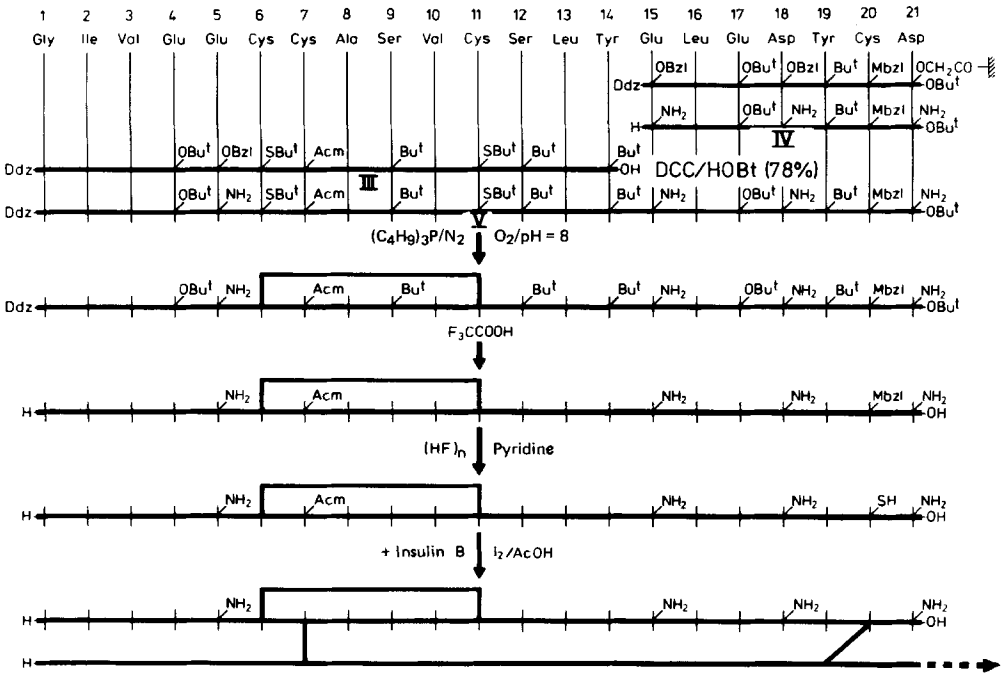

Scheme 1. Synthesis of the carrier-bound fully protected [5] fragment II (4 – 14) (left) and IV (15 – 21) (right) of the bovine insulin A-chain with the stepwise yields in two runs (a and b) of the synthesis. The overall yields are averaged for both syntheses and are determined with respect to initial loading of the carrier; they are 90 and 93% respectively.

We describe here the synthesis of an insulin A-chain, containing selectively cleavable sulfur protecting groups, on a polymer carrier and the reaction of this A-chain under stepwise oxidative formation of the disulfide bridges with a natural B-chain to give fully active crystalline bovine insulin. The concept applied here is a further development of the principles employed in the synthesis of MCD peptide[4].

We synthesized the fragment I (1—3) in 84% yield from Ddz-amino acids[5] in solution[6]. The fragments II (4—14) (Scheme 1, left) and IV (15—21) were each synthesized twice on 0.5% cross-linked polystyrene gel to check optimization of the syntheses. All the synthetic steps were followed photometrically[7] (cf. [4]). Instead of Gln^5 and Gln^{15} and Asn^{18}, we used Glu(OBzl) and Asp(OBzl) in order to avoid nitrile formation at the amide side function by the condensation reagent dicyclohexylcarbodiimide (DCC). In fragment IV, Asp^{21} is linked to the carrier with its β-carboxy function *via* an electrophilic 2-oxoethyl ester bond. In this way all the later amide side functions could be incorporated simultaneously at the end of the synthesis by ammonolysis of the benzyl ester and 2-oxoethyl ester bonds on release of IV and V from the carrier (Scheme 2).

On condensation of a 15-fold excess of I with the carrier-bound fragment II in the presence of DCC/1-hydroxybenzotriazole (HOBt), the fragment III was formed on the carrier in 86% yield (referred to II-gel polymer). Cleavage of III from the carrier (0.5 N triethylamine in methanol/dioxane 1:1 (v/v) + 0.5 vol-% 1 N NaOH) and subsequent chromatographic purification of the released and fully protected peptide acid afforded 1 gram of pure III (59% yield referred to III-gel polymer). Proof of the stability of the benzyl ester in position A^5 under the cleavage conditions was provided by the mass spectrum. The fragment IV was cleaved from the carrier by treatment with dioxane saturated with ammonia

Scheme 2. Synthesis of the fully protected bovine insulin A-chain by condensation in solution of the purified fragments III and VI removed from the carrier, and the liberation of the A-chain and its selective disulfide bridging with natural B-chain. Fragment III was formed in 86% yield on the carrier by reaction of I (1 – 3) with carrier-bound II.

and then with liquid ammonia/methanol 4:1 (v/v) under pressure at 20 °C. After chromatographic purification (DEAE A25 Sephadex/methanol-0.5 N acetic acid 4:1 (v/v) and Sephadex LH 20/methanol) we obtained 1.45 g (86% based on the carrier-bound precursor) of pure IV. The formation of the C-terminal β-amide could be confirmed by model experiments.

Condensation of 0.5 mmol of III with 1 mmol IV for the synthesis of the fully protected sequence V (1—21) using DCC/HOBt (4 days) in dimethylformamide gave after chromatographic separation 1.3 g of V (78%, based on III). Simultaneous condensation of III in 2.4-fold excess with IV on the carrier using carbonyldiimidazole afforded V in 12% yield; 50% of the excess of III in this case could be recovered. In V the benzyl ester at position A^5 can be converted into the amide with NH_3/methanol under pressure. For selective formation of the intrachain disulfide ring A^6—A^{11} by air oxidation (Scheme 2) the *tert*-butyl disulfides in position A^6 and A^{11} were reductively cleaved with tributylphosphane (84% yield of ring formation, based on fully protected V). All *tert*-butyl groups were subsequently cleaved with trifluoroacetic acid. The *p*-methoxybenzyl group can be removed selectively with HF in pyridine in the presence of anisole (*ca.* 80%, by analogy with model studies). The remaining A-chain containing a single free SH-function was immediately dissolved in 30% acetic acid, mixed with the acetic acid solution of an equimolar amount of reduced natural B-chain from bovine insulin (two free SH-functions), and oxidized with 0.1 N iodine solution. The desired interchain disulfide bridge A^{20}—B^{19} was formed; subsequently, in the same reaction vessel the last Acm protective group was removed iodolytically and then also the second interchain disulfide bridge was formed oxidatively. The reaction product was immediately chromatographed in 10% acetic acid on Sephadex G 50. The fourth and fifth fractions of this first purification contained pure bovine insulin, which was electrophoretically and thin-layer chromatographically identical with authentic samples; yield 25%. This lyophilized crude product already showed 52% activity in the biological lipogenesis assay on fat cells and 65% activity in the competitive receptor binding assay. The Zn-complex showed the characteristic crystal form of insulin. After repeated gel chromatography on Biogel P6 in 1% acetic acid and ion-exchange chromatography on carboxymethylcellulose our semisynthetic bovine insulin was completely biologically active in both of the above mentioned assay systems.

Selectively cleavable sulfur protecting groups only on the insulin A-chain thus improve the yields of the combination of A- and B-chains (1:1) by more than 100% compared to the random combination. The strategy outlined here will be totally effective when B^7 is protected with Acm, and B^{19} protected with Mbzl allowing the SH-groups to be selectively liberated also in the B-chain.

Boat Conformation of *cyclo*-[L-Pro_2-D-Pro][**]

By *Jan Willem Bats, Axel Friedrich, Hartmut Fuess, Horst Kessler, Werner Mästle,* and *Manfred Rothe*[*]

Small cyclic peptides are particularly well suited for conformational studies since their restricted molecular mobility permits only few conformations. Most cyclotripeptides exist in solution in a crown conformation having C_3 skeletal symmetry[1] and in an unsymmetrical boat conformation[2]. In the crystalline state only the crown conformation has been detected so far[3]. NMR studies and stereochemical considerations showed that crown and boat forms coexist in solution whenever the cyclotripeptide contains at least one achiral amino acid (sarcosine, *N*-benzylglycine)[2]. However, if it consists exclusively of chiral amino acids then the conformation will be determined by their chirality: three amino acids of identical chirality impose the crown form; for differing chiralities the boat form has been predicted. Indeed we have proven that *cyclo*-[L-Pro_2-D-Pro][4] exists in the boat conformation in solution and in the crystal.

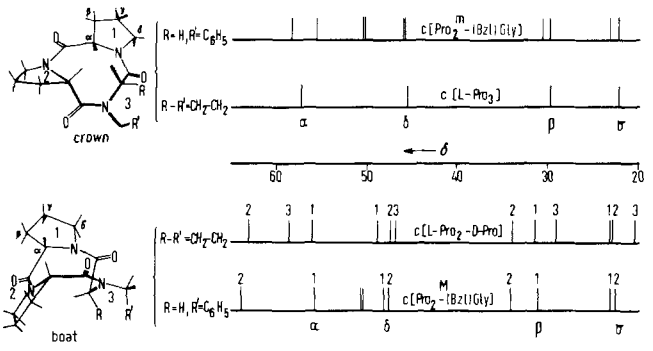

Fig. 1. Correlation of the ^{13}C-NMR chemical shifts of the aliphatic proline carbon atoms in cyclic tripeptides.

The ^1H- and ^{13}C-NMR spectra of the title compound show differences in the environment of the three proline rings. The chemical shifts of the ^{13}C-NMR signals in the aliphatic region (Fig. 1) closely resemble those of the conformation M of *cyclo*-[L-Pro_2-(Bzl)Gly] predominating in chloroform which has been shown to have the boat form[2a,5]. They differ characteristically from the spectra of *cyclo*-[L-Pro_3][6] which adopts the crown conformation and the crown form m of *cyclo*-[L-Pro_2-(Bzl)Gly][2a]. The signals of C_α and C_β of the proline ring 2 (Fig. 1) are shifted downfield as a consequence of the unusual value of the angle ψ at Pro^2 (see Table 1). In the 270-MHz ^1H-NMR spectrum recorded in $CDCl_3$, the α-protons appear as two triplets at $\delta = 4.47$ (ring 1) and 4.72 (ring 2), and as a doublet at $\delta = 4.70$ (ring 3)[7]. The coupling constants with the β-protons are in full accord with the values expected from the spectrum of *cyclo*-[Pro_2-(Bzl)Gly] and from consideration of models: Pro^1, $J_{12} \approx J_{13} \approx 7.2$ Hz; Pro^2, $J_{12} \approx J_{13} \approx 7.4$ Hz; Pro^3, $J_{12} \approx 1.4$ Hz, $J_{13} \approx 6.4$ Hz.

[**] Peptide Conformations, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Calculations were performed at the University Computing Center at Frankfurt.—Part 6: *H. Kessler, P. Kondor*, Chem. Ber., in press.

The title compound crystallizes from ether in the orthorhombic space group $P2_12_12_1$ with two independent molecules in the asymmetric unit. X-ray structure analysis also revealed the boat conformation for both molecules in the crystalline state[3c]. One of the two molecules is shown in Figure 2. The corresponding second molecule shows only minor differences. The conformational angles[8] are compared in Table 1 with those of *cyclo*-[L-Pro-(Bzl)Gly_2] which adopts the crown conformation in crystals obtained from methanol solution. The corresponding values in previously studied "crowns" are similar[3a, b].

Table 1. Conformational angles [°] in cyclic tripeptides [a].

	cyclo-[L-Pro-(Bzl)Gly_2] [3c]			*cyclo*-[L-Pro_2-D-Pro] Molecule A			Molecule B		
ϕ	−95	−103	−104	−45	−52	104	−47	−50	108
ψ	95	96	88	107	−21	−56	109	−20	−48
ω	0	9	6	−12	6	3	−17	7	−8
θ	93	80	82	131	137	−77	120	133	−89
$\theta-\phi$	188	183	186	176	189	−181	167	183	−197

[a] Definition of angles according to [8]: $\phi = C' \; C^{\alpha} \; N \; C$; $\psi = N \; C_{\alpha} \; C' \; N'$; $\omega = C_{\alpha} \; C' \; N \; C^{\alpha}$; $\theta = C_{\alpha} \; N \; C_{\alpha} \; C'$.

Surprisingly, the crystal structure deviates from the "ideal" boat conformation (Fig. 1) deduced from molecular models: steric hindrance between the C_{α} protons of Pro^1 and Pro^2 and between the C_{α} proton of Pro^3 and the peptide bond Pro^1–Pro^2 is alleviated by a twisting of the boat, although this leads to a certain degree of ring strain in a Dreiding model. The conformational angles for the "ideal" boat and for the twisted form (from models) are compared with the X-ray data in Table 2. The conformation in the crystal is seen to lie somewhere between the two idealized models.

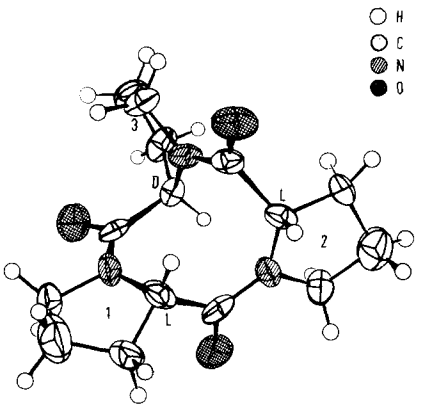

Fig. 2. Crystal structure of *cyclo*-[L-Pro^1-L-Pro^2-D-Pro^3].

Table 2. Comparison of the conformational angles ϕ and ψ [°] in the crystal (X-ray structure analysis) and in models.

	Pro	Boat [a]	Crystal [b]	Twisted boat [a]
ϕ	1	−33	−45	−70
	2	−85	−52	−20
	3	+100	+104	+105
ψ	1	+100	+107	+110
	2	+20	−21	−50
	3	−95	−56	−55

[a] Error ±5°. [b] Error ±2°.

Further remarkable features of the crystal structure are (i) the relatively slight deviation of the peptide bonds from coplanarity ($\omega = 0°$, $\theta - \phi = 180\,°C$, cf. Table 1) and (ii) the difference between the six proline rings in the two molecules of the crystal: only one of them has a twisted conformation while the other five have envelope conformations[3b, 3c]. These structures are probably separated by only slight energy barriers. This follows (a) from the difference in the proline ring conformations, which would appear to have its origin in crystal packing effects, and (b) from the large values of the thermal parameters of the β and γ carbons in the proline rings 2 and 1 (Fig. 2). We found that the volume of the ellipsoids of the title compound correlates well with the individual ^{13}C-NMR relaxation parameter (NT^1)[9] indicating a similar mobility in the solid state and in solution. A detailed report will be given elsewhere.

[7] The complex ^1H-NMR spin system of three superimposed 7-spin systems is resolved sufficiently by addition of benzene for the individual spin systems to be determined by decoupling experiments. Selective stepwise ^1H-decoupling also leads to correlation of the ^1H-spin systems with the corresponding ^{13}C-NMR signals. Assignment to the three proline rings is based on the absence of Pro^3 in M (Fig. 1), on the characteristic C_{α} and C_{β} shifts for Pro^2, and on the ^1H-NMR coupling constants.

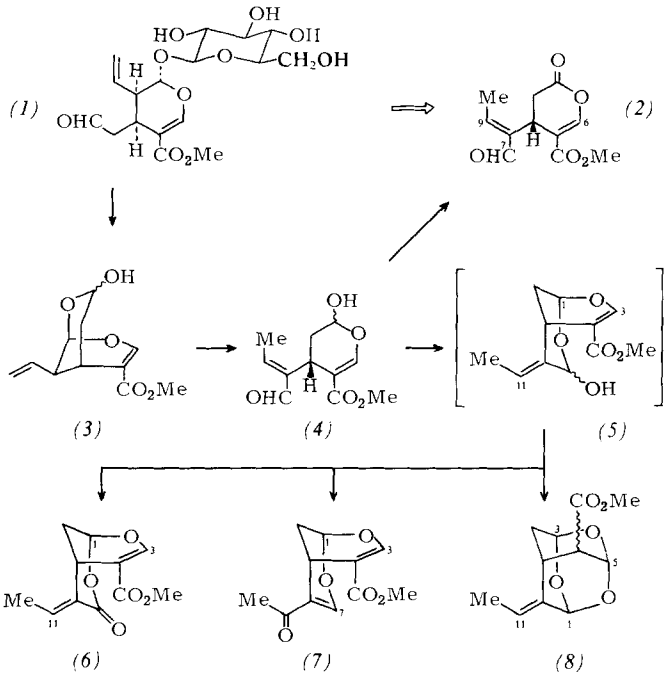
Use of Biogenetic Key Compounds for the Biomimetic Synthesis of Natural Products: (*S*)-Elenolide from Secologanin[**]

By *Lutz-F. Tietze* and *Horst C. Uzar*[*]

Biogenetic key compounds are excellent starting substances for the biomimetic synthesis of natural products and their analogs, since they can lead in a few steps to formation of enantiomerically pure products. Particularly interesting in this respect is the use of the monoterpene glycoside secologanin *(1)*, from which more than 1000, in part highly biologically active, alkaloids and other monoterpenes are formed *in vivo*[1]. In the present communication we describe a three-step synthesis of (*S*)-elenolide *(2)* from secologanin *(1)*.



Elenolide *(2)* was isolated together with the secologanin derivative oleuropein from *Olea europa* L.[2]; hence, it can be assumed that *(2)* is also formed from *(1)* in these plants[3]. We therefore examined the products of the enzymic cleavage of the glycoside bond in *(1)*. Acid catalyzed rearrangement (ether/HCl, 72 h) of the initially formed bicyclic compound *(3)* furnished the semiacetal *(4)* (53% yield) with *E*-configu-

[**] Iridoids, Part 11. This work was supported by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie.—Part 10: *L.-F. Tietze, P. Marx*, Chem. Ber. *111*, 2441 (1978).

ration of the exocyclic double bond[4]. Oxidation of *(4)* with pyridinium chlorochromate in the presence of sodium acetate[5] afforded elenolide *(2)*[6] in 85% yield [CH_2Cl_2, 20 °C, 90 min; $R_F = 0.31$ (silica gel/ether), m.p. 156 °C (155–156 °C[2])] and, *via* the semiacetal *(5)*, 5% of the lactone *(6)*[6] ($R_F = 0.38$).

From the NMR signal of the aldehyde proton of *(2)* at $\delta = 9.20$ we assume that the exocyclic double bond is in the *E*-configuration (*Z*-configuration, see [2, 7]). Synthesis of *(2)* from *(1)* with known absolute configuration shows the chirality center in *(2)* to be in the *S*-configuration.

Oxidation of *(4)* in the absence of sodium acetate requires 9 h and, in addition to *(2)* (28% yield) and *(6)* (16%), ketone *(7)*[6] (11%, $R_F = 0.26$) and the trioxaadamantane *(8)*[6, 8] (1.2%, $R_F = 0.54$) are also formed. The formation of *(7)* can be explained by oxidation of an intermediary allyl cation formed from *(5)* by acid catalysts, and formation of *(8)* by addition of the hydroxy group to the α,β-unsaturated ester system in *(5)*.

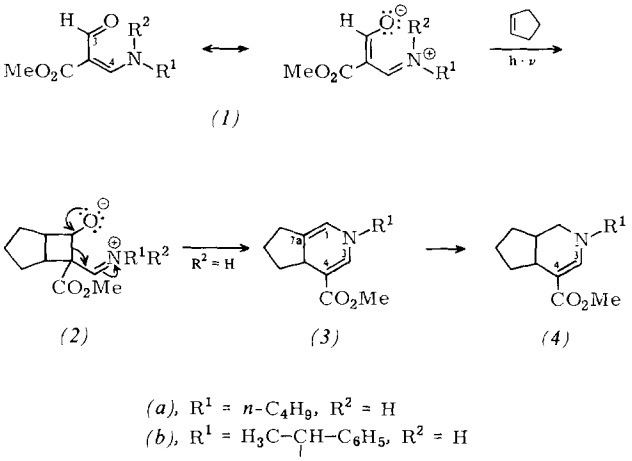
Synthesis of 1,4-Dihydronicotinic Acid Derivatives by Photochemical Cycloaddition[**]



By *Lutz-F. Tietze* and *Klaus Brüggemann*[*]

1,4-Dihydronicotinic acid derivatives are of great therapeutical value in the treatment of coronary circulatory disorders[1]. They are also of interest as components of the oxidoreductases. We describe here a facile synthesis of this class of substances by photochemical cycloaddition of vinylogous formamides to olefins.

Irradiation of the *N*-monosubstituted compounds *(1)*[2] in cyclopentene at −40 °C with a high-pressure mercury vapor lamp affords the 1,4-dihydronicotinic acid derivatives *(3)*[3] in almost quantitative yields. A possible intermediate formed during the irradiation can be formulated as a cyclobutane derivative *(2)*, which can undergo hetero-retroaldol cleavage and recyclization to *(3)*. Hydrogenation of *(3)* with Pd/C in methanol affords *(4)*, and with Pt/C in glacial acetic acid the perhydrogenated products.

In contrast to *(1a)* and *(1b)* the *N,N*-diethyl- and *N,N*-dibenzyl-analogs fail to give any cycloaddition products. This is presumably due to the fact that the *cis*-s-*cis*-configuration[4] in these cases cannot be stabilized by hydrogen bonding[5].

The vinylogous formamides *(1)* can readily be obtained in 60–90% yield by reaction of methyl diformylacetate[6] with the corresponding amines in the presence of sodium sulfate (toluene, 20 °C, 2 h).

(a), $R^1 = n\text{-}C_4H_9$, $R^2 = H$
(b), $R^1 = H_3C\text{–}\underset{|}{C}H\text{–}C_6H_5$, $R^2 = H$

Procedure

A solution of *(1a)* (3.00 g, 16.2 mmol) in 300 ml cyclopentene/ether (1:1) was cooled to −40 °C, flushed with nitrogen to remove oxygen and irradiated in a Pyrex apparatus for 7 h with a high-pressure mercury vapor lamp (TQ 718, Hanau, cooling jacket −40 °C). The progress of the reaction could be followed chromatographically (silica gel/ether) and UV-spectroscopically. After removal of solvent by evaporation in a high vacuum the product *(3a)* was purified by preparative thin-layer chromatography (yield 82%). *(3a)* rapidly decomposes in the pure state and can be stored only for a limited period in solution at −30 °C.

Fragmentation of γ-Hydroxyammonium Compounds to Unsaturated Aldehydes by Flash Thermolysis[**]

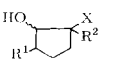
By *Lutz-F. Tietze, Günther Kinast*, and *Horst C. Uzar*[*]

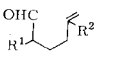
The base-induced fragmentation of the monotosylates of 1,3-diols[1] is a simple and well-known method for the synthesis of unsaturated ketones. Only in exceptional cases can unsaturated aldehydes, *e.g. (3a)*, be synthesized *via* this route, *e.g.* from *(1)*, since addition occurs as a rapid secondary reaction[2]. We have now demonstrated that flash thermolysis[3] of the analogous γ-hydroxyammonium hydroxides *(2)*, *(4)* and *(6)* at 350—450 °C, on the other hand, leads to the aldehydes *(3)*, *(5)*, and *(7)* in good yields[4]. Unsaturated ketones can also be prepared by this method[5].

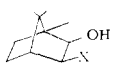
A 1 M aqueous solution of the γ-hydroxyammonium hydroxides or hydrogen carbonates is used for the reaction. The ammonium acetates or halides give only small amounts of fragmentation product, while the ammonium hydrogen sulfides are almost quantitatively demethylated at the nitrogen.

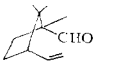
The difficult problem of optimization of the contact times in the flash thermolysis is not encountered since the reactants are non-volatile salts. Likewise, other than in *(1)*, the relative configuration of the substituents on the ring system has no influence on the proportion of fragmentation in the overall decomposition[2,6]. The results are listed in Table 1.

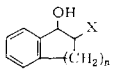
The requisite γ-hydroxyammonium compounds can be prepared from cyclic ketones by aminomethylation[7], reduction ($NaBH_4/MeOH/NH_3$), reaction with MeI and ion-exchange. The synthetic sequence with subsequent fragmentation permits conversion of cyclic ketones into open-chain, terminally unsaturated aldehydes containing one more carbon atom. Thus, this method could also be used for the synthesis of the aglycon *O*-methyl ether *(10)*[2] of secologanin[8], a key compound for the biogenesis of more than 1000 alkaloids and other monoterpenes. The ammonium hydrogen carbonate *(9)* was prepared from the ketone *(8)*[9]. Subsequent thermal fragmentation in a flow system at 350 °C/15 torr led to *(10)*, which was isolated by column chromatography in a total yield of 10% (based on *(8)*; not optimized). Structural isomers of *(10)*, which could be formed by aminomethylation at C-5, could not be detected.

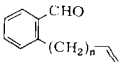












(8) → *(9)* → *(10)*

Procedure

A 1 M aqueous solution of γ-hydroxyammonium hydroxide (50 mmol) is introduced dropwise at a rate of *ca.* 1 ml/min onto heated silica beads (350—450 °C) in a thermolysis system fitted with a quartz condenser (length: 25 cm, diameter: 1.6 cm, external heating up to condenser) and through which a stream of N_2 is flowing at the rate of 20 ml/min. The system is subsequently flushed twice with 5 ml H_2O and twice with 5 ml dichloromethane. The thermolyzate is extracted three times with 50 ml dichloromethane, washed with 3 × 5 ml 2 N HCl and twice with 5 ml 5% $NaHCO_3$ solution, and the residue left on removal of solvent is distilled.

(1) *(2)* *(3)*

Table 1. Unsaturated aldehydes by fragmentation of γ-hydroxyammonium hydroxides. X = CH_2 $\overset{\oplus}{N}Me_3OH^{\ominus}$.

	Reactants [a]		M.p. of the iodide [°C]		Products [a]	Reaction temp. [°C]	Yield [b] [%]
(2a)		$R^1 = R^2 = H$	183	*(3a)*		450	73/43
(2b)		$R^1 = H$, $R^2 = Me$	166	*(3b)*		350	78/62
(2c)		$R^1 = R^2 = Me$	—	*(3c)*		350	82/70
(4)			298—299	*(5)*		450	89/80
(6a)		$n = 1$	219—220	*(7a)* [d]		450	82/60 [c]
(6b)		$n = 2$	189—191	*(7b)*		350	62/55
(6c)		$n = 3$	234—235	*(7c)*		350	81/70

[a] Constitution and configuration of the reactants (as ammonium iodides instead of hydroxides) and products are confirmed by spectroscopic data and combustion analysis. [b] Gas-chromatographically determined yields (2.5% silicone rubber SE 52 on Chromosorb G-NW-DMCS, 2 m, internal standard)/yields isolated after distillation. [c] The 2-methyl-1-indanone that is also formed was separated by column chromatography on silica gel (benzene). [d] Double-bond isomers are also formed.

Co^{II} with Coordination Number 3: $Na_4[CoO_3]$—The First Oxocobaltate(II) with an Island Structure[1]

By *Wilfried Burow* and *Rudolf Hoppe*[*]

"Cation-rich" oxides of the alkali metals[2] exhibit surprising structural characteristics. Thus $K_2[NiO_2]$[3] contains CO_2-analogous dumbells O Ni O having an extremely short interatomic distance d(Ni O) = 1.68 Å with a three-dimensional arrangement corresponding to the XeF_2 type[4]. The first CO_3^{2-}-analogous "anion" in such oxides was found in the case of $Na_4[FeO_3]$[5], the only oxoferrate(II) known so far. The search for the corresponding cobaltate led first to $Na_{10}[Co_4O_9]$[6] with an anion analogous to tetracarbonate.

We have now been able to synthesize $Na_4[CoO_3]$, which is an oxocobaltate having an island structure [mixture of Na_2O + CoO, Na:Co = 4.4:1, sealed Co tube, 550 °C, 20 d, under dry argon in Supremax ampoule]. The preparation of untwinned single crystals proved extremely difficult.

$Na_4[CoO_3]$ appears bright red; the single crystals are coarse and transparent. Hydrolysis occurs immediately on contact with atmospheric moisture; this is accompanied by oxidation of Co^{II} to Co^{III} with dark coloration.

According to Weissenberg photographs, $Na_4[CoO_3]$ forms triclinic crystals with $a = 8.14_4$, $b = 6.22_0$, $c = 5.75_8$ Å, $\alpha = 117.5_4$, $\beta = 89.9_9$, $\gamma = 111.2_4$° in the space group P1; $Z = 2$ (four-circle diffractometer data). The structure was determined from 2358 symmetry-independent reflections (Mo-Kα, graphite monochromator, $6° \leq \theta \leq 36°$)[7] by three-dimensional Patterson synthesis; refinement with anisotropic temperature parameters for all particles gave $R = 5.97\%$ for 1808 reflections (cf. Fig. 1).

Primary structure: Each Co atom is in a planar environment of three O atoms d(Co^1 O) = 1.81, 1.86, 1.92 Å; d(Co^2 O) = 1.80, 1.88, 1.90 Å; sum of the O Co O angles = 359.8° for the two Co. One quarter of the eight Na particles have coordination number (C.N.) 3, and the others C.N. 4 with regard to oxygen. This follows from the composition, assuming that all O have C.N. 6 with respect to the cations and each Co a C.N. of at least 3 with regard to O (cf. the motives of the mutual adjunction in Table 1). The distances d(Na O) vary between 2.21 and 2.54 Å; d(Na^2 O^5) = 2.79 and d(Na^3 O^6) = 2.80 Å were also considered.

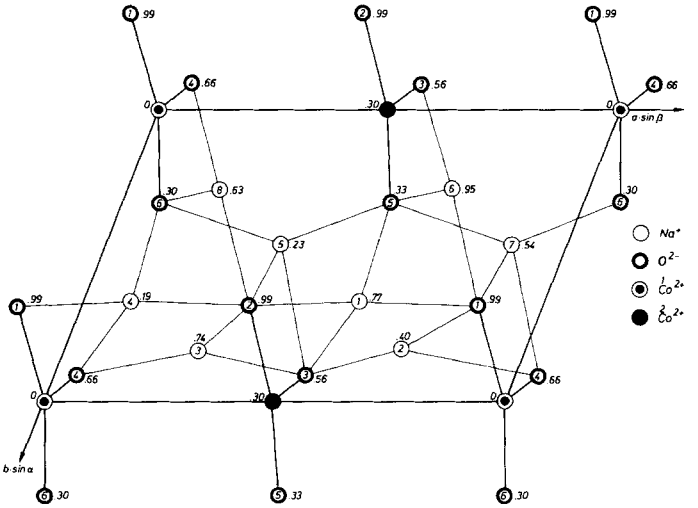

Fig. 1. Crystal structure of $Na_4[CoO_3]$ projected along [001]. Heights z as fractions of c.

Table 1. Motives of mutual adjunction in $Na_4[CoO_3]$.

	O^1	O^4	O^6	O^2	O^3	O^5	C.N.
Co^1	1/1	1/1	1/1				3
Co^2				1/1	1/1	1/1	3
Na^4	1/1	1/1	1/1	1/1			4
Na^7	1/1	1/1	1/1			1/1	4
Na^2	1/1	1/1			1/1	1/1 (2.79)	3 (+1)
Na^3		1/1	1/1 (2.80)	1/1	1/1		3 (+1)
Na^1	1/1			1/1	1/1	1/1	4
Na^5			1/1	1/1	1/1	1/1	4
Na^6	1/1				1/1	1/1	3
Na^8		1/1	1/1	1/1			3
C.N.	6	6	5 (+1)	6	6	5 (+1)	

"Long" Na O distances [Å] given in parentheses.

Secondary structure: Neither the coordination polyhedra around Co nor those around Na form discrete groups such as $[Co_2O_6]$.

Tertiary structure: The coordination polyhedra of O around Na undergo complicated three-dimensional linkage, with Co occupying vacancies in the three-dimensional Na_8O_6 network.

The Madelung part of the lattice energy (MAPLE[8] = 5006.6 kcal/mol) is in accord with the sum of the MAPLE values of the binary oxides (4957.2 kcal/mol, ΔMAPLE = 0.99%).

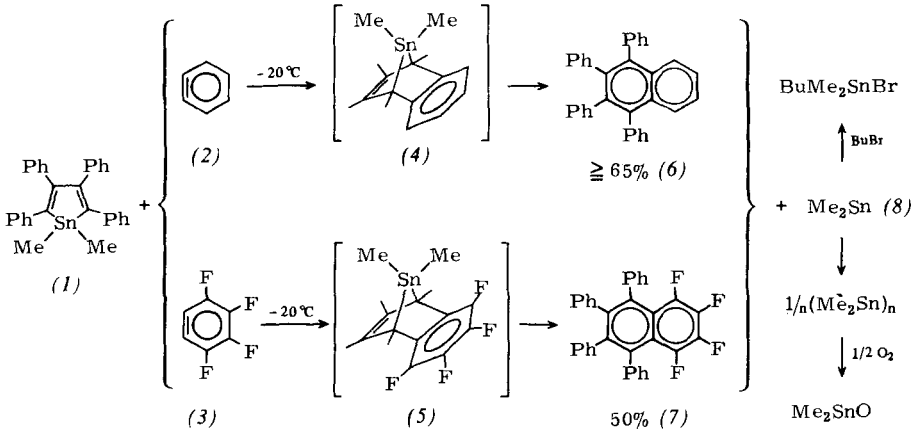
Reaction of *(1)* with tetracyanoethylene at $-30\,^{\circ}C$ proved more successful: The [4+2]-cycloadduct 5,5,6,6-tetracyano-7,7-dimethyl-1,2,3,4-tetraphenyl-7-stannanorbornene *(9)* could be isolated as colorless crystals and was unequivocally identified by elemental analysis and ^1H-NMR spectroscopy [CH_2Cl_2; $\delta = 1.2$ (3H, s), $J(SnCH_3) = 52$ Hz; 1.43 (3H, s), $J(SnCH_3) = 48$ Hz; 6.8–7.5 (20H, m)].



The new compound *(9)* is stable at $-30\,^{\circ}C$ for at least several weeks but decomposes above $-20\,^{\circ}C$ in a first order reaction [$t_{1/2} = 17$ min, $k_2 = 6.8 \times 10^{-4}\ s^{-1}$ at $-10\,^{\circ}C$] to *(8)* and 5,5,6,6-tetracyano-1,2,3,4-tetraphenyl-1,3-cyclohexadiene *(10)*, hitherto unknown. In the presence of the strong stannylene scavenger dimethyl acetylenedicarboxylate *(8)* gives a polymer or is trapped as the adduct *(11)* of still unknown structure. As can be seen, k_2 is much smaller than k_1

The First Stable Derivative of 7-Stannanorbornane and Its Thermolysis[1]

By *Christian Grugel, Wilhelm P. Neumann*, and *Michael Schriewer*[*]

Unsaturated 7-heteronorbornanes are important as precursors of carbene analogues[2]. In connection with our investigations on "stannylenes" (stannanediyls) R_2Sn[3], we became interested in the unsaturated 7-stannanorbornanes which were apparently hitherto unknown[4]. Attempted Diels-Alder type reaction of the stannol *(1)* with the highly reactive dienophile dehydrobenzene *(2)* or 1,2,3,4-tetrafluorodehydrobenzene *(3)* failed to give the expected 7-stannanorbornadienes *(4)* or *(5)*. Instead, we isolated only *(6)* and *(7)*, and products apparently resulting from the transient stannylene Me_2Sn *(8)*:

at $-10\,^{\circ}C$, and is neither increased nor diminished by the scavenger.

^{119}Sn-CIDNP effects, which could occur as a two-step mechanism by recombination (k_3) of the diradical *(12)*, have not been observed during thermolysis of *(9)*[5]. Thus, we assume the *formation of a free stannylene (8) by a concerted mechanism.*

Procedure

(1) (1.00 g, 2 mmol) and tetracyanoethylene (0.26 g, 2 mmol) are dissolved in 5 ml CH_2Cl_2 at $-30\,^{\circ}C$. The reaction mixture is stirred for 1 h before adding 10 ml of previously cooled pentane. Within 2 h a colorless finely crystalline precipitate of *(9)* is formed. This is filtered off at $-30\,^{\circ}C$, washed with pentane, and dried at 10^{-3} torr; yield *ca.* 1 g (80%).

When a solution of *(9)* (0.63 g) in CH_2Cl_2 (5 ml) prepared at $-30\,^{\circ}C$ is allowed to warm to room temperature, subsequent passage of air leads to precipitation of Me_2SnO (106

mg, 64%). After filtration and addition of ethanol to the filtrate (v/v = 1:1), cooling of the mixture affords *ca.* 300 mg (60%) of colorless feathery crystals of *(10)* which slowly turn yellow on exposure to air, decomp. pt. 217 °C ^{1}H-NMR: $\delta = 7.3$ (m), 7.7 (m). The kinetics of the thermolysis of *(9)* can be determined by ^{1}H-NMR spectroscopy from the diminution of the two $SnCH_3$ singlets.

1,3-Di-*tert*-butylcyclooctatetraene[**]

By *Gregory Wells, Yuji Hanzawa*, and *Leo A. Paquette*[*]

Despite a recent renewed surge of interest in cyclooctatetraene chemistry, directed synthetic approaches to certain derivatives of this ring system are still lacking. The problem is most acute when the 1,3-disubstitution plan is desired, 1,3-dimethylcyclooctatetraene, available by pyrolysis of 2,8-dimethylsemibullvalene, constituting the only known example. Presently, we describe an expeditious new entry to such molecules as exemplified by the preparation of 1,3-di-*tert*-butylcyclooctatetraene *(4)*.

Oxidation of commercially available 3,5-di-*tert*-butylcatechol *(1)* according to literature directions[1] gave the *o*-quinone *(2)* (maroon needles, m.p. 114–115 °C). On treatment with cyclobutadiene as liberated from its $Fe(CO)_3$ complex[2], *(2)* was transformed in 51% yield to the Diels-Alder adduct *(3)* which was isolated as a bright yellow crystalline solid (see Table 1).

Advantage was now taken of the reported ease of photochemical bisdecarbonylation of unsaturated bicyclic α-diketones to dienes and carbon monoxide[3]. Thus, irradiation of chloroform solutions of *(3)* with a 450-W Hanovia lamp at 0 °C for 90 min afforded the title cyclooctatetraene *(4)* in 77% yield. Compound *(4)* enters into cycloaddition with 4-phenyl-1,2,4-triazolinedione in refluxing ethyl acetate solution and delivers exclusively the cycloadduct *(5)* (Table 1) where the bulky *tert*-butyl substituents are expectedly[4] positioned on the cyclobutene ring. Submission of *(5)* to sequential alkaline hydrolysis and manganese dioxide oxidation[5] regenerated *(4)*, a colorless liquid.

Table 1. Physical data of the new compounds *(3)*—*(5)*.

(3), m.p. 120–122 °C; ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 6.0$—5.75 (m, 3H), 3.6–3.38 (m, 1H), 3.34–3.12 (m, 2H), 1.14 (s, 9H), 0.98 (s, 9H); MS: $m/e = 272.1776$ (calc.), 272.1783 (exp.)

(4), ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 6.08$–5.37 (m, 6H), 1.08 (s, 9H), 1.05 (s, 9H); ^{13}C-NMR ($CDCl_3$, TMS): $\delta = 153.66$, 150.86, 132.61, 132.32, 130.43, 130.00, 123.41, 120.90, 36.55, 36.27, 29.87, 29.77

(5), m.p. 149–150 °C; ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 7.38$ (m, 5H), 6.3 (ddd, $J = 7$, 6.5, 2 Hz, 1H), 5.94 (ddd, $J = 6.5$, 6.5, 1.5 Hz, 1H), 5.60 (d, $J = 2$ Hz, 1H), 5.2–4.82 (m, 2H), 3.12 (dd, $J = 4.5$, 2 Hz, 1H), 1.13 (s, 9H), 1.02 (s, 9H)

Consideration of the ground state "tub" geometry of *(4)* reveals the molecule to belong to the C_1 point group. This asymmetry requires the two *tert*-butyl groups to be chemically different, barring rapid π-bond shifting under the conditions of spectral measurement. In agreement with the *apparently* static nature of *(4)* at ambient temperature, its ^{1}H-NMR spectrum (Table 1) consists of a series of multiplets due to the six olefinic protons and a pair of singlets at $\delta = 1.08$ and 1.05 (9H each). Additionally, the ^{13}C-NMR spectrum (Table 1) displays 12 peaks. The chiral nature of *(4)* is currently being investigated[6].

The scope of the illustrated cyclooctatetraene synthesis is, of course, dictated by the availability of monocyclic *o*-benzoquinones. This class of compounds has proven to be conveniently accessible[7].

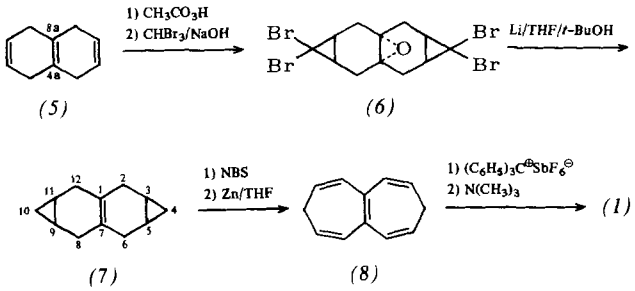
Heptalenebis(tricarbonyliron)

By *Emanuel Vogel, Dimitrios Kerimis, Neil T. Allison, Robert Zellerhoff,* and *Jürgen Wassen*[*]

Dedicated to Professor Tetsuo Nozoe on the occasion of his 77th birthday

In accord with expectation, the 12π-electron system heptalene *(1)* previously characterized by spectroscopic[1a] and structural[1b] investigations as being an olefin, readily reacts with electrophilic agents, but the heptalenium salts formed thereby in some cases have hitherto defied all attempts at transforming them into substituted heptalenes. However, after independently synthesized disubstituted heptalenes had been shown to be stable compounds[2], renewed attempts at the derivatization of *(1)* seemed warranted. We have now found that *(1)* can be substituted in the 1,6 position by way of heptalenebis(tricarbonyliron) *(2)*.



Heptalenebis(tricarbonyliron) *(2)*, which in contrast to the free ligand is completely air-stable, is formed as the major product when *(1)* is heated with benzylideneacetone(tricarbonyliron) (molar ratio 1:2.5) in toluene for 15 h at 50 °C. After chromatographic separation on silica gel (ether/pentane), *(2)* crystallizes from tetrachloromethane as deep-red rhombs; yield 35—40%.

The structure of the new heptalene-transition metal complex *(2)* (excluding the stereochemistry) follows from the ^{1}H-NMR spectrum (Table 1). This shows an ABCDE spin system which, considering both decoupling experiments and the fact that the protons of diene-Fe(CO)$_3$ moieties absorb at higher field strength than the protons of uncomplexed double bonds, is compatible only with the structure *(2)*. The number and positions of the ^{13}C-NMR signals also lend support to structure *(2)*. The stereochemistry of the complex *(2)* has recently been elucidated by an X-ray structure analysis by *H. J. Lindner et al.*[3]: surprisingly, it is found that both Fe(CO)$_3$ groups are located on the same side of the heptalene ligand.

From experience gained with other olefin-tricarbonyliron complexes[4] it appeared that formylation by the Vilsmeier method would be the most favorable approach for electrophilic substitution of *(2)*. Indeed, it was found that reaction of *(2)* with phosphorus oxide chloride (molar ratio 1:20) in dimethylformamide (initially at 0 °C and then 12 h at 50 °C) afforded a formylation product, which was isolated as red-brown crystals after chromatography on silica gel (ether/pentane) and recrystallization from ether/pentane; yield 20%. Interestingly, this product proved to be the uncomplexed 1,6-heptalenedicarbaldehyde *(3)*. Like the known heptalenes bearing two electronegative substituents, *(3)* is also air-stable.

It could be concluded from the changes observed in the ^{1}H-NMR spectrum of *(3)* below −40 °C that a rapid π-bond shift takes place in the molecule and that the two nonequivalent double bond isomers existing in equilibrium with each other are present in a ratio of 1:1. From the coalescence ($T_c = -70$ °C; $\delta\nu = 38$ Hz) of the aldehyde proton signals it follows that the activation enthalpy $\Delta G^{\neq}$ of the π-bond shift is 9.9 kcal/mol.

1,6-Heptalenedicarbaldehyde *(3)* is a suitable starting compound for the synthesis of dimethyl 1,6-heptalenedicarboxylate *(4)* and other 1,6-disubstituted heptalenes. The diester *(4)*, readily accessible by *Corey*'s method[5] [red prisms (from hexane); yield 41%], is likewise a dynamic system containing almost equal proportions of the two double-bond isomers, as was deduced from the temperature dependence of the ^{1}H-NMR spectrum (Table 1) (changes in the methyl proton signals: $T_c = -17$ °C; $\delta\nu = 2.8$ Hz). It seems remarkable that the replacement of the aldehyde groups in *(3)* by the carbomethoxy groups increases the free enthalpy of activation of the π-bond shift from 9.9 to 14 kcal/mol. This is undoubtedly due to steric effects.

The complex *(2)* promises to open up new perspectives in heptalene chemistry provided that better routes to the hydrocarbon become available. A practical novel synthesis of heptalene, based on the observation that the tetrasubstituted double bond of isotetralin *(5)* can be protected by a reversible epoxidation, has now been developed.

11-Oxatricyclo[4.4.1.0]undeca-3,8-diene, which can be obtained selectively from isotetralin *(5)*, reacts with bromoform (fivefold excess) and 50% sodium hydroxide in the presence of benzyltriethylammonium chloride (TEBA) to give the bisadduct *(6)*[6] having cyclopropane rings *trans* to the oxirane ring [m.p. 100 °C (decomp.); yield 60—70%]. Treatment of *(6)* with lithium and *tert*-butanol in tetrahydrofuran (24 hours' heating under reflux after the initially vigorous reaction has subsided) leads both to the reductive elimination of the four bromine atoms as well as to deoxygenation of the epoxide ring, *i.e.* the hydrocarbon *(7)* is formed in one step (yield 50—55%; see Table 1). Since the bromine atoms are removed more rapidly than the epoxide oxygen, it is possible to isolate the epoxide of *(7)*, *trans,trans*-13-oxapentacyclo[5.5.1.0^{1,7}.0^{3,5}.0^{9,11}]tridecane (m.p. 71—72 °C; yield 60—65%) if the duration of reaction is kept short. In order to transform *(7)* into *(8)*, *(7)* was heated with *N*-bromosuccinimide (NBS) (molar ratio 1:6) in the presence of azobisisobutyronitrile in tetrachloromethane (60 min), and the resulting semicrystalline mixture, consisting mainly of the expected tetrabromo-substitution product (stereoisomers), was then dehalogenated in the crude state with zinc in tetrahydrofuran (30 min reflux). Subsequent distillation in a high

vacuum afforded the previously unknown 3,8-dihydroheptalene (b.p. 44—45 °C/*ca.* 10 $^{-4}$ torr) having a purity of 95% (yield 35—40%). At this stage *(8)* is sufficiently pure for use in further reactions, but if necessary it can be purified by crystallization from pentane at low temperature, albeit at the expense of loss in yield[7]. Conversion of *(8)* into *(1)* could be accomplished, as already described for the isomeric dihydroheptalenes[1a], by dehydrogenation–hydride abstraction with triphenylmethyl hexafluoroantimonate in dichloromethane and deprotonation with trimethylamine (yield 88—93% and 55—60%, respectively). The hitherto unknown intermediary heptalenium salt was isolated, m.p. 155 °C (decomp). Another practical heptalene synthesis, also starting from isotetralin, has been developed independently by *Paquette* and co-workers[8].

Table 1. Physical data of compounds *(2)*, *(3)*, *(4)*, *(7)*, and *(8)*.

(2). m.p. 185 °C (decomp.); UV (cyclohexane): $\lambda_{max} = 286$ nm ($\varepsilon = 17200$), 329 (21100), 443 (8800); IR (CCl_4): 2058, 2040, 1988, 1975 cm^{-1} (C O); ^{1}H-NMR (C_6D_6): $\delta = 2.44$ (t, H-4, 9), 2.98 (d, H-1, 6), 4.60 (m, H-2, 7), 4.79 (m, H-3, 8), 5.46 (d, H-5, 10) [a]

(3). m.p. 105 °C; UV (ethanol): $\lambda_{max} = 290$ nm ($\varepsilon = 15800$), 362 (5100), 485 (860); IR (CsI): 1670 cm^{-1} (C O); ^{1}H-NMR [$CDCl_3$; room temperature (region of rapid exchange)]: $\delta = 6.11$ (d, H-5, 10), 6.65 (m, H-3, 4, 8, 9), 7.08 (d, H-2, 7), 9.80 (s, 2 CHO)

(4). m.p. 90–91 °C; UV (ethanol): $\lambda_{max} = 271$ nm ($\varepsilon = 1700$), 334 (4300), 420 (790, sh); IR (CsI): 1720 cm^{-1} (C O); ^{1}H-NMR [[D_2]-tetrachloroethane; +110 °C (region of rapid exchange)]: $\delta = 3.70$ (s, 2 CH_2), 6.13 (m, H-5, 10), 6.50 (m, H-3, 4, 8, 9), 7.15 (d, H-2, 7)

(7). b.p. 52–53 °C/0.4 torr: ^{1}H-NMR ($CDCl_3$): $\delta = 0.22$ (m; H-4, 4, 10, 10), 0.95 (m, H-3, 5, 9, 11); 2.1 (m, H-2, 2, 6, 6, 8, 8, 12, 12)

(8). m.p. 33–34 °C; UV (cyclohexane): $\lambda_{max} = 230$ nm ($\varepsilon = 40900$, sh), 234 (43100), 299 (7700); ^{1}H-NMR (CCl_4): $\delta = 2.16$ (t, $J = 6.8$ Hz, H-3, 3, 8, 8), 5.50 (dt, $J_{12} = 10.2$ Hz, $J_{23} = 6.8$ Hz, H-2, 4, 7, 9), 6.25 (d, $J = 10.2$ Hz, H-1, 5, 6, 10)

[a] A closer study of the ^{1}H- and ^{13}C-NMR spectra of this complex has shown that the double bonds which are localized at room temperature, as in structure *(2)*, migrate at higher temperature with simultaneous 1,2-shift of the $Fe(CO)_3$ groups, the reactant and product being in the relationship of enantiomers; cf. the dynamic behavior of cyclooctatetraene(tricarbonyliron): *F. A. Cotton, D. L. Hunter*, J. Am. Chem. Soc. *98*, 1413 (1976).

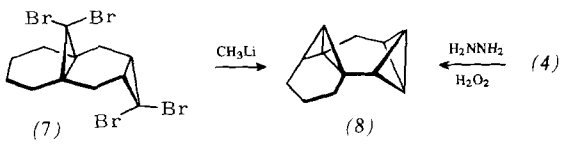
An Expeditious Synthesis of Heptalene from Naphthalene *via* a Bis(bicyclo[1.1.0]butane) Intermediate[**]



By *Leo A. Paquette, Alan R. Browne*, and *Ernest Chamot*[*]

To the present time, two syntheses of heptalene *(1)* have been reported[1,2] and access has been gained to a few derivatives. While both routes to *(1)* are elegant in their conception, they are lengthy, and the hydrocarbon has therefore remained difficultly accessible. As a result, theoretical predictions often have preceded the execution of experimental work in this field.

In this communication we describe an efficient six-step conversion of naphthalene to *(1)*. The new methodology capitalizes on the regiospecificity of two-fold intramolecular carbene insertion to give *(4)*[3] and the ability of silver(I) ions to promote the isomerization of bicyclo[1.1.0]butanes to ring-opened conjugated dienes[4].

Addition of dibromocarbene to tetrahydronaphthalene (isotetralin) *(2)*[5] using a modification[6] of *Vogel*'s procedure[7] afforded bisadduct *(3)* (38%) admixed with the corresponding mono- (12%) and tris-adducts (0.8%). These products could be efficiently separated by recrystallization; resubmission of the monoadduct to the same reaction conditions returned additional *(3)* in 72% yield. When the tetrabromide *(3)* was treated with 2 M ethereal methyllithium at 0—25 °C for 3 h, the colorless bis(bicyclo[1.1.0]butane) *(4)* was obtained in 59% yield *after molecular distillation* (80—100 °C/0.3 torr). The ^{1}H-NMR spectrum of *(4)* (C_6D_6) contains two series of multiplets at $\delta = 6.03$—5.06 (2H) and 2.46—1.11 (10H) while its ^{13}C-NMR exhibits 12 lines, thus demonstrating the isomeric homogeneity of the hydrocarbon. The definitive structural assignment follows from the Ag^+-catalyzed isomerization of *(4)* exclusively to 1,6-dihydroheptalene *(5)* and catalytic hydrogenation of this pentaene to *cis*-bicyclo[5.5.0]dodecane[2]. Whereas *(5)* belongs to the C_{2h} point group, the 1,10 isomer *(6)* has C_{2v} symmetry; a clear distinction between them becomes apparent upon ^{13}C-NMR analysis (in $CDCl_3$) which reveals the six lines ($\delta = 132.8$, 131.0, 125.6, 123.6, 123.0, and 33.6) demanded uniquely by *(5)*.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0707-0546 $ 02.50/0

The regiospecificity observed in the carbene insertion step to give *(4)* would appear to have its origins in the geometric constraints generated by one bicyclobutane unit upon formation of the second. Molecular models reveal that closure of either the central or peripheral carbene produces conformationally rigid intermediates in which the second insertion is forcibly directed away from the first-formed bicyclobutane ring. To establish that the double bond in *(3)* did not contribute additionally to the regiospecificity, the tetrabromide *(7)*[6] was reacted with methyllithium. Separation of *(8)* (46%) from an ether insertion product was achieved by distillation (b.p. 52—58 °C/0.2 torr). The homogeneity of hydrocarbon *(8)* was established spectroscopically and by VPC methods. As a check on the directionality of the ring closure, *(4)* was transformed into *(8)* by diimide reduction.

Although the pair of bicyclo[1.1.0]butane rings within *(4)* and *(8)* are formally conjugated, these molecules show only customary end absorption in the ultraviolet. Thus, electronic interaction between bicyclobutane orbitals becomes observable only when the connective bond is linked to the bridgehead carbon atoms[8]. A remarkable feature of these molecules is their stable nature, despite a strain energy which must be in excess of 120 kcal/mol[9].

(9)   *(10)*

The ultimate conversion of *(5)* into *(1)* was carried out according to *Dauben*'s original procedure[2]. The brownish red heptalene *(1)* entered readily into reaction with 4-phenyl-1,2,4-triazolinedione to give in good yield a 10:1 mixture of an amorphous solid and a microcrystalline substance (m.p. >310 °C). The monomeric nature of these cycloadducts was deduced by mass spectrometry (M^+ 329) and their inherent symmetry by ^{13}C-NMR spectroscopy (seven signals arising from the carbocyclic ring C atom of which two are quaternary). The closely similar ^{1}H-NMR spectra are characterized, *inter alia*, by an eight-proton olefinic multiplet and a multiplet (2H) for the allylic protons vicinal to nitrogen. Their almost superimposable ultraviolet spectra [$\lambda_{max}^{C_2H_5OH}$ 250 sh nm (ε = 11500—12000)] compare closely to that exhibited by *(8)*[2]. On this basis, the adducts are formulated as *(9)* and *(10)*, although no distinction between the C_2 and C_s forms has been made.

Tellurium-Catalyzed Reaction of Amines with Carbon Monoxide

By *Nobuaki Kambe, Kiyoshi Kondo, Hideo Ishii, Shinji Murai*, and *Noboru Sonoda*[*]

The simplest way of making urea derivatives from amine and carbon monoxide may be represented by eq. (a). In this communication, we wish to report that the reaction (a) can be catalyzed by elemental tellurium. This is the first example of activation of carbon monoxide by tellurium and of the formation of equimolar amounts of ureas and hydrogen:

$$\underset{(1)}{2\,RNH_2} + CO \xrightarrow[Te]{} \underset{(2)}{(RNH)_2CO} + H_2 \qquad (a)$$

No typical element was previously known to catalyze this reaction. Among group 6B elements, selenium catalyzes the formation of ureas from amines and carbon monoxide, but only in the presence of oxygen; moreover, water is then produced instead of hydrogen[1]. Sulfur is uneffective in catalyzing reaction (a)[2]. Various transition metal complexes have been reported to catalyze formation of ureas from amines and carbon monoxide; little is known about hydrogen formation or the exact stoichiometry of the reaction[3].

The tellurium-catalyzed carbonylation reaction (a) furnishes equimolar amounts of ureas and hydrogen; formamides appear as by-products (Table 1). The monoamines *(1a)*—*(1d)* are suitable starting materials. Ammonia, dialkylamines, and aniline failed to react under the reaction conditions reported.

Table 1. Tellurium-catalyzed carbonylation of amines *(1)* to give ureas *(2)*, hydrogen, and formamides *(3)* [*(1)*, 100 mmol; Te, 1 mmol; CO, 29 bar; *T*, 140 °C; *t*, 10 h].

	Amines *(1)*	Ureas *(2)* [mmol]	Hydrogen [mmol]	Formamides *(3)* [mmol]
a	$PhCH_2NH_2$	4.7	5.0	1.1
b	n-$C_4H_9NH_2$	7.3	7.4	15.3
c	n-$C_8H_{17}NH_2$	2.3	1.9	1.0
d	*cyclo*-$C_6H_{11}NH_2$	4.1	3.3	7.2

Experimental

Freshly distilled benzylamine (100 mmol, 10.7 g) and powdered tellurium (1 mmol, 128 mg) are placed with a magnetic stirring bar in a 50-ml stainless steel autoclave. The apparatus is then flushed several times with CO and charged with CO at 29 bar. The reaction is conducted at 140 °C for 10 h with vigorous stirring. On completion of reaction, the resulting gas (5.0 mmol H_2) is collected in gas sampler at room temperature and analyzed by gas chromatography (molecular sieve 5 Å, 3.3 m; 150 °C; carrier gas, N_2, *ca.* 1 bar). Air is introduced into the reaction mixture to precipitate tellurium. Filtration followed by evaporation gives a mixture of products; GLC analyses and comparison with authentic samples showed dibenzylurea *(2a)* (4.7 mmol) and *N*-benzylformamide *(3a)* (1.1 mmol) to be present.

Reactions of Molybdate(VI) with Hydroxylamine and *N*-Methylhydroxylamine[**]

By *Karl Wieghardt, Wolfgang Holzbach, Johannes Weiss, Bernhard Nuber,* and *Boris Prikner*[*]

Mo^{VI} oxoanions react with hydroxylamine in alkaline or acidic aqueous solution without evolution of gas (N_2, N_2O, NO, NH_3) to give yellow products which have not yet been isolated[1,2]. The question whether Mo^{VI} is reduced[2] or whether complexes of Mo^{VI} containing an H_2NOH ligand have been formed[1] remained unsettled. On addition of 2,2'-bipyridine (bpy), we have now been able to isolate a yellow salt *(1)* from such a solution. Its IR spectrum exhibits a strong band at 1615 cm^{-1} which we assign to a $\nu(N{-}O)$ stretching vibration[3].

$$MoO_4^{2-} + 3[H_3NOH]Cl + bpy \rightarrow [Mo(bpy)(H_2NO)_2(NO)]Cl + 4H_2O + 2Cl^- \quad (1)$$

The structure of the cation of *(1)* was determined by X-ray methods[4] (Fig. 1). The central molybdenum atom has a coordination number of 7 (pentagonal pyramid); it is surrounded by one bpy and two hydroxylamido-*O,N* ligands ($H_2N{-}O^{\ominus}$), all of which are bidentate, and a nitrosyl ligand. Thus a nitrosyl complex of type $\{Mo{-}N{-}O\}^{[4]}$ has been formed; the MoNO group is approximately linear and the Mo—N5 bond is relatively short[3].

The clear-cut reaction course and the stoichiometry of formation of *(1)* suggest intramolecular two-electron oxidation of a coordinated hydroxylamine ligand to a nitrosyl ligand (formally $NO^{\ominus}$) with concomitant reduction of Mo^{VI} to Mo^{IV}. We have already proposed analogous processes to occur in the reaction of vanadium(v) with H_2NOH[5].

Reaction of the weaker reducing agent *N*-methylhydroxylamine with Mo^{VI} at pH = 6 affords a colorless neutral complex *(2)*, whose structure has likewise been determined by X-ray methods[6] (Fig. 2).

$$MoO_4^{2-} + 2[MeH_2NOH]^+ \rightarrow [MoO_2(MeHNO)_2]^0 + 2H_2O$$

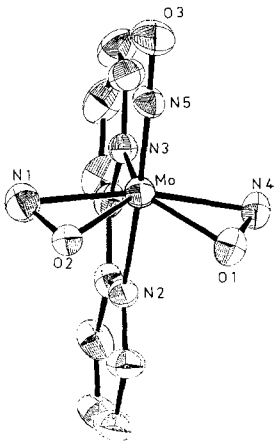

Fig. 1. Structure of the complex cation in *(1)* (without H atoms). Principal bond lengths [pm] and angles [°]:

O2—Mo—O1	92.6(2)	Mo—N4—O1	66.9(3)	N5—Mo—N2	169.6(2)
N2—Mo—N3	74.5(2)				

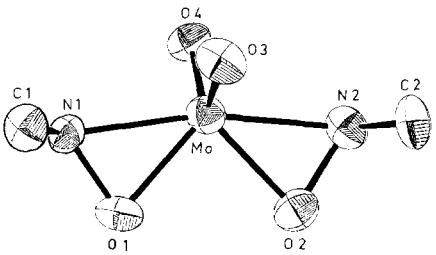

Fig. 2. Structure of the neutral complex *(2)* (without H atoms). Principal bond lengths [pm] and angles [°]:

Mo—N1	213.0(10)	Mo—O2	196.4(9)	N2—C2	148.6(18)
Mo—N2	211.9(11)	Mo—O3	170.0(8)	N1—C1	147.1(17)
Mo—O1	196.1(9)	Mo—O4	172.8(8)	O2—N2	143.1(13)
				O1—N1	142.8(13)
O3—Mo—O4	113.7(3)	O2—Mo—N2	40.8(4)	O1—Mo—O2	85.6(4)
N1—Mo—N2	166.6(5)	C1—N1—Mo	124.1(8)	O4—Mo—N1	95.1(4)
O1—Mo—N1	40.6(4)	C2—N2—Mo	123.3(8)	O3—Mo—N2	91.7(4)

In compound *(2)*, one Mo^{VI} center is surrounded by two terminal *cis*-oxo and two *N*-methylhydroxylamido-*O,N* ligands (C.N. 6). No redox process has therefore taken place in this case. To our knowledge, *(2)* is the first example of a coordination compound between a hydroxylamine derivative and molybdenum(VI).

Procedure

Synthesis of *(1)*: A solution of hydroxylammonium chloride (2.8 g, 40 mmol) in water (10 ml) is added dropwise at 60 °C to a solution of MoO_3 (0.3 g, 2 mmol) and NaOH (0.4

g) in water (20 ml). Addition of 2,2'-bipyridine (0.65 g, 4 mmol) to this clear yellow-orange solution deepens its color. Analytically pure yellow crystals are obtained (0.7 g) on slow cooling (0 °C).

Synthesis of *(2)*: *N*-Methylhydroxylammonium chloride (1.75 g, 20 mmol) is added to a solution of MoO_3 (1.5 g, 10 mmol) in 2.5 M KOH (20 ml) at 40 °C. Colorless crystals are obtained (2.1 g) on cooling (0 °C).

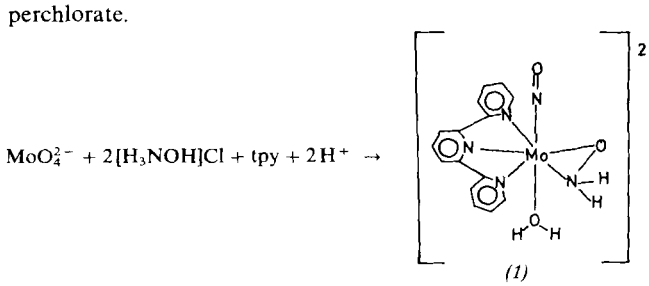
[6] *(2)* forms monoclinic crystals, space group C_{2h}^5-$P2_1/a$, $a = 637.3(1)$, $b = 1174.7(4)$, $c = 900.5(2)$ pm, $\beta = 92.47(2)°$, $Z = 4$. Refinement with the structure factors of 1251 independent reflections with anisotropic temperature factors coverged to an unweighted R value of 6.3%. The positions of the H atoms were not determined.

Synthesis of a Hydroxylamido(2−)-*O,N*-(nitrosyl)molybdenum Complex



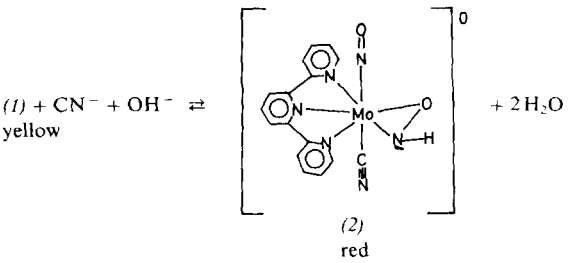
By *Karl Wieghardt* and *Wolfgang Holzbach*[*]

Transition metal complexes containing a negatively charged *O,N*-coordinated hydroxylamido ligand have recently been described by our group[1] and by other workers[2]. A uranium(VI) complex with a neutral *O*-coordinated azane oxide ligand is also known[3]. We have now accomplished the first stabilization of a doubly negatively charged hydroxylamido ligand in a nitrosylmolybdenum complex[4].

Hydroxylamide(2−) Hydroxylamide(1−) Azane oxide

Reaction of Mo^{VI} oxoanions with an excess of hydroxylamine in the presence of 2,2':6',2''-terpyridine (tpy) gives the yellow diamagnetic cation *(1)* which was isolated as the perchlorate.

(1)



$+ 2Cl^- + 3H_2O$

The course of reaction can be interpreted as an intramolecular redox process[5]. We propose a distorted pentagonal bipyramidal environment for the Mo^{IV} center in *(1)* with one coordinated H_2O molecule[1,5]. The principal IR data are compiled in Table 1.

Table 1. IR data of the new complexes *(1)* and *(2)* (KBr discs, cm^{-1}).

(1): ν(O H): 3450 (b); ν(N H): 3220, 3030; ν(N O): 1695
ν(O D): 2570 (b); ν(N D): 2420, 2250; ν((N O): 1695
(2): ν(N H) or ν(C—H): 3080; ν(N O): 1630; ν(C N): 2138

(1) reacts with cyanide in aqueous solution at 70 °C to give the dark red neutral complex *(2)*. Treatment of *(2)* with 0.5 M perchloric acid quantitatively regenerates *(1)*.

(1) + CN^- + OH^- ⇄ yellow

(2)
red

The composition of the diamagnetic compound *(2)* has been confirmed by elemental analysis and the IR spectrum (Table 1)[6].

Procedure

A solution of $[H_3NOH]_2SO_4$ (4.10 g, 25 mmol) in H_2O (10 ml) is added at 75 °C to a solution of MoO_3 (0.30 g, 2 mmol) in 0.5 M NaOH (10 ml). 2,2':6',2''-Terpyridine (0.48 g, 2 mmol) is dissolved in the clear yellow solution; the pH is adjusted to 1 with conc. $HClO_4$, and 1 M $NaClO_4$ solution (5 ml) is added. The analytically pure crystals of $[(1)\cdot(ClO_4)_2\cdot 2H_2O]$ obtained on cooling are filtered off, washed with ethanol and ether, and dried in the air; yield 1.2 g (93%).

$[(1)\cdot(ClO_4)_2\cdot 2H_2O]$ (1.0 g, 1.6 mmol) is dissolved with stirring at 70 °C in water (45 ml). On addition of NaCN (2.7 g, 55 mmol) in H_2O (5 ml) a fine pale yellow precipitate appears, which turns into dark red crystals within 3 min. The crystals are filtered off, washed with ethanol and ether, and dried *in vacuo* over P_2O_5; yield 0.6 g (89%).

Simple Route to Li- or Zn-Metalated η^5-Cyclopentadienyliron-Olefin Complexes

By *Klaus Jonas* and *Ludwig Schieferstein*[*]

The method developed by us[1] for the synthesis of reactive transition metal-olefin and alkali metal-transition metal-ole-

[*] Prof. Dr. K. Wieghardt, Dipl.-Chem. W. Holzbach
Institut für Anorganische Chemie der Universität
Callinstrasse 9, D-3000 Hannover 1 (Germany)

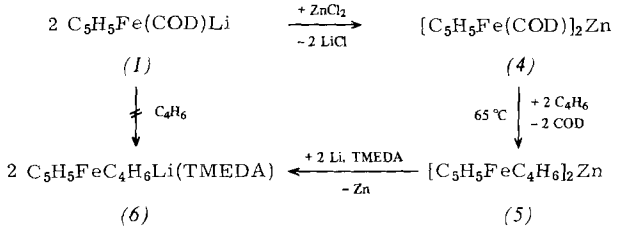
fin complexes is based upon the reaction of metallocenes with alkali metals in the presence of olefins. Starting from ferrocene the first alkali metal-olefin complexes of iron could be prepared[1a,2], which in turn are suitable precursors for the synthesis of numerous novel organoiron compounds[2].



Reaction of ferrocene at low temperature (−60 to −40 °C) in dimethoxyethane (DME) or tetrahydrofuran (THF) with lithium sand and 1,5-cyclooctadiene (COD) or ethylene leads, *via* exchange of *only one* C_5H_5-ligand, to formation of the hitherto unknown iron complexes $C_5H_5Fe(COD)Li(DME)$ *(1a)* or, after addition of *N,N,N',N'*-tetramethylethylenediamine (TMEDA), to crystalline $C_5H_5Fe(COD)Li(TMEDA)$ *(1b)* or $C_5H_5Fe(C_2H_4)_2Li(TMEDA)$ *(2)* in high yields (*ca.* 80%).

$$(C_5H_5)_2Fe + 2\,Li + COD \xrightarrow[-60\text{ to }-40\,^\circ C]{\text{THF or DME}} C_5H_5Fe(COD)Li + C_5H_5Li$$
(1)

The ^{13}C-NMR spectrum[3] of *(1b)* in [D_8]toluene at −60 to −20 °C shows besides the TMEDA signals ($\delta = 56$, t; 46, q) and the C_5H_5-signal ($\delta = 75.5$, d) also two signals each for the olefinic C-atoms ($\delta = 52.5$ and 41.6, both d) and methylene C-atoms ($\delta = 35.5$ and 32.9, both t) of the COD ligand; at +80 °C only one resonance is observed for each of the two groups of signals, namely at $\delta = 47.9$ (d) and 34.1 (t). As in the case of the other alkali metal-transition metal-olefin complexes, *e.g.* $(COD)_2CoLi(THF)_2$[1b], we ascribe this equilibration of the COD signals to the increasing mobility of the cationic Li-atom bound to the anionic $C_5H_5Fe(COD)$ core in the ion pair *(1b)* with increasing temperature. In the more strongly solvating THF, *(1b)* shows a relatively high equivalent conductivity of $\Lambda = 8.7$ cm$^2/\Omega \cdot$mol (0.25 M at −30 °C).

The π-bonded olefin ligands in *(1)* and *(2)* are quantitatively replaced by carbon monoxide (1 atm) even at −78 °C: $C_5H_5Fe(CO)_2Li$ *(3)* is obtained [isolated as crystalline $C_5H_5Fe(CO)_2Li(TMEDA)$]. The corresponding sodium compound $C_5H_5Fe(CO)_2Na$ is already well-known in solution[4].

The complexes *(1)* and *(2)* can be used as precursors for preparation of the hitherto unknown polynuclear complexes *(4)*, *(5)*, and *(6)* having olefin ligands bound to iron atoms. They are obtained from *(1)* and *(2)* and metal halides such as $ZnCl_2$ or $CdCl_2$.

Replacement of the cyclooctadiene in the zinc derivative *(4)* by butadiene leads to the trinuclear complex *(5)*, which can be converted by reaction with lithium into *(6)* and metallic zinc. Under mild reaction conditions *(6)* cannot be obtained directly from *(1)* and butadiene. Reaction of *(1)* with trityl chloride affords η^5-cyclopentadienyl(η^4-1,5-cyclooctadiene)iron *(7)* in high yields (70%), which, in contrast to the dimeric $[C_5H_5Fe(CO)_2]_2$[4a,5], is obtained as the monomer with an unpaired electron.

$$(1) + (C_6H_5)_3CCl \xrightarrow[-LiCl]{} C_5H_5FeCOD\cdot + (C_6H_5)_3C\cdot$$
(7)

The iron(I) compound *(7)*, which is stable for several hours at room temperature, exhibits a wide range of interesting reactions; its structure, like that of *(2)* and *(5)*, was elucidated by X-ray crystallography[6].

Procedure

Ferrocene (50.0 g, 269 mmol) is stirred in THF (350 ml) and COD (100 ml) with Li-sand (5.2 g, 755 mmol) for 5–6 h at −50 °C. The reaction mixture is then allowed to warm to room temperature, filtered free of excess lithium, and the filtrate concentrated to 250 ml by evaporation *in vacuo*. Addition of ether (600 ml) and TMEDA (150 ml) leads to precipitation of crystalline *(1b)* (71.2 g, 75%).

Tetrakis(ethylene)irondilithium and Bis(η^4-1,5-cyclooctadiene)irondilithium

By *Klaus Jonas, Ludwig Schieferstein, Carl Krüger*, and *Yi-Hung Tsay*[*]

Recently we reported the alkali metal-transition metal-ethylene complexes $(C_2H_4)_3NiLi_2$[1] and $(C_2H_4)_4CoK$[2a,3]. We have now been able to synthesize the isoelectronic iron compound $(C_2H_4)_4FeLi_2$[2a,4]. As in the case of the more electron-rich metallocenes[2] it was possible to replace systematically both C_5H_5-ligands in ferrocene *via* a similar route.

Reaction of ferrocene in tetrahydrofuran (THF) or dimethoxyethane (DME) at room temperature under slightly increased ethylene pressure (≈ 5 atm) with an excess of lithium sand and subsequent addition of a mixture of diethyl ether and *N,N,N',N'*-tetramethylethylenediamine (TMEDA) to the filtered reaction solution leads on cooling (−30 °C) to crystallization of the yellow-green colored complex $(C_2H_4)_4FeLi_2(TMEDA)_2$ *(1)* (45% yield).

[**] X-ray structure analysis.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0707-0550 $ 02.50/0

(1) reacts with acetic acid and ethylenebis(diphenylphosphane) (diphos) to give $C_2H_4Fe(diphos)_2$[5] according to:

$$(1) + 2\,\text{diphos} + 2\,CH_3COOH \rightarrow C_2H_4Fe(\text{diphos})_2 + 2C_2H_4 + C_2H_6 + 2\,CH_3COOLi$$

In the presence of stoichiometric amounts of alcohol or $ZnCl_2$, *(1)* exhibits the well-known activity of iron(0) catalysts[6] towards butadiene.

At −78 °C, *(1)* reacts with carbon monoxide (1 atm) with uptake of four equivalents of CO and liberation of four equivalents of C_4H_4. Reaction of *(1)* with 1,5-cyclooctadiene (COD) at 40—70 °C affords $(COD)_2FeLi_2$ [isolated as crystalline *(2a)* or *(2b)*],

$$(1) + 2\,\text{COD} \xrightarrow{40\text{–}70\,^\circ C} (COD)_2FeLi_2 + 4\,C_2H_4$$

$$(COD)_2FeLi_2 \xrightarrow{\text{DME}} (COD)_2FeLi_2(DME)_2 \quad (2a)$$

$$(COD)_2FeLi_2 \xrightarrow{\text{TMEDA}} (COD)_2FeLi_2(TMEDA)_2 \quad (2b)$$

thus completing the series of isoelectronic transition metal-cyclooctadiene complexes of the 3d elements of subgroup 8—namely $(COD)_2Ni$[7], $(COD)_2CoLi$[2] and $(COD)_2CoK$[2a,3], $(COD)_2FeLi_2$.

The X-ray structure analysis[8] of *(1)* shows the central Fe atom in a distorted octahedral environment with four equatorial C_2H_4 ligands and two Li atoms in the apical positions. The iron-olefin moiety has approximately the geometry expected for d^{10} systems with ethylene ligands[9]. A twofold crystallographic axis runs through the iron atom and bisects the C1 C1′ vector. Short Li C bond lengths (Li C2: 2.174, Li C3′: 2.215 Å), as in $(COD)_2CoLi(THF)_2$[2b], indicate strong iron-pair interactions between the tetrahedrally surrounded Li atom and the olefin C-atoms. The Li Fe distances are 2.619 Å.

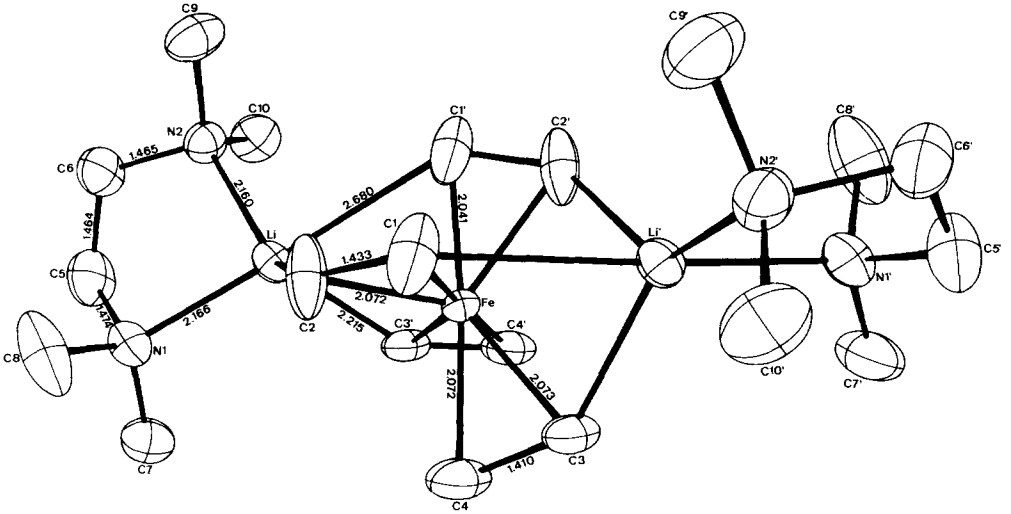

Fig. 1. Structure of $(C_2H_4)_4FeLi_2(TMEDA)_2$ *(1)* in the crystal; bond lengths in Å.

The method of reductive C_5H_5-detachment by means of alkali metal can also be used in the case of other η^5-cyclopentadienyl-transition metal compounds. It has also proved to be a useful method in the case of complexing agents other than olefins—*e.g.*, with phosphanes or molecular nitrogen.

Structure and Reactivity of the Orthocarbonic and Orthosilicic Acid Esters of Pyrocatechol

By *Heinrich Meyer* and *Günter Nagorsen*[*]

The observation that glassy bis(*o*-phenylenedioxy)silane *(1)* and other ring-strained orthosilicic acid esters are capable of being polymerized even in the solid state[1] urged us to investigate the structure of *(1)* and the corresponding derivative of orthocarbonic acid, 2,2′-spirobi-1,3-benzodioxole *(2)*.

Zuckerman[2] believed that he had prepared monomeric *(1)*; however, the product obtained by him could very well have been a mixture of oligomers. Polymeric *(1)* is readily obtained by the following reaction:

$$2\,C_6H_4(OH)_2 + SiCl_4 \rightarrow 1/x[(C_6H_4O_2)_2Si]_x + 4\,HCl$$

Complete depolymerization takes place on transition into the gas phase—no signals were observed above the molecular peak $m/e = 244$ in the mass spectrum. From the gas phase, we were able to grow clear and colorless single crystals of monomeric *(1)* which are very sensitive to moisture and have a sharp melting point of 116 °C. We obtained monomeric—but X-ray crystallographically amorphous—*(1)* by a procedure resembling that described by *Allcock et al.*[3].

[*] Dr. H. Meyer, Dr. G. Nagorsen
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

For comparison, we prepared the orthocarbonic acid ester *(2)* as described in the literature[4]. X-ray crystallographic investigation on single crystals surprisingly showed that *(1)* and *(2)* do not crystallize isotypically.

In the structure analysis (automatic four-circle diffractometer, Siemens-AED) of *(2)* 220 of 872 measured symmetry-independent reflections could be phased by direct methods of sign determination. The positions of the hydrogen atoms were determined by difference Fourier synthesis. With anisotropic temperature factors for the carbon and oxygen atoms the structure was refined to an R_w value = 4.8%[5a].

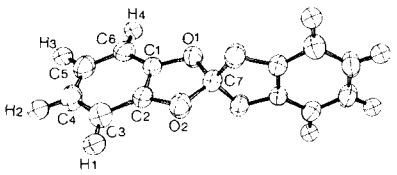

Fig. 1. Structure of the orthocarbonic acid ester *(2)*. Crystallographic data: space group Pccn; $a = 5.342$, $b = 11.496$, $c = 16.962$ Å; $\rho_{exp} = 1.48$, $\rho_{calc} = 1.46$ g/cm^3; $Z = 4$; $V = 1041.57$ Å^3.

As can be seen from Figure 1 the bonding arrangement at the spiro carbon atom C7 corresponds to a very slightly distorted tetrahedron; the ring strain of the dioxole rings is evidently accommodated by the whole molecule, the valence angles at the oxygen atoms and at C1 and C2 apparently being influenced the most.

The crystal growth of the homologous orthosilicic acid ester *(1)* was extremely difficult to reproduce, in the majority of experiments only glassy products were obtained; this difficulty along with the sensitivity of the single crystals has so far thwarted satisfactorily accurate determination of the intensities of a greater number of reflections. Precession and Weissenberg photographs led to the space group $P2_1/c$ (monoclinic) with the cell data $a = 10.56$, $b = 5.60$, $c = 10.96$ Å, $\beta = 122°$, $V = 550$ Å^3. The density of the substance could not be determined, but it follows from a comparison of the volumes of the unit cells of *(1)* and *(2)* that Z must be equal to 2, since both molecules ought to have approximately the same spatial requirements. If there are only two silicon atoms in the unit cell they must be located on a special centrosymmetric equivalent position. This, however, would mean that *(1)* must be planar, at least in the solid state. Evidence for the centrosymmetric equivalent position is based on a few unobserved reflections ($0k0 \neq 2n$) for the space group determination. We consider the different space groups of *(1)* and *(2)* to be further evidence supporting the planar structure of the silicon compound—it is highly unlikely that replacement of the almost completely shielded central spiro atom C7 by Si alone causes alteration of the crystal lattice.

These conclusions are confirmed by EH calculations[5b], which for *(1)* give only slight preference for the tetrahedral arrangement (6.4 kcal/mol, using standard bond lengths) over the planar arrangement (cf. Fig. 2). A consideration of Si 3d-orbitals and experimentally determined bond lengths from the anion $[(C_6H_4O_2)_3Si]^{2-}$ (the average Si–O bond length here is 1.770 Å[6]) indicated only slight divergence in the energy differences.

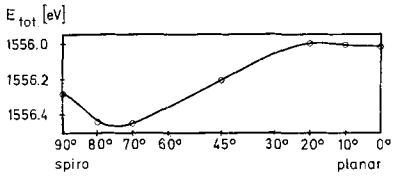

Fig. 2. Change in total energy for the "spiro- planar" transition of bis(*o*-phenylenedioxysilane) *(1)*.

In contrast, a considerable energy difference (104.5 kcal/mol) is calculated between the spirocyclic and planar orthocarbonic acid ester *(2)*.

On the other hand, there is a striking similarity in the energy level diagrams for the tetrahedral carbon and silicon compounds, the HOMO-LUMO difference in the former is only about 6 kcal/mol greater than in the latter, giving no indication of the highly reactive nature of the silicon compound, which not only forms adducts of high coordination number with donors[1b,7] but also reacts with itself. This becomes explainable only when one considers the frontier orbitals of planar *(1)* (cf. Fig. 3): At a slightly lesser HOMO-LUMO difference of about 1.7 kcal/mol, $\psi(43)$ with a distinct Si(p_z) component is obtained. In addition, a lowering of the energy gives $\psi(47)$ as a further orbital with a large eigenvalue coefficient for Si(p_z). If 3d-orbitals are taken into consideration then a further orbital, very similar to $\psi(47)$—but at higher level and having a very large Si(d_{z^2}) component—is obtained.

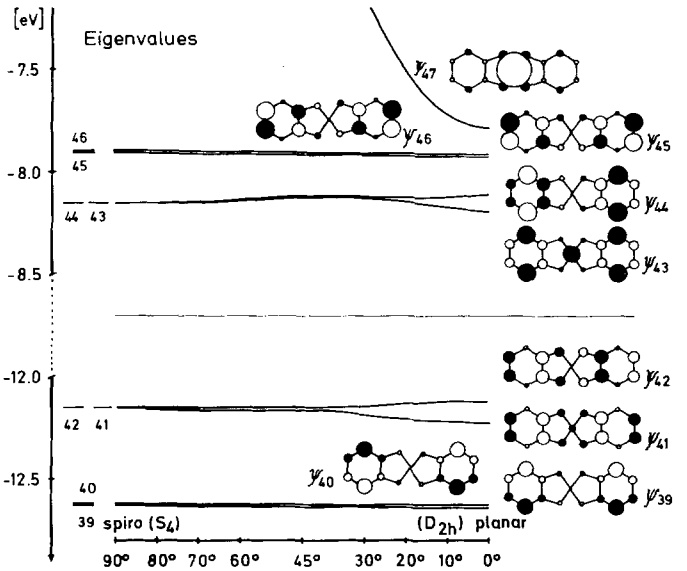

Fig. 3. Section from the correlation diagram for the spiro-to-planar transition of bis(*o*-phenylenedioxy)silane *(1)*.

It appears perfectly possible to stabilize the planar arrangements by sufficient interaction with donor orbitals. We assume this to take place in the crystal lattice, and the resulting coordination can thus also be regarded as pseudooctahedral. Each molecule in the crystal functions simultaneously as donor and acceptor.

From the total energy curve it can be seen that the spirocyclic compound ($\alpha = 90°$) does not lie at the energy minimum; this occurs at an angle $\alpha \approx 75°$ between the planes of the rings. According to the conservation of orbital symmetry

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0707-0552 $ 02.50/0

the "spiro-planar" transition of *(1)* is thermally permissible. The π system of the benzene rings is important for easy planarization of the tetrahedral bonds on the silicon: calculations for bis(vinylenedioxy)silane favor the tetrahedral form by about double the energy difference (13.1 kcal); here also the HOMO-LUMO gap for the tetrahedral arrangement is about 4.8 kcal greater.

It is still unclear whether the ease of planarization and associated generation of low-lying acceptor orbitals is a widely applicable principle. Should this be so, then current ideas on the course of substitution reactions at silicon will have to be further reviewed. In our opinion an essential point is that our explanation of the reactivity of *(1)* without implication of Si-3d-orbitals is perfectly possible.

Calculations on the orthocarbonic acid esters *(2)* show that the small C7 O bond length restricts planarization; approximation of the four oxygen atoms, as in the square planar arrangement, is energetically strongly disfavored (on the problem of planar carbon compounds cf. [8]).

Solutions of monomeric *(1)* are not stable, oligomerization or polymerization takes place. This is true in particular for non-polar solvents, which favor association of the polar molecules. Solvents having good donor properties often form adducts. Dipolar or ambidentate solvents ought to form associates with *(1)* and render oligomerization difficult. In fact this reaction can be suppressed in nitromethane to such an extent that solutions are stable at $-15\,^{\circ}C$ for about a day, thus enabling molecular weight determinations to be carried out ($M_{obs}=243\pm3$, average of five measurements; $M_{calc}=244$[9]). The recording of ^{13}C- and ^{29}Si-NMR spectra is difficult because of sparing solubility and the oligomerization that takes place during prolonged measuring times, even at low temperatures.

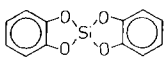
Planar Tetracoordinate Silicon[**]



By *Ernst-Ulrich Würthwein* and *Paul von Ragué Schleyer*[*]

X-ray crystallographic investigations on the orthocarbonic *(1)* and orthosilicic *(2)* acid esters led *Meyer* and *Nagorsen*[1] to a startling conclusion. While the bond angles at the central carbon atom of *(1)* are essentially tetrahedral *(1a)*, the completely different space group adopted by *(2)* ($P2_1/c$, monoclinic) indicates a planar structure *(2b)*. *(2b)* may be regarded as the first example of planar tetracoordinate silicon.

(1)

(1a): perpendicular (D_{2d})
(1b): planar (D_{2h})

(2)

(2a): perpendicular (D_{2d})
(2b): planar (D_{2h})

Because of our continuing interest in non-tetrahedral four-coordination involving elements of the second and third periods[2], we have studied this problem theoretically by means of quantum mechanical calculations in order to clarify the electronic basis for the difference between *(1)* and *(2)*.

We began by examining CH_4 and SiH_4 in tetrahedral (T_d) and artificially constrained square planar (D_{4h}) geometries. Standard calculational methods[3] were employed (Table 1).

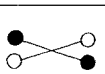


Table 1. Differences in total energies E (*ab initio*)/heats of formation ΔH_f^0 (MNDO) between perpendicular and planar structures (kcal/mol) [a].

	STO-3G	4-31 G	STO-3G*	MNDO
CH_4	240.0 [b, c]	168 [b]	—	140.7 [d]
SiH_4	152.2 [c]	—	114.1 [c]	82.2 [e]
CH_3OH	230.8 [f]	200 [b]	—	130.1 [g]
SiH_3OH	108.2 [h]	—	84.3 [i]	68.5 [j]
(1)	—	—	—	116.3 [k]
(2)	—	—	—	32.9 [l]
(3)	—	—	38.9 [m]	30.7 [n]

[a] All structures were fully optimized (ref. [3]); D_{4h} or D_{2h} symmetry was imposed on the planar species.
[b] Ref. [2a].
[c] Ref. [2b].
[d] $\Delta H^0_{perp} = -11.9$ kcal/mol; $\Delta H^0_{pl} = 128.8$ kcal/mol.
[e] $\Delta H^0_{perp} = 11.5$ kcal/mol; $\Delta H^0_{pl} = 93.7$ kcal/mol.
[f] $E_{perp} = -113.54598$ a.u.; $E_{pl} = -113.17811$ a.u.
[g] $\Delta H^0_{perp} = -57.4$ kcal/mol; $\Delta H^0_{pl} = 72.7$ kcal/mol.
[h] $E_{perp} = -361.77187$ a.u.; $E_{pl} = -361.59937$ a.u.
[i] $E_{perp} = -361.88011$ a.u.; $E_{pl} = -361.74579$ a.u.
[j] $\Delta H^0_{perp} = -65.2$ kcal/mol; $\Delta H^0_{pl} = 3.3$ kcal/mol.
[k] $\Delta H^0_{perp} = -97.2$ kcal/mol; $\Delta H^0_{pl} = 19.1$ kcal/mol.
[l] $\Delta H^0_{perp} = -211.9$ kcal/mol; $\Delta H^0_{pl} = -179.0$ kcal/mol.
[m] STO-3G*-single-point-calculation on fully optimized MNDO geometries.
$E_{perp} = -733.18633$ a.u.; $E_{pl} = -733.12430$ a.u.
[n] $\Delta H^0_{tetr} = -228.8$ kcal/mol; $\Delta H^0_{pl} = -198.1$ kcal/mol.

All theoretical levels show clearly that the tetrahedral-planar energy difference is much smaller with SiH_4 than with CH_4. Planar tetracoordination is fundamentally easier to realize with silicon than with carbon.

There is an even more important *qualitative* distinction between planar CH_4 and planar SiH_4: the preferred hybridization is different[2b]! The highest occupied orbital (HOMO) in CH_4 (a_{2u}) has pure p character; in SiH_4 this orbital is unoccupied (LUMO). The HOMO in SiH_4 (the LUMO in CH_4) is a sigma orbital (b_{1g}) with d-type symmetry. This orbital ordering is found even when no d-orbitals are included in the Si basis set (MNDO and STO-3G); inclusion of d-orbitals (STO-3G*), as expected, favors the planar forms even more[2b].

		
orbital symmetry	a_{2u}	b_{1g}
CH_4 (D_{4h})	HOMO	LUMO
SiH_4 (D_{4h})	LUMO	HOMO

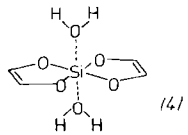
[**] This work was supported by the Fonds der Chemischen Industrie (Liebig-Stipendium to E.-U. W.) and benefited from discussions with Dr. *J. Chandrasekhar* and Dr. *T. Clark*.

This interchange of orbital ordering has fundamental consequences for the stabilization of planar structures: π-acceptor-σ-donor substituents (*e.g.* Li, Be, and B[2a]) preferentially stabilize planar tetracoordinate carbon, but silicon requires π-donor-σ-acceptor groups (*e.g.* F, OR and NR_2).

Model calculations on methanol H_3COH and silanol H_3SiOH illustrate these predictions: the effect of the OH group in stabilizing planar silanol is much greater than in planar methanol (Table 1). Additional electronegative, π-donor substituents should lower the energy difference between planar and tetrahedral forms of silicon compounds even more.

Since the large size of *(2)* precludes *ab initio* calculations, our investigation was carried out at the semiempirical MNDO[3b] level. Comparisons in Table 1 indicate that MNDO and STO-3G* *ab initio* trends are in good agreement. Although the perpendicular arrangement *(2a)* is still preferred, a drastic reduction in the planar-perpendicular energy difference (to 32.9 kcal/mol) is indicated by MNDO calculations on *(2)*.

This result was checked by examining the closely related model compound *(3)*. The MNDO difference is 30.6 kcal/mol; single point STO-3G* calculations on the MNDO geometries of planar *(3b)* and perpendicular *(3a)* gave $\Delta E = 38.9$ kcal/mol, thus confirming the semiempirical result. A planar structure for the orthocarbonic ester *(1b)* is out of the question. According to MNDO, the perpendicular form *(1a)* should be 116.3 kcal/mol more stable.



(3)

(3a): perpendicular (D_{2d})
(3b): planar (D_{2h})

Meyer and *Nagorsen*[1] suggest that the planar structure *(2b)* in the crystal was favored by additional intermolecular interactions of silicon with two oxygen atoms of neighboring molecules (pseudooctahedral coordination). This suggestion is supported by our model calculations on *(4)* which simulate the postulated coordination by placing water molecules above and below silicon as shown. The total energy of coordination to the water molecules in going from planar *(3b)* to *(4)* is 47.3 kcal/mol, 16.7 kcal/mol more than necessary to overcome the residual preference of *(3)* for the perpendicular geometry *(3a)* in the absence of such additional coordination. In *(4)* the MNDO Si O distances involving the water molecules are 1.94 Å in comparison with the 1.75 Å value for the four covalently bound oxygens[4].

Since we are dealing with a known substance[1], it would be exciting not only to ascertain the full crystal structure of *(2)* for comparison with our calculated geometries, but also to determine its conformation in solution as a function of solvent character. The barrier to planar inversion of *(2a)* may well be low enough for experimental measurements, *e.g.*, by determination of the rate of racemization of chiral analogs of *(2a)*.

(4)

We conclude that silicon is inherently better suited than carbon for the detection and observation of planar tetracoordinate structures. Classical compounds, such as the orthosilicic acid esters, should exhibit reduced energy differences between planar and tetrahedral forms, which may be small enough to permit experimental observation of planar inversion. The additional possibility of silicon six-fold coordination in the solid phase or in suitable solvents may render planar arrangements more stable than the tetrahedral.

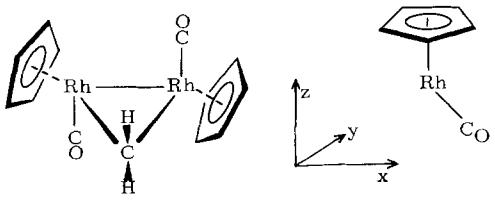
[4] This comparison is not quite fair; *(2a)* might also be stabilized, if only slightly, by interaction with solvent oxygen.

Electronic Structure of μ-Methylene-Transition Metal Complexes[**]

By *Peter Hofmann*[*]



Apart from classical transition metal carbene complexes of type *(1)*, μ-methylene complexes containing M_2C (MM'C) structures such as *(2a)*—*(2d)* have been synthesized and their geometries analyzed[1]. They warrant theoretical and practical interest as intermediate members in the series cyclopropane (C_3 ring) ... metal-olefin complexes (MC_2 ring) ... trinuclear metal clusters (M_3 ring).

MO calculations[3] on the rhodium complex *(2a)*, whose geometry[2] as established by X-ray methods is shown in *(3)*, provide typical data regarding the electronic structure of such singly methylene-bridged compounds. A particularly simple description[4] of the bonding in *(2a)* can be constructed from the interaction of the MOs of one CH_2 group and two d^8-(η^5-C_5H_5)Rh(CO) sixteen electron fragments.

The valence orbitals of *(4)* (Fig. 1, left) can be readily interpreted in terms of the MOs already described[5] for a half-sandwich complex such as $CpRh(CO)_2$ and the perturbational consequences of the absence of a CO ligand: the disappearance of σ antibonding and the loss of π back bonding lead, with appropriate energetic modifications, to the HOMO 2a″ and LUMO 3a′ of *(4)* (both MOs hybridized towards the missing ligand) and to the d levels 2a′, 1a′, and 1a″ of CpRh(CO) separated energetically from the frontier orbitals[6a].

Two identical units *(4)* make up the partial skeleton *(5)* for bonding the μ-methylene group in *(2a)*. Calculations on *(5)* assuming a geometry like that found for the $Cp_2Rh_2(CO)_2$ moiety in the complex[6b], lead to the MO scheme shown in Figure 1 (right).

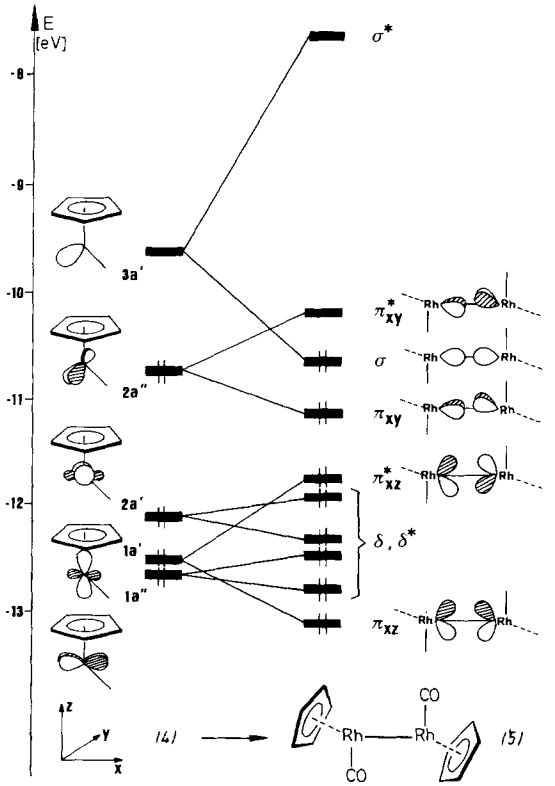

Fig. 1. Energy level scheme of fragment *(5)* as derived from the interaction of two sixteen-electron fragments *(4)*. Only the contributions to the wave function at the metal center are shown in the case of *(4)*, and only those in the Rh Rh region for *(5)* (taken from the corresponding contour diagrams).

Given a choice of axes suitable for *(5)*, the molecular orbital π^*_{xy} [which is π-antibonding in the *xy* plane] becomes the lowest acceptor function, and the bonding linear combination (σ) of two 3a′ orbitals of *(4)* emerges as the highest occupied orbital. Pronounced splitting is also caused by interaction of the two 1a′ functions so that the π^*_{xz} orbital, which is "orthogonal" to π^*_{xy}, appears at relatively high energy and the corresponding bonding combination π_{xz} is the lowest MO of the d group of *(5)*. Interaction involving 1a″ and 2a′ is much less extensive; the four resulting molecular orbitals are δ bonding or δ antibonding and do not play a significant role

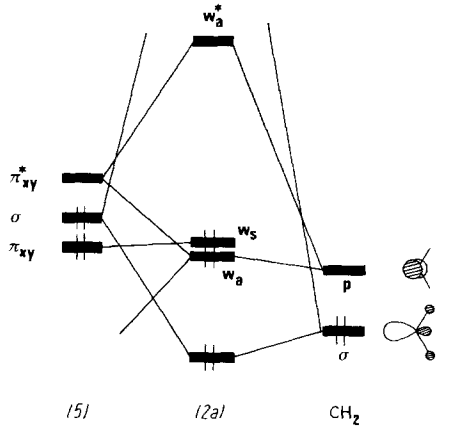

Fig. 2. Scheme for construction of MOs of *(2a)* from *(5)* and CH_2 (section).

here. In the d^8 case, the energy levels (Fig. 1) formally resemble those of a Rh Rh double bond.

The valence MOs of the CH_2 bridge, p and σ, acquire symmetrically suitable partners in the frontier orbitals π^*_{xy} and σ. Apart from the σ-type bonding between the methylene group and *(5)*, the qualitative interaction scheme (Fig. 2) demonstrates the existence of a situation corresponding exactly to the Walsh description of cyclopropane, derived on the basis of an ethylene and a methylene structural unit. The two highest occupied MOs (w_a and w_s) of the μ-CH_2-rhodium complex are accordingly regarded as an essentially unperturbed π_{xy} orbital of *(5)* (w_s) and as a bonding linear combination of π^*_{xy} with p of the CH_2 unit (w_a). The LUMO of the three-membered ring is the antibonding counterpart of w_a. Contour diagrams of w_a, w_s, and w^*_a in the plane of the three-membered ring (Fig. 3) clearly underline the relationship with the Walsh orbitals of a cyclopropane.

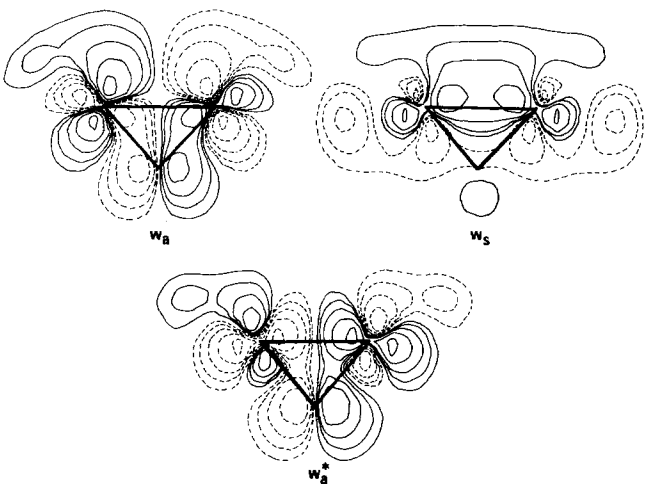

Fig. 3. Contour diagrams of the MOs of the three-membered ring w_a, w_s, w^*_a (values of wave functions: ±0.2, ±0.1, ±0.05, ±0.025, ±0.0125).

The w_a orbital appears slightly destabilized with respect to p, in spite of its bonding interaction with π^*_{xy}, because one of the δ* levels mixes in an antibonding manner with w_a and plays a role in determining its energy. Like π_{xy}, π^*_{xz} cannot avail itself of a symmetrically suitable orbital on the bonding ligand and remains essentially unaffected; π_{xz} experiences a small repulsive interaction with the low-lying π_{CH_2} orbital of the methylene group, giving rise to interesting consequences with regard to the H C H angle in such systems[7].

The most important result of the occupation of w_a is an electron transfer from the Rh Rh σ-bond into an orbital

containing a π^*_{xy} component and to the carbon atom. The formal metal-metal double bond in fragment *(5)* becomes a "single bond". In accord with NMR data, the C atom exhibits a far greater charge density than in complexes of type *(1)*[1a]. Electrophilic attack at the bridging carbon atom should take place in addition to reactions at the electron-rich rhodium centers[8]. "Carbene rotation" as in molecules *(1)*, *via* a geometry with the carbon in a planar ligand environment in the present case is clearly unattainable for energetic reasons: the π^*_{xy}/p interaction would be supplanted by the far weaker π_{xz}/p interaction and a very high energy occupied orbital with p character would result[9]. As in the situation known for cyclopropane, μ-methylene complexes can be expected to adopt preferred conformations of "single-faced" π-acceptor substituents ($CH_2^{\oplus}$, COR, ...) in which the stabilizing donor property of w_a on electron-deficient centers comes into operation[10].

This bonding situation is not limited to the specific case of *(2a)* but is valid for *(2b)*—*(2h)* in which the CpRh(CO) fragment is replaced by other isolobal units ML_n or the CH_2 group by other bridges[11]. Predictions concerning concomitant changes are possible. Thus it becomes understandable that an additional π* acceptor orbital of bridging ligands such as CO orthogonal to the plane of the three-membered ring should have hardly any effect on the overall geometry of *(2e)* relative to that of *(2a)*; the additional interaction with π_{xz} is small and weakens the metal-metal bond only slightly. A similar situation is encountered in *(2f)*—*(2h)*.

Further interesting consequences of this MO model come to mind in molecules of the general type *(2)* with regard to questions of reactivity, structure, and possible intramolecular dynamic processes[12].

[12] Interest attaches to barriers for CO exchange phenomena (cf. point made in ref. [1a]). In the ground state, two μ-CO groups are present in the anion $[Cp_2Rh_3(CO)_4]^-$ (CH_2 in *(2a)* replaced by the isolobal moiety $Rh(CO)_2$): *W. D. Jones, M. A. White, R. G. Bergman*, J. Am. Chem. Soc. *100*, 6770 (1978). The terminal CO ligands in *(2a)* do not exchange sites: *W. A. Herrmann*, personal communication.

Spectroscopic Identification of Polymethyl-Substituted 2,4-Cyclohexadienones[**]

By *Gerhard Quinkert, Gerd Dürner, Erna Kleiner, Erhard Haupt*, and *Dieter Leibfritz*[*]

Ultraviolet spectra should be used whenever one has to distinguish between 2,4- and 2,5-cyclohexadienones[1]. By and large it is accepted that close correlations of those spectra with structure are not possible within the class of linearly conjugated cyclohexadienones[2]. In actual fact there is a notable relationship, however, between the location of the maximum of the relatively strongly absorbing π*,π-band (in nm, alcoholic solution) and the number and position of additional methyl groups in 6-acetoxy-6-methyl-2,4-cyclohexadienones: If the absorption maximum of *(1a)* (298 nm) is ad-

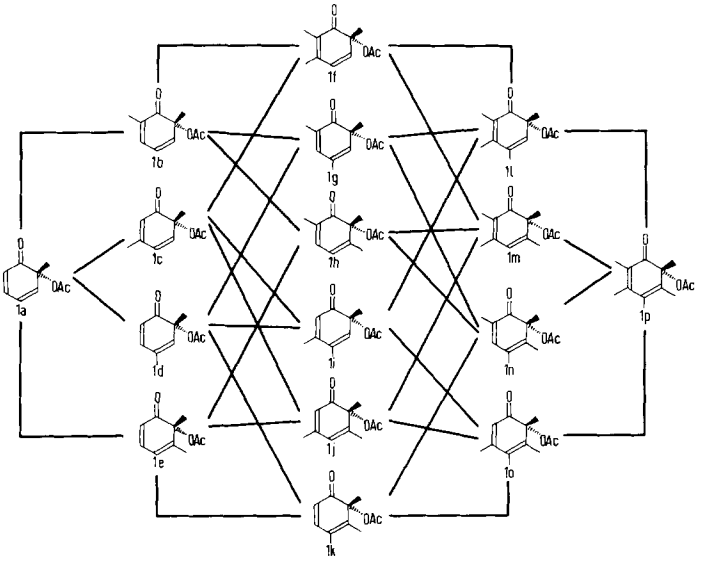

Fig. 1. Family tree of all 6-acetoxy-6-methyl-2,4-cyclohexadienones *(1)* having 0 to 4 methyl-substituents in positions 2 to 5 (the designations of compounds *(1a)* to *(1p)* deviate from those in the text in that they are not printed in italics).

opted as the basic value, each successive methyl substituent in positions 2, 3, 4 or 5 [according to *(1b)* to *(1e)*] generates increments of 6, 1, 7, and 9, respectively (cf. Table 1)[3].

The observed and calculated UV maxima are found to exhibit good agreement for those members of the family of methylated *o*-quinol acetates having 0 to 4 methyl substituents in positions 2 to 5 (see Fig. 1) whose constitution is known *a priori*[4] (Table 2: data in normal print) or whose constitution is to be determined[5] (Table 2: data in bold-face type).

Table 1. Non- and mono-methylated *o*-quinol acetates whose π^*,π absorption maxima in alcohol provide the basic value and positional increments (in nm) for more highly methylated derivatives.

Dienone	UV Maximum recorded
1a	298 nm
1b	304.5nm
1c	299 nm
1d	305.5nm
1e	307.5nm

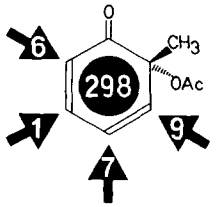

Table 2. π^*,π absorption maxima (in nm) calculated with the parameters found for *o*-quinol acetates (Table 1) and experimental values recorded in alcoholic solution.

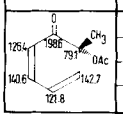
Dienone	UV Maximum calculated	recorded
1f	**305**	**306**
1g	311	311
1h	**313**	**313**
1i	306	307
1j	308	308
1k	314	317
1l	**312**	**313**
1m	314	314
1n	**320**	**320**
1o	315	316
1p	321	321

The assignment receives further support from an analogous correlation of chemical shifts of ^{13}C-NMR-spectra with the number and position od additional methyl groups at unsaturated ring carbon atoms[6]. Table 3 shows the corresponding basic figures and positional increments for all the ring carbon atoms. Table 4 indicates, by means of a selection including the interesting cases *(1f)* and *(1h)*, as well as *(1l)* and *(1n)*, how reliably the individual members of the family studied can be recognized.

Table 3. Basic values and positional increments for calculation of ^{13}C-NMR shifts for methyl-substituted 6-acetoxy-6-methyl-2,4-cyclohexadienones *(1f)* to *(1p)*.

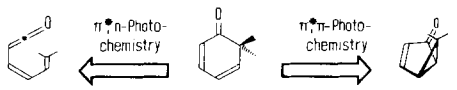


δ	Methyl position	Shift [ppm] of the ring carbon atoms on methyl substitution C-1	C-2	C-3	C-4	C-5	C-6
	C-2	+0.5	+7.7	-3.8	+0.1	-2.8	-0.1
	C-3	-0.9	-2.8	+12.0	+3.8	-1.2	-1.1
	C-4	-0.3	-0.7	+4.1	+8.1	-6.1	-0.8
	C-5	+1.1	-2.6	+1.2	-2.7	+10.1	+3.2

Table 4. ^{13}C-NMR shifts calculated with the parameters found for *o*-quinol acetates (Table 1) and experimental values recorded in $CDCl_3$.

Dienone \ Carbon		C-1	C-2	C-3	C-4	C-5	C-6
1f	calc.	198.2	131.3	148.8	125.7	138.7	77.9
	exp.	198.0	129.6	146.2	127.0	138.2	77.9
1g	calc.	198.8	133.5	140.9	130.0	133.8	78.2
	exp.	198.7	133.1	141.0	129.9	133.9	78.3
1h	calc.	200.2	131.5	138.0	119.2	150.0	82.2
	exp.	199.9	131.4	137.9	118.8	149.3	82.1
1j	calc.	198.8	121.0	153.8	122.9	151.6	81.2
	exp.	198.6	121.5	153.5	123.1	151.3	81.2
1l	calc.	197.9	130.6	152.9	133.8	132.6	77.1
	exp.	198.2	129.5	148.2	131.6	134.2	78.2
1n	calc.	199.9	130.8	142.1	127.3	143.9	81.4
	exp.	199.9	130.4	143.8	124.3	141.8	81.9

The values for *(1f)* and *(1h)* and for *(1l)* and *(1n)* differ sufficiently to permit unambiguous identification.



Received: March 21, 1979 [Z 248a IE]

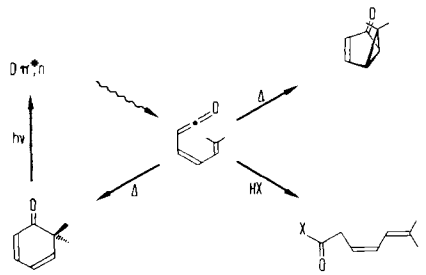
[3] If carbon of coordination number 4 is the central atom of both ligands attached to C-6 then the basic value is 301 and the positional increments amount to 7, 0, 10, and 16.
[4] 12 members of the family expressed by the graph of Fig. 1 leave no doubt as to their constitution, provided the constitution of each of the phenolic reactants is known. In the case of *(1a)*, *(1c)*, *(1d)*, *(1e)*, *(1i)*, *(1j)*, *(1h)*, *(1o)* only one of the *ortho* positions is substituted; the acetoxy ligand must enter that site if an *o*-quinol acetate is to be formed. In the case of *(1b)*, *(1g)*, *(1m)*, *(1p)*, the parent phenols exhibit homotopic methyl ligands at C-2 and C-6; the same *o*-quinol acetate always results regardless of which *o*-position the acetoxy ligand enters.
[5] 2,3,6-Trimethylphenol and 2,3,4,6-tetramethylphenol are each linked to a pair of constitutionally isomeric *o*-quinol acetates.
[6] It has already been demonstrated that chemical shifts of ^{13}C-NMR spectra are suitable for determining the number and position of methyl ligands in linearly conjugated cyclohexadienones: *R. Hollenstein, W. von Philipsborn*, Helv. Chim. Acta *55*, 2030 (1972).



The Question of π^*,n- and π^*,π Selective Photochemistry of 2,4-Cyclohexadienones[**]

By *Gerhard Quinkert, Franz Cech, Erna Kleiner*, and *Dieter Rehm*[*]

Electro isomers[2] differ fundamentally in their structure, energy content, and chemical reactions. Linearly conjugated cyclohexadienones are often cited as relevant examples[3]. It is generally accepted that electro isomeric 2,4-cyclohexadienones having mainly π^*,n-character afford constitutionally isomeric dienylketenes[4] while electro isomeric 2,4-cyclohexadienones having predominantly π^*,π-character furnish constitutionally isomeric bicyclo[3.1.0]hex-3-en-2-ones[5]:

The $\pi^*\pi$ photochemistry of linearly conjugated cyclohexadienones originally postulated by *Griffiths* and *Hart*[5a], and initially accepted in our laboratory[2,4b,6], does not stand up to experimental scrutiny. In fact, the bicyclic ketones are also undoubtedly products of π^*,n photochemistry[7]. They arise by bicyclization of the dienylketene transients. This process principally competes with recyclization[8] and/or addition of protic nucleophiles:

[**] 20th Communication on Light-Induced Reactions. This work was supported by Deutsche Forschungsgemeinschaft, Fonds der Chemischen Industrie, and Hoechst AG.—Part 19: ref. [1].

The relative ratio in which the dienylketene in a given case partitions itself between the three reaction channels depends upon the reaction medium and the pattern of substitution[9]. Table 1 selects prototypes from the family of methylated *o*-quinol acetates[1] whose photoproducts are leveled in methanol and are individualized in 2,2,2-trifluoroethanol (TFE).

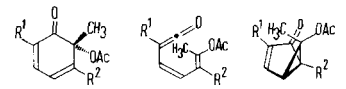

Table 1. The effects of methanol and TFE (leveling and individualizing, respectively) on photoreactions, shown for prototype reactants *(1a)*—*(1c)* (the formulas—not printed in italics as in the text—stand for racemates and for the ligand orientation at the individual CC double bonds or three-membered rings).

Reactant	Methanol		Trifluoroethanol	
	Product	Reaction	Product	Reaction
1a	4a	A	4d	A
1b	4b	A	3b	B+R
1c	4c	A	1c	R

A: Adduct formation
B: Bicyclization
R: Recyclization

4

1 2 3

a: $R^1 = R^2 = H$; b: $R^1 = CH_3$, $R^2 = H$; c: $R^1 = H$, $R^2 = CH_3$

a: $R^1 = R^2 = H$, $X = OCH_3$
b: $R^1 = CH_3$, $R^2 = H$, $X = OCH_3$
c: $R^1 = H$, $R^2 = CH_3$, $X = OCH_3$
d: $R^1 = R^2 = H$, $X = OCH_2CF_3$

Dienone *(1b)* demonstrates that the dienylketene transient *(2b)* can be clearly identified by flash spectroscopy in cyclohexane, methanol, or TFE.

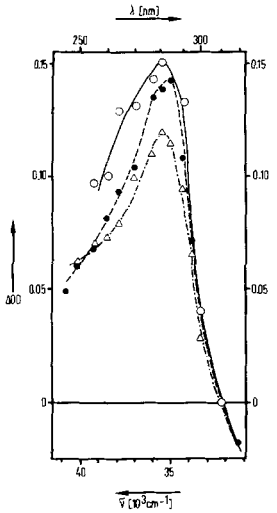

Fig. 1. Spectra of absorption differences of flash photolysis of *(1b)* at room temperature in cyclohexane (- -, 5.15×10^{-5} M), methanol (---, 9.03×10^{-6} M), and TFE ----, 3.32×10^{-5} M).

The transmission/time plot of Figure 2 shows that in TFE *(2a)* gives exclusively the 1,2-adduct *(4d)*, that *(2b)* partly recyclizes to *(1b)* and partly bicyclizes to *(3b)*, and that *(2c)* undergoes recyclization only, affording *(1c)*[9].

A chemical pathway which starts on the $\pi^*\pi$ energy surface is still open to *o*-quinol acetates. This is the light-induced dienone/phenol rearrangement leading to resorcinol monoacetates[4a]. Thus, *e.g.*, *(1b)* isomerizes to 3-acetoxy-2,6-dimethylphenol on direct irradiation in anhydrous ether.

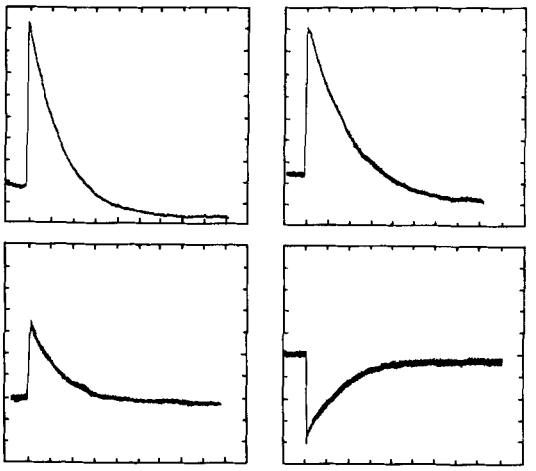

Fig. 2. Flash photolysis (*ca.* 300 J of electrical energy per flash) at room temperature in TFE.—Above left: *(1a)* [1.04×10^{-5} M, $\lambda = 280$ nm, $TB = 2$ s/scale unit, sens./scale unit. = 0.05 V, $Vo = 1.00$ V] reacts completely to *(4d)* *via (2a)* [*(4d)* absorbs less than *(1a)* at 280 nm] without any recyclization being observed [only *(1a)* effectively absorbs at 325 nm].—Above right: *(1b)* [3.32×10^{-5} M, $\lambda = 283$ nm, $TB = 1$ s/scale unit, sens./scale unit. = 0.10 V, $Vo = 3.17$ V] reacts *via (2b)* to give both *(3b)* [*(3b)* absorbs less than *(1b)* at 283 nm] and *(1b)* [only *(1b)* effectively absorbs at 370 nm]. Bottom left: The transient *(2c)* formed from *(1c)* [1.37×10^{-5} M, $\lambda = 250$ nm, $TB = 50$ ms/scale unit, sens./scale unit = 0.05 V, $Vo = 1.35$ V] exhibits neither adduct formation nor bicyclization [*(3c)* and the corresponding adduct would absorb more strongly than *(1c)* at 250 nm].—Bottom right: The transient *(2c)* formed from *(1c)* [1.37×10^{-5} M, $\lambda = 325$ nm, $TB = 50$ ms/scale unit, sens./scale unit = 0.05 V, $Vo = 2.53$ V] recyclizes completely to *(1c)* [only *(1c)* effectively absorbs at 325 nm].

This rearrangement also occurs on warming of *(1b)* in the presence of the "depot sensitizer" tetramethyl-1,2-dioxetane as well as on photosensitization. Since sensitizers are effective down to a triplet energy of 42 kcal/mol, only the energetically lowest-lying triplet spin isomer of the electro isomeric 2,4-cyclohexadienone with $\pi^*\pi$ character has to be taken into account (see footnote [27a] in ref. [2]).

Phase Transfer Catalysis in Organic Chemistry. By *W. P. Weber* and *G. W. Gokel*. Springer Verlag, Berlin—Heidelberg—New York 1977. 280 pp., bound, DM 64.70.—**Phase Transfer Catalysis. Principles and Techniques.** By *C. M. Starks* and *C. Liotta*. Academic Press, New York—San Francisco—London 1978. 365 pp., bound, $ 38.00.

Phase transfer catalysis is a term characterizing an essential advance in chemical synthesis techniques over the last decade. Several review articles have already appeared[*], and now we have the first two monographs (there is already a publisher's announcement of a third[**]). They are written by authors who have taken active part in the development of the technique, *Starks* even coining the term "phase transfer catalysis". The books have been conceived and printed in a pleasantly readable manner, and the number of printing errors has been kept within limits. Both books have been slightly inflated by the repetition of the same subject matter in several chapters and by the tabulation of every compound treated, together with yields, which seems unnecessary in the case of homologous or analogous series with little difference between the individual members. In each book the material in the synthesis section is arranged by the type of reaction: simple substitutions, alkylations and condensations, methods for carbene production, ylide reactions, oxidations and reductions, miscellaneous further phase transfer catalysis reactions (this is the arrangement in *Starks* and *Liotta*). Efforts have been made to cover the literature as comprehensively as possible. *Weber* and *Gokel* cover it to the end of 1976, and there is an appendix with further references from 1976—77, arranged by chapter, giving a total of 650 references. *Starks* and *Liotta* cover just 700 of the 900 references known to them to the end of 1977. The field is developing rapidly; for the period 1978—79, the present reviewer already has more than 200 new references in his file!

There are marked differences in the way that the two books deal with the theoretical foundations (*Starks* and *Liotta* take three chapters with 90 pages, *Weber* and *Gokel* one chapter with 17 pages), and in their printing of typical preparative details (lacking in the case of *Weber* and *Gokel*). While *Weber* and *Gokel* deal briefly with general, mechanistic, and theoretical problems, *Starks* and *Liotta* have put a lot of effort into collecting data on the extraction of anions and cations into organic solvents, on the reactive behavior in different media, and on other fundamental questions. Kinetics, limiting conditions, and possible mechanistic alternatives are discussed, and hints are given on the choice of the catalyst and the solvent and also of the conditions for a new reaction. *Weber* and *Gokel* do give all this material as well, but in a very summary form. Although we are still far from being able to predict the catalyst activity or the exact course of a new phase transfer catalysis process, *Starks* and *Liotta* give the essential starting points for a general theory, and in the case of substitution reactions a fair amount of progress has been made. Difficulties arise in the explanation of alkylation and carbene production in the presence of concentrated caustic soda. *Starks* and *Liotta*'s critical approach, which is otherwise impeccable, breaks down here, for example, in the use of different values for the selective extraction of OH^- (p. 173: Br^- is 10^5 times more readily extracted than OH^-, in Table 7, p. 24, however, it is only 1650 times. Although in other places the difficulty of dissolving tetrabutylammonium hydroxide in benzene is mentioned, the extraction value given in Table 3 on p. 18 is obviously wrong). Notwithstanding these minor blemishes, this is a very good book. Despite the better layout and better paper in *Weber* and *Gokel*, *Starks* and *Liotta*'s book must still be the first choice for anyone who cannot wait for further developments.

Ekkehard V. Dehmlow [NB 471 IE]

[*] For example Angew. Chem. *86*, 187 (1964), *89*, 521 (1977); Angew. Chem. Int. Ed. Engl. *13*, 170 (1974), *16*, 493 (1977).

[**] Phase Transfer Catalysis. By *E. V.* and *S. S. Dehmlow*; Verlag Chemie International, New York and Weinheim, in press.

Principles of Chemical Kinetics. By *G. G. Hammes*. Academic Press, New York 1978, x, 268 pp., bound, $ 19.50.

Despite some pleasing recent publications, there is still a lack of introductory books on reaction kinetics that deal with the fundamentals of formal kinetics and at the same time lead on to the major areas of current research. The present book partly fills this gap. Based on the book by *Amdur* and *Hammes*, it has now been revised by *Hammes* after *Amdur*'s death. It contains chapters on formal kinetics, collision theory, and the theory of the transition state. After examples of bimolecular and unimolecular gas reactions and the more recent theories concerned with them, the author discusses molecular beam experiments and experiments on energy transfer (including recent work with lasers). Shock-wave techniques are dealt with in an appendix. Next comes a survey of reactions in solution, first on the basis of electrochemical relationships and then oriented toward more recent techniques such as relaxation methods and NMR spectroscopy. After a survey of protolytic reactions and acid-base catalysis, the book closes with a chapter on enzyme kinetics.

The author has succeeded in producing a lively and compact presentation of selected topics in modern reaction kinetics. Because it is only a selection, a number of areas have obviously been touched on only lightly if at all. Because of its choice of topics of current interest, the book can be highly recommended as an introduction to some major areas of modern research in reaction kinetics, and as a supplement to the basic lectures of a course on kinetics for advanced students.

Jürgen Troe [NB 466 IE]

Inorganic Polymers. By *N. H. Ray*. Academic Press, London 1978. viii, 174 pp., £ 8.40.

The book gives a concise account of the current stage of development of inorganic polymers, which are defined here as large molecules with no carbon in the main chain and with mainly covalent bonds. Polyphosphoric acid esters, and in particular silicones, which come under this definition, are not dealt with because of their high proportion of organic side groups. There is a brief discussion of the most important physical parameters: modulus of elasticity, tensile strength, brittleness, solubility, and glass transition temperature. From the fact that most inorganic polymers, even if they are highly cross-linked, can be heated beyond the glass transition temperature without decomposition (which is generally not true of organic polymers) and can be processed in this way, the author deduces that the earlier assumption that linear inorganic polymers could be produced by reducing the functionality of elements like B, Si, or P is fundamentally false.

Inorganic polymers may be classified as follows on the basis of the coordination number of the element(s) making up the polymer skeleton:

CN 2: Linear polymers: S, Se, Te, linear metaphosphates, polycarboranes, and the currently much discussed polyphosphazenes and SN polymers.
CN 3: Chalcogenide glasses such as As_2S_3 and ultraphosphates.
CN 3—4: Borate and boron phosphate glasses.
CN 4: Quartz glass, alkali metal silicates, borosilicate glasses, glass ceramics, BeF_2, phosphorus oxide nitride, crystalline silicates such as ladder and layer silicates, three-dimensional networks such as felspars and zeolites, and boron and aluminum phosphate.
CN >4: Titanium, zirconium and tin phosphate, SiP_2O_7.

The main emphasis of the work is on glasses.

Next comes a section on inorganic fibers, *e.g.* on the basis of Al_2O_3 and ZrO_2; there is no discussion of glass fibers, but the reactions involved in the setting of cement are mentioned. There is no reference to enamels.

The author's opinions on the need to replace organic polymers by inorganic ones—for example because of the increasing shortage of oil—are highly debatable.

For whom is the book intended? It will certainly stimulate the thinking of chemists involved in research and development. To evaluate it critically, however, the author assumes that the reader has a very good grounding in inorganic, organic, and polymer chemistry.

Reinhard Schliebs [NB 463 IE]

The Donor-Acceptor Approach to Molecular Interactions. By *V. Gutmann*, Plenum Press, New York 1978, xvi, 279 pp., bound, £ 33.00.

Over the last ten years the author has won considerable respect with a series of papers in which he has attempted to extend the donor-acceptor model of coordination chemistry into a unified concept for the description of all types of molecular interactions. The present monograph contains a detailed presentation of this approach.

The approach is described in two relatively short introductory chapters. The essential effects of a donor-acceptor interaction between two subsystems (two molecules, molecule and solvent, *etc.*) on the properties of these subsystems in the complex can be summarized in three rules concerning the change in bond lengths (the bond-length variation rules). The ability of the subsystems to form donor-acceptor bonds is characterized by empirical parameters specific to the molecule (donor number, acceptor number), and these may be determined by calorimetric, kinetic, or NMR measurements.

In the next fifteen chapters this concept is applied to a wide variety of chemical phenomena, from the formation of simple coordination compounds between isolated molecules, such as $H_3N \cdot BF_3$, *via* solvent effects to enzyme reactions. In each case the donor and acceptor numbers of the subsystems are related to the properties of the complex formed, such as geometric structure, partial charges, stability, chemical behavior, reaction mechanisms, *etc.*

The author has succeeded in discussing a wealth of widely scattered material from all fields of chemistry under one unified viewpoint, and has summarized a large number of different reactions in one concept. Sometimes the approach seems too simple, and sometimes it is also not very satisfactory to have a concept constructed purely upon empirical parameters without any attempt being made to understand the details of a chemical bond and to discuss them. Be that as it may, we must agree with the author when he states in the foreword that the donor-acceptor model is a useful general concept that enables a number of phenomena to be explained and predicted.

Volker Staemmler [NB 472 IE]

Thin Films—Interdiffusion and Reactions. Edited by *J. M. Poate et al.* John Wiley & Sons, London 1978. 1st edit., x, 578 pp., bound, £ 25.00.

The title does not give much indication of the book's great relevance for current problems in semiconductor technology. The work contains information on almost every aspect of interfacial reactions between two solids: interdiffusion, diffusion across the grain boundaries, formation of intermetallic phases, and—in the case of the silicides—formation of chemical compounds.

The techniques and the scope of analytical methods for the characterization of films are described, as are the methods of depth profile analysis, and are illustrated with examples of successful applications. Contact between metals and semiconductors is discussed for the cases of Schottky barriers and ohmic contacts. There is also a chapter on electron migration, *i.e.* on material transport in metal films. The section on solid phase epitaxy may, at first, seem to be of less immediate relevance, but this is not the case, because, for example, recrystallization after ion implantation falls within this field. Finally the effects of ion implantation in metal films on the properties of the metals are considered.

The editors have shown great skill in their choice of topics and authors, but have not intervened to coordinate the contents of the various sections. For example, electron migration appears in two different places in the book.

The unifying element of this book is the relevance of the theme for the further development of semiconductor technology. An understanding of the fundamental physical and chemical processes in the interface and in the metal film itself will result in ideas that may help to solve important problems in the development of new generations of semiconductor components. The book is not a textbook, nor is it a reference book. One should read it for its wealth of information.

Konrad Eisele [NB 455 IE]

The Spectrum in Chemistry. By *J. E. Crooks.* Academic Press, London 1978. 1st edit., x, 313 pp., bound, £ 12.60.

Dozens of monographs, summarizing reports, handbook articles, *etc.* appear every year on various individual aspects of chemical spectroscopy. What is lacking is a monograph or an introductory textbook that would present the chemist with an authoritative guide to the whole range of spectroscopy in chemistry. The present book is directed toward this requirement and meets it well.

The various subfields of spectroscopy with electromagnetic waves are dealt with in 14 chapters. A short introduction is followed by sections on the microwave region, NQR, IR, VIS, UV, Raman, NMR, EPR, fluorescence and phosphorescence, circular dichroism, photoelectron spectroscopy, and Mössbauer spectroscopy. Relevant literature references are appended to each chapter. The use of SI units is dealt with in an appendix. The reader can acquaint himself with the questions raised by means of worked examples. There is a good subject index.

The author assumes a certain knowledge of the fundamentals of physical chemistry, as he makes clear in the introduction.

The requirements are low—even a less advanced student should be able to meet them. In general, the weight of the individual chapters is matched to the importance of the method concerned in the field of chemistry. One or two readers would certainly have wished for a stronger emphasis on the theoretical relationships in contrast to the experimental aspects. Experimental details can sometimes quickly become obsolete (*e.g.* on p. 214 the resolution for a Si solid state detector is given as ≈ 1 keV at 10 keV. However, there are already X-ray detectors on the market that can resolve about 250 eV at 6 keV and 600 eV at 120 keV).

There are a few printing errors that will need correcting in the next edition, *e.g.* Table 6.1 (S incorrectly given for d^2) or p. 44 (the boiling point of nitrogen is 77 K and not 70 K). The reviewer would have preferred a rather more general treatment of the Beer-Lambert Law. The chapter on Mössbauer spectroscopy is perhaps kept too qualitative.

In all, however, the book constitutes a very good introduction to chemical spectroscopy, which will bring both the advanced student and the practising chemist closer to the problems, show them how the techniques are applied, and prepare them for reading specialist monographs. It can be recommended to any scientist requiring a survey of this branch of physical chemistry.

Alarich Weiss [NB 456 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

Frontiers in Physicochemical Biology. Edited by *B. Pullman.* Academic Press, New York 1978. xvi, 503 pp., bound, $ 45.00.—ISBN 0-12-566960-7

Characterisation of Protein. Conformation and Function. Edited by *F. Franks.* Symposium Press, London 1978. 157 pp., paper, £ 9.25.—ISBN 0-905927-05-2

Topics in Stereochemistry, Vol. 10. Edited by *E. L. Eliel* and *N. L. Allinger.* John Wiley & Sons, London 1978. xiii, 349 pp., bound, £ 27.50.—ISBN 0-471-04344-3

General Chemistry, Principles and Structure. By *J. E. Brady* and *G. E. Humiston.* John Wiley & Sons, London 1978. 2nd Edit., xiv, 786 pp., bound, £ 12.65.—ISBN 0-471-01910-0

Metal Alkoxides. By *D. C. Bradley, R. C. Mehrotra,* and *D. P. Gaur.* Academic Press, New York 1978. viii, 411 pp., bound, $ 58.00.—ISBN 0-12-124250-1

Jahrbuch für den Praktiker. Edited by Verlag für Chemische Industrie H. Ziolkowsky KG, Augsburg 1979. 22nd Edit., 497 pp., paper, DM 36.00.—ISBN 3-87846-140-2

Marine Natural Products. Chemical and Biological Perspectives, Vol. 2. Edited by *P. J. Scheuer.* Academic Press, New York 1978. xiii, 392 pp., bound, $ 38.00.—ISBN 0-12-624002-7

Luftverunreinigungen durch Vinylchlorid (VC) aus PVC-Erzeugnissen. By *E.-G. Kohl* and *D. Pruggmeyer.* Erich Schmidt Verlag, Berlin 1978 (Umweltforschungsplan des Bundesministers des Innern—Luftreinhaltung—). 23 pp., paper, DM 14.60.—ISBN 3-503-01737-2

Physical Methods in Modern Chemical Analysis, Vol. 1. Edited by *T. Kuwana.* Academic Press, New York 1978. x, 320 pp., bound, $ 33.00.—ISBN 0-12-430801-5

Catalysis, Vol. 2. Senior Reporters: *C. Kemball* and *D. A. Dowden.* The Chemical Society, London 1978. xi, 276 pp., bound, DM 95.00.—ISBN 0-85186-544-5.—A volume in the series, "Specialist Periodical Reports"

Proceedings of the 5th European Symposium on Polymer Spectroscopy. Edited by *D. O. Hummel.* Verlag Chemie, Weinheim 1979. xi, 332 pp., paper, DM 88.00.—ISBN 3-527-25777-2

Analytical Methods for Coal and Coal Products, Vol. 2. Edited by *C. Karr, Jr.* Academic Press, New York 1978. xvi, 669 pp., bound, $ 55.00.—ISBN 0-12-399902-2

Stereochemistry of [2,3]Sigmatropic Rearrangements

By Reinhard W. Hoffmann[*]

Stereoselective synthesis is attracting more and more attention. Successful stereoselective syntheses require the availability of reactions of known stereochemistry which give maximum yields of the desired products. This is particularly so with reactions proceeding *via* cyclic transition states. Of these, the stereochemistry of [3,3]sigmatropic processes has long been known. This article now summarizes the factors determining the stereoselectivity of [2,3]sigmatropic rearrangements.

1. Introduction

[3,3]Sigmatropic rearrangements (a) (Scheme 1; Claisen, Cope, oxy-Cope, hetero-Cope rearrangement)[1-4] have been thoroughly studied with regard to their stereochemical course[5,6] and belong to the standard repertoire of stereoselective syntheses of olefins[3-7] or centers of chirality[8-11]. Recent outstanding applications can be seen in a juvenile hormone synthesis[12], transformation of sugars into prostaglandins[13], or the synthesis of tocopherol[14].

Scheme 1. Survey of [3,3]- and [2,3]sigmatropic rearrangements. The suggested valences may be bonds to other atoms or lone pairs. Formal charges follow from the nature and the bonding situation of atoms X, Y, Z.

[*] Prof. Dr. R. W. Hoffmann
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)

Among the [2,3]sigmatropic rearrangements there is a great variety of reactions of types I and II [Scheme 1, eq. (b) and (c)][15-21] which frequently occur at lower temperatures than the [3,3]sigmatropic rearrangements. The five-membered cyclic transition state of [2,3]sigmatropic rearrangements shows greater conformational "flexibility" than the six-membered transition state of [3,3]sigmatropic rearrangements and should therefore be far more susceptible to the effects of stereochemical control by substituents[22]. In view of this synthetic potential it was most appropriate that studies on [2,3]sigmatropic rearrangements should have been accompanied by a thorough examination of their stereochemistry which began almost simultaneously[23]. It is thus all the more surprising that the starting materials for the preparative investigation of [2,3]sigmatropic rearrangements were (purposely?) chosen in such a way that no stereochemical problems occurred. However, this meant forgoing stereochemical information.

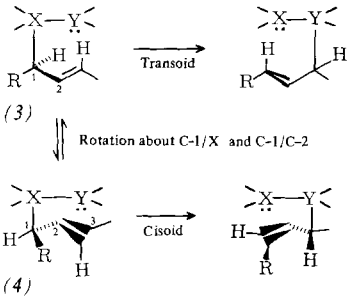
The following compilation of results should provide an insight into the stereochemistry of [2,3]sigmatropic rearrangements.

1.1. Stereochemical Observables

The rearrangements (b) and (c) lead to formation of a new double bond between C-1 and C-2. Given two different substituents on C-1 this double bond may result in an *E* or *Z* configuration. Hence the factors determining the configuration of the new double bond are of interest.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0808-0563 $ 02.50/0

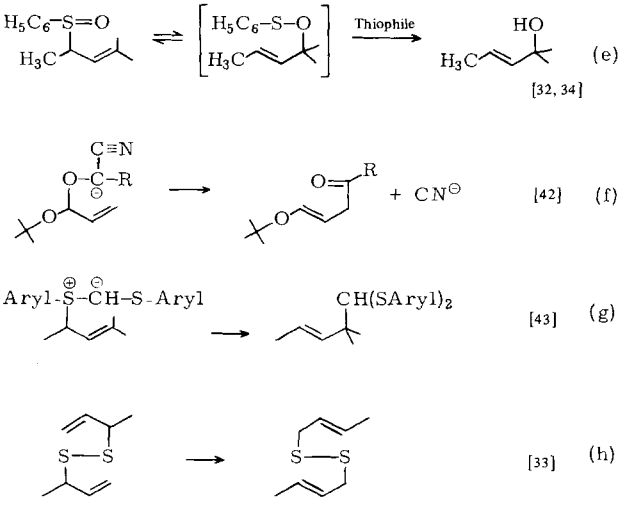
The centers X and C-1 of the reactants of rearrangements (b) and (c) are chiral if they each bear two different substituents. A lone pair will also be regarded as a substituent in these considerations. C-3 [rearrangements (b) and (c)] and Y [rearrangements (b)] are prochiral if the substituents on these centers are different. In the course of rearrangement, the chirality of X and C-1 disappears and new chiral centers are created at C-3 and Y. Interest attaches here to the factors determining the extent to which chirality is transferred to C-3 and Y.



This article will consider only reactions whose products are formed by kinetic control, and reactions which are concerted, *i.e.* no reactions proceeding *via* a dissociation-recombination mechanism[24-27].

2. Configuration of the New Double Bond

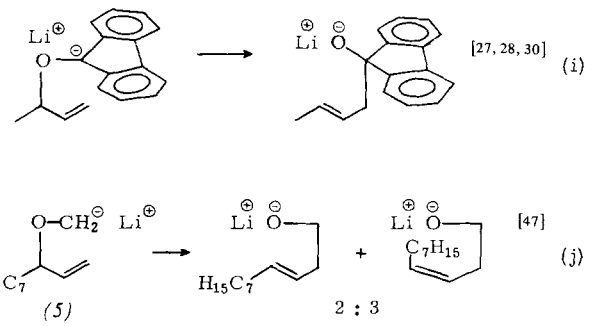
[3,3]Sigmatropic rearrangements are often employed for the stereoselective construction of di- and tri-substituted olefins. The [2,3]sigmatropic rearrangements considered here exhibit a stereoselectivity comparable with, or even higher than, similar [3,3]sigmatropic rearrangements.



2.1. 1,2-Disubstituted Double Bonds

In the case of a 1-monosubstituted derivative of *(1)* (Scheme 1), rearrangement starting from *(3)* and *(4)* can proceed *via* two transition states, designated as transoid and cisoid by *Mislow*[23] [eq. (d)].

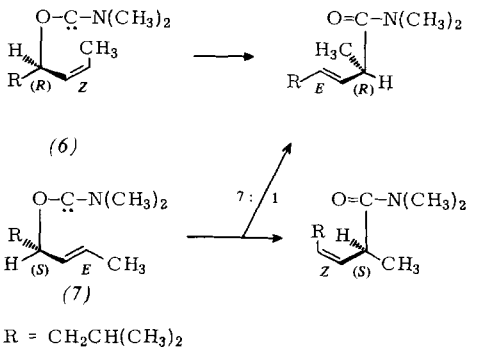
(3) (4) (d)



Examples (e)—(h) show that the rearrangement generally leads with a high degree of selectivity *via* the transoid transition state to *E* olefins[27-45] (R = *i*-butyl, *n*-hexyl, Aryl = phenyl).

(e) [32, 34] (f) [42] (g) [43] (h) [33]

Formation of the *E* double bond can be rationalized by assuming the substituent R to preferentially adopt an equatorial position in a five-membered cyclic transition state, *versus* a pseudoaxial position leading to the *Z* double bond. This amounts to saying that the substituents on C-1, C-2, and C-3 come to rest in a plane during the rearrangement. In the cisoid transition state, a destabilizing 1,3-allyl interaction[46] would become operative between R and the hydrogen atom on C-3; in the transoid transition state only a 1,3-hydrogen-hydrogen interaction will occur.

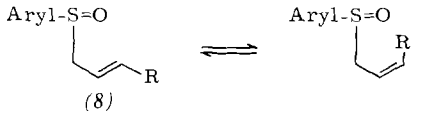


The regularity with which *E* olefins are formed serves to underscore exceptional behavior: while Wittig rearrangement (i)[*][27,28,30] proceeded entirely *E*-selectively according to these rules, reaction (j)[47] followed an exceptional course, giving mainly the *Z* olefin.

(i) (j) (5)

In contrast to reaction (i), reaction (j) is probably strongly exothermic. This would indicate an early transition state and hence diminished selectivity[48]. The charge distribution in reactant *(5)* also suggests the migrating allyl group to have considerable carbanion character. This could favor formation of the *Z* olefin owing to the greater stability of a *Z*-substituted allyl anion[49]. The regioselectivity of the rearrangement rules out dissociation[50] to formaldehyde and an allyllithium derivative.

A low stereoselectivity was also found in a rearrangement of type II[51,52]. The species *(6)* and *(7)* are reactive intermediates; this fact and the high reaction temperature (130 °C) would offer a reasonable explanation of the diminished selectivity.



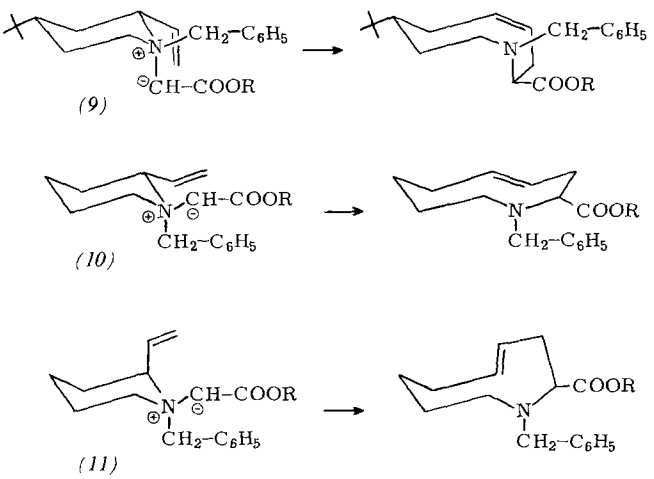
(6) (k) (7)

R = $CH_2CH(CH_3)_2$

These exceptions show that the energy difference between the transoid and the cisoid transition state cannot be large. In full accord with this conclusion, *E*/*Z* isomerization of the double bond was found to occur in reversible sigmatropic

[*] Designations such as Wittig or Stevens rearrangement are used in the widest sense.

rearrangements, such as that of *(8)*[23,53,54] (Aryl = *e.g. p*-tolyl; R = methyl, *n*-pentyl).

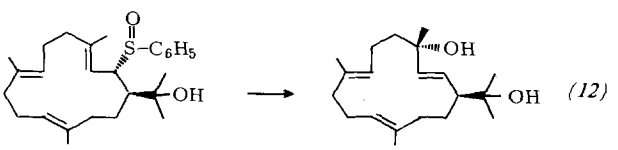


(8)

In the irreversible allyl sulfoxide/allyl sulfenate rearrangement of type (e), the *E*-allyl sulfoxide reacts nine times as fast as the *Z* isomer[55]. This result and the position of equilibrium between *E* and *Z*-allyl sulfoxide permit us to estimate the cisoid transition state for *(8)*, Aryl = phenyl, *p*-tolyl, R = *n*-pentyl, to be only *ca.* 1.5 kcal/mol less stable than the transoid transition state. This estimate does not include interactions with the substituents on X or Y [see eq. (d)]. Moreover, these values are also in agreement with data reported for the [3,3]sigmatropic Claisen rearrangement according to which *E*-allyl ethers react three- to nine times as fast as their *Z* isomers[56,57].

The slight energy difference between cisoid and transoid transition states also explains why [2,3]sigmatropic rearrangements proceed readily *via* cisoid transition states if they are constrained to occur by incorporation of the double bond into a ring[51,58,62].

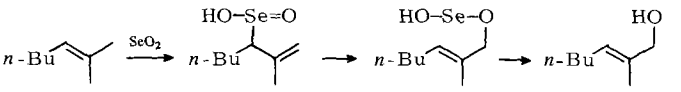
[2,3]Sigmatropic rearrangements have also been used to advantage for ring enlargement[63]. The new endocyclic double bond is formed with high stereoselectivity: if Y (CH COOR in this case) in a reactant such as *(9)* is in an axial arrangement a *Z* olefin will be formed; if Y assumes an equatorial position as in *(10)* and *(11)* an *E* olefin will result, regardless of the arrangement (equatorial or axial) of the vinyl group in the reactant (R = ethyl).



(9)

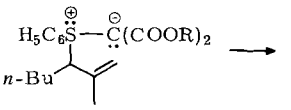
(10)

(11)



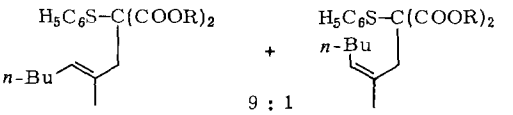
According to what has been said so far, [2,3]sigmatropic rearrangements are just as suitable as [3,3]sigmatropic rearrangements[3] for the stereoselective construction of 1,2-disubstituted double bonds, with *E* olefins generally being formed. A further example may be seen in the *E* selective introduction of a double bond into the cembrene derivative *(12)*[44].

(12)

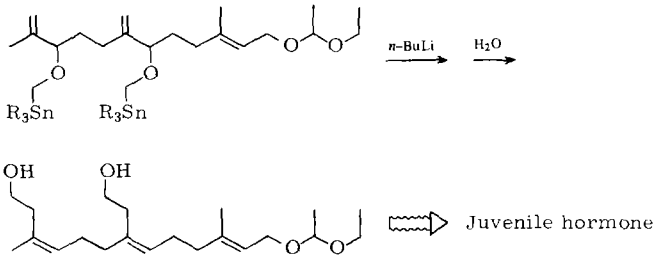


2.2. Trisubstituted Double Bonds

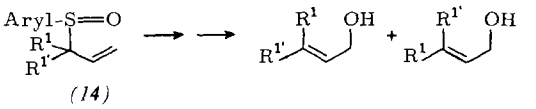
If a substituent is introduced into compounds such as *(3)* at C-2, this will have no effect on the cisoid transition state but should destabilize the transoid transition state by way of an additional 1,2-allyl interaction[46] between the substituents on C-1 and C-2. Nevertheless, as in the case of [3,3]sigmatropic rearrangements[3], the tendency to form an *E* double bond is retained: in the allyl sulfoxide/allyl sulfenate rearrangement of type (e) the products were found to have exclusively an *E* double bond[64,65] or to show pronounced *E* preference (20:1)[66]. This also applies to the corresponding allyl selenoxide rearrangement[67]; the *E* selective oxidation of isopropylidene groups as in *(13)* by selenium dioxide can probably be attributed to the stereoselectivity of the [2,3]sigmatropic rearrangement[67].



(13)

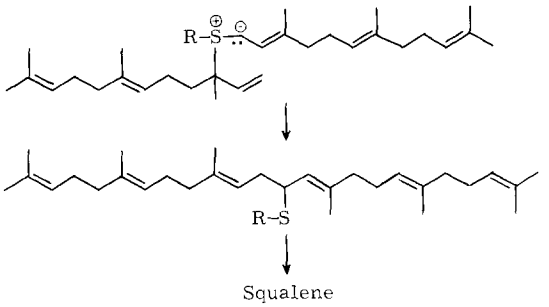


The Stevens rearrangement [eq. (l)][68] gave less *E* olefin than the reactions just considered, and the Wittig rearrangement [eq. (j)] of 2-methyl-substituted *(5)* was unexpectedly



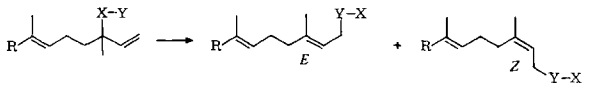
(1)

completely *Z* selective[47]. This unusual *Z* selectivity found an ideal application in a new juvenile hormone synthesis[69].



Trisubstituted olefins also result from the rearrangement of 1,1-disubstituted derivatives of *(1)*. The *E* or *Z* stereoselectivity depends upon the relative sizes of the substituents attached to C-1. Thus *E* preferences ranging from 3[66] *via* 10[66]

(14)

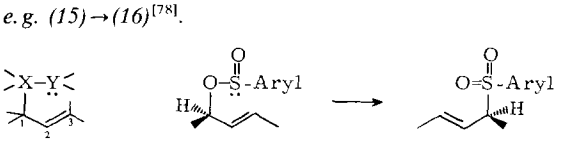


to > 20[70,71] were found in the rearrangement of 1,1-disubstituted allyl sulfoxides of type *(14)*. A corresponding rearrangement of a sulfonium ylide is presumably involved in

the *E* stereospecific biochemical linkage of two farnesyl units to give squalene[72,73]. The reaction can be accomplished *in vitro* with $R = C_6H_5$.

Model studies on comparable systems show that the Stevens rearrangement is *E* stereospecific[73] whereas Wittig rearrangements and carbene rearrangements of type II eq. (c) show a considerably diminished selectivity towards formation of an *E* double bond. Examples are shown in Table 1.

Table 1. Stereoselectivity in [2,3]sigmatropic rearrangements.



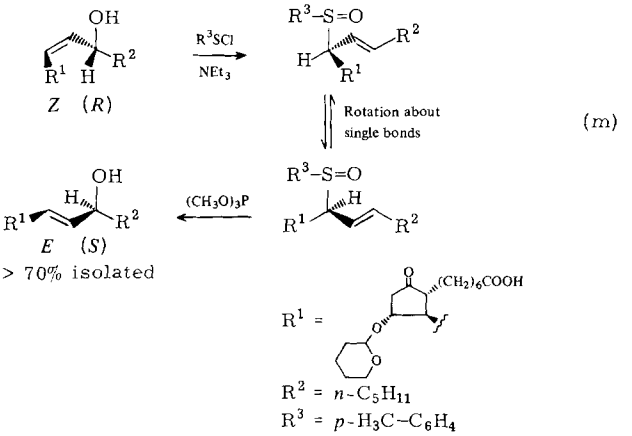
R	X	Y	*T* [°C]	Result	Ref.
$(CH_3)_2CH$ ^{f} $C(CH_3)_2$	$C_6H_5S^{\oplus}$	$\ddot{C}H$ $[CH=^f C(CH_3)(CH_2)_2]_2CH=C(CH_3)_2$	65	only *E*	[73]
H	$C_6H_5S^{\oplus}$	$\dot{O}^{\ominus}$	25	*E*:*Z* = 9:1	[66]
H	S	$\ddot{C}H$ $CH=C(CH_3)_2$	−30	*E*:*Z* = 3:2	[74]
H	O	$\ddot{C}H$ C_6H_5	−20	*E* and *Z*	[24]
H	O	$\ddot{S}(O)$ $CH_2CH=C(CH_3)(CH_2)_2CH=(CH_3)_2$	110	*E* and *Z*	[75]
CH_3	O	$\ddot{C}$ $N(CH_3)_2$	139	*E* and *Z*	[51]

In some cases[70-74], the [2,3]sigmatropic rearrangement of 1,1-disubstituted allyl derivatives thus exhibits a significantly greater stereoselectivity than the corresponding [3,3]sigmatropic rearrangement[6].

3. Transfer of Chirality

3.1. 1→3 Chirality Transfer

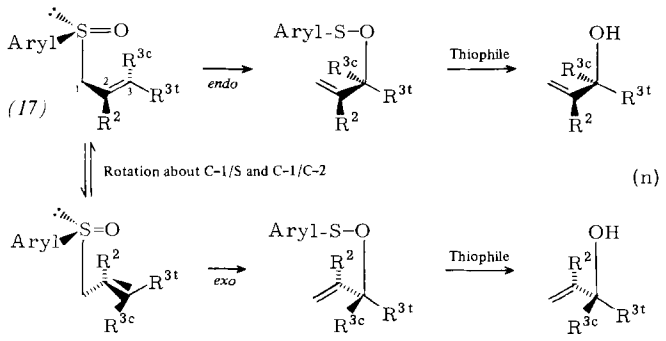
On rearrangement of 1,3-disubstituted derivatives of *(1)*, the chiral center at C-1 is eliminated and a new one created at C-3. The term "self-immolative" asymmetric synthesis has been introduced to describe syntheses of this kind[21,76]. Provided that the reactant has a uniform configuration of the C-2/C-3 double bond, quantitative 1→3 chirality transfer will follow from the suprafacial[18,77] course of rearrangement, *e.g. (15)→(16)*[78].



(1) *(15)* *(16)*

This has been repeatedly confirmed by experiment[52,78,79] and accords with experience gained in [3,3]sigmatropic rearrangements[80]. Homogeneous products can be obtained directly if the new double bond is formed stereoselectively (see Section 2.1). Only Wittig rearrangement[18] or carbene rearrangement [eq. (k)][52] gave mixtures of *E*/*Z* isomers in which the stereochemistry at C-3 nevertheless results from complete chirality transfer. The example of a prostaglandin synthesis [eq. (m)] illustrates how the *E* preference is exploited on formation of the new double bond in order to invert both the double bond geometry and the chirality of an allyl alcohol at one stroke by a series of [2,3]sigmatropic rearrangements[37]; for the chemical aspects, cf. eq. (e) and (n).

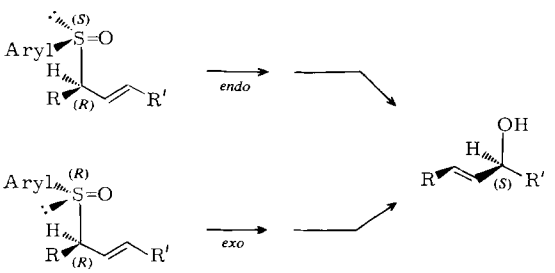
3.2. X→3 Chirality Transfer



For preparative reasons, the reactants of [2,3]sigmatropic rearrangements are usually obtained by linking the allyl system with the X–Y fragment. In the case of 1→3 chirality transfer, the chirality is shifted by two carbon atoms along the same synthon (the allyl component). In contrast, an X→3 chirality transfer permits the preparatively more useful transfer of chirality from one synthon—the X–Y fragment—to another (achiral) synthon, specifically to C-3. Rational utilization of this chirality transfer requires that the prochiral center C-3 has a uniform configuration[55] (*i.e.* that the double bond in *(1)* has either *E* or *Z* configuration)—a requirement that leads to further preparative complications.

The fundamental stereochemical concepts concerning the transition states of [2,3]sigmatropic rearrangements are due to *Mislow*[23], who developed them for the example of allyl sulfoxide/allyl sulfenate rearrangement. This rearrangement can proceed *via* two diastereomeric transition states, *viz.* *"exo"* and *"endo"*[27], which interconvert by rotation about the C-1/C-2 and the C-1/C–S bond [eq. (n)].

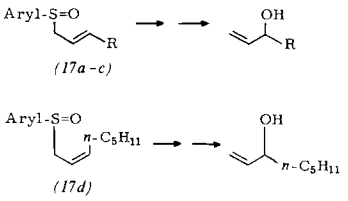
Since the different enantiotopic sides of the C-2/C-3 double bond are attacked in the *exo* and the *endo* transition state, a reactant of uniform chirality will give enantiomeric products *via* the *exo* and the *endo* transition state. The extent of chirality transfer therefore depends upon the relative energy of the two transition states.



In similar manner, the energy difference between the transition states having chair and boat conformation determines the degree of a corresponding 1→3′ chirality transfer in [3,3]sigmatropic rearrangements[5]. Owing to the energy difference of *ca.* 3 kcal/mol, extensive (>94%) 1→3′ chirality transfers are observed in these cases[11,81]. Thus the transition states with chair and boat conformation in [3,3]sigmatropic rearrangements correspond to the *exo* and *endo* transition states of [2,3]sigmatropic rearrangements with regard to the stereochemical results.

(n)

The situation is most readily discussed in which the two "freely available" ligands on the chiral X atom of *(1)* differ considerably in size, as with *(17)* whose X ligands are an aryl group and a lone pair. It may then be assumed that the energy difference between the two transition states is determined by the extent of aryl-R^2 interaction (destabilizing the *endo* transition state) and aryl-R^{3c} interaction (destabilizing the *exo* transition state).



These interactions must first be examined in relation to other substituent effects for they are considerably weaker than those between a 1-substituent and R^2 and R^{3c} [cf. eq. (l) and eq. (k)]. Thus experience shows that a substituent on C-1—if present—will determine the stereochemistry of rearrangement. This is why we were able to discuss the controlling influence of such a substituent in Section 2 without paying the slightest attention to the chirality at centers X and Y. Even when both diastereomeric reactants were present[44,64], allyl sulfoxide/allyl sulfenate rearrangement gave the *E* olefin. This means that under the influence of the substituent on C-1 one diastereomer reacts selectively *via* the *exo* transition state and the other selectively *via* the *endo*-transition state [eq. (o)].

(o)

Hence, any attempt to establish the influence of the chirality of center X on the stereochemistry of rearrangement must be undertaken with derivatives of *(1)* which are unsubstituted at C-1 or bear two identical substituents at that site. We therefore first examined C-1-unsubstituted derivatives of *(17)* with $R^2 = R^{3c} = H$. Examples are shown in Table 2[55].

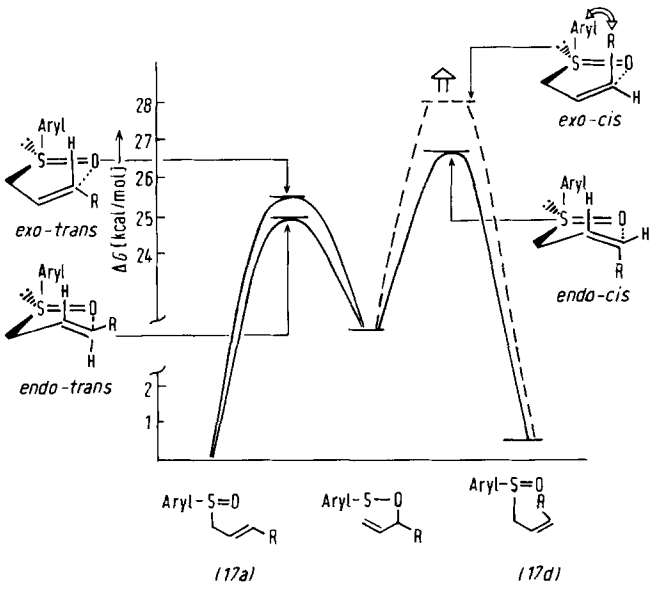
Table 2. X→3 chirality transfer for sulfoxides *(17)*. Aryl = *p*-CH_3-C_6H_4.

Cpd.	R	Reaction *via* *exo* transition states [%]	*endo* [%]	Chirality transfer [%]
(17a)	*n*-C_5H_{11}	30±5	70±5	40±10
(17b)	*t*-C_4H_9	≈50	≈50	5
(17c)	C_6H_5	50	50	0
(17d)	*n*-C_5H_{11}	< 5	>95	>90

The modest transfer of chirality reveals that the energies of the *exo*- and *endo* transition states hardly differ for the *E*-allyl sulfoxides *(17a—c)*. In contrast, the *exo* transition state can be selectively destabilized by the R^{3c} substituent in the *Z*-allyl sulfoxide *(17d)*. In this case the rearrangement proceeds largely *via* the *endo* transition state and is therefore, close to stereospecific.

The relative energies of the four conceivable diastereomeric transition states could be estimated from the rate and the stereochemical course of rearrangement of *(17a)* and *(17d)* (Fig. 1)[55].

A number of earlier observations can be discussed with the aid of Figure 1: *Mislow et al.*[23] found that at room tempera-



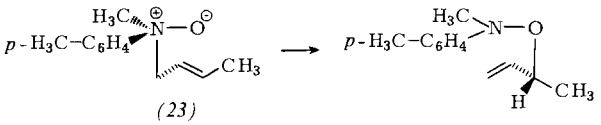


Fig. 1. Relative energies of the four conceivable transition states of the [2,3]sigmatropic rearrangement of *(17a)* and *(17d)* (see text for details). R = *n*-pentyl, Ar = *p*-tolyl.

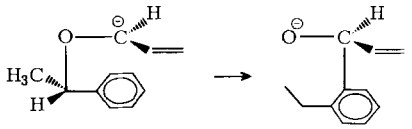
ture allyl sulfoxides undergo fast racemization [at the asymmetric S atom, see eq. (o)] and slow *E/Z* isomerization. Racemization of, say, the *E*-configurated allyl sulfoxide *(17a)* requires that it must rearrange *via* the *exo-trans* and the *endo-trans* transition state. *E/Z* isomerization additionally requires that the *endo-cis* transition state be transversed, which is rate-determining for this isomerization. The *Z*-configurated allyl sulfoxide *(17d)* can also racemize: to this end it first transforms *via* the *endo-cis* transition state into the *E* isomer *(17a)*, which undergoes fast racemization so that racemic *(17d)* is ultimately regenerated *via* the *endo-cis* transition state. Thus only three of the four possible diastereomeric transition states are necessary for the stereoisomerizations observed by *Mislow*. The least favorable *exo-cis* transition state (greatest steric interaction) therefore probably fails to play any significant role. On suitable destabilization of the *endo-cis* transition state, slow rearrangements *via* the *exo-cis* transition state have been observed[101].

In the same way as an R^{3c} substituent destabilizes the *exo-cis* transition state, and thus compells reaction *via* the *endo-cis* transition state, an R^2 substituent should, depending upon its size, hinder rearrangements *via* the *endo* transition states[79b,81a] and thus lead to reactions *via* the *exo* transition state. This was examined in the case of the aryl-1-cycloalkenylmethyl sulfoxides *(18)*—*(22)* (Table 3)[82].



The annelated secondary alkyl group R^2 [see eq. (n)] leads to preferential rearrangement of the cyclopentene derivative *(18) via* the *exo* transition state. This tendency is further enhanced with the cyclohexene derivatives *(19)* and *(20)*; and in the case of compounds *(21)* and *(22)*, which contain a tertiary and a quaternary group R^2, respectively, reaction proceeds exclusively *via* the *exo* transition state. The allyl sulfoxide/allyl sulfenate rearrangement [eq. (e)] can therefore be employed for complete transfer of chirality from X to C-3 provided that a R^{3c} substituent or a bulky group R^2 is present. Also in the case of the *N*-oxide *(23)* with two substituents attached to X not differing much in bulk a remarkable transfer of chirality (>81%) was observed[21].

(23)

It is rather unclear, however, why the *exo* transition state should be preferred in this instance.

Complementary to X→3 chirality transfer is a transfer of chirality from C-1 to Y. Wittig rearrangement of *(24)* is an example[83] (cf. also ref. [18]); it proceeds selectively *via* one of the four diastereomeric transition states (cf. Fig. 1). However, secondary reactions mask which transition state is actually preferred.

(24)

3.3. X→Y Chirality Transfer

X→Y chirality transfer in the diatomic element of [2,3]sigmatropic rearrangement correspond to 1→3 chirality transfer in the triatomic element. Most accounts of such effects have been reported for rearrangements of sulfur ylides; however, stereochemical assignments are not given [Table 4, *(25)*—*(27)*].

Chirality transfer has recently also been found in Pummerer rearrangements, although it is not clear whether a competing dissociation into two fragments might be respon-

[90]

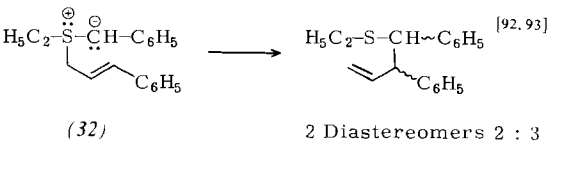
(30)

25 : 1

[90]

(31)

A considerably higher selectivity was observed in the reactions of the ylides *(29)—(31)* in which not only the chirality of the center X is a controlling factor, but probably also the diastereoselectivity on linkage of the C-3/Y bond.



4. Diastereoselectivity in Bond Formation

4.1. Diastereoselective C-3/Y Bond Formation

On rearrangement of the ylides *(29)-(31)*, pronounced diastereoselectivities were found on linkage of the C-3/Y bond. However, exclusive formation of one diastereomer[27,91] is not the general rule. Only modest diastereoselectivity was frequently observed for conformationally mobile substrates[18,27,92-94].

In these cases, the diastereoselectivity is determined primarily by the relative energies of the *exo* and *endo* transition state.

The fact that a reciprocal diastereomeric ratio is established starting from *(34)* or *(35)* shows the influence of *exo* or *endo* folding (cf. Section 2.1) of the allylic moiety in the transition state to be the determining factor in this case. In contrast, the rearrangement (q)[18,27] leads to different diastereomeric ratios starting from the *E* or the *Z* reactant—a sign that the energy difference between the *threo* and *erythro* arrangement on formation of the new bond cannot generally be neglected. In the rearrangement (p) a further controlling

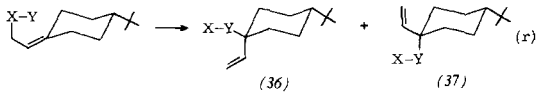
(35)



influence of unknown magnitude is exerted by the chirality at the center X.

Thus, while in [3,3]sigmatropic rearrangements the new C-3/C-3′ bond is formed with high diastereoselectivity owing to the comparatively large energy difference between the chair and boat conformation in the transition state[5,57,96], only slight diastereoselectivity is generally encountered in [2,3]sigmatropic rearrangements owing to the smaller energy differences between the *exo* and the *endo* transition state.

4.2. Diastereoselectivity on Formation on Other Stereocenters

The stereoselective formation of quaternary carbon centers is of importance in terpene syntheses, particularly with regard to the construction of spiro linkages. Results available so far suggest that the use of [2,3]sigmatropic rearrangements is of particular advantage for this purpose[22]. Examples are shown in Table 5.

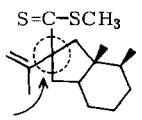


Table 5. Diastereoselectivity in reactions according to eq. (r).

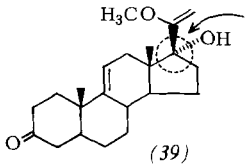
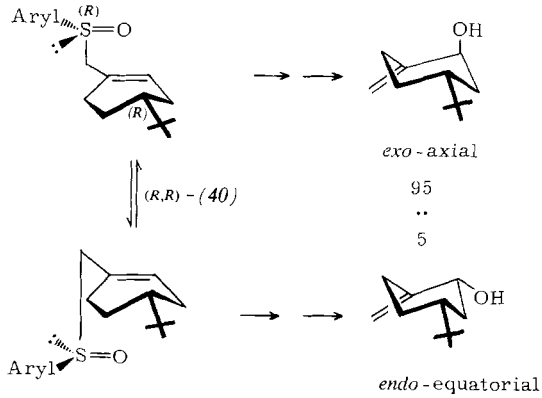


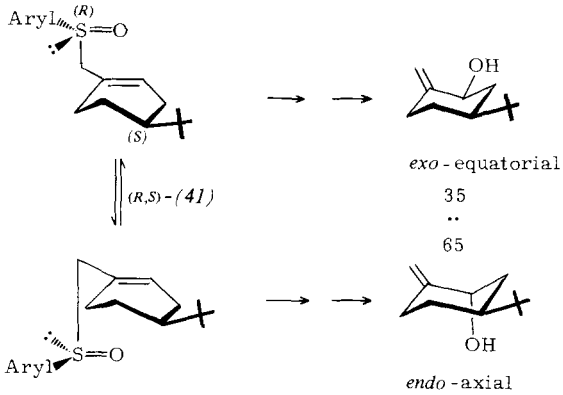
(36) (37)

X	Y	T [°C]	(36):(37)	Ref.
$C_6H_5S^{\oplus}$	$\overset{\ominus}{C}Cl_2$	25	97:3	[97]
$C_5H_5S^{\oplus}$	$\overset{\ominus}{O}$	25	92:8	[98]
$C_6H_5S^{\oplus}$	$\overset{\ominus}{C}H\ COOC_2H_5$	25	91:9	[97]
$\overset{\oplus}{N}$	$\overset{\ominus}{C}H\ CN$	−10	90:10	[99]

In contrast to these reactions, the corresponding [3,3]sigmatropic Claisen rearrangement[100] at 200 °C proceeded with very low stereoselectivity. It is also remarkable that the stereoselectivity in reactions (r) is largely independent of the nature of X and Y. This enhances the preparative flexibility in the use of [2,3]sigmatropic rearrangements for diastereoselective syntheses. Formation of the stereocenters marked in *(38)*[22] and *(39)*[101] serves as example.



(38)

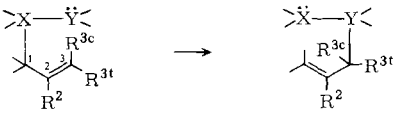


(39)

Diastereoselectivities with regard to another ring substituent are also found in the rearrangement of allyl sulfoxides *(40)* having an endocyclic double bond[102]. For example, the *R,R*-diastereomer *(40)* showed a pronounced tendency to rearrange *via* the *exo*-axial transition state. The *R,S*-diastereomer *(41)* reacts preferentially *via* the *endo*-axial transition state (Aryl = *p*-tolyl).

This situation can be interpreted[102] by assuming a 3.1-fold preference for rearrangement *via* the *exo* as against the *endo* transition state (cf. Section 3.2) and, moreover, a 6.2-fold preference for formation of an axial as against an equatorial bond[*]. These effects reinforce each other in the case of the diastereomer *(40)* and oppose each other in that of the diastereomer *(41)*. This striking preference for formation of

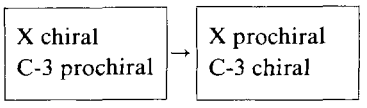
axial bonds has parallels in [3,3]sigmatropic rearrangements[6] and is in accord with general stereoelectronic principles[103].



5. Conclusion

The *clou* of the stereochemistry of [2,3]sigmatropic rearrangements and of the corresponding [3,3]sigmatropic rearrangements, discussed in this article, lies in the mutual transformation of potentially chiral groups into prochiral ones, and prochiral groups into chiral centers—as is adequately illustrated by reactions (k) and (m). Its importance in stereoselective synthesis is apparent from fact that the stereochemical situation at an sp^3 center is transformed into a defined configuration of the resulting double bond and *vice versa*.

An attempt has been made in this article to draw up the rules governing transformation of chirality into prochirality and prochirality into chirality in [2,3]sigmatropic rearrangements. In preparative applications particular importance attends those factors which determine the degree of stereoselectivity in these reactions.



The stereochemical consequences of [2,3]sigmatropic rearrangements of type I [see eq. (b)] are recapitulated in Scheme 2.

Adiabatic Photoreactions of Organic Molecules

By Nicholas J. Turro, Jeffrey McVey, V. Ramamurthy, and Peter Lechtken[*]

An adiabatic photoreaction is a chemical process that occurs entirely on a single excited electronic energy surface. As a rule, most photoreactions of organic molecules start on an excited electronic surface but "jump" to a lower surface somewhere along the reaction coordinate. There are, however, exceptions to this general rule. For example, photoreactions involving small structural changes and minor alterations in covalent bonding (*e.g.*, proton transfers and complex formation) are commonly found to occur adiabatically. The purpose of this review is to survey examples of more complicated adiabatic photoreactions such as fragmentations, electrocyclic rearrangements, and geometrical isomerizations. The concepts employed are presented in an introductory discussion.

1. Introduction

What is an "adiabatic photoreaction"? According to *Förster*[1]: *an adiabatic photoreaction is a chemical process that occurs entirely on a single excited electronic energy surface.* The notion of electronic excitation is a key ingredient in any *photochemical* process and the notion of passage along a *single energy surface* is the essence of an *adiabatic* process. In this spirit, most thermal reactions are adiabatic because they tend to occur entirely on a ground state electronic surface. *Every overall photoreaction,* on the other hand, is diabatic (or nonadiabatic) since it is initiated with molecules on excited electronic surfaces, but terminates with (isolated) products in their ground states. In order to visualize more precisely what is happening at the molecular level, let us first discuss the "three state" and the "energy surface" concepts.

2. The Three State Concept: S_0, T_1, and S_1

An important paradigm of organic photochemistry is the *three state concept,* or the rule that understanding the mechanisms of most organic photoreactions in solution requires explicit consideration of only three electronic states: S_0, the electronic ground state, T_1, the lowest energy triplet state, and S_1, the lowest energy excited singlet state. The postulate that T_1 and/or S_1 are the starting points of all chemically significant photochemical processes is an extension of *Kasha*'s rule[2] that electronic emission from organic molecules (in the condensed phase) generally occurs only from S_1 (fluorescence) or from T_1 (phosphorescence).

The three state concept is a good starting point for analyses of the electronic spectroscopy of organic molecules, which involves (more or less) "vertical" radiative or radiationless jumps between surfaces at geometries similar to the initial equilibrium geometry of S_0. A useful extension of the three state concept to photochemistry involves the S_0, T_1, and S_1 *surfaces* that occur along a reaction pathway. We now briefly review the key features of the energy surface concept.

3. The Energy Surface Concept[3]

A molecule in a particular electronic state may exist with various spatial configurations of its nuclei, each nuclear configuration corresponding to a definite potential energy (*i.e.*, kinetic energy due to nuclear motion equals zero) of the molecule. A map of a molecule's potential energy in a given electronic state *versus* nuclear configuration is termed a *potential energy surface.* It is important to realize that for any given nuclear change (say, from nuclear structure R, corresponding to an initial reactant structure, to a nuclear structure P, corresponding to a final product structure) a different potential energy surface exists for *each electronic state.*

Imagine now a nuclear configuration that happens to be of interest to you and label the initial nuclear structure R and the final nuclear structure P. Now imagine proceeding from structure R to structure P *via* a number of different specific molecular choreographies. Each of these "pathways" from R to P will possess a set of energy surfaces corresponding to the change in potential energy of each initial state of R as a function of nuclear configuration. However, for a given electronic state there will generally exist a unique lowest energy surface. Schematically, a given R→P pathway may be visualized in terms of *energy curves* (a topological simplification of an energy surface) as shown in Figure 1.

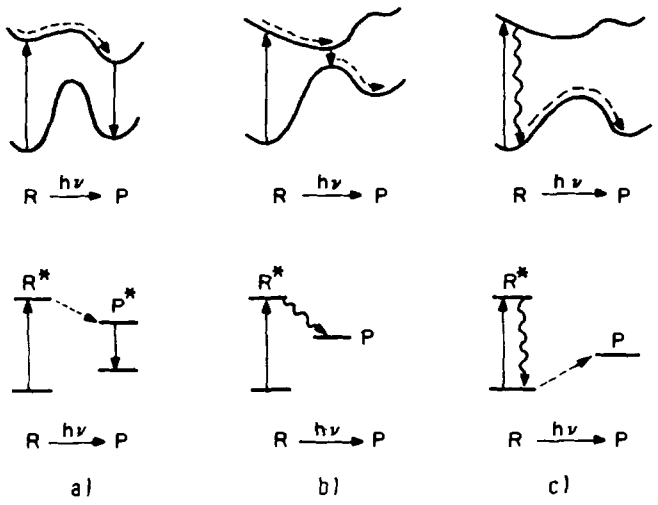

Fig. 1. Schematic representation of (a) an adiabatic photoreaction, (b) a diabatic photoreaction, and (c) a "hot" ground state reaction. The upper drawings provide a surface description and the lower drawings provide a state level description. →, radiative "jump"; - - →, motion on surface; ⇝, radiationless "jump".

The important points to remember when employing such structure-energy diagrams are: (1) they are too good to be true, *i.e.*, they are oversimplified; (2) they contain very general, qualitative topological information only; (3) the surfaces corresponding to many configurational transformations which take R→P may possess common topological features.

3.1. The Trajectory of a "Representative Point" on an Energy Surface

An adiabatic photoreaction occurs when an electronically excited reactant R* is converted into an electronically excited product P* on a single energy surface. We may discuss this interconversion in terms of the trajectory of a "representative point" on an energy surface. The "point" represents the state of the molecule and contains information on the molecule's energy and nuclear, electronic, and spin structure. The trajectory of the point on a given energy surface corresponds to motion along a reaction coordinate with the molecule in a given (S_0, T_1, or S_1) electronic state. Thus,the overall conversion of structure R to structure P may be viewed as occurring on the S_0, T_1, or S_1 surfaces. Although the choreography of the nuclei in space may be similar (or nearly identical) for the overall R→P transformation on each surface, the actual shape of the S_0, T_1, or S_1 surface traversed may be quite different.

A representative point on an excited surface is always subjected to a force that attracts it to a lower surface. The origin of this force is the electrostatic interactions of nuclei and electrons. If, for a given nuclear configuration, the electronic configuration is excited, there will always exist an attracting force to produce states of lower energy. Thus, during its trajectory along *any* excited surface, the representative point is being inexorably "attracted" to lower surfaces and jumps from upper surfaces to lower energy surfaces will occur spontaneously and inevitably. However, the *rates* (and efficiencies) of spontaneous surface jumps, in analogy to spontaneous chemical reactions, depend on *available mechanisms* open to the representative point as it surveys various nuclear configurations during its motion on a given surface.

If an adiabatic photoreaction is to occur on the T_1 or S_1 surface, then along the reaction coordinate there can occur no nuclear geometries from which the representative point can efficiently "jump" to a lower surface. Jumps between surfaces are most efficient when the representative point finds itself in a fairly stable energy minimum (a large energy barrier exists for further motion along the same energy surface) or when the representative point approaches a nuclear geometry for which two surfaces (one of which it is on) become close in energy (potential for strong mixing of states).

Thus, if the representative point is on an excited surface which is "far away" from all lower energy surfaces for the entire trajectory corresponding to the structural conversion R→P, in the absence of energetic restraints, the adiabatic photoreaction R*→P* should be efficient. In the absence of dynamic effects, there is one important exception to the expectation that a surface jump by the representative point will occur efficiently when two surfaces come close to each other. The jump will be inefficient if the two approaching surfaces differ substantially in electronic or spin structure[3c].

For example, "zero order" crossings of singlet surfaces and triplet surfaces remain as crossings unless a very strong spin orbit coupling force exists when the representative point is in the "crossing region."

3.2. Adiabatic, Diabatic, and "Hot" Ground State Photoreactions[3c]

It is convenient to classify photoreactions in terms of three types which are based on the distinction as to whether electronic de-excitation occurs (a) when the nuclear configuration is essentially that of the primary product(s); (b) when the nuclear configuration is intermediate between that of the reactant(s) or primary product(s); (c) when the nuclear configuration is that of the reactant(s). Case a is an adiabatic photoreaction. Although both case b and case c are diabatic photoreactions, we shall term case b as a "diabatic photoreaction" and c as a "hot" ground state photoreaction.

To illustrate these distinctions consider Figure 1, in which three energy surface situations for an overall R→P conversion are shown schematically (for simplicity just one excited surface is shown).

In each case light is employed to take the representative point from the ground surface to the excited surface ($R + h\nu \rightarrow R^*$). Thermal energy will when "propel" the repre-

sentative point (dotted line indicates the trajectory) along the reaction coordinate.

For case (a) the representative point is imagined to move over a relatively small energy barrier from R* to P*. Since the surfaces are "far apart" at all nuclear geometries along the reaction coordinate, a surface jump is improbable over the entire reaction coordinate. The photoreaction, therefore, is *adiabatic*. Commonly, energy barriers separating reactant geometry from product geometry are *smaller* on the excited surface for the *same reaction coordinate*. In favorable cases the occurrence of an adiabatic reaction is manifested by the observation of emission of light as a result of the radiative transition $P^* \rightarrow P + h\nu$. If the excited-state barrier is too high for the representative point to progress from R* to P*, emission from R* to R may occur instead of emission from P* to P.

In case (b) an excited surface and a ground surface approach one another at some geometry that is intermediate between that of R and P. Near this geometry, radiationless jumps from the excited surface to S_0 are favored. However, with respect to the maximum on the S_0 surface we can imagine jumps leading to geometries "to the left" (return to R and a net photophysical process) or "to the right" (formation of P and a net photochemical process). For case (b), it is clear that the terms photophysical and photochemical may become blurred when one is discussing processes occurring for the nuclear geometries in which the two surfaces *come close*. When the representative point proceeds "to the right" after the surface jump, it does so on the ground state surface until the nuclear geometry of P is achieved. Since the photoreaction involves a surface jump between structures R and P it is *diabatic*.

As a third example, in case (c) we suppose that a vertical jump from the excited surface puts the representative point on the ground surface with a *large excess of thermal energy*. As a result the minimum on the ground surface (corresponding to an intermediate on the ground surface) cannot "hold" onto the representative point and the latter escapes from the minimum (corresponding to the vertical jump) to a second minimum corresponding to P. We suppose that by the time the representative point reaches P its excess energy has been removed (say, by collisions with molecules in its environment) and eventually settles into the $v = 0$ level of P. Case (c) is a special kind of diabatic reaction and is called a "hot" ground state reaction.

It appears that most organic photoreactions conform to case (b). As a result, a knowledge of both photophysical and photochemical radiationless processes is crucial for an understanding of the molecular photochemistry of organic compounds. Of special importance is knowing when surfaces "get close" and what mechanisms are available to allow the representative point to make its jump to another surface.

Classically, we may view radiationless transitions as occurring from a "hole" or "funnel" in an upper surface at critical molecular geometries[3f]. When the representative point must search for a considerable time for the correct geometry required for a surface jump (thermal equilibrium), we speak of a "hole" on the excited surface at that geometry. When the representative point makes a surface jump nearly every time it achieves a certain geometry, we speak of a "funnel" on the excited surface of that geometry.

From the preceding discussion it is clear that energetically allowed adiabatic photoreactions can be anticipated when the following features of the surfaces are known:

1) the location of the minima in S_0, S_1, and T_1;
2) the location of maxima in S_0, S_1, and T_1;
3) the electronic interactions which cause the separation of the surfaces;
4) the geometries for which two surfaces come "close together";
5) the mechanisms which mix electronic states when the representative point is in an excited state minimum or near a geometry for which surfaces come "close together".

3.3. Typical Surface Topologies

Scrutiny of a broad range of photoreactions reveals that several "surface topologies" suffice to serve as a starting point for mechanistic analysis. For simplicity, we shall consider the following categories:

(a) "orbital symmetry allowed" ground state reactions;
(b) "orbital symmetry forbidden" ground state reactions;
(c) reactions producing diradical products.

Surface topologies typical of each of these categories are shown in Figure 2. In case (a) the ground surface and the excited surfaces are generally "far apart" along the reaction coordinate (small ground state barrier).

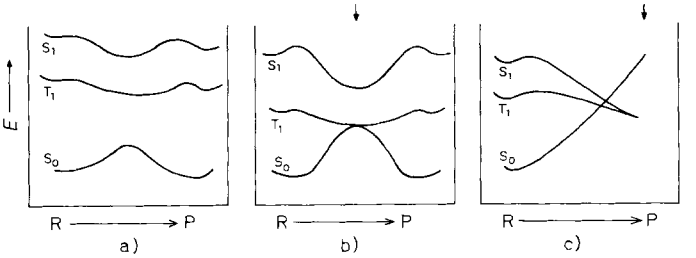

Fig. 2. Three commonly encountered surface topologies for the conversion of R into P. (a) Orbitally allowed ground state reaction; no diradical structure along the reaction coordinate; (b) orbitally forbidden ground state reaction; diradical structure between reactant and product (arrow); (c) reaction producing a diradical product (arrow).

In case (b) the ground and excited surfaces come "close together" at the geometry of the transition state for the ground state reaction. The important features of this topology are:

(1) the occurrence of minima in the S_1 and T_1 surface near the geometry corresponding to the transition structure;
(2) the diradical electronic character of the transition structure;
(3) the close approach of the S_0 and T_1 surfaces at the transition structure.

In case (c) the ground surface and excited surfaces come "close together" and as the primary photochemical product is formed at this diradical geometry the S_1 and T_1 surfaces essentially "touch".

4. Examples of Adiabatic Organic Photoreactions

Several years ago *Förster* pointed out[1] that adiabatic organic photoreactions involving protolytic processes (acid-base reactions)[4a] and weak complexation (excimer and exciplex

formation)[4b] are well known, but that documented examples of adiabatic organic photoreactions involving carbon-carbon bond breaking and making were almost unknown[5]. During the past five years this situation has changed. We now review the several classes of photoreactions for which there is substantial evidence for an adiabatic step involving an electronically excited surface.

4.1. Adiabatic Photochemical Electrocyclic Reactions

Several important examples of adiabatic photoreactions have been found in the electrocyclic ring opening and ring closing reactions of aromatic compounds. In particular, aromatic systems based on "Dewar" structures [*e.g.*, *(1)*, *(2)*, and *(3)*] undergo smooth electrocyclic ring opening to the corresponding aromatic hydrocarbon upon heating or photochemical excitation[6-9]. The thermal rearrangement of *(1)* to produce benzene is chemiluminescent[10]. Significantly, there is evidence that each "Dewar" compound undergoes a photochemical adiabatic ring opening on a S_1 and/or T_1 surface.

(1) *(2)* *(3)*

In the case of *(1)*, excitation of S_1 does not lead to formation of S_1 of benzene[7]. The experimental support for this conclusion is based on the observation of a "quantum chain" process involving T_1 of benzene upon triplet photosensitized excitation of *(1)* [confirming the occurrence of a *(1)* (T_1)→benzene (T_1) pathway] and the failure to observe fluorescence of benzene upon direct photoexcitation of *(1)* [denying the occurrence of a *(1)* (S_2)→benzene (S_1) pathway].

(1) S_1 T_1

The quantum chain pathway involves the reaction of triplet benzene with *(1)* to yield benzene (S_0) plus benzene (T_1)[7]. The process is formally catalytic and, since a benzene triplet is produced, a chain propagation sequence is possible. Indeed, the limiting quantum yields for photosensitized ring opening of *(1)* are considerably greater than unity.

T_1 *(1)* S_0 T_1

In the case of *(2)*, the situation is a bit more interesting since both *(2)* (S_1) and *(2)* (T_1) undergo adiabatic ring opening to naphthalene S_1 and T_1, respectively[8] (Fig. 3).

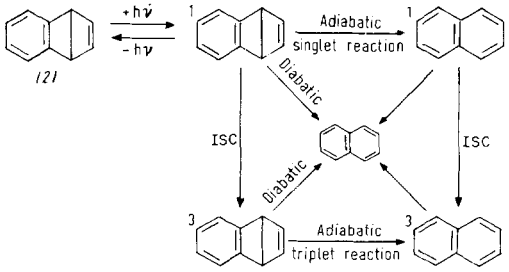

Fig. 3. Summary of the photochemistry and photophysics of Dewar naphthalene *(2)*.

The experimental support for the reactions shown in Figure 3 is derived from the following studies. The photochemical conversion of *(2)* into naphthalene was examined in solution at room temperature and at 77 K in EPA matrices[8]. Excitation of *(2)* in *n*-hexane solution at 300 K results in two emission bands. One of the emissions (290 nm, $\Phi_f = 0.001$) was that of normal fluorescence of *(2)* whereas the second structured emission (310–380 nm, $\Phi_f = 0.095$) was identical to that of naphthalene fluorescence. The naphthalenic emission was shown not to be due to small amounts of naphthalene contaminants by doping experiments and analysis of excitation spectra. The fluorescence lifetime of this emission was measured as 110 ± 5 ns, identical to that of photoexcited naphthalene fluorescence. No phosphorescence was observed in fluid solutions.

At 77 K in an EPA matrix, excitation of *(2)* at 268 nm leads to fluorescence of *(2)* ($\Phi_f = 0.11$) and to both a naphthalenic fluorescence (310–380 nm, $\Phi_f = 0.14$) and a naphthalenic phosphorescence (460–560 nm, $\Phi_p = 0.04$). The lifetime of the phosphorescence was 2.3 ± 0.25 s, identical to that of photoexcited naphthalene phosphorescence. Triplet sensitization of *(2)* in EPA at 77 K with acetophenone also leads to naphthalenic phosphorescence[8].

At 300 K, the adiabatic conversion of singlet Dewar naphthalene into singlet naphthalene is 49% efficient and the adiabatic path to ground state naphthalene is 34% efficient. At 77 K the efficiency of the adiabatic triplet state conversion, triplet *(2)* into triplet naphthalene, may approach unity.

It appears that *(3)* (S_1) undergoes adiabatic ring opening to anthracene (S_1), but no data relevant to the behavior of *(3)* (T_1) are available at the present time[9].

(3) (S_1) S_1

The conversion of Dewar anthracene *(3)* into anthracene was studied in solution at 300 K[9]. The fluorescence emission spectra of *(3)* consist of the fluorescence of *(3)* and an anthracene-like emission. Doping experiments and excitation spectra indicate that the anthracene emission is derived directly from *(3)* and not from energy transfer to trace anthracene contaminants. The emission lifetime was 24.5 ± 0.3 ns, considerably longer than that of photoexcited anthracene (4.9 ns). This means that some precursor of anthracene S_1, *i.e.*, *(3)* (S_1), persists for about 25 ns and that the emission from anthracene (S_1) is fast relative to the *(3)* (S_1) → anthra-

cene (S_1) rearrangement. Quantitative analysis showed that the adiabatic conversion in the singlet state, *(3)* (S_1) → anthracene (S_1) accounts for 10% in the overall decay kinetics of *(3)* (S_1).

These adiabatic photoreactions may be analyzed in terms of the surface topology for an orbital symmetry forbidden ground state reaction, since each is formally a disrotary electrocyclic ring opening[11, 15]. Ground state forbidden electrocyclic reactions possess a characteristic S_0, T_1, and S_1 surface topology, related to that for simple *cis-trans* isomerization of an ethylene *via* twisting about the C C bond (Fig. 4). The latter serves as a prototype for ground state forbidden pericyclic reactions[3]. The important features of this simple surface topology are:

(1) the presence of a maximum in the ground state surface corresponding to an antiaromatic or diradical transition structure;
(2) the presence of a minimum on the S_1 surface near the structure corresponding to the diradical structure;
(3) the occurrence of a "touching" or close approach of the T_1 and S_0 surfaces at the diradical structure.

The reaction coordinate is that of the rehybridization of the 1-C and 4-C orbitals to sp^2 geometry. The presence of a lower state maximum at the S_0 equilibrium geometry and upper state minimum on S_1 corresponding to the diradical structure provides for a very effective deactivation. A jump from the excited state surface to the ground state surface, a diabatic process, is possible and evidently occurs when S_1 of *(1)* is excited, *i.e.*, *(1)* (S_1) → benzene (S_0).

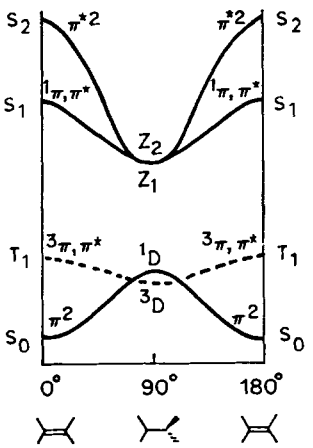

Fig. 4. The surface topology for *cis-trans* isomerization about a carbon-carbon double bond. This topology is a prototype for ground state forbidden pericyclic reactions. Z = zwitterionic states, D = diradical states.

In the case of Dewar compounds *(2)* and *(3)* the high exothermicity of the conversion of Dewar into aromatic species may distort the normal energy surfaces and tilt[15] the excited state surface, theoretically allowing for the production of excited state products (Fig. 5). The close approach of S_0 and T_1 at the diradical geometry will provide an efficient pathway for a $T_1 \rightarrow S_0$ jump only if the diradicaloid structure possesses strong spin-coupling. This is *not* the situation in general for any hydrocarbon structure. As a result, the conversions of the triplets of *(1)*, *(2)*, and *(3)* to the T_1 states of the corresponding aromatic hydrocarbons are efficient.

Should thermolysis follow the reaction coordinate of Figure 5, a low yield of *triplets* is expected in a *chemiluminescent*

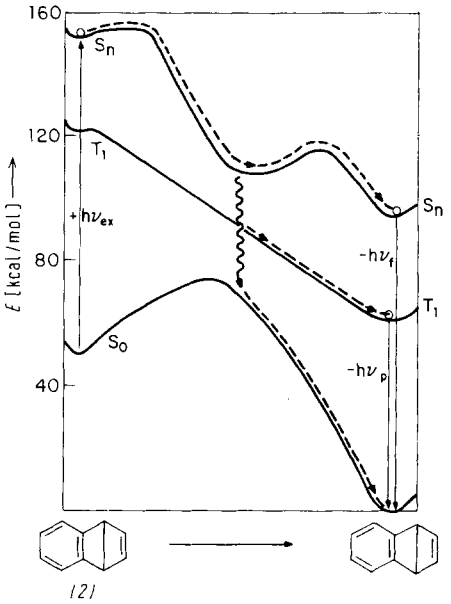

Fig. 5. Interpretation of the conversion of Dewar naphthalene *(2)* to naphthalene in terms of the surface topology for a ground state forbidden pericyclic reaction.

diabatic process, as is found to be the case for the parent of the series, Dewar benzene *(1)*.

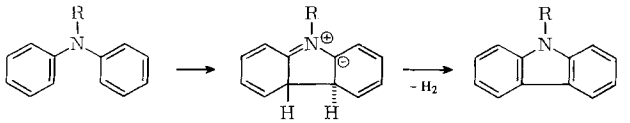
The benzvalene structure [*e.g.*, *(4)* and *(5)*] has also been found to be involved in adiabatic photoreactions. In analogy to Dewar benzene, *(4)* was found to undergo adiabatic ring

(4) *(5)*

opening to benzene on the triplet surface but not on the singlet surface[16].

In the case of *(5)*, the conversion of *(5)* (T_1) → naphthalene (T_1)[17] occurs very efficiently. No evidence for a significant efficiency of the *(5)* (S_1) → naphthalene (S_1) reaction has been obtained.

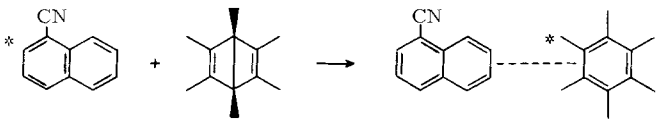
As in the case of *(1)*, the evidence for the triplet adiabatic reaction *(4)* (T_1) → benzene (T_1) stems from the occurrence of a triplet photosensitized "quantum chain" sequence[16]. In this case, benzene triplets interact with benzvalene to yield benzene (S_0) and benzene (T_1).



T_1 *(4)* S_0 T_1

The occurrence of such a quantum chain was found to depend on the energy of the triplet sensitizer. It was found that if the sensitizer triplet energy was >63 kcal/mol, the formation of benzene (T_1) was efficient, whereas if the sensitizer triplet energy was <63 kcal/mol, the formation of benzene (T_1) was inefficient. These observations were interpreted in terms of excitation of *two* triplets of *(4)*. Sensitized excitation of the lower energy triplet of *(4)* ($E <$ 63 kcal/mol) does not result in adiabatic ring opening to benzene (T_1), whereas excitation of the higher energy triplet of *(4)* ($E >$ 63 kcal/mol)

results in adiabatic electrocyclic ring opening to benzene triplet.

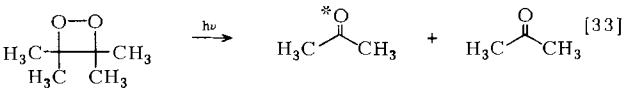


In contrast to photochemical electrocyclic ring openings, photochemical electrocyclic ring closures are not generally adiabatic. These reactions often are constrained to be diabatic because reaction endothermicity makes the adiabatic pathway energetically forbidden. There is, however, one case for which the photochemical generation of an excited state product has been suggested[18,19]. Excitation of triphenylamine (or *N*-methyl-*N*,*N*-diphenylamine) in hydrocarbon solvents at room temperature yields corresponding carbazoles under oxidative conditions from their excited triplet state[20-22]. The suggested intermediate for this reaction is ylide *(6)*, possibly resulting from "6e" cyclization. Evidence for this ylide comes from the detection of an absorption due to *(6)* during flash

R = C_6H_5, CH_3 *(6)*

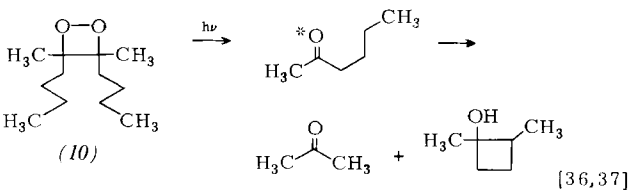
photolysis. The results of these flash spectroscopic studies suggested that the triplet of diphenylamine converts adiabatically into the triplet of *(6)*.

Photoexcitation of 1-naphthalenecarbonitrile *(7)* in the presence of hexamethyldewarbenzene *(1a)* (hexane solution, room temperature) results in generation of a singlet exciplex of hexamethylbenzene-1-naphthalenecarbonitrile *(8)*[23]. It is proposed that the reaction is adiabatic, *i.e.*, excited 1-naph-



(7) *(1a)* *(8)*

thalenecarbonitrile *(7)* interacts with the Dewar compound *(1a)* to cause isomerization and formation of the singlet exciplex, all on the S_1 energy surface.



4.2. Cycloeliminations

Cycloelimination reactions provide a second general type of process that, in a few special cases, exhibits adiabatic photochemistry. As in the case of valence isomerization, the general feature of the close approach in coordinate space and energy of the excited electronic surface to that of the ground state surface along the reaction coordinate is expected to favor a diabatic photochemical process yielding ground state products[24,25]. Product luminescence has, however, been observed in several reaction systems in which an adiabatic process successfully competes with surface jumps to S_0.

One remarkable example is that of the adiabatic photodissociation of 1,2-dioxetanes. Dioxetanes ("dimers" of corresponding carbonyl compounds) undergo quantitative dissociation to carbonyl products both upon thermolysis and upon photolysis[26-41]. Dioxetanes possess a high energy content with respect to carbonyl products ($\approx$63 kcal/mol), require low energy of activation for thermal decomposition ($\approx$24 kcal/mol) and exhibit efficient thermal generation of triplet carbonyl products[27]. Direct or sensitized excitation of dioxetanes, *e.g. (9)* and *(10)*, has been shown to produce electronically excited carbonyl products.

(9) [33]

(10) [36,37]

The generation of electronically excited products was identified in these cases either directly by their emission or indirectly through consideration of the photochemical products. One of the important observations was the dependence of the ratio of singlet to triplet excited acetone on the wavelength of excitation in the case of tetramethyldioxetane *(9)* as given in Table 1[33]. Similarly, in the case of *(10)* the yield of triplet 2-hexanone was dependent on the triplet energy of the sensitizers used, but the mechanism of decomposition by these sensitizers is not clear[36,37].

Table 1. Production of electronically excited acetone in the photochemical decomposition of tetramethyl dioxetane *(9)* [33].

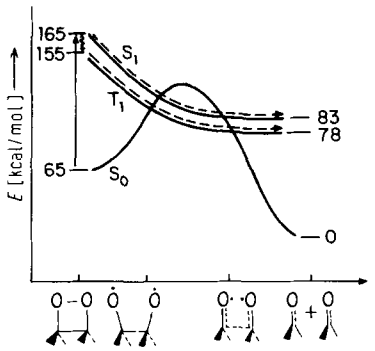
Irradiation conditions	$(CH_3)_2CO$ S_1 [%]	$(CH_3)_2CO$ T_1 [%]	Comments
Direct, 366 nm	10	43	[a]
Direct, 320 nm	25		[b]
Direct, 297 nm	30		[b]
Direct, 240 nm	35		[b]

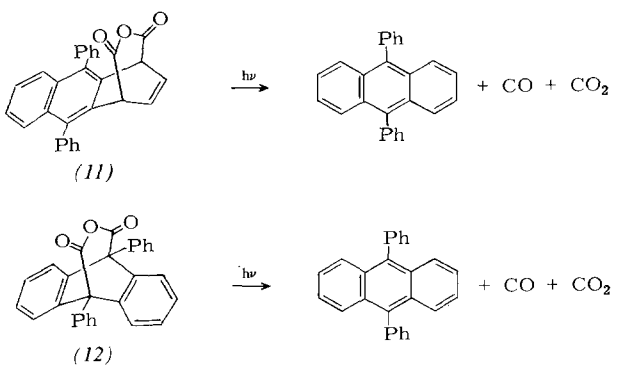
[a] At 6 °C in benzene solution by the method of *P. Lechtken* and *N. J. Turro*, J. Am. Chem. Soc. *94*, 2886 (1972). The exciting light was absorbed solely by *(9)*. [b] Determined by comparison of dioxetane luminescence with that of equally absorbing acetone solutions.

The photolysis of *(9)* has been studied by picosecond spectroscopy[39] in order to determine the rate of formation of acetone singlet from *(9)**. Remarkably, the "rise time" of acetone fluorescence was found to be $<10\times10^{-12}$ s, *i.e.*, the conversion of *(9)** into acetone (S_1) occurs in just a few vibrations.

The observation of electronically excited products allows one to categorize the photodecomposition of dioxetanes as an adiabatic process. A model[41] for the adiabatic photoreactions of dioxetanes bearing a topological similarity to the general picture presented for photocycloreversions of valence isomers of aromatic compounds is available (Fig. 6)[6,11,12]. A feature that may allow the decomposition of dioxetanes to be adiabatic as opposed to most other fragmentation reactions is once again the large tilt in the excited state surface of the correlation diagram brought about by the thermal content of dioxetanes. This may result in a *shallow* minimum on the excited surface and allows the molecules to "spill over" this shallow minimum on the excited surface to excited carbonyl products. We do not wish to rule out "dynamic" effects as

the source of the high efficiency of adiabatic photochemistry, *i.e.*, the nuclear motion on the T_1 surface may be so fast that intersystem crossing at S-T crossings cannot compete with motion on the T_1 surface. Shallow minima on the excited singlet surface may facilitate conversion to the lower surface (triplet). This leakage to the T_1 surface would occur in competition with crossing the barrier on the excited surface. The wavelength dependence of the ratio of singlet to triplet excited acetone production may then be indicative of the competition between crossing the barrier on the same excited surface and jumping to the lower surface. Molecules with higher energy content (short wavelength excitation) cross the barrier more efficiently (to produce singlet excited acetone) than those of lower energy (longer wavelength excitation) which jump to the lower surface to produce triplet acetone.





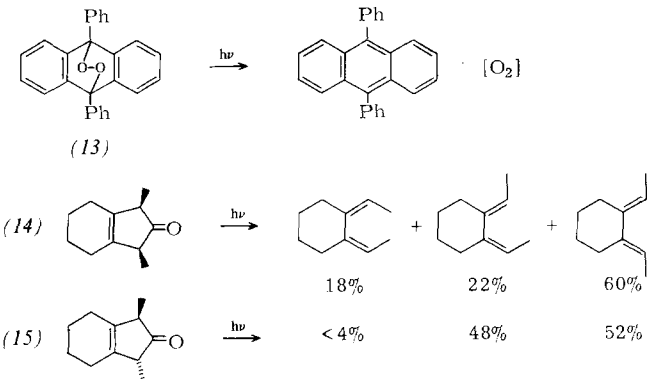


Fig. 6. Schematic representation of the S_0, T_1, and S_1 surfaces of tetramethyl-1,2-dioxetane *(9)* for the decomposition into two acetone molecules.

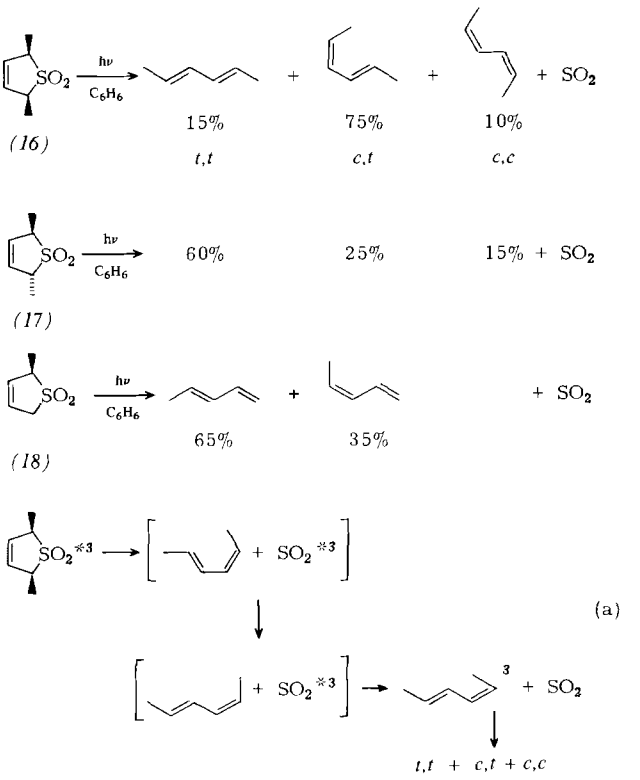
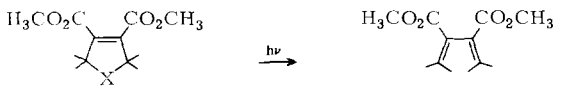


Although the cycloreversion of "Dewar arenes" and the photodecomposition of dioxetanes are different in kind, their adiabatic character may be due to the same tilting of the excited state surface due to the large relative energy content of the reactants (Fig. 6). This results in an effective decrease in the energy barrier between the "funnel minimum"[42] and the product excited state on the excited hypersurface allowing for adiabatic passage to excited state products. Although the large imbalance between reactant and product states exists in many other exothermic reactions, the diabatic processes are present in competition and often prevent the observation of product state luminescence. An example of this is found in the direct singlet state excitation of 1,4- and 9,10-dicarboxylic anhydrides *(11)* and *(12)* which results in the formation of 9,10-diphenylanthracene[43, 44]. An extensive search for excited state products was not successful. This illustrates that there are many factors controlling the nature of photoreactions and points out the need for further study in this area.

Short wavelength excitation of 9,10-diphenylanthracene endoperoxide *(13)* gives 9,10-diphenylanthracene and oxygen[45]. In analogy with the behavior of dioxetanes this photodecomposition might possibly generate singlet oxygen, but results of such an adiabatic channel have not been reported. This reaction may be adiabatic for the additional reason that generation of ground state oxygen (triplet) is a spin forbidden process. It should, however, be cautioned that if the molecular motion and spin motion are coupled (availability of a spin flip mechanism)[46] the conversion of singlet excited reactants into ground state triplet products (or triplet excited state reactants into ground state singlet products) would be allowed and an adiabatic path may not be important. This is illustrated by the excited triplet decarbonylation of cyclopentenone *(14)* and *(15)* where no excited triplet product was observed[47].

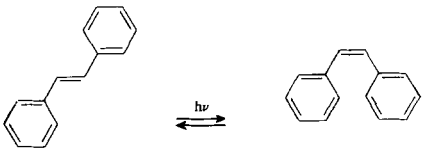


Another triplet photofragmentation reaction in which an adiabatic channel has been suggested is in the elimination of sulfur dioxide from sulfolenes *(16)—(18)*[48]. Benzene sensi-

tized photolysis of *(16)—(18)* resulted in the extrusion of sulfur dioxide to give the diene. Based on the known photochemistry of dienes[49], the formation of the diene triplet is ruled out. Formation of *cis-cis* hexadiene prompts the authors to suggest an adiabatic generation of triplet excited sulfur dioxide ($E_T \approx 72$ kcal/mol) which is expected to transfer energy to the cage pair diene [eq. (a)].

These arguments, however, are based on the assumption of the concerted nature of the reaction process. Recently, evidence has been provided for the biradical nature of similar photoextrusion reactions [eq. (b)][50]. Similar involvement of biradicals in reactions of *(16)—(18)* could, however, explain

(b)



X = S, SO, SO_2

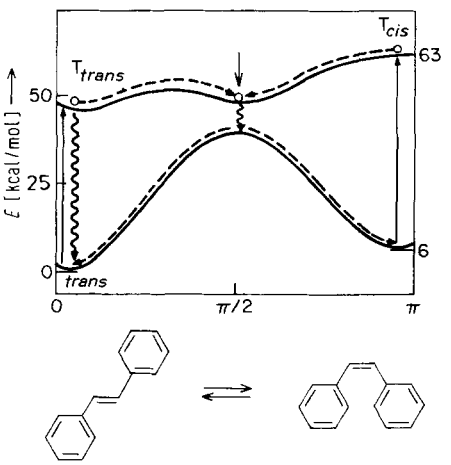
the result without involving the excited states of sulfur dioxide.

4.3. Geometric Isomerization

Some interesting examples of adiabatic photochemistry are provided by the geometric isomerization of certain polyenes. Alkenes, including polyenes in general, upon direct or triplet sensitized excitation undergo geometric *(cis-trans)* isomerization about the double bond(s)[49]. All theoretical studies directed toward understanding the energy surfaces for this reaction suggest a preference for twisting about the double bond on the singlet and triplet excited surfaces of monoenes and dienes (*i.e.*, the surface topology of Fig. 4). Although the calculations do not all agree with respect to the stabilization of the twisted geometries in higher polyenes, they all favor a lower stabilization of the twisted geometries in higher polyenes, and they all favor a lower stabilization as compared to monoenes and dienes. The above model suggests the general occurrence of a maximum on the ground surface and minimum on the excited surface near the twisted geometry. This would facilitate a jump of the representative point from an excited surface to the ground surface near the twisted geometry. In spite of the availability of this diabatic geometric isomerization several olefins appear to undergo adiabatic geometric isomerization.

Triplet sensitized and direct $S_0 \rightarrow T_1$ excitation of stilbene results in geometric isomerization[49,51-64]. The photostationary state ratio of *cis* product to *trans* product as well as the quantum yield of isomerization is found to be dependent on the concentration of low energy triplet sensitizers as well as on the concentration of *trans*-stilbene. Furthermore, during benzophenone sensitized geometric isomerization of stilbene, quenching with azulene [$E_T \approx 38$ kcal/mol] favors the formation of *trans*-stilbene. Thus, both azulene and low energy triplet sensitizers are able to deactivate the excited stilbene triplet selectively to the *trans* isomer. This is consistent with the postulate that the *trans* triplet and a twisted triplet are in thermal equilibrium on the triplet surface and that the *trans*-stilbene triplet is selectively quenched by the above-mentioned quenchers. This model, due to *Hammond* and coworkers[61], involves the adiabatic conversion of *cis*-stilbene triplet to *trans*-stilbene triplet *via* the twisted triplet. A recent flash photolysis study of *p*-nitrostilbene is consistent with the model[65]. Both *cis*- and *trans-p*-nitrostilbene give rise to a common transient with the same absorption and decay constant upon flash excitation. Furthermore, this transient is quenched by oxygen and azulene in a manner similar to that found in the studies of stilbene. If the common transient is in fact due to the triplet of *trans-p*-nitrostilbene, it represents an adiabatic conversion from *cis* triplet to *trans* triplet.

Since the *cis* and *trans* isomers of stilbenes do not possess a large energy difference either in the ground (S_0) or excited triplet (T_1) states, the structural feature responsible for the adiabatic channel is probably different than in the cases of Dewar arenes and dioxetanes. It appears that a small energy difference in the triplet state between the isomers is sufficient to tilt the surface toward the *trans* isomer[61]; this is pictured in Figure 7. This tilt permits an equilibration between the twisted and *trans* triplet configurations such that the *trans* shape is favored for deactivation to the ground state surface. The closeness of approach of the S_0 and T_1 surfaces at the twisted geometry does not lead to a "funnel" through which the representative point can jump efficiently, since spin-orbit coupling is required as a mechanism for intersystem crossing and since spin-orbit coupling is very weak in hydrocarbon systems, the $T_1 \rightarrow S_0$ interconversion is slow at all geometries. It is interesting to speculate that the twisted geometry may, in fact, be the best geometry for effective spin-orbit coupling since the *p*-orbitals of the central carbon-carbon bond are roughly orthogonal to one another in this structure[46].



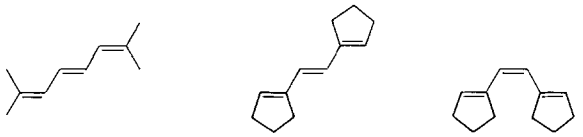


Fig. 7. Qualitative surface description of the geometric isomerization of *trans*- and *cis*-stilbene. π = angle of twist around the central bond. Arrow indicates "phantom triplet".

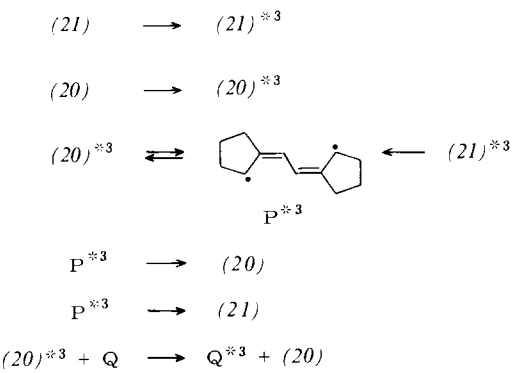

Photochemically-induced geometric isomerization of 2,4-hexadienes and 1,3-pentadienes have been studied in considerable detail. One early report[66] proposed an adiabatic interconversion among geometric isomers of 2,4-hexadiene in the triplet manifold. The system was later shown to be complicated due to impurities[67]. There have been several reports

on the concentration-dependent geometric isomerization of dienes in the triplet excited state[68-71]. Both 2,4-hexadienes and 1,3-pentadiene undergo concentration dependent isomerization from *cis* to *trans* isomers only at high concentrations (≈ 1 M)[70]. No definitive experiments have been carried out to delineate the reasons for the above observation. Studies of isomerization in several trienes [*(19)* and *(20)*] have

(19) *(20)* *(21)*

also demonstrated a concentration dependence in their geometric isomerization reactions[72-76]. Also, azulene is found to have a profound influence on the photostationary state. As with the stilbenes, these observations suggest the presence of a quantum chain process and the data are presented in Table 2. These experimental results are explained by the postulate that the planar *trans* triene triplet must be energetically close to, and hence exist in equilibrium with twisted and quenchable triene triplet, as in the case of stilbene[61]. Then these triplets must be the ones quenched by azulene and by ground state cisoid trienes as shown below for *(20)*. Apparently, a small difference in triplet energy be-

tween *cis* and *trans* isomers is able to tilt the triplet surface toward the *trans* isomer and thus allow an adiabatic conversion of *cis* to *trans*-triplet.

Table 2. Ratio of *trans- (20)* to *cis*-1,2-bis(1-cyclopentenyl)ethylene *(21)* at photostationary state. Sensitizer: 2-naphthylphenyl ketone [a].

[a] 2-Naphthylphenyl ketone: 2.5×10^{-2} M; solvent: benzene. [b] Quencher: guaiazulene.

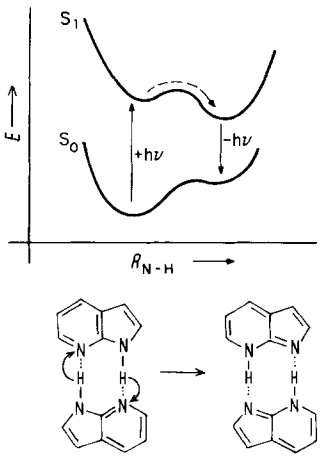
As in the studies of stilbene, the adiabatic channel in the photochemistry of *(19)* and *(20)* probably represents a special case since most other trienes appear to isomerize by diabatic processes[76].

4.4. Proton Transfer and Electron Transfer

As we have seen in the previous examples, the occurrence of a minimum in the excited state surface near a maximum in the ground state surface may predispose a system to undergo diabatic conversion of excited state reactants to ground state products. There are several cases for which the two surfaces are well separated throughout, a favorable condition for adiabatic reaction. One of the most striking cases involves that of proton transfer. Numerous studies of the acidity of electronically excited species have demonstrated that proton transfer processes, being very rapid, often establish a dynamic equilibrium during the lifetime of an excited state[4a]. The pK_a^* and pK_a, the acidity constant for the excited state and ground state species respectively, are often very different due to the difference in electronic configurations[4, 77, 78]. The transfer of electric charge from a donor to an acceptor (one of which is electronically excited) may lead to an electronically excited charge transfer complex or an electronically excited radical ion pair. Several excellent reviews on excited state acid and base reactions and electron transfer reactions are available[79-82]. In this section, we shall discuss only a few prototypical examples.

Interesting excited state prototropic behavior is shown by 1,7-diazaindene. In non-hydrogen bonding solvents, it exhibits two fluorescence bands[83, 84]. Studies of methylated derivatives and of the effect of temperature and concentration on these bands indicate that the second fluorescence band originates from an electronically excited tautomer formed by double proton transfer on the excited singlet surface of a hydrogen bonded dimer [eq. (c)].

Dimer formation, which is concentration dependent, is not necessary for proton transfer since the solvent can also serve



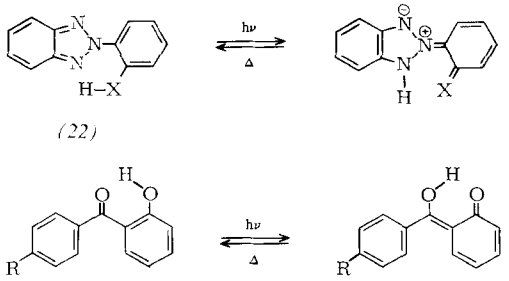


Fig. 8. Schematic representation of the adiabatic proton transfer on the excited singlet surface of the 1,7-diazaindene dimer.

as a proton donor. For example, in ethanol solution similar fluorescence bands which are not concentration dependent are attributed to double proton transfer between ethanol and excited singlet 1,7-diazaindene[84]. The double proton transfer can be visualized using the surface diagram shown in Figure 8.

Reversible intramolecular proton transfer is probably the basis of the effectiveness of certain photostabilizers that have a great commercial importance because of their ability to protect polymers from photodegradation[85]. These photostabilizers [*e.g., (22)* and *(23)*] absorb light and form an unstable tautomer, possibly *via* an adiabatic proton transfer. The tautomer thermally reverts to the starting material and, in the cycle, photon energy, potentially capable of causing rupture and crosslinking of polymer chains, is degraded harmlessly into heat.

(22)

(23)

The production and study of radical ion pairs *via* flash spectroscopy has revealed that the ions may be produced in electronically excited states[86]. For example, following an initial flash, a triplet radical ion pair may be monitored spectroscopically. In the case of [pyrene]* and 3,5-dimethoxy-*N,N*-dimethylaniline, the decay of the triplet radical ion pair is due to intersystem crossing to a singlet radical ion pair followed by an electron transfer that regenerates pyrene and 3,5-dimethoxy-*N,N*-dimethylaniline in their ground states[86]. Both a "fast" and a "slow" decay of the radical ion pair have been observed and ascribed to "geminate" or cage electron transfer and to "homogeneous" or diffusion-reencounter electron transfer, respectively.

4.5. Excimers/Exciplexes; Excited State Complexes

The formation and reactions of weakly bound molecular complexes involving electronically excited molecules may also be considered as an adiabatic photochemical process. An excimer is a short-lived excited state complex formed from two molecules that are identical in their ground state[87]. Aromatic hydrocarbons, such as pyrene, readily form such associations in the excited state and are not complexed in the ground state[87]. The excimer is often luminescent and its spectrally broad and red-shifted emission is characteristic of a bound state to repulsive surface transition (Fig. 9).

Similarly, exciplexes[86, 88, 89] are complexes of excited state and ground state molecules of dissimilar nature. For example, exciplexes are readily formed between excited aromatic hydrocarbons and 1,3-conjugated dienes[90-93] or amines[89, 94]. The approach of the excited and ground state species to form the excited state complexes, $^*A + B \rightarrow {}^*(AB)$ is an adiabatic process. Many excellent review articles are available on the nature of the bonding in these complexes[95], the kinetics of excimers[86] and exciplexes[96] and the possible role of such complexes in photodimerization[97, 98] and photo-

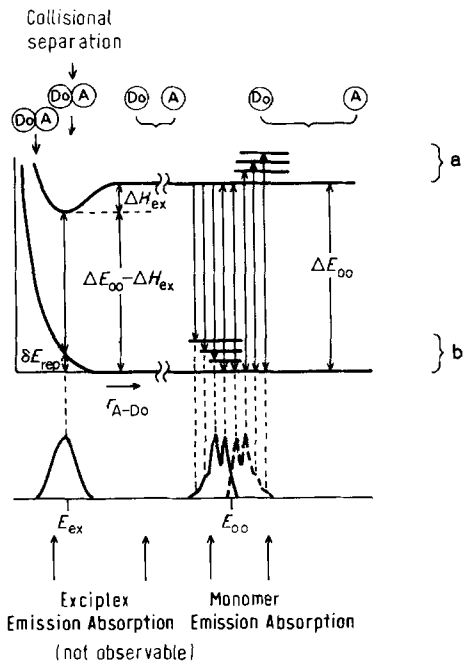

Fig. 9. Schematic description of excimer (Do = A) or exciplex (Do ≠ A) emission. The abscissa represents approach of the two partners. At the left, Do (donor) and A (acceptor) are colliding; at the right, Do and A are separated in space. a) Discrete vibrational states of the electronically excited monomer; b) discrete vibrational states of the monomer in the electronic ground state.

cycloaddition[99]. One such case, involving formation of an excimer, will be considered in more detail.

In the case of anthracene[5] and 9-methylanthracene[100, 101] a stable dimer exists in the ground state. The dianthracene species, when excited to its singlet state, produces luminescent products and displays both an excimer (*(AA), $\Phi_f = 4 \times 10^{-3}$) and monomer (*A, $\Phi_f = 3.7 \times 10^{-3}$) anthracene emission through adiabatic channels. In Figure 10 a surface diagram as suggested by *Förster* is presented to show the details of these processes. As might be expected, the close approach of the excited and ground state surfaces at intermediate values of r the intermolecular separation would favor a diabatic relaxation from the upper to lower surfaces and this appears to be the dominant reaction channel. This decomposition is similar to the photodecomposition of dioxetanes (see Section 4.2), but the presence of an additional minimum due to the excimer in the excited surface allows adiabatic conversion of excited anthracene dimers to both excimer and excited anthracenes. A recent investigation of the solvent viscosity and temperature dependence of the photodissociation of dianthracene and di-9-methylanthracene and related compounds suggests a benzyl-like radical precursor to the excimer state[101].

Charge transfer luminescence[95] may also be envisioned as the result of a more subtle adiabatic process. Charge transfer complexes have a bound ground state surface, and excitation to an electronically excited and bound surface is often possible. This excited state complex, the result of a vertical transition, has the geometry of the ground state complex and is subsequently collisionally relaxed to a new configuration of

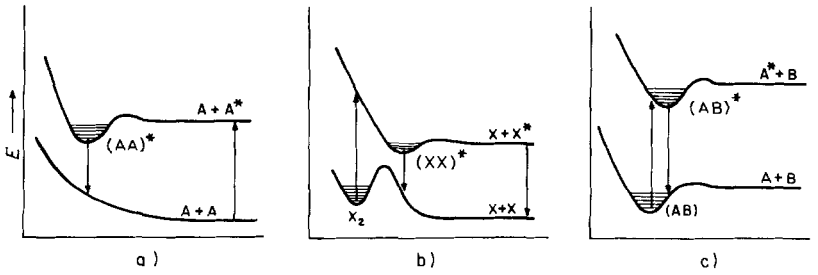

Fig. 10. Schematic representation of excimer (or exciplex) emission: (a) excimer formation with large separation of ground and excited surfaces at all geometries; (b) excimer formation with dimer formation providing a maximum on the ground surface; (c) exciplex or charge transfer complexation with large separation of ground and excited states for all geometries.

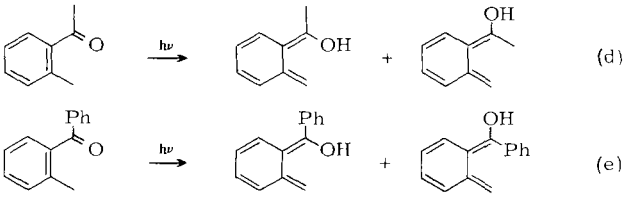
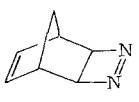


the preferred excited state geometry. Luminescence from this bound state to the ground state shows a large Stokes shift, and the adiabatic process is that of the change in geometry and bonding in the excited state relaxation process as portrayed in Figure 10c. Salts of methylpyridinium cations with anions such as Br^- or N_3^- form strongly bound ground state complexes (ionic) and weakly bound excited state complexes (radical pair)[102]. Following direct excitation of the ionic species an adiabatic transformation to the excited radical pair geometry occurs with subsequent emission and relaxation to the ground state. The Stokes shift between the frequency of absorption and of fluorescence is 33600 cm^{-1} ($\approx$96 kcal/mol) for the methylpyridinium-bromide system, reflecting the large stabilization energy of the process.

Similarly, the observation of spectral shifts between absorption and emission frequencies due to interactions between a molecule and its solvent sphere[103] is indicative of an adiabatic process. Excitation of a molecule to an excited state by a vertical transition results in an excited species with ground state geometry and a ground state orientation of the solvent molecules. A rapid adiabatic relaxation leads to an excited state geometry of the molecule and a different solvent environment. The fact that the solvent geometry and stoichiometry have been altered may be considered as a photochemical transformation in a supermolecule. Analysis of spectral shifts as a function of temperature, solvent type, and solvent viscosity are very helpful in the elucidation of such excited state adiabatic transformations[104].



4.6. Pseudo-Adiabatic Process

In the previous examples of adiabatic photochemistry, the identification of products in excited electronic states is facilitated by their luminescence or by chemical inference from quenching studies; however, there exist several types of photochemical reactions for which this straight-forward identification is not possible. The problem lies in defining the "chemical step": *if an excited state reactant converts to an excited state intermediate species generally differing in nuclear configuration and electronic charge density distribution from that of the reactant, this step may be viewed as an adiabatic chemical process even if a subsequent diabatic process leads to ground state products.* For example, if photochemical *trans-cis* isomerization occurs (Fig. 4) *via* the pathway *trans* (S_1)$\rightarrow$Z$\rightarrow$*cis* (S_0) or *trans* (T_1)$\rightarrow{}^3$D$\rightarrow$*cis* (S_0), the classification of these reactions as adiabatic or diabatic depends on whether Z and ^{3}D are considered as primary products. We will term overall reactions for which diradical primary products or minima are produced in an adiabatic fashion as pseudo-adiabatic; some discussion of several examples of this behavior may prove illuminating.

One example of a pseudo-adiabatic reaction is provided by the photoenolization of *o*-alkylacetophenones and -benzophenones[105-107]. Excitation of *o*-methylacetophenone and *o*-methylbenzophenone gives rise to two geometric isomers of the enol in the excited triplet state [eq. (d) and (e)]. At the outset, it appears that an adiabatic process occurs in which an enol is produced directly in its triplet state, which isomerizes to either of two different isomeric ground state enols. A more recent study[108, 111] suggests the generation of an excited triplet intermediate of twisted geometry rather than the

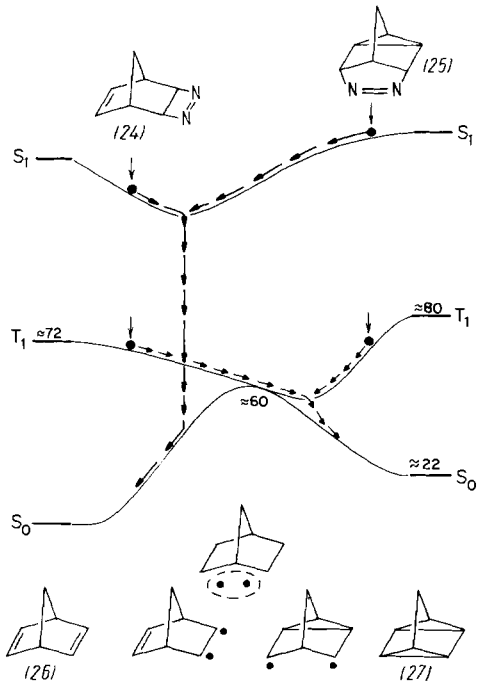
vertically excited enol triplet. A quenchable intermediate of lifetime $\approx 10^{-7}$ s is observed upon flash excitation of *o*-methylacetophenone. The diradical character of this intermediate is evidenced by its reaction with the paraquat ion[112], an efficient electron transfer radical trap. Quenching by oxygen causes a concomitant increase in enol yield. This result leads to the conclusion that the excited enol intermediate is probably present on the excited surface common to the two geometric isomers of the enol. No evidence is currently available to favor the formation of the vertically excited enol triplet. On the other hand, based on the known mechanistic details of photohydrogen abstraction[113, 114], one would expect the formation of the *twisted* enol as the primary intermediate because the favored approach for hydrogen abstraction would generate this geometry. The feature which makes this reaction "pseudo-adiabatic" is the availability of another ground state surface (due to rotation of the double bond in the enol), into which the intermediate can leak, in addition to the surface due to hydrogen abstraction. At this stage, it is debatable whether the minima on the excited surface corre-

(24)

(25)

sponding to hydrogen abstraction and adiabatic isomerization are the same or different.

Further examples of "pseudo-adiabatic" photoreactions are provided by the photodissociation of the cyclic azoalkanes *(24)*, *(25)*, and *(28)*[115,116]. Results of sensitized and direct photolysis of *(24)* and *(25)* are presented in Figure 11.



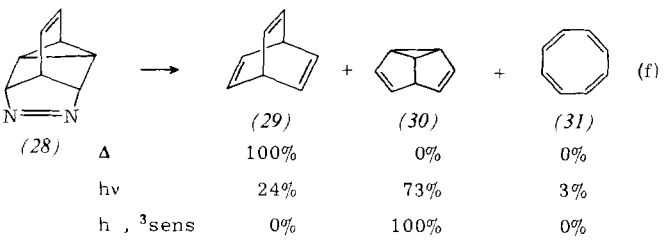


Fig. 11. Schematic representation of the potential surfaces for the conversion of norbornadiene *(26)* into quadricyclane *(27)*. Results of direct and sensitized photolysis of *(24)* and *(25)* (arrows). Energy given in kcal/mol.

Triplets of *(24)* and *(25)* prefer to give quadricyclane, whereas singlets proceed to give norbornadiene *(26)* preferentially. The triplet state of *(28)* shows a preference for formation of semibullvalene *(30)* while the singlet S_1 shows a preference for formation of barrelene *(29)* [eq. (f)]. Results of sensitization studies of *(26)* are reminiscent of the triplet photochemistry of the corresponding barrelenes[117]; but, the generation of triplet excited barrelene in the decomposition of *(26)* is inconsistent with known barrelene photochemistry[13]. The results are actually compatible with the generation of a triplet intermediate on the excited surface connecting barrelene and semibullvalene. Thus, what appears to be an adiabatic process is in fact a "pseudo-adiabatic" process. The excited triplet intermediate formed by the decomposition of cyclic azoalkanes has access to another ground surface connecting semibullvalene and barrelene.

(f)

Similarly, preferential formation of quadricyclane upon sensitized irradiation of *(24)*, *(25)*, and norbornadiene *(26)* is consistent with the formation of a common intermediate, most probably on the excited triplet surface[118]. This can be visualized using the model presented in Figure 11. It should be mentioned, however, that the excited hypersurface correlating the molecular rearrangements of the corresponding hydrocarbons can be reached from azoalkanes *(24)*, *(25)*, and *(28)* either directly or through additional minima on the excited surface.

Further examples of "pseudo-adiabatic" photoprocesses may be found in the geometric isomerization of polyenes[75]. Direct excitation of dienes and trienes in general results in geometric isomerization of one of the many possible double bonds. On the other hand, triplet sensitization induces isomerization of more than one bond per excitation[66,67]. Similar multibond isomerization per excitation process has been observed in 2,6-dimethyl-2,4,6-octatriene (alloocimene)[73,74] and 3,5-heptadien-2-one[119]. This multibond isomerization, in the case of hexadiene, can be imagined to proceed through a diabatic process involving "1,4-diradical-type"[66,67] twisted geometry.

This would involve simultaneous rotation of both bonds on the excited surface followed by leakage onto the lower surface at an intermediate geometry as shown in Figure 4. The other possibility would be an adiabatic process involving direct conversion of the triplet TT isomer to that of TC and CC through successive one bond rotations, but consideration of the concentrations and quencher dependence chemistry of hexadiene rules out this possibility. A final possibility, which is favored by temperature and viscosity dependent triplet isomerization of 2,4-hexadiene, is the pseudo-adiabatic process[120]. This involves the relaxation of the excited triplet diene through one bond rotation to the "allylmethylene" type diradicaloid geometry. This twisted triplet which exists on the excited surface can undergo rapid equilibration with other possible twisted "allylmethylene" geometries and leakage to all three isomers occurs from these minima. Similar arguments also tend to explain the observed multibond rotation of trienes[72-75]. Thus, this multibond isomerization like photoenolization and photodissociation of azo compounds becomes "pseudo-adiabatic" due to the presence of several minima on the excited surface which can attain thermal equilibrium during the lifetime of the triplet state.

4.7. Adiabatic Photoreactions Leading to Primary Diradical Products. Ditopic and Polytopic Reactions

Correlation diagrams and the postulate that a plane of symmetry serves as a good zero order model have been used to elucidate the mechanism of n,π^* states[3a,6]. Such diagrams are termed Salem diagrams. This approach emphasizes the behavior and electronic symmetries of the diradical (D) and zwitterionic (Z) states that are characteristic of systems in which a sigma or pi bond is broken or made. A discriminating feature of these reactions is the reaction *topicity* or *the total number and nature of radical sites generated in the primary photoproduct.* For example, the diradical-forming photochemical reactions which occur when a n,π^* state of acetone (S_1 or T_1) reacts with methane [eq. (g)] or with ethylene [eq. (h), R = H] are *ditopic* because the primary products [a radical pair in eq. (g) and a diradical in eq. (h)] contain only *two* low-lying electronic states. On the other hand, the hydrogen abstraction and addition reactions [eqs. (i) and (j)]

$$(CH_3)_2C{=}O + CH_4 \xrightarrow{h\nu} (CH_3)_2\dot{C}OH + \dot{C}H_3 \quad (g)$$

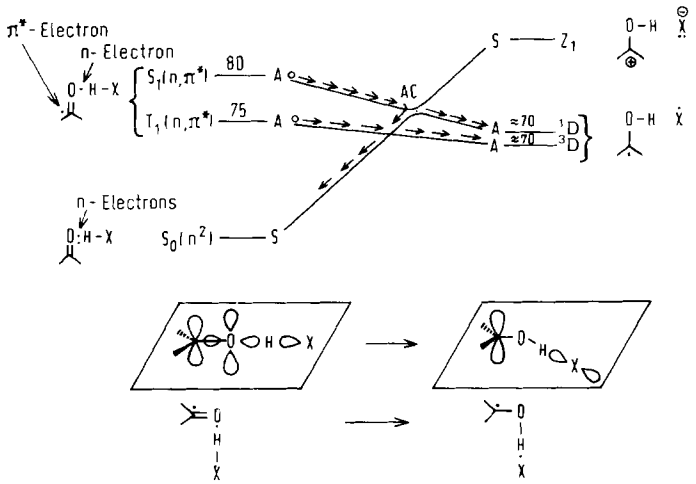
$$(CH_3)_2C{=}O + RCH{=}CHR \xrightarrow{h\nu} \text{oxetane} \quad (h)$$

are *tritopic:* three low lying radical sites are formed due to the degeneracy at the oxygen radical site.

$$(CH_3)_2C{=}O + HO{-}R \longrightarrow (CH_3)_2\dot{C}OH + \dot{O}R \quad (i)$$

$$(CH_3)_2C{=}O + RCH{=}CHR \longrightarrow \text{oxetane} \quad (j)$$

Surfaces for reactions of n,π* states to form diradical primary products commonly involve a surface crossing near the primary product geometry or a surface touching near the primary product geometry (Fig. 12). The crossing between the S_0 and S_1 surfaces is weakly avoided, but the S_0 and T_1 surface crossing persists for realistic situations which do not involve the strictly planar symmetry. Whether the weakly avoided crossing (AC) of the singlet surfaces is a true minimum (from which jumps to S_0 or to ^1D may occur) or is a funnel (leading predominantly to ^1D) will depend on the system under study. In some favorable cases, the minimum (an exciplex!) may be detected by kinetic, spectroscopic or chemical means.



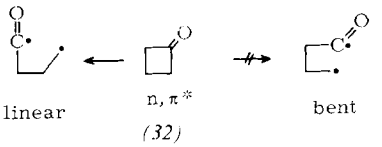


Fig. 12. First order correlation diagram for coplanar hydrogen abstraction. The energies of S_1, T_1, ^1D, and ^3D (in kcal/mol) are typical for hydrogen abstraction by an alkanone. AC = weakly avoided crossing.

The difference between an adiabatic and diabatic photoreaction is subtle in cases corresponding to Figure 12. If the representative point travels directly from $S_1(n,\pi^*)$ to ^1D without pausing in the minimum due to the avoided crossing, the reaction would be termed as adiabatic. If the representative point pauses in the exciplex minimum and then jumps to the lower singlet surface and travels to ^1D, the reaction is formally diabatic. The chemical consequences of these two situations are manifest in reaction efficiency from S_1. In the adiabatic passage to ^1D, the reaction efficiency is higher than in the diabatic passage since in the latter case transitions to S_0 occur in competition with transition to ^1D.

In contrast to the $S_1(n,\pi^*)\rightarrow{}^1D$ pathway, the $T_1(n,\pi^*)\rightarrow{}^3D$ pathway does not have a leakage point back to S_0. As a result the adiabatic $T_1(n,\pi^*)\rightarrow{}^3D$ process is expected to be more efficient than the diabatic $S_1(n,\pi^*)\rightarrow{}^1D$ process.

Experimental support for the occurrence of a diabatic pathway from S_1 and an adiabatic pathway from T_1 is found in the Type II reactions[121] and cycloaddition reactions[122] of alkanones: reaction efficiency from S_1 is much less efficient than from T_1.

In the case of the photochemical α-cleavage of alkanones both ditopic and tritopic pathways are possible. The ditopic (or bent acyl) pathway is often thermochemically allowed from S_1 or T_1, but is electronically forbidden, while the tritopic (or linear acyl) pathway is often thermochemically forbidden but electronically allowed. The photochemical α-cleavage of cyclobutanones *(32)* (Fig. 13) probably proceeds *via* the electronically allowed tritopic pathway. The adiabatic photoreaction $S_1(n,\pi^*)\rightarrow{}^1D$ (linear acyl) produces an *electronically excited* radial center since the linear acyl fragment is an excited electronic state of the bent acyl fragment.

(32)

The difference between the linear (electronically excited state) and bent (electronic ground state) acyl moieties is manifested in their chemistries[123]. The loss of CO from a bent acyl radical of the type $RCH_2\dot{C}O$ requires an activation energy of ≈14 kcal/mol, but the loss of CO from a linear acyl radical has a much lower activation energy. Indeed, cyclobutanone undergoes photodecarbonylation even at 77 K, consistent with the idea that loss of CO is essentially unactivated.

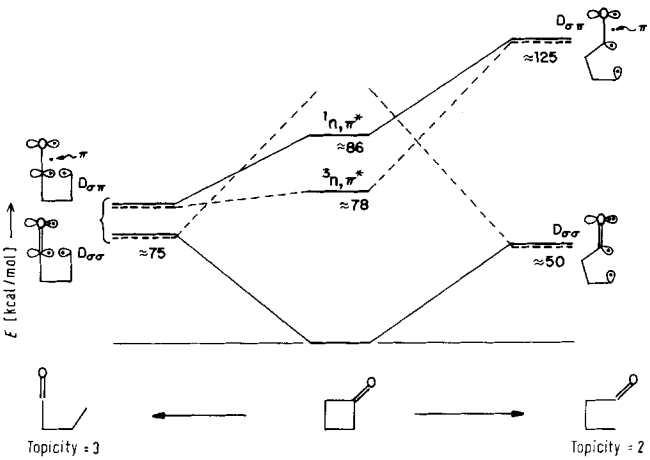

Fig. 13. Comparison of the planar α-cleavage of cyclobutanone *(32) via* bent (right) and linear (left) reaction pathways. The diradical states are labeled σ if an odd electron is contained in the molecular plane and π if an odd electron exists above and below the molecular plane.

5. Conclusion

Only a few adiabatic photoreactions have been substantiated by convincing experimental support. It is possible,

however, that many photoreactions are pseudo-adiabatic and that the experimental distinction between these and adiabatic photoreactions may be difficult. Pseudo-adiabatic reactions, in turn, may be difficult to distinguish from photophysical radiationless processes. Despite their scarcity in number, adiabatic photoreactions provide an insight into the nature of electronically excited surfaces and help to define the structural features that allow a representative point on an excited surface to make it "all the way" from the reactant geometry to the product geometry before it makes its inevitable jump to the ground state.

The "rules of the game" for predicting adiabatic photoreactions are still developing. However, excited state reactions involving small changes in covalent bonding (proton and electron transfer, excimer and exciplex formation) are commonly found to occur adiabatically. Photoreactions involving more extensive changes in covalent bonding may occur as a result of reaction exothermicity which causes tilting in surfaces leading from R* to P* and causes the representative point to sweep past geometries that "get close" to S_0 without making a jump to the lower surface. Triplet reactions should generally be adiabatic if the R*→P* conversion is exothermic and if no large energy barrier occurs between these structures (*i.e.*, even if S_0 "comes close" to T_1). Unless strong spin-orbit coupling occurs a surface jump is unlikely. Finally, reactions for which the excited singlet (S_1) and S_0 surfaces are far apart for all geometries ("allowed" pericyclic ground state reactions) are candidates for efficient adiabatic photoreactions.

In conclusion, the notion of adiabatic organic photoreactions completes a troika of related surface processes (Fig. 14):

(1) adiabatic photochemistry;
(2) diabatic photochemistry;
(3) chemiluminescence.

In process (1) the energy of an absorbed photon puts the representative point on an excited surface. Nuclear motion commences and continues on the excited surface until "chemistry" has occurred (the nuclear shape becomes sufficiently different from that of the reactant so that a "primary product" can be said to be formed).

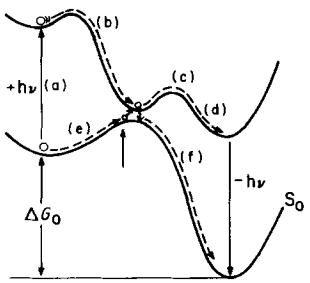

Fig. 14. Schematic representation of an adiabatic photoreaction: (a)→(b)→(c)→(d); a diabatic photoreaction: (a)→(b)→(f), and a chemiluminescent reaction: (e)→(c)→(d). Radiationless jumps occur at place indicated by arrow.

In process (2), the representative point jumps to S_0 before "chemistry" has occurred. Ambiguous cases will arise for this process. The notion of pseudoadiabatic photoreactions provides some insight into the problem but does not clarify it.

Finally, in process (3) the representative point of a high energy reactant commences motion on a ground surface and then "jumps" to an electronically excited surface at a geometry which brings S_0 and an excited (usually a T) surface "close together." In this regard, the observed chemiluminescence of the high energy content reactants—dioxetanes and Dewar benzenes—is easy to understand.

The authors at Columbia University thank the National Science Foundation, The Air Force Office of Scientific Research, and the National Institutes of Health for their generous support of this research.

Compounds of Alkali Metal Anions

By James L. Dye[*]

Anions of sodium, potassium, rubidium, and cesium are stable both in suitable solvents and in crystalline solids. The latter can be prepared either by cooling a saturated solution or by rapid solvent evaporation. Thermodynamic arguments show that alkali metal anions can probably exist in saturated solutions of the alkali metals in any compatible solvent, but that below saturation, dissociation into the cation and solvated electrons is favored in highly polar solvents such as ammonia. The key to solvent-free salts of the alkali metal anions is stabilization of the *cation* by incorporation into a suitable crown or cryptand complex. By using such complexes it also appears possible to produce "electride" salts in which the charge of the complexed cation is balanced by a trapped electron. The chemical, electrical, and optical properties of salts of the alkali metal anions and "electrides" could provide useful applications.

1. Introduction

Alkali metals are exceptionally good electron donors, tending to form monopositive ions by donation of one electron to an acceptor atom or molecule. The resultant cation has a stable inert gas electron configuration with a filled outer p-shell. Because of this, the history of compounds of the alkali metals has been that of the cations and it was long thought that, except in metals and alloys, only the +1 oxidation state could exist. Yet the existence of alkali metal anions *in the gas phase* has been recognized for 30 years[1,2]. These anions were proposed as major species in metal-ammonia solutions in 1965[3,4] and in metal-amine solutions in 1969[5]. The isolation and characterization of a crystalline Na^- salt[6,7] in 1974 firmly established that the −1 oxidation state of alkali metals could exist in condensed phases. This has opened a new field of research on the properties of these highly-reducing species both in solutions and in solids. It is the purpose of this article to describe the current status of research in this field and to speculate on possible future developments.

2. Properties of Alkali Metals in Solution

The preparation of salts of the alkali metal anions has its origins in the study of metal-ammonia solutions and solvated electrons[8-11]. However, the discovery of alkali metal anions may have actually been delayed by the fact that ammonia is "too good" a solvent so that the dissociation reaction

$$M^- \rightleftharpoons M^+ + 2e^-_{solv} \qquad (1)$$

lies far to the right in dilute solutions and most properties are only mildly influenced by the cation. This does not mean that metal-ammonia solutions are simple: quite the contrary; ion-pair formation, electron spin-pairing and the onset of metallic behavior occur as the solutions are concentrated[8]. Because of these complications, alkali metal anions could be present in concentrated metal-ammonia solutions, but there is no specific evidence of such species in this solvent.

2.1. Solutions in Amines and Ethers

When any alkali metal except lithium is dissolved in an aliphatic amine, poly-ether or hexamethyl phosphoric triamide (HMPA), two prominent optical absorption bands are observed. One, in the infrared region at 1200—2000 nm, is the relatively metal-independent band of the solvated electron. The other band, whose position depends upon the metal, solvent and temperature, can be assigned to the alkali metal anion[5]. The proof of this assignment has been discussed in detail elsewhere[6,7,12-17] and will be included here only as needed for the description of specific systems or properties.

Progress in identifying the species in metal-amine and metal-ether solutions was hampered by low solubility, rapid decomposition, and the ease of extraction of sodium from borosilicate glass[18]. The problem of low solubility was overcome by the use of crown ether[19] and cryptand[20] complexing agents. Extraction of sodium from glass presents a major problem only at low concentrations and can be completely eliminated by using a fused silica apparatus. Unfortunately, problems arising from solution decomposition are still with us but can be minimized by working with rigorously clean vessels[21] and at reduced temperatures.

2.2. Optical Spectra

Each alkali metal anion is characterized by a broad, intense, structureless absorption band which depends upon metal, solvent and temperature and is strongly asymmetric on the high-energy side. These features are characteristic[5] of the so-called charge-transfer-to-solvent (ctts) bands[22,23] of other anions such as the halides, hydroxide, amide, *etc.* The spectra are also similar in shape and in solvent-[12] and temperature-dependence to those of the solvated electron in various solvents[12] but the absorption maxima occur at higher energies. Figure 1 shows the spectra of Na^-, K^-, Rb^-, Cs^- and e^-_{solv} in ethylenediamine[24]. The spectrum of e^-_{solv} obtained by pulse-radiolysis[25] (solid circles) compares well with that obtained by dissolving lithium (solid line) in ethy-

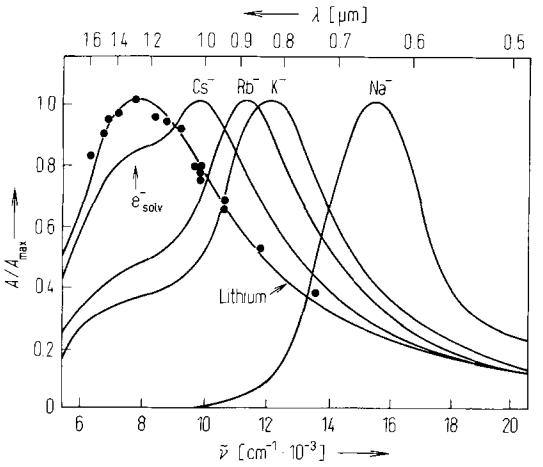

Fig. 1. Optical spectra of Li, Na, K, Rb, and Cs in ethylenediamine [24] with identification of absorption peaks of Na^-, K^-, Rb^-, Cs^- and e^-_{solv}. Solid circles are for e^-_{solv} produced by pulse radiolysis [25].

lenediamine. The infrared shoulders obtained for solutions of K, Rb and Cs are attributed to the solvated electron and the ratio of this absorbance to that of the anions depends strongly on concentration (see Eq. 1). The solvent-dependence of the peak positions is illustrated by Figure 2, which compares the peak positions of Na^-, K^- and e^-_{solv} in various solvents. The solvent-dependence of the absorption maximum of e^-_{solv} correlates in turn with that of I^- [23].

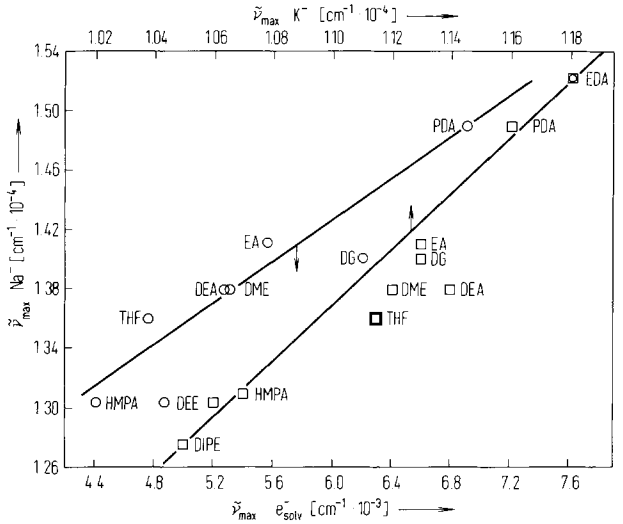

Fig. 2. Wavenumbers of the absorption maxima of Na^-, K^- and e^-_{solv} at 25 °C in various solvents. Open squares are for K^-, open circles are for e^-_{solv}. Solvent identification: DEA = diethylamine; DEE = diethyl ether; DG = diglyme; DIPE = di-isopropyl ether; DME = dimethoxyethane; EA = ethylamine; EDA = ethylenediamine; HMPA = hexamethyl phosphoric triamide; PDA = 1,2-propanediamine; THF = tetrahydrofuran.

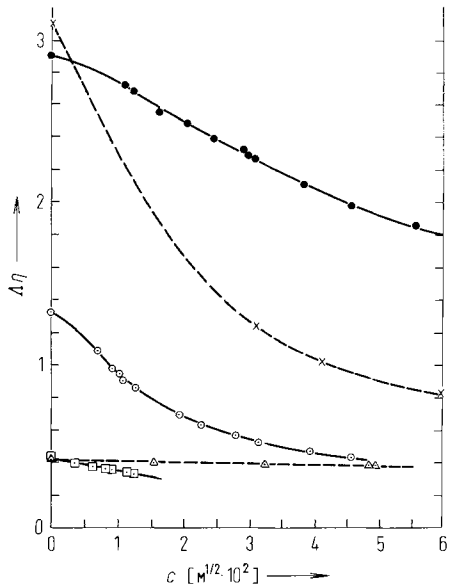
Matalon, Golden and *Ottolenghi*[5] showed that the wavenumber of maximum absorbance of the alkali metal anions varies inversely with the estimated anion radius, in accord with the predictions of ctts theory. The observed temperature-dependence of the peak position is also predicted by this theory[5, 12]. We conclude that the absorption spectra of M^- in solution are similar to those of other anions.

An examination of ctts theory might lead one to conclude that the excited state bears no relation to excited states of the isolated anion. This does not necessarily follow, however. Excited states of the anion might lie above the ionization limit in the gas phase, yet be observable in solution or in crystals, either because of a strong perturbation of the continuum level or because of low probability for direct excitation to the continuum level of the solvent. In fact, auto-ionization apparently occurs from excited states of the alkali metal anions and other anions in solution[26-28] suggesting that the continuum level lies at lower energies than does the first excited state. It is probably appropriate to consider the intense absorption band of M^- in solution and in crystals as originating from an s to p transition, modified by the presence of solvent molecules or neighboring ions and including a contribution from direct bound-continuum transitions[28].

2.3. Conductivity

The conductivities of sodium and cesium solutions in ethylenediamine[29] and methylamine[30] have been measured. The optical spectra show that sodium solutions in these two solvents consist primarily of Na^+ and Na^- while dilute cesium solutions contain mainly Cs^+ and e^-_{solv}. The differences in conductivity of these solutions are striking—as shown in Figure 3. The rapid drop in conductivity with increasing concentration for solutions containing Cs^+ and e^-_{solv} in the amines resembles the behavior in ammonia and can be readily accounted for in terms of ion-pairing between Cs^+ and e^-. The high limiting conductance of e^-_{solv} in both ethylenediamine and methylamine is also similar to the behavior in ammonia especially when the appropriate viscosity corrections are made as in Figure 3. The conductivities and the similarity in optical spectra thus provide strong evidence that metal solutions in methylamine and in ethylenediamine which do *not* contain alkali metal anions are similar to metal-ammonia solutions. By contrast, the conductivities of sodium solutions in methylamine and ethylenediamine show that the mobility of Na^- is "normal" and that the extent of



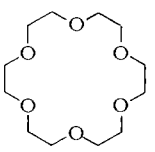


Fig. 3. Product of equivalent conductance (Λ) and solvent viscosity (η) for solutions of Na in methylamine ⊡ [30], and ethylenediamine △ [29], and of Cs in methylamine ⊙ [30], ethylenediamine × [29], and ammonia ● [83].

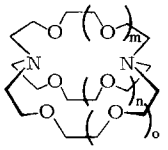

ion pairing between Na^+ and Na^- is small, as expected for a large interionic contact distance.

2.4. The Effect of Crown Ethers and Cryptands

One of the major barriers to experimental studies of alkali metal solutions in amines and ethers is the generally low solubility. Combined with the ever-present tendency towards decomposition, this low solubility has made reproducible measurements difficult. By using crown-ether and cryptand complexes such as those of [18]crown-6 *(1)*, and C222, we

[18] crown-6

Cryptands
C222, $m = n = o = 1$

were able to dramatically increase metal solubilities in a number of solvents[12, 19, 20, 31]. For a cation complexing agent (Cry = cryptand) the equilibrium (2) shifts the equilibrium (3) to the right, thus increasing the concentration of M^- in

$$M^+ + Cry \rightleftharpoons M^+Cry \quad (2)$$

$$2M_{(s)} \rightleftharpoons M^+ + M^- \quad (3)$$

the saturated solution. (This also applies for crown ethers as complexing agent.) When excess metal is present, equilibrium (4) determines the relative concentrations of M^- and

$$M^- \rightleftharpoons M_{(s)} + e^-_{solv} \quad (4)$$

e^-_{solv}. In the absence of excess metal, equilibrium (1) governs the relative concentrations of M^- and e^-_{solv}. The addition of a cation-complexing agent shifts reaction (1) to the right by reducing the concentration of M^+. Equilibrium (3) requires that the product of the activities of M^- and *free* cation cannot exceed the limit imposed by the solubility of metal. These reactions permit a measure of control over the composition tion of the solutions. The maximum value of the ratio $[M^-]/[e^-_{solv}]$ for a given metal is determined by the solvent and the temperature according to reaction (4). If this ratio is large, solutions consisting of primarily complexed M^+ and M^- can be prepared by maintaining an excess of metal in the preparation vessel. Alternatively, if K_1[*] is not too small and K_2 is large, the addition of equimolar amounts of complexing agent and metal can yield solutions whose composition is mainly complexed M^+ and e^-_{solv}. Section 3 considers the thermodynamics of these reactions in more detail.

2.5. Nuclear Magnetic Resonance

The ability to prepare concentrated metal-amine solutions (up to 0.2 M and higher) by using crown ethers and cryptands opened the door to NMR studies of alkali metal anions[32, 33]. It was known[34, 35] from NMR studies with salts that the release of Na^+ from a Na^+C222 complex is slow on the NMR time scale, so that separate ^{23}Na-NMR signals were expected and found for Na^+Cry and for Na^-. Figure 4 shows the spectra obtained in three solvents[33]. The calculated diamagnetic shift of $\delta = -2.6$ for Na^- compared with Na(g)[33, 36] is

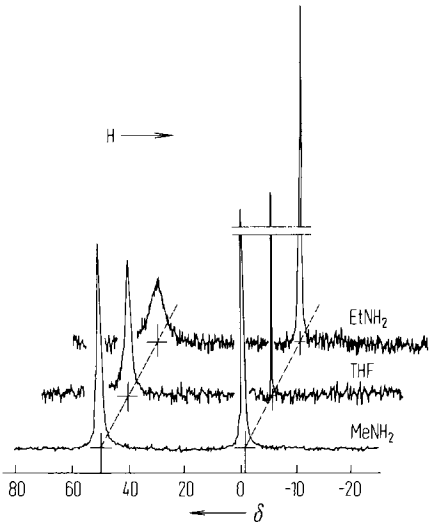

Fig. 4. ^{23}Na-NMR spectra of Na ' C222, Na solutions ($\approx$0.1 M) in three solvents [33]. All shifts are referred to $Na_{(g)}$. Positive shifts are paramagnetic. The peaks of Na ' C222 at the left are at $\delta = +49.5$. The peaks of Na at the right are at $\delta = -2$.

very close to the measured shifts[33] of $\delta = -1.4$, -1.6, and -2.3 for Na^- in methylamine, ethylamine and tetrahydrofuran respectively. This is to be compared with *paramagnetic* shifts of 60.5, 72.2 and 50.4 for Na^+ in water, methylamine and the cryptate complex respectively. The absence of an appreciable paramagnetic shift for Na^- in solution proves that the solvent is prevented from interacting appreciably with the 2p electrons by the presence of the outer 2s electrons. This, in fact, provides the strongest evidence that Na^- in solution is truly an alkali metal anion rather than, say, a solvated cation with two solvated electrons in the vicinity or a solvated cation attached to a solvated electron pair.

The NMR spectra[33] of Rb^- in ethylamine and in tetrahydrofuran (THF) show single lines at $\delta = +26.2$ and $+14.4$ ppm respectively relative to Rb(g) while the peak for Cs^- in THF occurs at $\delta = +52.3$ ppm relative to Cs(g). These are to be compared with values of $\delta = +213$ and $+348$ for aqueous Rb^+ and Cs^+ respectively. Exchange effects[17] sometimes prevent the observation of the NMR signal of M^- and may be the reason that we have not yet been able to observe K^- by NMR even in solutions whose optical spectra show the existence of high concentrations of this species.

2.6. Other Solution Properties of Alkali Metal Anions

The rate of reaction of Na^- with water in ethylenediamine is much slower than that of e^-_{solv} and the reaction order in water is also different[21, 37]. The rate of formation of Na^- from solvated electrons and Na^+ has been studied by pulse radiolysis[14, 38]; the reaction is second order w.r.t. e^-_{solv}. The dependence of the rate on the concentration of Na^+ is complex and suggests[14] that electron-pairing precedes the formation of Na^-. Photolysis of M^- in the wavelength region of the absorption maximum leads to the production of solvated electrons[39-47], sometimes in a spin-polarized state[40, 46, 47] (CIDEP). Photoelectron emission has also been

[*] K_1 is the equilibrium constant for reaction (1).

observed[28] from e^-_{solv} and from Na^- in HMPA. These observations generally support the assumption that alkali metal anions are new species and not just a combination of the solvated cation and two solvated electrons.

2.7. Ion pairs and "Monomers" in Solution

The electron spin resonance (ESR) spectrum of the solvated electron consists of a single narrow line with a g-value near that of the free electron. When the electron interacts strongly with an alkali cation so that appreciable electron density exists at a metal nucleus with spin I, and when this electron-cation pair has a long enough lifetime (generally microseconds or longer) then a hyperfine pattern results with $2I+1$ nearly equally spaced lines[48-51]. Pulse radiolysis[38,52,53] and photolysis[43] studies in the presence of alkali cations have shown that the optical spectrum of e^-_{solv} is blue-shifted by formation of the ion-pair (also referred to as an alkali metal "monomer"). The magnitude of this blue-shift increases as the polarity of the solvent decreases and correlates well with the electron contact density at the alkali nucleus as determined by ESR measurements[53]. Changes in the cation-electron contact density and in the spectrum with solvent and temperature have been attributed to the formation of solvent-shared and contact ion-pairs[51]. Although the sensitivity of the ESR technique permits easy detection of the monomer species, the equilibrium concentration of monomers, M, in amines and ethers is generally small compared with M^- and e^-_{solv}. Crown ethers or cryptands shift the equilibrium

$$M \rightleftharpoons M^+ + e^- \qquad (5)$$

to the right in the absence of excess metal. Although the concentration of monomers is low, they may play important roles in the exchange kinetics of complexed M^+ and M^- and in the rate of decomposition of metal solutions.

3. Thermodynamic Considerations

The proposed existence of alkali metal anions in ammonia[3,4] was based on thermodynamic arguments. Our search for salts of the alkali metal anions (which we refer to as "alkalides") was also based on thermodynamic predictions of their stabilities and we continue to be guided in the search for appropriate metals, solvents and complexing agents by approximate calculations of stability constants. Questions have also arisen about the possible existence of anions of other metals such as the alkaline earths. It is a simple matter to show thermodynamically that the existence of an ion such as Ca^- in solution is thermodynamically impossible while the gold anion, Au^-, may well be thermodynamically stable. In this section some of the pertinent thermodynamic arguments will be given. Some of the predictions can be made with reasonable accuracy; others are far less certain, either because key measurements have not yet been made or because of limitations of the theory of solvation free energies or lattice energies. In either case, it is often possible to make reasonably accurate *relative* calculations which at least permit comparisons among the alkali metals.

3.1. Stability of Metal Anions in Ammonia as Solvent

It is possible to calculate accurate values of ΔH^0 and ΔG^0 for the process

$$e^-_{(g)} + M_{(s)} \rightarrow M^-_{(g)} \qquad (6)$$

from electron affinities[2,54], properties of the solid and gaseous elements[55], and statistical thermodynamics calculations of entropies[56]. The values of ΔH^0_6 and ΔG^0_6 for the alkali metals and some other metallic elements at 25 °C are given in Table 1[*].

Table 1. Thermodynamic estimates [a] used to judge the stability of anions in ammonia to dissociation into metal and solvated electrons.

Metal	Estimated anion radius r (Å)	Electron Affinity	ΔH^0_6	ΔG^0_6	ΔH^0_7	ΔG^0_7	
						298 K	238 K
Li	2.35	59.8	96.7	67.7	− 65.8	1.8	− 11.8
Na	2.72	52.9	53.4	30.6	− 78.1	− 5.6	− 20.2
K	3.27	48.4	39.1	18.2	− 59.3	13.5	− 1.1
Rb	3.39	46.9	36.4	14.4	− 56.3	15.2	0.8
Cs	3.55	45.5	30.7	10.9	− 54.9	18.5	3.8
Au	2.00	222.7	140.9	109.0	− 61.5	5.1	− 8.3
Ag	2.00	125.7	156.4	125.4	− 46.0	21.4	7.9
Cu	1.93	118.3	217.5	185.7	5.5	72.5	59.0
Ba	3.5	− 52.1	225.4	202.3	137.7	207.9	193.7
Pt	3.55	205.3	357.5	320.6	271.9	328.2	316.9
Te	2.3	183.3	11.0	− 20.8	− 156.5	− 91.4	− 104.5
Pb	2.2	101.3	91.2	66.0	− 86.8	− 14.7	− 29.2
Bi	2.2	101.3	103.3	72.3	− 74.7	− 8.4	− 21.8
Tl	2.1	48.2	131.5	104.6	− 58.1	12.8	− 1.4
Sb	2.2	101.3	158.6	126.3	− 19.5	45.6	32.5
Sn	2.2	120.6	179.0	152.2	1.0	71.4	57.3

[a] All values given in kJ mol^{-1}; $\Delta H^0_8 = 247 - 535\,(1/r)$; $\Delta G^0_8 = 334 - 511\,(1/r)$ evaluated by fitting data for the halide ions (see text).

If the solvation free energy of $M^-_{(g)}$ is more negative than that of $e^-_{(g)}$ by an amount equal to or greater than that given in Table 1 then the reaction

$$e^-_{solv} + M_{(s)} \rightarrow M^-_{solv} \qquad (7)$$

[*] Many of the thermodynamic estimates described in this article have not been previously published. Details of the calculations are available from the author on request.

is feasible and we can expect M^- to be stable to dissociation into the (solid) metal and solvated electrons. According to the Born equation[57] both the Gibbs free energy of solvation and the enthalpy of solvation of an ion are inversely proportional to the ionic radius. Since the Born equation is based on a continuum model and fails to account for specific solvation of the ions, it is not appropriate to use it directly. A better procedure is to use the known free energies and enthalpies of formation of Cl^-, Br^- and I^- in ammonia[58] together with the thermodynamics of formation of the corresponding gaseous anions to calibrate the dependence of the solvation enthalpy and Gibbs free energy upon radius. Specifically, ΔG_8^0 and ΔH_8^0 for

$$X^-_{(g)} + e^-_{(Pt)} \rightarrow X^-_{(NH_3)} + e^-_{(g)} \tag{8}$$

are linear functions of the reciprocal of the anion radii of Cl^-, Br^- and I^-. These thermodynamic functions were obtained by combining the reactions

$$\frac{1}{2}X_2 + e^-_{(Pt)} \rightarrow X^-_{(NH_3)} \tag{9}$$

$$\frac{1}{2}X_2 \rightarrow X_{(g)} \tag{10}$$

$$X_{(g)} + e^-_{(g)} \rightarrow X^-_{(g)} \tag{11}$$

The values of ΔG_9^0 and ΔH_9^0 were obtained from the tabulation of *Latimer* and *Jolly*[58] and are based upon $\Delta G_f^0 = 0$ and $\Delta H_f^0 = 0$ for H^+ in ammonia. The values of ΔG^0 for reactions (10) and (11) were obtained from known atomization free energies and enthalpies[55] of the halogens and their electron affinities[54]. By assuming that the solvation free energy and enthalpy of other anions depend upon radius in the same way as those of Cl^-, Br^- and I^-, we can calculate ΔG_8^0 and ΔH_8^0 for any anion if we know its radius. Following the suggestion of *Matalon, Golden* and *Ottolenghi*[5] we can estimate the radius of an alkali metal anion by subtracting its ionic radius from the interatomic distance in the metal. The radius of Au^- (2.0 Å) was obtained by subtracting the radius of Cs^+ from the cesium-gold distance in the ionic compound CsAu[59]. The values[58] $\Delta G_f^0 = -182$ kJ mol^{-1}, $\Delta H_f^0 = -159$ kJ mol^{-1} for Na^+ in NH_3 at 25 °C and $\Delta H_f^0 = -182$ kJ mol^{-1} for $e^-_{(NH_3)}$ combined with $\Delta G_{12}^0 \approx 0.0$ at 25 °C[60] for the process

$$Na_{(s)} \rightarrow Na^+_{(NH_3)} + e^-_{(NH_3)} \tag{12}$$

gives $\Delta H_{13}^0 = \Delta G_{13}^0 = -182$ kJ mol^{-1} for

$$e^-_{(NH_3)} \rightarrow e^-_{(Pt)} \tag{13}$$

at 25 °C based upon the convention that the enthalpy and free energy of formation of $H^+_{(NH_3)}$ are zero. Addition of reactions (6), (8) and (13) gives reaction (7). The values of ΔH_7^0 and ΔG_7^0 at 25 °C and ΔG_7^0 at −35 °C for a number of metallic elements are given in Table 1. The results show that the reaction of solvated electrons with metal to produce ammoniated metal anions with filled outer s-orbitals may be thermodynamically permitted for all of the alkali metals and for gold[*] and silver. It appears that Cu^- would not be stable to dissociation into $Cu_{(s)}$ and e^-_{solv}.

For ions which do not have the added electron in an s-orbital, the calculations predict stability for Te^-, Pb^-, Bi^-, and Tl^-. The first three of these elements do form anions in ammonia[61,62] which have also recently been isolated in crystalline salts[63–68], but in these cases the anions are polymeric rather than monomeric. Salts which contain polymeric anions of antimony and tin have also been isolated[63,65,67]. Our calculations indicate instability of *monomeric* Sb^- and Sn^- in ammonia but the addition of metal-metal bonding would stabilize polymeric anions.

The existence of detectable concentrations of such ions as Ba^- and Pt^- in ammonia is clearly impossible from a thermodynamic viewpoint. In the former case, the negative electron affinity of barium shows that Ba^- is not even stable in the gas phase. On the other hand, while platinum has a large electron affinity the lattice energy is so great that conversion of $Pt_{(s)}$ to Pt^- by the action of solvated electrons is not thermodynamically permitted.

3.2. Dissociation of M^- to M^+ and Solvated Electrons in Solution

The calculations described above were made for ammonia solutions because we have sufficient data to calculate Gibbs free energies and enthalpies of formation of ions in ammonia, but not in amines and ethers. Similar calculations could be made for amine and ether solvents if sufficient solubility and/or e.m.f. data were available. Yet ironically, we have no *specific* evidence for the existence of alkali metal anions in ammonia. Let us examine the predicted concentrations for the most favorable case, that of Na^-. From the data in Table 1 we can calculate that for the reaction

$$e^-_{(NH_3)} + Na_{(s)} \rightleftharpoons Na^-_{(NH_3)} \tag{14}$$

at −35 °C, $K_{14} \approx 3 \times 10^4$. However, in a dilute solution away from metal we must also consider the equilibrium

$$Na^-_{(NH_3)} \rightleftharpoons Na^+_{(NH_3)} + 2e^-_{(NH_3)} \tag{15}$$

for which $K_{15} \approx 4 \times 10^{-6}$ M^2. This predicts that at a sodium concentration of 10^{-3} M (neglecting the effect of activity coefficients) the ratio $[Na^-]/[e^-]$ should be about 0.15. If the optical spectrum of Na^- were appreciably different from that of e^- in ammonia as it is in amine and ether solvents, then the presence of this concentration of Na^- would be easily detectable. Certainly, upon addition of a sodium salt the presence of Na^- should be observable. However, no prominent optical band of Na^- has been observed either in the presence or absence of sodium salts. We must conclude that either the calculation given for Na^- in Table 1 is in error by 15 kJ mol^{-1} or more, or the optical band of Na^- is shifted into the infrared in ammonia as originally suggested by *Golden et al.*[3]. We conclude that, while such calculations as these cannot be used to determine concentrations, they do demonstrate that the existence of alkali metal anions in ammonia, amines, and ethers is not prohibited on thermodynamic grounds.

[*] *W. J. Peer* and *J. J. Lagowski* [J. Am. Chem. Soc. *100*, 6260 (1978)] have recently shown that Au^- can be formed in liquid ammonia.

3.3. Stability of Metal Anions in Amine and Ether Solvents

Alkali metal solubilities[29] and spectra[24,69] have been measured for ethylenediamine solutions at 25 °C. The extinction coefficients of Na^- and e^-_{solv} in ethylenediamine are 8.2×10^4 and 2.0×10^4 M^{-1} cm^{-1} respectively[13,14]. These measurements permit estimation of the equilibrium constants K_1, K_3, and K_7 for ethylenediamine as solvent (see Table 2).

Although (excluding Li^-) Na^- is most stable and K^- is least stable relative to e^-_{solv} in the presence of excess metal, the concentration of M^- in the saturated solution increases regularly from Na^- to Cs^-. The dissociation of M^- to $M^+ + 2e^-_{solv}$ is least likely for Na^- and most likely for K^-. This apparently anomalous position of potassium solutions seems to reflect extra stabilization of the solvated electrons in the presence of K^+, perhaps *via* ion pairing. Such an effect has actually been observed both by the addition of a potassium salt to a solution of sodium in ethylenediamine[13] and by pulse radiolysis studies[14]. The appearance of the spectral peak of the solvated electrons occurs in this case but not when Rb^+ or Cs^+ are added.

Solubility and spectral data in other solvents are too sparse to permit evaluation of equilibrium constants. However, it is clear that the values of K_2 increase while K_1 and K_3 both decrease as the solvent polarity decreases. Thus, all metals except lithium when dissolved in ethylamine show primarily the optical band of M^- with little contribution from e^-_{solv}. Based upon the effect of C222 on the optical spectrum[70] we estimate that $K_1 < 10^{-20}$ for sodium in tetrahydrofuran. Therefore, solutions of sodium in this solvent, even in the presence of excess cryptand consist essentially of $Na^+C222\,Na^-$ with no detectable solvated electron concentration. By contrast, solutions of potassium in tetrahydrofuran with cryptand contain largely $K^+C222\,K^-$ when excess potassium is present, but mainly $K^+C222\,e^-_{solv}$ when an equivalent of cryptand is present[70].

Table 2. Estimation of equilibrium constants K_1, K_3 and K_7 for reactions of alkali metal anions in ethylenediamine at 25 °C from optical spectra and solubilities.

Metal	Solubility (M)	Path lenght (cm)	Absorbance Data Used A_e	A_M	Ref.	K_1 (M^2)	K_3 [a] (M^2)	K_7
Li	0.29	0.1	2	<0.05 [b]	[24]	$>4 \times 10^{-4}$	$<2 \times 10^{-2}$	<7
Na	2.39×10^{-3}	1.0	0.09	0.91	[69]	3×10^{-11}	1.4×10^{-6}	220
K	1.04×10^{-2}	1.0	2.0	0.46 [c]	[69]	1.6×10^{-6}	2.7×10^{-5}	4.1
		0.01	0.2	0.65	[24]	2.3×10^{-6}	2.7×10^{-5}	3.4
Rb	1.31×10^{-2}	1.0	0.84	0.40	[69]	1.7×10^{-8}	4.3×10^{-7}	50
		0.1	0.36	0.68	[24]	1.0×10^{-7}	4.3×10^{-5}	20
Cs	5.4×10^{-2}	0.01	0.6	0.9	[24]	4×10^{-5}	7×10^{-4}	5

[a] $K_3 = K_1 K_7^2$. [b] Estimated conc. of $Li = 3 \times 10^{-3}$ M. [c] In the presence of 1×10^{-3} M added K^+.

3.4. Stability of Metal Anions in Crystals

Attempts to grow crystals containing alkali metal anions were based upon their stability in solution, and the realization that stabilization of the cation by its inclusion in a cryptand cavity might prevent the spontaneous recombination of M^+ and M^- to form the metal. The fact that alkali cations are strongly complexed by the appropriate cryptand, even in as good a solvent as water, means that the gas phase complexation reaction

$$M^+_{(g)} + Cry_{(g)} \rightarrow M^+Cry_{(g)} \quad (16)$$

is strongly exothermic and highly favored. There are no direct data for this reaction, but indirect methods can be used to evaluate ΔH^0_{17} and ΔG^0_{17} for the reaction

$$Cry_{(s)} + M_{x(s)} + M_{y(s)} \rightarrow M^+_x Cry M^-_{y(s)} \quad (17)$$

in which M_x and M_y may be the same or different. If ΔG^0_{17} is negative then the salt $M^+_x Cry M^-_y$ is stable to decomposition into its components Cry, M_x and M_y. By adding all of the ΔH^0 and ΔG^0 values for the reactions listed in Table 3 one obtains ΔH^0_{17} and ΔG^0_{17}. While the *absolute* values of ΔH^0_{17} and ΔG^0_{17} given in Table 4 may be in error by as much as ± 50 kJ because of errors of measurement and the various approximations made, their *relative* values should be much more reliable. Since we can prepare the crystalline salt $Na^+C222\,Na^-$, even in the presence of an excess of sodium and cryptand, it appears to be thermodynamically stable. The calculated value of ΔG^0_{17} for this salt is $+32$ kJ mol^{-1} which is within the estimated absolute error of the value $\Delta G^0_{17} \leq 0$ required for thermodynamic stability. It appears safe to assume that any proposed salt with a value of ΔG^0_{17} equal to or more negative than that of the reference salt $Na^+C222\,Na^-$ is likely to be thermodynamically stable. Of course, these calculations do not preclude decomposition *via* destruction of the cryptand moiety, a process which we have found to be very common.

A critical quantity in these calculations is the interionic distance in the crystalline salt. The sum of the calculated radii r_{Na^+Cry} and r_{Na^-} is larger than the measured distance in the salt $Na^+C222\,Na^-$ by 14%. This could be caused by lack of sphericity of the cryptated cation, an error in the estimate of its size or that of Na^-, and/or compression of these relatively "soft" ions in the crystal. The cation-anion distances in $Na^+C222\,I^-$[76] and $K^+C222\,I^-$[77] are within a few percent of those calculated on the basis of the ionic radius of I^- and the radii of Na^+C222 and K^+C222 calculated from the ligand thickness[73]. Therefore, the most likely source of error in the estimate of the interionic distance in $Na^+C222\,Na^-$ is an error in the estimated radius of Na^- or neglect of the compression of this ion and of the cryptated cation in the crystal. In order to compensate for this reduction in interionic distance, all of the calculated anion radii were reduced by 14% in computing the lattice energy and entropy in step (h) of Table 3.

Table 3. Steps in thermodynamic cycle used to evaluate ΔH^0_{17} and ΔS^0_{17}.

	Reaction step	Origin of data or estimate	Typical data source
a)	$M^+_{(aq)} + Cry_{(aq)} \rightarrow M^+Cry_{(aq)}$	Enthalpies of complexation and equilibrium constants	[71]
b)	$Cry_{(s)} \rightarrow Cry_{(aq)}$	Solubility of cryptand as a function of temperature, enthalpies of solution of pure cryptand in water	[b]
c)	$M_{(s)} \rightarrow M^+_{(g)} + e_{(g)}$	ΔH^0 and ΔG^0 of atomization plus ionization potentials of $M_{(g)}$. Use Sackur-Tetrode equation for entropies of gaseous species.	[55, 56]
d)	$M^+_{(g)} \rightarrow M^+_{(aq)}$	Tabulated hydration enthalpies and free energies	[72]
e)	$M^+Cry_{(aq)} \rightarrow M^+Cry_{(g)}$	Born equation plus estimate of size of M^+Cry from ligand thickness	[57, 73, 74]
f)	$M_{(s)} + Cry_{(s)} \rightarrow M^+Cry_{(g)} + e_{(g)}$	Sum of a—e	
g)	$M_{(s)} + e_{(g)} \rightarrow M_{(g)}$	ΔH^0 and ΔG^0 of atomization plus electron affinity of $M_{(g)}$ and calculation of entropy as in (c) above	[54, 55]
h)	$M^+_x Cry_{(g)} + M_{x(g)} \rightarrow M^+_x Cry M^-_{y(s)}$	Kapustinskii equation for lattice energy; ΔS^0 from size and comparison with alkali metal halides [a]	[74, 75]
i)	$Cry_{(s)} + M_{x(s)} + M_{y(s)} \rightarrow M^+_x Cry M^-_{y(s)}$	Sum of f, g, and h	

[a] A plot of ΔS^0_h for formation of alkali halide lattices from the gaseous ions *vs.* $(r_{M^+} + r_{X^-})^{-1}$ is linear, following the equation $\Delta S^0_h = -47.8 - 29.2\,(r_{M^+} + r_{X^-})^{-1}$, while for the alkaline earths the equation is $\Delta S^0_h = -72.2 - 53.6\,(r_{M^{2+}} + r_{X^-})^{-1}$ (S in JK^{-1} mol^{-1}, r in Å).
[b] Data not available so $\Delta H^0_h = \Delta G^0_h = 0.0$ was used in preparing Tables 4 and 5. Recent calorimetric measurements give $\Delta H^0_h = -24.5$ kJ mol^{-1}; *M. H. Abraham*, University of Surrey (England), private communication, (1979).

Calculated values of ΔH^0 and ΔG^0 for steps (f), (h) and (i) of Table 3 are given in Table 4 for a few selected salts. Calculations involving the cryptated alkaline earth cations included the necessary valence corrections but are probably less certain than those for the alkali metals. Nevertheless, they indicate that salts such as $Ba^{2+}C222(Na^-)_2$ should be thermodynamically stable.

These calculations also provide estimates of the thermodynamic stability of "electrides"[78]. To calculate ΔH^0_{18} and ΔG^0_{18} for the process

$$Cry_{(s)} + M_{(s)} \rightarrow M^+Cry e^-_{(s)} \qquad (18)$$

we assume that the electron occupies the octahedral holes in a closest-packed lattice of cryptated cations. Therefore the effective "radius" of the trapped electron is $0.414\,r_{M^+Cry}$ and the lattice energy is assumed to be the same as that of a salt in which a hard monovalent anion just fits into the octahedral hole. Compression of the packed cations or delocalization of the electrons would be expected to predict even greater stabilities. The conservative estimates given in Table 4 suggest that "electrides" should be stable. The values of ΔH^0_{16}, ΔG^0_{16}, ΔH^0_{18}, and ΔG^0_{18} for a number of other possible compounds are given in Table 5.

At the very least, the results given in Tables 4 and 5 for a variety of crystalline salts of "alkalides" and "electrides" suggest that this field is potentially a very rich one for the synthesis of a variety of new compounds. The predicted thermodynamic stabilities of salts of the alkaline earth cryptates are particularly striking. In the following sections we will describe our progress in the preparation of "alkalide" and "electride" salts and speculate about possible future developments.

Table 4. Estimated thermodynamic data [a] for assessment of the stability of some crystalline salts of the type $M^+_x Cry M^-_y$ ($M_x = M_y$, $M_x \neq M_y$) and $M^+Cry e^-$ at 25 °C. The subscripts f, h, and i refer to the corresponding reactions in Table 3.

$M^+_x Cry M^-_y$ $M^+Cry e^-$	ΔH^0_f	ΔG^0_f	ΔH^0_h	ΔG^0_h	ΔH^0_i	ΔG^0_i

4. Solid Compounds Containing Alkali Metal Anions

By late 1973 the evidence for alkali metal anions in solution was very strong, and thermodynamic estimates indicated potential stability of crystalline ionic salts of the type M^+CryM^-. Rapid evaporation of methylamine or ethylamine from concentrated solutions of sodium or potassium in these solvents in the presence of cryptand C222 left deposits of metallic-looking gold-colored films on the glass walls. Upon cooling a solution of Na^+C222, Na^- in ethylamine (≈ 0.1 M) from +5 °C to dry-ice temperatures, a gold-colored powder precipitated from solution. Slow cooling resulted in the growth of hexagonal crystals of the salt $Na^+C222\,Na^-$. Analysis[6] and a crystal structure determination[7] confirmed the existence of this first solid compound containing an alkali metal anion. The isolation and characterization of other members of this class of compounds has been hampered by difficulties with stabilities and with finding the proper solvents for crystallization, but recently we have made considerable progress in this area.

4.1. Preparation and Characterization of $Na^+C222\,Na^-$

4.1.1. Preparation of Powdered and Crystalline Forms

The preparation of this salt is relatively simple provided one pays close attention to solvent purity and cleanliness of the glassware. The type of vessel used is shown in Figure 5.

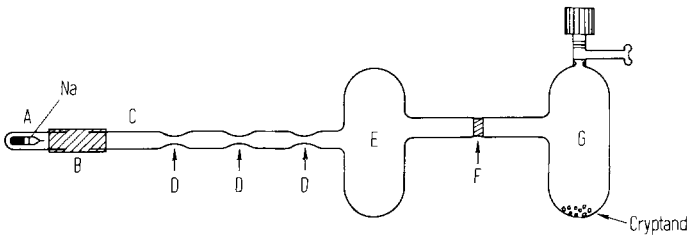

Fig. 5. Apparatus for the preparation of the crystalline salt $Na^+C222\,Na^-$ [74]. A to G see text.

The sodium, previously transferred under vacuum into small diameter glass tubing is inserted into glass tube A after scoring the metal-containing tube with a glass knife. Heat-shrinkable Teflon tubing B is used to connect tube A to side-arm C. Cryptand is then introduced into vessel G and the entire apparatus is evacuated. Then the tube containing sodium is shaken into the flexible connection B between A and C, broken under vacuum and moved to the constriction. A vacuum seal-off is made behind the metal sample and with the vessel re-attached to the vacuum manifold, metal is successively distilled into vessel E through two or three constrictions while pumping ($\approx 10^{-5}$ torr). (With volatile cryptands vessel G must be cooled during this operation.) Solvent sufficient to produce about 0.05 M cryptand is condensed in G, the cryptand is dissolved and the solution is transferred into E and allowed to contact the metal mirror at 0 °C for a few hours. The solution is then poured through the frit F into G and cooled to −78 °C, resulting in the precipitation of finely-divided crystals of $Na^+C222\,Na^-$. To improve the yield, the supernatant blue solution is poured from the crystals at −78 °C back through the frit F into E for further agitation on the metal at 0 °C. After pouring the supernatant liquid into E for the last time it is distilled into a waste flask and either diethyl ether or *n*-pentane is condensed on the salt in order to remove any unreacted cryptand or other organic-soluble impurities. Provision is usually made on vessel G for transfer of the washed salt into a number of tubes which can be individually sealed-off under vacuum. Crystals of $Na^+C222\,Na^-$ up to ≈ 1 mm in diameter can be grown by slowly cooling a solution which is formed by redissolving the salt in ethylamine.

4.1.2. Crystal Structure of $Na^+C222\,Na^-$

In its gross features, the crystal structure[7] of this salt may be viewed as hexagonal closest-packing of the large cryptated cations with the smaller Na^- ions occupying the octahedral holes. The cryptand forms a cage for Na^+ with three-fold symmetry and an anti-prismatic arrangement of the ether oxygens. Views down the three-fold axis and side-on are shown in Figure 6. The shape of the cryptate moiety and relative positions of Na^+ and Na^- are similar to those in

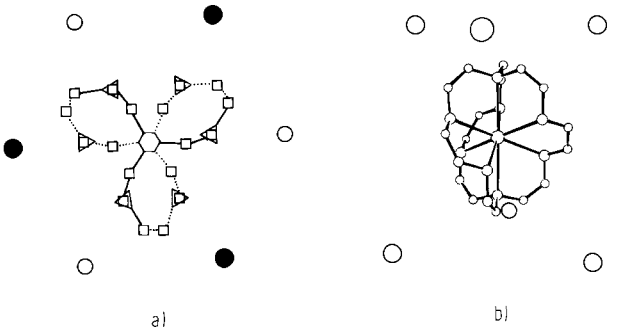

Fig. 6. Views of the structure of $Na^+C222\,Na^-$ [7]. (a) Looking down the three-fold axis; filled-in circles represent the "top" Na^- ions; open circles the bottom ones. Triangles represent O atoms, squares represent CH_2 groups. The two N atoms and Na^+ are co-linear at the center. Solid lines connect atoms above the center; dotted lines below the center. (b) Perspective side-view of the structure.

$Na^+C222\,I^-$ [76]. The closest Na^- to Na^- distances are 8.83 Å in the packing planes perpendicular to the three-fold axis while the closest distance between Na^- ions in different planes is 11.0 Å. This could result in considerable anisotropy of those properties which depend upon the distance between anions such as the electrical conductivity.

4.1.3. Properties of $Na^+C222\,Na^-$

Crystals of this salt frequently grow as thin hexagonal plates with shiny metallic-looking faces. Their color at liquid nitrogen temperature is bright yellow-gold, which darkens reversibly to a yellow-bronze appearance at room temperatures. The crystals melt with decomposition at 83 °C to yield gray particles suspended in a clear fluid. Analysis after cooling shows that most of the cryptand remains intact and apparently sodium metal is released upon melting. By contrast, crystals left in evacuated tubes for several days at room temperature and under ambient light conditions darken irreversibly, apparently with decomposition of the cryptand. When a sample was kept in the dark at room temperature for three weeks, no apparent decomposition occurred, but the apparent photosensitivity has not yet been investigated further.

Packed powders of $Na^+C222Na^-$ have the temperature-dependent electrical conductivity expected for a semiconductor. As shown in Figure 7, $\log\rho$ *vs* $1/T$ gives a straight line over six decades of resistance where ρ is the specific resistance. The magnitude of the resistance depends upon the packing pressure and decreases with time as the sample anneals. Considering this salt as a semiconductor gives a band

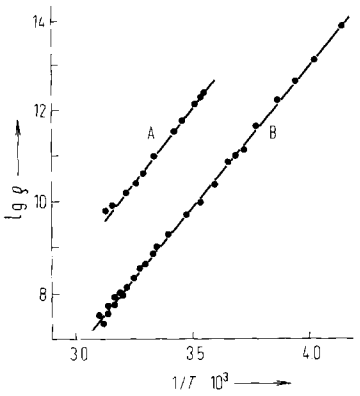

Fig. 7. Semi-log plot of specific resistance of powdered samples of $Na^+C222Na^-$ *versus* the reciprocal of the temperature. Sample A was relatively loosely-packed. The data shown for the tightly-packed sample B were measured at both increasing and decreasing temperatures [82].

gap of 2.4 eV. This salt is diamagnetic, as indicated both by ESR studies and by static susceptibility measurements. No magnetic anomalies have been found between 300 and 4.2 K. The ESR spectrum shows only an extremely weak signal probably caused by trapped electrons.

4.1.4. The Optical Spectrum of Thin Films of $Na^+C222Na^-$

Powdered or crystalline samples of this compound can be dissolved in a number of amines and ethers to give deep blue solutions. Upon cooling such solutions (except in methylamine and ammonia) the salt precipitates. When solutions in methylamine, ethylamine or THF are rapidly evaporated, the walls are covered with a thin film which appears gold by reflected light and blue by transmitted light. The absorption spectrum of such a film is shown in Figure 8. In all cases with this compound the three distinctive features shown in Figure 8 were observed[78]. The major peak at 15400 cm^{-1} (650 nm) is characteristic of Na^- in solution[12] and probably arises from a 3s to 3p transition, modified by crystal-field effects. The origins of the pronounced shoulder at 18900 cm^{-1} and the small but distinct peak at 24500 cm^{-1} are unknown although the latter could arise from a bound-free transition corresponding to the band-gap of 2.4 eV shown by conductivity. Figure 8 also shows that the gold-colored film formed by using [18]crown-6 in the presence of solvent vapor has the major absorption band at 15400 cm^{-1} but shows neither the extra peak at 24500 cm^{-1} nor the shoulder at 18900 cm^{-1}.

The spectrum shows clearly why crystals of $Na^+C222Na^-$ appear metallic by reflected light. The high absorption in the near-infrared and sharp cutoff in the visible mimic the plasma absorption of metals. This can lead to a striking metallic appearance even for nonconducting crystals[79].

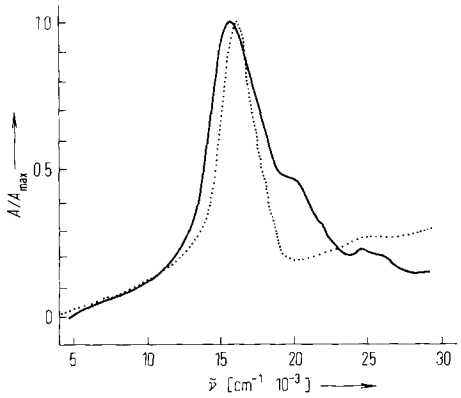

Fig. 8. Absorption spectra of a thin, solid solvent-free film of $Na^+C222Na^-$ (solid line) [78] and of a film of Na^+ 18C-6 Na^- containing some methylamine (dotted line) [81].

4.1.5. Summary of the Properties of $Na^+C222Na^-$

The structure and properties of the salt $Na^+C222Na^-$ in the crystalline state and in solution, confirm that Na^- is a "genuine" spherical anion with two electrons in the 3s orbital. Were it not for the tendency of Na^- to donate electrons to any available acceptor, a variety of salts could probably be prepared. However, stability requires that the counterion be extremely reluctant to pick up an electron. Any bare metal cation would probably be reduced by Na^- and we will probably be forced to continue to use complexed metal cations or perhaps such species as tetraalkylammonium cations. While the latter will probably not pick up the electron by simple attachment, it is known that solvated electrons can react with small tetraalkylammonium ions, breaking the C N bond. Therefore, salts such as $R_4N^+Na^-$ may not be stable.

4.2. Other Salts of Alkali Metal Anions

The crystalline compound described in the previous section can be prepared either by crystallization from a solution containing largely Na^+C222 and Na^- or by rapid evaporation of solvent from such a solution. By controlling the complexing agent, metal, and solvent, one can prepare a wide variety of concentrated solutions containing M^+Cry (or M^+ crown ether), M_y^- and/or e^-_{solv}. The metals M_x and M_y may be the same or different. In this section we describe some (as yet incompletely characterized) solids prepared either by crystallization from such solutions or by rapid solvent evaporation.

4.2.1. Solids Prepared by Crystallization

The only crystalline solids which we have prepared to date contain the cryptand C222 with various alkali metals—no crystals have been made with other cryptands or with crown ethers, nor have any "electrides" been crystallized. However, there seems to be no fundamental restriction on the preparation of such compounds if one can find the appropriate solvent and conditions for crystallization.

In addition to the salt of Na^-, we have prepared other crystalline solids which appear to be K^+C222K^-, $K^+C222Na^-$, $Rb^+C222Rb^-$ and $Cs^+C222Cs^-$. The methods of preparation are similar to those used for $Na^+C222Na^-$(s) except that isopropylamine was used rather than ethylamine for salts of K^-, Rb^- and Cs^-. All of the

crystals have a metallic appearance which ranges in color from light gold for $Na^+C222Na^-$ to greenish-gold for $K^+C222Na^-$ to dark copper-bronze for $Cs^+C222Cs^-$. Solutions containing K^-, Rb^-, Cs^- and e^-_{solv} are much more subject to irreversible decomposition than are those containing Na^-. This makes it difficult to prepare crystalline salts of these anions since all solution manipulations must be done at low temperatures. Once the solvent has been removed, however, all of the crystalline solids prepared so far seem to be reasonably stable and it is likely that we will be able to handle them and characterize them in much the same way as for $Na^+C222Na^-$.

4.2.2. Preparation of Thin Films by Solvent Evaporation

By adjusting the solution stoichiometry and flash-evaporating the solvent (practical only with highly volatile solvents) it is relatively easy to prepare solvent-free transparent films or powders whose spectral properties[78] indicate the presence of M^- and/or e^-. Such films have been prepared from solutions of all of the alkali metals in methylamine in the presence of both crown ethers and cryptands. Films which show optical bands of M^- appear blue by transmitted light and vary in color from gold to dark-bronze by reflected light, depending on the metal, while films which have only an infrared band (presumably the absorption band of trapped electrons) appear blue by transmitted light and very dark blue-black by reflected light.

Attempts to prepare crystals or powders by slow solvent evaporation have been generally unsuccessful, with irreversible decomposition usually occurring instead of precipitation of the desired compound. Solutions and solids that contain [18]crown-6 tend to be more stable to irreversible decomposition than those that contain C222. However, in the former case[74], solid films of $Na^+18C\text{-}6Na^-$ also require the presence of some solvent. Removal of solvent leads to the formation of solid sodium and [18]crown-6, without apparent decomposition of the crown ether. Evidently the axial position(s) in the $Na^+18C\text{-}6Na^-$ salt must be occupied by solvent in order for the salt to be stable. It is interesting that films prepared by evaporating solutions containing [18]crown-6 and either K, Rb or Cs give spectra which do *not* change when all of the solvent is removed.

4.2.3. Absorption Spectra of Films

Films prepared by evaporation of methylamine from solutions with stoichiometric amounts of M^+, C222 and M^- (M^+C222M^-) show strong absorption bands which are characteristic of the anion. The shoulder and extra peak seen with films of $Na^+C222Na^-$ are not observed for any of the other metals. Indeed, when films are prepared from solutions of $K^+C222Na^-$ the peak of Na^- is a single narrow band. The origin of this change in spectrum and that obtained with [18]crown-6 (see Fig. 8) remains a mystery although we expect a change in crystal structure from $Na^+C222Na^-$ to $K^+C222Na^-$ or to $Na^+18C\text{-}6Na^-$. Since we are now able to prepare crystalline samples of $K^+C222Na^-$, it may be possible to determine the origin of these spectral differences.

Even before the isolation and characterization of $Na^+C222Na^-$, we had prepared dark blue solid powders and films by solvent evaporation from solutions which contained largely M^+ cryptand (or M^+ crown ether) and solvated electrons[7]. The ESR spectra of such powders consists of a very intense narrow line at the free-electron g-value, suggesting the presence of trapped electrons and extensive motional narrowing of the ESR signal. Recently *Harris* and *Lagowski*[80] observed narrow ESR lines from solids produced by freezing metal-ammonia solutions which contained [18]crown-6. They attribute the signal to an ammoniated electron in the vicinity of a complexed cation. In our case, *solvent-free* blue solids are obtained so that the electrons can no longer be solvated but may simply occupy the anion sites in the crystal lattice. We refer to these solids as "electrides" although the disposition of the electrons with respect to the complexed cations is unknown.

We have measured the absorption spectra of "electride" films with both cryptand C222 and [18]crown-6 as complexing agents (cf. Fig. 9)[81]. Often the infrared band which we attribute to trapped electrons is accompanied by an M^- absorption. In some cases the relative intensities of the two bands shifts in favor of M^- as the solution is allowed to contact excess metal[78] (cf. Fig. 10). In addition to the "electride" band at 7400 cm^{-1} and the band of M^-, intermediate absorption peaks of unknown origin are often observed (cf. Fig. 9).

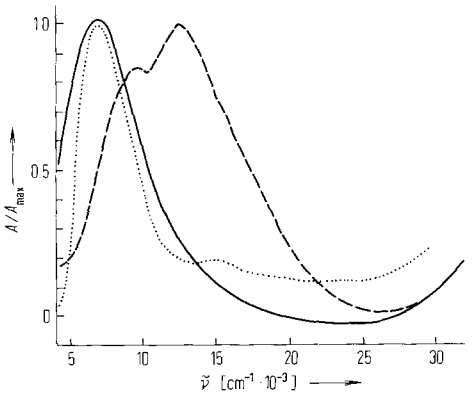

Fig. 9. Spectra of solvent-free thin "electride" films produced by rapid evaporation of methylamine from solutions of $K^+C222e^-_{solv}$ (solid line), $Cs^+18C\text{-}6e^-_{solv}$ (dotted line) and $K^+18C\text{-}6K^-$ (with e^-_{solv}?) (dashed line) [81].

5. Speculation about Properties and Future Potential

Since we have only limited information about the structure and properties of "alkalide" salts, and even less information about "electrides", it is difficult to predict in what ways these substances might be useful. Certainly, as examples of a new oxidation state of a whole family of elements, alkali metal anions are fundamentally interesting. The strongly reducing nature of these compounds may prove useful in syntheses, and the solid-state properties may provide useful materials in such areas as semiconductor behavior, photoelectron emission, photoconductivity, *etc.* In this section we will speculate about the nature of these compounds and indicate some areas of potential usefulness.

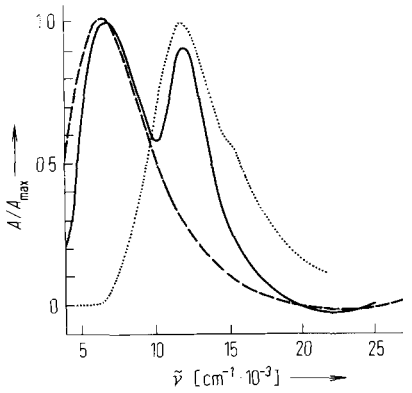

Fig. 10. Spectra of solvent-free thin films produced by evaporation of methylamine from solutions containing cryptand C222 and various relative concentrations of potassium [78]. Spectra for progressively higher concentrations of potassium are in the order, dashed line ("electride"), solid line (mixture), and dotted line K ("potasside").

5.1. Solution Properties

The use of crown-ether and cryptand complexing agents makes it possible to prepare concentrated solutions containing either M^- or e^-_{solv} in a variety of amine and ether solvents. For example, a solution of 0.1 M sodium in THF can be prepared by using the cryptand C222. Since this solution contains mostly Na^+C222 and Na^- and very little e^-_{solv} it might be useful for two-electron reductions. If a one-electron reductant in this aprotic solvent were desired, a solution of potassium with an equivalent quantity of the cryptand C222 would produce K^+C222 and e^-_{solv} with little interference from K .

5.2. Possible New Compounds of "Alkalides" and "Electrides"

The thermodynamic estimates described in Section 3 suggest that compounds such as $Ba^{++}C222(Na^-)_2$ should be thermodynamically stable. Similarly, we predict that solid compounds containing Li^- should be stable. The present challenge is to find appropriate synthetic routes to such substances. In solution, Li^- tends to dissociate into Li^+ and e^-_{solv}. Perhaps a direct vapor-phase reaction or reaction in an inert matrix would avoid some of the problems associated with the use of a polar solvent to dissolve the reacting species. One of the problems which we have encountered in working with lithium and the alkaline earths is the inability to purify these metals by distillation in glass or quartz. As a result, solutions tend to be unstable. Distillation of these metals directly into the apparatus from a metal container might eliminate some of these difficulties.

It should be possible to substitute other cations for cryptated cations provided they are non-reducible. Long chain tetraalkylammonium ions seem attractive at present since they are stable in solution in the presence of Na^-. We are attempting to find suitable conditions for metathesis reactions in solution such as

$$M^+CryM^- + R_4N^+X^- \rightarrow M^+CryX^-_{(s)}\downarrow + R_4N^+M^- \quad (19)$$

If tetraalkylammonium "alkalides" could be prepared, they might eliminate one of the major barriers to practical utilization of alkali metal anions—the complexity and cost of cryptands.

If the solids which we call "electrides" prove to be stoichiometric compounds with one trapped electron for each cation, then it might be possible to prepare a variety of electride salts such as $Ba^{++}C222(e^-)_2$. The increase in electron density in such compounds compared with M^+C222e^- might be enough to give them the properties of "expanded metals", similar to the metallic compound $Ba(NH_3)_6$[8]. The optical and ESR properties of uni-univalent "electrides" such as K^+C222e^- suggest that the electrons are largely localized, perhaps in the traps formed by the octahedral holes between closest-packed cations. As the electron density increases, enough electron-electron overlap may occur to give metallic behavior.

5.3. Possible Uses for the Solid Compounds

Whether the semiconducting properties of $Na^+C222Na^-$ and similar salts of the other alkali metal anions will be useful depends primarily on their stability. It now appears that the parent compound is stable at room temperature *in vacuo* in the dark. Even its reactivity with air is not as great as we first thought. For example, a compressed pellet of powdered $Na^+C222Na^-$ remained gold-colored and shiny in air until reaction with moisture in the air began on the surface. Further surface reaction, as observed under a microscope, occurred at water droplets with little or no general surface corrosion.

Light absorption by Na^- in the solid is very efficient and covers a broad spectral range extending throughout the visible and near infrared (cf. Fig. 8). If solids can be found in which this absorption is followed by auto-ionization as in solution[26, 28], and if the lifetime of the conduction electron so produced is long enough, sodium anions might be efficient for photoelectric energy conversion. Because the electron is only weakly bound to such anions as Cs^- and may be even more weakly bound in "electride" salts the photoelectric properties of these substances would be most interesting. At least in principle, such compounds have the potential to extend the wavelength of photoelectron emission farther into the red than is possible with currently available photoemissive surfaces.

Of course, such speculation about potential uses for "alkalides" and "electrides" is based upon very little fundamental information about their properties. Before more can be done to utilize these compounds, a great deal of study is needed to determine their properties. Measurements are not easy with such reactive materials even when they can be prepared in pure form. However, we hope that the demonstration that the −1 oxidation state of the alkali metals is stable will stimulate others to investigate such systems and find uses for them.

Spatial Structure Formation in Protein Gels

By M. G. Bezrukov[*]

The present article is concerned with the practical and theoretical aspects of gelation in protein systems. The processes involved are, *inter alia,* so complicated that several types of protein molecule assemblies and conformational changes during the association have to be considered. The gel network can be stabilized by five types of interaction: covalent crosslinking, polar interactions, hydrogen bonding, salt bridges and hydrophobic interactions. The microstructures of gels formed from fibrillated proteins (collagen) and from globular proteins (*e.g.* α- and β-casein) differ considerably. Of practical interest are methods of controlling the solubility of gels, including *e.g.* the use of cross-linking agents and addition of salts.

1. Introduction

The gelatinous state of biopolymers is the structural basis of all living objects. Whereas the structural functions in plants are, as a rule, performed by polysaccharides, in animal organisms this role is played by proteins. Protein gelation has not only been the subject of numerous investigations in biochemistry and molecular biology, it has also been studied from the point of view of protein processing technology. This latter, technological aspect has recently acquired special importance in connection with the development of large-scale industrial methods for the processing of proteins used in the manufacturing of foodstuffs and animal feeds.

The review on protein gels published by *Ferry*[1] in 1948 reflects the views then held on the gelatinous state. A complete picture of the gelatinous state is still lacking. Numerous new experimental data have, however, appeared and require generalizing. In this review we have concentrated our attention on the organization of the spatial arrangements of protein molecules in gelatinous systems, on the causes of their occurrence, as well as on certain practical aspects of controlling the protein functional properties.

2. The Classification of Gels

"The colloidal state of a system such as a gel is easier to observe than to define"—for more than sixty years this statement has led a nomad's life in various papers on the gelatinous state. We see it also *e.g.* in the well known review of *Lipatov* and *Proshlyakova*[2], published in 1961. Nevertheless, a number of sufficiently acceptable definitions of a gel had already been formulated before 1960. In the following we shall consider some of the currently acceptable definitions.

According to *Flory*[3] a system can be regarded as gelatinous if it is characterized by the following properties:

1) It is a colloidal system containing no less than two components;
2) it manifests certain mechanical properties of a solid;
3) both the dispersed component and the dispersion medium are continuously distributed in the volume of the system.

This the most comprehensive definition is of a purely formal nature and does not reflect the reasons for the appearance and the existence of the gelatinous state of a system.

In the works of *Papkov*[4-7] gels are defined as multicomponent systems characterized by two properties: almost complete absence of fluidity and high reversible deformation.

Rogovina and *Slonimsky*[8] define a gel as "a polymer-solvent system in which there exists a spatial network of fairly stable non-fluctuating bonds (*i.e.* those which are not destroyed by thermal motion)". This definition appears to be the most suitable for the aspects of the problem examined in the present paper. It enables an understanding of many features of gelatinous systems.

In accordance with *Papkov*'s classification it is customary to distinguish two types of systems, with participation of a polymer component.

Type 1: Gels formed on the swelling of cross-linked polymers or on the covalent cross-linkage of macromolecules in solution. These gels are thermally irreversible. The absence of fluidity in such systems is caused by the presence of a three-dimensional molecular skeleton of a polymer, stabilized by chemical bonding.

Type 2: Gels formed on the separation of a single-phase polymer solution into two phases caused by a change in thermodynamic conditions or the composition of a system. The absence of fluidity is caused by the formation of a three-dimensional skeleton made up of supermolecular formations whose properties are close to those of a solid; the reversible deformation is due to the elastic bending of the skeletal components.

It is characteristic for a system in the gelatinous state to have a network of polymer molecules. The structure of this three-dimensional network and the causes of its formation can, however, be highly diverse.

A major role in the build-up of the skeleton of polymer molecules in solution is played by the energy balance of the interaction of polymer chain sections with one another and with the solvent. A limited polymer solubility is considered necessary for the system to acquire the gelatinous state[2,7,8].

In the case of polymers with limited solubility some sections of the polymer molecule adhere to each other forming nodes of interaction, while other sections remain in solution. Such a behaviour is due to the diphility of a polymer molecule, *i.e.* to the presence of both lyophilic and lyophobic sections. The nodes of a three-dimensional network are formed as a result of the lyophobic sections coming into contact with one another, whereas the solvation of lyophilic sections ensures the continuity of the network. The nature of the contact interactions between lyophobic sections has been exam-

ined[2]; all the possible types of physical bonds (dispersive, polar, hydrogenous, *etc.*) can be involved.

When the three-dimensional network is formed as a result of covalent interactions, all the sections of the polymer molecule can be solvated sufficiently well by the solvent, *i.e.* it is unnecessary for the molecule to be diphilic. The possibility of the existence of gel networks made up of individual polymer molecules remains, however, purely theoretical and is not confirmed by actual examples. All the gels whose microstructures are known to date are characterized by a network made up of supermolecular structures.

The region of gel stability is limited by the temperature at which either the spatial skeleton forming a gel is destroyed and the system passes into the fluid state, or the system loses the solvent and changes to a xerogel. According to their meltability gels can be subdivided into thermally reversible and thermally irreversible gels.

Rogovina and *Slonimsky*[8], as well as *Papkov*[7] attribute the thermal irreversibility of gels mainly to the chemical (covalent) interactions of polymer molecules in the three-dimensional network. This interaction is the strongest of all those possible ($\Delta G > 80$ kcal/mol) in the gel network.

Thermally reversible gels are characterized by the physical interactions of macromolecules with one another. The energy contributions of hydrogen bonds, polar interactions, and hydrophobic interactions are considerably smaller than those of covalent interactions ($\Delta G < 10$ kcal/mol). These physical interactions can be destroyed by the thermal motion at the temperature at which the liquid phase exists.

It should be noted that gels formed by the interaction of polymer chains with polyvalent cations can also be thermally irreversible. Such interactions, in which segments of different polymer chains function as ligands at one complex nucleus, are energetically intermediate between the chemical and the physical interactions. In synthetic polymers they are quite rare and, as a rule, are not taken into consideration. In protein systems, however, the interaction with cations is a factor which in many respects determines the structure.

It is possible to classify gels by a number of other features, *e.g.* by the peculiarities of microstructure or by the phase state.

The most comprehensive classification of gels according to their microstructure is given by *Flory*[3]. He subdivides them into four types:

1. Highly ordered lamellar structures, including also gelatinous mesophases.
2. Polymer networks formed by physical aggregation, mostly disorganized but with local ordering in some portions.
3. Disordered structures formed by dispersed particles.
4. Absolutely disordered covalently cross-linked molecular networks.

The first type of gels can be exemplified by the systems containing phospholipids or soaps. Lamellar structures are unknown for proteins, but some sections of native collagen fibrillae can, with certain reservations, be regarded as mesophases.

It should be noted that any classification of proteins and their gels will be to a great extent arbitrary, and often will not reflect the significant features of their structure. The spatial network of the molecules of a certain protein differs from the network of the molecules of any other protein. The difference lies, primarily, in the individuality of the primary structure of the polypeptide chain.

The possibility of a certain type of interaction occurring lies in the amino acid composition and sequence (primary structure) of the polypeptide chain. The primary structure determines also all the higher levels of protein organization[9] and, in the final analysis, the capability of forming the spatial network of molecules—the basis of the gelatinous state.

3. Collagen and its Degradation Products

We shall not deal with the gels of fibrillar proteins in great detail here since the potential objects of industrial processing—vegetable and single cell proteins (biomasses)—are, according to current thinking, non-fibrillar. Nevertheless, it would seem to us most justifiable to examine the gels of collagen and its degradation products, called gelatin in conventional terminology. Until very recently gelatin was the only protein isolate produced on an industrial scale, and because of this it has been studied in greatest detail.

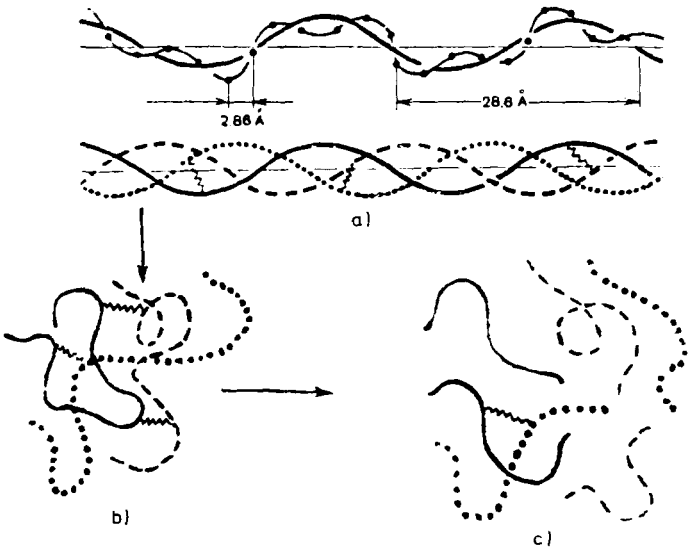

Fig. 1. a) Triple helix of the collagen molecule in the native state, b) its thermal denaturation, and c) hydrolytic cleavage.

The collagen molecule consists of three polypeptide chains: two α_1-chains and one α_2-chain. The three spiral α-chains intertwine with each other and at the same time wind round a common axis, thus forming a triple helix (Fig. 1). Whereas the amino acid sequence in the α_1-chain has already been fully established (Fig. 2), the α_2-chain has not yet been completely deciphered; it is known, however, that the structure of the α_2-chain is very similar to the primary structure of the α_1-chain[10]. Similarity of the primary structure of both these chains, *viz.* the fact that every third amino acid is glycine, is highly important. This highly ordered primary structure ensures the strength of the triple-helix structure of the collagen molecule, as well as the ordering of the arrangement of collagen molecules during fibrillae formation. In the course of fibrillogenesis under natural conditions, collagen molecules are arranged longitudinally and shifted relative to one another by a distance equal to one fourth of the length of the molecule (Fig. 3). This shift is caused by polar interactions between the amino acid side groups; the polar groups

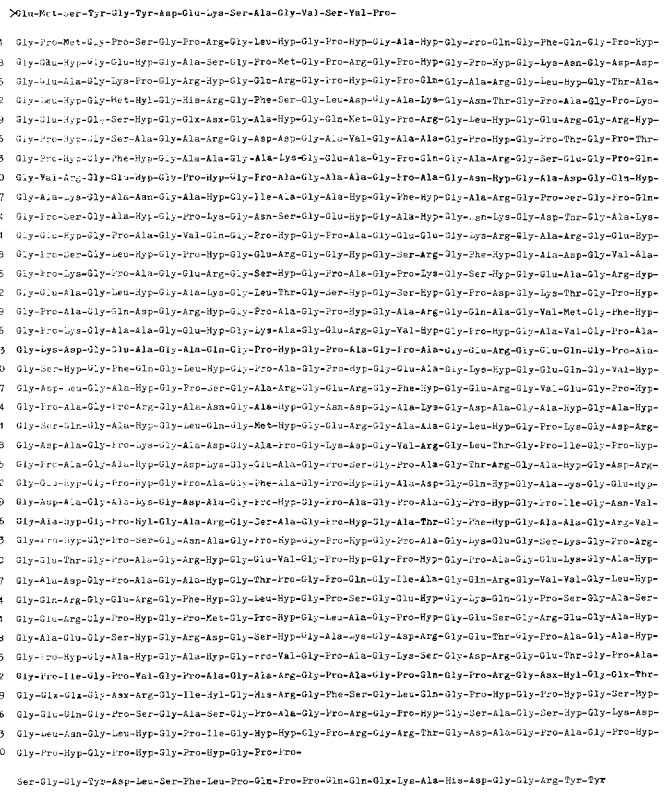

Fig. 2. Primary structure of the α_1-chain of collagen.

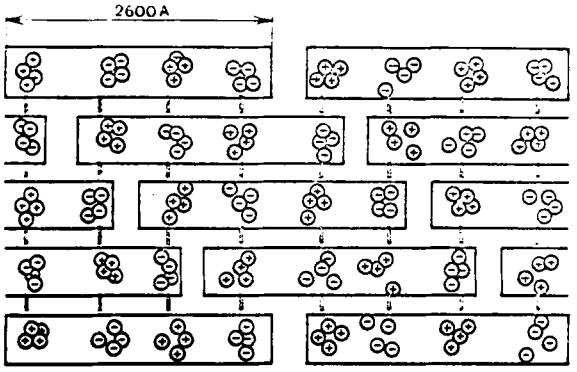
are not uniformly distributed along the length of the polypeptide chain, but concentrated in clusters. This spatial concentration of polar groups, together with the shift of a quarter of the length, ensures firm placement of molecules in the fibrilla.



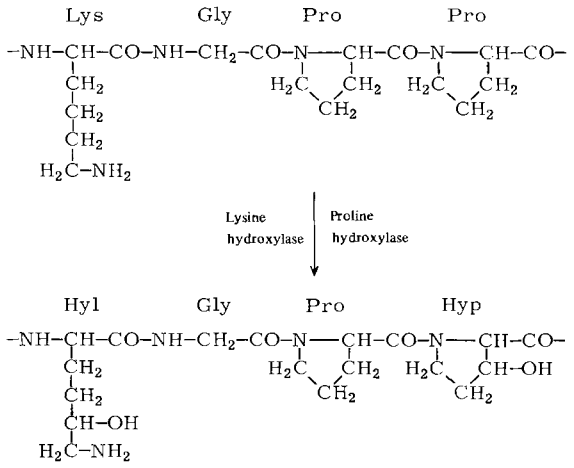


Fig. 3. Arrangement of collagen molecules in the fibrillae.

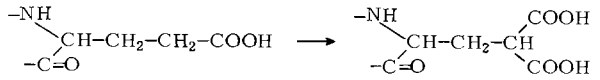

It is as yet impossible to give a comprehensive explanation of the way in which the collagen molecules acquire the limited solubility necessary for fibrillae to be formed and a continuous network to be constructed. It is only known that the collagen molecules are synthesized in the soluble form which at this stage does not contain any typical amino acids, such as, *e.g.* oxylysine, oxyproline, *etc.* The primary molecules (tropocollagen) are transferred by the intercellular liquid to the place where the connective tissue is to be formed and subjected there to enzymic oxidation, first of all by proline and lysine hydroxylases. This formation of hydroxyproline and hydroxylysine leads to the appearance of additional hydrogen bonds (besides the α peptide ones) and an increase in the energy of the interaction of polypeptide chains with one another.

Lysine oxidation does not stop here, and is followed by ε-amino group elimination with the formation of 5-oxonorleucine (see Table 1). The aldehyde group reacts with the free ε-amino groups of lysine with formation of covalent cross-links. More complex bridges (of the desmosine type) are formed if four or more amino acids participate in the cross-linking (Table 1 lists some examples).

In addition to lysine, also glutamic and aspartic acid take part in the formation of cross-links. They form γ-peptide bonds (with lysine) and ester bonds (with serine). The dityrosine cross-linkage should also be mentioned here. It is formed when peroxydases act upon the connective tissue.

Covalent cross-links are formed not only on interaction of the functional groups of the polypeptide chain, but also on bridging of these groups by polyfunctional low-molecular compounds, *e.g.* aldoses (with the formation of a glycoside and an ether bond), aldehydes, and ammonia (yielding amide bridges)[19]. Covalent cross-links also develop inside and between molecules. In this way the supermolecular structure of collagen ceases to be supermolecular and all the spatial protein network becomes a single macromolecule.

During the aging of collagen, which is accompanied by chemical changes in the amino acids of the polypeptide chain, glutamic acid is carboxylated to a γ,γ-dicarboxy derivative[20]. This chelate group of the polypeptide chain captures calcium ions, which results in calcium bridges being formed between the molecules and in the fibrillae losing their flexibility. This process is most characteristic of the collagen of cartilages, tendons and bone tissue.

Thus, if we put aside the participation of other biopolymers in the stabilization of the collagen structure, four types of interaction can be distinguished which determine the rigidity of the spatial arrangement (cf. Fig. 4) of this protein: hydrogen bonds, polar interactions, salt bridges, and covalent cross-linking. For these interactions to take place the initial soluble tropocollagen has to be subjected to three types of changes: 1) oxidation of a number of amino acid groups in

Table 1. Covalent cross-links of protein molecules.

No.	Group 1	Group 2	Type of Crosslinking	Ref.
1	Cys	Cys	Cystine	[11,12]

the polypeptide chain, 2) covalent cross-linkage by reaction of functional groups of the protein molecule, and 3) covalent cross-linkage by polyfunctional low-molecular reagents.

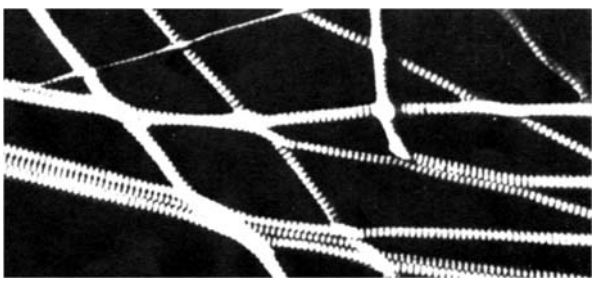

Fig. 4. Photomicrograph of human tendon collagen (× 14000).

Gelatin production processes and the properties of gelatin gels have been examined in sufficient detail by *Veis*[21], *Mikhailov*[19] and *Raikh*[22]. We shall only note here that neither choice of starting material nor of its treatment make it possible to obtain gelatin having a standard composition. This is due to the fact that collagen, even when produced from one and the same type of stock, has a varying degree of hydroxylation (lysine/hydroxylysine and proline/hydroxyproline ratio) and a varying number of cross-links. The procedure for manufacturing gelatin from collagen-containing materials does not make it possible to standardize the extent of chemical degradation of collagen fibers: both the covalent cross-links and the α-peptide bonds in the polypeptide chain are hydrolyzed (Fig. 1). As a result, a mixture of polypeptides having approximately the same amino acid sequence and molecular weights of 30000 to 40000 is obtained. Variations in the gelatin composition naturally affect the properties of gels.

The thermostability of gelatin gels of different origin, however, differ comparatively little and in this respect gelatin may be regarded as a sufficiently standardized substance. As was shown by *Bello et al.*[23,24], α-peptide hydrogen bonds constitute the governing type of interaction during the gelation of gelatin, all other types of interaction are insignificant. It is for this reason that gelatin gels may be considered as uniform with regard to thermostability; for the polypeptide

chains the triple-helix structure remains the most favorable at temperatures below 30 °C. The solubility of gelatin is, however, much higher than that of the initial collagen, and its gel network is thermally less stable. The network of gelatin gels can be fixed, either by coordination coupling (treating the gel with polyvalent cations[25]) or by covalent cross-linking with polyfunctional reagents[26]. In this way one can obtain non-melting gelatin gels.

Electron microscopic studies[27] are in accord with data on the optical rotatory dispersion in gelatin solutions and gels[28] and indicate that the gelatin polypeptide chains pass into solution in the form of a random coil when heated. On cooling, the polypeptide chains once again take on the helical form, with concomitant appearance of spherical aggregates of protein molecules. These spherical particles associate with each other forming unilinear chains with branches (Fig. 5a). This

Fig. 5. Photomicrograph of 2% gelatin gel: a) × 12500 and b) × 50000.

chiefly two-contact type of interaction is observed up to protein concentrations of 12%; above this concentration a random type of aggregation with lateral attachment of spherical particles takes place, resulting in the thickening of fibrillae and in a decrease in the ordering of the system. The structural unit in gelatin gels is thus formed, not by the rod-shaped triple-helix molecules, but by their spherical aggregates. When the unilinear fibrillae are being formed these spherical particles come into contact not only on their surfaces, rather the polypeptide chains of associated protein particles become intertwined. In the fibrillae observed in gelatin gels at a concentration of 1—12% the structural units lose their individuality (Fig. 5b). The only reminder of gelatin fibrillae having originated from the spherical particles is that they have constrictions which create an impression of transversal striation similar to that of the native collagen fibrillae. The periodicity in gelatin fibrillae is much less regular than in collagen, due to a much lower degree of ordering in the arrangement of molecules. In the first place, not all initial spherical particles contain the same amount of protein, as is manifested in their differing size (600—900 Å) and, as a result, in the varying thickness of fibrillae along their length. The ordering of the molecular arrangement in gelatin is disturbed by the differences in molecular weight and, naturally, one cannot expect the shift of a quarter of the length of the molecule observed in the native collagen (Fig. 3). In addition to this, a rapid association of gelatin polypeptide chains on cooling prevents their complete spiralization and decreases the system ordering[29].

The cross-linkage of gelatin molecules in hot solutions (60 °C) fixes the polypeptide chains in the random coil state, resulting in the formation of a non-melting gel. Future investigations on such gels could perhaps give us an indication of how such a gel network is built up of individual polypeptide chains.

Hydrophobic interactions are known to play a substantial role in the stabilization of protein structures, and to predominate in the formation of globules[30].

The hydrophobic interactions differ from the other lyophobic interactions in their energetics, determined by two factors: 1) dispersive forces between the contacting non-polar molecules and 2) changes in the structure of the solvent (water) when it interacts with non-polar molecules.

Contacts of non-polar molecules with water lower the system entropy by increasing the fraction of ordered elements in the water. The minimization of such contacts (transition of molecules to the non-polar environment or their association) is accompanied by an increase in entropy; the system shifts into an energetically more favorable state[31].

The hydrophobic and hydrophilic properties of the amino acids in the polypeptide chain have been studied in great detail by *Tanford*[32]. According to *Tanford* the side groups of serine, histidine, aspartic and glutamic acids are hydrophilic, while all the other amino acids are to a varying degree hydrophobic (from 0 cal/mol for glycine to 3000 cal/mol for tryptophan) and must avoid contact with water.

The polypeptide chain is arranged in space in such a way that the hydrophobic amino acids form the globule nucleus and the hydrophilic amino acids are located on its surface. *Bigelow*[33] showed that the spatial structure of a protein is associated with its averaged hydrophobicity, which characterizes the ratio between the hydrophobic and the hydrophilic groups in the polypeptide chain. When calculating the averaged hydrophobicity, only the quantitative ratios between the hydrophobicities of amino acid radicals and their volumes are used; the position of the amino acids in the polypeptide chain is not taken into account. Such an approach is incapable of reflecting fully all the features of the protein tertiary structure, but nevertheless serves as a first approximation. From *Bigelow*'s calculations it follows that a protein must have a certain averaged hydrophobicity for its globular tertiary structure to be stable. For an equal volume, the geometric figure with the smallest surface is the sphere; when a protein molecule is present in this form it requires only a minimum number of hydrophilic groups to screen the hydrophobic nucleus. This calculated "limiting value" of hydrophobicity is seen to agree with the actual shape of protein molecules in solution. With a larger excess of hydrophobic groups (averaged hydrophobicity higher than the limiting value) the number of hydrophilic groups is not sufficient to screen the nucleus, and the molecules associate; the protein particle in solution then consists of several subunits. With an excess of hydrophilic groups (averaged hydrophobicity lower than the limiting value) the shape of a protein particle in solution can be other than spherical; it will be the more elongated the greater the surface area which can be occupied by hydrophilic groups.

From the above mentioned facts it follows that the increasing hydrophilicity of a collagen molecule in the course of oxidation must facilitate the formation of linear structures and

of a spatial molecular network due to non-hydrophobic interactions. At the same time, the possibility of hydrophobic interactions occurring must decrease. A number of authors, however, point out that hydrophobic contacts contribute to the formation of the gelatin gel network. The bonding of hydrocarbons by gelation can be regarded as proof of the existence of hydrophobic regions within it. Randomly coiled gelatin molecules manifest maximum solubility in benzene[34]. Benzene solubilization decreases with increasing formation of the gel network[35,36], and gel rigidity decreases as a result of interactions with benzene. These findings are in accord with the view of *Mikhailov*[19] that an ordered alternation of hydrophobic and hydrophilic groups in the gelatin polypeptide chain facilitates the occurrence of hydrophobic contacts between molecules in the course of the gel network formation. The role of hydrophobic interactions in the formation of the gelatin structure is, however, much smaller than in the formation of the spatial structures of globular proteins.

4. Spatial Structures of Globular Proteins

Globular proteins, like fibrillated ones, are capable of forming gels in aqueous medium, though only under special conditions and at higher concentrations. As distinct from gelatin, whose gelling is accompanied by the process of protein renaturation, the gelling of non-fibrillated proteins is accompanied in most cases by denaturation. As a rule, denaturation precedes the aggregation of protein particles into linear structures and the formation of a three-dimensional gel network. Specific features of the aggregation of spherical protein particles, particularly the effect of the type of aggregation and the extent of the unfolding of polypeptide chains on the structure of the gel network (cf. Table 2) have been studied by *Tombs*[37].

Proceeding from purely geometric considerations *Tombs* calculated that the protein concentration necessary for formation of a three-dimensional network with fixed pore size is five times greater for a randomly coiled protein molecule than for an unfolded polypeptide chain; for the formation of a compact sphere it is 40 times greater. *Tombs* then considered two extreme types of protein particle aggregation in gelling, the statistical and the ordered (into unilinear chains) types, and calculated that for a three-dimensional gel network to be formed, all other things being equal, the required concentration is 10—12 times greater when the aggregation is random than when it is ordered.

The information available on the microstructure of protein gels is most inadequate. As can be seen from Table 2, a certain agreement can be traced between the sequence of experimental data and the calculations, even though the quantitative ratio of protein concentrations in real systems does not accord with *Tombs'* calculations. This is primarily due to a considerable arbitrariness in the assigning of a gel network to a certain type, since such correlations are carried out "by inspection". Besides, the data on the extent of protein polypeptide chain unfolding are semiquantitative, whereas one can only make a qualitative appraisal of the degree of system ordering. It would seem expedient in future to take into account the number of contacts of network sites with each other (*i.e.* the coordination number). The ordered type of aggregation would be characterized by a coordination number of slightly more than 2. Raising the coordination number corresponds to a decrease in system ordering.

A more definite formulation can be arrived at for gels whose network element is the compact spherical particle. The gels of some lactoprotein fractions can serve as example for such systems. Casein, the chief protein component of milk, is a phosphoprotein and consists of at least 25 fractions[38]. The major part is composed of the α-fraction (up to 60%) and the β-fraction (up to 35%). The two fractions differ only slightly in their molecular weight (23600 and 24000, respectively) and amino acid composition. The main differences between these fractions are their amino acid sequence and degree of phosphorylation[39,40]. A spherical aggregate of

Table 2. Relationship between the structure of the gel network and protein concentration (BSA = bovine serum albumin).

molecules (micelle) has been shown to be a structural unit of casein and its fractions in solutions, gels and films.

Optical rotatory dispersion and electron microscopy data[41] show that the aggregation of α- and β-casein spherical particles in acid medium occurs without any conformational changes, which in itself is a fairly rare phenomenon. There exists only one other example of such a kind of aggregation without any change in the native structure of protein: β_A-lactoglobulin gels[42]. However, the structure of such gels is not known. At concentrations of >4% casein forms gels in acid media and aggregates into a network in a very ordered way (Fig. 6a). When the concentration increases to 8% the morphology of the gels does not change: unilinear, branched chains of micelles are observed, and the concentration of network nodes increases with increasing protein concentration. During aggregation the spherical particles do not undergo any conformational changes, they preserve their individuality and have only surface contacts (Fig. 6b). Such an ordered aggregation is only possible with the sites of interaction being localized on the surface of spherical particles in a few (probably two polar) zones.

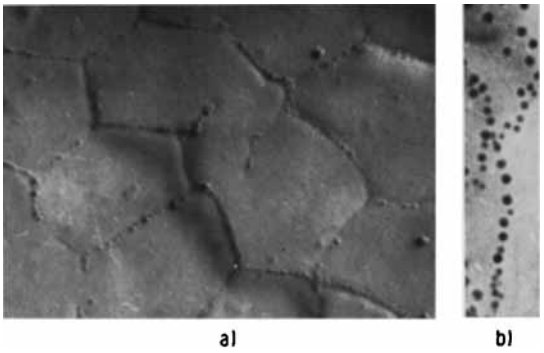

Fig. 6. Photomicrograph of 4% β-casein gel in acid medium: a) × 12500 (freezing-staining) and b) × 50000 (contrasting with phosphotungstic acid).

In contrast to β-casein, α-casein shows no clearly defined localization of the interaction sites, or they occur much more frequently. The aggregation of α-casein globules is thus of a statistical nature. The minimum concentration of α-casein for gelling in acid medium is equal to 18% (Table 2), and

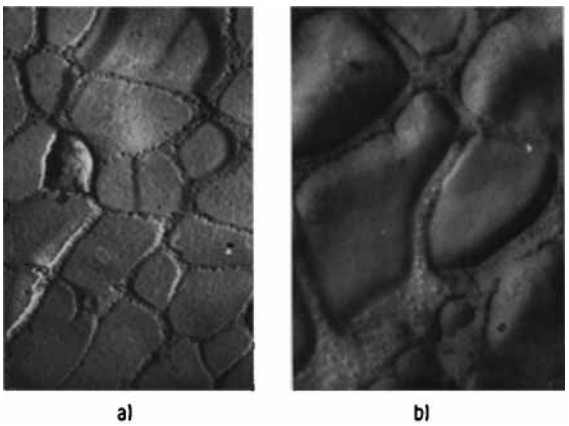

Fig. 7. Photomicrograph of α-casein gel: a) 18% in acid medium (× 12500) and b) 15% in alkaline medium (× 25000).

even at this concentration the gel network is made up of distended globular aggregates (Fig. 7a). With increasing protein concentration the thickness of the fibrillae increases owing to the lateral attachment of globules, while the concentration of network nodes decreases.

In alkaline media the aggregation of α-casein globules is also of a statistical nature (Fig. 7b), but the conformation of the protein molecules changes considerably and approaches that of the random coil. Spherical α-casein particles remain the structural units of the network, but their boundaries are no longer clearly defined. Particle deformation is observed, and mass exchange is possible, as well as the intertwining of polypeptide chains when the network is being formed. With the unfolding of micelles the concentration necessary for gelation decreases and amounts to 15%. The change in concentration is much smaller than one would expect (according to *Tombs*), probably because α-casein particles under gelation conditions are still far removed from the state of a random coil.

Bovine serum albumin (BSA) aggregates on heating owing to the formation of disulfide cross-links[43,44]. On varying the conditions, absolutely different types of aggregation and, consequently, different systems can be obtained— from gels with controlled mechanical properties to amorphous coagulates. The BSA molecule contains a considerable number of disulfide and mercapto groups. On heating to 69 °C the conformation changes only slightly. Only some of the SH groups become accessible to intermolecular cross-linking, and, as assumed by *Tombs*[44], BSA aggregates in a more or less orderly manner, forming a gel network. Heating up to 100 °C causes a more complete unfolding of the polypeptide chain, the number of interaction centers increases and aggregation is of a random nature. Since with such an aggregation the protein concentration required for the gel network to be formed is higher than BSA solubility (7%), flocculation and phase segregation occur.

There are no reliable enough data available on the existence of protein gels having a random coil conformation. We can cite examples of protein gelation where conformational changes from a sphere to a coil or from a coil to an unfolded polypeptide chain occur. Thus, it is well known that gelatin gelation is accompanied by a coil/helix transition[28]. In the collagen gel there are practically no disordered sections of polypeptide chains, whereas in the gelatin gel it is highly probable that some sections are in such a state. Therefore, in Table 2 we have placed gelatin below the level corresponding to the random coil. Collagen is placed above the "unfolded chain" because, as has already been mentioned, the network of its gels is not made up of individual polypeptide chains, but of elongated triple-helix molecular aggregates.

We are thus convinced that real gelatinous systems are much richer in microstructure than would follow from presently existing classifications. These classifications are, however, very useful for making predictions, which albeit are still very far from being quantitative.

Of great interest is the question concerning the reasons for the formation of a continuous gel network in the course of spherical particle aggregation. In 1970 *Tombs*[44] stated that "statistical aggregation must lead to more or less spherical particles, and so gelation is only possible with oriented aggregation". He thought it possible to explain the appearance

of fibrillae by the autocatalytic effect during aggregation of globules, *i.e.* the growth rate of fibrillae is proportional to their length and the growth centers are located at the ends of asymmetric aggregates. *Tombs* refers to the calculations of *Joly et al.*[45], who showed that such an effect can constitute a general phenomenon in the aggregation of globular proteins and can be widely used to explain fibrillae formation.

In 1974, however, *Tombs*[37] pointed out that the most probable shape of the aggregate formed as a result of random interaction between spherical particles must be a non-spherical associate (ellipsoid), serving as the nucleus for linear structures and for the three-dimensional network.

In a real system, complete statistical aggregation seems to be unlikely, since for this to occur the aggregating particles must have absolutely the same properties at any point on their surface. Protein globules, as a rule, have a surface of mosaic structure, *i.e.* there are sites differing in charge density and sign, degree of hydrophobicity, presence of mercapto groups, etc. This leads to a definite orientation, resulting from the interaction of globules. Any increase in orientation of aggregation, however, facilitates the creation of fibrilla-like structures and, hence, of a three-dimensional network.

The types of interactions taking place on aggregation of globular proteins in the gel network are the same as those we have noted for collagen (covalent cross-linkage, polar interactions, hydrogen bonds, salt bridges, hydrophobic contacts). The role of hydrophobic contacts, however, is much greater than in the case of collagen. The contribution of these types of interaction to the formation of a gel network is examined in the following section.

5. Formation of Globular Protein Gels. Interactions in the Gel Network

When examining the interaction of protein molecules in the gel network we should not overlook any one of the five types of interaction enumerated above. The build-up of the three-dimensional network involves the cooperative effect of all these types of interaction. One can, however, distinguish systems where certain forces play a prevailing role.

Gelation of globular proteins by physical aggregation takes place, as a rule, under specific conditions ensuring the denaturation of globules and a limited protein solubility in the system. Thermally reversible gels are, therefore, obtained only at specific values of pH, ionic strength, dielectric constant of the medium, *etc.* Thermally irreversible gels, on the other hand, can be obtained under a much broader range of conditions.

A glycinine solution[37], for instance, gelates at room temperature after addition of urea and alcohol (glycinine is a soya bean protein). This gel, formed as a result of physical interactions, melts reversibly at a temperature of about 60 °C. If the melt is heated to 80 °C a thermally irreversible gel is formed as a result of covalent cross-linking. This gel can be obtained even without adding any urea or alcohol.

Covalent interactions are primarily significant for the proteins which contain a considerable amount of cystine and cysteine and thus form disulfide bonds. Cross-links are, however, possible in other proteins (Table 1)[46,47].

5.1. Covalently Cross-linked Gels

A characteristic property of soya bean proteins is their capability of selfstructurizing and forming gel-like systems on denaturation. This property is widely exploited in the manufacturing of artificial products based on soya protein solutions or dispersions. According to *Aoki* and *Sakurai*[48], and *Wolf*[49], this phenomenon is mainly associated with the formation of intermolecular disulfide bonds, although it cannot be ruled out that other, non-covalent types of interaction also participate in the gelling process. As proof of the validity of this concept the authors refer to the thermal irreversibility of the gels and the influence of various additives. Oxidants accelerate gelation, while reductants (*e.g.* cysteine, sulfites) hinder structurizing and decrease the mechanical strength of gels. According to *Saio et al.*[50] soya bean fractions containing large amounts of sulfur-containing amino acids form gels with a higher strength.

Soya protein denaturation, accompanied by gelling due to covalent disulfide cross-linking, is usually achieved by heating dispersions or solutions[51,52]. The same result is obtained on freezing soya protein solutions[53]. In the latter case denaturation is due to the growth of ice crystals causing the deformation of protein molecules and the appearance of protein concentrated regions (unfrozen solution) and protein diluted regions (ice crystals).

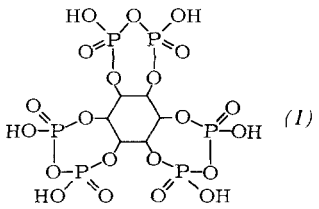
Covalent disulfide cross-linkage, resulting from protein denaturation, plays a major role in the gelation of most proteins which contain mercapto groups.

In the previously mentioned BSA association, disulfide cross-links play the leading role. Data are available on the intermolecular cross-linking capacity by means of the disulfide bonds of $\varkappa$-casein[54]. *Jones et al.*[55], assume an important role to be played by disulfide bonds in the rheological properties of the gels of wheat proteins.

Control of the number of disulfide bonds is widely used in alimentary gels. Addition of disulfide-group reducing agents (cysteine, glutathione, sulfites and their mixtures) to durum wheat-flour decreases the viscosity of dough as a consequence of the decrease in the number of disulfide cross-links. This enables a reduction in consumption of energy necessary for the kneading, extruding and drying of macaroni food products[56,57], and also a control on the quality of bakery products[58,59].

Adding oxidants (KIO_3) to water before cooking rice decreases the protein extraction from grains in the course of boiling and the consistency of the rice remains more compact. *Shintaro* and *Katsuharu*[60] attribute this phenomenon to the transformation of mercapto groups into intermolecular disulfide groups. An unequivocal interpretation is, however, difficult because of the possible oxidation of rice polysaccharides to dialdehydes and their subsequent interaction with the protein.

During the heat treatment of proteins, in addition to the formation of disulfide intermolecular bonds, all other types of covalently bonded cross-linkages can occur (cf. Table 1). For proteins containing large amounts of lysine it is especially characteristic for the formation of cross-links of the desmosine and lysinoalanine types to occur[61].



The above mentioned processes can be referred to as the autovulcanization or selfstructurizing of protein systems.

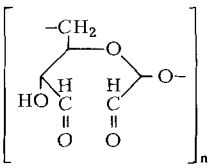
Several authors[62,63] believe that the formation of disulfide bonds does not significantly decrease the protein nutritive value; the other types of cross-linkage mentioned above, however, result not only in substantial changes of rheological properties, but also in a noticeable deterioration of the nutritive properties of foodstuffs.

Many proteins are capable of selfstructurizing, but not always under the conditions convenient from the technological point of view. Therefore, cross-linking agents are added to structurize proteins and control the thermomechanical properties of protein gels.

Sulfur has been used for the structurizing of vegetable proteins[64]; for carrying out the process it is necessary to add 0.1—3% of sulfur with respect to protein. The paste-like system containing 25—30% of protein is treated with the finely dispersed sulfur and then heated under pressure up to a temperature of 170 °C during two minutes. After release of pressure, on cooling a texturized product is obtained which is suitable for use as imitation meat. The nature of the processes taking place is still unclear; it is possible, however, to draw an analogy with the vulcanization of synthetic polymers by sulfur.

Saio et al.[50] have shown that phytic acid *(1)*, and its salts, which are always present in legumes, take part in the structurizing of soya proteins. It has been suggested that phytic acid should be used for the gelation of milk[65]. Skimmed milk containing 3—4% of proteins is treated with 8—15 mmol of an alkaline metal salt of phytic acid at pH 6.1—7.5 and then heated to 85 °C.

(1)



The flour of soft wheats contains proteins having a smaller number of sulfur-containing amino acids than in the flour of durum wheats. When this flour is used in manufacturing macaroni food products, cross-linking agents are necessary to impart the desired rheological properties to the finished product. For this purpose, it has been proposed to add oxidized polysaccharides, in particular dialdehyde starch[66], to the kneaded dough.

Dialdehyde polysaccharides are polyfunctional cross-linking agents capable of forming cross-links with cysteine, lysine and arginine groups of the polypeptide chain. Dialdehyde saccharides are used to fix the fibrous structure of protein solutions in the course of spinning[67].

It has also been suggested that dialdehyde starch be used for the production of various protein gels with controlled mechanical properties[68]. The gels are formed when 0.5—5% of dialdehyde starch is added to protein solutions or dispersions over a broad range of pH and concentrations.

For the same purpose, attempts are known to have been made to use the simplest aldehydes and dialdehydes. *Dürr* and *Neukom*[69] have studied the effect of nine different aldehydes (formaldehyde, propanal, hexanal, glyoxal, glutaraldehyde, α-hydroxyadipaldehyde, *etc.*) on the properties of macaroni food products. All the aldehydes studied imparted a higher rigidity to macaroni and prevented protein extraction during boiling. Dialdehydes gave the finished products a reddish brown color. Aldoses are also used as a cross-linking agent for the production of protein gels[70].

The cross-linking of proteins with the aid of lower aldehydes is used in the production of edible films for the packing of sausagemeat, and of mixtures enriched with fish protein[71]. These films, through which water and hot oil can

pass, are produced by extruding the protein solution through a circular extruder into a coagulation bath with a 0.01—0.1% solution of aldehyde (formaldehyde, acetaldehyde, glutaraldehyde, *etc.*) at a pH of about 6.5. The film stays in this solution for about ten minutes. It is then washed with a 5% sodium chloride solution at pH 8—11 to fix the cross-links and remove the unreacted aldehyde, and finally dried.

Aldehydes are also known to be used for obtaining and stabilizing technical protein gels and films in tanning and in the treatment of furs[72-74]. Many of the cross-linking agents employed are potentially toxic, and while for technical purposes their use is quite justified, their harmlessness in foodstuffs is doubtful. Proteins treated with formaldehyde[75] find application in animal feeding. There are, however, no comprehensive data on the toxicity and nutritive value of protein products containing aldehydes when used as food for human consumption. For a maximum preservation of the nutritive value the protein molecule should undergo the smallest chemical changes during the course of treatment. From this point of view the gels formed as a result of the physical association of proteins are more promising as foodstuffs, although they necessitate media having specific physico-chemical properties and they are more difficult to handle technologically.

5.2. Gelation with Salt Bridges

Until recently only alkaline gels of casein were known; concentrated alkaline casein solutions have been intensively studied in connection with the investigation of glue compositions (based on such solutions). *Fidney*[76] was the first to show that one can obtain casein gels at pH > 11.5. At lower pH values the systems formed are highly viscous but not rigid. Adding the ions of divalent metals results in a reversible gelation of these viscous systems[77]. Casein gels obtained in the presence of $Ca(OH)_2$ have been shown to be thermal reversible in the pH range 11.5—12.5[78]. Of interest from the point of view of being used in foodstuffs are casein gels formed in a neutral medium. *Anson* and *Pader*[79] have proposed a method for obtaining thermally irreversible calcium caseinate gels at pH 6.0. The method involves precipitation of casein from solution with any soluble calcium salt at pH 6.5, followed by heating a 25% aqueous suspension of the freshly precipitated calcium caseinate in an autoclave at 120—125 °C.

Of great interest is the question concerning the formation of a three-dimensional lattice made up of casein molecules in concentrated gels. According to *Rose*[80] the main role in the presence of calcium ions must be played by salt bridges: after removal of calcium from the milk, protein aggregation sharply decreases, and milk curdling is delayed. *Payens*[81] also believes that calcium ions, which react with the carboxy and phosphoric groups of the casein, are located on the surface of the casein micelle and cause the interaction of micelles with each other.

Kalab et al.[82,83] have described a method of producing gels from dried milk. Dried milk is suspended in such an amount of distilled water as to make the protein concentration no less than 17%. The suspension is placed in a sausage casing and kept in boiling water for about 10 minutes. In slightly acid or neutral media the calcium ions are firmly bonded with the protein and do not diffuse into the boiling water. Gel formation is mainly caused by salt bridges, but interaction of the lactose with the protein occurs, especially in the outer layer which is in contact with the boiling water. Hence, covalent cross-links characteristic for the reaction of aldoses with proteins also take part in the formation of the gel network. These two types of interaction cause the spontaneous gelling of condensed milk when it is kept at elevated temperatures. *Kirshmeyer*[84] has shown that a similar process can be effected by heating whole milk concentrated to a protein content of more than 15%.

Addition of calcium and magnesium ions allows smooth control of the solubility and gelation, not only of lactoproteins but also of vegetable proteins[85]. In contrast to the ions of group 2 metals, addition of divalent iron ions sharply reduces protein solubility and causes flocculation[86]. This effect can be due to the directivity of calcium and magnesium interactions, mainly with the protein bound carboxy groups. Iron coordinates with a much larger number of ligands: carboxy, mercapto, disulfide, α-peptide groups, *etc.* In the presence of iron, protein particles will, therefore, aggregate in a less oriented way; the aggregation is of a random nature, and the protein precipitates.

5.3. Gelation Resulting from Physical Interactions

Izmailova et al.[87,88] have studied the process of casein gelation in alkaline medium. They have shown that gels are not formed at a protein concentration of less than 15% and pH below 10.5. A spatial structure of maximum rigidity is observed in the pH range 12.9—13.3. At pH 13.3 the structural rigidity decreases with time, apparently because of protein hydrolysis. The authors believe that intermolecular hydrogen and hydrophobic bonds participate in the gelation process, and the role of disulfide cross-links is insignificant. In many cases of globular protein association hydrophobic contacts play a significant role. According to *Payens*[81], the hydrophobic portions of polypeptide chains are located both inside and on the surface of the casein micelle. The intramicellar hydrophobic interactions stabilize the spherical form of the micelle and make it extremely stable to denaturating effects. The hydrophobic sites on the surface cause micellar association even in the absence of calcium ions.

The important role of hydrophobic contacts in the intermolecular interactions of lactoproteins is confirmed by the results of investigations performed by *Thompson et al.*[89]. The main fractions of casein contain hydrophobic amino acids on the C-terminal ends of the peptide chain. When carboxypeptidases act upon α-casein, tryptophan and leucine split off; when they act upon β-casein, valine and leucine are split off. The ability of these proteins to associate, sharply decreases after the action of the enzyme.

The physical parameters of the hydrophobic nucleus of globular proteins are known to resemble those of ethanol[90]. The addition of hydrophilic organic solvents to the protein solution disturbs the hydrophobic interactions, since the structure of the water changes and facilitates unfolding of the compactly arranged protein molecule. Thus, yeast protein gelates when its solutions are heated in the presence of organic solvents[91].

Unfolding of protein molecules also occurs on addition of urea to the solution. It disrupts the hydrogen and the hydrophobic bonds. This also takes place in a highly acid or highly alkaline medium owing to the mutual repulsion of the similarly charged ionogenic groups in the protein molecule.

Denatured ovalbumin gels in mixtures of water and *n*-propyl alcohol have been studied by *Jirgensons*[92]. The alcohol in these systems acts both as a denaturizing agent and as solvent preventing protein precipitation. Gels are only formed if the alcohol concentration is in the range 40—60%. Outside this range protein precipitation is observed. Gelation occurs at an ovalbumin concentration of over 2%; at lower concentrations, only the viscosity of the solutions increases. Gels of 2% ovalbumin in 50% *n*-propyl alcohol melt reversibly at a temperature of about 67 °C.

Myers and *France*[93] have investigated ovalbumin gels in acetic acid solutions. A 5% protein solution was diluted with aqueous acetic acid solution to give a system containing 1% of protein and 3% of acid. Addition of NaCl in concentrations of up to 0.6 M at 25 °C accelerates gelation and increases gel rigidity. Higher concentrations of NaCl cause protein deposition. *Donnely*[94] obtained ovalbumin gels on adding an alkali to the protein solution. These gels liquefy more readily with increasing pH. According to *McKenzel et al.*[95] the addition of urea decreases the quantity of alkali necessary for gelation. *Jaenike*[96] was able to obtain ovalbumin gels by addition of urea in the pH range 4.7—10.8. It is also possible to cause ovalbumin denaturation and obtain a gel in neutral solutions under the effect of high pressures[97].

Bulankin et al.[98] conclude that ovalbumin gels are formed without the participation of disulfide bonds and that gel formation is a purely physical process. The results obtained by *Izmailova*[99,100], who studied the mechanism of ovalbumin gelation at pH <3 and >10, are in accord with this conclusion: the minimum concentration for gelation of the ovalbumin is equal to 2% in acid medium and 3.5% in alkali medium. A study of gels with the addition of substances which selectively disrupt different types of interactions showed the structural strength in ovalbumin gels to be mainly determined by hydrophobic bonds. This is also indicated by the increase in gel rigidity on warming to 55 °C.

The occurrence of hydrophobic interactions is facilitated by an increase in the ionic strength of a system: many proteins gelate in the presence of alkali metal salts. Gelation of lactoglobulin mixtures was observed on addition of potassium phosphate in concentrations of up to 0.1 M to skimmed

milk at pH 6.8[101]. It is of interest to note that apart from phosphate no other anions, glycerophosphate included, cause gelation. β-Lactoglobulin gelates[40] on acidification to pH 4.6 of a solution containing 4—5% of protein and 50% of ammonium sulfate (see Section 4). Removal of ammonium sulfate from the system by dialysis causes gel liquefaction, with the protein that has not undergone any chemical or conformational changes remaining in solution.

Addition of sodium chloride makes it possible to control the gelation time and the rigidity of ovalbumin[93] and arachin[102, 103] gels (arachin is a groundnut protein). An arachin gel is obtained by heating a 15% protein solution at pH 5—6 to 110 °C or by decreasing the pH from 12 to 4 at room temperature.

The equilibrium between hydrophobic and hydrophilic interactions and the solubility of globular proteins are also controlled by chemical modification of the protein macromolecules. Directed partial hydrolysis of the protein macromolecule can result in its unfolding and can be accompanied by aggregation. Thus the treatment of casein solutions with abomasum enzyme (rennin) is accompanied by cleavage of the hydrophilic portion of the casein κ-fraction. The κ-fraction contains a hydrophobic polypeptide and hydrophilic polysaccharide portions and, as a result, manifests surface-active properties. It screens the hydrophobic nucleus of the casein micelle and holds it in solution. The loss of the hydrophilic part of the molecule results in aggregation of the disorganized components of the casein micelle, which in turn results in protein flocculation and phase separation in the system[104, 105]. It should be remembered that the cleavage of hydrophobic amino acids from α- and β-casein fractions, conversely, impedes aggregation and raises the protein solubility[89].

Preliminary partial hydrolysis of soya protein improves its gelating capacity and makes it possible to control the properties of the gel. For this purpose, the protein is treated with acid, alkali[106] or proteolytic enzymes of vegetable origin[107, 108].

Partial hydrolysis of fish protein, on the other hand, decreases its gelating capacity, while acylation of the amino groups improves both the gelating and the emulsifying capacities of this protein[109]. Acylation affects the properties of different proteins in different ways: it impairs the solubility and the functional properties of yeast protein[110] and improves the solubility of soya protein[111] and casein[112, 113]. The acylation of casein with long-chain acyl halides leads to gelation in the vicinity of the isoelectric point of this protein[114].

Phosphorylation and sulfation of proteins facilitates an increase in the hydrophilicity of protein molecules, disturbance of the globular structure, and unfolding of the polypeptide chains. Vegetable proteins modified in this way acquire gelating capacity, phosphorylated proteins forming gels of a smaller rigidity as compared with those formed by sulfated proteins[115, 116].

Changes in the physico-mechanical properties of the medium and chemical modification of the protein molecule have a different effect on the properties of different kinds of protein. Directed control of the functional properties of proteins requires an individual approach for each and every protein or mixture of proteins.

6. Concluding Remarks

The material collected in this review is not claimed to give an exhaustive coverage of all the aspects and methods of producing protein gels. It does, however, enable one to systematize the current views on gelation in protein systems and to draw a number of conclusions which are of practical use.

The gelatinous state of a system is an intermediate quasi-stable state occurring either during protein dissolution or, on the contrary, during the transition from the dissolved state to the precipitate.

For attainment of this intermediate state there are four fundamental principles:

1. Oxidative thermal structurization of proteins owing to the covalent interaction of their functional groups.

2. Cross-linking of proteins by polyfunctional agents (including metal ions) in solutions.

3. Selection of the physico-chemical conditions of limited protein solubility in a system.

4. Chemical modification of the protein molecule, leading to limited protein solubility.

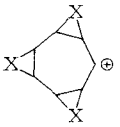
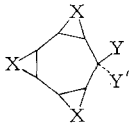
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.



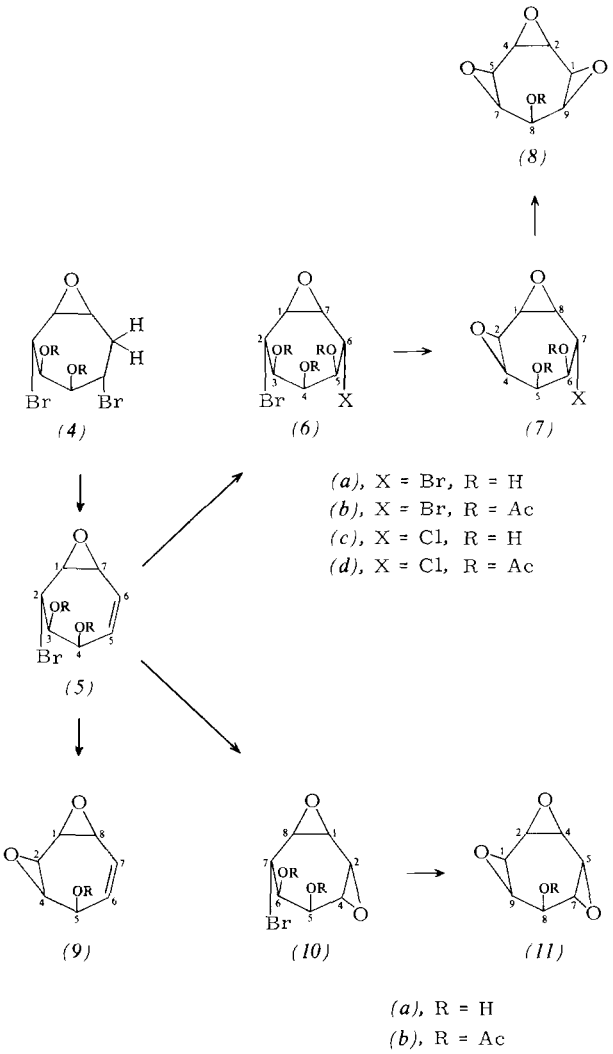
endo-Hydroxytrioxatris-σ-homotropilidenes[**]

By *Horst Prinzbach, Christoph Rücker,* and *Hans Fritz*[*]



Interesting aspects of the chemistry of trisheterotris-σ-homobenzenes *(1)* include the thermal $[_\sigma 2_s + _\sigma 2_s + _\sigma 2_s]$ cycloreversion to trisheteronins[1a] and the regio- and stereoselective ring cleavage to give biologically important aminohexitols[1b]. Preparation of similar target molecules—such as potentially "trishomobenzenoid" carbenium ions of type *(2)* (X = O, NR), aminoheptitols—requires specifically *endo*-substituted trisheterotris-σ-homotropilidenes *(3)* (X = O, NR; Y = OR, Y′ = H). We have developed preparatively useful syntheses for two (*cis*; α,α,β) of the three isomeric trioxa compounds 1α,2α,4α,5α,7α,9α- and 1α,2α,4α,5β,7β,9α-3,6,10-trioxatetracyclo[7.1.0.0^{2,4}.0^{5,7}]decan-8β-ol [*(8a)* and *(11a)*][2] which comprise the reaction sequences *(4b)*→*(5b)*→*(6c)*→*(7c)*→*(8a)* and *(4b)*→*(5a)*→*(10a)*→*(11a)*[3].

(1)



(2)

(3)

The starting material *(4b)*[4] is readily accessible from tropilidene; under controlled conditions in the presence of the weakly nucleophilic base diazabicyclononene (DBN) (THF, 20 °C, 15 h), HBr elimination proceeds without competition, in contrast to the reaction involving, *e.g.*, sodium methoxide/methanol. According to ^{1}H-NMR analysis [($CDCl_3$); $J_{1,2}=6.5$, $J_{2,3}=8.5$, $J_{3,4}=4.5$, $J_{4,5}=5$, $J_{5,6}=10.5$, $J_{6,7}<3$, $J_{1,7}=4.5$ Hz] the diacetate *(5b)* [m.p. 83 °C (CCl_4), isolated quantitatively], as well as the diol *(5a)* [m.p. 113 °C (acetone)], should prefer a twisted conformation[5] (Br, 3-OR quasiequatorial, 4-OR quasiaxial) in which the center of the C C double bond is effectively shielded on the β-side by 2β-H.

The advantage of using *(5b)* as a precursor of *(8a)* is that the site of OH addition on reaction with HOX is immaterial (C-5, C-6) as long as it occurs from the side of the epoxide ring (*i.e.* from the β side); double ring closure always leads exclusively to *(8)*. Since vicinal *trans*-diaxial H/X systems are absent, olefin formation cannot compete. Only unsatisfactory regio- and stereoselectivities are obtained on addition of HOBr [NBS, acetone/water (1:1), 50 °C, 24 h]: never more than 10% of *(6a)* (isolated as *(6b)*; m.p. 173 °C (CCl_4); plane of symmetry evidenced by ^{1}H- and ^{13}C-NMR spectra; $J_{1,2}$ ($J_{6,7}$) ≈ 7, $J_{2,3}$ ($J_{5,6}$) = 11, $J_{3,4}$ ($J_{4,5}$) = 2.5 Hz) together with two epoxide cleavage products (H_2O, HBr). In contrast, addition of HOCl is almost specific [*tert*-butyl hypochlorite, water/acetone (1:1), 50 °C, 8 h]: subsequent hydrolysis affords 90—95% *(6c)* [m.p. 170 °C (subl.); *(6d)*: m.p. 163 °C (acetone/CCl_4); $J_{1,2}=J_{6,7}=7.5$, $J_{2,3}=J_{5,6}=11$, $J_{3,4}=J_{4,5}=2.5$, $J_{1,7}=4.5$ Hz] and 2—5% of the Cl_2 addition product of the same configuration. The price paid for the high yield of *(6c)* is a considerable drawback in the next stage. As expected, only the transformation into *(7c)* proceeds readily in the case

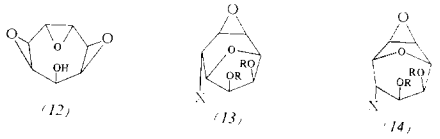
of *(6c)* [>90%, m.p. 127 °C (methanol/CCl_4); *(7d)*: m.p. 145 °C (CCl_4/$CHCl_3$); $J_{1,2} \approx 1$, $J_{2,4} = 4$, $J_{4,5} \approx 1$, $J_{5,6} = 4.5$, $J_{6,7} = 8$, $J_{7,8} = 7$, $J_{1,8} = 4.5$ Hz]. During the long time required for elimination of HCl (24 h) the product uniformity is lost; for example, after complete reaction with KOH/methanol (20 °C, 24 h) only 30—35% of *(8a)* is obtained [m.p. 207 °C (subl.); *(8b)*; m.p. 197 °C (subl.); ^{1}H-NMR ($CDCl_3$, 360 MHz): $\delta = 5.65$ (t, 8-H), 3.44 (m, 2-, 4-H), 3.34 (m, 1-, 5-, 7-, 9-H), 2.21 (s, OCH_3); $J_{7,8}$ ($J_{8,9}$) = 1 Hz; ^{13}C-NMR ($CDCl_3$): $\delta = 170.3$ (CO), 67.0 (C-8), 58.7 (C-7, -9), 52.3 (C-1, -5), 48.2 (C-2, -4), 20.9 (CH_3)]; products resulting from substitution at C-2, C-4 and transannular ether formation arise preferentially[6]. The yield rises to the fairly respectable value of 45—50% of *(8a)* [42—48% based on *(4b)*]—with similar by-products—on use of the reagent sodium glycolate/THF which has proved of value in similar cases[7]; only nonspecific decomposition occurs with DBN.

The critical step *en route* from *(5b)* to *(11a)* is epoxidation: the diacetate *(5b)* is resistant to *m*-chloroperbenzoic acid (in $C_2H_4Cl_2$) between 25 and 80 °C. The diol *(5a)* is also oxidized very slowly (3 d, 20 °C) yet with an expectedly high *trans*-selectivity; polymeric material is accompanied by 45% of *(10a)* [m.p. 175 °C (ethyl acetate/benzene); *(10b)*: m.p. 119—120 °C (CCl_4); $J_{2,4} = 4$, $J_{4,5} = 7$, $J_{5,6} = 4.5$, $J_{6,7} = 9$, $J_{7,8} = 8$ Hz] and traces of *(7a)* [m.p. 115 °C (ethyl acetate/benzene); $J_{1,2} = 1.5$, $J_{2,4} = 4$, $J_{4,5} \approx 1$, $J_{6,7} = 8$, $J_{7,8} = 6.5$, $J_{1,8} = 4.5$ Hz]. Nor could the early initiation of decomposition and secondary reactions be delayed by variation of the reaction conditions (peracid, temperature, buffer). No *(10a)* is formed with CF_3CO_3H/Na_2HPO_4 (CH_2Cl_2, 20 °C). Epoxide ring closure *(10a)*→*(11a)* is fast and practically uniform [85—90%; 36—40% based on *(5b)*, m.p. 93—94 °C (acetone/CCl_4); *(11b)*: m.p. 85 °C (CCl_4/pentane); ^{1}H-NMR ($CDCl_3$, 360 MHz): $\delta = 4.90$ (d, 8-H), 3.59 (dd, 1-H), 3.35—3.45 (m, 4-, 5-H), 3.30 (d, 9-H), 3.20 (dt, 2-H), 3.16 (dt, 7-H), 2.21 (s, OCH_3); $J_{1,2} = 3$, $J_{1,9} = 4.5$, $J_{2,4} = 3$, $J_{4,5} = 0$, $J_{5,7} = 5$, $J_{7,8} = 5.5$, $J_{8,9} = 0$ Hz; ^{13}C-NMR ($CDCl_3$): $\delta = 170.4$ (CO), 73.2 (C-8), 57.5, 55.8 (C-7, -9), 51.9, 50.8, 49.2, 48.6 (C-1, -2, -4, -5)].

The alternative of first converting *(5a)* into *(9a)*—the conformation having quasi-*trans*-diaxial OH/Br substituents is readily accessible—and epoxidizing the product is less favorable. Although *(9a)* is formed quantitatively under standard conditions [m.p. 93—94 °C (ethyl acetate/benzene); *(9b)*: m.p. 108—109 °C (CCl_4)], its epoxidation is even slower and more complex than that of *(5a)* and, moreover, non-stereoselective [*ca.* 5—10% of each *(8a)* and *(11a)*][8].



Compounds *(5)*—*(14)* are fully characterized by elemental analysis and spectral data (MS, IR, ^{1}H- and ^{13}C-NMR), and the stereochemistry of the end products *(8)* and *(11)* is chemically confirmed, *e.g.* by oxidation to the tropone trioxides and by comparison with the *exo/endo* alcohols[2] formed from the latter compounds.

Hexamethyldisilane/Iodine: Convenient *In Situ* Generation of Iodotrimethylsilane[**]

By *George A. Olah, Subhash C. Narang, B. G. Balaram Gupta*, and *Ripudaman Malhotra*[*]

Iodotrimethylsilane[1] has recently found extensive use in organic syntheses. Because of the relative difficulty of preparation and its hydrolytic and photoinstability, emphasis was placed on continued work on the *in situ* generation of the reagent. Work in this area has resulted in the use of phenyltrimethylsilane/iodine[2], allyltrimethylsilane/iodine, and 3,6-bis(trimethylsilyl)-1,4-cyclohexadiene/iodine reagents[3]. These reagents, however, can either produce undesirable by-products or involve tedious syntheses of starting materials. Recently, chlorotrimethylsilane/sodium iodide was also introduced as an iodotrimethylsilane equivalent, but its utility is confined to the essential use of acetonitrile as solvent[4].

We now wish to report the use of hexamethyldisilane/iodine [*(2)*/I_2] as an extremely effective and mild *in situ* iodotrimethylsilane reagent giving no by-products. This reagent can be advantageously used for the mild cleavage of esters *(1)*, carbamates *(5)*, ethers *(3)*, and sulfoxides. Alcohols can be equally well transformed into corresponding alkyl iodides with the reagent.

Esters *(1)* are cleaved to the corresponding acids in very high yield. The reaction was applied with equal ease to methyl, ethyl, and benzyl esters of aliphatic and aromatic carboxylic acids.

$$\underset{(1)}{RCO_2R'} \xrightarrow[2.\ H_2O]{1.\ Me_3SiSiMe_3\ (2)/I_2} RCO_2H + R'I$$

Aliphatic ethers *(3)* can be cleaved to the corresponding alcohols or further transformed into alkyl iodides by varying the reaction conditions. When cyclohexyl methyl ether *(3d)* was reacted with HMDS/I_2 reagent in chloroform solution at

[**] Part 74 in the Series: Synthetic Methods and Reactions. Support for this work by the National Science Foundation and the National Institutes of Health is gratefully acknowledged. Part 73: *G. A. Olah, Y. D. Vankar, M. Arvanaghi*, Tetrahedron Lett., in press.

room temperature, cyclohexanol was obtained in excellent yield. When the reaction mixture was heated under reflux in the absence of chloroform, cyclohexyl iodide was obtained with no alcohol present. Alcohols themselves can be cleanly converted into the corresponding iodides.

$$\underset{(3)}{ROR'} \xrightarrow{(2)/I_2} \underset{(4)}{ROH} + R'I$$

$$\underset{(4)}{ROH} \xrightarrow{(2)/I_2} RI$$

It was observed that cleavage of both esters *(1)* and ethers *(3)* is catalyzed by excess iodine in the system (see Table 1)[5].

General Procedure

To a solution of hexamethyldisilane *(2)*[6] and I_2 (for amounts, see Table 1) in chloroform (15 ml), the substrate [ester *(1)*, ether *(3)*, or carbamate *(5)*] (5 mmol) is added with continuous stirring under a nitrogen atmosphere. The reaction mixture was then heated under reflux and the reaction monitored by TLC and ^{1}H-NMR [cf. ref. [4]]. Usual workup afforded the desired products, which were purified by crystallization or distillation.

A similar procedure was employed in the conversion of alcohols *(4)* into iodides and in the deoxygenation of sulfoxides to sulfides.

[a] Isolated yield of the product. [b] Product composition determined by NMR spectroscopy.

The present reagent was also found to be more selective in the cleavage of protective groups frequently employed in peptide chemistry. For example, carbamates *(5)* can be cleaved cleanly in the presence of a benzyl ester.

$$\underset{(5)}{RNHCO_2R'}$$

$$\underset{(5d)}{\text{Boc-Gly-OBz}} \xrightarrow[5\text{ min}]{(2)/I_2} \text{GlyOBzl} \xrightarrow[30\text{ min}]{(2)/I_2} \text{Gly}$$

Sulfoxides, including dibenzyl sulfoxide, diphenyl sulfoxide, dibutyl sulfoxide, and tetramethylene sulfoxide are also rapidly deoxygenated by *(2)*/I_2 to the corresponding sulfides in quantitative yield.

Formic Anhydride[**]

By *George A. Olah, Yashwant D. Vankar, Massoud Arvanaghi,* and *Jean Sommer*[*]

Formic anhydride *(1)*, the parent carboxylic acid anhydride, has long eluded preparation and characterization. *Olah et al.*[1] first reported in 1955 the possible formation of *(1)* in the reaction of formyl fluoride with metal formates at low temperature. No spectroscopic observations or physical data were, however, obtained. In 1964, *Muramatsu et al.*[2] assumed the intermediacy of *(1)* in the formylation of *p*-nitrophenol and L-leucine with an ethereal solution of formic acid and dicyclohexylcarbodiimide (DCC); no isolation was attempted nor were physical data obtained. *Stevens et al.*[3], in the same year, reported the formation of *(1)* by the thermal disproportionation of formic-acetic anhydride and of mixtures of formic acid and carboxylic anhydrides; proof of formation of *(1)* was based on the appearance of a ^{1}H-NMR singlet at $\delta = 9.0$, which, however, might have been due to a mixed anhydride or other species.

We now wish to report the unequivocal preparation of formic anhydride by four independent methods (*A*—*D*) and its characterization by ^{1}H-NMR, ^{13}C-NMR, and IR spectroscopy. Further, the ethereal solution of *(1)* (obtained by any of the four methods), gave *p*-nitrophenyl formate in uniformly good yield when allowed to react with *p*-nitrophenol.

In the formylation method (method *A*), formyl fluoride dissolved in anhydrous ether is reacted at −78 °C with an excess of sodium formate in the presence of formic acid. In the three dehydration methods (methods *B*—*D*), formic acid (2 mol. equiv.) was dissolved in anhydrous ether at −78 °C and treated with a base (2 mol. equiv.; no base required in case *B*) followed by one mol. equiv. of the dehydrating reagent.

[**] Support of our work by the National Institutes of Health and the National Science Foundation is gratefully acknowledged, as is a Senior U.S. Scientist Award of the Alexander von Humboldt foundation to *G. A. O.* facilitating this research.

The ^{1}H-NMR spectrum (−40 °C) of *(1)* formed by all these methods showed a singlet at $\delta = 8.45$ (TMS as external standard). The proton decoupled ^{13}C-NMR spectrum (−40 °C) of the same solution showed a singlet at $\delta = 158.54$, which on coupling displayed a doublet with $J_{^{13}CH} = 242.8$ Hz. The corresponding signals in the spectra of formic acid lie at $\delta = 8.83$ and 163.38 ($J_{^{13}CH} = 216.3$ Hz); thus the C and H atoms are, as expected, more strongly shielded in the anhydride *(1)* than in the acid. The infrared spectrum of *(1)*, recorded at −78 °C using a Beckman Instruments low temperature IR cell, shows strong carbonyl stretching frequencies at 1795 cm^{-1} and 1775 cm^{-1}, characteristic of an acid anhydride.

Attempts to isolate *(1)* from the ethereal solutions by distillation, including low temperature distillation, gave only products contaminated with formic acid.

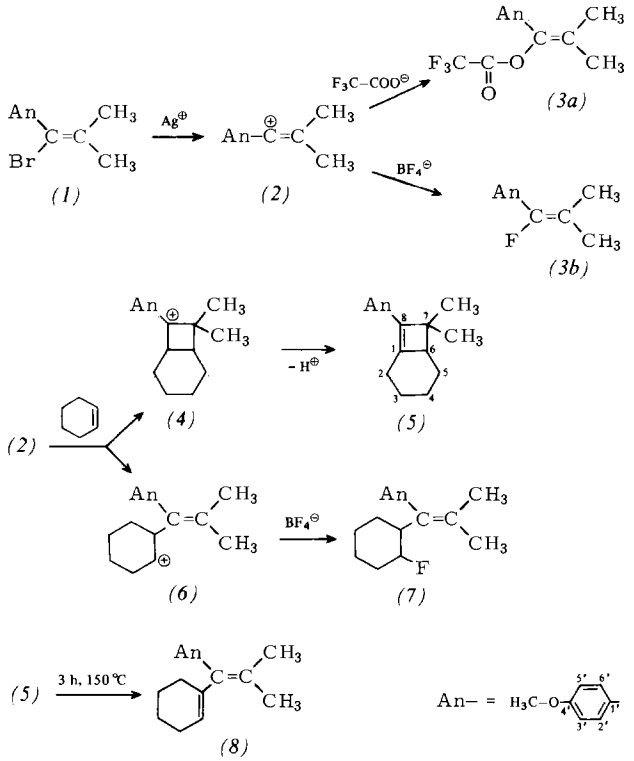
[2 + 2]-Cycloaddition of a Vinyl Cation[**]

By *Günter Hammen* and *Michael Hanack*[*]

The reaction of propargyl halides and cyclopentadiene in pentane with silver trifluoroacetate has recently been reported[1]. The allenyl cations formed in the reaction undergo 1,4-addition to cyclopentadiene and, after hydrolysis of the trifluoroacetate, afford cyclopentenols; [4 + 3]-cycloaddition leads *via* vinyl cations to bicyclic products.



We report here on the first cycloaddition with a vinyl cation[2], which was generated from a vinyl halide by solvolysis in the presence of silver salts. The vinyl halide chosen was 1-bromo-1-(4-methoxyphenyl)-2-methyl-1-propene *(1)*, whose ready solvolysis to the vinyl cation *(2)* is well-known[3].

Reaction of *(1)* in cyclohexene with silver trifluoroacetate and pyridine as buffer at room temperature leads almost quantitatively to the vinyl ester *(3a)*. The products *(5)* and/or its isomer *(8)* expected to be formed on reaction of *(2)* with cyclohexene were obtained in only 1% yield.

On the other hand, when a solution of *(1)* in cyclohexene is allowed to react with silver tetrafluoroborate and pyridine (molar ratio 1.0:1.6:2.0) at 25 °C, subsequent workup with aqueous ammonia affords a mixture of 82% 8-(4-methoxyphenyl)-7,7-dimethylbicyclo[4.2.0]octa-1(8)-ene *(5)*, 11% 1-fluoro-1-(4-methoxyphenyl)-2-methyl-1-propene *(3b)*[4], and 7% 1-(2-fluorocyclohexyl)-1-(4-methoxyphenyl)-2-methyl-1-propene *(7)* in 70—80% yield. The structure of the products was confirmed by ^{1}H-, ^{13}C-NMR, and mass spectroscopy (Table 1). At 150 °C *(5)* isomerizes smoothly within 3 h to 1-(1-cyclohexenyl)-1-(4-methoxyphenyl)-2-methyl-1-propene

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

(8) (Table 1); this is regarded as valuable additional proof of structure.

Table 1. Spectroscopic data for the products (5) and (8).

(5), ^{1}H-NMR (CCl_4): δ = 0.90—2.40 (m, 8H, H-2, 3, 4, 5), 1.21 (s, 3H, CH_3), 1.26 (s, 3H, CH_3), 2.50—2.94 (m, 1H, H-6), 3.69 (s, 3H, O CH_3), 6.56—7.38 (m, 4H, arom.); ^{13}C-NMR ($CDCl_3$): δ = 21.78 (CH_3), 26.42 (CH_3, superimposed), 24.63, 26.42, 27.02, 27.93 (C-2 to C-5), 44.94 (C-7), 50.43 (C-6), 55.12 (O CH_3), 113.84 (C-3', C-5'), 127.27 (C-2', C-6'), 128.63 (C-1'), 139.67, 140.52 (C-1, C-8), 157.85 (C-4'); MS: m/e = 242 (M^+, 100%), 227 (66), 199 (50), 161 (42)

(8), ^{1}H-NMR (CCl_4): δ = 0.70—2.40 (m, 8H, $4CH_2$), 1.59 (s, 3H, CH_3), 1.70 (s, 3H, CH_3), 3.69 (s, 3H, O CH_3), 5.41—5.68 (m, 1H, olefin H), 6.66—7.20 (m, 4H, arom.); MS: m/e = 242 (M^+, 100%), 227 (75), 199 (66), 187 (56), 185 (56), 119 (65), 117 (68)

The products are formed as follows: a concerted or stepwise cycloaddition[5] of (2) and cyclohexene leads to the cation (4), which by loss of a proton is stabilized to the cyclobutene derivative (5). Reaction of (2) with BF_4^- affords the vinyl fluoride (3b)[6]. Finally, (2) can also be added electrophilically to cyclohexene to give the cation (6), which reacts with BF_4^- to give (7).

The comparatively high nucleophilicity of the trifluoroacetate ion (cf. [1,7]) essentially prevents cycloaddition of (2) to cyclohexene: Reaction of (2) and F_3C COO^- in cyclohexene yields almost exclusively (3a). (2) is stable enough however to avoid stabilization by the gegenion F_3C COO^-[7] and reacts without difficulty in the presence of silver tetrafluoroborate[8].

Synthesis and Intramolecular 1,3 Cl,H Disproportionation of Ethyl 2,2-Dichloro-2-(dimethylamino)-acetate[**]

By *Fabienne Huys, Robert Merényi, Zdenek Janousek, Lucien Stella,* and *Heinz Günter Viehe*[*]

Amide chlorides (α,α-dichloroamines), *i.e.* compounds containing the CCl_2 NR_2 partial structure, exist as electrophilic iminium salts CCl $NR_2^{\oplus}Cl^{\ominus}$ if they are substituted at the α-C atom by alkyl or aryl groups or generally by electron-donating substituents[1]. Because of our interest in geminal capto-dative substituent effects[2] we have synthesized the title compound (1) as an example of an amide chloride bearing an electron-attracting substituent. Like other amide chlorides, compound (1) can be prepared from the corresponding thiooxamate (2) and phosgene or chlorine, or PCl_5.

Depending upon the presence or absence of complexing agents such as PCl_5 or even HCl, (1) has an ionic [(1b), (1c)] or a covalent structure [(1a)] (NMR data compiled in Table 1). Chemical evidence for structure (1) is provided by its smooth hydrolysis to the oxamate (3).

The most interesting feature of (1a) is its isomerization to the glyoxalic ester derivative (4), which takes place within

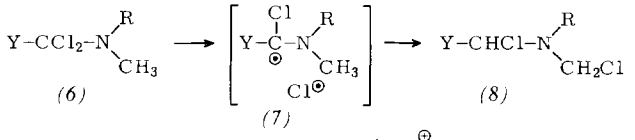
Table 1. NMR data (δ values) of *(1a)*—*(1c)* and *(4)* in $CDCl_3$.



^{1}H-NMR	OCH_2	CH_3	NCH_3	NCH_2Cl	NCHCl	N CCl	COO	$^1J(NCH_3)$ [Hz]
(1a) [a]	4.45	1.25	2.98					
(1b) [b]	4.5	1.4	3.76					
(1c) [c]	4.51	1.47	4.05					
(4)	4.28	1.32	2.77	5.21	5.68			
^{13}C-NMR								
(1c)	66.7	13.3	49.6			160.9	154.2	146.7
(4)	62.5	13.9	38.4	72.9	79.9		165	138.4

[a] At −20 °C. [b] In CD_3CN. [c] If less than 1 equiv. is present on formation of *(1c)*, intermediate values are observed for $\delta(NCH_3)$ indicating occurrence of fast exchange *(1a)*⇌*(1c)*.

1 h at room temperature. *(4)* is characterized by its NMR data (Table 1); as a 1,3-biselectrophile it reacts with *p*-toluidine to give the benzpyrimidine derivative *(5)*.

Intramolecular Cl,H disproportionations such as *(1a)*→*(4)*, apparently represent a general type of reaction. Thus amide chlorides *(6)* bearing electron-withdrawing substituents isomerize to *(8)*[3].

$-Y = -CO-R', -CN, -CCl_3, -CF_3, R'-\overset{\oplus}{C}=\overset{}{N}R''_2\ X^{\ominus}$

This disproportionation formally corresponds to a 1,3 hydride shift. However, the fact that the hexachlorophosphate *(1b)* does not isomerize, and that the weakly complexed salt *(1c)* isomerizes much more slowly (several days) than *(1a)* excludes this possibility. Although a concerted or ionic mechanism cannot be ruled out, the most probable pathway involves homolysis of the C Cl bond favored by the capto-dative substitution of the presumed radical intermediate *(7)*[6].

Procedure

Synthesis of *(1b)*: Thiooxamate[4] *(2)* (0.8 g, 5 mmol) is added to a stirred suspension of PCl_5 (2.08 g, 10 mmol) in dry CH_2Cl_2 (15 ml). The resulting clear solution is stirred for 30 min, concentrated, and the residue is washed with ether. 3.95 g (98%) of *(1b)* is obtained. Hydrolysis with aqueous $NaHCO_3$ yields the known oxamate *(3)*[5] in 68% yield.

Disproportionation *(1a)*→*(4)*: Thiooxamate *(2)* (1.61 g, 10 mmol) in CH_2Cl_2 (30 ml) is treated with $COCl_2$ in 2—4 fold excess. After about 1 h at room temperature, chlorination to *(1a)* and its isomerization are complete. The solvent is removed to give 1.64 g (82%) of *(4)* as a very hygroscopic, ether-soluble oil.

Reaction *(4)*→*(5)*: *p*-Toluidine (3.21 g, 30 mmol) and *(4)* (2 g, 10 mmol) are stirred in dry CH_2Cl_2 (75 ml) for 2 h. The hydrochloride is filtered off and the solvent is evaporated. The residue is washed with benzene/ether (1:1), dried, and exposed to air for 12 h. The resulting hydrochloride of *(5)* is recrystallized from CH_3CN; yield 0.85 g (37%), m.p. 219 °C (decomp.); ^{1}H-NMR ($CDCl_3$): δ = 1.18 (3H, t), 2.32 (3H, s), 3.33 (3H, s), 4.19 (2H, q), 5.76 (1H, s), 7.17 (1H, s), 7.24 (2H, s), 8.78 (1H, s).

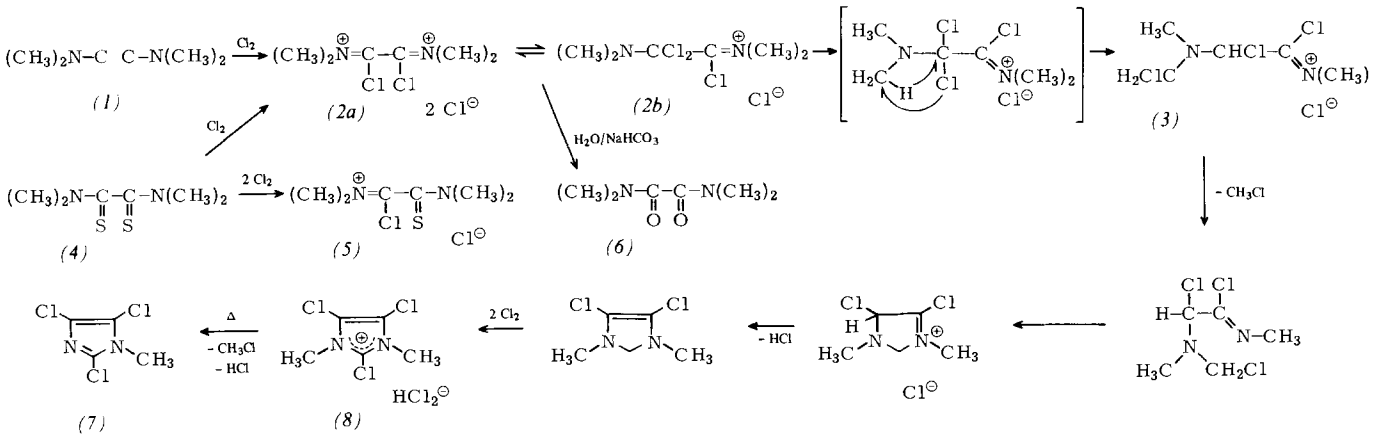
Intramolecular Cl,H Disproportionation of an Oxamide Chloride. An Entry to Imidazole Derivatives[**]



By *Zdenek Janousek, Fabienne Huys, Loïc René, Michèle Masquelier, Lucien Stella, Robert Merényi*, and *Heinz Günter Viehe*[*]

Radicals can be stabilized by capto-dative substitution[1,2]; capto-dative substitution of compounds in which the central CCl_2 moiety is linked to a dimethylamino group and an electron-withdrawing group have been observed to undergo Cl,H disproportionation[3]. Compound *(2)*, an amide chloride of oxalic acid, is a further substrate capable of such rearrangement. We have now been able to synthesize and trap, but not isolate, the highly unstable compound *(2)* and to elucidate reaction sequences in which it occurs as intermediate.

Attempts to synthesize *(2)* by exhaustive chlorination of tetramethyldithiooxamide *(4)* led instead to the new stable trichloroimidazolium salt *(8)*. The disproportionation *(2)*→*(3)* can be envisaged as the key step of this reaction. Although the monoamide chloride *(5)* could be detected on chlorination of *(4)* in the molar ratio 1:2, the reaction could not be stopped at the stage of *(2)*. Chemical proof for the structure of *(8)* is provided by its smooth thermolysis to the known imidazole derivative *(7)* (m.p. 76 °C; ref. [4]: 75—76 °C). This new synthesis resembles the Wallach reaction which has been employed for the synthesis of chloroimidazoles[5].

The formation of *(7)* and more highly chlorinated products on chlorination of dimethylaminoacetonitrile is already known[4]. This reaction can also be explained in terms of intramolecular Cl,H disproportionation.

We finally succeeded in preparing the oxamide chloride *(2)* by chlorination of the highly reactive bis(dimethylamino)acetylene *(1)* at −60 °C under high-dilution conditions in CH_2Cl_2. Compound *(2)* precipitates but is too unstable to be isolated. The structure of *(2)* was established by hydrolysis to tetramethyloxamide *(6)* and reaction with *o*-phenylenediamine to give the known quinoxaline derivative *(9)* (m.p. 66—67 °C).

(9)

Experimental

Synthesis of *(8)* from *(4)*: A fast stream of chlorine is passed through a solution of *(4)* (1.76 g, 10 mmol) in dry CH_2Cl_2 (30 ml) such that the solution boils under reflux. After about 30 min the precipitate is collected and washed with benzene containing some styrene to remove excess Cl_2; yield 2.26 g (96%); m.p. 186 °C (acetonitrile); ^{1}H-NMR ($SOCl_2$): $\delta = 3.85$; IR (KBr): 1580, 1510, 1390, 1330, 1155, 1070, 840 cm^{-1}.

Synthesis of *(2)*: A solution of chlorine (2.8 g, 40 mmol) in CH_2Cl_2 (250 ml) is transferred at −78 °C to a 1-l flask equipped with a dry-ice cooler and a dropping funnel. After dropwise addition of *(1)* (1.12 g, 10 mmol) in CH_2Cl_2 (250 ml) with stirring at −78 °C, a precipitate of *(2)* appears; it is hydrolyzed by aqueous $NaHCO_3$ to *(6)* (63%).

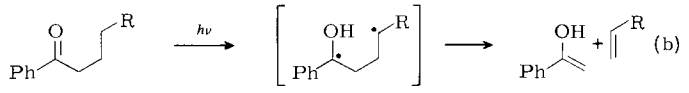
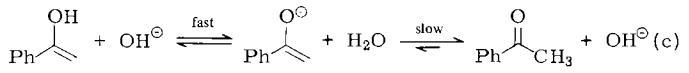
Acidity of Acetophenone Enol in Aqueous Solution[**]

By *Pavel Haspra, Alfred Sutter*, and *Jakob Wirz*[*]



Thermodynamically unstable enols are of importance as reactive intermediates and are often the primary products of photochemical reactions. The formation of enols during the Norrish type II cleavage of ketones was first demonstrated directly by *Henne* and *Fischer*[1]. The subsequent transformation of the enols into stable ketones necessitates protonation of a carbon and proceeds much slower than the establishment of the acid-base enol-enolate equilibrium. This would suggest the possibility, hitherto not exploited, of *determining the acidity of enols directly by flash spectroscopy*. Since enolization constants, $K_e = [\text{enol}]/[\text{ketone}]$, are accessible from thermochemical[2a] or kinetic[2b] data, the α-CH acidity constant K_a of the corresponding ketone in aqueous solution can be calculated according to eq. (a).

$$pK_a(\text{ketone}) = pK_a(\text{enol}) + pK_e \qquad \text{(a)}$$



Novak and *Loudon*[3a] have recently estimated the pK_a of acetophenone enol *(1)* in aqueous solution by a somewhat tedious indirect method to be 11 ± 1, from which the pK_a of acetophenone *(2)* was calculated as 15.8 ± 1.0. Since this value deviates considerably from the result of an earlier measurement (19.2[4]) and since the pK_a value of *(1)* serves as a reference for relative measurements[3b] on derivatives of *(1)*, we decided to test the feasibility of the flash-spectroscopic "titration" method on *(1)* as an example.

(3) (1) (b)

(1) $(1)^-$ (2) (c)

In order to increase the solubility of butyrophenone *(3)* (R = H) in water we used the γ-hydroxy derivative (R = OH)[5]. Figure 1 (left) shows the increase in extinction of a 10^{-4} M solution of *(3)* (R = OH) in 0.1 M air-saturated sodium hydroxide in the range 270 to 350 nm immediately after the photo-flash (1000 J, 20 μs; fresh solution used for each measurement). In neutral and acidic solutions the photo-flash effects no increase in absorption at $\lambda > 300$ nm. To interpret the results it is assumed that the increase in absorption at $\lambda > 300$ nm in basic solutions can be ascribed exclusively to the enolate $(1)^-$, while the enol *(1)* does not absorb in this region.

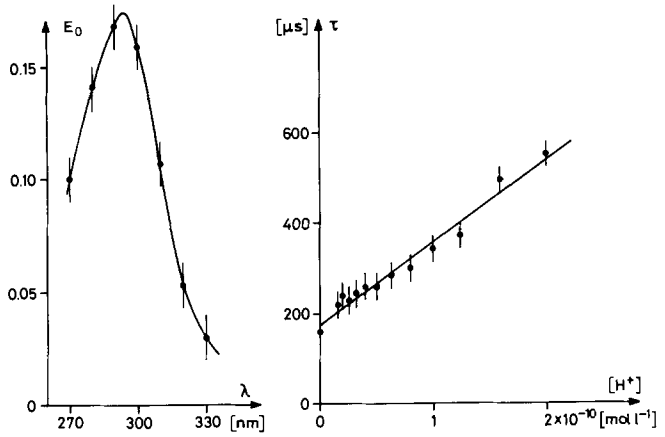

Fig. 1. Left: absorption spectrum of the enolate *(1)* in 0.1 M sodium hydroxide.—Right: lifetime of $(1)^-$ (in equilibrium with the enol *(1)*) as a function of the proton concentration [H^+]; room temp.

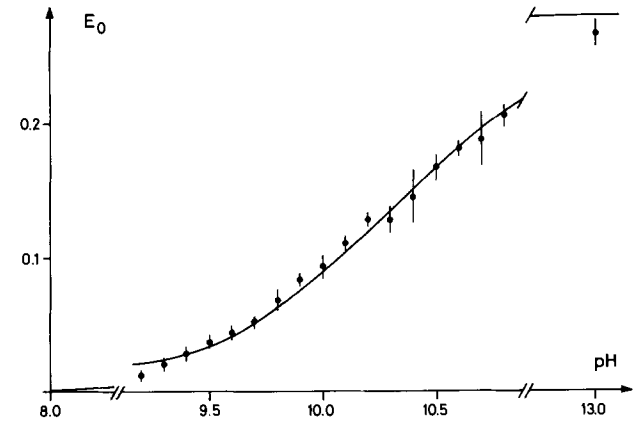

Fig. 2. Flash spectroscopic titration curve of $(1)/(1)^-$

The decrease in the concentration of enolate in equilibrium with the enol obeys a (pseudo) first-order rate law within the accuracy of measurement. On the basis of the reaction scheme (c) the dependence of the lifetime $\tau((1)^-)$ on pH can be expressed as follows

$$\tau((1)^-) = \frac{1}{k((1)^- \rightarrow (2))} + \frac{1}{K_a((1)) \cdot k((1)^- \rightarrow (2))} \cdot [H^+] \qquad (d)$$

In Figure 1 (right) the lifetime measured at room temperature is plotted against the proton concentration of a borax buffer[6] (ionic strength $I = 0.1$). At pH values below 9.5 there is a systematic deviation from the linear equation (d), caused by the acid-catalyzed decomposition of *(1)* and not taken into account in scheme (c). Consequently only an estimate of the acidity constant $K_a((1)) < 10^{-10}$ can be obtained from the ratio of the slope and intercept of the regression line. The rate constant $k((1)^- \rightarrow (2))$ for the *C*-protonation of $(1)^-$ by water is 6×10^3 s^{-1}. The acidity of *(1)* can be determined much more accurately from the "titration curve" (Figure 2), where the initial extinctions E_0 (310 nm) of $(1)^-$, obtained by linear extrapolation of the logarithmic decay curves to a reference time $t = 0$ (maximum of the photo-flash), are plotted against the pH value of the borax buffer. Each point represents the mean of three individual measurements in fresh solutions. The results were fitted by heteroscedastic regression to the linear equation

$$(E_0)^{-1} = A + A \cdot [H^+]/K_a((1)) \qquad (e)$$

where

$$A^{-1} = ([(1)]_0 + [(1)^-]_0) \cdot \varepsilon((1)^-, 310\,nm) \cdot d.$$

For weighting the measured points, the absolute mean error of E_0 was assumed to be constant. We thus obtained a value of $pK_a((1)) = 10.34 \pm 0.05$ (95%) for the acidity of acetophenone enol. With $pK_c((2)) = 6.7 \pm 1.0$[2a], equation (a) gives a value of 17 ± 1 for $pK_a((2))$. A second series of measurements with *(3)* (R = H) as starting material gave $pK_a((1)) = 10.29 \pm 0.04$ (95%); in this case 5% acetonitrile had to be added to the buffer in order to achieve sufficient solubility of butyrophenone.

The assignment of the short-lived absorption above 300 nm (Fig. 1, left) to the anion $(1)^-$ is confirmed as follows. The formation of *(1)* as a primary product of the photolysis of *(3)* ($R = CH_3$) has been demonstrated NMR spectroscopically[1]; the position of the first absorption band of $(1)^-$ is consistent with PPP-SCF-CI calculations using standard heteroparameters[7] [*(1)*: 286 nm ($\log\varepsilon = 3$), $(1)^-$: 306 nm ($\log\varepsilon = 4$)]; the evaluations of the results according to equations (d) and (e) are in agreement with each other and are consistent with the estimated value of *Novak et al.*[3a]; the absorption maximum of $(1)^-$ in basic dimethyl sulfoxide (DMSO) lies at 342 nm ($\log\varepsilon = 3.6$)[8], and in aqueous solution at *ca.* 295 nm (Fig. 1, left). Qualitatively, a hypsochromic shift of the first absorption band with increasing solvation is to be expected: according to the PPP model calculation the charge density at the oxygen atom in the first excited state is about ⅓ less than in the ground state. In the gas phase $(1)^-$ absorbs at still longer wavelengths, $\lambda_{max} \approx 420$ nm[9a]. An analogous solvatochromic shift was also observed for phenolate, $\lambda_{max} = 332$ nm (g)[9b], 287 nm (H_2O). To obtain an authentic example for the difference between such an anion in DMSO and in water we have determined the absorption spectrum of 2-naphtholate in both solvents: the first maximum shifts from 399 nm (DMSO) to 346 nm (H_2O).

Redox Addition/Elimination Processes of Cluster-Bound Ligands: Oxidative Elimination of CO from $Co_3(CO)_9C$—OH and Reductive Addition of Acetylene to $Co_3(CO)_9H$[**]

By *Giuseppe Fachinetti, Sergio Pucci, Pier Francesco Zanazzi,* and *Uncharee Methong*[*]

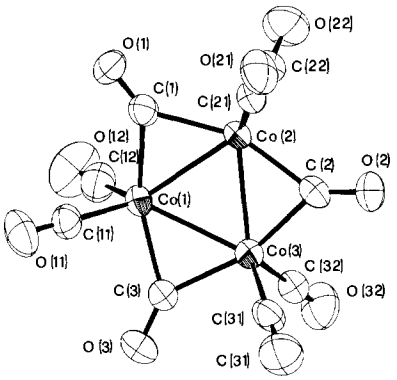
The preparation of $Co_3(CO)_9C$ OH *(1)* and its quantitative transformation at room temperature in a closed vessel into $HCo(CO)_4$ *(2)* and $Co_4(CO)_{12}$ *(3)* [eq. (a)] have recently been reported[1].

$$2\,Co_3(CO)_9C\ OH \rightarrow 2\,HCo(CO)_4 + Co_4(CO)_{12} \quad (a)$$
(1) *(2)* *(3)*

In the course of this reaction, which involves the oxidation of a C OH group to coordinated CO, a transient infrared active (ν_{CO} 1879 cm^{-1}) species was observed. In view of the current interest in redox processes involving carbon monoxide[2], a special effort was made to establish the nature of the transient carbonyl. We have now succeeded in isolating this species and characterizing it as the hydrido cluster *(4)* [eq. (b)].

$$Co_3(CO)_9C\ OH \rightarrow CO + HCo_3(CO)_9 \quad (b)$$
(1) *(4)*

(4) is a blackish green, crystalline substance which is thermally (30 °C) labile, giving $Co_4(CO)_{12}$ *(3)* in solution (verified by IR); it can be kept at 0 °C under argon without appreciable decomposition. The IR spectrum in the carbonyl stretching region (*n*-hexane, 2054, 2037, and 1879 cm^{-1} of comparable intensity) is consistent with a highly symmetrical structure, with both terminal and bridging carbonyl groups. The mass spectrum of *(4)* (*m/e* 430, M^+), and of ^{2}H-*(4)* (*m/e* 431) established the presence of a hydrogen atom in the molecule. Moreover, treatment of *(4)* with CO at atmospheric pressure and room temperature resulted in the formation of $HCo(CO)_4$ *(2)* and $Co_4(CO)_{12}$ *(3)* (with $Co_2(CO)_8$ in relative amounts depending on the rate of CO diffusion in solution) as the only IR-active species. The structure of *(4)* was confirmed by X-ray methods (Fig. 1)[3].



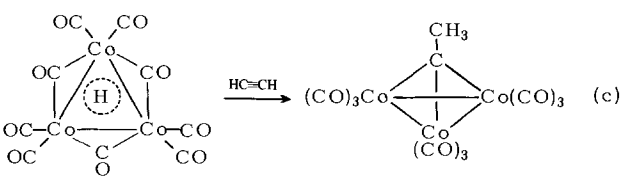


Fig. 1. The $Co_3(CO)_9$ molecular skeleton of the $HCo_3(CO)_9$ cluster *(4)*. Some important molecular parameters averaged assuming D_{3h} symmetry are: Co Co, 2.459 ± 0.008 Å; bridging CO: Co C, 1.949 ± 0.009 Å; C O 1.154 ± 0.017 Å; non-bridging CO: Co C, 1.825 ± 0.022 Å; C O, 1.122 ± 0.012 Å.

Molecular bond lengths and angles between non-hydrogen atoms show nearly perfect D_{3h} symmetry. Concerning the problem of hydrogen location, a difference Fourier map showed many peaks with electron density in the range 1.00—0.64 e/Å^3, all within 0.8 Å from cobalt atoms, except for two maxima (0.53 and 0.48 e/Å^3) near the threefold molecular axis, above and below the tricobalt plane. These could represent two possible positions for the hydrogen atom linked to the cluster of the three cobalt atoms. A reasonable hypothesis is that the hydrogen atom occupies these positions statistically with half occupancy at each site. This hypothesis is indirectly supported by the results of potential energy computations[4] which reveal two nearly equivalent minima in regions very close to those where residual electronic density was found. An attempt to refine the two positions of the H atom was carried out by imposing the constraint that all H Co distances must remain equal. The refinement converged to an *R* value of 4.26%, with H Co distances of 1.93(6) Å. However, this result is not significant from a statistical point of view.

Attachment of hydrogen to one of the oxygen atoms of the carbonyl groups is ruled out by the simplicity of the IR spectrum in the carbonyl stretching region; terminal bonding of hydrogen to one of the cobalt atoms is excluded on the same basis. Hence, a μ_3-type structure appears most likely, although it is rather uncommon among transition metal hydrides[5].

Having observed the oxidative elimination of CO from *(1)* [eq. (b)], we also verified the possibility of using the "unsaturated" cluster *(4)* as promoter of the reverse process, namely the reductive addition of a more easily reducible triply bonded molecule. Compound *(4)* reacts with acetylene at room temperature to give $Co_3(CO)_9C$ CH_3 *(5)* [eq. (c)][6] (IR, MS).

(4) *(5)* (c)

This four-electron cluster-assisted reduction of acetylene represents a step in the hydrogenation to ethane. Hydrogen-

olysis of the cobalt-carbon bonds has already been reported[7] to occur photochemically.

Experimental

A solution of *(1)* (1.8 g, 3.93 mmol) in a *n*-hexane/toluene (50 ml + 10 ml) mixture was maintained at 15 °C/20 torr for about 10 min, and then cooled to −30 °C for about 36 h. Black crystalline *(4)* was then collected by filtration at low temperature and dried briefly *in vacuo* (0.18 g, 10%).

A solution of *(4)* (0.090 g, 0.21 mmol) in *n*-hexane was treated with an excess of acetylene at 15 °C. The brilliant green solution of the hydride immediately turned red-brown. After 0.5 h, chromatography (silica-gel, hexane) gave 0.040 g (42%) of *(5)*.

Asymmetric Hydrogenation of (*Z*)-α-(Acetylamino)-cinnamic Acid by a Rh/norphos Catalyst[**]

By *Henri Brunner* and *Willigis Pieronczyk*[*]

$RhCl[P(C_6H_5)_3]_3$ catalyzes the hydrogenation of olefins in homogeneous solutions at room temperature and atmospheric pressure[1]. If $P(C_6H_5)_3$ is replaced by optically active phosphanes, the chiral information is transferred from a small amount of catalyst to large amounts of hydrogenation products[2]. Within the last 10 years Rh complexes of about 150 different optically active phosphanes have been used for the asymmetric hydrogenation of about the same number of different prochiral substrates[3]. Especially high optical yields could be obtained using chelating phosphanes which were either derived from optically active natural products in multistep syntheses (diop[4a], prophos[4b]) or obtained *via* tedious optical resolutions (dipamp[5a], chiraphos[5b]). Taking norphos as an example, we describe a generalizable procedure for the preparation of optically active chelating phosphanes by the surprisingly facile resolution of the respective phosphane oxides, in this case norphosO, with L-(−)-dibenzoyltartaric acid, abbreviated (−)-DBT.

norphosO is obtained by Diels-Alder reaction of cyclopentadiene and *trans*-vinylenebis(diphenylphosphane oxide)[6]. When an ethanolic solution of (±)-norphosO is treated with (−)-DBT, the less soluble diastereoisomer (−)-norphosO/(−)-DBT precipitates. Treatment with KOH removes (−)-DBT from both fractions. After one separation step the optical purity of norphosO lies between 70 and 80%; it is optically pure after one repetition of the separation procedure. (+)- and (−)-norphosO can be reduced by $SiHCl_3$ to (+)- and (−)-norphos[7].

Scheme 1. Catalyst (cat.) = $Rh_2Cl_2(cod)_2$ (7 mg) and (−)-norphos (14.5 mg) in ethanol (5 ml); substrate = *(1)* (500 mg) in ethanol (10 ml); hydrogenation for 10 h at room temperature; workup, see ref. [8]; chemical yield quantitative; *(R)-(2)*:*(S)-(2)* = 2:98.

Scheme 1 shows the catalytic hydrogenation of (*Z*)-α-(acetylamino)-cinnamic acid *(1)* by $Rh_2Cl_2(cod)_2$/(−)-norphos (cod = 1,5-cyclooctadiene). The optically active catalyst differentiates so effectively between frontside and backside attack that (*R*)- and (*S*)-(*N*-acetyl)-phenylalanine *(2)* are formed in methanol (and methanol/benzene) in a ratio of 3:97, and in ethanol in a ratio of 2:98, corresponding to an optical yield of 96%. Thus, norphos is one of the most easily prepared optically active chelating phosphanes and gives one of the highest optical yields reported for asymmetric hydrogenation. In contrast to many other chelating phosphanes, both enantiomers of norphos are available and thus both configurations of the hydrogenation products can be obtained.

Like norphos, chiraphos and prophos form five-membered chelate rings with the Rh atom in the catalyst. (*S,S*)-chiraphos hydrogenates *(1)* to *(R)-(2)*[5b], whereas (*R*)-prophos gives *(S)-(2)*[4b]. Because it likewise affords *(S)-(2)*, we ascribe the (2*R*,3*R*)-configuration to (−)-norphos.

Experimental

Optical resolution of (±)-norphosO: A solution of (±)-norphosO (25.5 g) in 99% ethanol (105 ml) is added to L-(−)-dibenzoyltartaric acid monohydrate = (−)-DBT (19.5 g) in 99% ethanol (20 ml) and stirred for 2 h. The less soluble diastereomer (−)-norphosO/(−)-DBT (19.5 g) is filtered off and shaken together with a solution of KOH (4 g) in water (160 ml) until dissolution is complete. The organic phase is separated off and the aqueous phase is washed with chloroform (30 ml). The united organic phases yield 11 g of (−)-norphosO, $[\alpha]_{578}^{20} = -47°$ ($c = 1$, $CHCl_3$). Repetition of this separation step gives a further 9 g of (−)-norphosO, $[\alpha]_{578}^{20} = 62°$. — The ethanolic solution of the more soluble diaster-

Universitätsstrasse 31, D-8400 Regensburg 2 (Germany)

[**] We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG for support of this work.

eoisomer (+)-norphosO/(−)-DBT is concentrated and the residue mixed with dry acetone (100 ml). The resulting solution contains 19.2 g (+)-norphosO/(−)-DBT from which 9.5 g of (+)-norphosO $[\alpha]_{578}^{20} = +50°$ ($c = 1$, $CHCl_3$) is isolated as above. Repetition of this separation step yields a further 5.7 g of (+)-norphosO, $[\alpha]_{578}^{20} = +58°$.

Reduction to (+)- and (−)-norphos: (−)-norphosO (9 g) is stirred in an autoclave with a solution of $HSiCl_3$ (15 g) in benzene (200 ml) for 15 h at 65—75 °C. After evaporation of the solvent the residue is dissolved in benzene (100 ml). The cooled solution is treated with 25% NaOH until the precipitate has dissolved. After separation of the aqueous phase the benzene phase is washed with water (10 ml). It contains 6.2 g of (−)-norphos (75%), which is recrystallized from acetone; $[\alpha]_{578}^{20} = -43.5°$ ($c = 1$, $CHCl_3$), m.p. 129—130 °C. (+)-norphos $[\alpha]_{578}^{20} = +45°$, m.p. 129—130 °C.

Regioselective Alkylation of 1,4,5-Trihydroxy-9,10-anthraquinone with Formaldehyde and Glyoxylic Acid[**]

By *Karsten Krohn*[*]

In addition to Diels-Alder reactions[1], intramolecular cyclizations of Marschalk type[2] are becoming increasingly important for synthesizing the tetracyclic ring system of the cytostatically active anthracycline antibiotics since they permit the synthesis of anthracyclinones bearing a methoxycarbonyl group at C-10[3] and provide a simple solution to the problem of regioselectivity[4]. Marschalk[2] alkylation of the leuco compound *(1)* with straight-chain aldehydes (C_2—C_4) gave *C*-2-alkylated products with satisfactory regioselectivity (80—90%)[5]. We now describe the reaction of *(1)* with formaldehyde or glyoxylic acid as a simple alternative to known syntheses[6] of anthracycline precursors.

Reaction of *(1)* with these aldehydes (aqueous sodium hydroxide, 50—60 °C[5]) gave polyalkylated products as well as chromatographically indistinguishable compounds alkylated at C-2 or C-3. However, on treatment at −5 to −3 °C (12 h) with alcoholic potassium hydroxide, *(1)* undergoes regioselective reaction to give 2-(hydroxymethyl)-1,4,5-trihydroxy-9,10-anthraquinone *(3)* in 18–21% yield. On filtration through a short silica gel column (3 × 20 cm, dichloromethane) about 60% of *(2)* was recovered; the polar species *(3)* could be isolated by elution with dichloromethane/2% methanol. The constitution of *(3)* is established by a downfield NMR shift of 1-OH ($\Delta\delta = 0.38$ ppm) and confirmed chemically by reduction with alkaline dithionite to give islandicin *(4)*[6]. Compound *(3)* is an attractive precursor of anthracyclinones.

(1) *(2)-(7)* *(8)*

(2)-(5), $R^1 = R^2 = H$; *(2)*, $R^3 = H$; *(3)*, $R^3 = CH_2OH$; *(4)*, $R^1 = CH_3$; *(5)*, $R^3 = CH_2CO_2CH_3$; *(6)*, $R^1 = H$, $R^2 = CH_3$, $R^3 = CH_2CO_2CH_3$; *(7)*, $R^1 = R^3 = CH_2CO_2CH_3$, $R^2 = H$

The analogous reaction of *(1)* with glyoxylic acid and subsequent reduction and esterification of the initially formed α-hydroxy acid gave the monoester *(5)* in 33% overall yield. Small amounts (<5%) of the anthraquinone substituted at C-3 could be eliminated by recrystallization from chloroform. The constitution has again been assigned by means of the NMR chemical shift of 1-OH ($\Delta\delta = 0.40$ ppm). The diester *(7)* could also be isolated in about 1% yield from some runs. Methylation of *(5)* with an excess of diazomethane[7] led selectively in 55% yield to the monomethyl ether *(6)*, suitable as starting material for a second alkylation at C-3 and further transformation into ε-rhodomycinone[3a]. It was possible to synthesize 9-deoxy-ε-rhodomycinone *(8)* in only two steps from *(5)*[3c].

Procedure

Synthesis of *(5)*: A solution of glyoxylic acid hydrate (3.68 g, 40 mmol) in methanol (100 ml) is added dropwise (6 h) to a solution of *(1)* (10.16 g, 40 mmol) [prepared from *(2)* by reduction with alkaline dithionite and precipitation with dilute sulfuric acid] in 0.5 N methanolic KOH (500 ml) cooled in an ice/salt mixture (internal temperature −5 to −3 °C). After a total of 12 h the mixture is acidified with 1 N HCl (500 ml), the precipitate is filtered off, dissolved in 1 N aqueous NaOH (400 ml), treated under N_2 with 85% sodium dithionite (8.30 g, 40 mmol), and heated under reflux for 2 h. A vigorous current of air is then passed through the solution at room temperature for 3 h; the precipitate is filtered off and dried *in vacuo* at 80 °C. Crude *(5)* is boiled in a mixture of chloroform (1 l), methanol (10 ml), and conc. sulfuric acid (5 ml) for *ca.* 12 h. The solution is washed twice with water, dried ($NaSO_4$), and filtered over a short silica gel column (3 × 20 cm). Some 2.20 g of *(2)* is recovered from the first fraction (chloroform) and then *(5)* is eluted; m.p. 197—200 °C (chloroform); yield 4.33 g (33%); IR (KBr): 1730 (C=O), 1598 cm^{-1} (quinone, chelated); ^{1}H-NMR ($CDCl_3$, 270 MHz): $\delta = 3.75$ (s; 3H, CO_2CH_3), 3.79 (s; 2H, CH_2), 7.36 (dd, $J_{6,7} = 8.1$, $J_{6,8} = 1.1$ Hz; 1H, 6-H), 7.71 (t; 1H, 7-H), 7.89 ($J_{7,8} = 7.4$, $J_{6,8} = 1.1$ Hz; 1H, 8-H), 12.21, 12.26 (each s, 2H, 2OH), 13.44 (s; 1H, 1-OH).

Competition in the Three-Component System Triphenylphosphane/Azo Ester/3-Hydroxy-Carboxylic Acid: OH- *versus* COOH-Activation

By *Johann Mulzer, Gisela Brüntrup,* and *Alexander Chucholowski*[*]

The question of hydroxy group activation (HGA) *vs.* carboxy group activation (CGA) always arises when dehydrating agents react with hydroxy carboxylic acids; this problem is of particular importance in the synthesis of macrolides[1] (stereocontrol[2] of a chiral center at the lactone-O) and peptides[3] (problem of hydroxy protection on preparing the active ester derivatives of hydroxyamino acids). It has generally remained unclear so far whether a given dehydrating agent exclusively effects HGA or CGA, or whether a variation of the substituents in the substrate may lead to a change in the activation mode.

In the case of the adduct *(1)* of triphenylphosphane and diethyl azodicarboxylate, a frequently employed dehydrating agent[4], only HGA was known in the system alcohol-carboxylic acid[5]. We now report on the first CGA reactions of *(1)* and reveal the factors determining the HGA/CGA competition.

As can been seen from the formula scheme our model system—the reaction of *(1)* with *threo*-3-hydroxycarboxylic acids *(2)*[6]—allows a simple and unambiguous differentiation between CGA and HGA. Proton transfer generates the ion pair *(3)*, from which the zwitterions *(A)* or *(B)* are formed by elimination of hydrazo ester. Of the reaction products, *(4)* and *(5)* can be unequivocally assigned to *(A)*, while *(6)* can only be formed from *(B)*; the alternative *(B)*→*(7)*+*(8)* is about 30 kcal/mol[7] less favorable and can be ruled out. The ratio HGA/CGA can thus be expressed by the quotient $Q=[(4)]+[(5)]/[(6)]$ (Table 1).

The relationship between Q and R^1/R^2 is attributed to the fact that the energy levels of *(A)* and *(B)* are shifted relatively to each other under steric effects. For small R^1 and R^2 *(A)* is much more stable than *(B)* due to the high resonance energy of its carboxylate function; so exclusively HGA is observed in cases *(a)*—*(e)*. On the other hand, bulky R^1 and R^2 in *(A)* strongly interact with each other and the $P(C_6H_5)_3$ group, whereas the steric interference is far less in *(B)*; hence, in the systems *(f)*—*(l)* the reaction path *via (B)*, and thus CGA, is progressively preferred. This interrelationship can be described semiquantitatively by correlating Q with the expression $\sum E_s = E_s(R^1) + 2E_s(R^2)$ [Table 1; E_s = steric parameter according to *Taft*[8].—Owing to its immediate proximity to the hydroxy group greater consideration must be given to R^2 than R^1 in $\sum E_s$; this is taken care of by an arbitrarily chosen

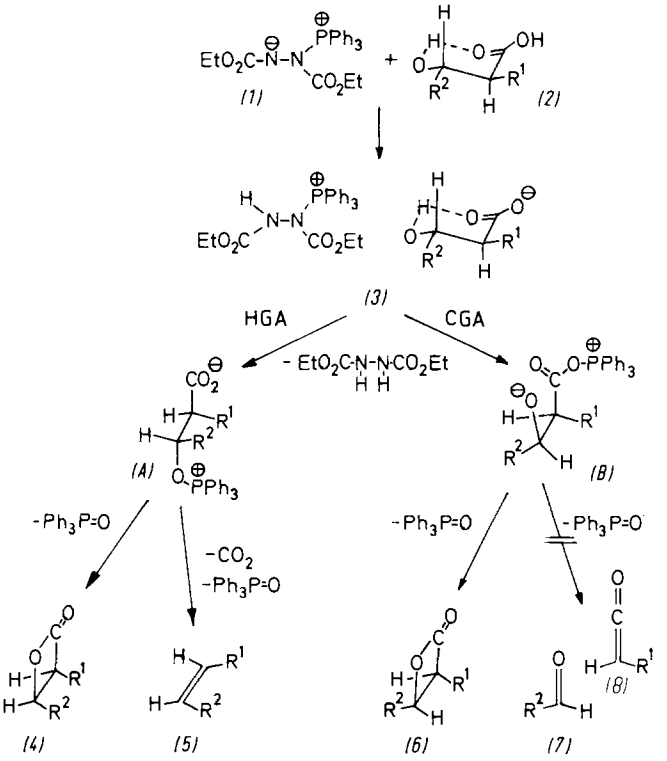

Table 1. Ratio Q = HGA/CGA in the reaction of *(1)* with *(2)*. The systems are listed according to falling $\sum E_s$ values.

factor 2]. Table 1 shows that the transition from HGA to CGA occurs in the range $-6.2 < E < -4.2$. If the smaller tri-*n*-butylphosphane is employed instead of triphenylphos-

phane CGA is only found in the heavily crowded systems *(k)* ($Q = 33/67$) and *(l)* ($Q = 0/100$), quite in accordance with the interpretation given above.

The preference of *(1)* to react with the sterically least hindered OH group is further demonstrated by the fact that it transforms *(2f)* and *(2k)* exclusively into the methyl esters if one equivalent of methanol is present. Apparently, of all the OH groups in the system that of the methanol is most rapidly activated, thus leading to an *inter*molecular reaction.

That the problem hydroxy-group *versus* carboxy-group activation plays a decisive role in biochemistry is clearly demonstrated by the transformation of mevalonic diphosphate into isopentenyl diphosphate, the key step in the terpene- and cholesterol-biosynthesis[9]. The enzyme, which utilizes a positively charged pentavalent phosphorus like *(1)*, apparently succeeds in avoiding steric congestion at the hydroxy function. The undesirable carboxy group activation thus is completely suppressed.

Complexes of γ-Cyclodextrin with Crown Ethers, Cryptands, Coronates, and Cryptates[**]

By *Fritz Vögtle* and *Walter M. Müller*[*]

The cyclodextrins (CD) have a lipophilic cavity which enables them to incorporate guest molecules and perform enzyme-analogous reactions[1]. Space-filling models show that smaller crown ethers and cryptands[2] just fit into the conical cavity of γ-CD enclosed by eight glucose units (Fig. 1).
For example, mixing of aqueous solutions of γ-CD and [12]crown-4 *(1)* in various stoichiometric ratios at room temperature or slightly elevated temperatures leads, within a few minutes or few hours, to crystallization of a 1:1 complex.

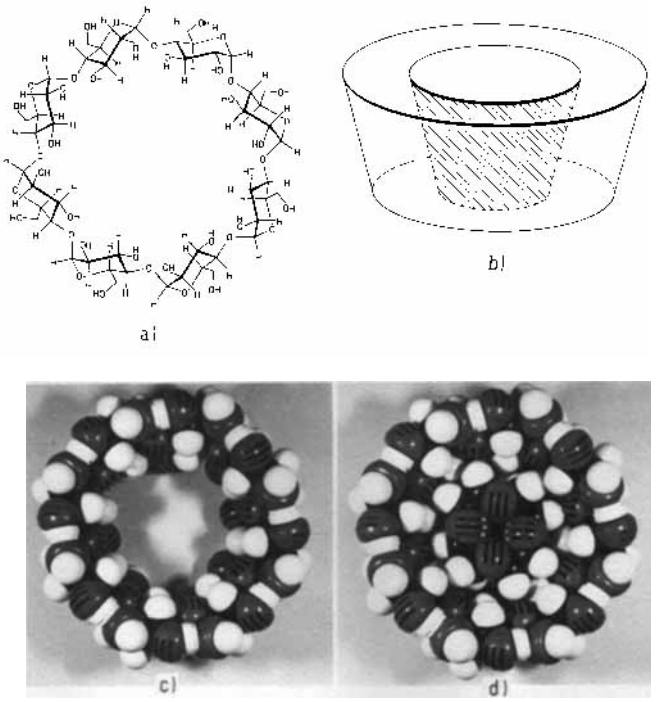

Fig. 1. a) Formula of γ-cyclodextrin (γ-CD); b) conical cavity in γ-CD; c) space-filling model of γ-CD; d) space-filling model of γ-CD with [12]crown-4 *(1)* in the cavity.

A similar ease of cavity accommodation (cf. Fig. 1[3]) is demonstrated by models of the γ-CD complexes of [2.1.1]cryptand *(9)* and of [1.1.1]cryptand *(8)*. The complexes form colorless needles and are so stable that they can be recrystallized from water.

Table 1 lists a series of further CD ⊂ crown ether and CD ⊂ cryptand combinations[4] whose elemental analyses indicate exact 1:1 or 2:1 stoichiometry. IR, ^{1}H-NMR, ^{13}C-NMR, and mass spectra confirm the presence of both components. According to model considerations crown ether—metal ion complexes (coronates)[2], though much more rigid, should also be capable of being accommodated in the CD cavity. Reaction of aqueous solutions, *e.g.* of the [12]crown-4-LiSCN complex *(1a)*, or of the [2.2.2] ⊂ $Ca(SCN)_2$- or [2.2.2] ⊂ $Ba(SCN)_2$-cryptates *(10a)* and *(11a)* at room temperature with aqueous solutions of γ-CD leads to crystallization of "cascade complexes"[5] with the stoichiometric ratios 1:1, 2:1 and 2:1, respectively, whose thiocyanate anions are easily detectable by IR spectroscopy (2070 cm^{-1}). Since the changeover from 1:1 to 2:1 stoichiometry coincides with the transition from smaller to larger host molecules, such as from [2.1.1]- to [2.2.2]-cryptands, it can be assumed that if the guest molecule is too large, an arrangement is preferred in which it is enclosed by two CD molecules from opposite sides[6]. This also applies if the guest molecule contains several lipophilic groups suitable for accommodation, as in *(6)* and *(7)*. On the other hand, we have so far been unable to isolate complexes with the bulky molecules[8] dibenzo[24]crown-8 and $[2_B.2_B.2]$cryptand[7]. CD-crown ether complexes could also be useful for the transport of ions through cellulose membranes[9].

Procedure

Colloidal Redox Catalysts for Evolution of Oxygen and for Light-Induced Evolution of Hydrogen from Water[**]

By *John Kiwi* and *Michael Grätzel*[*]

Redox catalysts such as PtO_2 and IrO_2 are known to promote the evolution of oxygen[1] and the light-induced evolution of hydrogen[2,3] from water. The ultimate aim of such studies is the production of systems in which water is decomposed into its components in high yield by visible light. We have now found that colloidal ruthenium (oxide) and other colloidal metals catalyze the evolution of oxygen and the light-induced evolution of hydrogen from water more efficiently than less finely divided substances.

The colloids were characterized by light scattering measurements[4]. Figure 1 shows autocorrelation functions obtained with poly(vinyl alcohol) (PVA) alone and with Ru in the presence of PVA as protective colloid. The hydrodynamic radius can be calculated from the correlation times (Table 1); the substances are therefore present as colloidal dispersions.

Table 1. Evaluation of correlation measurements by Stokes-Einstein equation. D = diffusion coefficient; τ = decay time; r_h hydrodynamic radius (at 25 °C)

$D = kT/(6\pi\eta r_h)$; $D = 1/(2K^2\tau)$, $K = 1.039 \times 10^4$ cm^{-1} [4]

Substance	D [cm²/s]	τ [ms]	r_h [Å]
Poly(vinyl alcohol) (PVA) (mol. wt. 60000)	2.3×10^{-7}	19.7	101
Ru colloid (from $RuCl_3$) PVA	8.5×10^{-8}	56.0	280
Pd colloid (from $PdCl_2 \cdot H_2O$) PVA	4.7×10^{-8}	101.2	500
Pt colloid (from H_2PtCl_6) PVA	3.6×10^{-8}	132.1	564

The test system used for O_2 evolution was an aqueous cerium(IV) sulfate solution in 1 N H_2SO_4[1,3a]. The kinetically inhibited reaction

$$4Ce^{4+} + 2H_2O \rightarrow O_2 + 4Ce^{3+} + 4H^+ \quad (1)$$

is known to be accelerated by dispersed noble metal oxides; $k = 0.3\ h^{-1}$ was observed with 5×10^{-3} mol/l of RuO_2 at room temperature[1b].

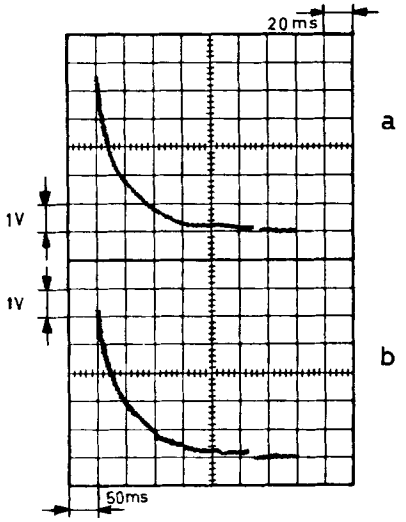

Fig. 1. Autocorrelation function for (a) poly(vinyl alcohol) (PVA, mol. wt. 60000, $\theta = 4.5°$) and (b) ruthenium with PVA as protective colloid. Measuring time 2 ms; data acquisition time 10 minutes; Ru concentration 3.3×10^{-4} mol/l. 1 V on the ordinate is equivalent to 0.2×10^{20} (autocorrelator, resolution 0.1 μm, 64 channels).

The catalytic activity of colloidal Ru in reaction (1) follows from Figure 2. The spectrum of the Ce^{4+} ions is completely transformed into that of Ce^{3+} ions within 4 min. Oxygen is liberated in the course of this process[5]. The differential concentration ratio $-d[Ce^{4+}]/d[O_2]$ falls from an initial high value of about 6 to the calculated value of 4 during the reaction. The physical properties of the colloidal system change during the initial phase of the reaction. The solution becomes pale red ($\lambda_{max} = 460$ nm). According to *Mie*[6] this corresponds to spherical particles having a narrow size distribution centered around 140 Å. Under the conditions of pH and potential required for the oxygen evolution step RuO_2 is the stable oxidation state of Ru[7]. Hence the active form of the catalyst may be considered to be Ru particles covered by a thin layer of RuO_2, the colloid being stabilized by PVA. This accounts for the oxygen deficiency found at the onset of the reaction.

These entities act as microelectrodes: electron transfer to Ce^{4+} ions leads to anodic polarization until the potential of the particle is sufficiently positive for oxygen evolution to occur. The low overvoltage[8] allows the redox process to occur quantitatively and at high speed even though the free energy for reaction (1) is only −200 mV under standard conditions.

The transformation of Ce^{4+} into Ce^{3+} is a first order reaction. The rate constant obtained at a Ru concentration of 1.3×10^{-4} mol/l is $k = 0.5\ min^{-1}$ ($\approx 28\ h^{-1}$). This value is about 100 times higher than that obtained with RuO_2 powder at the same temperature[1b] although in the latter case about 40 times higher concentrations had to be used. A similar increase in activity was observed on evolution of O_2 from $Ru(bpy)_3^{3+}/H_2O$[1b]. These results demonstrate convincingly the advantage of employing colloidal systems as redox catalysts.

The advantage of colloidal catalysts becomes apparent in light-induced H_2-evolution from water. In order to examine the activity of various catalysts we employed a homogeneous test system consisting of an aqueous solution of tris(bipyridine)ruthenium(II) ($Ru(bpy)_3^{2+}$), methylviologen (MV^{2+}), and EDTA (the kinetics and mechanistic details of these light-induced processes have been elaborated previously[3]). In the presence of suitable redox catalysts, MV^+ reduces water according to

$$2MV^+ + 2H_2O \rightarrow 2MV^{2+} + 2OH^- + H_2 \quad (2)$$

Since under standard conditions this process is thermodynamically favorable only by several millivolts, we restricted our choice to materials for which the hydrogen overvoltage is low. The relative efficiencies of the catalysts are seen in Figure 3. Experimental conditions were not optimized with respect to maximum H_2 yields. Once again, the rate increases drastically when the macrodispersions are replaced by colloidal systems. In very recent work we obtained 12 l H_2 per day and per l solution with a colloidal Pt catalyst of very high dispersity[1c].

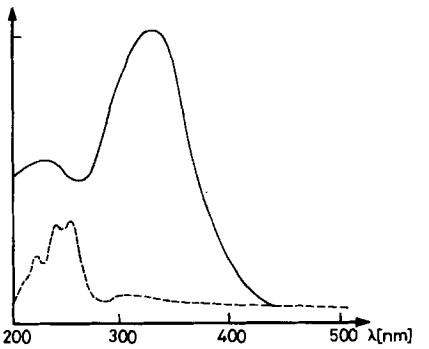

Fig. 2. Absorption spectra of $Ce(SO_4)_2 \cdot 2H_2O$ (8×10^{-3} mol/l) in 1 N H_2SO_4 solutions before (—) and 4 min after (---) addition of colloidal Ru catalyst.

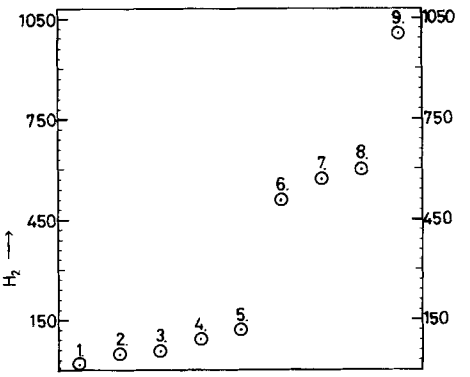

Fig. 3. Evolution of hydrogen in ml per day and per liter of aqueous solution containing 4×10^{-5} mol/l of $Ru(bpy)_3^{2+}$, 2×10^{-3} mol/l of methylviologen (*N,N*-dimethylbipyridine dication) (MV^{2+}), 2.5×10^{-2} mol/l ethylenediaminetetraacetic acid (EDTA). Catalysts: 1, PdO_2 powder; 2, IrO_2 powder; 3, Ru powder; 4, Ru powder, irradiated; all 5×10^{-3} mol/l. 6, colloidal Pd; 7, colloidal Ru (from $RuCl_3$); 8, colloidal Ru (from $(NH_4)_2(Ru_2OCl_{10})$); 9, colloidal Pt; all 1.3×10^{-4} mol/l. pH = 5, $\lambda > 400$ nm (cut off filter), optical pathlength 3.2 cm, hydrogen detected by gas chromatography, irradiation with Osram XBO 450-W lamp.

Experimental

Colloidal Ru: A 2% solution of PVA of mol. wt. 60000 (12.5 g) was dissolved in water (11 ml). To this solution was added $RuCl_3$ (41.4 mg) or $(NH_4)_4[RuOCl_{10}]$ (56 mg) and the pH adjusted to 8 with NaOH. After warming to 100 °C for 30 min the volume was made up to 42 ml and the Ru^{3+} reduced

to the metal by H_2. 3 ml of this stock solution was added to 100 ml of the reaction mixture; this corresponds to 1.4 mg Ru/100 ml or 10^{-4} mol/l.—The production of colloidal Pt and Pd is described in ref. [9].

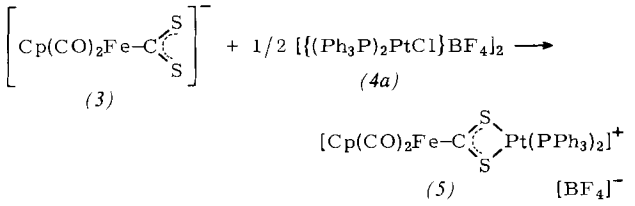
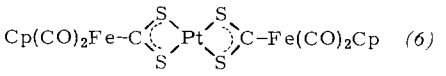
CS_2- and CS_3-Bridged Transition Metal Complexes—Directed Synthesis of Metallodithiocarboxylato-Metal Complexes[**]



By *Wolf Peter Fehlhammer, Andreas Mayr,* and *Heribert Stolzenberg*[*]

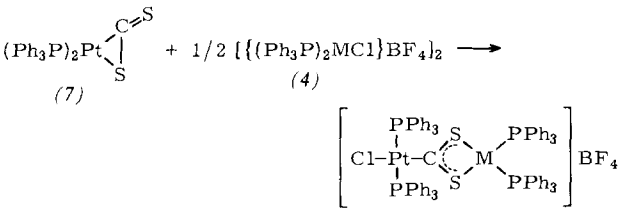
In 1975 the preparation and X-ray characterization[1] of a dinuclear CS_2-bridged platinum complex was reported combining the structural features of a dithiocarbenemetal *(1)* and a metal *S,S'*-dithiolate *(2)*. Attempts to prepare other compounds having the same interesting kind of linkage proved unsuccessful.



(1) *(2)*

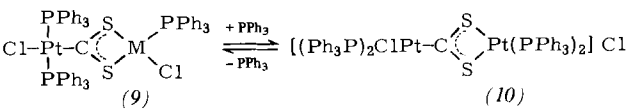
Studies on the *basic metal/heteroallene/acid* or *Lewis acid metal* system[2] have now enabled us to prepare a series of such stable dinuclear and trinuclear "metallodithiocarboxylato-metal complexes". The adduct[3] obtained from carbon disulfide and sodium dicarbonyl(cyclopentadienyl)ferrate

(3) *(4a)* *(5)*



reacts with *(4a)* in tetrahydrofuran (THF) to give the CS_2-bridged dinuclear complex *(5)*. A platinum complex *(6)* having two of the same "ferriodithiocarboxylatochelate ligands" can be obtained as red crystals on reaction of *(3)* with $PtCl_2$ in the molar ratio 2:1.

(6)



IR spectra [(KBr) *(5):* 2042, 1998 vs [ν(CO)], 870 s [$\nu(CS_2)$]; *(6):* 2028, 1973 vs [ν(CO)], 870 s [$\nu(CS_2)$] cm^{-1}], elemental analysis, molecular weight determination, and synthesis support the proposed structures[3].

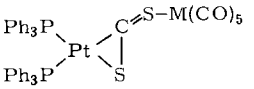
Another electron-rich adduct which, like *(3)*, should be able to react with electrophilic metal compounds is η^2-(carbon disulfide)bis(triphenylphosphane)platinum *(7)* described in 1966 by *Wilkinson et al.*[4]. Indeed, its reaction in dichloromethane with the chlorine bridged complex cation *(4a)* immediately and quantitatively leads to *Angelici's* complex *(8a)* which was formed in an *unexplained* manner on decomposition of $[(Ph_3P)_2Pt(Cl)(CS)]BF_4$[1]. The tendency of formation of the *hetero*metallic dinuclear complex *(8b)*, on the other hand, is much less pronounced.

(7) *(4)* *(8a)*, M = Pt; *(8b)*, M = Pd

Prolonged times are also required for reactions of $(Ph_3P)_2Pt(CS_2)$ with neutral dichlorobis(triphenylphosphane)nickel(II), -palladium(II), and -platinum(II); the nickel and palladium compounds exclusively giving respectively the red-brown and orange neutral complexes *(9)*, whereas *cis*-$(Ph_3P)_2PtCl_2$ also gives rise to the yellow cationic complex *(10)* which in solution readily eliminates triphenylphosphane to form *(9)* with M = Pt.

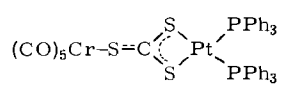
(9) *(10)*

A remarkably constant band pattern (*ca.* 930 s, 870 m [ν_{as}, $\nu_s(CS_2)$] cm^{-1}), which seems to be characteristic of the Pt CS_2M group, is found in the IR spectra of the complexes *(8)*—*(10)*.



The ^{31}P-NMR spectra prove the *trans* configuration at the *C*-bonded platinum and the equivalence of the *cis*-triphenylphosphane ligands on the chelated metal in *(8)* and *(10)*, which in turn provides evidence for the equivalent nature of the two *S* ligands in *trans* position.

We suspect the first step of formation of these platiniothiocarboxylato complexes to consist in coordination of the electropositive metal to the "exo-sulfur atom" of *(7)*, which is followed by intra- or intermolecular halogen transfer between the metals with concomitant opening of the PtCS three-membered ring and chelatization at the entering metal.



In the absence of mobile halogen ligands in the Lewis acid metal component the reaction with *(7)* ceases at the stage of primary coordination. The complexes *(11)* obtained in high

[**] Isocyanide- and Heteroallene-Bridged Metal Complexes, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 1: [2b].

(11), M = Cr, W

(12)

yield from (7) and $M(CO)_5THF$ (M = Cr, W) apparently contain the same kind of CS_2 bridge as considered for the known compounds
$Cp(CO)_2Mn(SCS)Mn(CO)_2Cp$[5],
$(R_3P)_2(CO)_2Fe(SCS)Mn(CO)_2Cp$[6],
and $Cp(Me_3P)_2Co(SCS)Cr(CO)_5$[7].

A variant of the *basic metal/CS_2* interaction is found in the reaction of $Na_2Cr(CO)_5$ with CS_2 and $(Ph_3P)_2PtCl_2$. The compound isolated as yellow crystals (37% yield) on work-up is not an isomer of (11) as would be expected from the method of preparation. Instead it contains more sulfur and is to be formulated as the trithiocarbonate-bridged species (12) (IR (KBr): 1040 m [$\nu(CS_3)$] cm^{-1}). CS_3 bridge formation has also been observed on reaction of pentacarbonylmanganate(−I) and -rhenate(−I) with CS_2[8].

Experimental

CS_2 (0.15 ml, 2.5 mmol) in THF (50 ml), and then $[(Ph_3P)_2PtCl]_2(BF_4)_2$[9] (2.1 g, 1.25 mmol), are added to a 0.1 M solution of $Na[CpFe(CO)_2]$ in THF (25 ml) [prepared from $[CpFe(CO)_2]_2$ (3.54 g) and $NaK_{2.8}$ (1.35 ml) in THF (200 ml)] at −70 °C under N_2. A clear light-orange solution arises on warming to 0 °C. The solvent is evaporated at this temperature, the residue dissolved in dichloromethane (*ca.* 50 ml), and the solution filtered through cellulose. After concentration of the filtrate to half the volume, the product crystallizes on addition of *n*-pentane. The yellow platelets of (5) (yield 76%, dec. pt. 170 °C) can be stored indefinitely at −20 °C.

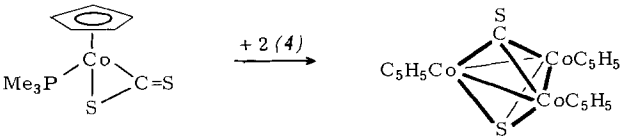
$(C_5H_5)_3Co_3(CS)(S)$; The First Complex to Have a μ_3-Thiocarbonyl Bridge[1]

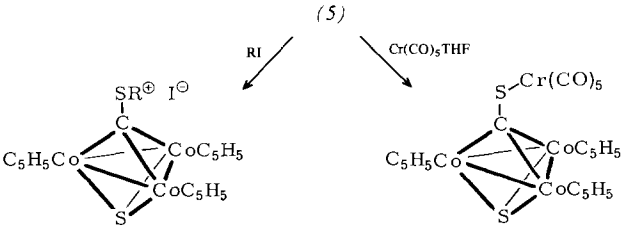
By *Helmut Werner* and *Konrad Leonhard*[*]



The complex $C_5H_5(PMe_3)Co(\eta^2\text{-}CS_2)$ (1) readily obtained from $C_5H_5Co(PMe_3)_2$ and CS_2 reacts with the tetrahydrofuran (THF) adducts $Cr(CO)_5THF$ and $C_5H_5Mn(CO)_2THF$ to give the dinuclear complexes $C_5H_5(PMe_3)Co(SCS)Cr(CO)_5$ (2) and $C_5H_5(PMe_3)Co(SCS)Mn(CO)_2C_5H_5$ (3) in which the CS_2 ligand bridges two different metal atoms[2]. The carbon disulfide moiety of (2) and (3) is rigidly fixed [as in (A)], *i.e.* isomerization according to

(A) (B)

is not detectable.



We expected a *non-rigid* structure (*i.e.* a flexible CS_2 bridge) for the analogous *symmetrical* dinuclear complex having $ML_n = Co(PMe_3)C_5H_5$. *Herberhold et al.*[3] observed a flexibility of this kind in $C_5H_5(CO)_2Mn(SCS)Mn(CO)_2C_5H_5$ which is completely frozen in at low temperature (210 K). However, reaction of (1) with $C_5H_5(PMe_3)Co(\mu\text{-}CO)_2Mn(CO)C_5H_4Me$ (4), which we used as a source for the 16-electron fragment $C_5H_5CoPMe_3$[4], followed a completely different course. Instead of the expected product $C_5H_5(PMe_3)Co(SCS)Co(PMe_3)C_5H_5$ we obtained the trinuclear complex $(C_5H_5)_3Co_3(CS)(S)$ (5) as black crystals that are only slightly air-sensitive. On reaction of (1) and (4) in a molar ratio of 1:2, compound (5) is isolated in *ca.* 80% yield.

(1) (5)

Crystal structure analysis[5] shows that the three cobalt atoms form an equilateral triangle with the two bridging ligands located above and below its midpoint. An analogous trigonal-bipyramidal arrangement of the skeletal atoms occurs in the complexes $(C_5H_5)_3Co_3(CO)(O)$[6] and $(C_5H_5)_3Co_3(CO)(S)$[7], which are obtained in very low yield by photolysis of $C_5H_5Co(CO)_2$ and by reaction of $C_5H_5Co(CO)_2$ with $S(N\text{-}tBu)_2$, respectively.

(5) behaves as a Lewis base and reacts smoothly with methyl and ethyl iodide and with $Cr(CO)_5THF$ to give the complexes (6)—(8). The sulfur atom of the CS bridge is apparently the site of maximum nucleophilicity, in accord with the results of X-ray crystal structure analysis (relatively long C S distance[5]).

(6), R = Me
(7), R = Et

(8)

A notable feature of the synthesis of (5) is the ease with which the carbon disulfide coordinated very strongly in (1) is cleaved to CS and S. Numerous carbon monosulfide (or thiocarbonyl) complexes having terminal CS ligands are known[8], and several dinuclear compounds of manganese,

[*] Prof. Dr. H. Werner, Dr. K. Leonhard
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

iron, and ruthenium containing bridging μ_2-CS groups have recently also been described[9]. To our knowledge, *(5)* is the first complex in which carbon monosulfide links *three* metal atoms together, and thus represents an example of the hitherto missing last member of the series $L_nM{-}CS$, $L_nM_2(\mu_2\text{-CS})$, $L_nM_3(\mu_3\text{-CS})$ established over 20 years ago in the case of the CO ligand.

Table 1. Spectroscopic data of complexes *(5)*—*(8)*.

(5): ^{1}H-NMR ([D$_6$]-benzene): $\delta = 4.50$ (s). IR (KBr): 1075 (s), 1039 (s) cm^{-1} (region expected for μ_3-C–S stretching vibrations). MS: $m/e = 448$ (M^+ with correct isotopic satellites).

(6): ^{1}H-NMR ([D$_3$]-nitromethane): $\delta = 5.11$ (15H; s), 3.89 (3H; s). IR (KBr): 1008 (s), 997 (s) cm^{-1}.

(7): ^{1}H-NMR ([D$_3$]-nitromethane): $\delta = 5.16$ (15H; s), 4.45 (2H; q, $J_{HH} = 7$ Hz), 1.95 (3H; t, $J_{HH} = 7$ Hz).

(8): ^{1}H-NMR ([D$_6$]-acetone): $\delta = 4.95$ (s). IR (THF): ν(CO) = 2050, 1970 (sh), 1925, 1895 cm^{-1}.

Experimental

A solution of *(1)* (330 mg, 1.2 mmol) and *(4)* (1 g, 2.4 mmol) in benzene (15 ml) is heated under gentle reflux for 5 h. A first crop of *(5)* crystallizes on cooling. The solvent is stripped off completely under vacuum, the residue washed several times with hexane, and recrystallized from THF/hexane. *(5)*, black crystals, dec. pt. = 289 °C; yield 450 mg.

$[\{Cu_3WS_3Cl\}(PPh_3)_3O]$, Directed Synthesis of a Compound Containing Different Metal Atoms in a Cubane-like Skeleton

By *Achim Müller, Theng Khing Hwang*, and *Hartmut Bögge*[*]

Synthetic approaches for the linking of different metals *via* sulfur in cluster structures are of special importance in current studies on polynuclear transition metal-sulfur complexes[1,2]. We are presently investigating the directed synthesis of compounds of this type with thiometalates such as MoS_4^{2-} and WS_4^{2-}. Polynuclear Cu^I-cage and -cluster compounds are of particular interest as regards structural variancy. However, although compounds with, *inter alia*, the central moieties $\{Cu_4S_4\}$ (ring structure), $\{Cu_4S_6\}$ (adamantane structure), and $\{Cu_8S_{12}\}$ (Cu_8 cube) are well-known[3] all attempts to synthesize cubane-like variants—including those containing other metals besides Cu^I—have so far failed.

We have now been able to synthesize yellow, crystalline $[\{Cu_3WS_3Cl\}(P(C_6H_5)_3)_3O]$ *(1)* having a cubane-like $\{CuWS_3Cl\}$ core and to characterize it by elemental analysis, IR spectroscopy, and a complete crystal structure analysis.

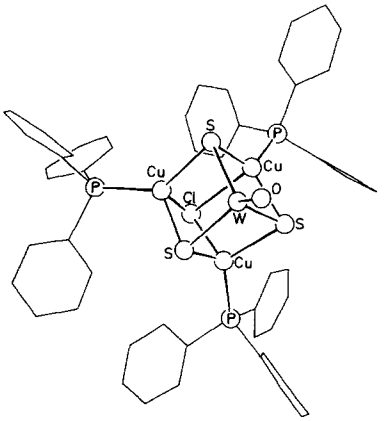

Fig. 1. Molecular structure of *(1)* in the crystalline state.

The structure of *(1)* was determined from single-crystal diffractometer data (Syntex $P2_1$, MoK_α radiation, 5349 independent reflections, $R = 0.088$). The compound crystallizes in the orthorhombic space group $P2_12_12_1$ ($a = 12.825(2)$, $b = 17.529(4)$, $c = 22.711(4)$ Å, $V = 5105.5$ Å^3; $\rho_{calc} = 1.70$ g cm^{-3}; $Z = 4$). The central unit corresponds to a highly distorted cube (average W–S, Cu–S, Cu–Cl distances 2.241, 2.315 and 2.610 Å, respectively). W and Cu are in a tetrahedral and a strongly distorted tetrahedral environment (with O and PPh_3 as terminal ligands, and W–O and average Cu–P bond lengths of 1.752(14) and 2.202 Å, respectively). The metal atoms form a distorted tetrahedral Cu_3W central unit[4].

The significance of metal-metal interaction in *homotetranuclear* clusters having a cubane structure has already been demonstrated[5]. The IR spectrum (solid, Nujol) also clearly indicates the presence of three W–S bridge bonds and a terminal W–O bond [ν(WO) = 929, ν(WS) = 436/432 cm^{-1}, cf. Ref.[6]].

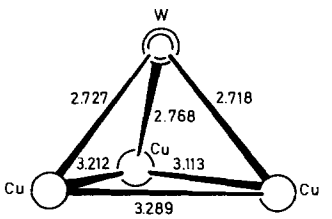

Fig. 2. Central Cu_3W unit in *(1)*.

(1) could be obtained by the first directed synthesis of a cubane unit starting from a partly formed cage: the formation of a compound with a cubane-like structure was to be expected on using the synthon OWS_3^{2-} (preferred formation of Cu–S over Cu–O bonds, preferred triple-bonding of S[1]).

Procedure

Solutions of $CuCl_2 \cdot 2H_2O$ (0.17 g) in H_2O (5 ml) and $(C_6H_5)_3P$ (0.4 g) in CH_2Cl_2 (25 ml) are mixed by vigorous stirring and treated with a freshly prepared solution of

Cs_2WOS_3 (0.35 g) in H_2O (100 ml). After briefly shaking, the aqueous phase is separated off and the organic phase is covered with a mixture of *n*-pentane (50 ml) and acetone (10 ml). After *ca.* 3—4 d orange-yellow crystals of *(1)* separate out (yield 0.05 g).

Existence and Bond Energy of the Cesium Auride Molecule

By *Bernd Busse* and *Konrad G. Weil*[*]

As prototypes of the metal-metal bond, isolated dimeric and oligomeric metallic species are investigated primarily by matrix isolation techniques[1]. This method, however, has the disadvantage that the properties of the species investigated can be strongly influenced in an, as yet, unclear manner by interaction with the matrix material. Mass spectrometry of metal vapors permits observation of not only the metal atoms but also dimers and oligomers. Investigations on binary systems can thus afford valuable information on the existence and properties of heterometallic molecules. We have therefore started a series of studies on systems in which there is a large difference in electronegativity of the metal partners—in anticipation of finding molecules having predictable bonding character in such systems.

As the phase diagram of cesium-gold[2] shows, this system forms an intermetallic compound with a 1:1 composition which crystallizes with a CsCl-type structure and has a melting point of 590 °C. In the liquid state it exists as a purely ionicmelt[3]. A stable molecule CsAu can be expected to exist in the vapor phase. In our experiments we used a MM 30 K mass spectrometer (VG-Micromass) especially developed for investigations by the Knudsen method (collector system with conversion dynodes, no mass discrimination). The ionization was achieved by electron impact. For preparation of the intermetallic compound stoichiometric amounts of the components—pure cesium, packed and stored under high vacuum (Merck), and pure gold (Degussa), cut into small pieces—were weighed under pure argon into a molybdenum Knudsen cell. The cell, sealed by a screw-top lid, was heated briefly in an evacuated oven at the melting temperature of gold and then annealed for 5—6 h at 700 °C. After cooling, an effusion orifice in the cell was rapidly opened in a stream of argon and the cell then directly attached to the mass spectrometer.

The mass spectrum obtained at 60 eV and 70 μA showed in addition to Cs^+, Cs^{2+}, and Au^+ a distinct signal for $CsAu^+$. In the temperature range 1200—1500 K the intensity of the signal at $m/e = 330$ is weaker by a factor of about 10^3 than that of the Cs^+ signal. Figure 1 shows plots of the ionization curves of $CsAu^+$ and Au^+ obtained at a Knudsen cell temperature of 1490 K.

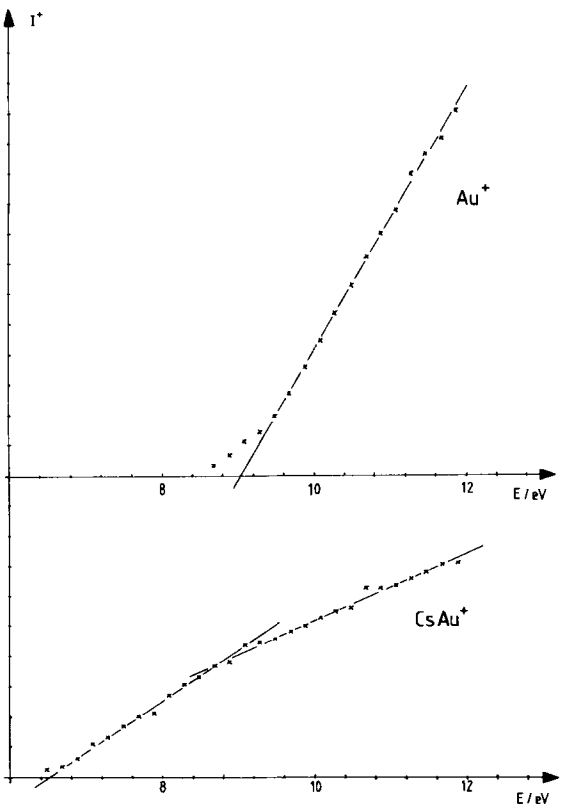

Fig. 1. Ionization curves of $CsAu^+$ and Au^+. Ion current in arbitrary units.

Extrapolation of the curves gave appearance potentials of 6.6 ± 0.3 eV for $CsAu^+$ and 9.0 ± 0.3 eV for Au^+. As a rule of thumb, an appearance potential near to the mean value of the ionization potentials of its atoms can be expected for molecules without free valence electrons. For Cs and Au this leads to 6.55 eV. The experimental value for Au^+ agrees within the limits of error with the ionization potential of Au (9.22 eV).

A decrease in the slope of the ionization curve of $CsAu^+$ at 8.7 eV can be interpreted in terms of the fragmentation process

$$CsAu + e^- \rightarrow Cs^+ + Au + 2e^-; \quad \Delta E^* = 8.7 \pm 0.3 \text{ eV}$$

A corresponding increase in the slope of the ionization curve of Cs^+ is not observable since the differences in intensity of the two reaction channels for formation of Cs^+ are too great.

Conclusions on the bond energy of the molecule can be drawn from the fragmentation energy if the ionization potentials of the fragment ions are known and if it can be assumed that the fragmentation products are formed without additional kinetic energy.

Institut für Physikalische Chemie der Technischen Hochschule
Petersenstrasse 20, D-6100 Darmstadt (Germany)

Thus, from a thermodynamic cycle we obtain for the bond energy

$$D(\mathrm{CsAu}) = \Delta E^* - I(\mathrm{Cs}) = 8.7\ \mathrm{eV} - 4.0\ \mathrm{eV} = 4.7\ \mathrm{eV}$$
$$\approx 460 \pm 30\ \mathrm{kJ/mol}$$

At first sight this value appears astonishingly high; however, it is consistent with the expected formation of an ionic bond due to the difference in electronegativities of gold and cesium. Calculation of the bond energy from the electronegativities and known dissociation energies of the dimers Cs_2 and Au_2 according to *Pauling*[4] gives a value of 430 kJ/mol. Also interesting is a comparison with the isostructural CsCl, for which the value $D(\mathrm{CsCl}) = 444$ kJ/mol was found[5].

Our findings clearly indicate that the stability of the cesium auride molecule is essentially determined by ionic bonding, with cesium acting as the donor and gold as the acceptor.

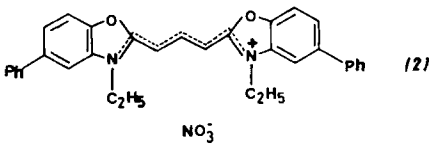
Complexes of Nitrogen-Containing Crown Ether Surfactants with Stable Silver Atoms[**]

By *Robin Humphry-Baker, Michael Grätzel, Pietro Tundo,* and *Ezio Pelizzetti*[*]

Nitrogenous crown ethers bearing long alkyl chains as substituents, such as *(1)*, are surfactants, form micelles, and complex cations[1,3]. We have now succeeded in reducing the complex *(1)*·Ag^+ photochemically and thermally to *(1)*·Ag^0. The complexed silver atoms do not aggregate to form clusters or crystalline silver.



(1)·Ag^+

(1)·Ag^0

The complex *(1)*·Ag^+ is formed spontaneously on treatment of 2-tetradecyl-1,4,10,13-tetraoxa-7,16-diazacyclooctadecane *(1)* (see ref. [2] for synthesis) with equimolar amounts of $AgNO_3$. The binding constant of Ag^+ ion with the crown ether containing no alkyl side chain has been reported[3] to be $\approx 7 \times 10^7$. Since alkyl substitution is not expected to change this value significantly, it may safely be assumed that practically all the Ag^+ ions are in the complexed state. All the experiments were carried out at concentrations above the CMC of *(1)*·Ag^+, *i.e.* 3.3×10^{-4} mol/l. The molecular weight of the relatively large micellar aggregates (6.3×10^6) was determined by quasielastic light scattering.

In the photochemical reduction of Ag^+ in *(1)*·Ag^+, the cyanine dye *(2)* was used as a sensitizer. This dye absorbs in

(2)

the visible region[4] ($\lambda_{max} = 500$ nm) and due to its hydrophobic nature is expected to associate quantitatively with *(1)*·Ag. In solutions of simple micelles such as sodium laurylsulfate *(2)* displays a strong fluorescence ($\phi_F = 0.45$). This emission is totally quenched ($\phi_F < 10^{-6}$) in micellar solutions of *(1)*·Ag^+. On illumination with visible light, rapid bleaching of the cyanine and formation of a new stable absorption band with a maximum at $\lambda = 415$ nm is observed (Fig. 1). The hydrophobic species produced is hence readily extracted into a chloroform solution ($\lambda_{max} = 410$ nm; Fig. 1).

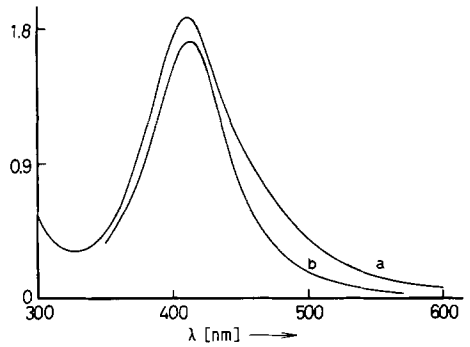


Fig. 1. Absorption spectra of *(1)*·Ag^0 (a) 8.5×10^{-4} M in $CHCl_3$ and (b) 8.5×10^{-4} M in H_2O.

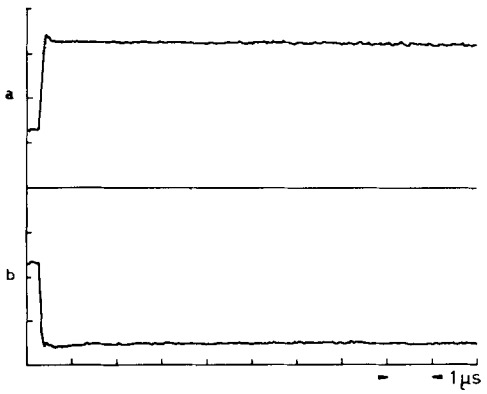

Fig. 2. Transient traces recorded on laser excitation (532 nm) of 1.0×10^{-6} mol/l of *(2)* in *(1)*·Ag^+ micelles. (a) Absorption of *(1)*·Ag^0 (415 nm) and (b) bleaching of the ground-state absorption of *(2)* (500 nm).

The dynamics of the photoreaction of *(2)* with *(1)*·Ag^+ were examined by laser photolysis. A 15 ns pulse of a Q-switched Nd-laser was used to excite the cyanine and resulting changes in the absorbance of the solution were monitored by kinetic spectroscopy (Fig. 2). An irreversible bleach-

ing is observed at 500 nm, while at 415 nm a stable absorption is produced. These events are so fast that they both occur within the duration of the laser pulse. The end-of-pulse spectrum is identical with that observed after steady-state illumination.

These observations are rationalized in terms of the one-electron reduction of the complexed silver ion according to:

$$(2)^* + Ag^+ \rightarrow Ag^0 + \text{products} \qquad (1)$$

where *(2)** stands for the excited cyanine dye. The spectrum in Figure 1 is attributed to silver atoms stabilized by the macrocyclic ligand *(1)*. This may be compared with the absorption of single silver atoms (matrix isolation spectroscopy)[5]. It appears that in our system Ag^0 is prevented from aggregation through insertion in the crown ether cavity.

Photoinduced reduction of Ag^+ can also be performed with a number of other donor chromophores, such as porphyrins, $Ru(bpy)_3^{2+}$, and pyrene[6]. In all those cases no back reaction between oxidized donor and Ag^0 is observed. Apparently, the donor cation is ejected from the positively charged aggregates by electrostatic interactions before back transfer of electrons can take place[7]. Once in the aqueous phase, re-entry of the donor cation into the micelle is prevented by the repulsive surface charge. We conclude that in the photoinduced reduction of Ag^+ to silver atoms the functional macrocyclic ligand *(1)* serves three important purposes: i) by permitting high local concentration of acceptor Ag^+ it drastically accelerates the forward rate—and hence the yield—of reaction (1); ii) it stabilizes the silver atoms; and iii) it prevents back transfer of electrons by means of a microscopic electrostatic barrier (lipid/water interface).

Quantitative conversion of *(1)*·Ag^+ into *(1)*·Ag^0 can be achieved, for example, by using $NaBH_4$ as a reductant. The spectrum of the product obtained is identical with that shown in Figure 1. The *(1)*·Ag^0 complex has reducing properties and is quantitatively reoxidized to *(1)*·Ag^+ by acceptors such as Cu^{2+} and $Fe(CN)_6^{3-}$.

The redox processes may be accomplished electrochemically. A reversible cathodic wave with a half-wave potential around 0.1 V (NHE) is observed[8]. Controlled potential electrolysis at −0.5 V produces a species with an absorption spectrum identical with that presented in Figure 1.

It is interesting to note that the standard potential $E^0(Ag^+/Ag^0)$ calculated from the silver electrode potential and the Ag sublimation energy is −1.25 V. A binding constant of 10^{21} would thence be calculated for complexation of Ag atoms by the macrocyclic ligand *(1)*. It is probably a consequence of the considerable increase in size on going from Ag^+ to Ag^0 that the stability of the complex increases in such a drastic manner.

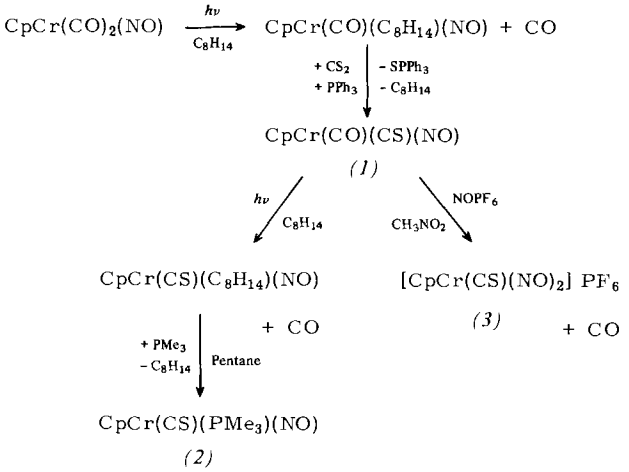
η^5-Cyclopentadienylchromium Complexes with Thiocarbonyl and Nitrosyl Ligands[**]



By *Max Herberhold* and *Paul D. Smith*[*]

Comparison of the acceptor properties of diatomic ligands (L = CO, CS, NO) requires the availability of model complexes containing different ligand combinations. We now report the new chromium complexes *(1)*—*(3)* containing the rare combination CS/NO hitherto found only in cations[1].

(1) *(2)* *(3)*

Incorporation of a CS ligand into the parent complex $CpCr(CO)_2(NO)$ can be accomplished by a method previously developed[2a] for the isosteric compound $CpMn(CO)_3$ which involves reaction of the *cis*-cyclooctene derivative $CpCr(CO)(C_8H_{14})(NO)$[3] with both CS_2 and a sulfur atom acceptor such as PPh_3. No carbon disulfide intermediate "$CpCr(CO)(CS_2)(NO)$" could be detected although a labile $CpMn(CO)_2(CS_2)$ complex is known[2].

The CO ligand remaining in *(1)* is more firmly bonded than that in the cation $[CpMn(CO)(CS)(NO)]^+$[1b] but can be replaced photolytically by two-electron ligands such as cyclooctene or by the nitrosyl cation ($L = NO^+$). Table 1 lists some spectroscopic data of the thiocarbonyl complexes *(1)*—*(3)* and of the corresponding carbonyl complexes. As a general rule, the stretching frequencies [ν(CO), ν(CS), ν(NO)] increase and the NMR signals of the cyclopentadienyl protons [δ(Cp)] are shifted downfield as the electron deficit on the metal increases.

Both the ν(NO) and $\delta(C_5H_5)$ values indicate that the thiocarbonyl group (L = CS) is a much more effective acceptor ligand than the carbonyl group (L = CO) in the neutral complexes CpCr(CO)(L)(NO). The thionitrosyl group in $CpCr(CO)_2(NS)$[4] is also superior as an acceptor to the nitro-

[e] The ν(CS) absorption in nitromethane solution appears at 1258 and 1221 cm^{-1} for *(1)* and *(2)*; ν(CS) for *(3)* could not be observed in the 1620—1340 cm^{-1} region because of the strong absorption of the solvent. [f] Stretching force constants [N/cm] according to *F. A. Cotton, C. S. Kraihanzel*, J. Am. Chem. Soc. *84*, 4432 (1962). [g] Doublet, J(P,H) = 2.45 Hz. [h] Doublet, J(P,H) = 2.1 Hz.

syl group in $CpCr(CO)_2(NO)$, even though the difference is only slight. In the cations $[CpCr(L)(NO)_2]^+$ (L = CO, CS), on the other hand, spectroscopic criteria show CO to be the better acceptor ligand. These results are in accord with a rule first stated by *Andrews*[5] which stipulates that the ratio of the π-acceptor to the $(\sigma+\pi)$-donor behavior, *i.e.* the acceptor capacity of the CS ligand in thiocarbonyl complexes of the $M(CO)_n(CS)$ type, exceeds that of the CO ligand only if the Cotton-Kraihanzel force constant k(CO) of the corresponding carbonyl complex $M(CO)_{n+1}$ lies below *ca.* 17.1 N/cm^{-1}.

Experimental[6]

Photolysis of a solution of $CpCr(CO)_2(NO)$[7] (*ca.* 1 g, 4.9 mmol) in *cis*-cyclooctene (250 ml) for 2 h proceeds with elimination of CO to form $CpCr(CO)(C_8H_{14})(NO)$[3]. The solvent is stripped off and the complex is dried for 2 h at 35 °C *in vacuo*. The dry olefin complex is then treated with triphenylphosphane (*ca.* 1.3 g, 5 mmol) and CS_2 (30 ml); once the IR spectrum of the green solution indicates completion of reaction after *ca.* 60 h, the CS_2 is stripped off. Purification is accomplished by filtration of *(1)*, first in benzene/pentane (1:5) and then in pure pentane, over a G3 frit covered with a layer of silica gel/pentane. *(1)* is finally crystallized from pentane (50 ml) at −78 °C. Yield *ca.* 0.43 g (40%) of green crystals, m.p. 42 °C (under argon).

A solution of *(1)* (0.175 g, 0.80 mmol) in *cis*-cyclooctene (200 ml) is irradiated for 1 h and then evaporated to dryness (0.1 torr, 25 °C). The residue is stirred for 24 h with pentane (50 ml) and trimethylphosphane (1 ml). After removal of the pentane and the PMe_3, the residue is taken up in benzene and filtered over a G3 frit covered with a layer of silica gel/pentane. The green complex *(2)* crystallizes from pentane (−78 °C). Yield 0.1 g (50%), m.p. 101 °C (under argon).

To a solution of *(1)* (0.19 g, 0.87 mmol) in nitromethane (30 ml) is added dropwise a solution of $NOPF_6$ (0.15 g, 0.87 mmol) in nitromethane (4 ml) at −25 °C (evolution of gas and change in color). After filtration (filter flocks) into cold ether (150 ml) the resulting precipitate of olive green *(3)* is washed once again with cold ether and with pentane, and dried at −30 °C. Yield 0.20 g (63%), dec. (in a sealed tube under Ar) 125 °C with liberation of gas.

Reaction of α-Lithioacetic Acid Esters with Succinic Anhydrides

By *Franz-Peter Montforts* and *Silvio Ofner*[*]

β-Ketoadipic acid esters have been prepared in relatively low overall yields as intermediates for the synthesis of natural products in multistep reaction sequences involving tedious purification operations *via* malonic ester and acetic ester syntheses[1]. We have now found that succinic anhydride *(1)* reacts with α-lithioacetic acid esters *(2)* in a single reaction step to give the corresponding readily crystallizing β-ketoadipic acid monoesters:

(1a), R^1 = H *(2a)*, R^2 = $CH_2C_6H_5$
(1b), R^1 = CH_3 *(2b)*, R^2 = $C(CH_3)_3$

(3) *(4)*

(3a)=*(4a)* : R^1=R^3=H, R^2= $CH_2C_6H_5$
(3b)=*(4b)* : R^1=R^3=H, R^2= $C(CH_3)_3$
(3c)≠*(4c)* : R^1=R^3=CH_3, R^2= $C(CH_3)_3$

Starting cpds.	Products	Product ratio	Yield [%]
(1a) + *(2a)*	*(3a)* = *(4a)*	—	62
(1a) + *(2b)*	*(3b)* = *(4b)*	—	78
(1b) + *(2b)*	*(3c)* + *(4c)*	71:29 [a]	96 [b]

[a] The isomeric esters *(3c)* and *(4c)* were identified by their 270-MHz ^{1}H-NMR spectra ($CDCl_3$/TMS) as well as by trifluoroacetic acid degradation affording (preparative gas chromatography) methyl 3,3-dimethyl-4-oxopentanoate *(5a)* and methyl 2,2-dimethyl-4-oxopentanoate *(5b)*. The product ratio was determined by GC analysis of the methyl esters *(3c)* and *(4c)* on 5% OV 210 Chromosorb W-AW-DMCS 80—100 (60 ml N_2/min) and ^{1}H-NMR spectroscopically. [b] After esterification with diazomethane and bulb-to-bulb distillation of the mixture of diesters.

The geminally dimethylated anhydride *(1b)* reacts preferably at the higher substituted carbonyl function. This finding is consistent with experiments on the reduction of geminally

disubstituted succinic anhydrides and succinimides[2] and can be explained in terms of *Bürgi*'s and *Dunitz*'s hypothesis[3], according to which the angle of nucleophilic attack at the carbonyl group is greater than 90°, thereby favoring reaction path *B* over *A* (cf. Fig. 1).

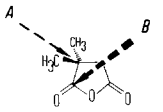

Fig. 1. Possible reaction paths for nucleophilic attack at the carbonyl group of geminally dimethylated succinic anhydride *(1b)*.

To our knowledge this is the first example of regioselective addition of a carbon nucleophile in such a system where there are two possible modes of attack.

Procedure

A solution of *n*-butyllithium (43.5 ml, 0.100 mol) in hexane (2.3 M) is added dropwise (within 30 min) at 0 °C under argon to a stirred solution of hexamethyldisilazane (21.3 ml, 0.102 mol) in anhydrous tetrahydrofuran (40 ml). After cooling to −78 °C, 0.101 mol of the ester *(2a)* or *(2b)* is added within 15 min to the solution and stirring continued for a further 45 min. To the resulting α-lithioacetic ester solution is added dropwise over 20 min a solution of the anhydride *(1a)* or *(1b)* (0.05 mol) in tetrahydrofuran (60 ml). The mixture is stirred for 2.5 h in a methanol/dry-ice bath while the temperature is allowed to increase to −20 °C. After treatment with 8 ml conc. hydrochloric acid and 50 ml water, it is then concentrated by evaporation in a rotary evaporator. The neutral solution is adjusted to pH 2 with conc. hydrochloric acid and extracted with ether (5 × 50 ml). The combined extracts are dried over sodium sulfate and the solvent removed in a rotary evaporator. The β-ketoadipic acid esters *(3a)* and *(3b)* crystallize from ether/hexane. The products obtained on reaction of *(1b)* with *(2b)* are esterified with ethereal diazomethane solution in the usual way and the esters *(3c)* and *(4c)* are purified by bulb-to-bulb distillation.

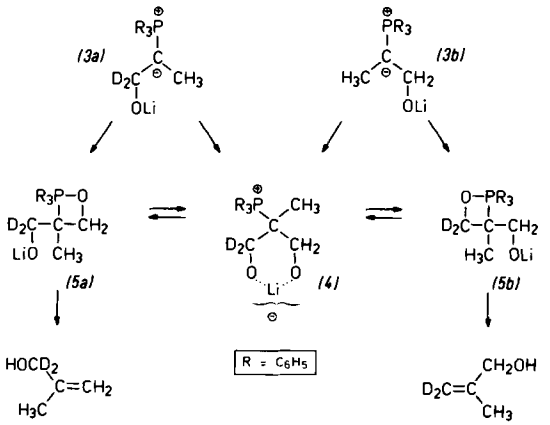
New Evidence for Zwitterionic Intermediates in the Wittig Reaction[**]

By *Manfred Schlosser* and *Huynh Ba Tuong*[*]



Dedicated to Professor André S. Dreiding on the occasion of his 60th birthday

For a long time open-chain "P-betaïnes" *(1)* were considered the decisive and momentarily stable intermediates of the Wittig reaction[1], whereas the four-membered heterocyclic oxaphosphetanes *(2)* were regarded as high-energy species too short-lived for detection. After low temperature NMR studies had revealed the presence of—fairly stable—oxaphosphetanes rather than the expected betaines[2], a new hypothesis emerged claiming that oxaphosphetanes would always form directly from the components, ylid and aldehyde, bypassing a zwitterionic precursor[2].

This simplification of the reaction mechanism has, however, one great drawback: the postulated[2] $[2_s+2_a]$-cycloaddition does not unequivocally account for the *cis*-stereoselectivity[3] of the Wittig reaction in "salt-free media" nor in any way explain the salt effect[3] on the stereochemistry and reaction rate. Therefore, we support the original view that adduct formation proceeds *via* a betaine-like transition state and that an equilibrium is rapidly established between the betaines *(1)* and the—generally but not always—more stable oxaphosphetanes *(2)*. Electrophilic reagents such as lithium iodide[4], formaldehyde[5], and triphenylborane[5] trap betaïnes from the equilibrium. We have now obtained further evidence for the fast and reversible transition between oxaphosphetanes and betaines by means of isotopic labeling.

A solution of salt-free triphenylphosphonioethylid in tetrahydrofuran was treated at −75 °C consecutively with formaldehyde solution[6] and *sec*-butyllithium. Dideuterioformaldehyde was then added to the resulting "betaine-ylid" *(3b)*. After subsequent addition of potassium *tert*-butoxide and warming to 25 °C, 2-methylallyl alcohol could be separated in 80% yield, being doubly deuteriated equally at the carbon adjacent to oxygen or at the terminal olefinic carbon (NMR results). The same product mixture was formed when deuterium-free formaldehyde was added to the deuteriated betaine-ylid *(3a)*.

The ^{31}P-NMR spectrum of the adduct formed from the zwitterion *(3)* and formaldehyde shows a major signal at $\delta = -55$ (accompanied by a weaker signal at $\delta = -51$, rel. to

85% H_3PO_4), compatible with an oxaphosphetane structure *(5)*. The question remains whether this intermediate is formed directly on combining the reaction partners or whether it is formed indirectly *via* a betaine precursor, formulated as the chelate *(4)*. In either respect, the two species (*(4)* and *(5a)/(5b)*) must be in an equilibrium with each other, which apparently is very mobile even at $-80\,^{\circ}C$. For, on addition of acetyl chloride, which reacts spontaneously with lithium alkoxides at $-80\,^{\circ}C$, to the betaine-ylid/formaldehyde adduct, we obtained 2-methylallyl acetate in which once again both types of methylene groups were isotopically labeled in equal distribution.

The reaction of aliphatic or aromatic aldehydes with betaine-ylids to give allyl alcohols usually proceeds with high regio- or stereoselectivity[6, 7]. This in no way contradicts the postulated betaine/oxaphosphetane equilibrium. On the contrary, due to this equilibrium the reaction can proceed *via* the sterically least hindered oxaphosphetane (no bulky groups in *cis* position) to give the energetically most favorable product[8].

A Fragmentational Approach to Macrolides: (5-*E*, 8-*Z*)-6-methyl-5,8-undecadien-11-olide[**]

By *Daniel Sternbach, Masayuki Shibuya, Fritz Jaisli, Marco Bonetti*, and *Albert Eschenmoser*[*]

The cleavage of C C single bonds according to the general scheme A[1] has proved to be an effective method for the modification of carbon frameworks and indeed constitutes the preparatively most useful reaction available today in

heterolytic fragmentations[2]. This type of process has found specific application especially in the synthesis of cyclic compounds of medium ring size[3]. Using the title compound *(3)* as an example, we demonstrate here the application of this reaction principle in the preparation of unsaturated macrolides[4], the key step being a decarboxylative double fragmentation of the type *B*.

Scheme 1. The yields are based on analytically pure products.

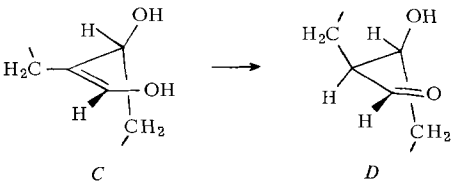
[**] 14th Communication on Synthetic Methods. This work was supported by the Anniversary Funds of the ETH Zürich. *Dr. D. Sternbach* thanks the Schweizerischer Nationalfonds for a postdoctoral study grant. Preliminary experiments on the work described here were performed by Dr. *M. Jung* (1974). We thank *S. Denmark* (ETH) for his help with the translation of the German manuscript. 13th Communication ref. [13].

Heating either of the diastereomeric amidinium salts *(1)* or *(2)* for three minutes at their melting points under argon affords uniformly in both cases under vigorous evolution of CO_2 the title substance *(3)* and the amidinium tosylate *(4)* (Scheme 1). The structural formula of the anion *(5a)* of the *trans* isomer *(1)* illustrates how the educts are programmed to undergo a double fragmentation: The central C–C bridge in *(5a)* is antiperiplanar[5, 3c] to the equatorial tosylate group as well as to the two "equatorial" electron pair sp^3 axes of the acetal function[6], and the equatorial carboxyl group is antiperiplanar to one of the two acetal linkages. The overall process most likely involves at least two reaction steps, *i.e.* proceeds *via* the corresponding bicyclic dioxonium ion as an intermediate: in any event, the two reaction planes are askew to each other.

Compounds *(1)* and *(2)* are prepared as outlined in Scheme 2. Condensation of β-trityloxypropionaldehyde[7] with α-lithioacrolein diethyl acetal[8] readily affords 2-(1-hydroxy-3-trityloxy) acrolein *(6)*. The aldehyde *(6)* reacts in good yield with 2-methyl-1,3-cyclohexanedione to afford a Michael-adduct in which the free aldehyde remarkably cyclizes to give a diastereomeric mixture of hemiacetals of the type *(7)* (with the requisite boat conformation of one of the rings). Oxidation of *(7)* with sodium metaperiodate and a catalytic amount of ruthenium dioxide produces a mixture of lactone diastereomers in which the crystalline lactone *(8)* is present to an extent of 86%[9]. Compound *(8)* can be converted in high yield by acid-catalyzed methanolysis into the crystalline ketoacetal esters *(9)* and *(10)*. Under conditions of predominantly kinetic control (0.05 equiv. *p*-toluenesulfonic acid in methanol, 60 °C, 3 h), *(9)* and *(10)* are formed in a ratio of 1:2; under more drastic conditions (0.3 equiv. *p*-toluenesulfonic acid, 7 h), the ratio inverts to approx. 5:1. The structure of the *trans* compound *(10)* (mp. 123 °C) is secured by X-ray crystallography[11].



Scheme 2 [10]. The yields are based on analytically pure products. *a:* $(C_2H_5)_3N$, *t*-BuOH, 20 °C (77%).—*b:* $NaIO_4$, RuO_2, CCl_4/H_2O, 20 °C (69%).—*c:* TsOH, CH_3OH, 60 °C [72% *(9)* + 13% *(10)*].—*d:* 4 N KOH, dioxane, CH_3OH, 20 °C.—*e:* Li, NH_3, −33 °C.—*f:* CH_2N_2, ether, CH_3OH [81% hydroxyacetal ester based on *(9)*].—*g:* TsCl, pyridine, 20 °C (90%).—*h:* 4 N KOH, dioxane, CH_3OH, 20 °C (91%).—*i:* 3,3,6,9,9-pentamethyl-2,10-diazabicyclo[4.4.0]dec-1-ene [13], CH_2Cl_2 [96% *(2)*].

The structure of the fragmentation product *(3)* is in accord with all spectral and microanalytical data (see Table 1). The assignment of the *Z*-configuration for the C-8, C-9 double bond is supported by the observed ^{1}H-NMR coupling constant of the two vinyl protons (10.8 Hz; see ref. [12a]), while the *E*-configuration for the double bond between C-5 and C-6 follows from the usual interpretation of stereospecific fragmentation processes[3c, 2c]. The selection of the special bicyclic amidine[13] used in *(1)* and *(2)* is based on the ready crystallizability, solubility and convenient melting properties of the salts derived therefrom. The simplicity of the experimental procedure and the high yields obtained from the fragmentation are consequences of the use of this amidine; the ability of the tosyloxycarboxylic acids to suffer fragmentation is, however, independent.

Table 1. Analytical data of *(3)* [10]. *(3)* is a liquid under normal conditions.

^{1}H-NMR ($CDCl_3$, 360 MHz): δ = 1.63 (s/3 H/CH_3 at C-6), 1.82–1.90 (m/2 H/H_2C-3), 2.07–2.18 (m/4 H/H_2C-2 and H_2C-4), 2.34–2.42 (m/2 H/H_2C-10), 2.64 (d/J = 8 Hz/2 H/H_2C-7), 4.17–4.21 (m/2 H/H_2C-11), 5.09 (t/1 H/J = 7 Hz with fine coupling/HC-5), 5.51–5.61 (m/1 H/HC-9), 5.71–5.80 (m/1 H/HC-8). Decoupling: 2.38 → 5.56 (d/J = 11.2 Hz) and 4.19 (s), 2.64 → 5.76 (d/J = 10.7 Hz).—^{13}C-NMR ($CDCl_3$, 25 MHz): δ = 16.1 (q), 24.0 (t), 27.4 (t), 28.0 (t), 34.1 (t), 36.3 (t), 63.9 (t), 122.7 (d), 128.9 (d), 129.4 (d), 136.7 (s), 174.4 (s).—IR ($CHCl_3$): *e.g.* 1722 (sharp) cm^{-1}.—MS (200 °C): *m/e* = *e.g.* 195 (5%), 194 (44%, M^+), 93 (100%)

The synthesis of the tricyclic fragmentation reactants according to the sequence shown in Scheme 2 is relatively simple and amenable to structural variation[12]. The steric pathway of the protonation of the enol (or enolate) formed by Michael-addition of 2-methyl-1,3-cyclohexanedione on *(6)* is decisive for the success of the reaction sequence. The protonation must proceed in the sense shown (C→D) so that the carboxyl function in *(9)* and *(10)* (as precursors for *(2)* and *(1)*, resp.), comes to rest in an equatorial orientation. The desired steric pathway prevails. This can possibly be explained in terms of a C-protonation antiperiplanar to the hydroxyl group (cf. *D*).

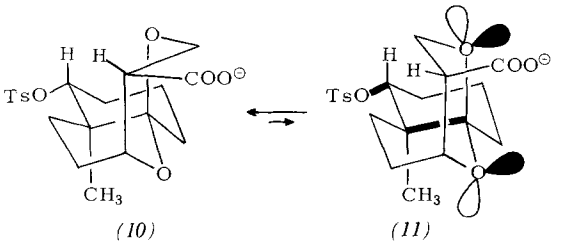
A Fragmentational Approach to Macrolides: (5-*E*, 9-*E*)-6-methyl-5,9-undecadien-11-olide[**]

By *Masayuki Shibuya, Fritz Jaisli,* and *Albert Eschenmoser*[*]

The principle for the synthesis of unsaturated macrolides through decarboxylative double fragmentation[1] offers fundamentally the possibility to vary the position of the C=C double bonds in the macrolide ring by changing the site of both the tosylate and carboxyl groups in the reactants. We report herein the realization of one of these possibilities.

Michael-addition of acrolein to 2-methyl-1,3-cyclohexanedione in methanol in the presence of a catalytic amount of sodium methoxide directly followed by condensation with dimethyl malonate in the same reaction medium afforded a crystalline ketohemiacetal diester *(1)*[2] in 60% yield (Scheme 1). Protection of the hemiacetal function by methanolysis, $LiAlH_4$ reduction of the ketoacetal diester *(2)*, intramolecular transacetalization of the mixture of diastereomeric trihydroxyacetals *(3)*, oxidation and esterification of *(4)* afforded a chromatographically separable 3:1 mixture of crystalline ketoacetal esters *(5)* and *(6)*. Starting from *(1)*, it is not necessary to purify the intermediate diastereomeric mixtures in order to prepare *(5)* and *(6)* in pure form (yield based on *(1)* is 20%)[3]. The assignment of configuration for the ring fusion in *(5)* and *(6)* is based on distinct configuration-specific differences in the ^{13}C-NMR spectra[4] of the two ketoacetal esters as well as the corresponding hydroxy derivatives[5]. Such differences run parallel to those observed in the series of isomers[1] in which the configurational assignment of the corresponding ketoacetal esters is established by X-ray crystallography[6]. From a stereochemical point of view, the key step is the transacetalization *(3)*→*(4)*; here we expect that the thermodynamic control of this step causes a differentiation of the diastereotopic hydroxymethyl groups such that the remaining hydroxymethyl group (which becomes the carboxylate function of *(5)* and *(6)* as well as of *(7)* and *(8)*) can occupy an equatorial position. This corresponds to the *endo*-configuration when the 1,3-dioxane ring exists in the chair form (as originally expected[7]) or, contrariwise, the *exo*-configura-



Scheme 1. *a:* CH_3OH, trace $NaOCH_3$, 50 °C; $CH_2(COOCH_3)_2$, 65 °C [60% *(1)*, m.p. 125 °C].—*b:* TsOH, CH_3OH, 65 °C.—*c:* $LiAlH_4$, ether, 20 °C.—*d:* TsOH, benzene, molecular sieve, 80 °C.—*e:* pyridinium chlorochromate, sodium acetate, CH_2Cl_2, 20 °C.—*f:* $KMnO_4$, dilute NaOH, 20 °C, followed by CH_2N_2, CH_3OH [15% *(5)*, m.p. 126 °C, und 5% *(6)*, m.p. 92 °C; yield based on *(1)*].—*g:* 4N KOH, dioxane, CH_3OH, 20 °C.—*h:* Li, NH_3, −33 °C, followed by CH_2N_2, CH_3OH [80% hydroxyacetal ester from *(5)*].—*i:* TsCl, pyridine, 20 °C.—*k:* 4N KOH, dioxane, CH_3OH, 20 °C.—*l:* 3,3,6,9,9-pentamethyl-2,10-diazabicyclo[4.4.0]dec-1-ene (*F. tion (compare *(5)* and *(6)*) if the ring prefers the boat conformation. According to an X-ray crystallographic analysis performed by *Dunitz et al.*[6], the 1,3-dioxane ring in the isomeric ketoacetal esters[1] prefers the boat form. Thus, the carboxyl function, as shown in *(5)* and *(6)*, probably exists in the *exo* configuration. This assignment is compatible with the ^{1}H-NMR data[8] and, above all, is in agreement with the stereochemical outcome of the fragmentation to *(9)* (see Schemes 1 and 2).

(10) *(11)*

Scheme 2 *(12)*

Heating the amidinium carboxylates *(7)* and *(8)* prepared from *(5)* and *(6)* respectively, for 1 minute at their melting points afforded the title compound *(9)* in stereochemically homogeneous form (see Table 1). That the disubstituted double bond takes up the *E*-configuration is evidenced by the ^{1}H-NMR coupling constant (15.5 Hz)[9] for the two adjacent vinyl protons. This corresponds to the *exo*-arrangement of the carboxyl group in *(7)* and *(8)* as illustrated by the conformational formulas in Scheme 2 for the carboxylate ion of the *trans* isomer *(8)*. Of the two reactant conformations *(10)* and *(11)*, the latter satisfies the stereochemical requirements for the first step of the fragmentation[10]. From the formula of the intermediate zwitterion *(12)* it is seen how this configuration of the carboxyl group can lead to the *E*-configuration of the C-9, C-10 macrolide double bond in a second step of the fragmentation[11].

Table 1. Analytical data of *(9)*. Experimental details, see ref. [3]. Compound *(9)* is a liquid under normal conditions.

^{1}H-NMR ($CDCl_3$, 360 MHz): $\delta = 1.49$ (s/3H/CH_3 an C-6), 1.77—1.86 (m/2H/H_2C-3), 2.06—2.11 (m/6H/H_2C-4, H_2C-7, H_2C-8), 2.21—2.24 (m/2H/H_2C-2), 4.48 (d/J = 7.4 Hz/2H/H_2C-11), 4.98 (t, J = 7.4 Hz/1H/HC-5), 5.42 (dt/J = 15.3 und 7.4 Hz/1H/HC-10), 5.67—5.76 (m/1H/HC-9). Decoupling: 4.48 ppm → 5.42 (d/J = 15.1 Hz); 2.09 → 5.73 (d/J = 15.5 Hz), 4.98 (doubled s/J = 1.2 Hz) and 1.49 (d/J = 1.2 Hz).—^{13}C-NMR ($CDCl_3$, 25 MHz): $\delta = 14.8$ (q), 24.5 (t), 28.7 (2t), 35.4 (t), 39.5 (t), 62.8 (t), 125.3 (d), 127.5 (d), 132.5 (s), 139.1 (d), 173.4 (s).—IR ($CHCl_3$): *e.g.* 1727 (sharp), 1670 w cm^{-1}.—MS (200 °C): m/e = 195 (3%), 194 (15%, M^+), 140 (100%)

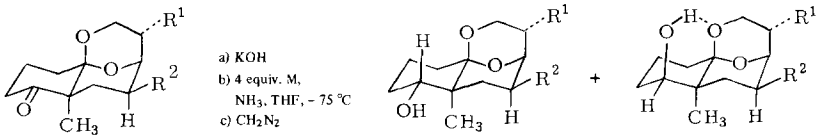
[11] The connection between the *E* configuration of the C^9 C^{10} double bond in *(9)* and the *exo* configuration of the carboxylate group in *(7)* and *(8)* is unequivocal only if the formation of the product does not involve a [3,3]-sigmatropic equilibration of the allylic lactone group (*via* a 10-membered ring). In analogous cases with 12- and 14-membered rings we did not observe a thermal equilibration of this kind at 220 °C but at 400 °C. *P. R. Jenkins, N. Beeley*, unpublished results.

Steric Course of the Reduction of Ketoacetal Esters with Alkali Metals in Liquid Ammonia[**]

By *Fritz Jaisli, Daniel Sternbach, Masayuki Shibuya*, and *Albert Eschenmoser*[*]

The most productive method of preparing the hydroxyacetal esters *(2)* and *(5)* starting with the two *cis*-ketoacetal esters *(1)*[1a] and *(4)*[1b] respectively, was found to be the following sequence of reactions: ester hydrolysis with potassium hydroxide in water/methanol/dioxane at ambient temperature, reduction of the crude ketoacetal carboxylic acids with *ca.* 5 equivalents of lithium in liquid ammonia/tetrahydrofuran at −33 °C (reaction quenched by addition of solid ammonium chloride) and re-esterification with diazomethane in methanol. Column chromatographic separation of the products afforded, along with a small amount of starting material, the hydroxyacetal ester *(2)* or *(5)* with an equatorial hydroxy group in 81 or 80% yield respectively. As expected[2] only trace amounts of the axial epimers *(3)* or *(6)* were formed[3] (see Scheme 1).



R^1	R^2			
(1), H	$COOCH_3$	⟶	*(2)*, 81%	*(3)*, 1% (+ 5% educt)
(4), $COOCH_3$	H	⟶	*(5)*, 80%	*(6)*, 2% (+ 3% educt)

Scheme 2: Product ratio (yields). [a] Reduction in the presence of ten equivalents of water in liquid ammonia at −75 °C. [b] 10% reactant recovered. [c] 15% reactant recovered.

An unexpected inversion in the stereochemistry of the reaction has been observed in the case of the *trans*-ketoacetal esters *(7)*[1a] and *(10)*[1b] under otherwise identical conditions (see Scheme 2). Reduction of *(7)* or *(10)* with lithium in liquid ammonia affords mainly the axial alcohol *(9)* or *(12)* respectively, independent of reaction temperatures of ca. −30° or −75 °C and the presence or absence of moisture[4]. An equatorial/axial ratio between 1:2.5 and 1:3 was reproducibly obtained in several experiments[5]. We have interpreted these findings by the assumption that the lithium alkoxides which arise as intermediates on the path to the axial alcohols are stabilized by intramolecular lithium ion bridging as illustrated in the structural formula *(13)* (Scheme 3). The behaviour of the *cis*-compounds *(1)* and *(4)* could then be attributed to greater steric hindrance in the region of the alkoxide oxygen and the lithium bridge (see *(14)*[6]). If this interpretation is correct, then the steric course of the reduction in the *trans*-series must be correspondingly sensitive to the nature of the metal employed. This proved to be the case. As suspected on the basis of the larger ionic radii and the weaker complexation tendency of sodium and potassium ions compared to lithium ions, the reduction of *(7)* and *(10)* (*trans*-series) with sodium or potassium in liquid ammonia provided the equatorial alcohols *(8)* and *(11)* as the principle products (see Scheme 2).

(13) *(14)*

Scheme 3

The assignment of configuration for the hydroxyacetal esters *(2)*, *(3)*, *(5)*, *(6)*, *(8)*, *(9)*, *(11)*, and *(12)* rests on the X-ray structure determinations by *Dunitz et al.*[7] of the ketoacetal ester *(7)*[1a] and the corresponding axial alcohol *(9)*[8]. For the four axial alcohols *(3)*, *(6)*, *(9)*, and *(12)* an intramolecular hydrogen bond between the hydroxyl and acetal oxygen is documented by IR spectroscopy (concentration independent OH-stretching vibration at 3560 cm^{-1} in CCl_4). In light of the previously found correlations between the generalized anomeric effect and ^{13}C-NMR shifts[9] it should be emphasized that for these four alcohols the ^{13}C-NMR signals of the angular methyl groups (antiperiplanar to the axial hydroxyl group) are shifted *ca.* 7 ppm *downfield* as compared to the corresponding signals of the epimeric (equatorial) alcohols (see Table 1).

Table 1. ^{13}C-NMR spectroscopic data for compounds *(1)*—*(12)* [a].

The Chemistry of Functional Groups. The Chemistry of the Carbon-Carbon Triple Bond. Ed. by *S. Patai.* John Wiley & Sons, London, 1978. Part 1: xiv, 522 pp.; Part 2: xiv, pp. 523—1065, bound, together £ 70.00.

These two volumes on the chemistry of the acetylene bond have been written by a total of 31 authors. The advantage of such collective works is that experts can report on their own particular field, but generally there is a price to pay: uneven emphasis is given to individual aspects, which normally does not make for uniformity and causes many topics to be overemphasized. The present work, however, gives an over-all impression of uniformity, and in particular the wealth of literature references gives access to practically all work in this field. As might be expected, the approach does lead to a certain amount of overlap, and a number of aspects are omitted. With the great wealth of material, however, one could hardly expect a book of this size to give an exhaustive treatment. Since consideration is given to both the theoretical and the purely preparative aspects, the book will certainly be of interest to a wide circle of readers.

Megawatt Infrared Laser Chemistry. By *E. Grunwald, D. F. Dever,* and *Ph. M. Keehn,* John Wiley & Sons, New York 1979. xii, 107 pp., bound, $ 21.50.

Currently there is a considerable interest in the applications of lasers, and in particular of high-power infrared lasers, in chemistry, and a large number of reviews have already appeared. The present book with its 107 pages looks rather thin in comparison. It is designed to meet the interests of the preparative chemist. In five chapters it offers some basic information, together with a quite comprehensive collection of individual examples. The level corresponds to that of an advanced chemistry student, which is perhaps only to be expected from the brevity of the chapters. The basic approach of the book derives from the authors' field of study; it is aimed less at a detailed understanding of the physical and spectroscopic aspects and more at an interpretation of laser-induced reactions in the gas phase at relatively high pressures, on the basis of the products and product distributions.

The collection of examples is undoubtedly useful. It includes the dissociations and eliminations of halogenated hydrocarbons, cyclizations and rearrangements, sensitized reactions, and reactions such as chloroboration, displacement of the chemical equilibrium, and isotope separation. But apart from this, the book has little new to offer. The material could have been covered in a review article, and the price seems far too high. It is certainly time that we had a chemically oriented review of laser-induced reactions, but an account at a higher level than this would be desirable.

Infrared and Raman Spectra of Inorganic and Coordination Compounds. By *Kazuo Nakamoto.* John Wiley & Sons, New York—Chichester—Brisbane—Toronto 1978. 3rd edit., xv, 448 pp., bound, $ 31.15.

After the first (1963) and second (1970) editions of Nakamoto we now have the third, considerably modified edition. This shows that vibrational spectroscopy is still a technique in current use by inorganic and organometallic chemists, although in the past 15 years other physical techniques have come to the fore and it has been possible to simplify greatly the use of X-ray single-crystal structure analysis.

The basic framework of the book remains unchanged. Chapter I gives an introduction to the theory of vibrational spectroscopy and deals with topics such as Raman intensities, resonance Raman spectra, vibrational spectra in the gas phase, matrix-isolation spectroscopy, and crystal spectra, Chapter II deals with inorganic compounds, Chapter III with coordination compounds, and Chapter IV (new) with organometallic compounds. In order to take account of developments over the past years, problems such as metal-isotope techniques, metal-ligand interactions, and the fixation of diatomic molecules are discussed. The present reviewer found Chapter III to be the most interesting, since the author reports among other things on his own field of work and discusses current problems in the chemistry of complexes.

This book may be recommended without any reservations. It is intended for anyone interested in becoming acquainted with the fundamentals of the theory of vibrational spectroscopy, and for the preparative chemist working in the fields of complex and organometallic chemistry who wishes to become familiar with the information content of the vibrational spectra measured. For chemists involved with elements in the main groups, Chapter II can serve as a reference work for characteristic vibrations.

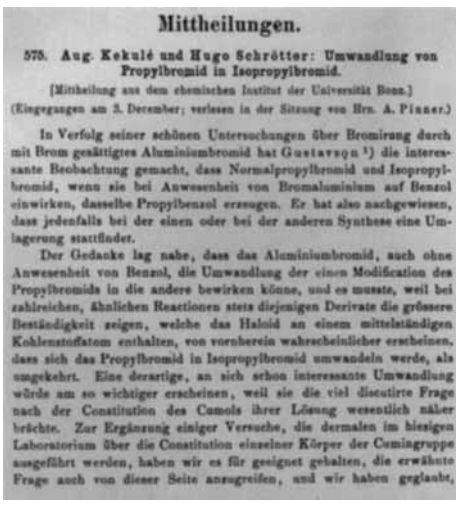
August Kekulé—The Architect of Chemistry Commemorating the 150th Anniversary of His Birth[**]



By Klaus Hafner[*]

Imagination, daring, and critical understanding are the sources of the impulses still felt today which chemistry received from the theoretical studies of *Kekulé*. "Let us learn to dream, gentlemen, then perhaps we shall discover the truth; but let us beware of publishing our dreams abroad before they have been scrutenized by our vigilant intellect ... Let us always allow the fruit to hang until it is ripe. Unripe fruit brings even the grower but little profit; it damages the health of those who consume it; it endangers particularly the youth which cannot yet distinguish between ripe and unripe." (*Kekulé* 1890).

"Eine Geschichte zu schreiben, ist immer eine bedenkliche Sache. Denn bei dem redlichsten Vorsatz kommt man in Gefahr, unredlich zu sein; ja, wer eine solche Darstellung unternimmt, erklärt im voraus, daß er manches in Licht, manches in Schatten setzen werde." (J. W. von Goethe, Introduction to the didactic part of the theory of colors)

Many scientific discoveries of bygone centuries have meanwhile become so commonplace that the achievement of their discoverer is often underestimated in spite of all the appreciation it receives. Yesterday's genius becomes today's banality. Pertinent examples are the foundation of organic structural chemistry and the proposal of the benzene formula by *August Kekulé* who, although of comparable genius with *Justus Liebig*, likewise born at Darmstadt, received far less recognition than the latter. The 150th anniversary of his birth provides an opportunity to call to mind his importance in the history of chemistry and for development of the chemical industry, and his part in the teaching of chemistry as viewed from a modern standpoint, and thus to reflect upon a great, almost unique scientific tradition, extending far into the present century, which is hardly known to the present generation.

When Kekulé published his paper on the isomerization of *n*-propyl bromide to isopropyl bromide in the presence of aluminum bromide[1] a hundred years ago and therein, without knowing it, provided one of the first experimental proofs of the existence of carbenium ion intermediates, he had

Mittheilungen.

575. Aug. Kekulé und Hugo Schrötter: Umwandlung von Propylbromid in Isopropylbromid.

[Mittheilung aus dem chemischen Institut der Universität Bonn.]

(Eingegangen am 3. December; verlesen in der Sitzung von Hrn. A. Pinner.)

In Verfolg seiner schönen Untersuchungen über Bromirung durch mit Brom gesättigtes Aluminiumbromid hat Gustavson [1]) die interessante Beobachtung gemacht, dass Normalpropylbromid und Isopropylbromid, wenn sie bei Anwesenheit von Bromaluminium auf Benzol einwirken, dasselbe Propylbenzol erzeugen. Er hat also nachgewiesen, dass jedenfalls bei der einen oder bei der anderen Synthese eine Umlagerung stattfindet.

Der Gedanke lag nahe, dass das Aluminiumbromid, auch ohne Anwesenheit von Benzol, die Umwandlung der einen Modification des Propylbromids in die andere bewirken könne, und es musste, weil bei zahlreichen, ähnlichen Reactionen stets diejenigen Derivate die grössere Beständigkeit zeigen, welche das Haloïd an einem mittelständigen Kohlenstoffatom enthalten, von vornherein wahrscheinlicher erscheinen, dass sich das Propylbromid in Isopropylbromid umwandeln werde, als umgekehrt. Eine derartige, an sich schon interessante Umwandlung würde um so wichtiger erscheinen, weil sie die viel discutirte Frage nach der Constitution des Cumols ihrer Lösung wesentlich näher brächte. Zur Ergänzung einiger Versuche, die dermalen im hiesigen Laboratorium über die Constitution einzelner Körper der Cumingruppe ausgeführt werden, haben wir es für geeignet gehalten, die erwähnte Frage auch von dieser Seite anzugreifen, und wir haben geglaubt,

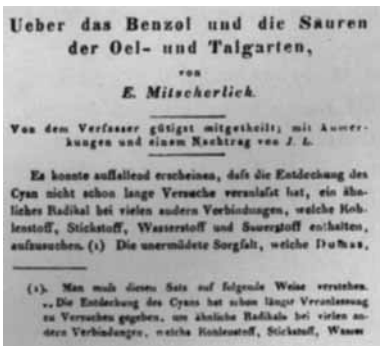
(Eingegangen am 30. Juni 1922.)

Vor einiger Zeit konnten wir zeigen[1], daß bei der vereinigten Einwirkung gasförmiger Salzsäure auf Camphen zunächst das wahre HCl-Anlagerungsprodukt, das tertiäre, bisher unbekannte Camphen-chlorhydrat entsteht:

Fig. 2. Title page of the first publication, by *H. Meerwein*, on ionic reactions in organic chemistry [2].

August Kekulé lived in a century between the world-shaking events of Napoleon's Hundred Days and the First World War. This was an age of scientific revolutions, ranging from the disproof of spontaneous generation and the discovery of microorganisms to the description of viruses and enzymes, from *Faraday*'s laws of electrolysis to the discovery of X-rays and that of the radioactivity of uranium compounds. It was also an age of engineering, ranging from the first railway to the discovery of the Diesel engine, and from the first electromagnetic telegraph to wireless telegraphy.

Kekulé's birth—on September 7, 1829—coincided with the actual beginning of organic chemistry. Just one year earlier, *Friedrich Wöhler* (1800—1882) had disproved the concept of vitalism[4] by synthesizing urea from ammonium cyanate[3]. Thus was initiated an incredibly productive and lively development of organic chemistry. *Michael Faraday* (1791—1867) obtained "bicarburetted hydrogen"[5] from compressed illuminating gas; shortly afterwards the same compound was obtained by *Eilhard Mitscherlich* (1794—1863) when benzoic acid was heated with quicklime[6], and was called benzene in accord with its mode of formation. 30 years later, its structural elucidation was destined to crown *Kekulé*'s life's work and also to initiate a tremendous upswing of the chemical industry. During the first years of *Kekulé*'s life, *Friedlieb Ferdinand Runge* (1795—1867) discovered aniline and phenol in coal tar[7], and *Jöns Jacob Berzelius* (1779—1848) introduced the concepts of catalysis[8] and of isomerism[9]. *Justus Liebig*'s (1803—1873) and *Wöhler*'s studies on benzoyl compounds[10] laid the foundations of the radical theory of carbon com-



XX. *On new compounds of carbon and hydrogen, and on certain other products obtained during the decomposition of oil by heat.* By M. Faraday, *F.R.S. Cor. Mem. Royal Academy of Sciences of Paris, &c.*

Read June 16, 1825.

The object of the paper which I have the honour of submitting at this time to the attention of the Royal Society, is to describe particularly two new compounds of carbon and hydrogen, and generally, other products obtained during the decomposition of oil by heat. My attention was first called to the substances formed in oil at moderate and at high temperatures, in the year 1820; and since then I have endeavoured to lay hold of every opportunity for obtaining information on the subject. A particularly favourable one has been afforded me lately through the kindness of Mr. Gordon, who has furnished me with considerable quantities of a fluid obtained during the compression of oil gas, of which I had some years since possessed small portions, sufficient to excite great interest, but not to satisfy it.

It is now generally known, that in the operations of the Portable Gas Company, when the oil gas used is compressed in the vessels, a fluid is deposited, which may be drawn off and preserved in the liquid state. The pressure applied amounts to 50 atmospheres; and in the operation, the gas previously contained in a gasometer over water, first passes into a large strong receiver, and from it, by pipes, into the

Life of *August Kekulé*

1829	Born at Darmstadt, Neckarstrasse 19, on September 7
1835 to 1847	Pupil at the private school run by *Heinrich Schmitz* and at the Ludwig-Georgs-Gymnasium, Darmstadt
1847 to 1848	Study of architecture at Giessen
1848 to 1849	Semester at Darmstadt Polytechnic
1849 to 1851	Study of chemistry at Giessen
1851 to 1852	Period of study at Paris
1852	Awarded degree of Dr. phil.
1852 to 1853	Private assistant to *A. von Planta* at Reichenau Castle, Chur
1854 to 1855	Private assistant to Professor *J. Stenhouse* at St. Bartholomew's Hospital, London
1855 to 1858	*Privatdozent* at Heidelberg University
1856	Habilitation for chemistry, physics, and geognosy
1857 to 1858	Publication of fundamental papers on the theory of valency
1858 to 1867	Professor of chemistry at the State University of Ghent, Belgium
1859	Publication of the first instalment of *Kekulé*'s textbook of organic chemistry
1860	Participation in the first international congress on chemistry at Karlsruhe September 3 to 5, 1860
1862	Marriage to *Stephanie Drory*
1863	Birth of son *Stephan*; death of *Stephanie Kekulé, née Drory*
1865	Proposal of formula of benzene
1867	Call to Bonn University
1868	Award of honorary degree of Dr. med. at 50th anniversary of the foundation of Bonn University
1875	Call to Munich University as successor to *J. von Liebig*—not accepted
1876	Marriage to *Luise Högel*
1877 to 1878	Chancellor of Bonn University
1878	Birth of son *Fritz*
1878, 1886, 1891	President of German Chemical Society
1882	Birth of daughter *Louise*
1885	Birth of daughter *Auguste*
	Award of Copley medal
1889	Award of Huyghens medal
1890	Benzene festival of German Chemical Society held in the City Hall of Berlin
	Award of the "Kronenorden II. Klasse" and election to "Ritter des Maximilian-Ordens für Wissenschaft und Kunst in Bayern"
1893	Nomination as "Ritter des Ordens pour le mérite für Wissenschaften und Künste"
1895	Prussian title of nobility *(Kekulé von Stradonitz)*
1896	Died at Bonn on July 13

pounds which was welcomed by *Berzelius*, the father of the then generally accepted electrochemical-dualistic concepts which were so very fruitful for inorganic chemistry, as the "dawn of a new day in vegetable chemistry"[11].

Fig. 5. From left to right: *J. J. Berzelius, M. Faraday, E. Mitscherlich, F. Wöhler.*

At this time, *Friedrich August Kekulé* grew up as the youngest child of the "Grossherzoglicher Oberkriegsrat" *Ludwig Karl Emil Kekulé* (1773—1847)[12] in Darmstadt. Although highly gifted and very interested in all scientific phenomena, the schoolboy showed no pronounced interest in chemistry. Like *Georg Christian Lichtenberg* (1742—1799), *Johann Heinrich Merck* (1741—1791), and *Georg Büchner* (1813—1837) before him, and like *Stefan George* (1868—1933) and *Friedrich Gundolf* (1880—1931) after him, he was a pupil of the Grossherzogliches Gymnasium[13] of his home town which he left in 1847 with a distinguished leaving certificate[14].

A gift of rapid comprehension coupled with an exceptionally good memory guaranteed his success, as did a vivid imagination which became almost visionary in later life. "His thoughts turned into pictures and at times he could visually observe his thoughts"[15]. Remarkable graphic and mathematical ability and several designs for houses in the old part of Darmstadt drawn while he was still at school predestined him for the study of architecture at the Hessian University at Giessen. At that seat of learning, it was his fellow Hessian *Liebig*, then at the zenith of his scientific career, who inspired him by his lectures and persuaded him to change over to chemistry in which he was soon to develop his constructive bent in such magnificent manner. Philology and classics were then, and later, the main props of German education and it is hardly surprising that *Kekulé*'s family, strongly influenced by such ideals, were reluctant to condone this change. Instead, a time of deliberation was prescribed at the Darmstadt Polytechnic, the forerunner of the Technical University[16]. He spent that winter-semester of 1848/49—far away from the political unrest of the time—performing analytical work in the laboratory of *Friedrich Moldenhauer* (1797—1866). He did not return to architecture, but instead to *Liebig*'s laboratory at Giessen, where he pursued analytical studies with enthusiasm, carefulness, and persistence, a dedication without haste, which was to characterize him throughout his life. "It was not practical chemistry which attracted him, but the philosophy of chemistry"[17]. He participated briefly in *Liebig*'s physiological work on plants and animals with an analytical study on gluten and wheat bran[18]; *Liebig* had already turned his attention away from pure organic chemistry. *Kekulé* was awarded his doctorate for an experimental thesis "Über die Amyloxydschwefelsäure und einige ihrer Salze"[19] completed under the supervision of *Heinrich Will* (1812—1890)[20], one of *Liebig*'s students.

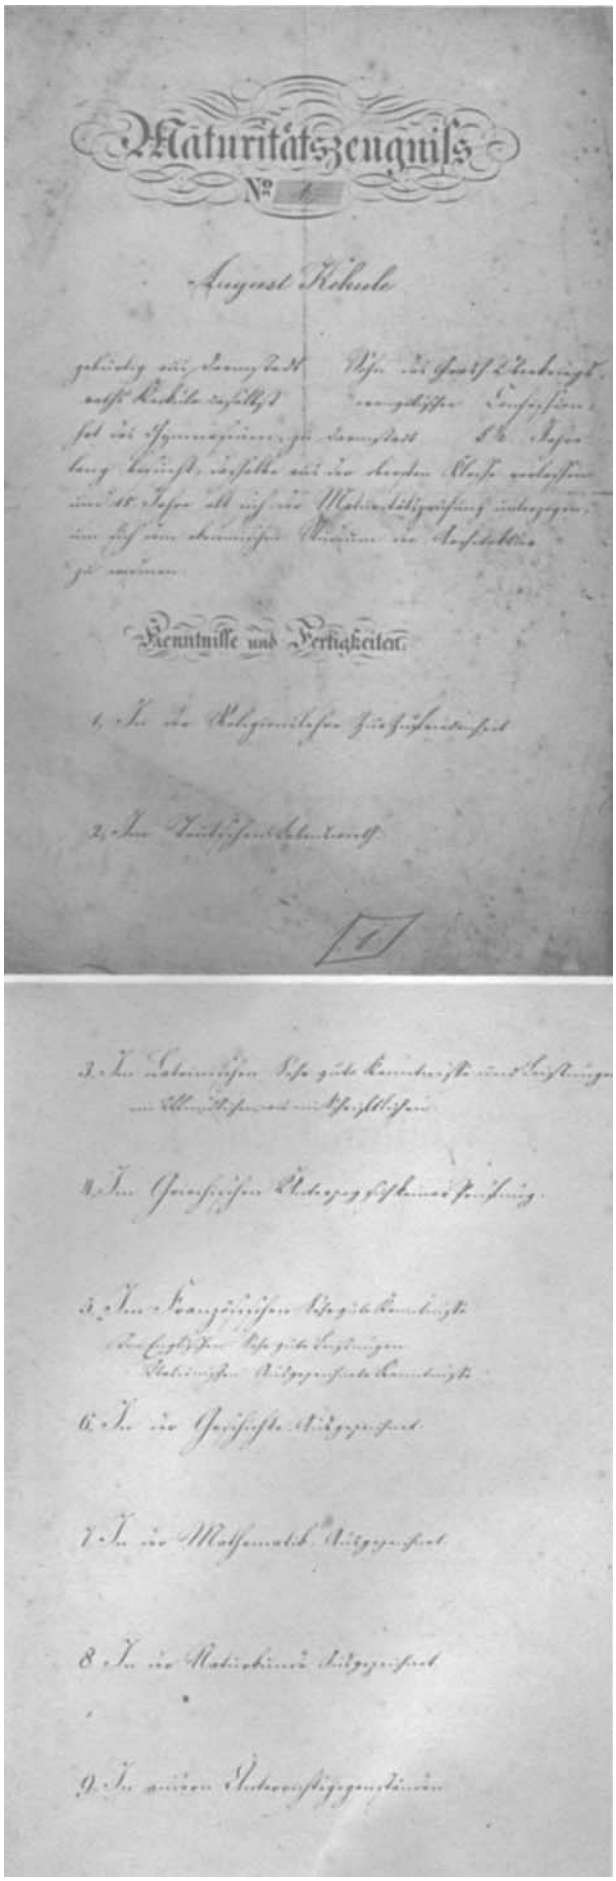

Fig. 6. *Kekulé*'s school leaving certificate.

Fig. 7. Drawing by *Kekulé* at age 13.

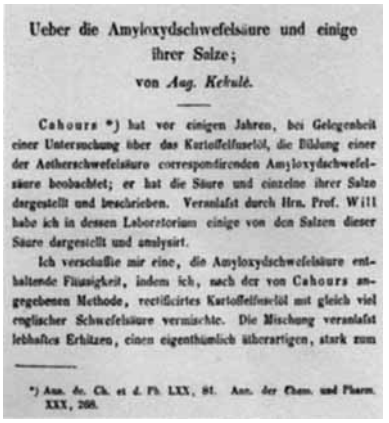

Fig. 8. Drawing by *Kekulé* at age 18.

It was an ingenious turn of history which took the young *Kekulé* from his studies at Giessen to meet *Charles Gerhardt* (1816—1856) in Paris and *Alexander William Williamson* (1824—1904) in London. Both of these contacts were to prove crucial for his intellectual work.

Fig. 9. Left: *Justus von Liebig ca.* 1850. Right: *H. Will.*

When *Kekulé* entered the scientific arena the first steps had just been taken towards a clearer understanding of the linkage between atoms of the simplest nitrogen and oxygen compounds. The nature of hydrocarbon "radicals" was still shrouded in mystery. They appeared, as aptly stated by *Jean Baptiste Dumas* (1800—1884), "as planetary systems, held together by a force resembling gravitation but acting in accord with much more complicated laws"[21]. Even concepts such as atom, molecule, and equivalent were used in different ways. Confusion surrounded both the significance and the magnitude of atomic weights, and molecular weights were not employed, although *Amedeo Avogadro* (1776—1856) and *John Dalton* (1766—1844) had already prepared the ground

Ueber die Amyloxydschwefelsäure und einige ihrer Salze;

von *Aug. Kekulé.*

Cahours *) hat vor einigen Jahren, bei Gelegenheit einer Untersuchung über das Kartoffelfuselöl, die Bildung einer der Aetherschwefelsäure correspondirenden Amyloxydschwefelsäure beobachtet; er hat die Säure und einzelne ihrer Salze dargestellt und beschrieben. Veranlafst durch Hrn. Prof. Will habe ich in dessen Laboratorium einige von den Salzen dieser Säure dargestellt und analysirt.

Ich verschaffte mir eine, die Amyloxydschwefelsäure enthaltende Flüssigkeit, indem ich, nach der von Cahours angegebenen Methode, rectificirtes Kartoffelfuselöl mit gleich viel englischer Schwefelsäure vermischte. Die Mischung veranlafst lebhaftes Erhitzen, einen eigenthümlich ätherartigen, stark zum

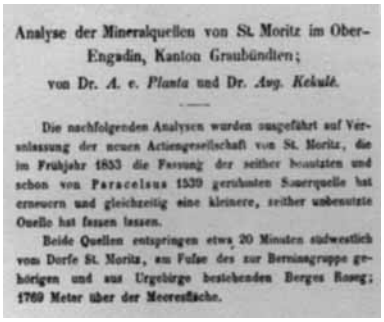
Fig. 10. *Kekulé*'s first publication (doctoral dissertation).



for their use at the beginning of the century. *Kekulé* later described the situation thus[22]: "At that time a general feeling of discouragement had just overcome the most influential chemists. Because whole categories of facts could be reconciled neither with one another nor with the general theoretical views of the time, it was believed that all speculations had to be banned from chemistry and all atomistic considerations relinquished."

A reasonable classification of the known organic compounds whose number had grown beyond comprehension was beyond the scope of the dualistic radical theory. The concept of building up chemical compounds from an electropositive and an electronegative partner was incompatible, in the realm of carbon compounds, with the feasibility of replacing electropositive elements such as hydrogen by electronegative ones such as chlorine without any great change in chemical character of a compound. *Dumas* and *Auguste Laurent* (1807—1853) attempted to explain these findings in terms of their unitary substitution theory, freed from the constraints of "dipolarity"; this theory provided preparative chemistry with fruitful stimulation but failed to supply a key to the understanding of the structure of carbon compounds. The "radicals" associated with an electric charge were replaced by "types" or "nuclei" susceptible to both substitution and addition. The desire for some kind of understanding of the complex phenomena, even if only in formal terms, prompted *Gerhardt* to propose his theory of types, which was a comprehensive classification destined to assume an intermediary role between the radical and substitution theory and the theory of valency soon to be developed by *Kekulé*. From a formal point of view, a satisfactory relationship was seen to exist in the case of simple substances by assigning a key role to simple parent compounds, *i.e.* "types" such as water or ammonia, in which hydrogen is replaced by various groups, *e.g.* of carbon compounds. However, an understanding of more complicated substances required the assumption of complex units, called "paired types", which were confusing and did not further the understanding of the mode of reaction. The sheer wealth of experimental data stood in the way of their correlation, and of a systematic overall classification.

Fig. 11. From left to right: *J. B. Dumas, A. Wurtz, C. Gerhardt.*

This was the time of *Kekulé*'s sojourn in Paris, then the stronghold of chemistry, and his meeting with *Dumas* and *Adolphe Wurtz* (1817—1884), the discoverer of the amines[23], which were so important for further development of theoretical concepts. Above all, however, a bond of friendship grew out of the innumerable discussions he had with the highly intellectual and quickwitted theoretician *Gerhardt*. The combination of *Gerhardt*'s principle of classification with the results of chemical reactions, paying due attention to *Avogadro*'s law and the concepts of equivalent and atomic and molecular weight, paved *Kekulé*'s way to his structural theory. Gifted with a vivid imagination which strove for visualization, with a critical intellect, and with an unusual memory, *Kekulé* could not have been better equipped to absorb all the available facts of his science and to collate them from a fresh angle. An interlude lasting one and a half years as private assistant to *Adolf von Planta* (1820—1895), another former student of *Liebig*, at Reichenau Castle near Chur gave him sufficient opportunity for contemplation to digest the multitude of impressions and stimulation gained in Paris[24].

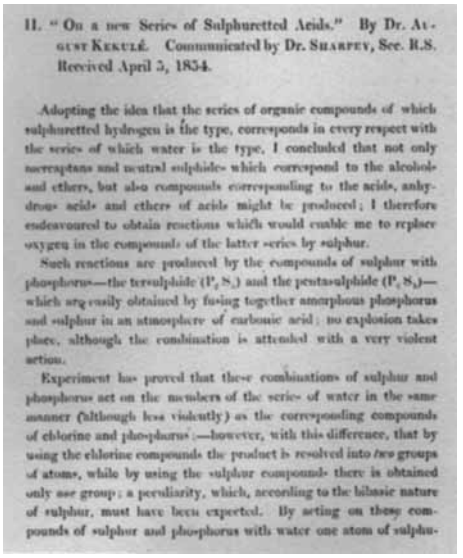
Analyse der Mineralquellen von St. Moritz im Ober-Engadin, Kanton Graubündten;

von Dr. *A. v. Planta* und Dr. *Aug. Kekulé.*

Die nachfolgenden Analysen wurden ausgeführt auf Veranlassung der neuen Actiengesellschaft von St. Moritz, die im Frühjahr 1853 die Fassung der seither benutzten und schon von Paracelsus 1539 gerühmten Sauerquelle hat erneuern und gleichzeitig eine kleinere, seither unbenutzte Quelle hat fassen lassen.

Beide Quellen entspringen etwa 20 Minuten südwestlich vom Dorfe St. Moritz, am Fuße des zur Berninagruppe gehörigen und aus Urgebirge bestehenden Berges Rosatsch; 1769 Meter über der Meeresfläche.

Fig. 12. One of *Kekulé*'s publications on work performed in Switzerland [24].



During a subsequent year of comparable importance for his life's work spent with *John Stenhouse* (1809—1880) in London he made the acquaintance of *Williamson*, who had just obtained further confirmation of the theory of types with his synthesis of ether[25]; he modified the theory by placing greater emphasis on atomic weights. While in London, *Kekulé* also met *Edward Frankland* (1825—1899), the discoverer of the first organometallic compounds[26] which underscored the significance of the concept of valency, and *William Odling* (1829—1921), a gifted young theoretician.

"Originally a scholar of *Liebig*", remarked *Kekulé* not without pride on a later occasion, "I became a scholar of *Dumas, Gerhardt,* and *Williamson*; I no longer belonged to any one school"[27]. In the course of his own experimental work "on a series of sulfur-containing organic acids"[28] and joint intellectual studies with *Williamson* the concept of the theory of valency took on shape. The parent "types" water and ammonia were supplemented by hydrogen sulfide[29] and ultimately by marsh gas[30], *i.e.* methane.

Fig. 13. From left to right: *A. W. Williamson, E. Frankland, W. Odling.*

In the winter of 1856, the 27-year-old *Kekulé* went to Heidelberg to work under *Robert Wilhelm Bunsen* (1811—1899) as Privatdozent. A confined appartment which he had to rent for himself became his work-place, with the kitchen serving as laboratory for experiments on mercury fulminate[30] and

II. "On a new Series of Sulphuretted Acids." By Dr. August Kekulé. Communicated by Dr. Sharpey, Sec. R.S. Received April 5, 1854.

Adopting the idea that the series of organic compounds of which sulphuretted hydrogen is the type, corresponds in every respect with the series of which water is the type, I concluded that not only mercaptans and neutral sulphides which correspond to the alcohols and ethers, but also compounds corresponding to the acids, anhydrous acids and ethers of acids might be produced; I therefore endeavoured to obtain reactions which would enable me to replace oxygen in the compounds of the latter series by sulphur.

Such reactions are produced by the compounds of sulphur with phosphorus—the tersulphide (P_2S_3) and the pentasulphide (P_2S_5)—which are easily obtained by fusing together amorphous phosphorus and sulphur in an atmosphere of carbonic acid; no explosion takes place, although the combination is attended with a very violent action.

Experiment has proved that these combinations of sulphur and phosphorus act on the members of the series of water in the same manner (although less violently) as the corresponding compounds of chlorine and phosphorus;—however, with this difference, that by using the chlorine compounds the product is resolved into *two* groups of atoms, while by using the sulphur compounds there is obtained only *one* group; a peculiarity, which, according to the basic nature of sulphur, must have been expected. By acting on these compounds of sulphur and phosphorus with water one atom of sulphu-

Fig. 14. Publication of *Kekulé* at the age of 25 during his sojourn in England [28].

cacodyl compounds[31]; cleaning of the room used as lecture hall was the duty of the young Privatdozent. He soon gathered a large following of enthusiastic friends and students,

Fig. 18. Title page of *Kekulé*'s famous publication on the theory of valency [34].

new world opened up to me in his lectures and in personal contact with him. Young chemists cannot gain an adequate idea from the literature of the influence exerted by the young *Kekulé* on his contemporaries. His textbook, in which he was frequently unfaithful to his own views, gives but an incomplete picture. His lectures were completely different. Captivated by the logical consistency of the new theory which was later known as structural theory, he constructed, before his enthusiastic listeners, the edifice of theoretical chemistry in which we still reside today"[32].

Fig. 17. From left to right: *E. Erlenmeyer, H. Landolt, F. C. Beilstein, A. Baeyer.*

For *Kekulé* the years spent in Heidelberg were a time of scientific maturation and the acquisition of complete independence. He developed his creative activity from the interaction between intuition and critical intellect. After the discovery of the methane type and of numerous other "radicals" derived therefrom, as well as the further development of the "mixed and double types" suggested by *Williamson* on the basis of the existence of dibasic acids, and the recognition of the significance of "atomicity", *i.e.* the valency of the elements themselves, the final step was taken with the discovery of the tetravalency of carbon and of its ability to join to itself. After years of hesitation, reconsideration, and repeated critical examination, he reported, in two papers published in 1857 and 1858[33,34], his brilliant and at the time daring ideas which were to bring about such a dramatic turn of events, perhaps the most decisive in the whole history of chemistry. The break with the old classification of chemical compounds was complete.

Kekulé wrote[34]: "I consider it necessary and, at the present state of chemical knowledge, feasible in many cases to go back to the elements themselves which make up a compound in explaining the properties of chemical compounds. I no longer consider it the primary task of our time to detect groups of atoms which can be regarded as radicals owing to certain properties and thus to ascribe the compounds to various types which have hardly any significance other than that of a typical formula. I rather believe that one should also extend the consideration to include the constitution of the radicals themselves, determine the relationship of the radicals with one another, and derive the nature of the radicals and that of their compounds from the nature of the elements. The considerations of the nature of the elements and of the basicity of atoms formerly compiled by myself are the starting point. The simplest combinations of the elements, as they are caused by the unequal basicity, are the simplest types. The compounds can be ascribed to certain types so long as the compound is attacked, during the reaction under consideration, in such a way that it shows the reaction characteristic of the type. I call that group a radical which is not attacked in the reaction concerned, and about whose composition one therefore need not concern oneself for the moment."

No sooner had *Baeyer*—still under the influence of *Bunsen*—attempted to establish the difference between methyl chloride and chloromethane[35], than *Kekulé* postulated the equivalence of the four hydrogen atoms of methane. He recognized that the endless variety of the carbon compounds is attributable to the ability of carbon to form single and multiple bonds with itself and other elements. He was the first to propose "rational formulae" for many of the more simple organic compounds. The theory of valency became the first classifying principle of far-reaching validity for the whole of chemistry. Time was ripe for publication of the new theory; the basic ideas were, so to speak, in the air after years of public discussion. Only a few months later, a treatise was published by the Scotsman *Archibald Scott Couper* (1831—1892) who was working with *Wurtz* at Paris but who was condemned all too soon to inactivity by illness, which likewise recognized the tetravalency of carbon and assumed the existence of carbon chains[36]. *Couper* was the first to symbolize

bonds in a manner resembling subsequent convention, *viz.* by dotted lines. In contrast, Kekulé initially continued to use "rational formulae", which—as he said—were intended only as "reaction but not constitutional formulae"[37] and in which the symbol for the element merely expressed the magnitude of the valency. They were jokingly called "sausages" by *Otto Nikolaus Witt* (1853—1915)[38], and "bread rolls" by the everbellicose *Hermann Kolbe* (1818—1884)[39]. *Alexander Michailowitsch Butlerow* (1846—1886), on the other hand, already considered it feasible to describe unequivocally the structure of a molecule[40].

Fig. 19. Left: *A. S. Couper.* Right: *A. M. Butlerow.*

This idea was also to gain *Kekulé*'s acceptance; he ultimately adopted the simpler formula notation of *Alexander Crum Brown* (1838—1922)[41], *Wurtz*[42], and *Hofmann*[43]. Meanwhile appointed professor of chemistry at the University of Ghent[44], he devoted his energy to the extension of structural theory, as is impressively documented in his four-volume textbook[45], which remained unfinished, and continued to exert a strong influence on his contemporaries.

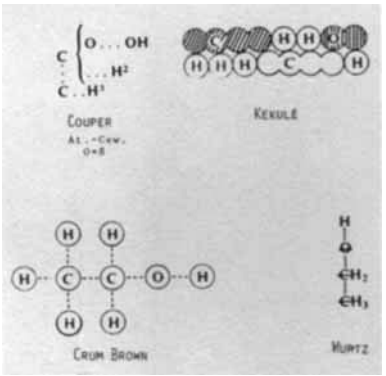

Fig. 20. Development of the notation of chemical formulae as illustrated for ethanol.

Various passages in *Kekulé*'s publications and particularly his lecture "Über die Constitution der Salze"[46] presented to the "Naturforschertagung" held at Innsbruck in 1869 bear witness to his early concepts of the three-dimensional arrangement of atoms. In 1867 he wrote in his important treatise "Über die Constitution des Mesitylens"[47]: "This imperfection"—of the older models—"can be avoided if the four relationship units of carbon instead of being located in a plane are allowed to project from the sphere of the atom in the direction of hexahedral axes such that they terminate in tetrahedral planes." He thus transferred the realm of the chemical bond out of the plane into three-dimensional space.

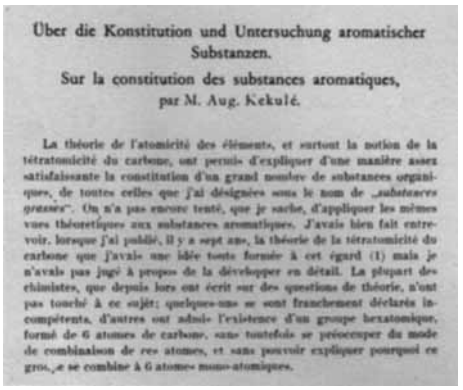
All that his student *Jacobus Henricus van't Hoff* (1852—1911) was to add to this idea seven years later was actually already present in *Kekulé*'s models. The 22-year-old *van't Hoff*[48] and the 27-year-old *Joseph Achille LeBel* (1847—1930)[49] however drew the ultimate consequences from the discoveries of *Jean-Baptiste Biot* (1774—1862)[50] and *Louis Pasteur* (1822—1895)[51] and thus laid the foundation of stereochemistry which has lost none of its topicality to this day[52]. A logical development took place from *Kekulé*'s structural chemistry and *van't Hoff* and *LeBel*'s hypothesis *via Baeyer*'s strain theory[53] and the geometrical isomerism of *Johannes Wislicenus* (1835—1902)[54] to *Emil Fischer*'s (1852—1919) studies on relative configuration[55], and thence *via* the isomerism of nitrogen compounds observed by *Arthur Hantzsch* (1857—1935)[56] and the coordination chemistry of *Alfred Werner* (1866—1919)[57], the steric hindrance of chemical reactions[58] discovered by *Victor Meyer*[59] (1848—1897), the Walden inversion [*Paul Walden* (1863—1957)], and the Sachse-Mohr theory[60] [*H. Sachse, Ernst Mohr* (1873—1926)] up to the study of conformation as introduced by *Kenneth S. Pitzer* (born 1914)[61], *Odd Hassel* (born 1897)[62], and

Fig. 21. From left to right: *J. H. van't Hoff, J. A. LeBel, J. Wislicenus, E. Fischer.*

above all *Sir Derek H. R. Barton* (born 1918)[63]. Experimental proof of the validity of the tetrahedral model was provided by X-ray structure analysis as performed by *Sir William Henry Bragg* (1862—1942) and *Sir William Lawrence Bragg* (1890—1971)[64]; the theoretical foundation was laid by *Linus Pauling* (born 1901)[65] and *Erich Hückel* (born 1896)[66] with the aid of quantum chemistry.

Structural chemistry provided a basis for the explanation of the composition and mode of reaction of aliphatic compounds, not least after clear conventions had been agreed upon concerning the terms atom, molecule, equivalent, *etc.*, at the first international congress on chemistry at Karlsruhe in 1860[67] instigated by *Kekulé*, and thanks mainly to *Stanislao Cannizzaro*'s (1826—1910) convincing statements concerning *Avogadro*'s law and the significance of atomic weights for chemical formulae. However, the large class of aromatic compounds still defied understanding, in spite of *Peter Griess*' (1829—1888) discovery of diazonium salts[68] and *Kolbe*'s synthesis of salicylic acid[69], as well as that of the first organic dyestuff mauvine[70], whose color resembles that of the mallow flower, by *William Henry Perkins* (1838—1907) in 1856.

Once more *Kekulé*'s efforts were crowned with success. His irrepressible striving for visual clarity and his exceptionally powerful imagination were again instrumental in this achievement. Derivation of the formula of benzene is basically a logical consequence of his structural theory—an ob-



vious step when viewed from the vantage point of present-day knowledge but a great leap more than a century ago, comparable perhaps with the intellectual effort once required for man to replace the sled by the wheel. Appreciation of the fact that carbon compounds could have cyclic

Fig. 22. Left: *S. Cannizzaro.* Right: *A. W. von Hofmann.*

structures was withheld from the chemists of that epoch. The circle was the symbol for the indivisible, the atom. *August Wilhelm von Hofmann* (1818—1892) remarked on a later occasion "I would forfeit all my discoveries for that thought of *Kekulé*'s"[71].

In his paper "Sur la Constitution des Substances Aromatiques"[72] submitted to the Paris Academy in 1865, once again after several years of deliberation and examination, and in the following contribution to Liebigs Annalen entitled "Untersuchungen über aromatische Verbindungen"[73] he refined his theory of the structure of benzene, *inter alia,* with the

Über die Konstitution und Untersuchung aromatischer Substanzen.

Sur la constitution des substances aromatiques,

par M. Aug. Kekulé.

La théorie de l'atomicité des éléments, et surtout la notion de la tétratomicité du carbone, ont permis d'expliquer d'une manière assez satisfaisante la constitution d'un grand nombre de substances organiques, de toutes celles que j'ai désignées sous le nom de „substances grasses". On n'a pas encore tenté, que je sache, d'appliquer les mêmes vues théoriques aux substances aromatiques. J'avais bien fait entrevoir, lorsque j'ai publié, il y a sept ans, la théorie de la tétratomicité du carbone que j'avais une idée toute formée à cet égard (1) mais je n'avais pas jugé à propos de la développer en détail. La plupart des chimistes, que depuis lors ont écrit sur des questions de théorie, n'ont pas touché à ce sujet; quelques-uns se sont franchement déclarés incompétents, d'autres ont admis l'existence d'un groupe hexatomique, formé de 6 atomes de carbone, sans toutefois se préoccuper du mode de combinaison de ces atomes, et sans pouvoir expliquer pourquoi ce groupe se combine à 6 atomes mono-atomiques.

Fig. 23. Titel page of *Kekulé*'s first publication on the structure of benzene [72].

striking sentence "These facts apparently justify the conclusion that in all aromatic substances one and the same atomic group, or, if one will, a common nucleus is present which is made up of six carbon atoms." This idea was also present in considerations of *Joseph Loschmidt* (1821—1895)[74] although he had no clear idea of the structure of this nucleus.

Even *Kekulé*'s first publications on benzene contain the symmetrical hexagonal formula and mention the equivalence of the six hydrogen atoms. Not long afterwards he and his students *Wilhelm Körner* (1839—1925)[75] and *Albert Ladenburg* (1842—1911)[76] were able to substantiate this idea experimentally. *Kekulé* supplemented his static concept of bonding by introduction of the hypothesis of oscillation[77].

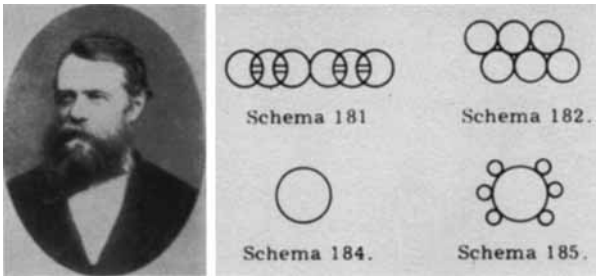


Fig. 24. Left: *J. Loschmidt.* Right: *Loschmidt*'s benzene formulae.

The discovery of the benzene formula was recounted in all developed countries 100 years later—14 years ago—and the significance of a theory which has retained its full validity for more than a century and the consequences of this theory were emphasized by qualified commentators[15]. *Kekulé*'s proposed structure of benzene also initiated a development

Fig. 25. Left: *W. Körner.* Right: *A. Ladenburg.*

that has continued to this day, and which has been especially promoted by quantum mechanics which provides all the necessary requirements for a "mechanical approach"[78] to

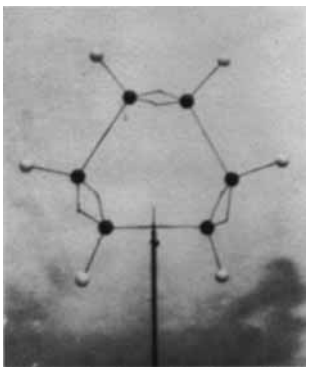

Fig. 26. Kekulé's benzene model of 1866 (original).

chemistry as already demanded by *Kekulé.* It acquired a new dimension in *Erich Hückel*'s theory of cyclic π-electron systems[79].

Fig. 27. Left: *E. Hückel.* Right: *August Kekulé* 1867.

After nine years of restless activity at Ghent, which made *Kekulé* the reformer of organic chemistry, he accepted a call to Bonn[80] in 1867. This was the last stage in the career of this truly European scholar and teacher whose years of international travel as apprentice and scientist call for emulation on the part of the younger generation, more urgently than ever before!

Fig. 28. *Kekulé*'s certificate of appointment at Bonn (bearing the signature of *Wilhelm I*) [80].

The three decades left to him were mainly devoted to further testing and confirmation of the benzene theory. Together with numerous students, including *Theodor Zincke* (1843—1928), *Ludwig Claisen* (1851—1930), and *Julius Bredt* (1855—1937), as well as *Richard Anschütz* (1847—1937) and *Otto Wallach* (1847—1931), many of whom were to become pioneers of chemistry in the closing 19th and early 20th century, he refuted other views and structural proposals of his colleagues by pointing out errors and false conclusions[81]. His sole motivation was the quest for knowledge of the true scientist, far removed from all striving after technical perfection and immediate utility. Views such as that propounded by his adversary *Kolbe*, "It is not so much a matter of explaining everything but of how things are interpreted"[82] contradicted the critical intellect of the seeker after truth[83].

During the years spent at Bonn, *Kekulé* saw the dramatic effect of his ideas on the expanding chemical industry. He was awarded the highest honors[84]. His benzene theory had made possible the directed synthesis of dyestuffs, initiated

Fig. 29. Above, from left to right: *H. Kolbe, Th. Zincke, L. Claisen.* Below: *J. Bredt, R. Anschütz, O. Wallach.*

the rise of the entire organic chemical industry—especially coal tar chemistry—and had an enduring stimulating effect on the imagination of chemists. Industry and chemical science drew closer together and adopted a symbiotic relationship[85]. This is compelling confirmation of the known fact that fundamental research, however abstract or "unpractical" its aims may appear, is indispensable and can crucially influence the development of technology sooner or later. "The depths of knowledge are never explored by him who seeks profit but by him who, motivated by a vital urge for inquiry, deploys his entire personality". Research is not just a matter for civil servants, neither does it thrive under the direction of burocracy and ideologies or the requirement of "relevance" of science. *Kekulé*'s fruitful work demonstrates convincingly that highly qualified fundamental research can be neither planned nor forced and can only rarely be assessed according to its immediate utility. This is a timely warning for the state and university administrations to reinstate research to its central position in universities and to give preferential consideration to conditions necessary for the development of the personalities required for such work rather than to formal aspects and matters of university politics.

In his famous, psychologically interesting address to the "Benzene Festival" of the German Chemical Society at Berlin in 1890[86] celebrated on the 25th anniversary of the benzene formula—probably one of the most ostentatious conferences ever held by a learned society—*Kekulé* himself contributed to the legends associated with his person. His great achievements will hardly have come to him merely in a dream on a London bus[87] or by his fireplace in Ghent[88]. Rather, they were the fruit of decades of hard work by day and often by night, loyal to the advice of his teacher *Liebig* "... whoever fails to ruin his health by study will not make his way in chemistry today"[89], or as expressed by *Max von Pettenkofer* (1818—1901): "The man who wishes to be superior to an animal must be prepared to sacrifice life and health for higher things"[90]. This condition is certainly not so rigorous in today's laboratories, but utter commitment and renunciation for the sake of increasing knowledge are still

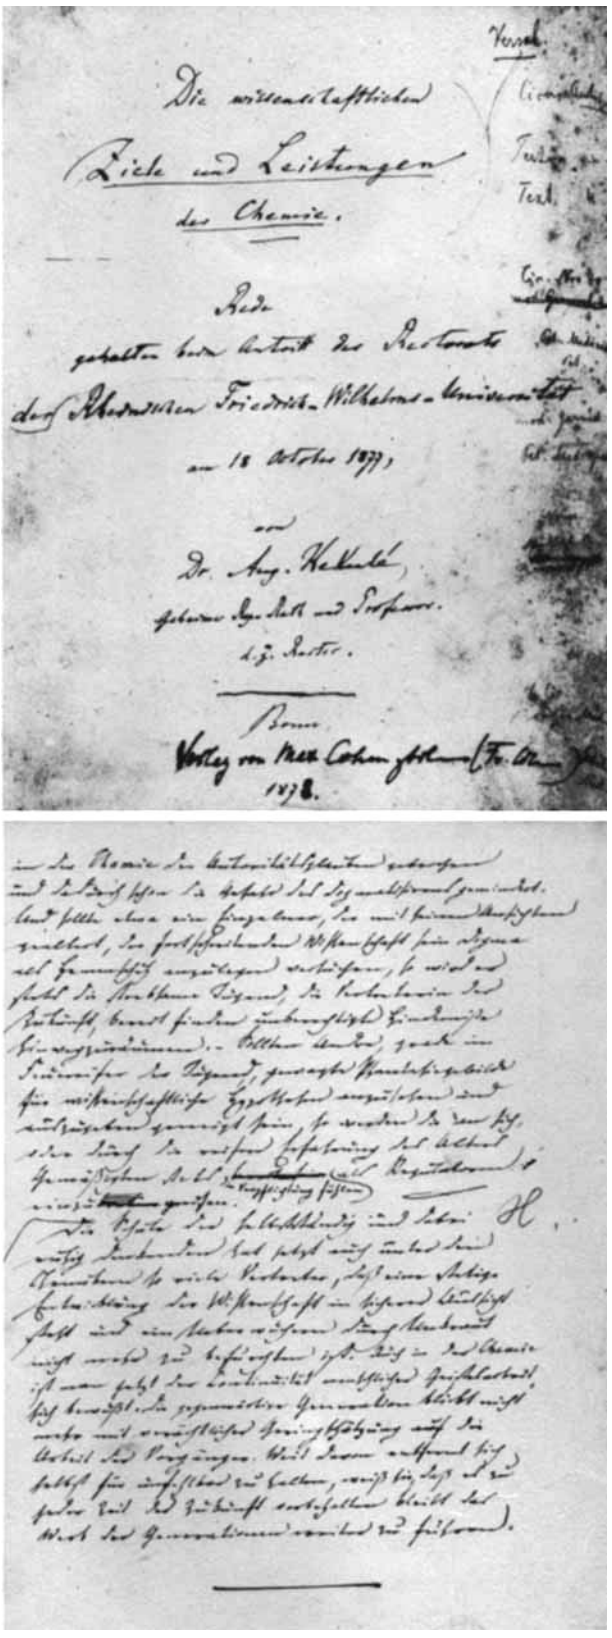

Fig. 30. Handwritten title page and last page of manuscript of *Kekulé*'s speech as University Chancellor in 1877 [14].

just as essential. Above all, however, we see *Kekulé*, the architect of chemistry, as an ideal researcher by virtue of his rare combination of daring and caution, his pronounced critical powers (also with regard to himself), his polite reservedness, always avoiding aggressive irony, conflicts, and polemics, in particular his great modesty which grew out of the recognition that all his ideas and practical work were only the extension of the achievements of his predecessors and teachers. That inner greatness which creates modesty moved him to say: "Something completely new has never been thought of, certainly not in chemistry"[91]. The warning and encouragement of the closing lines of his important speech as University Chancellor in 1877[92] still appear valid a century later: "As in all areas of knowledge in chemistry, too, faith in authority has been broken and the danger of dogmatization thus reduced. Should an individual who has aged with his ideas attempt to apply his dogma as a brake to an advancing science, he will always find zealous youth, as representative of the future, ready to clear away unjustified obstacles. Should others, in the ardor of youth, be inclined to regard and propound bold flights of fancy as scientific hypotheses, then those who are more moderate by nature or through the maturing experience of age will always feel obliged to intervene as regulators.

The school of independently and calmly reasoning people has now gained so many representatives among chemists that a constant development of this science is ensured and a takeover by weeds need no longer be feared. In chemistry too, the continuity of human intellectual work is recognized; the present generation no longer looks upon the work of its predecessors with scornful contempt; far removed from considering itself infallible, it knows that at any time it is the prerogative of the future to continue the work of generations."

July 13, 1896, was the last day in the life of this giant among men, who was privileged to know that his theories never led anybody astray but instead opened the way for innumerable discoveries.

I am indebted to my co-workers Dr. M. Gold and Dipl.-Ing. H. G. Kläs for extensive photographic work in the reproduction of original documents and portraits.

[86] Report by *G. Schultz*, Ber. Dtsch. Chem. Ges. *23*, 1265 (1890).

[87] In his address at the "Benzene festival", *A. Kekulé* recounted his discovery of the theory of valency: "During my stay in London I lived for some time in Clapham Road, near the Common. However, I often spent the evenings with my friend *Hugo Müller* in Islington, at the other end of the great city. We talked about diverse matters, but mostly about our beloved chemistry. One fine summer day I was traveling once again on the last omnibus through the empty streets of the otherwise so bustling metropole; 'outside', on the roof of the omnibus, as always, I began to dream. Atoms danced before my eyes. I had always seen them in motion, those little entities, but I had never succeeded in detecting the nature of their motion. Today I saw how two of them frequently joined to form pairs; how larger ones surrounded two smaller ones, yet larger ones held three and even four of the small ones, and how everything turned in whirling dance. I saw how larger ones formed a row, drawing along smaller ones only at the ends of the chain. I saw what past-master *Kopp*, my venerable teacher and friend, has described in such a charming way in his "molecular world": but I saw it long before him. The conductor's call: "Clapham Road" wakened me out of my reverie, but I spent part of the night committing at least sketches of that dream to paper. Thus arose the theory of structure (cf. [86], p. 1306).

[88] Concerning the enunciation of the benzene formula, *Kekulé* said, in the same speech (cf. [86], p. 1306): "It was a similar matter with the benzene theory. During my time at Ghent in Belgium, I lived in elegant bachelors' rooms in the main street. However, my study looked onto a dark side-alley and was without light during the day. That was no disadvantage for a chemist who spends the daylight hours in the laboratory. There I sat and wrote for my textbook; but things did not go well; my mind was occupied with other matters. I turned the chair towards the fireplace and began to doze. Once again the atoms danced before my eyes. This time smaller groups modestly remained in the background. My mental eye, sharpened by repeated apparitions of similar kind, now distinguished larger units of various shapes. Long rows, frequently joined more densely; everything in motion, twisting and turning like snakes. And behold, what was that? One of the snakes caught hold of its own tail and mockingly whirled round before my eyes. I awoke, as if by lightening; this time, too, I spent the rest of the night working out the consequences of this hypothesis".

Criteria for the Efficiency, Stability, and Capacity of Abiotic Photochemical Solar Energy Storage Systems[**]

By Hans-Dieter Scharf, Jörg Fleischhauer, Hans Leismann, Ingrid Ressler, Wolfgang Schleker, and Robert Weitz[*]

The utilization of simple photochemical reactions for the storage of solar energy in the form of chemical energy in energy-rich products has often been considered in the further development and improvement of *e.g.* simple thermosolar techniques. The hitherto proposed criteria for the qualification of an abiotic photochemical system are, however, mostly of a qualitative nature, so a mutal comparison of the systems is not precise enough. In this article it is shown how a useful correlation on the basis of time-independent experimental data can be achieved and how, from the viewpoint of photochemistry, a comparative classification of known reactions is possible. The following reactions are compared: the [2+2]-photocycloadditions of norbornadiene, dimethyl 2,3-norbornadienedicarboxylate, and dicyclopentadienone, the photoisomerization of *trans*- to *cis*-diacetylindigo, the photodissociation of nitrosyl chloride as well as a photocatalytic redox reaction. The quantity of material required and storage efficiency are by far the most favorable in the case of *trans*-diacetylindigo. The main disadvantage of the latter however, is that the energy-rich *cis*-form rapidly reverts to the stable *trans*-form at elevated temperatures.

1. Introduction

The utilization of solar energy for domestic and industrial purposes has acquired paramount importance in the research efforts of all industrialized nations. The principal aim of the investigations undertaken is the conversion of the sun's radiant energy into

1) low-temperature heat (thermosolar technique),
2) mechanical energy (thermomechanical solar power stations),
3) electrical energy (solar cells, photovoltaic processes, *etc.*),
4) chemical energy (production of "fuel").

The techniques involved in the conversions 1 and 2 as well as the solar cell technique have already been developed to the points of industrial application; however, their application is rendered difficult by the following facts:

a) solar radiation has a low energy density[1], so suitable collector systems require a lot of space and are costly,
b) the energy supply is not constant with time,
c) places enjoying high solar radiation density are often geographically unfavorable.

Therefore, in order to utilize solar energy independently of time and geographic position it is essential to generate "fuel" (free chemical energy) with the aid of sunlight. Worldwide research activities in this sector are at present primarily concerned with the fundamental principles of the following interdisciplinary topics:

4.1. the thermochemical decomposition of water[2], NH_3[3], SO_3[4] at high temperatures (>500 °C)
4.2. model systems for photosynthesis[5–7] (artificial membranes[8], micelles[9], synthetic molecular organizates[10])
4.3. photoelectrochemistry of semiconductors[11] (production of electrical and/or chemical energy)
4.4. photogalvanic cells[12]
4.5. photochemical redox systems (*e.g.* photolysis of water[13])
4.6. photochemical unimolecular solar energy storage in energy-rich inorganic or organic molecules

Some excellent reviews of the topics outlined under point 4 are to be found in the American[14], British[15], and Swedish[16] literature.

Obviously, the abiotic conversion of solar energy into a form of energy useful for domestic and industrial purposes is difficult. First of all, suitable storage processes are lacking, to bridge the time when the sun is not shining. The only example of long-term storage of solar energy (photosynthesis) is provided by nature. Disregarding the utilization of fossil fuels, the green plant is not an ideal energy-storage system for man, except from the point of view of its nutritional value, because its cultivation requires large amounts of water, fertilizers and entails a lot of work.

Whereas the efficiency of solar energy storage in photosynthesis is about 6—8%[17,18], the thermodynamic limitation for photochemical energy storage is 15—20%[17,19], so chemists are searching for synthetic compounds, which form energy-rich products by absorption of the sun's radiation. The energy thus stored must be regainable at a later date, with simultaneous recovery of the starting material.

In general the following advantages over the storage of solar energy in molecular movement in condensed phases or in latent heat (called simple thermosolar techniques) are well acknowledged: no elaborate heat insulation is required, energy "harvesting" is even possible in winter and from diffuse daylight and the storable energy can reach up to five times the heat storage value of water (209 J/g; 20—70 °C). This would favor especially the production of low temperature heat for everyday purposes.

A number of photochemical systems (topics 4.5 and 4.6) able to store solar energy have been proposed[20–30] in the

Prof.-Pirlet-Strasse 1, D-5100 Aachen (Germany)

[**] Presented in part at the meeting of the GdCh-Fachgruppe "Photochemie" in Mülheim/Ruhr, November 23, 1978, under the title "Utilization of solar energy—a challenge to photochemistry?"

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0909-0652 $ 02.50/0

past, but no great effort has been made to consistently and quantitatively compare the storage efficiencies, material requirements, and stabilities of the cited systems. Such criteria, however, are desirable in order to validate sometimes optimistically represented empirical data and to be able to evaluate known as well as new systems with regard to the above mentioned properties.

Therefore, in this paper we shall establish criteria based on quantum yields, reaction enthalpies, absorption spectra, and the extent of side reactions, and apply them, for purpose of comparison, to photochemical storage systems (topics 4.5 and 4.6), wherever the necessary experimental data are available.

2. Principles of Photochemical Storage Systems in Homogeneous Phases

Starting from a compound A the storage of photon energy as chemical energy in a product B requires a photon absorber, whose energy level (Jablonski) diagram is shown in Figure 1. This light absorber can be either compound A itself or a sensitizer (Sens), or a photocatalyst (Cat).

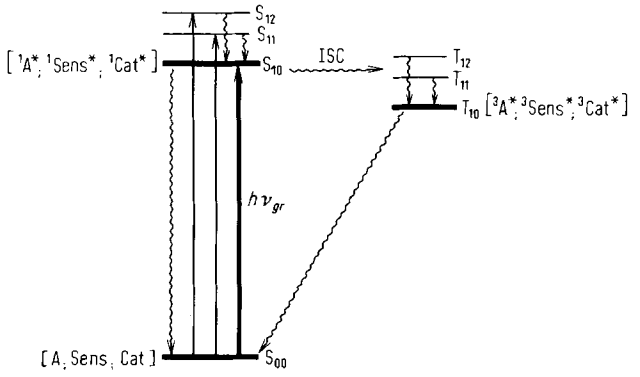

Fig. 1. Photophysical activation and deactivation processes of the photon absorbers A, Sens, and Cat respectively. A = starting material; Sens = sensitizer; Cat = photocatalyst; S_{00} = singlet ground state of A, Sens, or Cat; S_{10} = first excited singlet state: $^1A^*$, $^1Sens^*$, or $^1Cat^*$; S_{11}, S_{12} = higher vibrational levels of S_1; T_{10} = first excited triplet state: $^3A^*$, $^3Sens^*$, or $^3Cat^*$; T_{11}, T_{12} = higher vibrational levels of T_1; ISC = intersystem crossing; $h\nu_{gr}$ = energy of a photon capable of the excitation $S_{00} \rightarrow S_{10}$ (threshold energy); $\rightarrow \hat{=}$ optical transitions; $\rightsquigarrow \hat{=}$ radiationless transitions.

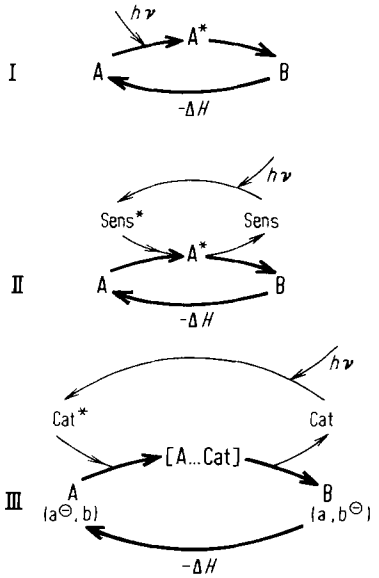

Fig. 2. Simple schemes of thermoreversible photoreactions (type I, II, and III). B = energy-rich photochemical product in ground state; A* = excited singlet or triplet state of starting material A; Sens* = singlet or triplet excited sensitizer; Cat* = singlet or triplet excited photocatalyst; $(a^{\ominus}, b)$, $(a, b^{\ominus})$ = A and B, respectively, as redox couples; {A.....Cat} = electron transfer complex; ΔH = enthalpy difference of the ground states of B and A.

According to this energy level diagram most of the thermoreversible photoreactions proposed in the literature[20-30] can be reduced to three simple types of reactions (see Fig. 2).

In cases I and II the starting material A is excited to A* by a photon or Sens* and then forms the energy rich product B. In case III, A and B are complementary redox couples. The couple A $(a^{\ominus}, b)$ reacts with the excited photocatalyst (Cat*) *via* an electron-transfer complex to form the redox couple B $(a, b^{\ominus})$. In all three cases the fuel B must be re-convertible into A, when the stored energy is subsequently required.

3. Efficiency of Abiotic Photochemical Solar Energy Storage Systems

Figure 3 shows the spectral energy distribution of the sun's radiation[31] for different angles of incidence on a collector.

For the storage of photochemical energy, as opposed to purely thermal energy, only the range b) of wavelengths up to about 700 nm is available, since this latter wavelength is the maximum threshold wavelength of all photochemical reactions known so far.

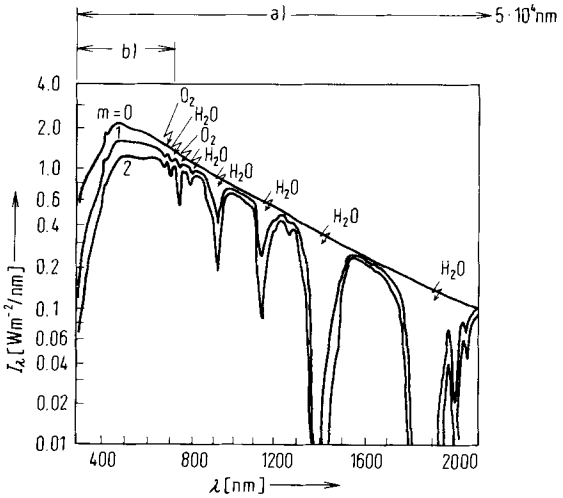

Fig. 3. Spectrum of the sun [31] for various angles of incidence δ to the normal of the earth. m = 0: irradiation of the sun outside the atmosphere (AM0-spectrum); $m = 1 \hat{=} \delta = 0°$ (AM1 spectrum); $m = 2 \hat{=} \delta = 60°$ (AM2 spectrum). a) thermally useful range of the spectrum of the sun [29]; b) photochemically useful range of the spectrum of the sun. I_λ = irradiation power per unit area and interval of wavelength at the wavelength λ of the terrestrial solar spectrum.

This range b) covers about 50%[29] of the incident radiation energy. For a quantitative assessment of the efficiency of photoreactions we can use an efficiency factor η_w, defined as follows:

$$\eta_w = \frac{n \cdot \Delta \bar{H}}{t_B \cdot F \int_0^\infty I_\lambda \, d\lambda} \qquad (1)$$

where n is the amount of substance B (in moles), which is formed in the photoreaction A→B during the irradiation time t_B. $\Delta \bar{H}$ is the difference in the molar standard enthalpies of the ground states of A and B ($\Delta \bar{H} = \bar{H}_B - \bar{H}_A$)[32]. I_λ is the sun's energy incident on a unit surface area in unit time per unit of wavelength at the wavelength λ (cf. Fig. 3). F is the collector area of the reaction cell. Hence, η_w is the ratio of

the stored enthalpy to the incident energy. Starting from the work of *Porter* and *Archer*[33,34] and *Bolton*[35], who, on the basis of earlier work [36–39], have formulated an efficiency for photochemical systems, η_w [eq. (1)] may be represented by a product of four factors (see Section 11):

$$\eta_w = \eta_E \cdot \phi_B^A \cdot \eta_a \cdot \eta_{abs} \tag{2}$$

In formulating such an expression certain assumptions have to be made, *e. g.* homogeneous concentrations in the cell (this can always be realized by stirring) and nearly time-independent concentrations (this may be achieved by short irradiation times). These four factors are discussed in detail in the following Sections.

3.1. Energy Conversion Factor η_E and Quantum Yield ϕ_B^A

The energy conversion factor η_E represents the ratio of the stored molar enthalpy ($\Delta\bar{H}$) to the energy of one mole of photons having the threshold wavelength λ_{gr}:

$$\eta_E = \frac{\Delta\bar{H}}{h \cdot c \cdot N_A/\lambda_{gr}} \leq 1 \tag{3}$$

where h is Planck's constant, c is the velocity of light, N_A is Avogadro's number and λ_{gr} is the wavelength for the 0-0-transition of A or Sens or Cat (threshold wavelength, cf. Fig. 1). The second factor in equation (2), ϕ_B^A, is the quantum yield[40] of the photoreaction, which is assumed to be independent of the wavelength λ for $\lambda \leq \lambda_{gr}$. (For sensitized processes the efficiency of energy transfer has to be taken into account in ϕ_B^A[41].) $\phi_B^A \cdot \eta_E$ corresponds to *Calvert*'s "Q-factor"[42].

3.2. Useful Fraction η_a of Incident Energy

In equation (2) η_a is the factor which has been carefully studied by *Archer*[34] for an ideal converter (*i. e.* complete absorption). η_a is referred to as "available energy" by *Archer*[34] and as "useful energy" by *Flynn* and *Trivich*[36]:

$$\eta_a = \frac{\int_0^{\lambda_{gr}} I_\lambda \cdot (\lambda/\lambda_{gr}) \cdot d\lambda}{\int_0^{\infty} I_\lambda \, d\lambda} < 1 \tag{4}$$

η_a is the ratio of the energy of one Einstein (1 Einstein = 1 mole photons) of the wavelength λ_{gr} multiplied by the number of Einstein available for $\lambda \leq \lambda_{gr}$ to the total incident solar energy of a special sunlight spectrum I_λ (cf. Fig. 3). The product $\eta_E \cdot \phi_B^A \cdot \eta_a$ was used by *Porter* and *Archer*[33,34] as a measure of the solar energy storage efficiency.

To illustrate more clearly the significance of the factor η_a the "used" energy (dark area) and the "wasted" energy (hatched + checkered areas) are show in Figures 4a—4d for four typical threshold wavelengths λ_{gr}. The photons whose energy is depicted by the hatched area will not be absorbed. The energy represented by the checkered area gets lost because the excited molecule relaxes into the S_{10}-state (cf. Fig. 1). It can be seen that η_a (dark area/total area) will always be smaller than unity and will have its highest value at $\lambda_{gr} \approx 1500$ nm (cf. Fig. 4c and 5).

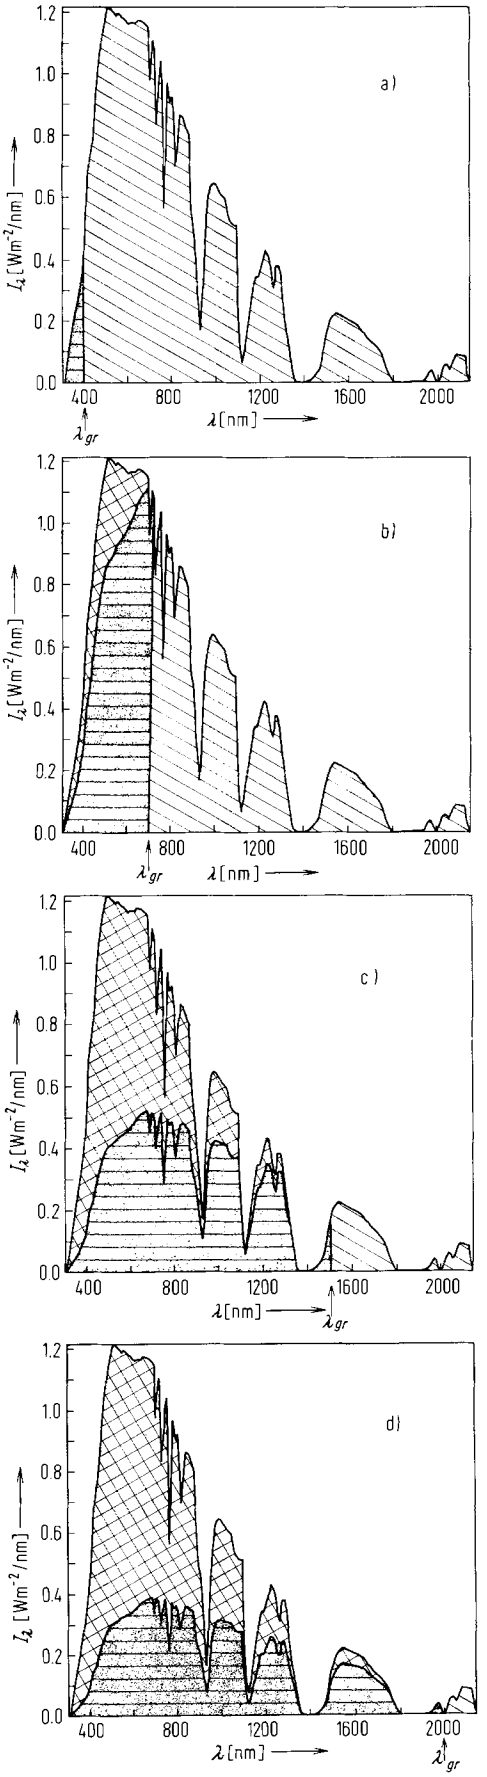

Fig. 4. Representation of the utilizable energy (▨), the unabsorbed energy (▨), and the energy "wasted" through relaxation into the S_{10} state (▨) of the AM2 solar spectrum for four sample threshold wavelengths [a) $\lambda_{gr} = 400$ nm; b) $\lambda_{gr} = 700$ nm; c) $\lambda_{gr} = 1500$ nm; d) $\lambda_{gr} = 2000$ nm]. The dark area is limited by the curve $I_\lambda \cdot \lambda/\lambda_{gr}$ [cf. eq. (4)]. Definition of the parameters, see Fig. 3.

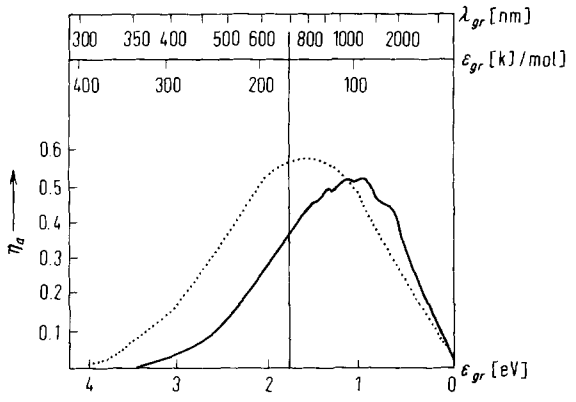

Fig. 5. Useful fraction η_a of the AM2 radiation of the sun [31] (—) and the diffuse component of daylight [34] (...) as a function of the threshold energy ε_{gr} corresponding to the wavelength λ_{gr}. 700 nm is the maximum threshold wavelength of photochemical reactions known up to now.—It is not expressed here that the intensity of the diffuse daylight is only 1% of the intensity of the direct irradiation of the sun.

This may be explained in the following way: In passing from small values of λ_{gr} to larger values of λ_{gr} the number of photons radiated below λ_{gr} increases with wavelength whereas the threshold energy ε_{gr} corresponding to λ_{gr} decreases. Up to λ_{gr}^{max} the first factor is greater than the second one. At $\lambda_{gr} > 1500$ nm, however, the increase in the radiated photons is less than the decrease in the threshold energy ε_{gr} and η_a decreases again. Photochemical reactions above 700 nm with a significant value of $\Delta\bar{H}$ are as yet unknown, *i.e.* the η_a value given at 700 nm in Figure 5 has not yet been exceeded.

3.3. Absorption Yield η_{abs}

η_{abs} [cf. eq. (2)] is the ratio of photons absorbed by A (or Sens or Cat) to all the photons of wavelength $\lambda \leq \lambda_{gr}$:

$$\eta_{abs} = \frac{\int_0^{\lambda_{gr}} I_\lambda \cdot \lambda \cdot (E_{A\lambda}/E_\lambda)(1-10^{-E_\lambda})\,d\lambda}{\int_0^{\lambda_{gr}} I_\lambda \cdot \lambda \cdot d\lambda} \leq 1 \qquad (5)$$

Here $E_{A\lambda}$ is the wavelength-dependent extinction of A (or Sens or Cat) and E_λ the analogous value for the total system. η_{abs} will have its optimal value 1 if all the sunlight is absorbed by A (or Sens or Cat) alone ($E_{A\lambda} = E_\lambda$) and if the sunlight is completely absorbed ($10^{-E_\lambda} = 0$).

Figures 6a and 6b show for the systems norbornadiene *(1a)*/acetophenone and *trans*-diacetylindigo *(5a)* the photons of wavelength between $\lambda = 300$ nm and λ_{gr} radiated by the sun (dark + checkered area) compared to those actually absorbed (dark area).

η_{abs} is the ratio of the dark area to the sum of the dark and checkered area. Though *trans*-diacetylindigo *(5a)* absorbs many more photons from the solar spectrum (50%) then norbornadiene *(1a)*/acetophenone (0.8%), the η_{abs}-values of both systems are nevertheless comparable (0.7 and 0.8), for by definition only the range up to λ_{gr} has to be taken into account in the evaluation of η_{abs}.

Thus the factors necessary for evaluating the efficiency of an abiotic photochemical solar energy storage system are defined and it is now possible to compare various systems.

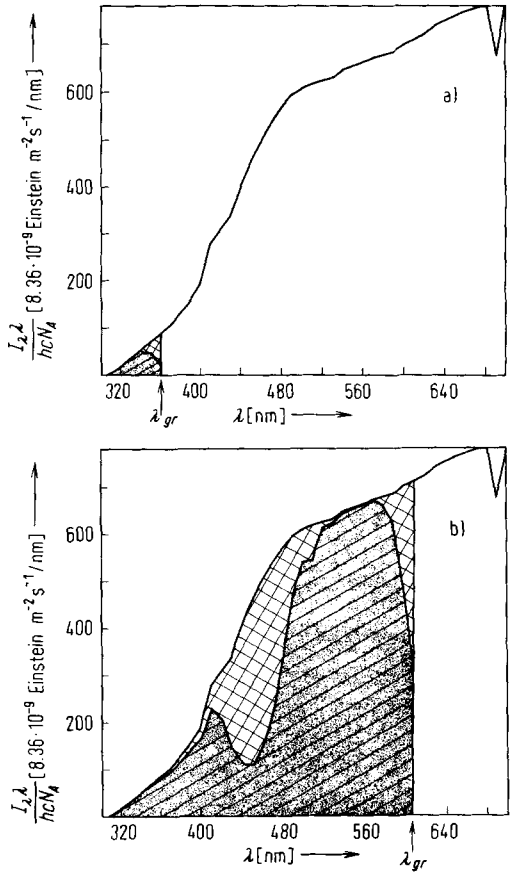

Fig. 6. Photons aborbed (▨) between $\lambda = 300$ nm and λ_{gr}, and the total amount of photons (▨ + ⊠) available in this wavelength range of AM2 solar radiation, for (a) norbornadiene *(1a)*/acetophenone ($\lambda_{gr} = 366$ nm) and (b) *trans*-diacetylindigo *(5a)* ($\lambda_{gr} = 610$ nm) for a maximum extinction of 3. The dark area is bounded by the curve $\frac{I_\lambda \cdot \lambda}{h \cdot c \cdot N_A} \cdot (1 - 10^{-E_\lambda})$ [cf. eq. (5) for $E_{A\lambda} = E_\lambda$].

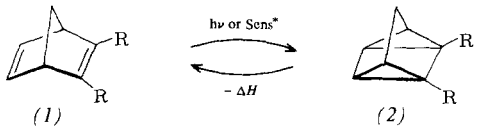


4. Examples of Photochemical Solar Energy Storage Systems

In the following a selection of those photochemical systems has been complied, which are mentioned in the literature as being "particularly promising". The efficiency factors η_w of these systems (see Tables 2 and 3 and Fig. 8) have been calculated according to equation (2) using what we consider are the most reliable data in the literature.

4.1. Intramolecular [2+2]-Cycloadditions: Norbornadiene/Quadricyclane

The photochemical system *(1)/(2)*, R = H, CO_2R', has long been known[23,46–60] and has been very thoroughly investigated both under direct irradiation as well as under sensitized conditions[23,24,52–54]. The large enthalpy difference $\Delta\bar{H}$ between the valence isomers *(1a)* and *(2a)* is often referenced as an advantage for its suitability as a solar energy storage system; in the case of *(1b)* and *(2b)*, however, it is one third smaller (referred to 1 g of material).

The conversion of *(2a)* into *(1a)* at room temperature and below can be neglected, so far as traces of metals or their ions can be excluded. The halflife for this reaction in the con-

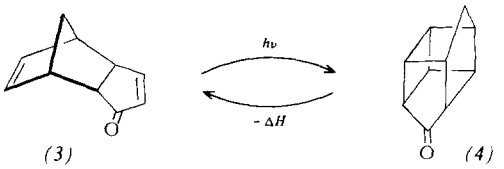
(1) (2)

(a), R = H; (b), R = CO_2CH_3

(a): $\Delta\bar{H} = -110$ kJ/mol ≙ −1.2 kJ/g [43]
(b): $\Delta\bar{H} = -77$ kJ/mol ≙ −0.39 kJ/g [44]

Phys. data \ Cpd.	(1a) [45]	(1b) [95]	(2a) [46]	(2b)
M.p. [°C]	−19.1	—	—	55—58
B.p. [°C/torr]	89.5/760	134—135/10	108/760	—
δ_4^{20}	0.9064	—	—	—
n_D^{20}	1.4702	—	1.4804	—

densed phase at 140 °C is about 14 h[46,61]. *(2b)* is completely stable up to its melting point. The rate constant of the thermal isomerization of *(2a)* in the gas phase is $K = 10^{12.8\pm1}\exp(-140.3\ \text{kJ mol}^{-1}/RT)\ \text{s}^{-1}$[62].



In the meantime tetraarylporphyrin-metal catalysts of high efficiency have been described which, as free[57] or polymer-bound[60] molecules, enable back-isomerization of *(2a)* to *(1a)* with liberation of the stored chemical energy as heat. This finding would at least serve as a model for a staggered "energy harvesting" (summer) and its effective utilization (winter). A number of disadvantages, however, should not be overlooked. Thus, the absorption data of the system *(1a)/(2a)* which are given in Table 1 show that the wavelengths necessary for excitation are not present in the sun's radiation reaching the earth (see Fig. 3). They lie in the UV-part of the spectrum. Even the free[46,50,52] or polymer bound[24] acetophenone sensitized reaction *(1a)*→*(1b)* requires light of very short wavelength (see Fig. 6a and 4a).

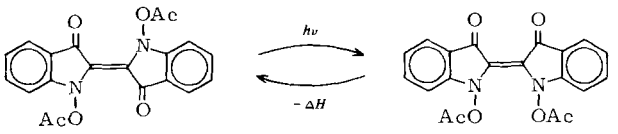
Other sensitizers[50,52] have proven to be inefficient[63]. The CuCl–CT complex of *(1a)*[23,53] and complexes with Cu^I-phosphane ligands[54] have a better chance of absorbing radiation from the short wavelength edge of the sun's spectrum (see Fig. 3).

Although *(1a)* is a commercially available product[64], the following disadvantages further restrict its utilization as a solar energy storage system. The compounds are combustible and are not miscible with water. *(1a)* reacts with oxygen irreversibly to give a copolymer[65] which does not further react photochemically. According to *Roquitte*[67] cyclopentadiene, acetylene, and toluene are formed during the gas-phase photolysis (and also to a smaller extent on photolysis in solution) of *(1a)*. According to *Hammond et al.*[50] arenes sensitize the reaction *(2)* $\xrightarrow{h\nu}$ *(1)*, but not, however, the reverse process. The cumulation of toluene for instance may decrease the quantum yields of the photochemical formation of *(2)* considerably—an effect which has hitherto not been checked.

4.2. Intramolecular [2 + 2]-Cycloadditions: *endo*-Dicyclopentadienone/Bishomocubanone

The *endo*-dicyclopentadienone *(3)* (*endo*-tricyclo[5.2.1.$0^{2,6}$]deca-4,8-dien-3-one) has two advantages as a solar energy storage system over the well known parent hydrocarbon *endo*-dicyclopentadiene[69], which is photochemically cyclizable to 1,3-bishomocubane. 1. The nπ*-transition of *(3)*[22] is on the short wavelength edge of the sun's spectrum (Tab. 1, Fig. 3). 2. Whereas the excitation energy has to

(3) (4)



$\Delta\bar{H} = -68.6$ kJ/mol ≙ −0.5 kJ/g [22]

Phys. data \ Cpd.	(3) [68]	(4) [63]
M.p. [°C]	80	122—126

be transferred intermolecularly to dicyclopentadiene from a suitable sensitizer[69], *(3)* "possesses" an "intramolecular sensitizer", the carbonyl group. Thus the quantum yield of cycloaddition is larger in this case than in that of the parent hydrocarbon.

The quantum yield of bishomocubanone *(4)* (pentacyclo[5.3.0.$0^{2,5}$.$0^{3,10}$.$0^{4,8}$]deca-6-one) formation is wavelength-dependent. Consequently, the chemical yield which can be obtained at 330—380 nm is >99%; at 305 nm, however, it amounts to only 90%[22]. *(4)* is stable up to 295 °C[22]. Again this system exhibits considerable disadvantages. At higher concentrations of *(3)* intermolecular [2 + 2]-cycloaddition is observed. The catalytic back reaction *(4)*→*(3)* proceeds at 140 °C in only 95%[22] yield. *(3)* is not commercially available and, like *(4)*, is insoluble in water. 1,3-Bishomocubane is back-isomerized by the iridium complex $Ir(CO)_3Cl_2$ to *endo*-dicyclopentadiene without formation of byproducts[70]; similar catalytic investigations on *(4)* have not been reported.

4.3. *cis-trans*-Isomerization: *trans*-Diacetylindigo/*cis*-Diacetylindigo

trans-(5) cis-(5)

$\Delta\bar{H} = -34$ kJ/mol ≙ −0.1 kJ/g [28]
trans-(5), m.p. 245—250 °C [71]

N,N'-Disubstituted indigo derivatives have been proposed by *Schwerzel et al.*[28] as combined solar energy storage systems. A smaller part of the solar energy is stored as chemical energy in the *cis-(5)* isomer, the larger part, however, in the molecular motion in solution. The advantages of this system are the absorption spectrum, which matches very well with the photochemically active part of the solar spectrum (see Fig. 6b and 3), the well known light stability of the indigo dyes, and the catalytic back-reaction *cis-(5)*→*trans-(5)*, which proceeds quantitatively[28].

Considerable disadvantages should, however, not be overlooked. On the one hand, the quantum yield ϕ_B^A of the pho-

tochemical *trans-cis*-isomerization (see Table 2) is very low and on the other the photochemically storable energy does not exceed half of that which can be stored in hot water between 20—70 °C (*i.e.* 0.209 kJ/g), and the indigo dyes are only sparingly soluble in most solvents. A further disadvantage is the low stability of the energy rich *cis* form, which rapidly back-isomerizes to the stable *trans* form at higher temperatures[28].

4.4. Photodissociation: Nitrosyl Chloride

$$NOCl_{(g)} \underset{-\Delta H}{\overset{h\nu}{\rightleftharpoons}} NO_{(g)} + 1/2\ Cl_{2(g)}$$

$\Delta H = -37.6$ kJ/mol $\hat{=} -0.58$ kJ/g [21]

Phys. data [21] \ Cpd.	NOCl	NO	Cl_2
M.p. [°C]	−64.5	−136.6	−100.9
B.p. [°C/760 torr]	− 5.8	−151.9	− 36.4

The photodissociation of nitrosyl chloride is very well known[72], and has been proposed for photochemical syntheses[73] as well for the storage of solar energy[21,26]. The mechanism very likely involves the following chain reaction:

$$NOCl + h\nu \rightarrow NO + Cl\cdot$$
$$Cl\cdot + NOCl \rightarrow NO + Cl_2$$
$$2\,NOCl + h\nu \rightarrow 2\,NO + Cl_2$$

Both the quantum yield ϕ_B^A (Table 2) of the reaction as well as the position of the threshold wavelength (Tab. 1) are unusually favorable. The back-reaction proceeds spontaneously; hence the photoproducts have to be separated immediately to keep the photodissociation running[72]. The extremely corrosive substances necessitate employment of high quality flow devices.

4.5. Photocatalytic Redox Reactions: Oxidation of Chloride to Chlorine

Recently, photoredox reactions in homogenous solution for the catalytic cleavage of water or other small molecules have been the subject of detailed investigation[13].

One key problem is the photochemical stability of the catalysts, which in most cases are based on complex-bound noble metal ions, mainly of rhodium or ruthenium.

These reactions lead over to photoelectrochemical[74] and photogalvanic systems[12] as well as to membrane techniques for charge separation on the basis of synthetic molecule organizates[10].

For evaluation of the efficiency criteria according to equation (2) one photocatalytic redox system of Type III (see Fig. 2) has been chosen from the plethora of published examples. This system represents the photocatalytic oxidation of chloride to chlorine[75–77]. The value of this system lies in the storage of photon energy as chemical energy of chlorine and in addition in its being a potential chemical process with an alternative energy source: Hydrogen chloride is thermally oxidized by oxygen according to *Deacon*[78] in the gas phase with CuCl as a catalyst. As an alternative to this exothermal process, which so far has not been realized technically[79], hydrochloric acid can be oxidized photocatalytically to chlorine.

Deacon process:

$$2\,HCl_{(g)} + {}^1\!/_2 O_2 \underset{>350\,^\circ C}{\overset{CuCl}{\rightleftharpoons}} Cl_{2(g)} + H_2O_{(g)}$$

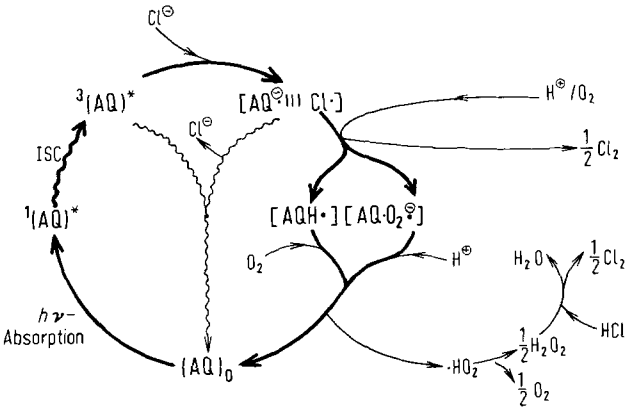
$\Delta H = -59$ kJ mol^{-1}

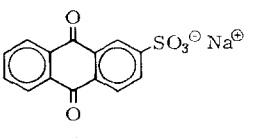
Photocatalytic process:

$$2\,HCl_{(aq)} + {}^1\!/_2 O_2 \xrightarrow[\Delta H]{{}^3(AQ)^*} Cl_{2(g)} + H_2O$$

$\Delta H = +49$ kJ/mol $\hat{=}$ 0.56 kJ/g

Potential photocatalysts are anthraquinone derivatives (AQ) such as *(6)* or *(7)*, which are soluble in aqueous hydrochloric acid and in the triplet excited state $^3(AQ)^*$ undergo a redox-reaction with chloride ions[75,76]. In the presence of oxygen the anthraquinone catalyst runs through a cycle (see Fig. 7) in which it is restored for further reaction sequences[77]. The chlorine which is formed is carried along with the air or oxygen stream which is bubbling through the reaction vessel.





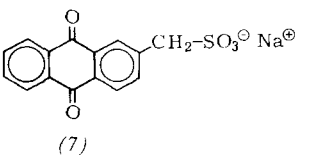


Fig. 7. Reaction cycle of anthraquinone derivatives (AQ) undergoing photocatalytic chloride oxidation in the presence of oxygen. $(AQ)_0$ = AQ in ground state; $^1(AQ)^*$ = AQ in the first excited singlet state; $^3(AQ)^*$ = AQ in the first excited triplet state; ISC = intersystem crossing; $[AQ^{\ominus} ||| Cl\cdot]$ = radical ion pair after electron transfer; [AQH·] = anthrasemiquinone radical of AQ; $[AQO_2^{\ominus}\cdot]$ = oxygen adduct of the AQ radical anion as an alternative intermediate.

The main problem in this photocatalytic chloride oxidation lies once again in the photochemical stability of the anthraquinone derivative, which is employed in concentrations of about 10^{-3} mol/l.

(6)

(7)

For example anthraquinonesulfonates such as *(6)* are very rapidly photosubstituted[76,80] in the excited singlet state to the corresponding chloroanthraquinones. Anthraquinone-2-methanesulfonate *(7)*[75] is slowly oxidized at the methylene

group under the reaction conditions. These degradation products cannot catalyze the reaction because of their insolubility in aqueous hydrochloric acid. Further research effort must therefore be directed toward the synthesis of photostable catalysts of the anthraquinone type.

The overall back reaction B→A (see Fig. 2, Type III) necessary with energy storage in mind

$$Cl_2 + 2e^- \rightarrow 2Cl^-$$
$$H_2O \rightarrow \tfrac{1}{2}O_2 + 2H^+ + 2e^-$$
$$Cl_2 + H_2O \rightarrow 2HCl + \tfrac{1}{2}O_2$$

has not yet been verified.

An alternative could be the utilization of the chemical energy of chlorine by an electrochemical fuel cell with hydrogen as electron donor.

$2HCl_{(aq)} + \frac{1}{2}O_2/Cl_{2(g)} + H_2O$ *(7)* as catalyst	0.17	0.15 [75]	0.040	2.6	0.10

[a] The UV spectra of the substances *(1)—(4)* and *(7)* were recorded with a Cary 14 spectrometer on punched tape for processing with a Dietz computer (Mincal 621/8). The UV spectra of the other compounds were taken from the literature [21, 28].
[b] The Q factor was determined according to *G. Jones* [26, 30] as $\Delta\bar{H} \cdot \phi_B^A / \varepsilon_{gr}$; $\varepsilon_{gr} = N_A \cdot h \cdot c / \lambda_{gr}$. $Q = \phi_B^A \cdot \eta_E \cdot 100$.
[c] Calculated for $\eta_{abs} = 1$.

Table 2 shows, for all the systems discussed, the complementary trend of the factors in equation (2). It can be seen that the Q-factor[42] does not correctly characterize the efficiency of a photochemical solar energy storage system[26,30], and moreover leads to wrong conclusions, as in the case of norbornadiene *(1a)*/acetophenone and nitrosyl chloride.

5. Efficiency of Solar Energy Storage in Photosynthesis

According to Table 2 comparable efficiency values for the photosynthetic process can be obtained under the following assumptions:

1) Only the overall chemical reaction is considered[25,35]
$$CO_2 + H_2O \rightarrow \tfrac{1}{6}C_6H_{12}O_6 + O_2$$
2) The stored energy is 470 kJ per mol CO_2 assimilated, corresponding to the thermal value of the glucose formed[18] or $\Delta\bar{H} = 467$ kJ/mol[25,35].
3) The assimilation of one mole of CO_2 requires *ca.* 10 Einstein[18], *i.e.* the quantum yield is ≈ 0.1[90].
4) The limiting wavelength is 700 nm and thus $\varepsilon_{gr} = 180$ kJ/mol and $\eta_a = 0.36$ (from Figure 5).

The above-mentioned assumptions lead to a formal η_E-value of 2.6. This value is larger than 1 (cf. Section 3.1), because photosynthesis essentially requires more than one photon and the fraction of energy provided by dark reactions involved cannot be estimated. Thus the Q-value is 26% and $\eta_{w(opt)} \cdot 100 = 8\%$. This value for the efficiency is large compared to those for abiotic systems but it is reduced to 0.1—0.3% under realistic field conditions[17,18,42].

6. Dependence of the Efficiency η_w on the Absorption Parameters of the Light Absorber

Table 2 shows the $\eta_{w(opt)}$-values of the systems investigated, that is the efficiency [eq. (2)] for the condition $\eta_{abs} = 1$.

Figure 8 shows the dependence of η_w on the product of absorber concentration and path length of the absorption cell.

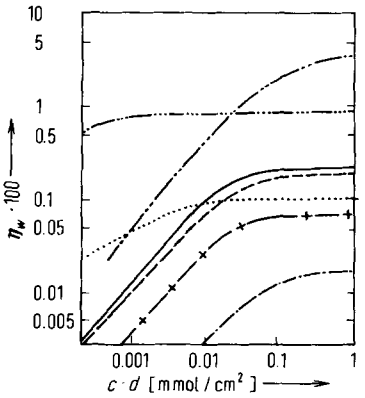

Fig. 8. Dependence of η_w on the quantity of photon absorber per area. c = concentration of light absorber; d = path length of absorption cell. ——≙ *(1a)/(2a)* with acetophenone; - - - - -≙ *(1a)/(2a)* as Cu^1Cl complex; -·-·-≙ *(1b)/(2b)*; —+—≙ *(3)/(4)*; —··—≙ *trans-(5)/cis-(5)*; ——··—≙ NOCl/NO + $\frac{1}{2}Cl_2$; ..... ≙ *(7)* as catalyst.

Hence it is seen that the efficiency η_w of a photochemical storage system is also strongly dependent on the absorption parameters of the photon absorber [cf. eq. (5)]. The required quantities of starting material A, Sens, and Cat can be calcu-

lated with the aid of the efficiency η_{abs}, thus providing an economic evaluation of the various systems.

Table 3 shows that *trans*-diacetylindigo, *trans-(5)*, is able to store 0.05% of incident solar energy at the smallest expense of material. For the same storage efficiency a 2000-fold quantity of the dienone *(3)* would be required, while the value of 0.05% cannot even been reached at all with the ester *(1b)*. Also in the range of optimal η_w-values, the diacetylindigo system *(5)* offers by far the best storage properties. The dramatic difference between *trans-(5)* (2.9 g/m^2) and NOCl (1500 g/m^2) is due to the difference in the extinction coefficients [ε_{max}(*trans-(5)*)/ε_{max}(NOCl) ≈ 2000 (cf. Table 1)].

Table 3. Required quantities and optimum storage capacity of selected photochemical storage systems. The required quantity is calculated for a fixed η_w value of 0.0005 and for a substance specific value of $0.9 \cdot \eta_{w(opt)}$. The storage capacity refers to the substance specific value only.

System	Quantities required [lg/m^2] for η_w = 0.0005	for η_w = $0.9 \cdot \eta_{w(opt)}$	Storage capacity [a] [mW/g] [b]	[g/m^2 h] [c]
(1a)/(2a) [91]	92	92	2.25	0.63
Acetophenone as Sens.	5.4	118	1.75	
(1a)/(2a) [92]	6.6	105	1.8	0.57
CuCl	7.1	113	1.7	
(1b)/(2b)	—	520	0.035	0.17
(3)/(4)	50.5	84.1	0.75	0.48
trans-(5)/cis-(5)	0.025	2.9	294.8	28.0
$NOCl_{(g)}/NO_{(g)} + \frac{1}{2}Cl_{2(g)}$	0.83	1500	2.96	27.5
(7) as catalyst [d]	3.6	34.7	2.6	0.58

[a] Relative to 100 W/m^2 [1] of the AM2 spectrum [31]. [b] Relative to substance A or Sens or Cat. [c] Relative to the energy-rich product(s) B. [d] System $2HCl_{(aq)} + \frac{1}{2}O_2/Cl_{2(g)} + H_2O$.

Thus absorbers with smaller extinction coefficients must be used in larger quantities per unit area in order to achieve optimal utilization of the incident energy. Concomitantly, however, the storable energy per gram of starting material is reduced (cf. Table 3, column 3). Thus the required quantity of *trans*-diacetylindigo is 100-fold more productive than the corresponding quantity of NOCl.

From the last column in Table 3 it can be seen, that the optimum production of energy-rich compound B in the case of *trans*-diacetylindigo and NOCl is about 50-fold compared to the other systems, which, however, has to be paid for by large amounts of material in the case of NOCl (cf. Table 3, second column).

The amounts of material required can be reduced if energy is withdrawn from a system during the storage. Cycles corresponding to Figures 2 and 9 have to be passed through. Then, however, the stability of the light absorbers and the extent of side reactions play an important role.

7. The Stability of Photochemical Storage Systems A, B

7.1. Types I and II

Figure 9 shows the possibility of the starting material A and the product B maintaining or breaking the storage cycle.

a) Deactivation:

$$A^* \rightsquigarrow A \text{ or } (Sens^* + A \rightsquigarrow Sens + A)$$

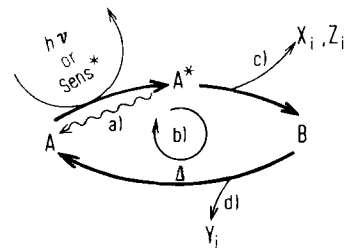

Fig. 9. Cycle referring to energy storage and recovery by a system A/B (cf. Fig. 2, I and II). The starting material A is excited to A* by absorption of a photon or interaction with an excited sensitizer Sens* and the product B is formed. (Further explanations, see text.)

b) Useful cycle

c) Wasteful photoreactions:

$$A^* \rightarrow \sum X_i,\ B \notin \{X_i\} \text{ or } (Sens^* + A \rightarrow Z_i,\ B \notin \{Z_i\})$$

d) Wasteful thermal reactions:

$$B \xrightarrow{\Delta} Y_i,\ A \notin \{Y_i\}$$

The lifetime of a storage system A/B depends on the fraction of side reactions X_i (or Z_i) and Y_i, *i.e.* on the probability ϕ_A of the recovery of A after the absorption of a photon (or interaction with Sens*) and after the possible processes a) to d).

Provided that A is thermally stable, the probability ϕ_A can be expressed by the measurable values ϕ_B^A [see eq. (2) and [40,93]], η_Δ (yield of the thermal back-reaction) and ϕ_{-A} (the quantum yield of the degradation of A after absorption of a photon or interaction with Sens*[93]).

$$\phi_A = 1 - \phi_{-A} + \phi_B^A \eta_\Delta \tag{6}$$

This probability has a formal value of 1 before the first absorption of a photon (or interaction with Sens*); it is $(\phi_A)^n$ after the n-th absorption of a photon (or n-th interaction with Sens*). Thus the expression

$$P_A = \sum_{n=0}^{\infty} (\phi_A)^n = 1/(1-\phi_A), \quad \phi_A < 1 \tag{7}$$

describes the sum of all probabilities with which a molecule A is successively available for renewed absorption of a photon (or interaction with Sens*) according to Figure 9. In this manner P_A is also the sum of all photons (or all Sens* molecules) with which A can react. The combination of equations (6) and (7) yields:

$$P_A = \frac{1}{\phi_{-A} - \phi_B^A \eta_\Delta} \tag{8}$$

as the mean number of possible excitations of A by a photon or Sens* molecule.

7.2. Type III

An analogous measure of the photostability of a catalyst accelerating a process corresponding to Type III in Figure 2 can be obtained from eq. (8), if the photon absorber A in

Figure 9 is replaced by the catalyst Cat. Assuming that Cat only forms Cat* and irreversible degradation products X_i ($\eta_\Delta = 0$), one obtains

$$P_{Cat} = 1/\phi_{-Cat} \tag{9}$$

as the mean number of photon absorptions, which can be endured by a molecule Cat before its complete degradation.

Eq. (9) is also valid for the stability of a sensitizer Sens in the cyclic system II (cf. Fig. 2) and in general for the photostability of light-absorbing substances (*e.g.* dyes). Thus the chlorophyll molecule in a leaf has a P_{Chl}-value of about 10^5[17], which corresponds to a degradation quantum yield of 10^{-5}.

8. The Number of Possible Storage Cycles

8.1. Types I and II

As one excitation of A is followed by a complete cycle (Fig. 9) with the probability $\phi_B^A \cdot \eta_\Delta$, the mean number of available cycles is:

$$P_{cy} = P_A \cdot \phi_B^A \cdot \eta_\Delta \tag{10}$$

Combination of equations 8 and 10 yields

$$P_{cy} = 1 \Big/ \left(\frac{\phi_{-A}}{\phi_B^A \cdot \eta_\Delta} - 1 \right) \tag{11}$$

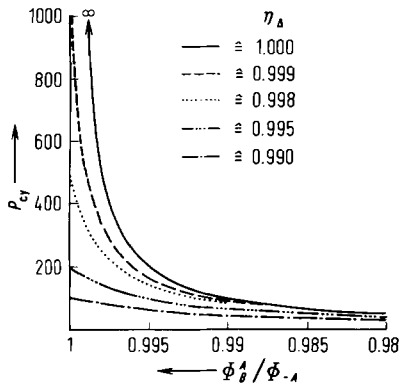

Fig. 10. The number of attainable storage cycles P_{cy} as a function of the yield of the photoreaction and of the thermal back-reaction. Definition of the parameters see Section 7.1; ϕ_B^A/ϕ_{-A} is the chemical yield of the photoreaction.

Figure 10 illustrates how "clean" both the photochemical and the thermal reaction must be in order to obtain appreciably more than 100 storage cycles. Even the number of cycles of 100[26], assumed by *Jones* for purposes of comparison, can only be achieved under the following conditions:

a) the photochemical step has no side reactions ($\phi_B^A/\phi_{-A} = 1$) and the thermal reaction has a yield $\geq 99\%$ ($\eta_\Delta \geq 0.99$), or

b) both the photochemical and the thermochemical steps have yields $\geq 99.5\%$ (*i.e.* ϕ_B^A/ϕ_{-A} and $\eta_\Delta \geq 0.995$), or

c) the thermal reaction is quantitative ($\eta_\Delta = 1$) and the photochemical step has a yield $\geq 99\%$ ($\phi_B^A/\phi_{-A} \geq 0.99$).

8.2. Type III

If a complete cycle according to Types I and II cannot be formulated, then in the case of a photocatalytic reaction the following relationship can be derived from eq. (9)

$$P_B = P_{Cat} \cdot \phi_B^A \tag{12}$$

where P_B is the mean number of product molecules B which can be generated with the photocatalyst Cat, if A is present in sufficient amount.

9. Capacity of Photochemical Energy Storing Systems

9.1. Types I and II

Multiplication of P_{cy}, the mean number of storage cycles, by the energy ΔH stored and recovered per cycle yields the maximum amount of energy, which can be converted up to complete degradation of A (Fig. 9):

$$W_{max} = P_{cy} \cdot \Delta H \tag{13}$$

9.2. Type III

By analogy with equation (13), for systems of Type III we have

$$W_{max}^{Cat} = P_B \cdot \Delta H \tag{14}$$

for the maximum value of the energy which can be stored through Cat up to its complete degradation. Equation (14) is also valid for photochemically unstable sensitizers.

Since the quantum yields of feasible solar energy storage systems described in the literature are not sufficiently accurate or not even given (*e.g.* ϕ_{-A}), it is difficult to make a comparison of the stabilities and capacities of the systems listed in Section 4. Nevertheless, if equations (11) and (13) are solved for the available literature values on the assumption that ϕ_B^A/ϕ_{-A} equals the chemical yield of the photoreaction and η_Δ is the optimum yield of the thermal back-reaction, the W_{max}-values in Table 4 are obtained.

From these W_{max} values, it can be seen that with sufficiently photo- and thermostable substances the combustion value of carbohydrates (15600 J/g; $C_6H_{12}O_6$) can be achieved by "pumping".

Table 4. Estimation of the number of cycles P_{cy} and of the storage capacity W_{max} of some abiotic systems (illustrations, see text).

System	η_Δ	ϕ_B^A/ϕ_{-A}	P_{cy}	W_{max} [J/g]
(1a)/(2a) with acetophenone [93]	1 [50]	1 [55]	"∞"[a]	"∞"[a]
(1a)/(2a) as CuCl complex	0.9 [23]	1 [55]	9	10710
(3)/(4)	0.98 [22]	0.95 [22]	13	6110
trans-(5)/cis-(5)	1 [28]	1 [28]	"∞"[a]	"∞"[a]

[a] According to Fig. 10, these values show extreme variations on slight modification of the yield parameters.

10. Concluding Remarks

The application of the criteria presented here to a potential photochemical system of Type I, II, or III enables one to estimate its storage capacity for solar energy in the form of chemical energy. In doing this the photochemical and chemical stability of the system have to be taken into account.

The factors η_w [eq. (1) and (2)], P_{cy} [eq. (11) and (12)] and W_{max} [eq. (13) and (14)] will be obtained from time-independent experimental data. For their determination very precise methods have to be developed. In so far as the production of material is concerned these factors are optimal values, which do not, or only indirectly, take into account the behavior of the systems over a long period of time. With these factors it is however possible to decide, if and how much experimental effort is justified in solving the problem of finding an acceptable storage system. The chemical problem to be solved is similar to that concerning the light stability of dyes. So long as it is uncertain from basic research whether a system is suitable or not, economical aspects such as price of starting material, *etc.*, environmental influences and technological considerations should be ignored in the initial studies.

11. Appendix

The Lambert-Beer law gives the intensity $I_\lambda(x)$ of the sunlight per unit of the wavelength at the distance x from the entrance area of the cell as

$$I_\lambda(x) = I_\lambda \cdot 10^{-e_\lambda x} \tag{15}$$

$$\text{with} \quad e_\lambda = \sum_i c_i(t) \cdot \varepsilon_{i\lambda} \tag{16}$$

[$c_i(t)$ is the time-dependent concentration of the i-th substance and $\varepsilon_{i\lambda}$ the corresponding molar decadic extinction coefficient, which depends on the wavelength.] The total extinction in the cell of length d is:

$$E_\lambda = e_\lambda \cdot d \tag{17}$$

Per unit time and wavelength, the volume element $F \cdot \Delta x$ absorbs the energy:

$$I_\lambda \cdot 10^{-e_\lambda x} \cdot e_\lambda \cdot \ln 10 \cdot F \cdot \Delta x \tag{18}$$

The fraction which is absorbed by A is

$$I_\lambda \cdot 10^{-e_\lambda x} \cdot \varepsilon_{A\lambda} \cdot c_A(t) \cdot \ln 10 \cdot F \cdot \Delta x \tag{19}$$

If stirring makes the concentration independent of x integration of eq. (19) from 0 to d gives the total amount of energy which has been absorbed by the substance A per unit wavelength and time:

$$(\varepsilon_{A\lambda} \cdot c_A(t)/e_\lambda) I_\lambda \cdot F \cdot (1 - 10^{-E_\lambda}) = (E_{A\lambda}/E_\lambda) I_\lambda \cdot F (1 - 10^{-E_\lambda}) \tag{20}$$

$$\text{with} \quad E_{A\lambda} = \varepsilon_{A\lambda} \cdot c_A(t) \cdot d \tag{21}$$

Division of equation 20 by $h \cdot c \cdot N_A/\lambda$ yields the light quanta (in Einstein) absorbed by the substance A at the wavelength λ per unit time and wavelength. Multiplication by the quantum yield ϕ_λ gives the amount of B (in mol) formed at the wavelength λ per unit time and wavelength. Integration from $t=0$ to $t=t_B$ and from $\lambda=0$ to $\lambda=\infty$ one obtains

$$\int_0^{t_B} \mathrm{d}t \int_0^{\infty} \mathrm{d}\lambda \, (E_{A\lambda}/E\lambda) I_\lambda \cdot F \cdot \phi_\lambda \cdot (1 - 10^{-E_\lambda}) \lambda/(h \cdot c \cdot N_A) = n \tag{22}$$

n = amount of substance B (in mol)

If the concentrations are independent of time (addition of A, removal of B) or if one considers only small yields (small n), integration over the time gives:

$$t_B = n \cdot h \cdot c \cdot N_A \Big/ \left(F \int_0^{\infty} I_\lambda \cdot (1 - 10^{-E_\lambda}) \cdot \lambda \, (E_{A\lambda}/E_\lambda) \, \phi_\lambda \, \mathrm{d}\lambda \right) \tag{23}$$

Assuming ϕ_λ to be independent of λ for $\lambda \leq \lambda_{gr}$ and to be zero for $\lambda > \lambda_{gr}$ (λ_{gr} = threshold wavelength (cf. Fig. 1)), *i.e.*

$$\begin{aligned} \phi_\lambda &= \phi_B^A \quad \text{for} \quad \lambda \leq \lambda_{gr} \\ \phi_\lambda &= 0 \quad \text{for} \quad \lambda > \lambda_{gr} \end{aligned} \tag{24}$$

equation (23) affords:

$$t_B = n \cdot h \cdot c \cdot N_A \Big/ \left(F \cdot \phi_B^A \int_0^{\lambda_{gr}} I_\lambda \cdot \lambda \cdot (E_{A\lambda}/E_\lambda)(1 - 10^{-E_\lambda}) \, \mathrm{d}\lambda \right) \tag{25}$$

and thus, after rearrangement, we obtain from (1) equations (2) (see Section 3) and (26) for the efficiency η^w:

$$\eta_w = n \cdot \Delta\bar{H} \Big/ \left(t_B \cdot F \int_0^{\infty} I_\lambda \, \mathrm{d}\lambda \right) \tag{1}$$

$$= \Delta\bar{H} \cdot \phi_B^A \int_0^{\lambda_{gr}} I_\lambda \cdot \lambda \, (E_{A\lambda}/E_\lambda)(1 - 10^{-E_\lambda}) \, \mathrm{d}\lambda \Big/ \left(h \cdot c \cdot N_A \int_0^{\infty} I_\lambda \, \mathrm{d}\lambda \right)$$

$$= \frac{\Delta\bar{H}}{h \cdot c \cdot N_A/\lambda_{gr}} \cdot \phi_B^A \cdot \frac{1}{\lambda_{gr}} \cdot \frac{\int_0^{\lambda_{gr}} I_\lambda \cdot \lambda \cdot \mathrm{d}\lambda}{\int_0^{\infty} I_\lambda \mathrm{d}\lambda} \cdot \frac{\int_0^{\lambda_{gr}} I_\lambda \cdot (E_{A\lambda}/E_\lambda)(1 - 10^{-E_\lambda}) \, \mathrm{d}\lambda}{\int_0^{\lambda_{gr}} I_\lambda \cdot \lambda \cdot \mathrm{d}\lambda} \tag{26}$$

$$\eta_w = \eta_E \cdot \phi_B^A \cdot \eta_a \cdot \eta_{abs} \tag{2}$$

We thank the "Deutsche Forschungsgemeinschaft" for providing the laboratory data system (Mincal 621 and periphery), the "Minister für Wissenschaft und Forschung des Landes NRW" for financial support, the "Stiftung Volkswagenwerk" for providing the Cary 14 Spectrometer, and the "Fonds der chemischen Industrie" for material support and Deutsche Shell AG for norbornadiene.

[91] [Norbornadiene *(1a)*] = 0.02 mol/l; this is sufficient for an energy tranfer yield > 99% [94], assuming that the triplet lifetime of acetophenone is about 6×10^{-7} s [66] and energy transfer is diffusion-controlled. By way of comparison the thickness of the absorption cell is assumed to be $d = 5$ cm; this value refers to a volume of 50 l/m^2.

[92] Stoichiometric amount of norbornadiene *(1a)* used on the assumption that $CuCl_2$ is complexed up to > 99% [53].

[93] Optimum energy transfer yield has to be established in the case of sensitized reaction. The required condition is [94]:
$K_{ET} \cdot [A] \gg 1/\tau_{Sens^*}$;
K_{ET} = rate constant of energy transfer $Sens^* \rightarrow A$;
τ_{Sens^*} = triplet lifetime of sensitizer.

Rates of Reactive Removal of Anthropogenic Emissions in the Atmosphere[**]

By Heinz Georg Wagner and Reinhard Zellner[*]

Anthropogenic emissions such as SO_2, CO, NO_x, and hydrocarbons constitute a perturbation of the natural equilibrium of the atmosphere. On a global scale, the extent of this perturbation does not significantly exceed the natural background levels as a result of direct or indirect photochemical "clean-up" processes in the atmosphere. Regionally, however, considerably increased concentrations of these trace components may occur. They are degraded by free radical reactions having widely differing yet substance-specific rates.

1. Introduction

The composition of the natural atmosphere is determined by a dynamic equilibrium between its components and by mass exchange with the hydrosphere and the biosphere[1]. Man-made, *i.e.* anthropogenic, emissions represent a perturbation of this equilibrium; the amounts and nature of compounds emitted vary widely with time and location. As a result, differing effects on the environment can be expected. Whereas on a global scale so far all emissions (except CO_2[2]) do not extend far beyond their natural levels, very prominent enhancements can be detected on a local or regional scale.

Table 1. Global emissions and characteristic concentrations of some atmospheric trace gases. R = enhancement (concentration ratio).

	Amount emitted [10^6 t a^{-1}]		Concentration [ppm]		
	natural	anthropogenic	pure air	polluted air	R
CO_2	1000000	14000	320	400	1.3
CO	33	300	0.1	60	600
CH_4	1600	50	1.5	2.5	1.7
NO_x	1090	53	0.001	0.2	200
SO_2	5	70	0.0002	0.2	1000

Table 1 surveys the global emissions of some important trace gases[3–5], subdivided into anthropogenic and natural contributions, and their characteristic concentrations in pure[3] and polluted air[6]. It is seen that the concentrations of CO, NO_x, SO_2 in polluted air are higher than their concentrations in clean air by 2—3 orders of magnitude; this does not apply to CH_4 and CO_2, a fact which clearly exemplifies the complexity of the relation between the amount of a compound emitted and its perturbation of the natural equilibrium. The extent of the enhancement of the pollutant concentrations is only loosely related to the relative strengths of the anthropogenic and natural sources (*i.e.* CO, SO_2). An additional important factor is the absolute concentration level in clean air: compounds with low concentrations in clean air (*i.e.* NO_x) are readily enhanced even by relatively weak anthropogenic sources. In contrast, compounds with high concentrations in clean air (CO_2) are hardly enhanced even by strong pollution sources. These considerations reflect the dynamics of the atmosphere which is determined by transport processes, causing spread and dilution of the emissions, as well as by chemical reactions, establishing concentration levels.

The extent of anthropogenic emissions from all groups of emitters (industry, energy production, transport) are well known[3,4,7]. Moreover, records of local and regional levels have been kept for many years. Although such immission monitoring is important for estimates of air quality (particularly near the ground), they tell us nothing about the rate of degradation of anthropogenic emissions. For such information we must turn to laboratory studies. Within the last five years the results from such investigations of homogeneous gas reactions (elementary reactions of free radicals and reactive trace components, simulation experiments of complex gas reactions, smog chamber experiments), as well as heterogeneous reactions (reactions on aerosol surfaces), and also from the investigation of photochemical primary and consecutive processes, have accumulated to such a stage that the important aspects of the rates of removal of anthropogenic emissions seem to be becoming clear. This is particularly true of emissions with relatively short lifetimes and clearly identified sinks. For emissions with longer lifetimes (removal rates of only a few percent per year) the sinks are not easily identifiable, so that their removal rates cannot yet be given precisely enough. This applies, for example, to the tropospheric removal of fluorocarbons such as CCl_3F (F-11) and CCl_2F_2 (F-12)[8].

This article is concerned with the rates and (probable) mechanisms of reactive degradation of characteristic anthropogenic emissions. We shall be concentrating on removal by homogeneous gas reactions which, together with surface adsorption, wash-out, and also heterogeneous chemical reaction, account for a fair proportion of degradation processes. Only the chemistry of the troposphere (0 to *ca.* 10 km high) will be considered. Owing to the relatively slow rate of mass transfer between troposphere and stratosphere[1], the former is by far the most important region for the removal of anthropogenic emissions.

2. Characterization of Emissions

Anthropogenic emissions are very unevenly distributed between the different groups producing emissions. This applies to the individual compounds and the occurrence of the emissions. Furthermore, this distribution will also depend upon the industrial conditions within a given country. The situation will be illustrated below for the Federal Republic of

Germany. Figure 1 summarizes the total annual emissions[9] of SO_2, CO, NO_x, as well as hydrocarbons and dusts recorded for 1974 in the Federal Republic. The compounds are subdivided according to: energy production (including domestic space heating), chemical industry, transport, and coal, iron, and steel. Characteristically, in this survey and in comparable compilations for other countries, individual substances are seen to be particularly associated with specific groups of emitters. Thus the emission of SO_2, NO_x, and dust is ascribable mainly to energy production and that of CO to automotive transport. The emission of hydrocarbons is distributed somewhat more evenly over the sectors energy, chemistry, and transport. The contribution of the chemical industry to the overall emission is comparatively small.

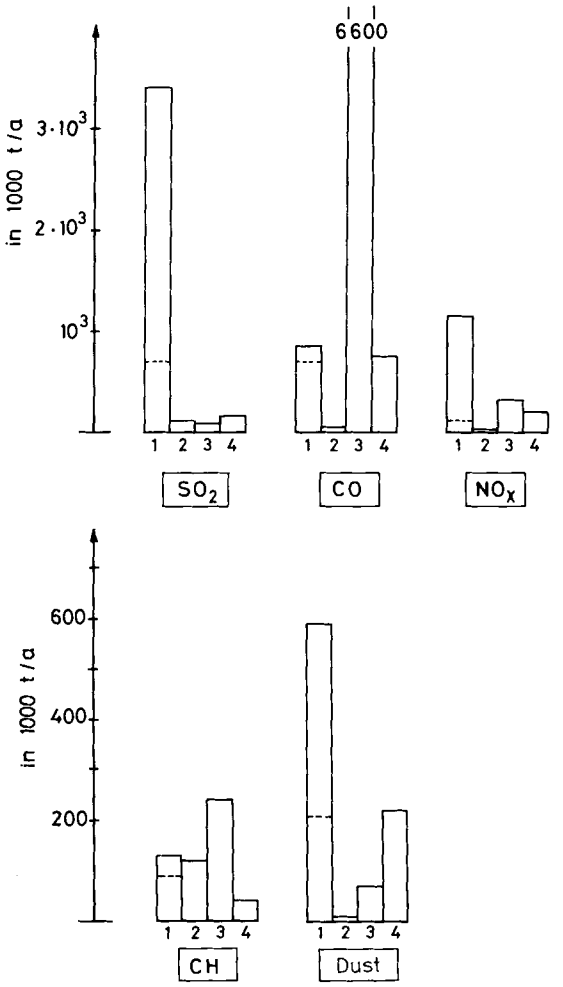

Fig. 1. Total annual emission (Federal Republic of Germany, 1974) of SO_2, CO, NO_x ($=NO_2$, NO), hydrocarbons, and dust, classified according to source. 1, energy production (including domestic space heating); 2, chemical industry; 3, transport; 4, coal, iron, and steel industry. Data in tonnes/year; the dashed line in (1) indicates contribution of domestic space heating [9].

With respect to the total burden of pollutant emissions, it is of interest to put these numbers on a more relative scale. To do this we go back to the emissions arising in connection with energy production. An emission of 3.3×10^6 t/a (SO_2) and of 1×10^6 t/a (NO_x) is caused by a total consumption of 225×10^6 t/a of primary fossil energy sources. The latter figure corresponds to a per capita consumption in West Germany of 3.7 t/a. The corresponding pollution is therefore 55 kg of SO_2 and 15 kg of NO_x per capita and annum. In this context, it is very important to indicate that the pollutant emissions are of the order of 1% by weight of the primary energy sources and further reductions cannot be achieved without considerable expense.

It should not go unmentioned that political and other decisions leading to a redistribution of the relative contributions of primary energy sources (*e.g.* less oil and more coal) will clearly lead to a redistribution of the relative anthropogenic emissions. However, this will essentially remain of a qualitative nature as long as there is no pronounced shift to non-fossil primary energy sources (nuclear and hydroelectric power), which are certainly far more favorable with regard to anthropogenic emissions.

It has already been pointed out that industry's contribution to the total emission is comparatively small. However, industrial emissions are responsible for the large variety of pollutants. This is demonstrated by Figure 2 for organic gases and vapors, and by Figure 3 for inorganic gases and vapors, in a typical pollution area (Cologne-Düsseldorf) with heavy chemical industry.

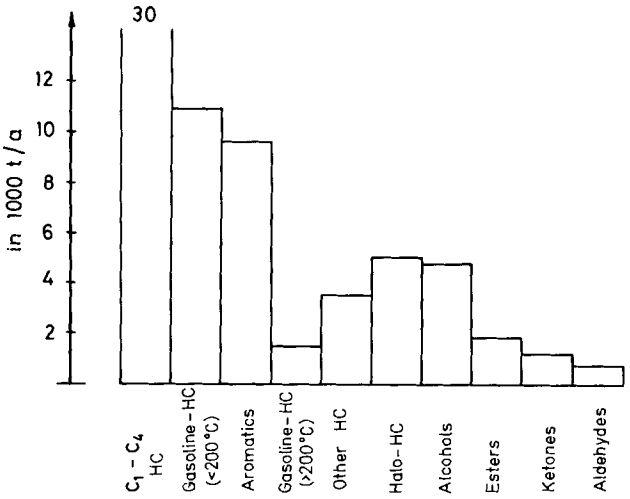

Fig. 2. Annual emission of organic gases and vapors from industrial sources in a typical pollution area (Cologne-Düsseldorf). HC = hydrocarbons.

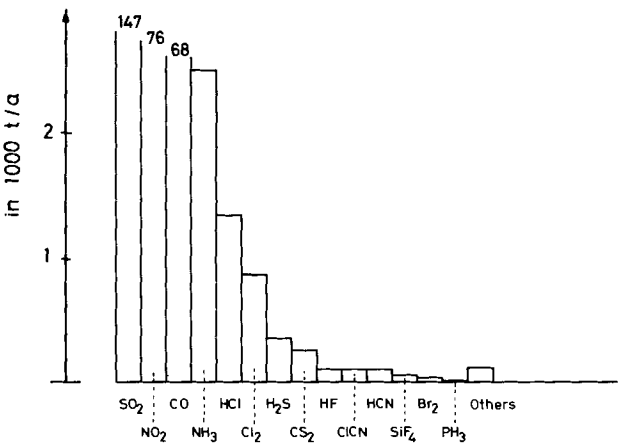

Fig. 3. Annual emission of inorganic gases and vapors from industrial sources in a typical pollution area (Cologne-Düsseldorf).

The classes of compounds and individual compounds accounting for most of the gaseous emissions (hydrocarbons, SO_2, NO_x, CO) affect the quality of air on a local and regional scale through their direct toxicological effect on humans (SO_2, NO_2), by their corrosive action on metal and stone

(SO_2), and by participation in photochemical smog (olefins, NO_x, CO) and its consequences (formation of peroxyacetyl nitrates and ozone, reduction of visibility). Moreover, unpleasant-smelling substances such as amines, H_2S, and thiols also impair the quality of air, although their total amount is very small. Among the emissions of particulate matter, dusts and soot from combustion processes are of interest in connection with their content of trace metals (Pb, Sb, Cd, Ni, Cr, Zn, V) and their possible catalysis of heterogeneous reactions. The metals are present as chelates in crude oil, often with porphyrin ligands. Since incorporation of metals occurs by condensation on soot particles forming in the cooling-down region, small particles ($<3\,\mu m$) have much higher metal contents than larger ones. This "enrichment" in small particles is of particular importance in connection with the toxicological action of suspended solids on absorption in the respiratory system.

3. Tropospheric Loss Processes of Anthropogenic Emissions

The removal of gaseous industrial emissions occurs predominantly by homogeneous gas reactions. This applies in particular to pollutants with short lifetimes ($\tau<1$ year) (see Section 4). Moreover, there are a number of other removal processes which assist in reducing the concentration of pollutants in the troposphere and which shall be briefly mentioned.

3.1. Physical Processes

3.1.1. Rain Out and Wash Out

Rain out (during the formation of clouds and fogs) and wash out (by falling rain drops) are removal processes for aerosol particles and for gases. Aerosols with radii $<0.1\,\mu m$ (so-called Aitken particles) are condensation nuclei which are subject to wet removal with a lifetime between 3—30 days[10]. The removal of gaseous compounds depends on their solubility in rain water. The amount of the gaseous trace component removed may easily be calculated from Henry's law[11]:

$$\varepsilon = \frac{N_L}{N_0} \approx 1 \Big/ \left(1 + \frac{KM_{H_2O}}{RTL}\right)$$

where N_0 and N_L are the trace gas concentration before and after condensation in the liquid phase; K is the equilibrium constant, M is the molar mass of H_2O and L is the liquid-water content of the air (typically 1 g H_2O/m^3 of cloud-laden air).

Such gas-liquid equilibria are generally not very effective loss processes. The amount of gas dissolved, however, can sometimes be very strongly increased by subsequent reactions in the aqueous phase. This is apparently the case for "acidic" gases such as SO_2 whose solubility in H_2O increases considerably with increasing pH. However, other gases are also involved in subsequent equilibria in the liquid phase. Thus the solubility of, *e.g.* formaldehyde is greatly enhanced by complex formation with hydrogen sulfite[11].

$$CH_2O + H_2O \rightleftharpoons CH_2(OH)_2 \overset{HSO_3^-}{\rightleftharpoons} CH_2(OH)SO_3H + OH^-$$

The rate of equilibration in solution depends upon the concentration gradients at the liquid/gas interface. Given "inverse" gradients, trace gases may accumulate in the air, for example when a saturated raindrop falls through "clean" air[4].

3.1.2. Adsorption on Surfaces, Vegetation

Both aerosols and gases may be removed by adsorption on surfaces (dry deposition). The adsorption of gases is a very important precursor to chemical reactions on vegetation (CO_2 photosynthesis, O_3) and on soil (microbiological activity).

3.1.3. Transport

Mass transport in the atmosphere generally serves to spread and dilute emissions. It is not a genuine loss process. Only in cases where the loss of pollutants occurs in areas of the atmosphere far removed from the point of their emission (*i.e.* the removal of fluorocarbons by photolysis in the stratosphere[8]), can transport be considered as a removal process. Because of the relatively slow mass exchange with the stratosphere (due to a strong discontinuity of the eddy diffusion coefficient around the tropopause), transport as a loss process is only important for pollutants with relatively long lifetimes.

3.1.4. Sedimentation

Sedimentation is a special form of transport and a typically size-dependent property of aerosol particles. Whereas the dynamics of small particles ($<0.1\,\mu m$) can be described by diffusion, "giant" particles ($>1\,\mu m$) are subject to sedimentation. Particles with radius of $10^2\,\mu m = 0.1$ mm "fall" through the whole troposphere within 2 h.

3.2. Chemical Processes

3.2.1. Photolysis

Because of the strong attenuation of shortwave radiation by stratospheric ozone the solar radiation available to the troposphere is limited to wavelengths above 300 nm. Correspondingly, photolysis is a tropospheric loss process only for compounds which absorb above this wavelength: 1) Ozone (relatively weak absorption in the region of the Huggins ($300<\lambda<360$ nm) and Chappuis bands ($450<\lambda<850$ nm); 2) NO_2 (very strong absorption in the whole visible region with photodissociation up to wavelengths of $\lambda=420$ nm); 3) HNO_2 (strong absorption and photodissociation up to 390 nm); 4) CH_2O (relatively weak absorption and photolysis below 360 nm)[11] and higher aldehydes which show a continuous absorption up to about 340 nm[12]; 5) SO_2 (weak triplet absorption $340<\lambda<390$ nm; strong singlet absorption $\lambda\leq320$ nm; but no photodissociation). The photochemical primary processes and the integrated tropospheric photodissociation rates

$$J^{TR} = \int_{300}^{\lambda} \phi(\lambda) f(\lambda)\, d\lambda$$

are shown in Table 2.

3.2.2. Heterogeneous Chemical Reactions (Reactions on Aerosol Surfaces)

It has been mentioned before that aerosols can be responsible for the heterogeneous removal of industrial emissions, mainly because of their trace contents of metals which may catalyze heterogeneous oxidation. For example, the oxidation of SO_2 is catalytically enhanced by $MnSO_4$-aerosols and by dusts from power plants in the presence of humidity[15].

other concentrations are estimated from photostationary relations, *e.g.* for $O(^3P)$:

$$NO_2 + h\nu \rightarrow NO + O$$
$$O + O_2 + M \rightarrow O_3 + M$$
$$\rightarrow d[O]/dt \approx 0 \Rightarrow J_{NO_2}[NO_2] = k_2[O][O_2][M]$$
$$\rightarrow [O]_{ss} = J_{NO_2}[NO_2]/k_2[O_2][M] \approx 10^5 \text{ molecules/cm}^3 \text{ for } [NO_2] = 50 \text{ ppb}$$

Table 2. Photochemical primary processes and tropospheric photodissociation rates for O_3, NO_2, HNO_2, CH_2O, and SO_2. All data for J^{TR} apply to 50° latitude in the northern hemisphere and maximum photon flux (summer, midday).

	Primary process	J^{TR} [s^{-1}]	Ref.
1)	$O_3 + h\nu$ ($\lambda \leq 313$) $\rightarrow O_2(^1\Delta_g) + O(^1D)$		
	($313 < \lambda < 360$) $\rightarrow O_2(^1\Delta_g) + O(^3P)$	4.5×10^{-4}	[13]
	($450 < \lambda < 850$) $\rightarrow O_2(^3\Sigma_g^-) + O(^3P)$		
2)	$NO_2 + h\nu$ ($300 < \lambda < 420$) $\rightarrow NO(x^2\pi) + O(^3P)$	8×10^{-3}	[13]
3)	$HNO_2 + h\nu$ ($300 < \lambda < 390$) $\rightarrow OH(x^2\pi) + NO(x^2\pi)$	2.8×10^{-3}	[13]
4)	$CH_2O + h\nu$ ($\lambda < 360$) $\rightarrow CHO(A') + H(^2S)$	5.4×10^{-5}	[11]
	$\rightarrow CO(^1\Sigma^+) + H_2(^1\Sigma_g^+)$		
5)	$SO_2 + h\nu$ ($\lambda < 320$) $\rightarrow SO_2^*(^1B_1)$	6.3×10^{-5}	[14]
	($340 < \lambda < 390$) $\rightarrow SO_2^*(^3B_1)$	4.5×10^{-7}	

As a result, SO_2 oxidation of up to 5% is observed within the stack plumes of common SO_2 and aerosol source strengths (40–300 mg dust/m^3; 0.5–5 g SO_2/m^3) at high relative humidities.

3.2.3. Homogeneous Chemical Reactions

Degradation by homogeneous gas reactions (reactions with radicals and reactive trace compounds) is nearly always the principal removal process for short-lived gaseous emissions. We shall therefore now consider such processes in greater detail.

4. The Troposphere as a Homogeneous Gas Phase Reactor

Before considering individual homogeneous gas phase reactions, let us first define the conditions under which such reactions occur in the troposphere.

4.1. Free Radicals and Reactive Trace Components

The basis for any chemical conversion in the troposphere is direct or indirect photochemical activation. The energy requirement for reactions between typical atmospheric components, *e.g.*

$$CO + O_2 \rightarrow CO_2 + O;\ E_A = 60 \text{ kcal/mol}$$
$$CO + NO_2 \rightarrow CO_2 + NO;\ E_A = 27.5 \text{ kcal/mol}$$

is too large for a chemical conversion to occur on a realistic time scale. The chemistry of the atmosphere is initiated by reactive trace components, like O_3 and $O_2(^1\Delta_g)$, or by free radicals (H, O, $O(^1D)$, OH, HO_2) which are formed from photochemical precursors. Table 3 summarizes formation processes and stationary tropospheric concentrations of these species. Only the concentrations of O_3 and OH (the latter with considerable uncertainty) were measured directly. All the

or from solution of the one-dimensional stationary continuity equation. (M = inert collision partner (N_2, O_2) subscript ss = steady state.)

Table 3. Formation processes and concentration range of free radicals and reactive trace compounds in the troposphere. The maximum concentration refers to the conditions of photochemical smog. 1 cm^3 of gas contains 2.3×10^{19} molecules at 0 °C and 1 bar.

Species	Formation process	Concentration [molecules/cm^3] max.	yearly average
H	$CH_2O + h\nu \rightarrow CHO + H$; $OH + CO \rightarrow CO_2 + H$		$< 10^{-1}$
O	$NO_2 + h\nu \rightarrow NO + O$	10^5	$\ll 10^5$
$O(^1D)$	$O_3 + h\nu \rightarrow O_2^* + O(^1D)$		$< 10^{-1}$
OH	$O(^1D) + H_2O \rightarrow 2OH$; $HONO + h\nu \rightarrow OH + NO$; $HO_2 + NO \rightarrow OH + NO_2$	5×10^6	5×10^5
HO_2	$H + O_2 + M \rightarrow HO_2 + M$	5×10^8	10^8
O_3	$O + O_2 + M \rightarrow O_3 + M$	5×10^{12}	10^{12}
$O_2(^1\Delta_g)$	$O_3 + h\nu \rightarrow O + O_2(^1\Delta_g)$; $NO_2^* + O_2 \rightarrow O_2^*(^1\Delta_g) + NO_2$		$< 10^7$

These formation processes are strongly coupled. The extremely small stationary concentration of H atoms for example is due to its fast conversion with O_2 to form HO_2. On the other hand, the concentration of OH is to a large extent determined by the fast conversion of HO_2 into OH in the presence of NO. This process is responsible for the enhancement of the OH concentrations in NO_x-catalyzed photochemical smog.

4.2. Spread of Emissions

Industrial emissions normally originate from point sources (stacks). Their *horizontal* spread is caused by a flow (winds), superimposed by eddy diffusion. The latter can be described by a Gaussian diffusion model. The corresponding spread in the *vertical* direction, however, is largely determined by the

local stability of the air layers. As shown by Figure 4, this stability is related to the vertical temperature profiles. The spread of emissions is said to be "neutral" if the actual temperature profile of the lower air layers is given by the adiabatic lapse rate (Fig. 4, case 2). For the troposphere, the average lapse rate is 6.5°/km and it is considerably lower than the adiabatic lapse rate for dry air (9.8°/km). Actual temperature profiles of the lower air layers, which correspond to

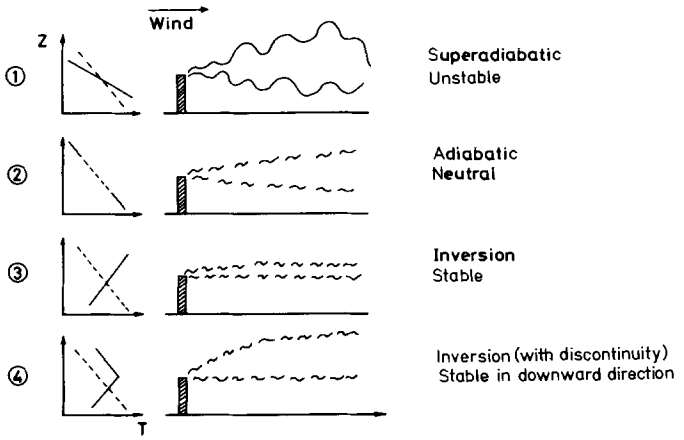

Fig. 4. Tropospheric temperature profiles and stability of low-lying layers of air. Left: plot of temperature T (x axis) *versus* tropospheric height z (y axis) for four cases of possible temperature profile (solid lines). The dashed line represents the mean adiabatic temperature gradient of the troposphere of 6.5°/km. Right: vertical propagation of emission from point sources (stacks) resulting from the given temperature profiles as a function of the horizontal distance from the site of emission. A wind of the direction indicated is superimposed upon the propagation. Pronounced vertical mixing is observed only for unstable layers (case 1). Propagation is "neutral" in case 2. In contrast, stable air layers (inversion, case 3) inhibit vertical mixing. In an inversion with discontinuity, stability is generated in an upward direction (not shown) or in a downward direction (case 4).

lapse rates higher (case 1) or lower (case 3) than adiabatic result in unstable or stable situations, respectively, with increased or decreased mixing. Of special interest in this context is a situation with inversion, in which the vertical mixing is strongly hampered and in which a local enrichment of emissions close to the surface is observed (case 4).

4.3. Definition of Lifetime

Assuming pseudo-first order reactions, the total rate of removal of a component A by homogeneous gas reactions can be described by the following expression:

$$R_A = -\frac{d\ln[A]}{dt} = \sum_i k_i[X_i]$$

where X_i represents all potential reactants (*e.g.* O, OH, HO_2, O_3). k_i are the corresponding rate constants. Assuming time independent (photostationary) concentrations for X_i, we may define "partial" lifetimes:

$$\tau_{Ai} = \{k_i[X_i]\}^{-1} \quad \text{(in time units)}$$

The total lifetime of A is then given by:

$$\tau_A = 1/\sum_i \tau_{Ai}^{-1}$$

An alternative formulation, which is used equally often, is the rate of removal R_i in %/time. It is related with the lifetime τ_i *via*

$$R_i = \tau_i^{-1} \cdot 63 \quad \text{(in units of \%/time)}$$

The preceding formulation of the lifetime of a compound A is only correct to a first approximation. It assumes that k_i and $[X_i]$ are independent of time and location. Owing to the uncertainty connected with the concentration of X_i, it will frequently suffice to use time- and site-averaged quantities. The lifetimes given in Tables 4 to 13 were obtained in this way. It should be emphasized, however, that a more precise approach (which becomes reasonable when X_i is known with sufficient accuracy) will require consideration of further effects:

1) Because of their coupling to tropospheric photochemistry, (*i.e.* to the altitude of the sun) the concentrations of some of the free radicals and reactive trace components are not constant, but show diurnal as well as annual variations[16, 17].
2) The concentration of the reactive component X_i may be influenced by the pollutant A to be degraded. In this case A appears in the steady state equation for X_i:

$$[X_i] = P_i / \sum_i k_i[M_i]$$

where P_i is a general production term and $\sum k_i[M_i]$ is a removal term with A as component of M_i. As a consequence, the concentration of X_i itself sinks to a minimum at site x_0 after emission of A (Fig. 5). Removal of A will then occur only in the boundary zones where A has become so dilute that it no longer affects X_i. The lifetime of A is, roughly speaking, enhanced by the corresponding transport time. This effect will be particularly large if A has a short lifetime, *i.e.* if A reacts fast with X_i.

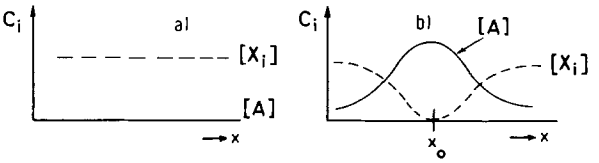

Fig. 5. Plot of concentration of a radical or a reactive trace compound X_i and an emitted substance A *versus* horizontal distance x. a) Prior to emission of A the value of $[X_i]$ is constant and independent of displacement and [A] is zero. b) After emission of A a gaussian diffusion profile is set up for [A] around the site of emission (x_0). (There is assumed to be no wind.) If the concentration of X_i is dependent upon A, then $[X_i]$ decreases with a minimum at x_0. As a result, A is removed only in boundary regions, in which it is sufficiently dilute.

3) Because of the relatively strong temperature gradients in the troposphere, the temperature dependence of the rate constants k_i of bimolecular reactions has to be considered for reactions having significant activation energies (E_i):

$$k_i(z) = k_i^0 \exp[-E_i/R(T_0 - lz)]$$

where T_0 (290 K) is the average temperature at the surface, $k_i^0 = k_i$ at 290 K; $l = 6.5°$/km is the adiabatic lapse rate, and z is the altitude in km.

Correspondingly we obtain for the "partial" lifetimes[18] in the troposphere:

$$\tau_i^{-1} = (1/z_T)\int_0^{zT} k_i(z)dz$$

$$= [X_i]k_i^0\left[1-\exp\left(-\frac{E_i}{R}\alpha z_T\right)\right]\Big/\left(\frac{E_i}{R}\alpha z_T\right)$$

where $\alpha = 1/T_0^2$, and z_T is the average height of tropopause (10 km).

In the case of recombination reactions, *e.g.*

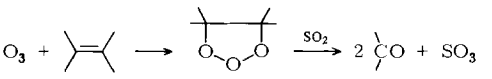
$$OH + NO_2 + M \rightarrow HNO_3 + M$$

the rate constants show an additional dependence on the total pressure ("fall-off" behavior). As a consequence, the variation of the rate constants with atmospheric height, $k_i(z)$, does not show a simple exponential dependence upon z but has to be described by effective "fall-off" curves of rather complex form[19].

5. Rates and Mechanisms of the Reactive Removal of Selected Anthropogenic Emissions

5.1. Removal of SO_2

Studies on homogeneous oxidation of SO_2 have shown that the reaction with OH radicals



$$OH + SO_2(+M) \rightarrow HSO_3(+M)$$

is the most important oxidation reaction from which, for a mean OH concentration of 10^6 mol/cm^3, a SO_2 lifetime of about 11 days results (see Table 4).

Recombination with oxygen atoms is two orders of magnitude slower and of no importance as a removal process. Nor does the reaction with HO_2 radicals

$$HO_2 + SO_2 \rightarrow OH + SO_3$$

make any significant contribution to the oxidation of SO_2, although $[HO_2] > [OH]$. Little is known about the rate of oxidation by alkoxy (RO) and alkylperoxy radicals (RO_2). The lifetime given in Table 4 is estimated from assumed rate constants[20]. If heterogeneous oxidation is also considered, then an overall lifetime τ_{SO_2} of about one week is calculated[20]. That is somewhat more than half of the lifetime for oxidation by OH only. Recent studies have shown that SO_2 hardly reacts with NO_2, O_3, or NH_3 in the homogeneous gas phase. In the presence of olefins, however, and under conditions of photochemical smog, SO_2 is oxidized by intermediates of the olefin/O_3 reaction[21]:

The assumed mechanism of the principal oxidation of SO_2 under atmospheric conditions—induced by OH—is shown in Figure 6[20]. The occurrence of nitrosyl hydrogen sulfate ($NOHSO_4$) has been confirmed by recent photolysis studies on NO_2/SO_2[23]. The final products of SO_2 oxidation are sulfuric acid aerosols.

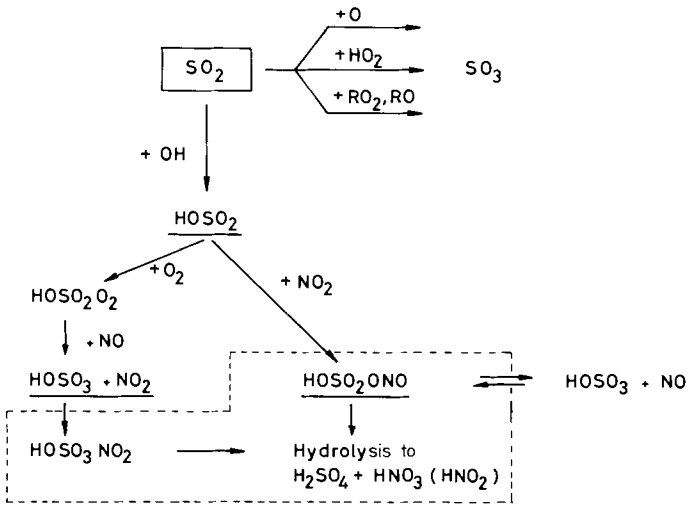


Fig. 6. Tropospheric oxidation of SO_2 by OH radicals. The initial step is recombination with formation of the $HOSO_2$ radical [19] (for thermochemical data of $HOSO_2$, see [22]). The final products of SO_2 oxidation are sulfuric acid aerosols (hatched box). The lifetime of SO_2 with respect to OH oxidation is 11 d; this is considerably less than in oxidations by O, HO_2, or RO/RO_2.

5.2. Removal of NO_x

In unpolluted air (no O_3, HO_2, RO_2) NO is oxidized only very slowly by the termolecular reaction

$$NO + NO + O_2 \rightarrow 2NO_2$$

At 50 ppb of NO, the "lifetime" (calculated for a decrease to 1/e of initial concentration) for oxidation by O_2 is about half a year. In the presence of O_3, HO_2, and RO_2, however, its oxidation is strongly accelerated (Table 5). This acceleration is characteristic of photochemical smog.

Table 4. Tropospheric oxidation of SO_2 by homogeneous gas reactions: primary reactions, rate constants, and partial lifetimes.

Reaction	k [cm^3 molecule^{-1} s^{-1}]	τ [days] [a]
$OH + SO_2(+M) \rightarrow HSO_3(+M)$	$\sim 10^{-12}$	~ 12
$O + SO_2(+M) \rightarrow SO_3(+M)$	1.8×10^{-14}	$>5\times10^3$
$HO_2 + SO_2 \rightarrow OH + SO_3$	8×10^{-16}	140
$(RO_2, RO) + SO_2 \rightarrow SO_3 + (RO, R)$		25
$SO_2 + h\nu \rightarrow SO_2(\tilde{a}^3B_1) \xrightarrow{O_2} SO_4$ (?)		360

[a] Here and in all the following tables the lifetimes τ have been calculated for the following concentrations of reactive components: $[OH] = 1\times10^6$, $[O] = 1\times10^5$, $[HO_2] = 1\times10^8$; $[O_3] = 1\times10^{12}$; $[RO] = 5\times10^5$; $[RO_2] = 1\times10^8$ molecules/cm^3. In this and the following tables, k and τ are for NTP unless otherwise stated.

Table 5. Homogeneous NO oxidation processes and NO lifetimes in the troposphere.

Reaction	k [cm^3 molecule^{-1} s^{-1}]	τ
$NO + NO + O_2 \rightarrow 2NO_2$		{ 0.5 a / 50 ppb NO }
$NO + O_3 \rightarrow NO_2 + O_2$	1.8×10^{-14}	1 min
$NO + HO_2 \rightarrow NO_2 + OH$	8×10^{-12}	20 min
$NO + CH_3O \rightarrow CH_3ONO$	8×10^{-14}	290 d
$\rightarrow CH_2O + HNO$		
$NO + CH_3O_2 \rightarrow CH_3O + NO_2$	1.2×10^{-12}	2 h
$NO + OH(+M) \rightarrow HNO_2(+M)$	1×10^{-11}	27 h

The oxidation of NO to NO_2, however, does not represent a removal process. Because of the photochemical instability

of NO_2, NO is regenerated with a lifetime of only 2 min. NO and NO_2 are always coupled *via* the photostationary relation $J_{NO_2}[NO_2] = k[NO][O_3]$, which has been experimentally established for numerous photochemical smog simulation studies.

The only true removal processes for NO_x are the recombination reactions

$$OH + NO_2(+M) \rightarrow HNO_3(+M)$$
$$HO_2 + NO_2(+M) \rightarrow HO_2NO_2(+M)$$

where the products may be washed out, as well as the formation of peroxyacetyl nitrate (PAN), whose rate of formation is probably several hours (Table 6). These results are shown schematically in Figure 7.

Table 6. Tropospheric removal processes and lifetimes of NO_2.

Reaction	k [cm^3 molecule^{-1} s^{-1}]	τ
$NO_2 + OH(+M) \rightarrow HNO_3(+M)$	1.5×10^{-11}	18 h
$NO_2 + HO_2(+M) \rightarrow HO_2NO_2(+M)$	10^{-12}	[b]
$NO_2 + CH_3O \rightarrow CH_3ONO_2$	3×10^{-13}	80 d
$CH_3CO(O_2) + NO_2 \rightarrow CH_3CO(O_2)NO_2$ (PAN)	—	several h
$NO_2 + h\nu \rightarrow NO + O$	$J = 8 \times 10^{-3}$ s^{-1} [a]	2 min

[a] This is the maximum photodissociation rate (summer, midday, 50° latitude, northern hemisphere) for NO_2. Since the photolytic lifetime of $NO_2 \ll 1$ d, correspondingly smaller photodissociation rates must be used for other times of day and year.
[b] Due to the low dissociation energy the reaction product (HO_2NO_2) is thermally unstable in the lower troposphere. There, an equilibrium is established from which NO_2 can be removed by wash out; the NO_2 lifetime is determined by the wash-out rate of HO_2NO_2 and not by its rate of formation.

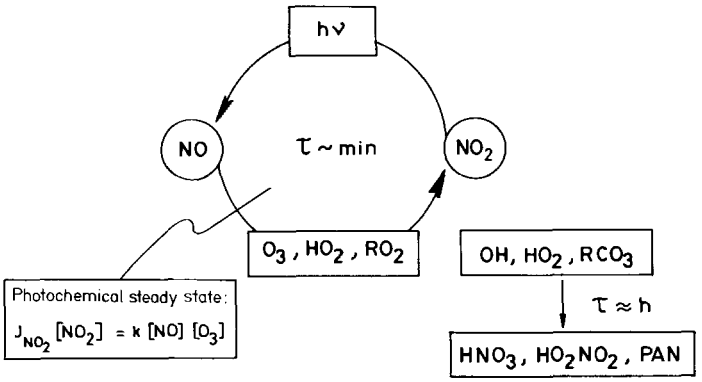

Fig. 7. NO/NO_2 conversion and NO_2 removal in the troposphere. The chemistry of NO_x is characterized by a relatively fast (several minutes) photostationary interconversion and comparatively slow degradation of NO_2 by recombination reactions with OH, HO_2, and RCO_3.

5.3. Removal of CO

The only significant removal reaction for CO is oxidation by OH radicals

$$OH + CO \rightarrow CO_2 + H$$

leading to a lifetime of *ca.* 40 d. Other oxidation reactions ($CO + O + M$, $CO + HO_2$) are unable to compete (Table 7).

Owing to the unique situation that the trace compound CO is oxidized exclusively by OH, the concentration of OH can be derived from the steady state concentration level of CO and its known rate of formation (see, *e.g.* [24]).

Table 7. Tropospheric oxidation processes and lifetimes of CO.

Reaction	k [cm^3 molecule^{-1} s^{-1}]	τ
$OH + CO \rightarrow CO_2 + H$	1.5×10^{-13} (several torr) 2.8×10^{-13} (760 torr) [a]	40 d
$CO + HO_2 \rightarrow CO_2 + OH$	10^{-19}	$>10^3$ a
$CO + O + M \rightarrow CO_2 + M$	5×10^{-17} (760 torr)	6×10^3 a

[a] This distinction is intended to indicate that the rate constant of the reaction $OH + CO$ increases with the total pressure, at least in the presence of O_2 [25].

5.4. Removal of Aliphatic Hydrocarbons

The oxidative removal of saturated hydrocarbons occurs almost exclusively by reaction with OH radicals. The corresponding reactions with O atoms are slower by several orders of magnitude (see Table 8)[*]. The calculated lifetimes decrease with increasing chain length of the alkane ($\tau_{CH_4} \approx 3.5$ a). The course of oxidative removal of saturated hydrocarbons under atmospheric conditions is shown in Figure 8.

Table 8. Tropospheric lifetimes of some aliphatic hydrocarbons with respect to their oxidation by O atoms and OH radicals.

Hydrocarbon	k_O [cm^3 molecule^{-1} s^{-1}]	k_{OH}	τ_O	τ_{OH}
Methane	6×10^{-18}	9×10^{-15}	5×10^4 a	3.5 a
Ethane	1×10^{-15}	3×10^{-13}	3×10^2 a	38 d
n-Butane	2.2×10^{-14}	3×10^{-12}	6.3 a	3.8 d
Isobutane	1×10^{-13}	2.5×10^{-12}	3.1 a	4.6 d

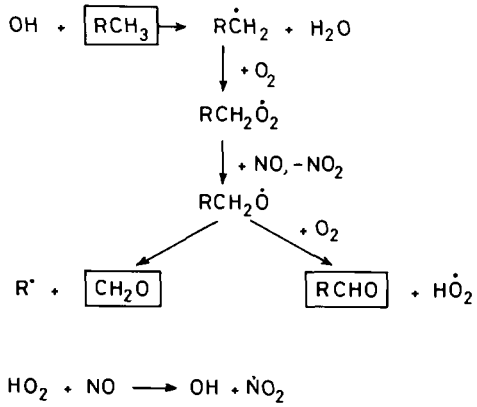

Fig. 8. Tropospheric oxidation of saturated hydrocarbons. The reactions lead either to oxidation of the terminal C atom ($RCHO + HO_2$) or to simultaneous C C cleavage ($CH_2O + R$). The branch of the reaction leading to $RCHO + HO_2$ is the basis of a chain reaction (regeneration of OH *via* $HO_2 + NO \rightarrow OH + NO_2$), through which 2 moles of NO are oxidized to NO_2 per mole of hydrocarbon. This reaction course is one of the causes of photochemical smog.

The mechanism involves the recombination with O_2 of the alkyl radical, formed in the primary step. The resulting alkylperoxy radical is then reduced by reaction with NO. The product of this process, the alkoxy radical, may then undergo unimolecular decomposition or be further oxidized by O_2 to give formaldehyde or a higher aldehyde. Halogenated alkanes (fluorocarbons) have lifetimes of several years with respect to reaction with OH radicals[18]. Only the perhalogen-

[*] Although excited oxygen atoms ($O(^1D)$) react very fast with hydrocarbons, their concentration is too low to significantly enhance the rate of removal.

Table 9. Tropospheric lifetimes of some selected olefins with respect to their oxidation by O atoms, OH radicals, and ozone.

Olefin	k_O	k_{OH} [cm³ molecule⁻¹ s⁻¹]	k_{O_3}	τ_O	τ_{OH}	τ_{O_3}
Ethylene	8.1×10^{-13}	8×10^{-12}	1.7×10^{-18}	142 d	34 h	6.8 d
Propylene	3.6×10^{-12}	1.5×10^{-11}	1.3×10^{-17}	32 d	11 h	21 h
1-Butene	3.8×10^{-12}	3.5×10^{-11}	1.2×10^{-17}	30 d	8 h	23 h
2-Methyl-2-butene	6.3×10^{-11}	8.7×10^{-11}	—	1.8 d	3.2 h	—
1,3-Butadiene	2×10^{-11}	6.8×10^{-11}	2.6×10^{-16}	5.7 d	4 h	1 h

ated compounds such as $CFCl_3$ (F-11) and CF_2Cl_2 (F-12) fail to react with OH; their lifetimes are several decades[8].

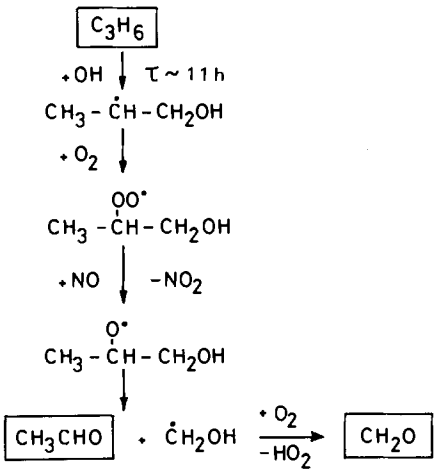
5.5. Removal of Olefins

Olefins are considerably more reactive than saturated hydrocarbons and have correspondingly shorter lifetimes. Apart from reaction with OH radicals, which leads to the highest rate of removal, those with oxygen atoms and with ozone are also important (Table 9).

The course of the OH/olefin reaction is highly complex, owing to primary addition of the OH radical to the double bond and the many possibilities of subsequent degradation:

$$C_2H_4OH^* \rightarrow CH_3CHO + H$$
$$\rightarrow CH_3 + CH_2O \text{[26]}$$

The rate constant is accordingly pressure dependent; the activation energy is negative[27]. Under atmospheric conditions, however, it can be assumed that the OH-olefin adduct is stabilized and reacts with O_2 to give aldehydes (Fig. 9).



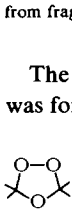


Fig. 9. Tropospheric oxidation of olefins (example: propylene), induced by OH radicals. This reaction course has not been unequivocally established; however, it appears that the double bond is preferentially oxidized. Aldehydes are formed from fragments of C–C cleavage.

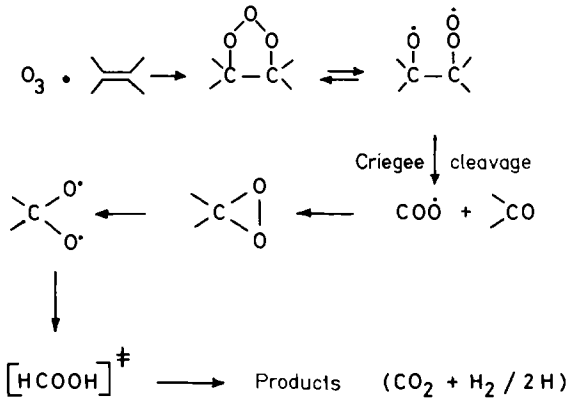
The extremely complex course of the O_3/olefin reaction was formerly known only for the liquid-phase reaction—formation of the secondary ozonide of type *(1)*. Recent investigations by *Martinez et al.*[28] seem to indicate that the Criegee intermediate methylene peroxide (H_2COO) decomposes *via* a dioxirane in the gas phase (Fig. 10). Moreover, at low pressures the O_3/olefin reaction is accompanied by luminescence arising from decomposition of dioxetanes such as *(2)*[29].

(1)



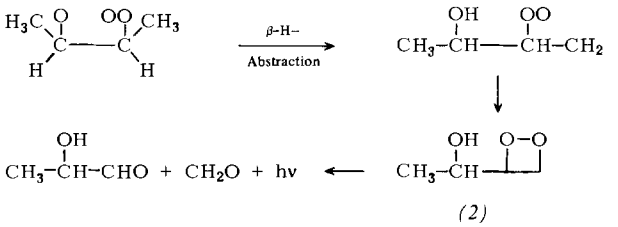


Fig. 10. Tropospheric ozone/olefin reaction illustrated for ethylene. The Criegee intermediate (methylene peroxide) presumably rearranges *via* a dioxirane [28] and decomposes to CO_2 *via* a highly excited formic acid molecule.

(2)

5.6. Removal of Aromatic Hydrocarbons

Reaction with OH is again the only significant pathway for removal of aromatic hydrocarbons. The lifetime of benzene is several days; it becomes considerably shorter on substitution by alkyl or OH groups (several hours, see Table 10).

Table 10. Tropospheric lifetimes of selected aromatic hydrocarbons with respect to their oxidation by OH radicals [27].

	k [cm³ molecule⁻¹ s⁻¹]	τ_{OH}
Benzene	1.2×10^{-12}	9.6 d
Toluene	6.4×10^{-12}	1.8 d
Ethylbenzene	7.9×10^{-12}	34 h
o-Xylene	1.4×10^{-11}	20 h
o-Cresol	3.4×10^{-11}	8 h

The OH radical adds preferentially to the ring; oxidation of ring C atoms occurs, and possibly also ring cleavage. Oxidation of alkyl side chains is observed to a slight extent (see *e.g.* [27]).

5.7. Removal of Aldehydes and Alcohols

Oxidative removal of partially oxidized hydrocarbons is particularly interesting as they are themselves intermediates of the oxidation of hydrocarbons. Reactions with OH radicals are again important degradation processes (Table 11).

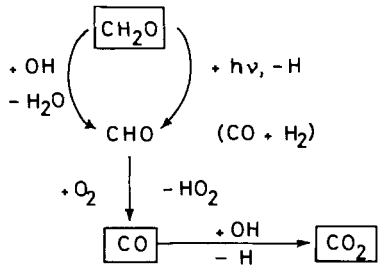

Table 11. Tropospheric removal processes and lifetimes of simple aldehydes and alcohols.

Reaction		k [cm^3 molecule^{-1} s^{-1}]	τ
$CH_2O + OH$	$\rightarrow H_2O + CHO$	9×10^{-12}	1.2 d
$CH_2O + h\nu$	$\rightarrow CO + H_2$ $\rightarrow CHO + H$	$J = 1.8 \times 10^{-5}$ s^{-1} [a]	15 h
$CH_3CHO + OH$	$\rightarrow CH_3CO + H_2O$	1.6×10^{-11}	17 h
$CH_3OH + OH$	$\rightarrow CH_2OH + H_2O$	1×10^{-12}	11.6 d
$C_2H_5OH + OH$	$\rightarrow$ Products	3×10^{-12}	3.8 d

[a] This is the photodissociation rate for 50° latitude, northern hemisphere, and annual average photon flux [11]. J is some three times higher at the maximum photon flux (summer, midday); the photolytic lifetime is correspondingly shorter.

Moreover, aldehydes are also photolabile. For example, photolytic degradation of formaldehyde is faster than its reactive removal by OH. The same final products are formed in either case (CO and HO_2; from $CHO + O_2 \rightarrow CO + HO_2$). Owing to the UV shift of the absorption spectrum, photolysis can no longer compete with the OH reaction in the case of higher aldehydes.

The course of oxidation of CH_2O and CH_3CHO by OH radicals is shown in Figure 11. The presumed formation of the acetyl radical (CH_3CO) during CH_3CHO oxidation and its further reaction with O_2 are deduced from the existence of peroxyacetyl nitrate and CO_2 as final products. It therefore seems that the CO oxidation stage can be omitted in the case of higher aldehydes (as opposed to CH_2O).

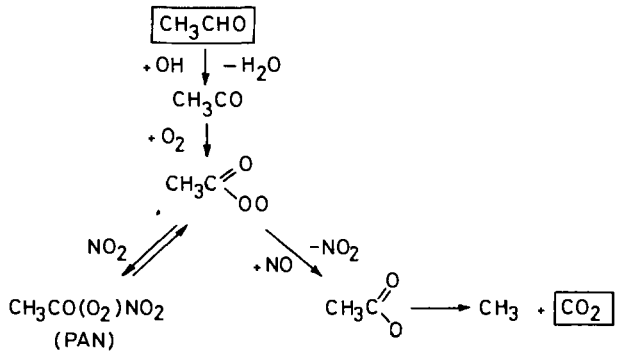

Fig. 11. Tropospheric removal of formaldehyde and of acetaldehyde. For CH_2O, both the OH reaction and photolysis are initiating primary processes. The resulting CHO radical is oxidized to CO by O_2. For CH_3CHO, photolysis cannot compete with the OH reaction. Primary oxidation by OH occurs at the aldehydic C atom. Final products are PAN and CO_2. Simultaneous oxidation of the methyl group is not observed.

5.8. Removal of Sulfur and Nitrogen Compounds

Emissions of H_2S, thiols, and aliphatic amines are also of importance as compounds with strong unpleasant odors owing to their low physiological thresholds. Their removal in the troposphere by reaction with O atoms and OH radicals, as well as the freshening of thiol-containing air by UV irradiation, have therefore been thoroughly investigated[30].

5.8.1. H_2S and Thiols

Rate constants for the removal reactions of some sulfur compounds and the lifetimes of these species are compiled in Table 12. They range from several hours to days for the reaction with OH radicals and months for the reaction with O atoms. Primary attack by O and OH leads preferentially to formation of alkylthio radicals (RS•) from which, as recently shown by *Kirchner* and *Vettermann*[30], SO_2 and aldehydes arise under atmospheric conditions; thus oxidative cleavage of the C–S bond occurs with accompanying oxidation of the C and S fragments (see Fig. 12).

Table 12. Tropospheric lifetimes of H_2S, alkanethiols, and $(CH_3)_2S$ with respect to their oxidation by O atoms and OH radicals.

	k_O	k_{OH} [cm^3 molecule^{-1} s^{-1}]	τ_O	τ_{OH}
H_2S	2.8×10^{-14}	3×10^{-12}	11 a	3.8 d
CH_3SH	1.6×10^{-12}	3.4×10^{-11}	72 d	8 h
CH_3SCH_3	—	1.0×10^{-11}	—	26 h
C_2H_5SH	2.5×10^{-12}	—	46 d	—
C_3H_7SH	2.6×10^{-12}	—	44 d	—

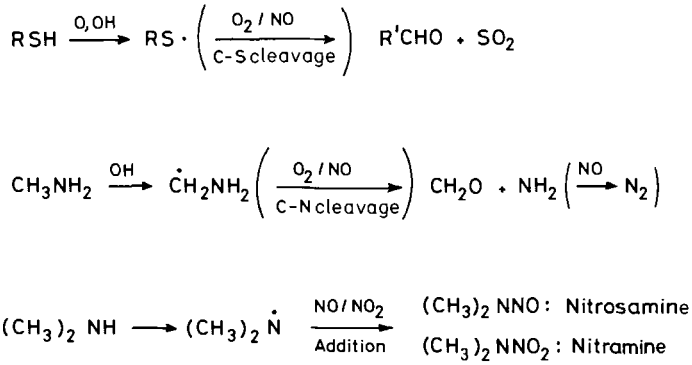

Fig. 12. Tropospheric removal of thiols and of primary and secondary amines, schematic.

5.8.2. NH_3 and Amines

Table 13 lists rate constants for the reactions of NH_3 and selected aliphatic amines with O and OH together with the respective lifetimes.

Table 13. Tropospheric lifetimes of NH_3 and amines with respect to their removal reactions with O atoms and OH radicals.

	k_O	k_{OH} [cm^3 molecule^{-1} s^{-1}]	τ_O	τ_{OH}
NH_3	1×10^{-16}	1.6×10^{-13}	$>10^3$ a	72 d
CH_3NH_2	3.4×10^{-13}	2.2×10^{-11}	1 a	12 h
$C_2H_5NH_2$	1.1×10^{-12}	2.7×10^{-11}	100 d	10 h
$(CH_3)_2NH$	5.3×10^{-12}	6.5×10^{-11}	22 d	4 h
$(CH_3)_3N$	1.5×10^{-11}	6.0×10^{-11}	8 d	4.6 h
$(C_2H_5)_2NOH$ (DEHA)	6.6×10^{-12}	—	17 d	—

The course of tropospheric degradation of amines is largely unexplained. However, comparison of the bond energies in primary and secondary amines [H—CH_2NH_2, 94.6 kcal/mol; CH_3NH—H, 103 ± 2 kcal/mol; $(CH_3)_2N$—H, 95 kcal/mol] suggests that a C_α—H atom is preferentially abstracted in primary amines; in contrast, N—H abstraction is expected in secondary amines. These reactions lead to different final products (see Fig. 12): primary amines are oxidized to aldehyde and N_2 *via* C—N cleavage, whereas the C—N bond is left intact in secondary amines; addition of NO and NO_2 presumably lead to nitrosamines[27] and nitramines, respectively.

It should be mentioned in conclusion that the reactions of O and OH with diethylhydroxylamine (DEHA) have been suggested as a means of inhibiting photochemical smog[31,32]. This inhibitory action consists in capture of O and OH which are the chain carriers of NO/NO_2 conversion in the presence of hydrocarbons (see Section 5.4 and Fig. 8).

As shown by *Filby* and *Güsten*[31], however, the reaction of diethylhydroxylamine with O atoms is too slow to compete with the O/hydrocarbon reaction unless rather dubiously high concentrations of the inhibitor (above the olfactory perception threshold) are sprayed into the atmosphere. Moreover, general reservations have been voiced concerning the possible combatting of the consequences of anthropogenic emissions (photochemical smog) by additional emission of inhibitors[33].

6. Summary and Outlook

Anthropogenic emissions are a burden on the environment. Such emissions are removed sufficiently fast on a global scale to dispel any misgivings about possible long term effects. We can aptly speak of a "self-cleaning action" of the atmosphere. However, the question of the limits of the self-cleaning capacity for individual classes of compounds remains open. For example, there is a slow but clearly detectable increase occurring in the concentration of CO_2. In the case of fluorocarbons, which we have purposely avoided discussing in this article, the present state of knowledge based on extremely broad-based and thorough studies would indicate that a slight reduction of the ozone concentration in the stratosphere by these substances cannot be ruled out in the long term.

These possible long-term global effects are certainly the exception rather than the rule. On a local and regional level, however, there is a significant pollution problem. What can be done?

A general requirement, which will certainly not be universally implementable, is to reduce the amounts of pollutants emitted. In addition, further studies are necessary on the removal and ecotoxological action of anthropogenic emissions, including those not discussed in this paper.

With regard to the predominant pollutants and classes of pollutants, it is most informative to consider the developments of the past fifteen years (Fig. 13). The situation in the Federal Republic of Germany again serves as example. There is a significant increase of NO_x, due to a) increased energy production in conventional power stations and b) increased motorization. SO_2 has remained roughly constant, in spite of increased energy production (improved sulfur removal from fuels and flue gases). Hydrocarbon emissions have likewise remained roughly constant. A significant decrease is seen only in the emission of particulate matter; this is due to improvements in electrostatic dust removal in coal-fired power stations, which are responsible for most of these emissions. The critical pollutants are therefore NO_x and SO_2.

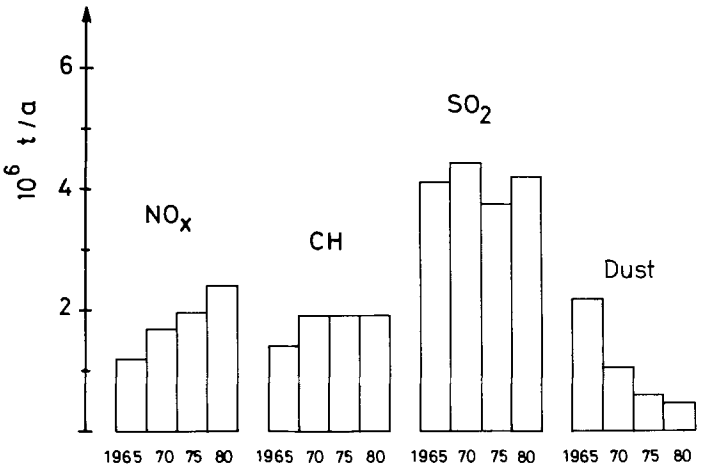

Fig. 13. Development of annual emission of NO_x, hydrocarbons, SO_2, and dust in the Federal Republic of Germany since 1965; values for 1980 estimated.

At this stage, the reader is again reminded that such emissions arise mainly from combustion of fossil fuels, at a rate of about 1% by weight; further reduction would incur enormous costs. Nobody would dispute that such reductions are technically feasible. With regard to the reduction of NO emissions from power stations, reference is made to fluidized-bed combustion[34]: Greatly improved heat transfer permits lower operating temperatures, and thus leads to considerably reduced formation of NO. This process was developed in its basic form more than 50 years ago at BASF; however, it has still not been employed in conventional power stations, apart from development work in pilot plant. Another process for reducing NO emission from combustion plant, recently patented by EXXON, involves the addition of NH_3/O_2 mixtures[35]. The observed drop in NO emission is due to the fast homogeneous gas reaction

$$NH_2 + NO \rightarrow N_2 + H_2O$$

A pilot plant has recently been built in Japan to test the technical applicability of this process.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

A New Bridging Mode of Carbon Disulfide in a Dinuclear Cobalt(I) Complex

By *Claudio Bianchini, Carlo Mealli, Andrea Meli, Annabella Orlandini*, and *Luigi Sacconi*[*]

The only X-ray structure determination[1] so far reported for a dinuclear complex containing a bridging CS_2 group shows a metal dithiocarboxylato fragment bonded *via* the two sulfur atoms to the second metal. Only IR and NMR information is available for analogous complexes[2], and suggests that the bridging CS_2 group is probably linked to one metal either *via* the carbon atom or *via* a η^2-bonded C=S linkage, while one sulfur atom is σ-bonded to the second metal.

By reaction of CS_2 with cobalt(II) tetrafluoroborate, $NaBPh_4$, and 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) we have obtained the dinuclear diamagnetic complex $[\{(triphos)Co\}_2CS_2](BPh_4)_2$ *(1)*. Its molecular structure has been established by single crystal X-ray analysis[3]. In the complex cation of *(1)*, a CS_2 molecule is found to hold together two Co(triphos) fragments. One cobalt atom is π-bonded to one C=S group, and the other forms two σ-bonds to the two sulfur atoms.

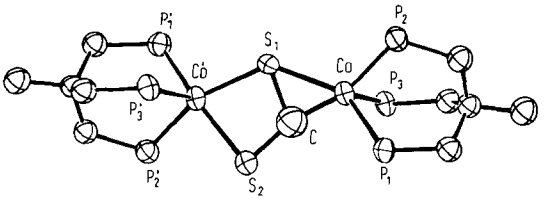

Fig. 1. ORTEP drawing of skeleton of the complex cation of *(1)*. Population parameters of S(1), S(2), and C atoms fixed at 0.5. Important distances [Å] and angles [°] are: Co P(average) = 2.22(2), Co S(1) = 2.27(1), Co S(2) = 2.31(1), Co S(1) = 2.29(1), Co C = 1.72(5), C S(1) = 1.75(7), C S(2) = 1.72(7), S(1) C S(2) = 112.2(3.7), S(1) Co S(2) = 77.7(5), C Co S(2) = 49.3(2.2).

The S—C—S angle of 112.2(3.7)° is somewhat smaller than that found in the structure of the mononuclear cobalt(0) complex with triphos and a terminally η^2-bonded CS_2 molecule (133.8(8)°)[4]. The two C—S distances (C—S(1) = 1.75(7), C—S(2) = 1.72(7) Å) are similar to each other and longer than those found in the above mononuclear complex (1.68(1), 1.62(1) Å). These geometrical details suggest a partial loss of double bond character of the C—S linkages and a consequent delocalization of the electron density toward the metal atoms. The absence of IR bands attributable to C=S stretching modes seems to support this view. Interestingly, the two Co—S σ-bonds are approximately of the same length (Co—S(1) = 2.27(1), Co—S(2) = 2.31(1) Å) indicating that the participation of CS_2 in π-bonding does not lead to any great difference in the σ-donor capacities of the two sulfur atoms.

Considering the CS_2 molecule as a 6-electron donor and adding the 16 electrons of the Co^I ions and the 12 electrons of the two triphos ligands, a configuration of 34 valence electrons is reached for the dinuclear complex cation. Particular stability has been predicted for such 34-electron species. The diamagnetism of the complex is thus also rationalized.

Procedure

All operations performed under N_2 and with oxygen-free solvents. CS_2 is bubbled for 5 min through a hot mixture of triphos (1 mmol) in acetone (40 ml) and $Co(BF_4)_2 \cdot 6H_2O$ (1 mmol) in butanol (30 ml). On addition of $NaBPh_4$ (2 mmol)

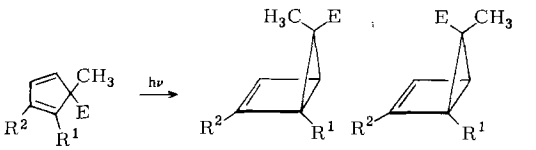
Thermal "Walk"-Rearrangement in the Bicyclo[2.1.0]pent-2-ene System[**]



By *Frank-Gerrit Klärner* and *Friedhelm Adamsky*[*]

In a large number of five-membered heterocycles, *e.g.* derivatives of furan, pyrrole, and thiophene, a photochemical isomerization is observed leading to a redistribution of the ring atoms. This unusual reaction has often been explained in terms of "walk" rearrangements in the intermediate valence tautomeric hetero-bicyclo[2.1.0]pent-2-enes[1a]. According to *Lemal et al.*[1b] a rapid "walk" rearrangement takes place in perfluorotetramethyl-5-thiabicyclopentene and its *exo-S*-oxide also on thermal excitation.

In the carbocyclic bicyclopentene system most of the interest was hitherto focused on the electrocyclic ring opening, which leads to chemically activated 1,3-cyclopentadienes[2a–c]. A "walk" rearrangement was observed only on photochemical excitation[2d]. We report here on the thermal "walk" rearrangement *(1a)*→*(2a)*, which precedes the competing bicyclopentene-cyclopentadiene isomerization and proceeds with high stereoselectivity even at 0 °C.

For experimental verification of this rearrangement the bicyclopentene derivatives *(1a), (1b), (2a), (2b),* and *(3a), (3b)* were synthesized by photolysis of the cyclopentadienes *(4), (5),* and *(6),* respectively (−50 °C, Hg low-pressure lamp NK25/7 Hanau, dimethyl ether)[3]. The assignment of the diastereomers *(1a), (1b), (2a), (2b)* and *(3a), (3b)* separated by column chromatography at −10 °C was largely based on the ^{1}H-NMR spectroscopic comparison with *exo-* and *endo*-5-methylbicyclo[2.1.0]pent-2-ene[2c,4].

$R^1=CH_3$, $R^2=H$ *(4)* — *(1a)* *(1b)*
$R^1=H$, $R^2=CH_3$ *(5)* — *(2a)* *(2b)*
$R^1=R^2=H$ *(6)* — *(3a)* *(3b)*
$E=CO_2CH_3$

At 0 °C the 1,5-dimethyl derivative *(1a)* already undergoes complete reorganization yielding two products (GC 93:7)[5]. The major product is identical with the independently synthesized 2,5-dimethyl derivative *(2a)*. The minor product proved to be the starting cyclopentadiene *(4)*. ^{1}H-NMR spectroscopic monitoring of the isomerization *(1a)*→*(2a)* at 0 °C gave a rate constant $k_{(1a),(2a)}$ of 2.4×10^{-5} [s^{-1}] and thus a Gibbs activation energy of $\Delta G^{+}=21.7$ kcal/mol.

A similar thermal behavior is exhibited by the diastereomeric 1,5-dimethyl derivative *(1b)*. However, in this case 97% electrocyclic ring opening *(1b)*→*(4)* and only 3% "walk" rearrangement *(1b)*→*(2b)* is observed.

The 2,5-dimethyl derivatives *(2a)* and *(2b)* are thermally more stable than *(1a)* and *(1b)*, comparable with *(3a)* and *(3b)* and with the parent system. Above room temperature *(2a), (2b)* and *(3a), (3b)* isomerize to the cyclopentadiene derivatives *(5)* and *(6)*, respectively. Their kinetic parameters are listed, together with those of the parent system, in Table 1. Thermolysis of *(2a)* leads not only to *(5)* (95%) but also to the 1,5-dimethylcyclopentadiene *(4)* (5%), whose formation indicates the "walk" rearrangement *(2a)*⇌*(1a)* to be reversible to a slight extent. In no case is an *exo-endo* isomerization at C-5 observed. This finding rules out a migration of C-5 with retention in the bicyclopentene systems, a process which was calculated by semi-empirical MO-methods[6] to be the favored one[6]. The observed stereochemistry corresponds to an inversion at C-5 and is in accord with the stereochemical requirements for an orbital symmetry controlled process[7].

The Gibbs activation energy of the reaction *(1a)*→*(2a)* is surprisingly small; it is considerably smaller than that of the "walk" rearrangements of the correspondingly substituted vinylogous systems *cis*-bicyclo[4.1.0]hepta-2,4-diene (180 °C, $\Delta G^{+}=37.1$ kcal/mol)[8a] and *cis*-bicyclo[6.1.0]nona-2,4,6-triene (102.5 °C, $\Delta G^{+}=28.8$ kcal/mol)[8b]. The observed activation parameter for the rearrangement of bicy-

clo[6.1.0]nonatriene has been interpreted by a participation of an aromatic transition state. The *ca.* 7 kcal/mol lower Gibbs activation energy of *(1a)*→*(2a)* would accordingly suggest an aromatic transition state for the bicyclopentene rearrangement. We assume, however, that the lower activation barrier of the bicyclopentene rearrangement does not only result from the resonance stabilization of the transition state, but largely from the high ground-state enthalpy of the bicyclopentene system. The heat of hydrogenation of the olefinic double bond in the parent compound, bicyclo[2.1.0]pent-2-ene (25 °C: $\Delta H = 42.5$ kcal/mol) is higher by *ca.* 9 kcal/mol than that of the double bond in bicyclo[2.2.0]hex-2-ene and bicyclo[3.2.0]hept-6-ene[9]. The additional energy content of 9 kcal/mol is attributed to an antiaromatic destabilization of the bicyclo[2.1.0]pent-2-ene ground state and must be considered for estimating the resonance stabilization of the transition state of the "walk" rearrangement *(1a)*→*(2a)*.

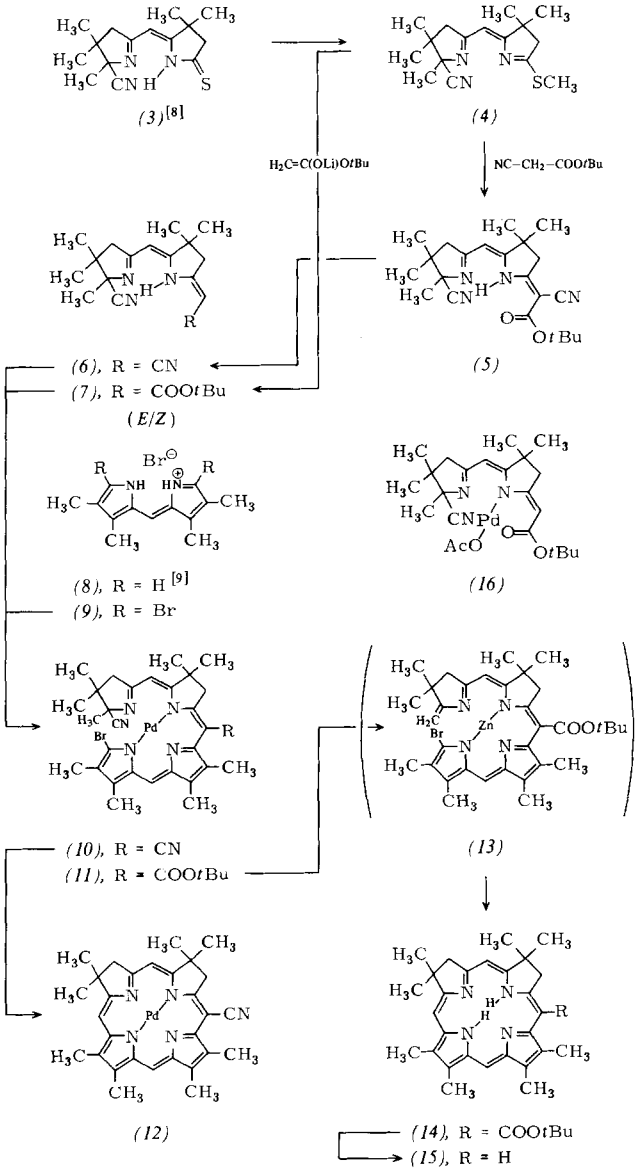
A Synthetic Approach to the Isobacteriochlorin Macrocycle[**]

By *Franz-Peter Montforts, Silvio Ofner, Vittorio Rasetti, Albert Eschenmoser, Wolf-Dietrich Woggon, Keith Jones*, and *Alan R. Battersby*[*]

The chemistry and biochemistry of porphinoid natural products has recently been enriched by the emergence of isobacteriochlorin systems *(1)* into the forefront of interest. The first example from Nature, sirohydrochlorin *(2a)*[1,2], was isolated in 1973 by *Siegel et al.*[1] from *E. coli*, where the iron complex of *(2a)* serves as cofactor for the enzyme sulfite reductase. Recently, *(2a)* (probably as a dihydro derivative) has been shown to be important in the biosynthesis of vitamin B_{12}[1–3]; this work led to the definitive structure *(2a)* for sirohydrochlorin. Then 20-methylsirohydrochlorin *(2b)* was isolated from organisms producing vitamin B_{12}[2c,4] and was shown to be converted biosynthetically into the vitamin[4]. These interlocking studies have given a new and unexpected direction to researches on the biosynthesis of vitamin B_{12}.

(1)

(2a), R = H
(2b), R = CH_3



The chemistry of isobacteriochlorins is largely unknown. Though "an octaethyl derivative" had been prepared by reduction of iron(II)-octaethylporphinate[5] or of iron(II)-octaethylchlorinate[5a] with sodium in isoamyl alcohol[6], no rational synthesis of this type of substance has so far been available[7]. We report here such a route (Scheme 1).

The synthesis in principle involves the combination of a corrinoid A/B-component of type *(6)* or *(7)* with a porphinoid C/D-partner of type *(9)*. The components *(6)* and *(7)* are prepared from the bicyclic thiolactam *(3)*[8b,c], by methods dependent on earlier synthetic studies on corrins[8], and *(9)* is available by bromination of the tetramethyldipyrromethene *(8)*[9] or of the corresponding tetramethyldipyrromethane-α,α′-dicarboxylic acid[10]. It was not possible to accomplish a base-catalyzed coupling of *(6)*+*(9)*→*(10)* either directly or with the help of "mild" coordinating metal ions such as zinc(II) or nickel(II). However, the reaction succeeded in the presence of palladium(II) owing to its known "hard" tendency towards planar coordination; this exerts a template effect which is often decisive for inducing a condensation step[11]. The coupling of *(6)* with *(9)* in the presence of palladium(II) diacetate and ethyldiisopropylamine gave a mixture of the palladium complexes *(10)* and *(12)*. The *seco*-complex *(10)* readily cyclizes to the palladium(II) isobacteriochlorinate *(12)*; the base acts by releasing the exocyclic methylidene double-bond (enamine) in ring A (cf. ref. [8,11]).

Neither the metal ion, nor the cyano group bound to the chromophore, could be removed from the palladium complex *(12)* without further changes [the cyano group of *(6)* served the purpose of fixing the enamine double bond in an exocyclic position]. The synthesis of metal-free isobacteriochlorins without a cyano group *(15)* therefore proceeded from the A/B-component *(7)* having *tert*-butyloxycarbonyl as the fixing group and this approach gave the *seco*-palladium complex *(11)*. In agreement with earlier experience[12] that corrinoid *seco*-complexes can be very readily demetalated (in contrast to the corresponding stable macrocyclic complexes), palladium(II) was removed smoothly from *(11)* by potassium cyanide. Potassium *tert*-butoxide in the presence of zinc(II) ions then cyclized the free *seco*-ligand to the zinc complex of *(14)* *via* the putative complex *(13)*. Acid ca-

talysis removed zinc(II) and also the *tert*-butyloxycarbonyl to afford *(15)*.

The critical step in the synthesis is the coupling of *(7)* and *(9)* to give the *seco*-complex *(11)*. Yields reproducibly over 40% for this delicate step could be obtained by first forming the mixed complex *(16)* from *(7)* and the $(DBU)_2$-adduct of palladium(II) diacetate; *(16)* was then coupled using an equimolar amount of DBU with an excess of *(9)* added portionwise, the course of the reaction being followed by UV/VIS spectroscopy. The data in the Table and Figure establish the constitution for the target substance, *viz.* 2,2,7,7,12,13,17,18-octamethylisobacteriochlorin *(15)*.

2,2,4,4,6,6-Hexamethylcyclotristannatellurane, a Sn_3Te_3-Ring with C_2-Symmetry[**]

By *Axel Blecher* and *Martin Dräger*[*]

Dimethylstannane reacts with tellurium to give the title compound *(1)*[1a], which, however, must be separated from the Sn_3Te_2-ring compound[1b] formed at the same time. We have now been able to obtain pure, crystalline *(1)* by reaction of dichlorodimethylstannane with sodium hydrogen telluride in aqueous solution:

$$3\,(CH_3)_2SnCl_2 + 3\,NaHTe \xrightarrow{H_2O} [(CH_3)_2SnTe]_3 + 3\,NaCl + 3\,HCl$$

(1)

The NaHTe is generated from tellurium and $NaBH_4$ in the reaction mixture[2].

(1) crystallizes from petroleum ether in the form of yellow needles which are stable for several days at room temperature in the absence of air and in the dark. The X-ray structure analysis[3] at 110 K shows that the molecule of *(1)* approaches C_2 symmetry (Fig. 1: twofold axis through Sn1 and Te2) resulting in a chiral ring. The crystal contains both enantiomers A and B, transforming *via* pseudorotation in solution[4]. The average Sn—Te distance is 275(2) pm; the mean Sn—Te—Sn angle is 96(1)°, distinctly compressed compared to the analogous Sn—S—Sn[5] and Sn—Se—Sn angles[4]. The coordination at the tin atom deviates only slightly from a tetrahedron.

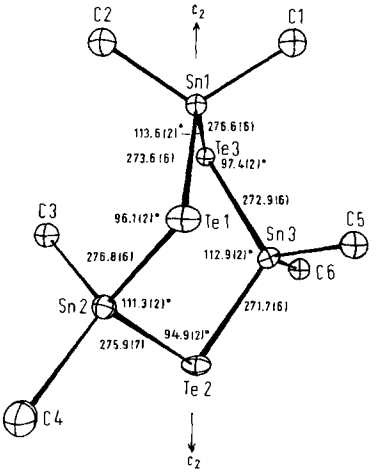

Fig. 1. Enantiomer A of *(1)* with distances [pm] and angles of the six-membered ring. Sn—C distances 220 (5) pm, C—Sn—C angles 113(2)°. Ring torsional angles [°]:

Te3—Sn1—Te1—Sn2 −34.2(2)	Sn3—Te3—Sn1—Te1 −33.3(2)
Sn1—Te1—Sn2—Te2 85.9(2)	Te2—Sn3—Te3—Sn1 84.1(2)
Te1—Sn2—Te2—Sn3 −44.5(3)	Sn2—Te2—Sn3—Te3 −41.2(3)

Procedure

All operations carried out under nitrogen and with nitrogen-saturated solvents: To a suspension of Te (3.7 g, 29 mmol) in H_2O (25 ml) is added a solution of $NaBH_4$ (2.3 g, 61 mmol) in H_2O (25 ml) and the mixture gently warmed. Te reacts vigorously and is dissolved. A solution of $(CH_3)_2SnCl_2$ (6.3 g, 29 mmol) in 25 ml H_2O is added dropwise with stirring to the red solution of NaHTe. A greenish-yellow precipitate is formed, which after 30 min is separated, dried and extracted with petroleum ether (b.p. 50—70 °C) in a Soxhlet apparatus. 5 g (62%) of yellow crystals of *(1)* precipitate from the solution, and on evaporation a further 1.5 g can be recovered.

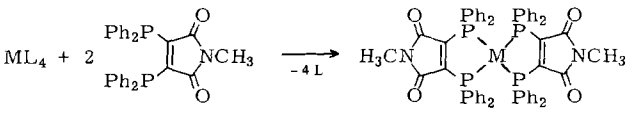
Radical Complexes of Palladium and Platinum with Bisphosphane Derivatives of Maleic Anhydride



By *Walter Bensmann* and *Dieter Fenske*[*]

The intrinsic color of bis(diphenylphosphino)maleic anhydride, thioanhydride, and (*N*-methyl)imide (PP), and the deep color of their metal(0) complexes urged us to extend our

[*] Priv.-Doz. Dr. D. Fenske, Dr. W. Bensmann

Gievenbecker Weg 9, D-4400 Münster (Germany)

investigations on this class of compounds[1]. We have found that not only normal diamagnetic metal(0) complexes of the type $(CO)_nM(PP)$ with M = Cr(Mo, W), Fe, Ni and $n = 4, 3, 2$ (in which (PP) is a neutral ligand) are formed, but also paramagnetic complexes of the type $(CO)_nM(PP)$ with M = Mn or Co and $n = 4$ or 3, respectively[2]. The magnetic measurements, ESR spectra, and the observed changes in bond lengths and vibration frequencies showed that in these complexes an electron is transferred from the metal into an antibonding orbital of the ligand, thus giving a complex of M^{1+} and $(PP)^-$ as radical anion ligand. (PP) was also intermediary to a complex bound radical anion in the reaction of nickelocene with (PP), but in this case a novel secondary reaction takes place in which a C_5H_5-group is inserted into a PC bond of the biphosphane ligand[3].

We now report on the ligand exchange reaction of metal(0) complexes of Ni, Pd, and Pt with bis(diphenylphosphino)maleic *N*-methylimide in the molar ratio 1:2.

(PP)

L = PPh_3; *(1)*, M = Pd
(2), M = Pt
L = CO; *(3)*, M = Ni

The product $Ni(PP)_2$ *(3)* is diamagnetic, air-stable, and its IR spectrum shows νCO bands which are characteristic for (PP) as neutral ligand. The analogous complexes of Pd and Pt, on the other hand, are very sensitive to air and special precautionary measures must be taken in their isolation. Their νCO bands appear at 1610 and 1665 cm^{-1}, about 100 cm^{-1} lower than in the case of the nickel complex. We conclude, therefore, that in the homologs *(1)* and *(2)* the ligands have become radical anions by taking up an electron from the metal. The ESR spectrum of *(1)* confirms this. In $C_2H_4Cl_2$ solution three groups of signals are observed in the ratio 1:2:1, corresponding to the coupling of the electron with the P-nuclei, with a hyperfine structure through coupling with N and the H-nuclei of the CH_3-group. The coupling constants ($a_p = 9.60$, $a_N = 3.0$, $a_{CH_3} = 0.68$ G) are very close to the values found for $(PP)Mn(CO)_4$ and $[PP]^-K^+$[2]. No coupling of the electron with Pd is detectable.

The X-ray structure analysis[4] on a single crystal of *(1)* confirms the spectroscopic findings. *(1)* crystallizes from 1,2-dichloroethane with five solvent molecules per unit cell. The solvent molecules are present in the two different conformations and are intercalated between layers of molecules of *(1)*. The Pd atom lies at the inversion center (0,0,0) and is square-planar coordinated by four P atoms (Fig. 1). The Pd–P distance of 237 pm falls within the range of values already observed in palladium-phosphane complexes[5]. This indicates that the tetrahedrally coordinated central atom in $Pd(PPh_3)_4$[5] changes its bonding symmetry in the course of the reaction.

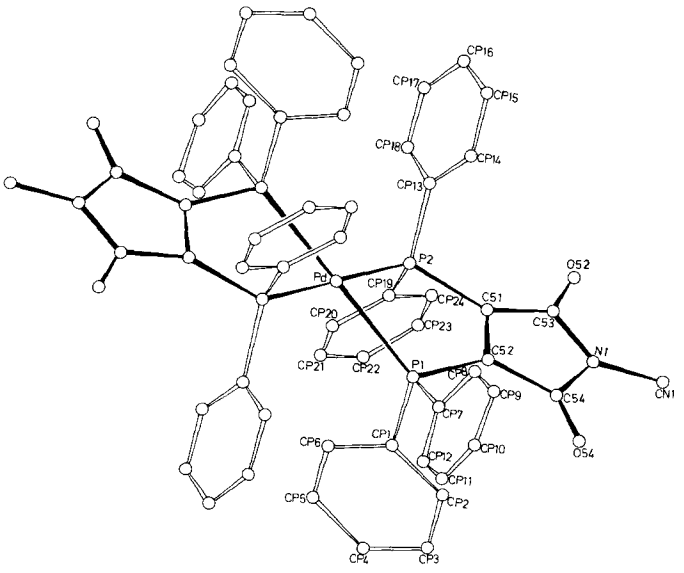

Fig. 1. Molecular structure of the palladium complex *(1)* in the crystal.

The bond angle P1–Pd–P2 has values of 83.4 and 96.6°, respectively, and the C atoms of the planar five-membered ring bound to P lie respectively 68 pm above and below the plane formed by the Pd and P atoms. The double bond in the five-membered ring is longer than that in comparable complexes which conform to the noble-gas rule[2], *e.g.* the C51–C52 distance of 139 pm is markedly longer than the corresponding CC double bond in $(PP)Fe(CO)_3$ (133 pm). Likewise the CO bond length of 124 pm is about 6 pm longer than in the Fe derivative. At the same time there is a noticeable shortening of the C51–C53 and C52–C54 bonds as well as a strengthening of the P2–C51 and P1–C52 (176 pm) bonds as compared to the P–C(phenyl) bonds (182–183 pm).

As in the case of $(PP)Co(CO)_3$ and $(PP)Mn(CO)_4$, it follows from these changes in bond lengths that low π^* acceptor levels of the ligand (PP) enable electron transfer from the Pd and Pt to the conjugated 6π-system of the maleic acid derivative. Therefore *(1)* is better regarded as $Pd^{2+}[PP^-]_2$—as is also reflected in the square-planar coordination typical for Pd^{2+}. It is still unclear why this does not apply in the case of the "more negative" nickel.

Procedure

Synthesis of *(1)*: A mixture of $Pd(PPh_3)_4$ (1 g, 0.87 mmol) and the bisphosphane ligand (0.83 g, 1.87 mmol) in $C_2H_4Cl_4$ (40 ml) is stirred at room temperature. An olive-colored solution is formed, from which *(1)* crystallizes at −20 °C in 45% yield. *(2)* is obtained analogously by reaction of $Pt(PPh_3)_4$ (1 g, 0.80 mmol) and ligand (PP) (0.77 g, 1.61 mmol).

Synthesis of *(3)*: To a solution of $(PP)Ni(CO)_2$ (1.61 g, 2.0 mmol) in xylene (50 ml) is added 0.96 g (2.0 mmol) (PP) and the mixture heated to boiling. Within 60 min the stoichiometric amount of CO is liberated and the solution turns intense green. On cooling, green crystals of *(3)* precipitate (yield 90%). *(3)* can also be obtained by direct reaction of $Ni(CO)_4$ with (PP).

Novel Polycyclic Phosphanes and Arsanes: $P_{11}(SiMe_3)_3$ and $As_7(SiMe_3)_3$

By *Hans Georg von Schnering, Dieter Fenske, Wolfgang Hönle, Michael Binnewies,* and *Karl Peters*[*]

From the products formed on reaction of Na/K alloy with white phosphorus and chlorotrimethylsilane in monoglyme *Fritz* and *Hölderich*[1] were able to isolate polycyclic phosphane derivatives such as P_7R_3, $P_{14}R_4$ and $P_{13}R_5$ ($R=SiMe_3$) in yields of up to 40% P. We have now found that reaction of the pure phosphides Na_3P_{11} and Cs_3P_{11} and of the arsenide Rb_3As_7 with chlorotrimethylsilane in toluene leads in a surprisingly simple way and in high yields to $P_{11}(SiMe_3)_3$ and $As_7(SiMe_3)_3$, respectively.

$P_{11}(SiMe_3)_3$: When a suspension of 20 g of Na_3P_{11}[2] or Cs_3P_{11}[3,4] (previously finely ground under inert conditions) in O_2-free toluene is treated with an excess of Me_3SiCl and the vigorously stirred mixture is heated under reflux for two days, deep yellow-orange solutions are obtained from which NaCl and CsCl, respectively, separate out. After filtration, removal of Me_3SiCl and half of the toluene, and cooling to 0 °C, $P_{11}(SiMe_3)_3$ crystallizes in *ca.* 60% yield (based on P, not optimized).—In the preparation of Na_3P_{11} and Cs_3P_{11}, often Na_3P_7 and Cs_3P_7[5] are also formed; in this case large amounts of $P_7(SiMe_3)_3$ are also obtained.

$As_7(SiMe_3)_3$: An analogous reaction is carried out with about 30 g of Rb_3As_7 (described in the system Rb/As as $RbAs_2$[6]), though at room temperature and in the absence of light. A deep-red solution is obtained. After 24 hours, removal of RbCl by filtration, concentration of the filtrate to 50% of its original volume and cooling to 0 °C leads to crystallization of $As_7(SiMe_3)_3$ in 70% yield.

4,7,11-Tris(trimethylsilyl)pentacyclo[6.3.0.0^{2,6}.0^{3,10}.0^{5,9}]undecaphosphane, $P_{11}R_3$, forms bright-yellow flat rhombic (lentil shaped) crystals which are much more reactive (H_2O, O_2) than P_7R_3, both under the mother liquor as well as in the isolated form. The mass spectrum (QMS) at 150 °C shows fragments differing from one another by P_2 or P_4 units [*m/e*; abundance]: $P_{11}R_3^+$ [560; 66], $P_9R_3^+$ [498; 80], $P_7R_3^+$ [436; 18], $P_7R_2^+$ [363; 77], $P_3R_3^+$ [312; 20], $P_5R_2^+$ [301; 100], $P_4R_2^+$ [270; 30], PR_3^+ [250; 45], $P_3R_2^+$ [239; 95], $P_2R_2^+$ [208; 95].

Of these, $P_9R_3^+$ seems noteworthy to us as a possible derivative of a P_6 prism[5]; it has also already been observed by *Fritz* and *Hölderich*[1]. At $T>200$ °C we also found a small amount of $P_{16}R_2^+$ [*m/e*=642]. $P_{11}R_3$ crystallizes monoclinically in the space group $P2_1/c$ (No. 14) with $a=1912.8(8)$, $b=1137.8(5)$, $c=1227.3(9)$ pm, $\beta=90.73(4)°$, $Z=4$. The structure determination is not yet complete, since the isolated crystals rapidly decompose. The molecular structure is, however, confirmed (390 *hkl*; $R=0.15$). The asymmetrically substituted enantiomers of the "ufosane" polycycle P_{11}^{3-}[2] are present with mean P···P distances of 221.5 pm (Fig. 1, above).

3,5,7-Tris(trimethylsilyl)tricyclo[2.2.1.0^{2,6}]heptaarsane, As_7R_3, forms bright-yellow rhombohedral crystals up to 2 mm in length which are astonishingly air-stable in the isolated state. On exposure to moisture, air, and light, arsenic separates out after a few hours (in the mother liquor, immediately). Its solubility in toluene is lower than that of $P_{11}R_3$. The mass spectrum at 80 °C shows $As_7R_3^+$ [744; 71], $As_4R_3^+$ [519; 29], $As_3R_3^+$ [444; 100], and As_4^+ [300; 85]. As_7R_3 crystallizes rhombohedrally in the space group $R\bar{3}$ (No. 148) with $a_R=1298.9(3)$ pm, $\alpha=50.29(1)°$, $Z=2$ ($a_H=1103.8(3)$, $c_H=3395.4(9)$ pm, $Z=6$). The structure determination (1721 *hkl*; $R=0.05$) confirms the expected configuration of the homologs P_7R_3[7] (Fig. 1, below). The As···As bond lengths are A=244.4(2), B=242.7(2) and C=240.7(1) pm [As···Si =239.7(3) pm]; the sequence A>B>C corresponds to that observed in P_7R_3[7] and differs from the sequence A>C>B in the anion As_7^{3-}[8].

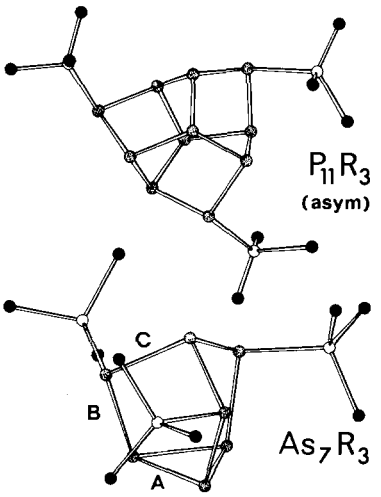

Fig. 1. Structures of the silyl-substituted polycyclic undecaphosphane $P_{11}R_3$ and of the heptaarsane As_7R_3 ($R=SiMe_3$).

Synthesis, Resolution, and Characterization of an Aminophosphane Rotamer Pair[**]

By *Otto J. Scherer* and *Michael Püttmann*[*]

On introduction of two different bulky substituents R^1, R^2 of the kind $X(CH_3)_3$ (X=C, Si, Ge), in addition to sterically active groups R, into aminophosphanes[1a] and -arsanes[1b] $R_2El-NR^1R^2$ (El=P, As), a pair of rotamers can be detected by NMR spectroscopy[1]; however, their resolution has so far proved impossible.

On reaction with a *N,N'*-bismetalated diaminosilane

(1)

R = CH_3

[a] *Ca.* 30% C_nD_n solution; ^{1}H- and ^{13}C: TMS internal, ^{31}P: 85% H_3PO_4 external; positive sign always means downfield shift (the problem of the sign of J is neglected except in one case); (r) = group on the ring nitrogen atom, (e) = group on the exocyclic nitrogen atom, R = CH_3. [b] Heat-up rate 5 °C/min beginning about 10 °C below the melting temperature given (*1a*) undergoes *ca.* 10% isomerization). [c] The signal showing a downfield shift is tentatively assigned to the $SiCH_3$ group located *cis* to the phosphorus "lone" pair.

we succeeded in synthesizing a cyclic aminophosphane derivative *(1)* which, owing to hindered rotation about the P—N bond of the three-coordinate phosphorus, forms a pair of rotamers *(1a)/(1b)* that has now been resolved and characterized individually[2].

(1a) *(1b)*

The rotamers differ in having the CR_3 group of *(1a)* (cf. Newman projection *(A)*), but the SiR_3 of *(1b)*, eclipsing the phosphorus "lone" pair.

(1a) initially predominates [*(1a)*:*(1b)* ≈ 4:1][3] in the synthesis of 1,3,2,4-diazaphosphasiletidine but is transformed into the thermodynamically more stable *(1b)* on distillation[4]. Both rotamers are very readily soluble in ether, pentane, and benzene; they differ considerably in their melting point and in some spectroscopic data (Table 1). In contrast to the ^{13}C-NMR results, *(1a)* shows only one signal for the SiR_2 group of the ring (accidental equivalence) in its ^{1}H-NMR spectrum even at 200 MHz. The greatest deviations of the values of *(1a)* and *(1b)* are found in the ^{31}P-NMR spectrum. For the groups bound to the exocyclic N atom we assign the greater coupling constant(s) to that located *cis* to the "lone" pair of the P atom (dihedral angle[5] of 0° for *(1a)*) (Table 1). Crystal structure analysis[7] of *(1a)* now confirms this assignment previously proposed for aminophosphane rotamers on the basis of ^{1}H-[6a], ^{13}C-[6b], and ^{29}Si-NMR[6c] data. Remarkably, the average value of 14.15 Hz calculated from 13.6 and 14.7 Hz for $J(PNC)_r$ agrees well with the value of 14.65 Hz calculated for a dihedral angle of 90°[8].

Synthesis of (1a)/(1b): A solution of $LiN(CR_3)SiR_3$ (R = CH_3) (50 mmol) in ether/hexane (*ca.* 80 ml) is added dropwise over 1.5 h to a solution of PCl_3 (6.97 g, 50.7 mmol) in ether (60 ml) at −18 °C and stirring is continued for 1 h at that temperature. $R_2Si[N(tBu)Li]_2$ (50 mmol) in toluene/hexane (*ca.* 110 ml) is then added dropwise within 1 h to the cooled (ice/salt) intermediate $Cl_2PN(CR_3)SiR_3$[9]. After warming to room temperature, the solvent is evaporated off, the residue dissolved in pentane (50 ml), LiCl filtered off, and the pentane is removed in vacuum. Crude yield: 16.3 g (87%) of a viscous dark red-brown oil containing *(1a)* and *(1b)* [≈4:1] accompanied by *ca.* 10% of $[ClPNtBu]_2$[9]. *(1a)* can be separated from the mixture by fractional recrystallization from acetonitrile. *(1b)* is isolated by repeated fractional distillation over a 5-cm Vigreux column; the fractions collected at 70—92 °C/10^{-3} torr (bath temp. 160—180 °C, cleanest fraction, 4.5 g) and 92—100 °C/10^{-3} torr (bath temp. 180—190 °C, 1.2 g) are finally purified by recrystallization from acetonitrile.

Mono- and Bis(η^3-allylnickel) Derivatives of 1,8-Dihydroxyanthraquinone and of Some 1,3,5-Triketones

By *Borislav Bogdanović* and *Miguel Yus*[*]

The known mono- and dimetallic derivatives of 1,3,5-triketones[1] have recently become the subject of renewed investigations, particularly regarding their magnetic properties[2,3]. According to X-ray crystal structure analyses[3], the metal atoms in dinuclear complexes of type *(1)* are almost coplanar with the ligands and are bridged to each other *via* the two central oxygen atoms.

In connection with our investigations on organometallic pentanedionates and their catalytic properties[4] our interest was directed to compounds of type *(2)*, in which two metal atoms are located very close to each other and, moreover, bear reactive η^3-allyl groups.

(1) *(2)*

We report here on the synthesis and characterization of the bis(η^3-allylnickel) 1,3,5-triketonates *(3a—c)* and the 1,8-bis(η^3-allylnickeloxy)anthraquinone *(3d)*, the first organometallic compounds very probably having structures of type *(2)*[5]. For comparison we have also synthesized the mono(η^3-allylnickel) 1,3,5-triketonates *(4b, c)* and the 1-(η^3-allylnickeloxy)-8-hydroxyanthraquinone *(4d)*.

By analogy with the synthesis of η^3-allylnickel pentanedionate[4b], we attempted the preparation of compounds *(4)* and *(3)* by reaction of the triketones *(5)* and of 1,8-dihydroxyanthraquinone with bis(η^3-allyl)nickel in the molar ratio 1:1 and 1:2, respectively. However, at −30 to 0 °C in ether, the reaction always afforded only the mono(η^3-allylnickel) derivatives *(4b, c)* of the triketones and 1-(η^3-allylnickeloxy)-8-hydroxyanthraquinone *(4d)*, respectively (see Table 1, Method A). The mono(η^3-allylnickel) 1,3,5-triketonates *(4b, c)* can also be prepared from the monothallium triketonates[7] and η^3-allylnickel bromide[8] (see Table 1, Method B)[9]. The synthesis of bis(η^3-allylnickel) 1,3,5-triketonates *(3a—c)* and of 1,8-bis(η^3-allylnickeloxy)anthraquinone *(3d)* was achieved by reaction of the dithallium salts *(6)*[7] with η^3-allylnickel bromide in CH_2Cl_2 at −50 to −78 °C.

The compounds *(3a—d)*, which are soluble in CH_2Cl_2, can be separated from thallium bromide by decantation at −78 °C. Subsequent removal of part of the solvent and addition of ether leads to their precipitation. The compounds *(3a—d)* are sensitive to air and heat: their thermal stability decreases along the series *(3d)* > *(3b)* ≃ *(3c)* > *(3a)*.

The ^{1}H-NMR spectra of the bis(η^3-allylnickel) 1,3,5-triketonates *(3a—c)* (Table 1) show signals for each of the triketonate ligands, together with characteristic signals of the η^3-allyl groups. The ^{1}H-NMR spectrum of *(3b)* in which two signals each for the *syn*- and *anti*-protons (H_s and H_a) appear at −65 °C, can be interpreted in terms of the structure *(3')* or *(3'')*, in which the two "inner" *syn*- or *anti*-differ from the two "outer" *syn*- or *anti*-protons.

(3') *(3'')*

On increasing the temperature to *ca.* −20 °C the signals of the *syn*- and *anti*-protons coalesce, so the ^{1}H-NMR spectrum corresponds to that of a symmetric η^3-allyl group—a phenomenon which is also observed in the case of bis(η^3-allylnickel) 2,4,6-heptanetrithionediate[6]. The ^{1}H-NMR spectrum of *(3a)* at −65 °C shows, *inter alia*, four signals for *syn*-, (at least) three signals for *anti*-, and one signal for *meso*-protons (H_m), together with three signals for methine protons of the triketonate ligands, a possible indication that *(3')* and *(3'')* and other conceivable stereoisomers are present together[10].

(5) *(4b)*, R^1, R^4 = CO_2Et; R^2, R^3 = H
(4c), R^1, R^4 = CO_2Et; R^2-R^3 = $-(CH_2)_2-$
(4d)

(6) *(3a)*, R^1, R^4 = CH_3; R^2, R^3 = H
(3b), R^1, R^4 = CO_2Et; R^2, R^3 = H
(3c), R^1, R^4 = CO_2Et; R^2-R^3 = $-(CH_2)_2-$

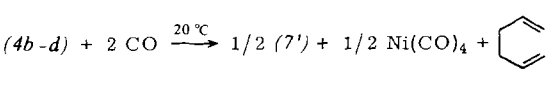
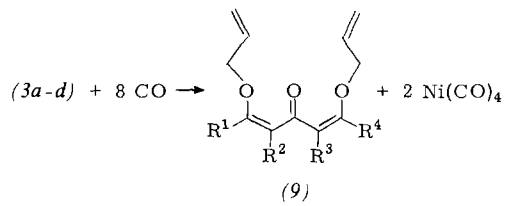
[a] Route A $(\eta^3\text{-}C_3H_5)_2Ni$ + *(5)*; Route B $(\eta^3\text{-}C_3H_5NiBr)_2$ + monothallium triketonate. Numbers in brackets: yields of TlBr. [b] Carbonylation at normal pressure in CH_2Cl_2. [c] Yields of $(\eta^3\text{-}C_3H_5)_2Ni$. [d] In $CDCl_3$ at −65 °C (100 MHz). [e] In $CDCl_3$ at −20 °C (60 MHz). [f] In $CDCl_3$ at −65 °C (60 MHz). [g] The absorptions of the aromatic groups also lie in this region. [h] No ^{1}H-NMR spectrum obtainable owing to sparing solubility. [i] Route A: at −30 °C in ether; Route B: at −30 °C in CH_2Cl_2. [j] Route A: at 0 °C in ether; Route B: at 20 °C in ether. [k] In C_6D_6 at 20 °C (60 MHz). [l] Carried out in THF.

The compounds *(4b—d)* and *(3a—d)* react with ammonia[4b] in ether at *ca.* −30 °C to give bis(η^3-allyl)nickel and the ammonia adducts of the mono- and dinickel derivatives, respectively, of the ligands *(7)* and *(8)* (see Table 1).



(7), x = 1-2
(7'), x = 0



(8), x = 1.5-3

A characteristic difference in the reactivity between the mono- and bis(η^3-allylnickel) derivatives of the 1,3,5-triketones and those of 1,8-dihydroxyanthraquinone is demonstrated in their carbonylation: the mono(η^3-allylnickel) compounds *(4b—d)* react at −20 °C (1 bar) with *ca.* 2 mol CO/mol *(4)* to give tetracarbonylnickel and mononickelbis(triketonates) *(7')*; in the case of *(4c)*, 1,5-hexadiene was found to be formed in 45% yield.

The bis(η^3-allylnickel) derivatives *(3a—d)*, on the other hand, react with a total of *ca.* 8 mol CO/mol *(3)*, whereupon two thirds or even the whole of the CO is taken up at −78 °C. Tetracarbonylnickel and the bis(allyl enol ether) of each triketone or the 1,8-dihydroxyanthraquinone *(9)* are formed by reductive elimination.

Bis(η^3-allylnickel) 2,4,6-Heptanetrithionediate

By *Borislav Bogdanović, Carl Krüger,* and *Oleg Kuzmin*[*]

We report here the synthesis, characterization, and X-ray crystal structure analysis of bis(η^3-allylnickel) 2,4,6-heptanetrithiodiate *(3)*, the first organometallic derivative of a 1,3,5-trithiotriketone[1]. Compound *(3)* was synthesized by reaction of 2,5-dimethyl-1,6,6aλ^4-trithiapentalene *(1)*[2] with bis(η^3-allyl)nickel *(2)* or η^3-allylnickel chloride. We have already prepared oxygen analogs of *(3) via* a different route[3].

(1) reacts with *(2)* in the molar ratio 1:2.0-2.2 in ether, tetrahydrofuran (THF) or toluene at 0 °C within 8—12 h to give intensely dark blue (in ether) or dark violet (in THF) solutions of *(3)*. Compound *(3)* crystallizes from the ethereal solutions at 0 or −78 °C as violet crystals having a metallic luster and can be isolated analytically pure in *ca.* 70% yield. In the synthesis of *(3)* in toluene, stoichiometric amounts of 1,5-hexadiene *(4)* could by isolated from the reaction products in addition to *(3)*.

(1) *(2)* *(3)* *(4)*

Reaction of *(1)* with η^3-allylnickel chloride (molar ratio 1:2) in THF at 0 °C affords *(3)* and nickel chloride; filtration of the THF solution and subsequent crystallization from ether furnishes *(3)* in *ca.* 48% yield. A green compound, apparently analogous to *(3)*, is formed on reaction of 2,5-diphenyl-1,6,6aλ^4-trithiapentalene[2] with bis(η^3-allyl)nickel in THF at 0 °C.

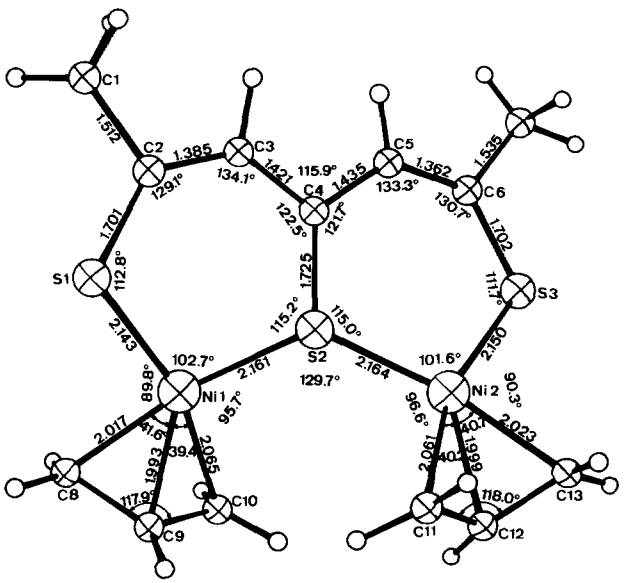

Fig. 1. Bond lengths [Å] and angles in bis(η^3-allylnickel) 2,4,6-heptanetrithionediate *(3)*.

The structure of *(3)* (Fig. 1) was confirmed by X-ray structure analysis[4]. Both nickel atoms are square planar coordinated; very slight and insignificant deviations arise due to steric hindrance of the neighboring opposingly oriented η^3-allyl groups. This hindrance causes distortion of the planar ligand[5] with maximum deviations of the plane through all S atoms of +0.17 Å (C2) and −0.24 Å (C6). S1 lies 0.898(8) Å above and S3 0.752(8) Å below a plane determined by Ni1, S2, Ni2. The S—S distances (3.361(1) and 3.342(1) Å, respectively) enlarge as a result of complexation; as a consequence there is no longer S—S bonding in the complex. The large distance between the neighboring Ni atoms (3.914(1) Å) likewise indicates an absence of metal-metal bonding. Apart from substantial broadening of the angles within the ring system at C2, C3, C5, and C6 (+12 to 13° w.r.t. the free ligand), the bond geometry of the sulfur ligand is maintained. Due to steric repulsion (C10, C11), or to a *trans*-effect of the different types of sulfur atoms S1—S2 and S2—S3, the η^3-allyl groups are bound asymmetrically to the nickel atoms. Their inclinations to the S—Ni—S planes[6] are 121.6 and 128.9 °C, respectively.

Consistent with X-ray structure analyses, the 100-MHz ^{1}H-NMR spectrum[7] of *(3)* in C_6D_6 at +10 °C shows the signals of two equivalent, asymmetric η^3-allyl groups: a signal for H_{meso} at $\tau = 5.15$ (m) and two signals each for H_{syn} and H_{anti} at $\tau = 6.98$ (d) and 7.17 (d) ($J_{meso,syn} = 7$ Hz) and 7.82 (d) and 7.96 (d) ($J_{meso,anti} = 14$ Hz), respectively. The signals of the methine protons and of the methyl groups of the trithiapentalene ligands appear as singlets at $\tau = 3.02$ and 7.59, respectively. An analogous spectrum with insignificant change in position of the signals is obtained at −50 °C in THF. On increasing the temperature to 20 °C the signals of the *syn*- and of the *anti*-protons coalesce. In the 60-MHz spectrum of *(3)* in C_6D_6 at 20 °C, the characteristic signals of symmetric η^3-allyl groups appear as a result of dynamic equilibration[8], the H_{meso} as a septet at $\tau = 5.07$ and H_{syn} and H_{anti} as sharp doublets at $\tau = 7.0$ and 7.86, respectively.

(3) reacts with carbon monoxide (1 bar) in toluene at 0 to 20 °C with uptake of *ca.* 3 mol CO/mol *(3)*. On distillation of the reaction mixture *in vacuo*, 37% of the nickel employed in the reaction is recovered as $Ni(CO)_4$; *(1)* can be recovered in 46% yield from the distillation residue by crystallization from THF at −78 °C.

The synthesis of *(3)* from *(1)* and *(2)* with formation of 1,5-hexadiene *(4)* and the reaction of *(3)* with CO to give $Ni(CO)_4$ and *(1)* respectively constitute C—C coupling reactions and formal redox processes with participation of two transition metal atoms.

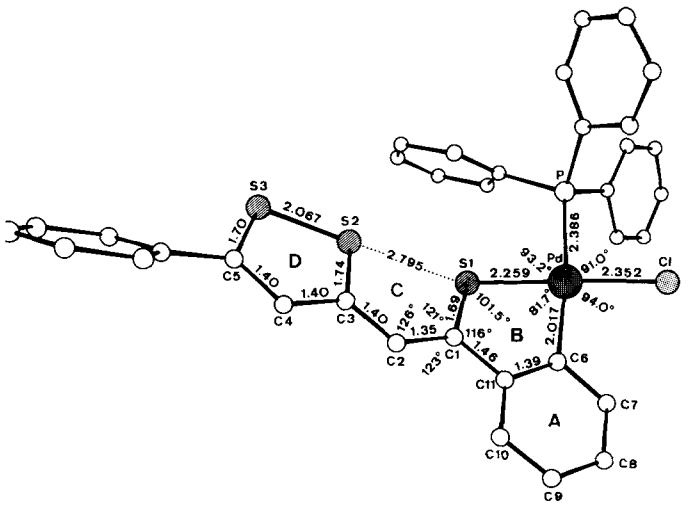
An *ortho*-Palladated Complex of 2,5-Diphenyl-1,6,6aλ^4-trithiapentalene

By *Borislav Bogdanović, Carl Krüger,* and *Paolo Locatelli*[*]

The previously reported reaction of 2,5-dimethyl-1,6,6aλ^4-trithiapentalene with bis(η^3-allyl)nickel leading to bis(η^3-allylnickel) 2,4,6-heptanetrithionediate[1] prompted us to investigate the reactivity of 1,6,6aλ^4-trithiapentalene towards other metallic and organometallic compounds.

2,5-Diphenyl-1,6,6aλ^4-trithiapentalene *(3)*[2] reacts with $PdCl_2$ in boiling methanol/benzene (10:1) in the presence of LiCl with loss of HCl to give a violet, air-stable complex *(1)* (yield 97%).

According to an X-ray crystal structure analysis[3], compound *(2)*, the triphenylphosphane adduct of *(1)* crystallizing from toluene, is a square-planar palladium complex (±0.05 Å) whose coordination geometry is determined by a Cl-, a P-, a S-, and a σ-bonded phenyl C-atom.



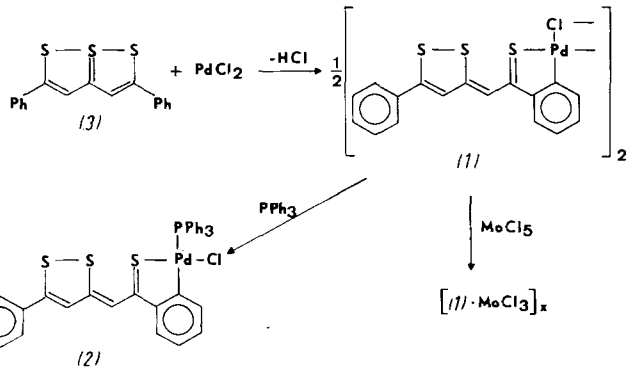


Fig. 1. Bond lengths [Å] and angles in the complex *(2)*.

The interaction of only one sulfur atom of the ligand with palladium leads to removal of the non-bonding resonance[4] in *(3)* and to rupture of a S—S bond. Whereas the S—S distances in *(3)* are 2.362 and 2.304[5], the S—S bond remaining in complex *(2)* is shortened to 2.067. This is accompanied by a disruption of the original planarity of the ligand with formation of planar (±0.01 Å) subunits (A, B, C, D; deviations from the best plane each ±0.01 Å) and an increase in the double bond character of the C1—C2 bond. The metallaheterocycle B is oriented along the S1—C6 vector (159°); the bond distances to the palladium correspond to those already reported in the literature[6].

By virtue of the structure of *(2)*, *(1)* is presumably a dimer with bridging chlorine atoms. The formation of *(1)* from *(3)* and $PdCl_2$ represents an example of the so-called *ortho*-metalation reaction[7] and can be compared with the *ortho*-palladation and -platination of diarylthioketones described by *Alper*[8].

Upon treatment of *(1)* with $PdCl_2$ in the presence of LiCl (molar ratio 1:1:3) in methanol/benzene (1:1) no reaction was observed even after five days' boiling under reflux. Thus, under analogous conditions as for the synthesis of *(1)*, palladation of the second phenyl group could not be accomplished. In contrast, reaction of *(1)* with $MoCl_5$ (molar ratio 1:1) in boiling toluene[9] quantitatively afforded a violet complex of the composition $[(1)\cdot MoCl_3]_x$ of presently unknown structure. Thus, the palladium compound *(1)* is suitable as starting material for the synthesis of complexes containing several different metal atoms.

Procedure[10]

Synthesis of *(1)*: To a suspension of *(3)* (3.10 g, 9.94 mmol)[2] in methanol (230 ml) and benzene (25 ml) was added 1.76 g (9.92 mmol) $PdCl_2$ and a solution of 1.33 g (31.3 mmol) LiCl in 20 ml methanol. The stirred suspension was heated for 3 h under reflux, and, after cooling to room temperature, the product was collected on a G3 filter. The mother liquor was shown to contain 93.6% of the liberated HCl by acidometric titration. The residue was washed with methanol and ether and dried at 10^{-3} torr; the yield of *(1)* (m.p. 304 °C, dec.) was 4.38 g (97%). *(1)* is soluble in pyridine, morpholine, and chloroform, but sparingly soluble in pentane, benzene, ether, ethanol, and tetrahydrofuran.

Synthesis of *(2)*: A mixture of *(1)* (0.36 g, 0.80 mmol) and triphenylphosphane (0.21 g, 0.80 mmol) in ether is stirred for 18 h at room temperature; the violet precipitate which is formed is filtered off, washed with ether, and dried at 10^{-3} torr. Yield of *(2)* (m.p. 203—205 °C): 0.50 g (87%).

Metal Complexes of Bredt Olefins: Synthesis and Structure of Bicyclo[4.2.1]non-1(8)-enebis(triphenylphosphane)platinum(0)[**]

By *Erich Stamm, Konrad B. Becker, Peter Engel, Otto Ermer,* and *Reinhart Keese*[*]

Bredt olefins[1] derived from *trans*-cyclohexene or *trans*-cycloheptene[2] have been detected as labile intermediates[3], yet they have never been studied in detail. Because of their unusual structural and chemical properties we decided to check whether Bredt olefins can be reversibly stabilized with transition-metal compounds[4]. We have investigated the reaction of ethylenebis(triphenylphosphane)platinum(0) *(1)* with bicyclo[4.2.1]non-1-(8)-ene *(2)*, a Bredt olefin of the *trans*-cyclooctene series stable at room temperature, to give the complex *(3)* (see Procedure).

(1) *(2)* *(3)*

The structure of *(3)* was determined by X-ray crystallography[5] (Fig. 1). The bridgehead double bond is bound on the *exo* side to the bis(triphenylphosphane)platinum. The platinum atom is almost planar coordinated; the angle between the P1—Pt—P2 and C1—Pt—C8 planes is 6° (cf. [6, 4c]). The most important bond lengths are: Pt—P1 = 2.30, Pt—P2 = 2.26, Pt—C1 = 2.16 and Pt—C8 = 2.11 Å. The length of the bridgehead double bond C1—C8 (1.41 Å) is comparable with that observed in other complexed olefins of this type (*e.g. (1)*: 1.43 Å)[6a].

The conformation of bicyclo[4.2.1]non-1(8)-ene in the crystalline platinum complex *(3)* corresponds to the energetically preferred conformation[7] of the free olefin *(2)* as obtained by force field calculations. In Figure 1 the double-bond geometry observed in the crystalline complex *(3)* is compared with that calculated for the free olefin. As can be expected from the back-bonding influence of platinum(0) on the olefinic double bond, the torsional angle C2—C1=C8—C7 in the complex *(3)* (124°) is smaller than the value calculated for the free olefin *(2)* (136.5°). The increased pyramidal character at the olefinic bridgehead, *i.e.* the angle between the C1, C2, C8 and C1, C8, C9 planes ("out-of-plane bending" parameter, see [7]) is also in accord with this observation: The value found for this angle in *(3)* (39°) is greater than the value (33.3°) calculated for the corresponding angle in *(2)*. X-ray structure analysis is not accurate enough to provide more detailed information.

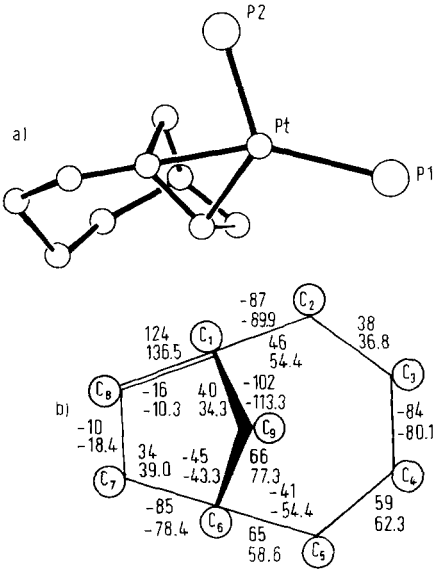

Fig. 1. a) Structure of bicyclo[4.2.1]non-1(8)-enebis(triphenylphosphane)platinum(0) *(3)* (phenyl groups not shown); b) torsion angles [°] in bicyclo[4.2.1]non-1(8)-ene *(2)*. Upper values: measured in complex *(3)*; lower values: calculated [7] for the free olefin *(2)*.

The complex *(3)* is stable at room temperature; surprisingly however, at higher temperatures in solution a mixture of four isomeric bicyclo[4.2.1]nonenes is formed[8]. Isomer-free bicyclo[4.2.1]non-1(8)-ene is obtained from *(3)* in toluene by addition of carbon disulfide or tetracyanoethylene (TCNE). Further experiments have revealed that the stability of complexes of the general formula $[(C_6H_5)_3P]_2Pt$—L in solution increases along the series $L = H_2C{=}CH_2 < (C_6H_5)_3P < O_2 < (2) < CS_2 \approx$ TCNE.

Procedure

To a solution of *(1)* (0.56 g, 0.75 mmol) in toluene (30 ml) is added *(2)* (0.095 g, 0.75 mmol) at −60 °C[9]. After 1 hour the mixture is allowed to warm to 0 °C and then concentrated *in vacuo*. The residue is dissolved in 1:1 ethyl acetate/dichloromethane (*ca.* 3 ml) and chromatographed at −10 °C on 60 g aluminum oxide (Camag, neutral, activity I). Olefins are eluted with hexane, and the complex *(3)* with hexane/ethyl acetate (1:1). The main fraction is concentrated *in vacuo* at 0 °C; the residue crystallizes spontaneously from ether at 0 °C. A total of 0.328 g (52%) of *(3)* is obtained as pale yellow crystals[10].

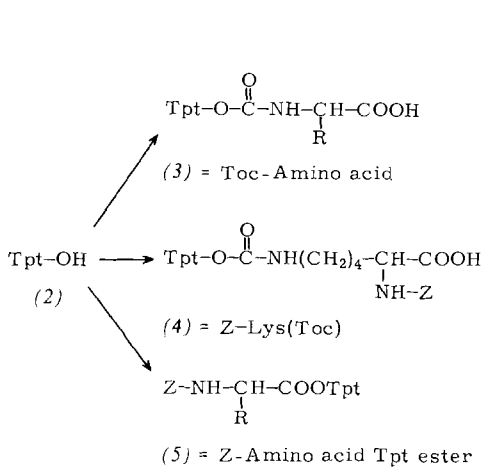
Solubilizing Acid-Labile Peptide Protecting Groups

By *Hermann Anzinger, Manfred Mutter*, and *Ernst Bayer*[*]

A central problem in the synthesis of polypeptides is the sparing solubility of larger peptides[1,2]. Particularly valuable as solubilizing protecting groups[2-5] are, *e.g.*, polyethylene glycol residues, which increase the solubility both in organic as well as in aqueous media[3,5].

For general application as amino acid protecting groups these solubilizing residues must be so modified that they can be cleaved off under the normal conditions of peptide synthesis. We describe here the first *O*-hydroxyalkylation of a primary alcohol to a tertiary alcohol [*(2)*] using triethyleneglycol monomethyl ether *(1)* as example. Acid-labile solubilizing protecting groups of the *tert*-butylcarboxyl and *tert*-butyloxycarbonyl type thus become accessible.

We synthesized *(2)* by addition of *(1)* to methyl vinyl ketone and subsequent Grignard reaction with CH_3MgI[6]. Direct reaction of *(1)* with epoxides[3,6] was unsatisfactory.



(1) *(2)* = Tpt–OH

The introduction of the Tpt–O–CO group ("Toc" group)[7] as acid-labile α-amino protecting group as in *(3)* or ε-amino protecting group of lysine as in *(4)* was achieved in high yields *via* the mixed carbonates[8]. The reaction of *N*-protected amino acids with *(2)* leading to the acid-labile Tpt esters *(5)* was accompanied by considerable racemization.

Investigations on model peptides showed that the Toc and Tpt groups are just about as acid-labile as the Boc and *t*-Bu groups, respectively. The new protecting group has already proven useful, especially in conformational studies[9].

Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)
[+] Author to whom correspondence should be addressed.

Procedure

Synthesis of *(2)*: *(1)* (8.2 g, 50 mmol) is treated with $NaOCH_3$ (81 mg, 1.5 mmol) and, after warming to 35 °C, methyl vinyl ketone (3.5 g, 50 mmol) is added dropwise to the stirred mixture such that the temperature remains constant. Stirring is continued for a further 2 h at 35 °C and the mixture neutralized with glacial acetic acid. The ketone is purified by column chromatography (silica gel); yield 4.8 g (41%) as colorless oil (characterization: ^{1}H-NMR).—A solution of the ketone (4.7 g, 20 mmol) in ether (40 ml) is treated with 40 mmol CH_3MgI. The resulting precipitate is filtered off and hydrolyzed with ice/NH_4Cl. The aqueous solution is washed with ether and then evaporated to dryness. The residue is digested with CH_2Cl_2/acetone (1/1) and filtered; the filtrate is dried over K_2CO_3, concentrated by evaporation, and purified by column chromatography (silica gel). 2.6 g (52%) of *(2)* is obtained as a colorless oil (characterization: ^{1}H-NMR).

Synthesis of *(3)*, R = CH_3: L-alanine (360 mg, 4.05 mmol) is dissolved in a 40% alcoholic solution of Triton B. After removal of solvent by evaporation the residue is stripped of water by azeotropic distillation with 2 × 10 ml dimethylformamide. The residue is taken up in 12 ml dimethylformamide, treated with 1.5 g Tpt-phenyl carbonate (4.05 mmol) and stirred for 3 h at 50 °C. The mixture is added to ice-water and washed three times with ether. The temperature is kept at 0 °C and the pH is adjusted to 2—3 with citric acid. The mixture is then saturated with NaCl, exhaustively extracted with CH_2Cl_2, and the combined extracts washed with NaCl solution, dried and evaporated down. The oil thus obtained is thin-layer chromatographically pure; yield 1.09 g (74%). Racemization test: <1% D-component (characterization: ^{1}H-NMR, elemental analysis).

Synthesis of *(5)*, R = H: 636 mg (3.04 mmol) of *Z*-glycine, 760 mg (3.04 mmol) of *(2)*, and 37 mg of 4-dimethylaminopyridine are dissolved in 5 ml of CH_2Cl_2. The solution is cooled to 0 °C and 3 mmol of dicyclohexylcarbodiimide (DCC) is added dropwise with stirring. After continued stirring for 0.5 h at 0 °C and 4 h at 25 °C, the mixture is filtered, the filtrate diluted with CH_2Cl_2, washed with dilute acetic acid (saturated with NaCl) and 5% $NaHCO_3$ solution (saturated with NaCl), dried, and evaporated down. Subsequent column chromatography (silica gel) affords 360 mg (27%) of *(5)*, R = H, as a colorless oil (characterization: ^{1}H-NMR, elemental analysis).

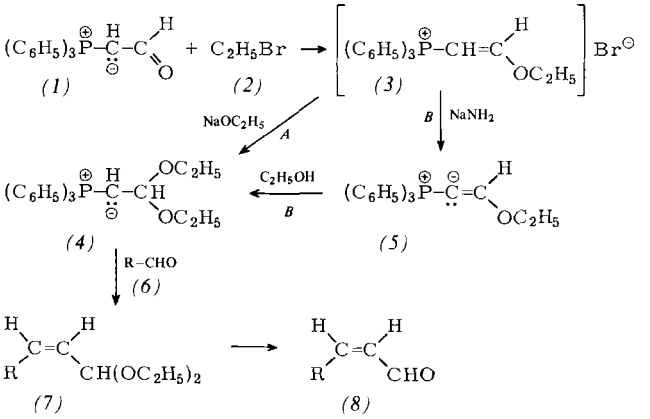
Stereoselective Synthesis of *Z*-α,β-Unsaturated Aldehydes

By *Hans Jürgen Bestmann, Kurt Roth*, and *Manfred Ettlinger*[*]



Dedicated to Professor Ernst Ruch on the occasion of his 60th birthday

Despite the variety of methods available for the synthesis of α,β-unsaturated carbonyl compounds[1], only limited success has been achieved with the preparation of the *Z*-α,β-unsaturated aldehydes *(8)*[2]. We describe here a generally applicable and extensively stereoselective method for the synthesis of compounds *(8)*.

Formylmethylenetriphenylphosphorane *(1)*[3] reacts with ethyl bromide *(2)* to give the vinylphosphonium salt *(3)*. Reaction of compound *(3)* with equimolar amounts of sodium ethoxide in anhydrous tetrahydrofuran affords the previously inaccessible[3,4] ylide *(4)*, which reacts with aldehydes *(6)* in a *Z*-stereoselective Wittig reaction to give the diethyl acetals *(7)* of the *Z*-α,β-unsaturated aldehydes (Method *A*); phosphorane *(1)*, on the other hand, reacts with *(6)* *E*-stereoselectively[3,5] (for an explanation of the different stereoselectivity see [6]).

The following variant often gives better yields of *(7)*:*(3)* is treated with sodium amide in liquid ammonia to give the phosphaallenylide *(5)* which is converted with an equimolar amount of anhydrous ethanol in ether into *(4)* and finally subjected to the Wittig reaction with aldehyde *(6)* (Method *B*).

Acetal-cleavage of *(7)* with catalytic amounts of *p*-toluenesulfonic acid in acetone/water (15 min at 0 °C; Method *C*) or with moist silica gel (2 days at room temperature; Method *D*)[7] affords the *Z*-α,β-unsaturated aldehyde *(8)*; the *Z*/*E* ratio was determined ^{1}H-NMR spectroscopically (cf. Table 1). The isomeric composition of *(7)* could not be determined, either by gas chromatography or by nuclear magnetic resonance.

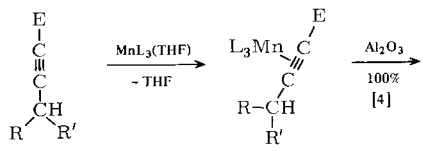
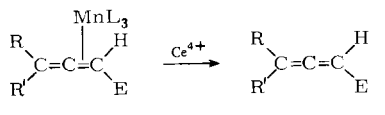
Synthesis of Allenes from Electrophilic Acetylenes *via* Novel Allenemanganese Complexes[**]



By *Michel Franck-Neumann* and *Francis Brion*[*]



The hydrogenating photocleavage of organic ligands from their tricarbonyliron complexes[1] is already well-known. We have now found that dicarbonyl(methylcyclopentadienyl)manganese complexes of electrophilic acetylenes can very easily isomerize to allene complexes under the conditions of this reaction. Thus, *e.g.*, the manganese complex *(2)*, which is formed selectively from the enyne ester *(1)* and an irradiated tricarbonyl(methylcyclopentadienyl)manganese solution in tetrahydrofuran (THF), gives the isoprene derivative *(4)* [*Z*-isomer: NMR $J_{HH} = 11.0$ Hz; IR δ=CH 770 cm^{-1}] on irradiation in acetic acid. Compound *(4)* is formed *via* a primary isomerization of the vinylacetylene complex *(2)* to the (isolable) vinylallene complex *(3)*.

MnL_3 =  ; R = CO_2Me

The rearrangement *(2)*→*(3)* is formally a [1,5] hydrogen shift. The simpler [1,3] isomerization, *i.e.* the direct acetylene-allene rearrangement, proceeds just as readily; in this case most readily in the presence of basic aluminum oxide. Manganese complexes *(6)* of functionalized acetylenes *(5)*—esters, aldehydes, or ketones—are converted quantitatively into the allene complexes *(7)* in this way. Since their oxidative cleavage with iron(III) chloride, or better cerium(IV) ammonium nitrate, usually proceeds in excellent yields[2], this rearrangement constitutes a preparatively useful and novel method for the synthesis of allenes[3]. Table 1 lists some examples for the synthesis of mono-, di-, and trisubstituted allene derivatives *(8)* from the readily accessible electrophilic acetylenes *(5)*.

MnL_3 =

Table 1. Acetylenemanganese complexes *(6)*, allenemanganese complexes *(7)* and allenes *(8)*.

	R	R'	E	*(6)* yield [%] [5]	*(8)* yield [%]	*(7)*, ^{1}H-NMR δ, *J* [b]
a	H	H	CO_2Et	70	81	2.66, t, 3 Hz
b [a]	*n*-C_4H_9	H	CO_2Me	75	95	2.67, d, 3 Hz
c [a]	*n*-C_5H_{11}	H	CHO	75	[2]	2.86, br. s
d	$(CH_2)_5$		$COCH_3$	70	72	2.71, br. s
e	$(CH_2)_5$		CHO	65	71	2.73, br. s

[a] *(7b)* and *(7c)* occur as chromatographically easily separable isomers.
[b] 90 MHz, C_6D_6, TMS; δ-values for the H atom α to E.

Special importance attaches to the complexes *(7)*, in which the allene is present as protected group. With these complexes reactions can be carried out successfully which with free allenes give only low yields. One example is the facile synthesis of the insect pheromone *(9)*, which contains a vinylallenyl moiety.

MnL_3 =

In contrast, with the free, less stable allenecarbaldehyde, which was accessible from nonanal (pelargonaldehyde) *via* a tedious method involving five steps[6], the Horner-Emmons reaction proceeded only with great difficulty (no yields quoted).

With exception of dicarbonyl(η-cyclopentadienyl)(6-methylene)manganese[7] the allenemanganese complexes *(7)* have not to our knowledge been previously reported. In the IR region of 1500—2500 cm^{-1} they show besides the absorptions of the carbonyl ligands (1992 and 1935 cm^{-1}) only bands which are due to the carbonyl groups of the substituents E (ester 1700 cm^{-1}, aldehyde 1665 cm^{-1}, ketone 1660 cm^{-1}). The ^{1}H-NMR spectra (90 MHz, C_6D_6, TMS) show in addition to the signals for the methylcyclopentadienyl group [1 singlet at δ = 1.40 (3 H) and 1 singlet (4 H) or 2 broad singlets (each 2H) between 3.86 and 4.08] and for the protons of the E, R and R' groups, a characteristic signal for the proton in the α-position to the substituent E whose chemical shift confirms the coordination at this double bond (Table 1).

Procedure

Synthesis of *(6)*: To a solution of 6.4 mmol $CH_3C_5H_4Mn(CO)_2(THF)$, prepared by UV irradiation of 1.40 g $CH_3C_5H_4Mn(CO)_3$ in 100 ml THF[8], is added 0.84 g (5.4 mmol) of methyl 2-octynoate *(5b)*. After 12 hours' stirring at room temperature and removal of solvent (water-pump vacuum), unreacted $CH_3C_5H_4Mn(CO)_3$ (0.30 g) and *(5b)* (0.15 g) are distilled off at 50 °C/10^{-2} torr. The residue is filtered through 10 g of silica gel. The orange zone of *(6b)* is eluted with petroleum ether/ether (6:1): yield 1.07 g (70%) [^{1}H-NMR (C_6H_6): δ = 2.79 (t, *J* = 7 Hz, CH_2 C≡C)].

Synthesis of *(7b)*: To a stirred solution of *(6b)* (1.0 g, 2.9 mmol) in diethyl ether (100 ml) under inert gas is added 50 g

 © Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0909-0688 $ 02.50/0

of basic aluminum oxide (activity I, Merck). After 6 hours' stirring at room temperature the aluminum oxide is filtered off and extracted several times with chloroform. After removal of the solvents the isomeric mixture *(7b)* is obtained quantitatively as a yellow oil, which can be separated by chromatography on silica gel [^{1}H-NMR (C_6D_6): $\delta = 6.09$ for the one isomer and 6.83 for the other (t, $J = 7$ Hz; d, $J = 3$ Hz; 4H)], though this is not necessary for the next step, *i.e.* for the synthesis of *(8b)*.

Synthesis of *(8b)*: A solution of cerium(IV) ammonium nitrate (9.0 g) in acetone (120 ml) is added dropwise (*ca.* 1 h) to a solution of *(7b)* (1.0 g) in acetone (50 ml) at 0 °C. The mixture is stirred for 0.5 h, treated with 200 g of ice and extracted twice with ether. The extracts are evaporated down and the residue taken up in ether again, washed with water and dried over $MgSO_4$. After removal of solvent the residue is dissolved in hexane and filtered through a small amount of Florisil: yield 0.42 g (95%) pure *(8b)*.

Ring-Opening of Lactones and Cyclic Carbonates with Bromo- or Iodotrimethylsilane

By *Hans R. Kricheldorf*[*]

It is known that iodotrimethylsilane is capable of cleaving acyclic, aliphatic esters[1,2], whereas bromotrimethylsilane fails to react. We have now found that the lactones *(1a—d)* and *(4)* undergo complete ring-opening on treatment with bromotrimethylsilane, while in the case of *(6)* only equilibrium with *ca.* 30% *(7)* is achieved. Iodotrimethylsilane also cleaves the lactones *(1a—d)*. The silyl esters of ω-bromo- and ω-iodocarboxylic acids *(2a—d)*, *(3a—d)*, and *(5)* are useful alkylating reagents, affording access to a wide range of compounds including ω-hydroxy-, ω-mercapto-, and ω-amino acid derivatives. Moreover, the esters of type *(2)*, *(3)*, and *(5)* can be converted with thionyl chloride directly into ω-halocarbonyl chlorides, *e.g.* *(8a—e)*. Of the numerous possible reactions of these acid chlorides we mention here the reaction with trimethylsilyl azide, which leads to the otherwise scarcely accessible ω-haloalkyl isocyanates *(9a—e)*. Table 1 lists the physical data of some of these compounds. The acid chlorides *(8a—c)* and the isocyanates *(9a—e)* are of interest not only for preparative organic chemistry but also for the synthesis and modification of polymers.

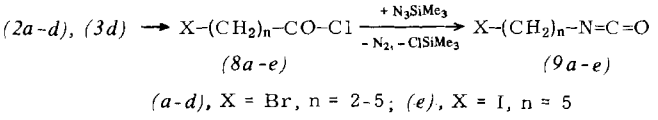

Table 1. Yield and physical data of ω-halocarboxylic acid derivatives, ω-bromoalkyl isocyanates, and ω-bromoalkoxysilanes.

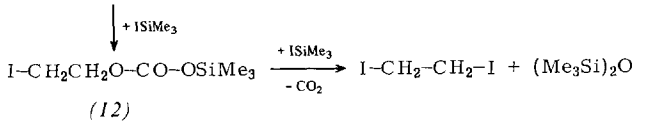
(11b)	79	1.4431	35—37/12

Cyclic carbonates can also be opened by bromotrimethylethylsilane, but the intermediary silyl carbonates immediately decarboxylate. In the case of *(10b)* ring-opening to *(11b)* is more than 95% regioselective. Since cyclic carbonates can readily be obtained from 1,2- and 1,3-diols, 1,2- and 1,3-disubstituted compounds containing two different reactive functions are accessible from them *via* this route. Iodotrimethylsilane reacts with cyclic and acyclic carbonates to give alkyl iodides. If ethylene carbonate is allowed to react with double the molar amount of iodotrimethylsilane in the cold, the initially formed carbonate *(12)* is attacked by the excess of $ISiMe_3$ before it decarboxylates; 1,2-diiodoethane is



[*] Dr. H. R. Kricheldorf

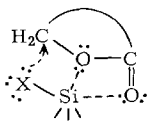
formed as main product. This reaction course and the strongly exothermic reaction with lactones indicate that iodotrimethylsilane is considerably more reactive than bromotrimethylsilane.



(10a, b), R = H, CH_3 *(11a, b)*

(12)

Sultones react neither with bromo- nor with iodotrimethylsilane, even though they are better alkylating reagents than lactones or carbonates. Since, however, the sulfonyl oxygen atoms are poorer nucleophiles than carbonyl oxygen atoms, we believe that the ring-opening of lactones and carbonates proceeds *via* a cyclic transition state *(13)*, in which the carbonyl oxygen is complexed by silicon *via* the vacant d-orbitals.

(13)

Procedure

Synthesis of trimethylsilyl 6-bromohexanoate *(2d)*: A mixture of 1 mol ε-caprolactone and 1.2 mol bromotrimethylsilane[3] is heated for *ca.* 10 h at 100 °C and *ca.* 30 h at 120 °C (or after addition of 20 ml CCl_4 heated under reflux for 30 h). *(2d)* is then isolated by distillation.—In the case of α-bromo-γ-butyrolactone *(4)* the reaction time must be prolonged; with β-propiolactone *(1a)* *ca.* 8 h suffices.

Synthesis of 6-bromohexanoyl chloride *(8d)*: A mixture of 1 mol *(2d)* and 1.1 mol distilled thionyl chloride in 250 ml anhydrous chloroform is heated to boiling until evolution of SO_2 ceases (*ca.* 4 h); *(8d)* is then isolated by distillation.—The reaction of *(8d)* with trimethylsilyl azide is carried out in chloroform or benzene[4].

Experiments on the HOMO-LUMO Nature of Metal-Metal Bonds[**]

By *Harald Beurich, Thomas Madach, Felix Richter,* and *Heinrich Vahrenkamp*[*]

Dedicated to Professor Lawrence F. Dahl

The results of theoretical studies on metal-metal interactions range from the prediction of maximum bond energies[1] to the ascertainment of the absence of a direct bond[2]. Verification of such predictions is often just as difficult as the critical evaluation of the calculational procedures employed[3]. Experimental investigations are usually limited to isolated measurements on individual compounds[3]. Synthesis of the phosphorus-bridged trinuclear cluster *(2)*[4] has now made it possible to compare the results of *different* experimental methods for *(1)*[5] and *(2)*.

(1) R = C_6H_5 *(2)*

The cluster *(1)* contains one more electron than required by the 18-electron rule. On replacement of a cobalt atom by iron, however, all the metal atoms in *(2)* have closed electron shells. The nature of the excess unpaired electron in the HOMO of *(1)* becomes clear in a crystallographic comparison of *(1)* and *(2)*[6]: it is antibonding with respect to the metal-metal interaction. For, as in the corresponding complexes with sulfur atoms as bridging ligands[7], the metal-metal distances in *(2)* are shorter by *ca.* 10 pm than in *(1)* with essentially the same molecular geometry (cf. Fig. 1).

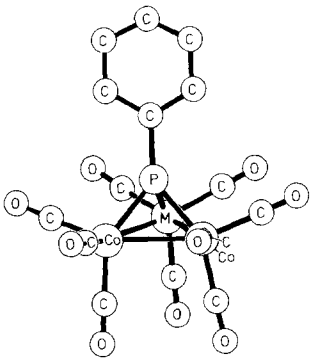

Fig. 1. Molecular structure of the clusters *(1)* (M = Co) and *(2)* (M = Fe). Principal bond lengths in *(1)*: Co Co = 271.2(3), 271.4(3), and 272.5(2); CO P = 212.3(4), 212.7(4), and 213.4(3); in *(2)*: Co Co = 263.2(2); Fe Co = 262.1(2) and 261.6(2); Co P = 212.0(2) and 212.2(2); Fe P = 216.2(3) pm.

This result is supplemented by the redox behavior of the two clusters. Only the oxidation of *(1)* to the monocation and the reduction of *(2)* to the monoanion can be observed as chemically and electrochemically reversible processes. Attempts at further oxidation led to destruction of the complexes. This means that occupation of the first antibonding orbital (*i.e.* the HOMO in *(1)* and the LUMO in *(2)*) does not effect decomposition but that this is brought about by an emptying of the highest bonding orbital (*i.e.* the HOMO in $(1)^{\oplus}$ and *(2)*). Since metal-metal single bonds number among the weakest bonds[3], it appears reasonable to assign essentially bonding metal-metal interactions to the HOMOs in $(1)^{\oplus}$ and *(2)*.

The ESR spectra (Fig. 2) supply further information about the first antibonding MOs of *(1)* and *(2)*. The 22-line pattern recorded for *(1)* demonstrates the interaction of the unpaired electron with all three cobalt atoms, and the 15-line pattern obtained for $(2)^{\ominus}$ reveals the corresponding interactions with the two cobalt atoms[8]. The good agreement of the HFS constants confirms the similarity of the two HOMOs. The most important result in both cases, however, is the absence of coupling with the phosphorus atom. The resolution of the ESR spectra is such that this coupling constant must be smaller than 1—2 gauss to escape detection. We have thus ob-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Rechenzentrum der Universität Freiburg. We are grateful to the Physical Chemistry Institute of this University for the possibility of conducting ESR measurements.

tained experimental proof that the HOMO of *(1)* and the LUMO of *(2)* are practically exclusively combinations of metal d-orbitals. This conclusion was also reached by *Dahl et al.* for $SCo_3(CO)_9$[9] but could not be verified because the normal sulfur atom does not have a nuclear spin.

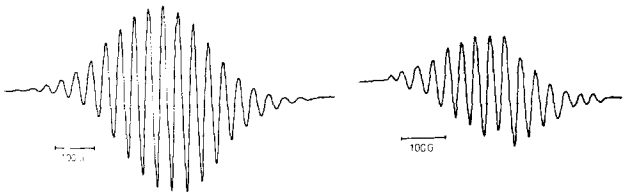

Fig. 2. ESR spectra of *(1)* and the anion of *(2)* in heptane/tetrahydrofuran. HFS constants 32.8(2) G for *(1)* and 29.1(2) G for $(2)^{\ominus}$.

The results of the crystallographic, electrochemical, and ESR measurements are consistent. They support the qualitative concept of significant energetic separation of metal-metal and metal-ligand bonding. The proven HOMO-LUMO nature of metal-metal interactions should be the starting point of an extensive and readily accessible chemistry of complexes having metal-metal bonds which has hardly been studied up to now.

A New Synthesis of Carbonyl Selenide

By *Kiyoshi Kondo, Satoshi Yokoyama, Noritaka Miyoshi, Shinji Murai,* and *Noboru Sonoda*[*]

We wish to describe a novel, convenient, and high yield synthesis of carbonyl selenide (Se=C=O) by the low-temperature reaction of ammonium selenolcarbamates *(1)* with acids. Carbonyl selenide has previously been prepared by the reaction[1] of selenium with carbon monoxide at 500—700 °C or by the reaction[2] of aluminum selenide with phosgene at 210 °C. Both these known methods require complicated apparatus and suffer from low yields; the former leads to blockage of the apparatus with selenium. Hence the chemistry of carbonyl selenide[3] has hardly been studied in contrast to that of carbonyl sulfide[4].

We have already reported[5] that amines react with carbon monoxide in the presence of selenium under atmospheric pressure at room temperature to give ammonium selenolcarbamate *(1)* quantitatively:

$$2\,RR'NH + CO + Se \rightarrow \underset{(1)}{[RR'NH_2]^+[RR'N{-}C(O){-}Se]^-} \qquad (a)$$

[*] Dr. K. Kondo [†], S. Yokoyama, N. Miyoshi, Prof. Dr. S. Murai, Prof. Dr. N. Sonoda
Department of Petroleum Chemistry, Faculty of Engineering
Osaka University
Suita, Osaka 565 (Japan)
[†] Author to whom correspondence should be addressed.

Cautious addition of this intermediate salt *(1)* to a tetrahydrofuran (THF) solution of strong acid at −78 °C (see Experimental) gives carbonyl selenide[6]:

$$H^+ (\text{excess}) + (1) \rightarrow SeCO + 2\,RR'NH_2^+ \qquad (b)$$

The results of the synthesis of carbonyl selenide from various ammonium selenolcarbamates *(1)* prepared *in situ* using different acids are given in the Table 1.

Table 1. Synthesis of SeCO according to eq. (b). Compound *(1)* (5 mmol) is added at −78 °C to an excess of acid (50 mmol).

$[RR'NH_2]^+[RR'N\ C(O)\ Se]^-$	$RR'N$	Acid	Se=C=O Yield [%]
(1a)	Et_2N	H_2SO_4	98
		p-$CH_3\ C_6H_4\ SO_3H$	96
		H_3PO_4	88
		HCl	97
		C_6H_5COOH	11
		CH_3COOH	0
(1b)	n-Bu_2N	H_2SO_4	83
(1c)	Piperidino	H_2SO_4	90
(1d)	n-BuNH	H_2SO_4	98

Viewed experimentally, the reaction of *(1a)* with sulfuric acid represents the best choice. The low solubility of p-toluenesulfonic acid precludes its use for large scale syntheses; the high viscosity of phosphoric acid at low temperature might cause difficulty in stirring; the vapor of hydrochloric acid could contaminate the sample of carbonyl selenide.

Experimental

Synthesis of SeCO from *(1a)* produced *in situ:* Metallic selenium (0.4 g, 5 mmol), diethylamine (1.2 ml, 12 mmol), and THF (20 ml) are placed in a 50-ml flask and CO (30 ml/min) is passed through the resultant solution at room temperature with vigorous stirring over a period of one hour. A colorless, homogeneous THF solution of *(1a)* is obtained. This solution is then cautiously added dropwise to a mixture of sulfuric acid (2.5 ml) and THF (20 ml) at −78 °C in a nitrogen atmosphere. A white precipitate, probably diethylammonium sulfate, is formed. Subsequent distillation from the reaction vessel at −50 °C/5 torr directly into a tube cooled to −196 °C gives essentially pure carbonyl selenide containing a little THF. Trap-to-trap distillation affords pure SeCO. The yield (98%) was determined by reaction with n-butylamine (1.2 ml, 12 mmol) in THF (20 ml) at −78 °C and subsequent oxidation with oxygen at room temperature to give selenium (0.392 g, 4.9 mmol) and 1,3-di-n-butylurea (0.843 g, 4.9 mmol)[7]. Other combinations of salts *(1)* and acids were subjected to reaction under identical conditions.

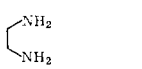
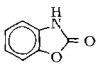
Reactions of Carbonyl Selenide with Amines and Aminoalcohols to Produce Ureas and Carbamates

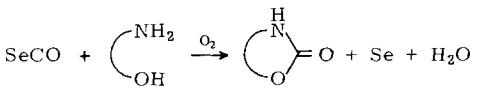
By *Kiyoshi Kondo, Satoshi Yokoyama, Noritaka Miyoshi, Shinji Murai,* and *Noboru Sonoda*[*]





Carbonyl selenide (Se=C=O) has now become readily available by a new synthesis[1]. We have found that it is highly reactive towards nucleophiles such as amines and aminoalcohols, even at low temperature. The carbonylations described below are the first reported reactions of SeCO with organic compounds.

The reaction of carbonyl selenide with amines *(1)* proceeds even at $-78\,^{\circ}C$; subsequent oxidation gives urea derivatives *(2)* as well as selenium and water:



$$SeCO + 2\,RR'NH \xrightarrow{O_2} (RR'N)_2CO + Se + H_2O$$

(1) *(2)*

Table 1. Synthesis of ureas *(2)* by reaction of SeCO (5 mmol) with amines *(1)* (12 mmol) and synthesis of cyclic carbamates *(4)* by reaction of SeCO (5 mmol) with aminoalcohols *(3)* (12 mmol); each in tetrahydrofuran (THF) (5 ml) at $-78\,^{\circ}C$ and subsequent oxidation at room temperature. The yields are based on SeCO.

	Reactant		Product	Yield [%]
(1a)	*n*-$BuNH_2$	*(2a)*	$(n\text{-BuNH})_2CO$	100
(1b)	*c*-$C_6H_{11}NH_2$	*(2b)*	$(c\text{-}C_6H_{11}NH)_2CO$	98
(1c)	Me_2NH	*(2c)*	$(Me_2N)_2CO$	100
(1d)	$PhCH_2NH_2$	*(2d)*	$(PhCH_2NH)_2CO$	80
(1e)		*(2e)*		86
(1f)	NH_3	*(2f)*	$(NH_2)_2CO$	80
(1g)	$PhNH_2$	*(2g)*	$(PhNH)_2CO$	4
(3a)		*(4a)*		70
(3b)		*(4b)*		72
(3c)		*(4c)*		57

Results are shown in Table 1. Alkylamines and ammonia give excellent yields, while aromatic amines do not. The reaction of SeCO with *n*-butylamine could be used for quantitative determination of SeCO[1].

(3) *(4)*

The reaction of SeCO with aminoalcohols *(3)* under the same reaction conditions gives cyclic carbamates *(4)*. Selected results are shown in Table 1.

Experimental

Synthesis of *(2b):* A solution of cyclohexylamine (12 mmol, 1.19 g) in THF (5 ml) is added dropwise at $-78\,^{\circ}C$ to vigorously stirred SeCO (5 mmol) prepared as previously reported[1]. After warming the reaction mixture to room temperature and passage of air, precipitated selenium is filtered off. Evaporation of the filtrate gives essentially pure *(2b)* (1.1 g, 4.9 mmol; corresponding to 98% yield).—Liquified ammonia (1 ml) is treated with SeCO at $-78\,^{\circ}C$. All ureas except *(2c)* (liquid) are obtained as solids at room temperature.—Cyclic carbamates are synthesized under identical conditions. All the carbamates except *(4b)* (oil) are solids.—The ureas and carbamates were identified by spectroscopic comparison with authentic samples.

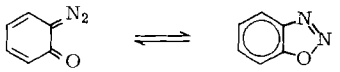
Existence of 1,2,3-Benzoxadiazole in the Gas Phase[**]



By *Reinhard Schulz* and *Armin Schweig*[*]

1,2,3-Oxadiazoles *(1a)*—in contrast to their thia- and aza-analogs *(1b)* and *(1c)*—are still unknown; so far only the valence isomeric dicarbonyl form has been described[1].

(1a) *(2)* *(1b)* *(1c)*

UV and IR investigations have given no indication of the existence of the 1,2,3-benzoxadiazole *(4)*[2], either in the solid state or in solution. We have now been able to show by UV photoelectron spectroscopy that 6-diazo-2,4-cyclohexadienone *(3)*[3] is formed in equilibrium with the benzoxadiazole *(4)* in the gas phase.

(3) *(4)*

The PE spectrum of *(3)* at $40 \pm 10\,^{\circ}C$ (Fig. 1) shows a weak band at 8.20 eV, which beyond doubt is to be assigned to the $^2A''$ (π) ionic state of the diazocarbonyl form. This follows from the comparison of the findings with a) the band position for the corresponding ionization in the isostructural and isoelectronic ketoketene *(5)* (8.43 eV)[4], b) earlier mass spec-

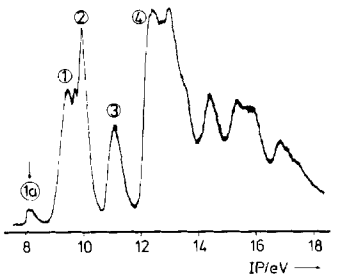


Fig. 1. He-I photoelectron spectrum of a mixture of 1,2,3-benzoxadiazole *(4)* and 6-diazo-2,4-cyclohexadienone *(3)* (80—90 and 10—20%, resp.) at $40 \pm 10\,^{\circ}C$. *(4)* predominates when crystalline *(3)* undergoes transition to the gas phase.

[**] Part 83 of "Theory and Application of Photoelectron Spectroscopy". This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 82: *A. Schweig, N. Thon,* to be published.

troscopic measurements (8.26 eV)[5], and c) the results of CNDO/S-[6] and MNDO-[7] PERTCI[8] calculations (Fig. 2).

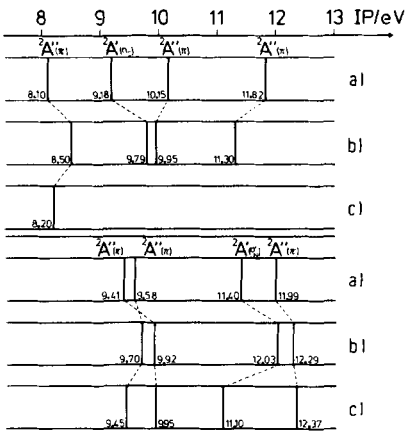

Fig. 2. Calculated CNDO/S- (a) and MNDO-PERTCI- (b) and measured (c) vertical ionization potentials of the valence isomers *(3)* (top) and *(4)* (bottom).

In the spectrum, a series of very much more intense bands starts at 9.45, 9.95, 11.10, 12.37 eV. On the basis of PERTCI calculations with MNDO-optimized molecular geometries (Fig. 2) we assign these bands to the benzoxadiazole *(4)*. The calculations fairly accurately reproduce the measured spectrum (exception: MNDO-$^2A'(\sigma_N)$ ionic state at 11.10 eV, which is about 0.9 eV too high in energy). The measured first ionization energy (9.45 eV), moreover, is in exceptionally good agreement with an estimated value (9.50 eV) quoted by other authors[5].

(5)

(6)

On heating the sample gas to 320 °C elimination of N_2 takes place with exclusive formation of 6-fulvenone *(6)*, whose spectrum contains no bands between 10 and 12 eV[4]. This finding proves that the intense bands observed above 9.45 eV in the spectrum shown in Figure 1 are not caused by a decomposition product of *(3)*.

From the relative band intensities of the ionization of diazocyclohexadienone (band 1a at 8.20 eV) and of benzoxadiazole (band 1 and successive bands)—assuming similar ionization cross-sections—it follows that in the gas phase at 40 ± 10 °C the product mixture consists of 80—90% *(4)* and only 10—20% *(3)*. This corresponds to a greater stability of the benzenoid structure of about 1 kcal/mol over that of the quinonoid structure.

Tris(trichlorophosphoranediylamino)carbenium Hexachloroantimonate, $[C(N{=}PCl_3)_3]^+SbCl_6^-$

By *Ulrich Müller, Inge Lorenz,* and *Fritjof Schmock*[*]

The Staudinger reaction of organic azides with phosphanes leads to iminophosphoranes. We have utilized the corresponding reaction of triazidocarbenium hexachloroantimonate[1] with phosphorus trichloride to synthesize the title compound *(1)*; UV radiation was necessary for activation:

$$[C(N_3)_3]^+SbCl_6^- + 3\,PCl_3 \xrightarrow{h\nu} [C(N{=}PCl_3)_3]^+SbCl_6^- + 3\,N_2$$

(1)

(1) forms colorless crystals which are sensitive to hydrolysis; they are soluble in polar solvents such as acetonitrile. We have characterized *(1)* by elemental analysis, by IR and Raman spectra, and by X-ray structure analysis.

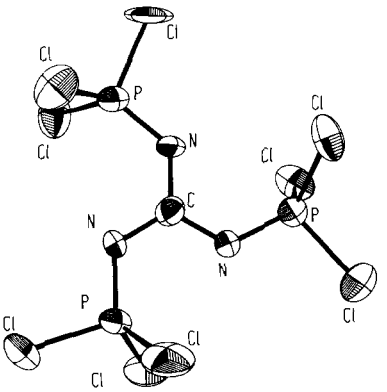

Fig. 1. Structure of the $[C(NPCl_3)_3]^+$ ion showing ellipsoids of thermal vibration (at 21 °C; 50% probability distribution).

The crystals of *(1)* are triclinic[2]. Neither the cation nor the anion is located in crystallographically defined symmetry positions. Nevertheless, a higher symmetry applies to both species to a good approximation: the $SbCl_6^-$ ion is octahedral, and the $[C(NPCl_3)_3]^+$ ion has almost C_{3h} symmetry (cf. Fig. 1). Mutually equivalent bonds are practically equal. The (averaged) C—N distance is 135 pm as in the guanidinium ion and comparable ions, corresponding to a 1⅓ bond. The P—N distance of 155 pm lies at the lower limit of the values found for λ^5-phosphazenes such as $(PNCl_2)_x$; it corresponds roughly to a P=N double bond. The averaged bond angles are: N—C—N 120°, C—N—P 123°, Cl—P—Cl 106°, N—P—Cl 116 and 106° (latter value for Cl in the plane of the molecule). Mean P—Cl distances: 196 pm.

In addition to the known bands of the $SbCl_6^-$ ion (IR: 335; Raman: 330, 285, 172 cm^{-1}), the vibrational spectrum contains the following bands: 1385 ($\nu_{as}C(N)_3$), 1016 and 1004 (νP—N), 750 (Raman, δNCN), 744 (IR, $\gamma C(N)_3$), nine bands between 647 and 450 (νP—Cl), further bands below 350 cm^{-1} (deformation modes); the bands are observed in the Raman and the IR spectra unless stated otherwise. The frequency of the P=N stretching vibrations (around 1000 cm^{-1}) suggests a weakened double bond.

Procedure

A solution of $[SbCl_4N_3]_2$ (*ca.* 3 g)[3] in CH_2Cl_2 (30 ml) is heated under reflux with CCl_4 (*ca.* 5 ml); $[C(N_3)_3]SbCl_6$ precipitates. The precipitate is filtered off after 12 h, washed

[*] Prof. Dr. U. Müller, I. Lorenz, F. Schmock
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg 1 (Germany)

with CCl_4 (1—2 ×), and dissolved in 1,2-dichloroethane (80 ml) at 50 °C. Freshly distilled PCl_3 (5 ml) (previously freed from HCl by Fe powder) is added and the mixture irradiated at 40—50 °C with an immersed Hg lamp. After *ca.* 2 h, evolution of N_2 has ceased and the solution is evaporated down to ¼ of its volume. Addition of a small volume of acetonitrile and heptane leads to crystallization of *(1)*.—All operations must be conducted with exclusion of moisture and precautions usual for azides.

Bonding in Bicyclo[1.1.0]butane Derivatives[**]

By *Hermann Irngartinger* and *Karl Ludwig Lukas*[*]

The bond between the two bridgehead atoms in bicyclo[1.1.0]butane exhibits properties of a CC multiple bond, though formally it is a single bond[1]. In order to investigate the dependence of the length of this bond on the interplanar angle δ between the two three-membered rings and its relationship to the hybridization state of the bridgehead atoms, we have determined the crystal and molecular structures of 1,5-diphenyltricyclo[2.1.0.$0^{2,5}$]pentan-3-one *(1)*[2] and of the analogous 1,5-dimethyl compound *(2)*[3], in whose bicyclobutane skeleton a smallest possible δ-angle ought to be reached by the short bridging of a carbonyl group. For comparison, we have also determined the structure of dimethyl 15,16-diazaoctacyclo[6.6.2.$0^{2,7}$.$0^{3,5}$.$0^{4,6}$.$0^{9,14}$.$0^{10,12}$.$0^{11,13}$]hexadeca-15-ene-1,8-dicarboxylate *(3)*[4], in which the bridging of the bicyclobutane skeleton is extended by one carbon atom. The crystallographic data are given in Table 1[5].

(1), R = C_6H_5
(2), R = CH_3

(3)

Table 1. Crystallographic constants.

	(1)	*(2)*	*(3)*
a	563.4(3) pm	1095.3(7) pm	1570.3(2) pm
b	865.3(2) pm	691.5(2) pm	548.2(1(pm
c	2584.6(5) pm	854.8(7) pm	1783.2(1) pm
β	100.85(2)°	111.16(8)°	99.65(1)°
	$P2_1/c$; $Z=4$	C2/c; $Z=4$	C2/c; $Z=4$

The molecules *(2)* and *(3)* each lie on a crystallographic twofold axis. The bond between the bridgehead atoms has pronounced π-character[1]. The orientation of the corresponding π-orbitals, above and below the C C bond line, is defined by the plane bisecting the interplanar angle δ. The two phenyl rings in *(1)* are arranged almost perpendicular to this plane (93.6 and 89.9°), so that there is optimal possible conjugation between the two phenyl groups *via* the π-population of the bridge bond. The conjugation effects lead to a lengthening of the bridge bond in *(1)* to 1.444 Å as compared to the corresponding bond length of 1.408 Å in the dimethyl compound *(2)*. The bridge bonds of all three bicyclobutane derivatives are considerably shorter than the standard value of 1.54 Å for a $C(sp^3)$ $C(sp^3)$ single bond. As can be seen from Figure 2, in which the values are plotted for molecules which are not influenced by conjugation effects, *the distance between the bridgehead atoms increases with increasing interplanar angle* δ.

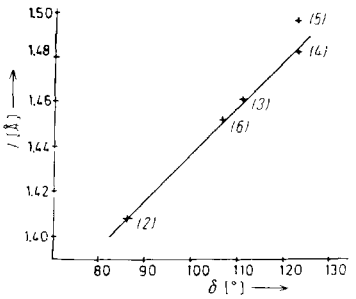

Fig. 2. Relation between the length of the bridgehead bond *l* of bicyclo[1.1.0]butane derivatives and the interplanar angle δ. The diagram contains the values for *(2)*, *(3)*, a bicyclobutane *(4)* bridged by the C=C S group [6], the parent compound *(5)* [7], and benzvalene *(6)* [8].

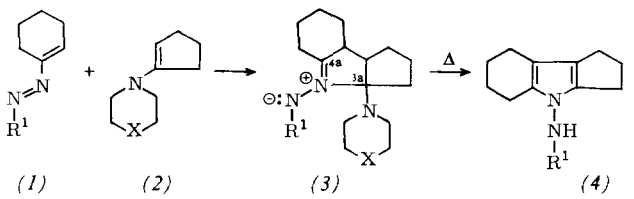
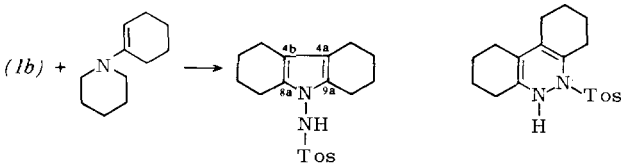
[3+2]-Cycloadditions of Azoalkenes to Enamines—Criss-Cross Cycloadditions to Azoalkenes[**]

By *Sven Sommer*[*]

Cycloadditions of multiple bond systems to 1,3-dienes usually take place at the 1,4-, but also at the 1,2-(or 3,4-)position. Cycloadditions at the 1,3-(or 2,4-)position, on the other hand, are a rarity, and to our knowledge have only been observed in the open-chain azines (2,3-diaza-1,3-butadienes)[1,8]. That this mode of reaction is not limited to azines is demonstrated by the [3+2]-cycloadditions of azoalkenes *(1)* (1,2-diaza-1,3-butadienes) to enamines *(2)*[2]: In the reaction of the azoalkenes[3] *(1a)* and *(1b)* with the enamines *(2a)* or *(2b)* analytically pure [3+2]-cycloadducts of the type *(3)* crystallize from the reaction solution after a few minutes (Table 1). On heating above the melting point (very slowly in solution at room temperature) they immediately form the *N*-aminopyrroles *(4)* (Table 1).



The azomethineimine structure *(3)* follows from the downfield position of the ^{13}C-NMR signals for C-4a [$\delta = 173.6$ *(3a)*, 179.5 *(3b)*] and C-3a [$\delta = 109.2$ *(3a)*, 110.4 *(3b)*, $CDCl_3$/TMS] and from the shift to lower wave numbers of the IR absorptions of the C=O group of *(3a)* [ν(C=O) = 1635 cm^{-1}, KBr and $CHCl_3$] and *(3c)* [ν(C=O) = 1640 cm^{-1}, KBr], and of the SO_2 group of *(3b)* [$\nu(S{=}O)_{antisym} = 1135$ cm^{-1}, $\nu(S{=}O)_{sym} = 1285$ cm^{-1}, KBr][4].



(5) (6)

Further evidence for the azomethineimine structure *(3)* is provided by the ability of *(3a)* and *(3c)* to undergo 1,3-dipolar cycloaddition with acetylenecarboxylates *(5)*[5] to give the compounds *(6)* (Table 2). The cycloaddition to *(6a)* and *(6b)* proceeds regiospecifically.

(6a)—*(6c)* are formed *via* a sequence of two [2+3]-cycloadditions to the 1,3- and 2,4-positions of the 1,2-diaza-1,3-butadiene skeleton of *(3a)* and *(3c)*. Such criss-cross cycloadditions have previously only been observed in the case of the azines[1a,6,8]. In many of the reactions of enamines with azoalkenes the [2+3]-cycloadducts *(3)* presumed to be formed initially cannot be isolated, but only compounds which can be regarded as their secondary products. Thus, on reaction of *(1b)* and *(2c)* the *N*-aminopyrrole *(4c)* is obtained (see Table 1).
